Table 2 shows the primary results of this study. After 12 weeks, the mean weight change in the intervention group was –0.9 (SD 1.9) kg, while it was 0.6 (SD 1.4) kg in the control group. The primary analysis revealed an adjusted mean difference of –1.6 (95% CI –2.5 to –0.8; *P*<.001) kg. The regression coefficients for covariates were as follows: baseline weight=–0.2 (95% CI –0.6 to 0.2) kg per 10-kg increase; sex (male)=0.5 (95% CI –0.5 to 1.4) kg; and age=–0.4 (95% CI –0.7 to 0.0) kg per 10-year increase.

Table 2. The effect of the intervention between the intervention and control groups (N=57)a.

Variable	Intervention (n=28)	Control (n=29)	Adjusted mean difference (95% CI)[b]	*P* value
Weight at baseline (kg), median (IQR)	75.8 (68.3-80.6)	74.8 (69.8-81.8)	—[c]	—
Weight at 12 weeks (kg), median (IQR)	74.5 (66.3-79.5)	74.8 (69.1-83.1)	—	—
Weight change (kg), mean (SD)	–0.9 (1.9)	0.6 (1.4)	–1.6 (–2.5 to –0.8)[b]	<.001

[a]Intention-to-treat analysis. Data were presented as median (IQR) for each measured weight and as mean (SD) for the weight change.

[b]Adjusted for stratifying factors (age and sex) and baseline weight by using the generalized linear regression model.

[c]Not applicable.

Sensitivity Analysis

Among the sensitivity analyses, the crude comparison showed a mean difference of –1.5 (95% CI –2.4 to –0.7; *P*=.001) kg, and the per-protocol analysis revealed a mean difference of –1.8 (95% CI –2.9 to –0.6; *P*=.004) kg. Additional sensitivity analysis for CS presented similar results; a mean difference of –1.8 (95% CI –2.7 to –0.9; *P*=.004) kg. In a worst-case scenario, where missing data were imputed (+3.3 kg to the weight change for the 3 missing participants in the intervention group and –4.7 kg to the weight change for the 2 missing in the control group), the adjusted mean difference was –1.0 (95% CI –2.1 to 0.2; *P*=.10) kg, and the crude mean difference was –0.9 (95% CI –2.0 to 0.3; *P*=.13) kg.

Exploratory Analysis

The post hoc analysis revealed that more participants (8/28, 29%; *P*=.01) achieved a MIC (3% reduction in initial weight) in the intervention group compared to the control group (1/29, 3%).

Changes in Secondary Outcomes

Changes in Continuous Variables

The results for secondary outcomes were presented in Table 3, showing the within-group changes and between-group differences. In line with weight changes, the BMI decreased more in the intervention group compared to the control group (mean difference=–0.4, 95% CI –0.1 to –0.8 kg). However, no significant difference was observed in fat mass changes (mean difference=–0.1, 95% CI –1.3 to 1.4 kg), whereas a decrease in muscle mass was implied (mean difference=–1.3, 95% CI –2.5 to –0.2 kg). In alignment with the changes in body composition, a decrease was suggested in the BMR (mean difference=–37.8, 95% CI –67.5 to –8.2 kcal). No significant differences were observed in other outcomes. The mean differences (95% CI) for each outcome were as follows: SBP= –4.6 (–10.6 to 1.3) mm Hg, DBP=–1.1 (–5.6 to 3.3) mm Hg, HbA_{1c}=–0.0 (–0.2 to 0.1) %, TG=–30.8 (–71.3 to 9.7) mg/dL, total cholesterol=–8.2 (–22.7 to 6.4) mg/dL, HDL-C=2.2 (–2.7 to 7.1) mg/dL, LDL-C=–4.1 (–17.1 to 8.9) mg/dL, physical QOL=0.6 (–2.6 to 3.9), mental QOL=–0.7 (–4.0 to 2.3), subjective health status=–0.2 (–0.5 to 0.3), and total physical activity=291 (–508 to 1090) METs.

Table 3. The changes in secondary outcomes from baseline to 3 months. (N=57)a.

Variable	Intervention (n=28), mean (SD)	Control (n=29), mean (SD)	Between-group difference[b], mean difference (95% CI)
BMI (kg/cm^2)	–0.3 (0.7)	0.2 (0.5)	–0.4 (–0.8 to –0.1)
Fat mass (kg)	–0.2 (1.7)	–0.3 (3.1)	0.1 (–1.3 to 1.4)
Muscle mass (kg)	–0.6 (1.0)	0.8 (2.8)	–1.3 (–2.5 to –0.2)
BMR[c] (kcal)	–17.9 (31.9)	19.9 (72.0)	–37.8 (–67.5 to –8.2)
SBP[d] (mm Hg)	–3.3 (9.4)	1.3 (12.7)	–4.6 (–10.6 to 1.3)
DBP[e] (mm Hg)	–3.6 (6.6)	–2.4 (9.8)	–1.1 (–5.6 to 3.3)
HbA_{1c}[f] (%)	–0.1 (0.2)	–0.0 (0.3)	0.0 (–0.2 to 0.1)
TG[g] (mg/dL)	1.1 (64.8)	31.9 (86.4)	–30.8 (–71.3 to 9.7)
Total-C[h] (mg/dL)	3.4 (24.4)	11.6 (30.2)	–8.2 (–22.7 to 6.4)
HDL-C[i] (mg/dL)	2.4 (7.4)	0.2 (10.8)	2.2 (–71.3 to 9.7)
LDL-C[j] (mg/dL)	0.9 (25.3)	5.0 (23.7)	–4.1 (–17.1 to 8.9)
QOL[k] score[l]			
Physical component summary	0.5 (5.8)	–0.1 (6.3)	0.6 (–2.6 to 3.9)
Mental component summary	–0.5 (6.8)	0.2 (4.6)	–0.7 (–4.0 to 2.3)
Subjective health status[m]	–0.3 (0.6)	–0.1 (0.9)	–0.2 (–0.5 to 0.3)
Total physical activity (METs[n])	350 (1679)	59 (1295)	291 (–508 to 1090)

[a]Intention-to-treat analysis. Data were presented as mean (SD) for the change in each outcome and as mean difference (95% CI) for the difference between groups in the change scores.

[b]The difference in secondary outcomes between groups was not adjusted and was presented as crude values, with 95% CI of the Welch *t* test.

[c]BMR: basal metabolic rate.

[d]SBP: systolic blood pressure.

[e]DBP: diastolic blood pressure.

[f]HbA_{1c}: hemoglobin $A_{1c.}$

[g]TG: triglyceride.

[h]Total-C: total cholesterol.

[i]HDL-C: high-density-lipoprotein cholesterol.

[j]LDL-C: low-density-lipoprotein cholesterol.

[k]QOL: quality of life.

[l]SF-12v2 (Short-Form 12-Item Survey-version 2) Japanese version was used to obtain each 2-component summary score, which is standardized T-scores with a mean of 50 (SD 10), where higher scores indicate better health.

[m]Calculated from the responses to the first question of the SF-12v2 questionnaire, “In general, would you say your health is:” with options ranging from (1) Excellent, (2) Very good, (3) Good, (4) Unsatisfactory, and (5) Poor.

[n]METs: metabolic equivalents-minutes per week.

Safety Analysis

Table 4 displays the reported number of events and the incidence—the number of participants who experienced it—for each of the 20 mild symptoms. A larger proportion of participants reported hunger in the intervention group (22/25, 89%; *P*<.001) compared to the control group (3/27, 11%). Additionally, fatigue (16/25, 64% vs 6/27, 22%; *P*=.06) and cravings (15/25, 60% vs 3/27, 11%; *P*=.01) were also more reported in the intervention group (vs control group). On the other hand, the participants in the control group reported hunger (43 vs 27) and cravings (70 vs 42) more frequently compared to the intervention group. Adverse events reported in free text included influenza-like illness (1/25 vs 3/27), sinusitis (0/25 vs 1/27), viral gastroenteritis (1/25 vs 0/27), loss of appetite (1/25 vs 3/27), and drowsiness (2/25 vs 0/27). Regarding the within-group difference in QOL scores, no significant changes were observed before and after in either group: physical QOL (intervention: mean 0.51, SD 5.84 vs control: mean –0.13, SD 6.27), and the mental QOL (mean –0.54, SD 6.84 vs mean 0.15, SD 4.60).

Table 4. Self-reported mild symptoms in the intervention and control groups (N=52)a.

Mild symptoms	Intervention (n=25)		Control (n=27)		*P* value[b]
	Events	Incidence (%)	Events	Incidence (%)	
Hunger	27	22 (88)	43	3 (11)	<.001
Fatigue	187	16 (64)	27	6 (22)	.01
Headache	125	12 (48)	74	7 (25)	.17
Cravings	42	15 (60)	70	3 (11)	.001
Diarrhea	30	5 (20)	68	7 (25)	.86
Dry mouth	118	8 (32)	68	4 (14)	.25
Back pain	66	6 (24)	21	6 (22)	>.99
Sensitivity to cold	36	5 (20)	25	6 (22)	>.99
Muscle pain	24	4 (16)	4	5 (18)	>.99
Abdominal bloating	9	4 (16)	14	5 (18)	>.99
Vertigo	17	4 (16)	9	5 (18)	>.99
Sleep difficulty	77	4 (16)	24	4 (14)	>.99
Dyspepsia	13	2 (8)	57	5 (18)	.48
Bad breath	7	4 (16)	12	2 (7)	.59
Blurred vision	6	2 (8)	0	4 (14)	.74
Nausea	0	3 (12)	13	2 (7)	.93
Muscular cramp	9	3 (12)	8	2 (7)	.93
Palpitation	1	1 (4)	7	3 (11)	.66
Skin rash	22	0 (0)	21	3 (11)	.26
Restless leg	4	2 (8)	2	0 (0)	.44

[a]Analysis population was the completers set. Participants were asked to report the number of incidences of 20 mild symptoms listed in the web questionnaire by answering 0-90 times per symptom.

[b]*P* values were presented for the incidences.

Discussion

Principal Findings

This study aimed to evaluate the effectiveness, feasibility, and safety of a 12-week OIF among adults with overweight and obesity in Japan. Overall, the program demonstrated effectiveness in promoting modest weight loss over 12 weeks, with high feasibility and safety indicated by low dropout rates and absence of serious adverse events.

The participants in the intervention group tended to lose weight (mean –0.9, SD 1.9 kg), whereas the control group, on average, gained weight (mean 0.6, SD 1.4 kg). Generally, individuals with overweight tend to continue to gain weight [35], but the result suggests this increase can be mitigated by the OIF. The adjusted mean difference was –1.6 (95% CI –2.5 to –0.8) kg, and more participants achieved a MIC in the intervention group compared to the control group (8/28 vs 1/29 participants). Among the sensitivity analyses, the per-protocol analysis showed a subtle larger effect (mean difference –1.8, 95% CI –2.9 to –0.6 kg), implying the efficacy of the OIF. The effect size calculated by the weight change (SD) was large (Cohen *d*=0.95), but the effect size based on the after-weight (SD) was small (Cohen *d*=0.19).

The dropout rate was low in the intervention group (3/28, 11%). Additionally, adherence rate exceeded our expectations, with 79% (22/28) of “adherent” and 68% (17/28) of “fully adherent,” indicating a modest level of feasibility. However, there were also concerns regarding their self-reported mild symptoms. Based on the incidence, more participants reported hunger or cravings in the intervention group, although the participants in the control group reported them more frequently in terms of the number of events they experienced. There was a slight trend that participants in the intervention group had more headaches (both in events and incidence), but the result was not statistically significant. Except for hunger, fatigue, and cravings, there were no statistically significant differences in reported symptoms between the groups.

Concerning safety, the intervention showed encouraging indications. No serious adverse events were reported, and QOL remained stable (insignificant within-group differences in QOL score between before and after, and insignificant between-group differences in change in QOL) throughout the study. These findings, coupled with the modest adherence observed, suggest that the intervention is generally safe. Nonetheless, the intervention group reported more hunger, fatigue, and cravings,

XSL•FO
RenderX

underscoring the importance of providing thorough explanations and follow-up.

Comparison to Prior Work

Many studies have demonstrated the effectiveness of web-based weight loss interventions [7,8,25]. A previous RCT among adults with overweight in Japan showed a moderate weight loss effect from a 12-week app intervention (adjusted mean difference=–1.60, 95% CI –2.83 to –0.38; *P*=.01) [26]. A recent meta-analysis indicated that web-based interventions facilitate weight loss compared to minimal care control groups (mean difference=–1.40, 95% CI –1.98 to –0.82; *P*<.001) [8]. This study observed similar effects to these. However, we initially had expected a potential weight loss of 2.7 kg through the OIF, but it was 0.9 kg, and the observed between-group difference was –1.6 kg, with both changes falling short of the expectation. A possible reason for the slight weight loss in the intervention group and the weight gain in the control group could be attributed to the timing of the study. The study was conducted from September 2023 to January 2024, and most participants completed their follow-up measurements during the Christmas and New Year holidays, which possibly contributed to the weight gain [36]. Since total physical activity did not change, another possible reason should also lie in diet. Participants in the intervention group might feel hungrier, which is consistent with the previous studies [37,38], and might have compensated for the energy reduced by fasting through consuming more food on nonfasting days. This was implied by several participants' feedback in the questionnaire. However, this is just speculative since prior works have demonstrated the lack of compensation for energy intake in IF [39-41], and this study did not collect information on a regular diet. The next study should consider comprehensive dietary assessments to elucidate these findings further.

This study showed no significant reduction in fat mass (mean difference=–0.1, 95% CI –1.3 to 1.4 kg) but a decrease in muscle mass (mean difference=–1.3, 95% CI –2.5 to –0.2 kg). However, it is natural that glycogen stored in muscles is used first during the initial phase of short-term weight loss, accompanied by a temporary decrease in water and muscle mass [42]. Thus, the observed reduction in muscle mass may not directly raise concerns. A systematic review and meta-analysis comparing conventional dietary restrictions with IF have not found evidence that IF promotes greater muscle loss [43]. Furthermore, other studies have shown that incorporating exercise during IF can increase muscle mass and exercise performance [44,45]. A recent systematic review has also concluded that combining IF with strength training can maintain lean body mass [46]. These findings suggest that the OIF does not necessarily worsen body composition, but on its own, it might not provide sufficient health benefits. Weight loss interventions should ideally include exercise therapy and comprehensive lifestyle modifications [47,48], a principle that we conclude also applies to online fasting interventions.

Strengths and Limitations

One of the strengths of this study lies in its study design. A randomized controlled design using minimal care as a control enabled us to obtain more valid estimates than study designs with single-arm or no-intervention controls. The sample size that was large for a pilot study led to demonstrating statistically significant results for weight loss, justifying conducting future trials.

In addition, we comprehensively evaluated the effects of the intervention, measuring multiple outcomes, allowing us to obtain invaluable insights into our program. For example, no observed change in physical activity implied that the OIF might facilitate weight loss through reduced energy intake.

This study has several limitations. First, we lacked important data on physical activity and dietary habits. In this study, physical activity was measured by self-report and was considered to be of low accuracy, which might prevent us from detecting potential changes. Additionally, the lack of data on a regular diet limited the interpretation of the results. In particular, evaluating why weight loss was below expectations is quite challenging. Future studies should evaluate the physical activity and dietary habits more accurately in order to distinguish the efficacy of IF from other lifestyle factors.

Second, our analysis is limited by the way of handling the missing values. We used the BOCF approach to impute missing body weight data. However, since missing data on body weight after the intervention could occur systematically, this approach may have introduced bias and compromised our conclusions. Notably, the statistically significant between-group difference in weight change diminished when considering the worst-case scenario (imputing +3.3 kg of weight change for the 3 missing participants in the intervention group and –4.7 kg for the 2 missing participants in the control group). Nevertheless, we believe that the BOCF approach is unlikely to have significantly overestimated the intervention effect. Participants in the control group were unlikely to lose weight without intervention and might even have gained weight as previously reported [35], whereas those in the intervention group were more likely to achieve weight loss. Thus, imputing the outcome weight with the baseline value is more likely to lead to diluting the weight loss effect, not overestimating it. Furthermore, our analysis demonstrated that a greater proportion of participants in the intervention group achieved a clinically meaningful weight loss (MIC; a 3% reduction in initial weight) compared to the control group, supporting the effectiveness of the intervention.

Third, as for the participants' recruitment, we used convenience sampling and cannot assume that it was a random sampling. Notably, participants included several direct acquaintances of the researchers (TN and TI). The proportion of participants considering themselves to be healthy was 88% (50/57), which is comparable to the results from the reference national survey [34], with 86.16% (91768/106507) for the total population and 89.66% (50816/56675) for those aged 20-65 years, implying that they were not far from the generally healthy population with overweight and obesity. However, our participants were exclusively Japanese, and it is unclear whether the findings would be applicable in other countries or regions with different lifestyles. Thus, the generalizability of the conclusions remains unclear. Nevertheless, we believe that our setting with multiple facilities possibly contributed to recruiting participants with a broad range of characteristics. In the future trial, we plan to

XSL•FO
RenderX

broaden the generalizability of the findings by using systematic recruitment methods and conducting the study in other countries.

Finally, we did not systematically collect data on concomitant care that participants may have received during the trial, such as seeking external dietary advice or using other commercial weight-loss programs. Therefore, we cannot completely rule out the possibility that such unmeasured care could have influenced the results.

Conclusions

The 12-week OIF can promote weight loss in apparently healthy adults with overweight and obesity; yet, it may not result in improvements in body composition. The observed low dropout rate and modest adherence, with no serious adverse events or significant changes in QOL, indicate the feasibility and safety of the program.

Acknowledgments

Special thanks to TANITA Corporation for lending the body composition analyzer at no cost. We extend our gratitude to Fujita Hideo and his coworkers at Kusaka Hospital, Daigo Goto at Cold Storage Japan Inc, and Yuzo Hoshino at Buddy Training Co, Ltd. for their collaboration. Our thanks also go to Toshiaki Furukawa, Yusuke Ogawa, and Hiroshi Okada for their invaluable advice. We are grateful to Ryuta Onodera, Daisuke Sasaki, and Nami Noda for their dedicated support as research staff. Finally, our sincere thanks to Kazuya Goto and Rina Kitabe for their thorough review of the manuscript. In preparing this manuscript, the author (TN) used the generative artificial intelligence ChatGPT-4 (OpenAI) for the English translation and proofreading of the text. The authors have carefully reviewed all content generated with this technology, making necessary modifications, and assume full responsibility for the submitted work.

Conflicts of Interest

Ritsuan Inc, a funder of this study, did not have any role in the design, conduct, analysis, and reporting of the study. The closed, test version of the publicly available “Kenko-Nikki” app was developed and provided for this study at a low cost by HTL (Healthtech Laboratory, Inc). The principal investigator (TI) serves as an external director (but unpaid) at HTL, and uses intellectual property that he has transferred to HTL in this study. He also accepts other collaborative research projects that use the intellectual property, making him subject to auditing. TS is employed through joint research funds between HTL and Kyoto University, and uses the intellectual property mentioned above in this study. YT is also employed under the joint research funds. TN owns the Nihonsouken LLC, running dietary guidance business that involves fasting and selling health food products that are partly related to fasting. These conflicts of interest have been reported in advance to the Kyoto University Conflict of Interest Management Office and were audited by the Audit Unit of the Department of Clinical Research Facilitation, Institute for Advancement of Clinical and Translational Science at Kyoto University Hospital.

Abstract

Background: Social exchange processes, such as social support and social control, can promote health behavior change. However, these processes are often neglected when studying health behavior change and designing interventions. Intervening on these social exchange processes using dyadic interventions may provide a promising approach to promote health behaviors.

Objective: This study aimed to investigate the effects of dyadic interventions to increase moderate-to-vigorous physical activity (MVPA) in romantic couples. Furthermore, we explored how the target, type, and timing of the interventions affect their effectiveness.

Methods: In total, 38 romantic couples (mean age 34.01, SD 11.03 y) were recruited through online advertisements and participated in a smartphone-based microrandomized trial over 55 days consisting of control and intervention phases. The fully automated dyadic interventions included a one-time psychoeducation intervention, weekly dyadic and collaborative planning, and dyadic just-in-time adaptive interventions (JITAIs). MVPA was measured through daily diaries and wrist-worn accelerometers. We used multilevel modeling to estimate the effect of the intervention phase and weighted and centered estimation for microrandomized trials to estimate the treatment effects of dyadic and collaborative planning, as well as the dyadic JITAIs.

Results: Participants indicated higher device-based (b=5.88, SE=3.04, t_{3665}=1.93; *P*=.03) and self-reported (b=8.26, SE=3.88, t_{3904}=2.13; *P*=.01) MVPA during the intervention phase compared with the control phase. Dyadic and collaborative planning did not increase device-based (b=6.31, SE=5.18; *P*=.12) but only self-reported (b=14.25, SE=5.16; *P*=.005) MVPA. However, the effects of the 2 kinds of planning on self-reported MVPA disappeared when additional covariates were included (b=0.14, SE=3.32; *P*=.48). Furthermore, the dyadic JITAIs targeting both the actor and the partner increased device-based (actor: b=11.17, SE=3.18; *P*<.001; partner: b=7.23, SE=3.60; *P*=.03) and self-reported (actor: b=17.34, SE=3.65; *P*<.001; partner: b=11.82, SE=4.10; *P*<.001) MVPA. However, the effects of the dyadic JITAIs targeting the actor disappeared for self-reported MVPA (b=2.20, SE=3.22; *P*=0.25) when additional covariates were included. Exploratory analyses revealed that different types and timings of dyadic JITAIs were differentially effective.

Conclusions: This study demonstrated the promising effects of dyadic interventions to promote MVPA and highlighted the importance of the target, type, and timing of the interventions. Further research should investigate the mechanisms underlying the effects of dyadic interventions on health behaviors.

Introduction

Background

Regular engagement in physical activity is essential for maintaining overall health and reducing the risk of chronic and noncommunicable diseases, including heart disease, stroke, diabetes, and cancer [1]. The World Health Organization recommends at least 75 to 150 minutes of moderate-to-vigorous physical activity (MVPA) per week. Even though most people know of its importance and intent to engage in MVPA, many struggle to engage in the recommended amount of MVPA [2]. For example, in Switzerland, where the study took place, about 24% of adults do not meet these recommendations [3].

Theoretical and empirical research has been conducted to support people in increasing their MVPA [4]. This research has primarily focused on behavior change on the individual level and neglected social relationships and social processes [5]. However, since people are embedded in social networks, health behavior change often occurs in a social context. These social networks promote interdependence among people, and especially close partners can influence each other's health behaviors [6,7]. Thus, involving close social relationships in the behavior change process and implementing dyadic interventions provides a promising approach to promoting health behavior change in people with low physical activity [8].

Dyadic Interventions for Health Behavior Change

Implementing dyadic interventions makes it possible to capitalize on the interpersonal resources of both partners, encouraging mutual support and enhancing investment in the partners' behavior change, thereby facilitating behavior change [9-11]. The empirical evidence regarding the effectiveness of dyadic interventions is promising but mixed. On the one hand, some studies have shown that dyadic interventions are effective in increasing physical activity [12] and are more effective than control interventions, including equivalent interventions targeting individuals [9]. On the other hand, systematic reviews found mixed evidence for improved physical health [13], and they did not demonstrate superior effectiveness in increasing physical activity compared with comparison groups involving individual or control interventions [11].

Dyadic interventions may be categorized along the continuum of dyadic interventions into different prototypes of dyadic interventions depending on the degree of partner involvement (eg, cross-over and joint interventions) [10]. Cross-over interventions prompt interactions between the individuals by explicitly instructing one dyad member to engage with or clearly refer to the other dyad member, but the intervention is not administered to both. Joint interventions actively involve both dyad members and consider the dyad as a unit, making it impossible to be delivered to only 1 dyad member present. Cross-over and joint interventions may work through different mechanisms and thus may differ in their effectiveness. However, little research has investigated the differences in their effectiveness, calling for a more nuanced examination of these 2 prototypes of dyadic interventions [10].

Dyadic interventions may work by applying different dyadic behavior change techniques (DBCTs) [10] that explicitly elicit various social exchange processes influencing health behavior change [14]. Social exchange processes are interactions between dyad members that affect one or both individuals' behaviors, emotions, or cognitions [15]. There are various social exchange processes, such as providing social support, exerting social control, or collaboratively establishing goals and plans. Social support refers to providing psychological, material, or informational resources intended to benefit the ability to cope with stressors, solve problems, and pursue life opportunities [16,17]. One common distinction of social support is between emotional and instrumental support. Emotional support concerns the emotional well-being of the recipient [18]. Regarding physical activity, this form of support may include encouragement and comfort, guidance, and help to stay motivated and committed. Instrumental support is defined as providing the recipient with practical help and resources, such as advice or assistance [18]. Regarding physical activity, this form of support could include providing help while exercising or taking over daily chores to free up time for the partner to engage in MVPA. Empirical evidence showed that emotional and instrumental support can be associated with higher levels of physical activity, but there is also substantial heterogeneity in the associations (eg, studies by Kouvonen et al [19], Rackow et al [20], and Scarapicchia et al [21]).

Another social exchange process is social control, which refers to a deliberate and intentional attempt to change what another person thinks, feels, or does toward an outcome desired by the person exerting control [22]. Social control can be categorized into positive or negative social control based on the means used to influence behavior [23]. Positive social control includes strategies such as persuasion, modeling, and discussions. Negative social control includes, for example, coercion, social pressure, elicitation of negative emotions, and withdrawal. These strategies may differ in effectiveness when used to promote health behaviors in the partner. A meta-analysis has found that positive control was associated with better health behaviors, whereas negative control was related to worse health behaviors [22]. Furthermore, negative control relates to increased reactance-related responses and resistance to change, rendering it ineffective in encouraging health behavior change [7]. So far, there is almost no research on the effectiveness of interventions promoting positive social control and reducing negative social control. This gap will be addressed in this study.

While social support and positive social control can enhance health behaviors, poorly executed or nonresponsive support may yield adverse outcomes, including diminished well-being, heightened stress, and decreased performance [24]. Therefore, when deploying dyadic interventions that leverage social

XSL•FO
RenderX

exchange processes, it seems crucial for partners to have the knowledge and skills to offer effective support. However, little research has included information on skillful social support in interventions.

Social exchange processes can also play a role in goal setting and action planning. Goal setting refers to defining behaviors or states one wants to accomplish in the future [25]. Action planning refers to linking behaviors to specific cues by specifying when, where, and how to act [26]. Action planning can be augmented by coping planning, a barrier-focused self-regulation strategy in which an association between anticipated barriers and suitable solutions to overcome these barriers is made [26]. Combining action planning with coping planning can have additive and synergistic effects to promote health behaviors [27]. Furthermore, setting goals and planning physical activities with a partner may facilitate adherence to these goals and plans [5,28]. There are 2 forms of planning in the dyadic context. Dyadic planning involves creating plans with a partner on when, where, and how one partner will implement a behavior [29]. Collaborative planning entails creating joint plans with a partner on when, where, and how both partners will engage in a behavior [30]. There is mixed evidence for the effectiveness of dyadic planning in promoting health behaviors. While some studies have found positive associations between dyadic planning and goal progress [31] and plan enactment [32], other studies have not supported its effectiveness [33,34]. However, empirical evidence generally supports the effectiveness of collaborative planning to foster health behaviors [28,35,36].

Just-in-Time Adaptive Interventions

Technological advancements and the widespread use of devices, such as smartphones and smartwatches, have opened up new possibilities for enhancing the design and implementation of interventions [37]. These technologies allow for tracking health behaviors and context variables, which provide information about the individual's current state. This information can be integrated with theoretical and empirical knowledge to tailor the intervention content to individual needs and deliver interventions at the right time. Such interventions are known as just-in-time adaptive interventions (JITAIs) [38]. A meta-analytical review found moderate to large effects of JITAIs compared with waitlist-control conditions and non-JITAI treatments to improve health behaviors [39]. However, regarding physical activity and sedentary behavior, the evidence supporting the effectiveness of JITAIs is mixed [37]. However, so far, only JITAIs aimed at individuals have been implemented. Combining DBCTs with JITAIs and intervening on a dyadic level may provide a promising approach to increasing their effectiveness in promoting MVPA.

This Study

This study aimed to examine the effectiveness of dyadic interventions in promoting MVPA in romantic couples. Specifically, we investigated the effectiveness of dyadic interventions containing various DBCTs that elicit social exchange processes for increasing MVPA in romantic couples. We implemented an intensive-longitudinal study over 55 days consisting of phases without dyadic interventions (ie, control phase) and with dyadic interventions, including a one-time psychoeducation intervention on skilled support, weekly planning interventions, and dyadic JITAIs (ie, intervention phase). In the psychoeducation intervention on skilled support, participants learned how to support their partner appropriately to increase their MVPA. In the planning interventions, the participants set a goal and planned the physical activities for the upcoming week. Finally, there were dyadic JITAIs targeting various social exchange processes to increase MVPA.

To investigate the effectiveness of the dyadic interventions, we compared the MVPA during the intervention phase with the control phase. To isolate the effects of the different dyadic interventions, we investigated the effectiveness of the planning interventions and the dyadic JITAIs separately. Note that we did not examine the effect of the skilled support intervention since this was a one-time intervention taking place right after the baseline week and is, therefore, highly correlated with the intervention phase.

We proposed the following hypotheses, all of which were preregistered on Open Science Framework (OSF):

- Hypothesis 1: Couples show higher MVPA (device-based and self-reported) during the intervention phase than during the control phase.
- Hypothesis 2: On days for which participants had planned to be physically active during the planning intervention, they engage in more MVPA (device-based and self-reported) compared with days for which they had not planned any physical activity.
- Hypothesis 3a: Participants indicate higher MVPA (device-based and self-reported) on days when a dyadic JITAI targeted the actor's MVPA compared with days without a dyadic JITAI targeting the actor.
- Hypothesis 3b: Participants indicate higher MVPA (device-based and self-reported) on days when a dyadic JITAI targeted the partner compared with days without a dyadic JITAI targeting the partner.

Additionally, we conducted 3 exploratory analyses. First, we explored the effect of different types of dyadic JITAIs by differentiating between cross-over and joint interventions. Second, we explored the effectiveness of the dyadic JITAIs depending on their timing (ie, when they were sent). There were dyadic JITAIs sent before the planning intervention, before a planned activity, and in the evening. These 3 timings target different aspects of the behavior change process, which may vary in their effectiveness. Finally, we explored how long the effects of the dyadic JITAIs last. Dyadic JITAIs may make lasting changes in the interaction patterns between the partners, allowing their effects to be maintained over time. Thus, these changes in the social exchange processes may go beyond the specific day targeted by the dyadic JITAIs, facilitating engagement in MVPA at a later occasion.

Methods

Funding and Preregistration

This study is part of the "Time and Ties: Dynamic modelling of temporal patterns in dyadic health behaviour change" project

XSL•FO
RenderX

funded by the Swiss National Science Foundation (grant 10001C_197471 / 1). A comprehensive description of the project can be found on the OSF page of the Time and Ties project [40]. The preregistration, including hypotheses, inclusion and exclusion criteria, and planned primary analyses, can be found on the OSF page of the study [41]. The study differs from the preregistration in that we conducted the dyadic analyses for indistinguishable instead of distinguishable dyads. This decision was made to be inclusive of same-gender couples. The completed CONSORT-EHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and Online Telehealth) checklist can be found in Multimedia Appendix 1.

Ethical Considerations

The study received approval from the Ethics Committee of the Faculty of Arts and Social Sciences of the University of Zurich (approval 21.9.11). All participants provided online informed consent using a checkbox before enrolling in the study and were free to withdraw at any time (the informed consent is provided in Multimedia Appendix 2). All collected data are stored in anonymized form on the server of the University of Zurich and are only accessible to the project team. All participants received 150 Swiss Francs (approximately US $189) for their complete participation.

Participants

Data collection took place from June to October 2022. Romantic couples were recruited from the Swiss population through online advertisements on Facebook (Meta) and Instagram (Meta). Inclusion criteria were (1) both partners must be at least 18 years old, (2) they must be in a romantic relationship with each other and live together, (3) both partners must be physically active for less than 150 minutes per week, (4) both partners must have the intention to be more physically active, (5) both partners must not have severe health conditions preventing physical activity, (6) both partners must have a smartphone that they use regularly and have sufficient literacy to operate it independently, and (7) both partners must speak German fluently.

Descriptive statistics of the sample are presented in Table 1.

Table 1. Descriptive statistics of the sample characteristics (76 participants; 38 couples).

Variable	Value
Gender, n (%)	
Women	39 (51)
Men	37 (49)
Education, n (%)	
Vocational education	8 (11)
High school diploma	24 (32)
Bachelor's degree	23 (30)
Master's degree	21 (28)
Married, n (%)	26 (34)
Having children, n (%)	21 (28)
Age (y), mean (SD; range)	34.01 (11.03; 19-60)
BMI (kg/m^2), mean (SD; range)	24.94 (4.11; 16.37-33.95)
Relationship duration (y), mean (SD; range)	9.23 (9.09; 0.58-36.00)
Cohabitation duration (y), mean (SD; range)	7.53 (9.20; 0.25-33.00)
Age of children (n=21; y), mean (SD; range)	16.16 (9.24; 4-32)

Study Design

We conducted an intensive-longitudinal microrandomized trial over 55 days. This study was the first empirical study within the larger Time and Ties project and aimed to inform a computational modeling approach on dyadic interventions as well as to test and improve the smartphone-based data gathering and intervention provision. Thus, the study was not powered for advanced statistical analyses of dyadic intervention effects. From this perspective, it can be considered a pilot trial. An overview of the larger Time and Ties project, including this study, can be found on OSF. The study was smartphone-based, using a self-developed app in collaboration with a company specializing in app development (Multimedia Appendix 3). Participants read the information about the study and provided written informed consent before the start of the study. They were informed that various interventions would be implemented during the study. After registration, the participants received a link to download and sign in to the app. Throughout the study, participants completed daily diaries and wore wrist-worn accelerometers. The study consisted of phases without dyadic interventions (ie, control phase) and with dyadic interventions, including a 1-time psychoeducation intervention about skilled support, weekly planning interventions, and dyadic JITAIs (ie, intervention phase). Random allocation was implemented using a computer program that assigned couples to the intervention conditions characterized with different intervention phases, while ensuring equal sample sizes across groups (ie, blocked

XSL•FO
RenderX

randomization). Each group started with a 1-week control phase to establish a baseline. Afterwards, group A received a 7-week intervention phase. Group B received a 3-week intervention phase followed by a 4-week control phase. Group C received a 4-week control phase followed by a 3-week intervention phase at the end of the study (Figure S1 in Multimedia Appendix 4). During the intervention phase, various dyadic interventions were implemented on designated days, but there were also randomly assigned control days without any interventions. Participants were aware that there were interventions during the study, but they did not know which intervention conditions there were. At the end of the study, participants completed a questionnaire similar to the baseline questionnaire, where they also had the opportunity to provide qualitative feedback. All questionnaires and interventions were sent using a smartphone app designed for this study.

Interventions

Skilled Support Intervention

The psychoeducation intervention about the principle of skilled support took place on the first Saturday after the 1-week control phase. During this intervention, couples learned about different types of social support and social control, the importance of the right timing and equity of support, and how to support each other effectively to help engage in MVPA (DBCTs: "one partner receives education for supporting the other partner," which was applied by both partners) [24]. Furthermore, partners discussed and reported how and when they would like to be supported and how they communicate about social support and social control (DBCTs: "one partner identifies preferred support strategies for the other partner," "one partner gives feedback on support provision of the other partner," and "one partner practices communication skills for health behavior of the other partner;" all of which were applied by both partners).

Planning Interventions

The planning interventions occurred each Sunday during the intervention phase and consisted of 3 parts. First, the couple set their weekly goal by indicating the desired duration of MVPA they aimed to achieve in the upcoming week (DBCTs: "the couple sets a goal for the couple" and "the couple commits to a goal of the couple") [42]. Second, they planned physical activities for the upcoming week. Thereby, they could either plan dyadically (ie, plan together activities they want to do individually) [29] or collaboratively (ie, plan together activities they want to do together) [30]. They planned the activity, timing, location, duration, and whether they would participate individually or together in the planned activity (DBCTs: "the couple plans for one partner" and "the couple plans for the couple"). Third, they engaged in coping planning by anticipating potential barriers that may prevent them from engaging in the planned activities and discussing solutions to overcome them (DBCTs: "the couple creates a coping plan for one partner" and "the couple creates a coping plan for the couple") [26].

Dyadic JITAIs

The dyadic JITAIs were designed in accordance with the recommendations proposed by Nahum-Shani et al [38]. The JITAIs targeted various social exchange processes within the couple that were hypothesized to promote engagement in MVPA (a complete list of all the DBCTs that were implemented can be found on OSF). Note that the target of the JITAI is not necessarily the person who receives the JITAI. For example, a JITAI prompting to provide emotional support to engage in MVPA may be sent to one partner (ie, execution level) but targeting the other (ie, target level) [10]. Depending on the content of the JITAIs, they could target either one or both partners' MVPA. However, due to the interdependence between the partners, the effects may spill over to the nontargeted partner [43]. Thus, this study included JITAIs targeting the actor's MVPA and JITAIs targeting the partner's MVPA. Note that both JITAIs targeting the actor and the partner may be present on the same day (ie, through joint or 2 cross-over interventions targeting different partners).

There were 2 types of dyadic JITAIs: cross-over and joint JITAIs [10]. Cross-over JITAIs were sent to one partner and included instructions to interact with the other partner (eg, provide emotional support to the partner). Joint JITAIs were sent to both partners and included instructions to both partners to actively interact with each other (eg, jointly create a list of advantages of physical activity). The JITAIs were sent to the participants at a specified time, hypothesized to be the most appropriate for the JITAI content. There were three timings when the JITAIs could be triggered: (1) before the planning intervention, (2) before a planned activity, and (3) in the evening. The dyadic JITAIs before the planning intervention targeted the social exchange processes during the planning; those before the planned activity targeted the social exchange processes (eg, social support and social control) before and during the activity; and those in the evening targeted the social exchange processes during the reflection about the engagement in MVPA. Depending on the timing of the JITAIs, the expected effect might not manifest on the same day the couple received the dyadic JITAI but may be on a subsequent day they intended to engage in MVPA (Figures S2-S4 in Multimedia Appendix 4).

Each day, a randomization process either selected a JITAI or not, the latter serving as a control condition. Multimedia Appendix 4 provides a description of the dyadic JITAIs and the selection process. All interventions were stand-alone interventions and were triggered automatically without human involvement.

Measures

Intervention Variables

This study comprised several variables for the different intervention components. First, the study was categorized into the control phase (ie, phase without any dyadic interventions, serving as the reference category) and intervention phase (ie, phase with dyadic interventions). Second, planning was categorized into days without planned physical activities (coded as 0) and days for which the couples had planned physical activities during the planning intervention (coded as 1). Third, regarding the dyadic JITAIs, we included various dummy variables to describe whether a specified JITAI targeted the MVPA that day or did not target the day. We defined two variables for JITAIs targeting the actor and the partner: (1) the

XSL•FO
RenderX

dyadic JITAI for the actor compared days on which a dyadic JITAI targeted the actor's MVPA (coded as 1) with days without dyadic JITAI targeting the actor's MVPA (coded as 0), and (2) the dyadic JITAI for the partner compared days on which a dyadic JITAI targeted the partner's MVPA (coded as 1) with days without dyadic JITAI targeting the partner's MVPA (coded as 0). For the exploratory analyses, we created two variables representing the types of JITAI: (1) cross-over JITAI (coded as 1) versus no cross-over JITAI (coded as 0) targeting the MVPA on that day, and (2) joint JITAI (coded as 1) versus no joint JITAI (coded as 0) targeting the MVPA on that day. Joint JITAIs were coded as targeting both the actor's and partner's MVPA. Moreover, we created three variables representing the timing of the JITAI: (1) JITAI before the planning intervention (coded as 1) versus no JITAI before the planning intervention (coded as 0) targeting the MVPA that day, (2) JITAI before the activity (coded as 1) versus no JITAI before the activity (coded as 0) targeting the MVPA that day, and (3) JITAI in the evening (coded as 1) versus no JITAI in the evening (coded as 0) targeting the MVPA that day. Finally, we computed three lagged terms of the JITAI variables to describe how many occasions ago the JITAI targeted the MVPA: (1) JITAI targeting the MVPA 1 occasion before (coded as 1) compared with no JITAI targeting the MVPA one occasion before (coded as 0), (2) JITAI targeting the MVPA 2 occasions before (coded as 1) compared with no JITAI targeting the MVPA 2 occasions before (coded as 0), and (3) JITAI targeting the MVPA 3 occasions before (coded as 1) compared with no JITAI targeting the MVPA 3 occasions before (coded as 0).

Physical Activity

Physical activity was assessed using both device-based and self-reported methods. The device-based physical activity in minutes of MVPA per day was measured using wrist-worn accelerometers (ActiGraph CentrePoint Insight Watches [Ametris]). The acceleration is measured on 3 axes from which a single vector magnitude count is calculated. Values above 2690 counts per minute were classified as MVPA [44]. The device-based MVPA was filtered for wear time of at least 10 hours per day, according to Choi et al [45], and for awake time, according to the algorithm proposed by Tracy et al [46]. Overall, 11.3% (n=474) of the responses on device-based MVPA are missing after excluding days with low wear-compliance. The self-reported MVPA was measured by adding up the 2 questions capturing the MVPA they did alone ("How many minutes did you spend today alone doing moderate-to-vigorous physical activity?") and with their partner ("How many minutes did you spend today together with your partner doing moderate-to-vigorous physical activity?"). Overall, 5.6% (n=236) of the responses for self-reported MVPA are missing.

Covariates

We assessed the intervention group with 2 time-invariant dummy covariates (group A serving as the reference category) to address differences due to different sequences in the intervention and control phases. Furthermore, we assessed various time-variant covariates. We included the wear time of the wrist-worn accelerometer (minutes per day) because increased wear time increases the potential duration of MVPA that can be recorded. Moreover, we included the time (per 7 days) to address potential time trends [47]. Furthermore, we included dummy variables for the weekend (weekday serving as the reference category) to address differences in the behavior between weekdays and weekends, and skilled support intervention (before the intervention serving as the reference category) to address the potential effects of this intervention on the MVPA. Finally, we assessed the barriers and facilitating factors. Barriers and facilitating factors were assessed with the item "What has made your physical activity easier or more difficult today?" on a bipolar scale from −5 to 5, on which the participants responded to 8 influences that hindered or facilitated engagement in physical activity (eg, "hindering conditions for physical activity" to "beneficial conditions for physical activity"). The scores of the barriers and facilitating factors were summed up into 2 separate scores, indicating the total barriers and facilitating factors today. We included the barriers and facilitating factors to control the internal and external influences that may change the probability or duration of the engagement in MVPA and to test if the interventions effectively increased MVPA over and above these factors [48].

Data Analysis

To estimate the treatment effect of the intervention phase, we calculated multilevel models for intensive longitudinal data and indistinguishable dyads [49]. This approach can be used to analyze dyadic data by accounting for the nonindependence of observations within dyads. We included the intervention phase as the predictor variable and the device-based or self-reported MVPA as the outcome variables.

We used weighted and centered least-squares estimation for microrandomized trials to estimate the treatment effects of the planning interventions and the dyadic JITAIs [50]. This approach addresses the potential biases of time-varying treatment effects and provides consistent causal effects in microrandomized trials. We extended this approach to dyadic data by considering the dyads as the units of analysis. To be inclusive of same-gender couples in our study, we treated the partners as indistinguishable rather than distinguishable based on gender [49]. We included the planning or the JITAI targeting the actor and partner as predictor variables, respectively. We ran separate models with device-based and self-reported MVPA as outcome variables. In all models, complete case analyses were conducted. Thus, days with missing data were excluded from the data analyses. We included time as a covariate in all models [47]. Additionally, in analyses of device-based MVPA, we included the wear time of the wrist-worn accelerometer as an additional covariate.

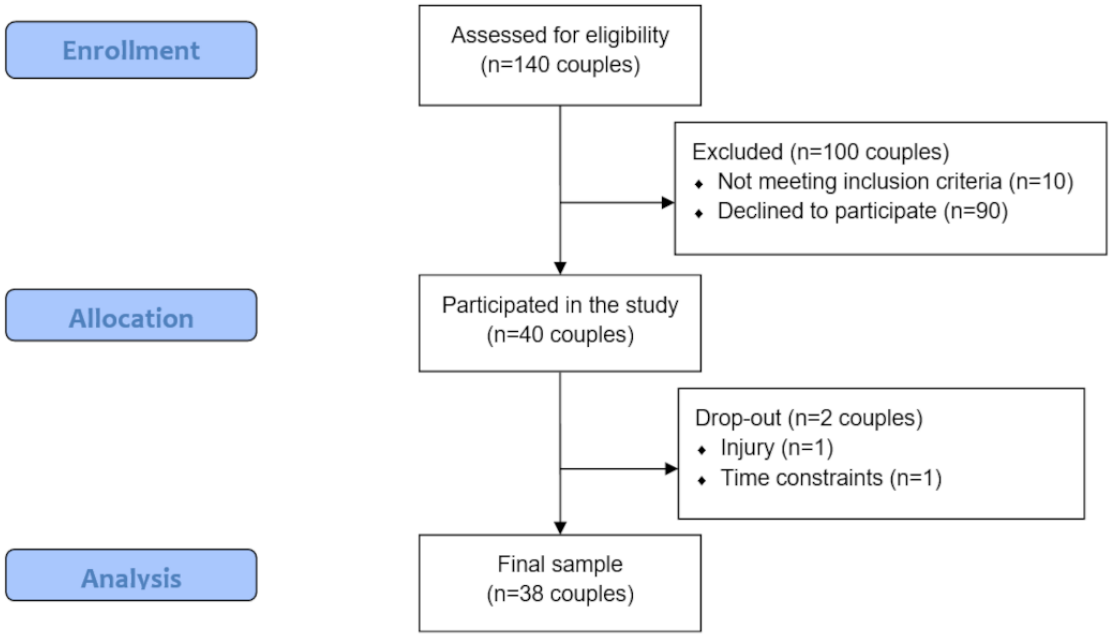
Furthermore, we conducted sensitivity analyses to account for potential influences of covariates. In these sensitivity analyses, we additionally included variables indicating the intervention group, weekend, skilled support intervention, barriers, and facilitating factors as covariates. All covariates were grand mean-centered. All analyses were complete-case analyses.

We ran 3 separate models for the exploratory analyses. In these exploratory analyses, we included the dyadic JITAI type (ie, cross-over and joint), the JITAI timing (ie, before planning,

XSL•FO
RenderX

before the activity, and evening), and the lagged terms of the JITAI as dummy variables.

Software



The analyses were conducted with R in RStudio [51,52]. We used the nlme package (v3.1-157) to estimate the effect of the intervention phase [53] and the xgeepack package (v1.3.9) to estimate the causal treatment effects of dyadic and collaborative planning and dyadic JITAIs [50,54,55]. All R codes are provided on OSF.

Results

Overview

Initially, 140 couples signed up for the study. However, 100 of them either chose not to participate or were excluded during screening. Thus, a total of 40 couples (80 participants) participated in the study, which accounted for an expected attrition rate of 20%. The recruitment stopped when the planned sample size was reached. Furthermore, 1 couple dropped out of the study due to an injury of 1 partner, and 1 couple discontinued the study because of time issues, leaving a total sample of 38 couples (37 mixed-gender and 1 same-gender couple). The CONSORT (Consolidated Standards of Reporting Trials) flow diagram is shown in Figure 1. The mean duration of MVPA was 116.64 (SD 35.40) minutes per day for device-based MVPA and 30.24 (SD 22.19) minutes per day for self-reported MVPA. There is a moderate to high correlation between the device-based and self-reported MVPA, with r_b=0.57 (P<.001) at the between-person and r_w=0.46 (P<.001) at the within-person level.

Figure 1. CONSORT (Consolidated Standards of Reporting Trials) flow diagram.

Tables 2 and 3 present the effects of the intervention phase on device-based and self-reported MVPA, expressed as the difference in minutes between days during the intervention phase compared with days during the control phase. In line with hypothesis 1, the results indicated that during the intervention phase, the couples had significantly higher device-based and self-reported MVPA than during the control phase. Furthermore, the intercepts and slopes showed significant variability, indicating heterogeneity in the mean levels of MVPA and the effects of the intervention phases on the MVPA between the couples.

The average treatment effects of the planning interventions on device-based and self-reported MVPA in minutes are presented in Table 4. The results indicate that on days the participants planned to be physically active during the planning interventions, they indicated higher self-reported but not device-based MVPA. Thus, hypothesis 2 is only supported for self-reported but not device-based MVPA.

The average treatment effects of the dyadic JITAIs on device-based and self-reported MVPA in minutes are presented in Table 5. In line with hypothesis 3, the results indicated that both the dyadic JITAIs targeting the actor as well as the partner significantly increased the device-based and self-reported MVPA.

Sensitivity Analyses

Results of the sensitivity analyses, including the effect of the intervention phase, the average treatment effects of the planning, and the dyadic JITAIs, are reported in Tables S1-S3 in Multimedia Appendix 5. The pattern of the effects of the intervention phase on the device-based and self-reported MVPA remained the same after controlling for various covariates, suggesting the robustness of the results. However, the average treatment effect of the planning intervention on self-reported MVPA disappeared when controlling for covariates. Similarly, the average treatment effect of the dyadic JITAIs targeting the actor on the self-reported MVPA was no longer significant when adding the covariates. We further explored which covariates were responsible for these different results compared with the main analyses. Excluding the barriers and facilitating factors from the sensitivity analyses led to the same patterns as in the main analyses, suggesting that the differences were mainly driven by the barriers and facilitating factors (Table S4 in Multimedia Appendix 5). Moreover, the skilled support intervention resulted in a negative effect on the self-reported MVPA in some sensitivity analyses.

Exploratory Analyses

We conducted 3 exploratory analyses to gain insights into the effects of the type, timing, and temporal dynamics of the dyadic JITAIs (Tables 6-8). Regarding the type of dyadic JITAIs (ie, cross-over or joint), the results showed significant effects of cross-over JITAIs for both targeting the actor as well as the partner on device-based and self-reported MVPA. That means that on days when cross-over dyadic JITAIs were sent, couples were more physically active. Joint JITAIs did not increase device-based but increased self-reported MVPA, indicating that on days when joint dyadic JITAIs were sent, couples reported being more physically active. Furthermore, the effect sizes of the cross-over and joint JITAIs were comparable for both device-based and self-reported MVPA.

[k]Not applicable.

The dyadic JITAIs varied in effectiveness depending on the time they were sent. The dyadic JITAIs sent before the planning intervention targeting the actor increased the device-based and self-reported MVPA. The dyadic JITAIs sent before the planning intervention targeting the partner increased the self-reported but not the device-based MVPA. Furthermore, the dyadic JITAIs sent before the planned activity targeting the actor did not increase device-based nor self-reported MVPA. The dyadic JITAIs sent before the planned activity targeting the partner increased self-reported, but not the device-based MVPA. Finally, neither the dyadic JITAIs sent in the evening targeting the actor nor the partner had any significant effect on the self-reported or device-based MVPA.

Regarding the temporal dynamics of the JITAIs, there was evidence for lagged effects of the dyadic JITAIs targeting the actor on self-reported and, to a lesser extent, on device-based MVPA. This finding indicates that the dyadic JITAIs targeting the actor not only affected the MVPA at the time they were initially aimed at, but their effects lasted and influenced subsequent self-reported MVPA. There was no evidence of lagged effects of dyadic JITAIs targeting the partner on device-based or self-reported MVPA.

Discussion

Principal Findings

This study demonstrated the promising effects of smartphone-based dyadic interventions in promoting MVPA in romantic partners. Participants reported higher device-based and self-reported MVPA during the intervention phase than during the control phase. Furthermore, planning physical activities increased the participants' self-reported but not device-based MVPA. Dyadic JITAIs targeting the actor as well as the partner increased the device-based and self-reported MVPA. However, sensitivity analyses indicated that some of these effects were not robust, suggesting that contextual factors play a relevant role in the effectiveness of dyadic JITAIs. Exploratory analyses showed that cross-over JITAIs promoted device-based and self-reported MVPA, and joint JITAIs promoted self-reported MVPA. Moreover, dyadic JITAIs aiming

XSL•FO
RenderX

at different times (ie, before a planning intervention, before a planned activity, and in the evening) were differently effective in increasing MVPA. Finally, there was evidence for lagged effects of the dyadic JITAIs targeting the actor for device-based and self-reported MVPA but not for lagged effects of dyadic JITAIs targeting the partner.

Effects of the Dyadic Interventions

Consistent with past research, this study found promising effects of dyadic interventions to increase physical activity. Overall, the complex intervention, including different dyadic interventions, was effective in increasing both device-based and self-reported MVPA (hypothesis 1). However, there was heterogeneity in the effects of the intervention phase across couples. This heterogeneity may reflect differences in couple dynamics or insufficient knowledge of moderating factors interacting with the intervention or control phase [48]. A better understanding of these factors may help improve the effectiveness of dyadic interventions [39,56]. Future research may investigate intrapersonal characteristics, relationship dynamics, and the broader social context to provide valuable insights into factors relevant to intervention development and implementation [56].

This study found significant effects of the planning intervention on the self-reported but not device-based MVPA (hypothesis 2). These results are comparable with previous studies that found mixed effects of dyadic and collaborative planning [28,31,32,35]. In contrast to previous studies, this study used a within-couple design and compared days with planned activities to days without planned activities instead of comparing the effects of various planning interventions (eg, dyadic, collaborative, and individual) on subsequent physical activity. Additionally, the participants could freely choose and vary if they wanted to plan dyadically or collaboratively. This approach aimed to enable participants to plan according to their needs and preferences to compensate for potential challenges associated with each form of planning. However, these attempts to better tailor the planning interventions to couples' needs and to use more contingent outcomes [57] were not sufficient to enhance the planning intervention's effectiveness, at least with regard to the device-based measure of MVPA. As discussed previously [58], it seems necessary to identify under what circumstances and for whom these forms of planning unfold the most beneficial effects.

To our knowledge, our study was the first to implement dyadic JITAIs to promote MVPA in romantic couples. In line with previous studies on the effectiveness of JITAIs on health behaviors [39], this study showed promising effects of dyadic JITAIs in promoting MVPA (hypothesis 3a). Furthermore, not only the dyadic JITAIs targeting the actor but also those targeting the partner increased the MVPA (hypothesis 3b). This finding may be explained by both the dyadic nature of the JITAIs as well as the interdependence between close partners in a romantic relationship [6]. One partner's engagement may motivate the other partner to engage in physical activity as well [59]. Furthermore, helping the partner engage in physical activity may have positive outcomes for the provider [43]. For example, providing social support or control to the partner may reiterate the importance of physical activity for the provider [60], increase self-esteem [61], and contribute to feeling more energized [62], promoting engagement in physical activity. Thus, deciding who to target with dyadic interventions appears to be an essential design choice when developing and implementing dyadic interventions.

The effect of the planning and the effect of the dyadic JITAIs targeting the actor on self-reported MVPA disappeared when controlling for additional covariates. Exploratory analyses suggested that these discrepancies were driven by the reported barriers and facilitating factors. Potentially, the barriers and facilitating factors may act as mediators in explaining the JITAIs' effects on MVPA. The planning and JITAIs prompted processes to help engage in MVPA, which may have removed barriers or facilitated engagement in MVPA. Furthermore, it is also possible that the causality goes in the other direction, in that engagement and nonengagement in MVPA influenced the perception of barriers and facilitating factors.

We found an unexpected negative effect of the skilled support intervention on self-reported MVPA in some of the analyses. However, it is important to note that this part of the intervention was not randomized.

This study found some differences in the effects of the dyadic interventions on device-based and self-reported MVPA. Interestingly, in this study, the device-based measure of MVPA was much higher than the self-reported measure. These 2 measures represent related but distinct indicators of MVPA [63]. There are several explanations for these differences. First, self-reported and device-based MVPA may capture different aspects of physical activity [64]. For example, self-reported physical activity may refer more closely to the activities perceived as physical activity by the participants, whereas device-based physical activity may also include other forms of movement, such as naturally-occurring MVPA. Furthermore, it may be possible that engaging in planned physical activities (captured by both the device-based and self-reported MVPA) leads to compensatory effects in that the engagement in naturally occurring MVPA (captured only by device-based MVPA) decreases [65], leading to some discrepancies between the measures. Second, there may be response biases in the self-reported but not device-based MVPA measure [64]. Participants may indicate higher MVPA if they received an intervention because they expect it to be effective. Finally, the device-based MVPA may have misclassified some motions as MVPA, which would also explain why the device-based MVPA was substantially higher than the self-reported MVPA [65].

Exploratory Analyses

Results from the exploratory analyses showed that cross-over JITAIs increased device-based and self-reported MVPA, and joint JITAIs increased self-reported MVPA while having similar effect sizes. Given the exploratory nature of our analyses, results need to be replicated in confirmatory designs and analyses in the future. In addition to examining the main effects of these different prototypes of dyadic interventions [10] and despite their comparable effect sizes found in our study, these 2 types of interventions may target different mechanisms of action [10,14]. For example, joint interventions, such as discussions

XSL•FO
RenderX

and collaborative planning, may trigger interactions in which both partners are equally involved. In contrast, cross-over interventions, such as prompting to provide social support and to exert social control, may trigger one-sided interactions where one partner is more involved than the other. Future research is needed to better understand the potential different effects of cross-over and joint interventions and how they may vary under specific circumstances.

The second set of exploratory analyses showed that dyadic JITAIs with different timings varied in effectiveness. Specifically, there was stronger evidence for the effectiveness of the dyadic JITAIs sent before the planning intervention and before the planned activity than those sent in the evening. These dyadic JITAIs targeted different aspects of the behavior change process. The dyadic JITAIs before the planning interventions aimed at increasing the quality of the dyadic and collaborative plans, a factor central to the effectiveness of planning [58]. The dyadic JITAIs before the planned activity aimed at helping to engage in this activity. Sending dyadic JITAIs at this specific time may be effective because they directly enhance commitment to the planned activities. The dyadic JITAIs in the evening aimed at the partners to reflect on their goal progress, discussing things that went well or poorly regarding physical activity, or prompting support or positive control in the future. A reason for the lack of effectiveness may be that these dyadic JITAIs were not matched to a particular state of vulnerability or opportunity since they did not target immediate preparation or engagement in MVPA directly. Furthermore, the participants may not have had the opportunity to engage in the prompted task because the interventions were sent too late in the day. Thus, future studies should also examine intervention fidelity and intervention engagement, which may vary with different timings of the interventions.

The final exploratory analyses showed that dyadic JITAIs may have effects over and above their targeted time point. Implementing dyadic JITAIs to improve the social exchange processes may translate to improved interaction patterns that sustainably facilitate engagement in health behaviors [11]. Since many health behaviors, such as physical activity, require consistent engagement over extended periods of time, this would be promising for promoting longer-term behavior change [66]. Specifically, this study found evidence for long-term effects of dyadic JITAIs targeting the actor but not for those targeting the partner. These results suggest that different mechanisms may explain these effects [43]. For example, receiving social support and control may establish a subjective norm or change attitudes regarding physical activity [67], which translates into regular engagement in physical activity. In contrast, providing social support and control may promote MVPA by increasing positive effects [43] and energy levels [61], which may entail more transient effects. Future research is needed to investigate these underlying mechanisms in more detail.

Past research has illustrated a need to better understand the boundary conditions moderating the effectiveness of (dyadic) JITAIs [39]. The exploratory analyses of this study contribute to this call by illustrating preliminary insights into the importance of the type and timing of the dyadic JITAIs for their effectiveness. Additionally, it showed the potential long-term effects of dyadic JITAIs, providing new insights and opportunities for health behavior promotion. Given the exploratory nature, however, the next steps are to replicate findings with confirmatory analyses. Moreover, in future studies with more participants, it might also be worthwhile to examine interactions between the different factors examined here. For example, it might well be that joint JITAIs work better when being sent in the evening to prompt joint reflection of past interactions, compared with cross-over JITAIs that might work better before a planning intervention. It is also possible that joint JITAIs might have longer-lasting effects, as the positive dyadic dynamics in supportive interactions promoted by these kinds of dyadic JITAIs might add to the maintenance of joint behavior change attempts.

Strengths and Limitations

This study has various strengths. First, the study investigated health behavior change from a dyadic rather than individual perspective, allowing for a more complete understanding of health behavior change processes in romantic relationships. Second, the microrandomized trial design allowed us to experimentally investigate the dyadic health behavior change as a process over time and to examine daily dynamics [47]. This also allowed us to examine the causal effects of the interventions on the outcomes [50]. Third, we were able to investigate shorter-term as well as lagged effects of the dyadic JITAIs. Finally, including device-based and self-reported MVPA measurements offered a more comprehensive understanding of the effects of dyadic interventions on MVPA [63], as well as addressed potential methodological challenges inherent to the measurement methods.

Despite these strengths, this study also has its limitations. As it was a pilot study, the sample size of 38 romantic couples was relatively small. This relatively small sample size may limit the statistical power, which may be especially the case for the exploratory analyses, where there have been fewer instances of interventions. However, the relatively large number of days examined per couple (ie, 55 days) partly compensates for this small sample size [47]. The limited number of couples also restricted the possibility of conducting more detailed analyses exploring the effectiveness of interventions targeting specific social exchange processes (eg, emotional support and positive social control) and potential mechanisms underlying the intervention effects or interaction effects as outlined above. Furthermore, there were different types of dyadic interventions (ie, skilled support intervention, planning interventions, and JITAIs) implemented in the study. These interventions were designed to build upon and facilitate each other. For example, the dyadic JITAIs were built on the knowledge of skilled support and were triggered in reference to the planned activities. However, this also implies that it remains unclear how exactly and to what extent these different dyadic interventions influenced each other (eg, if the dyadic JITAIs would have been effective without an initial skilled support intervention). Finally, the study targeted inactive romantic couples who expressed a willingness to increase their physical activity. Thus, the study sample was self-selected and therefore may not fully represent the general internet population.

XSL•FO
RenderX

Conclusion

This study extended the common approach of promoting health behavior change of individuals by including partners in the behavior change process. This allowed us to implement DBCTs that address social interactions between the partners. Overall, this study demonstrated the effectiveness of dyadic interventions, including planning interventions and dyadic JITAIs. Furthermore, the exploratory analyses provided first hints to the assumptions that conditions, such as the type, timing, and target, moderate the effectiveness of dyadic JITAIs, providing new insights into conceptual and design elements of dyadic JITAIs. Future research is needed to get a more comprehensive understanding of the effectiveness of dyadic interventions. Specifically, the moderating variables influencing the effectiveness of dyadic interventions and the mechanisms explaining dyadic interventions should be examined.

Abstract

Background: Behavior change interventions delivered through mobile phones often have low engagement among end users.

Objective: This study aimed to explore factors influencing engagement among Swedish high school students with access to LIFE4YOUth, a mobile-based multiple behavior change intervention targeting physical activity, diet, alcohol consumption, and cigarette smoking. Special emphasis was placed on understanding low engagement.

Methods: A sequential explanatory mixed methods design was used. Quantitative usage data from 377 students were analyzed to describe engagement patterns. This was followed by qualitative data collection through 3 focus groups and 2 individual interviews (n=20), analyzed using inductive content analysis. Finally, qualitative comparative analysis (QCA) was used to integrate findings and identify configurations of psychosocial and behavioral conditions associated with low engagement. The results from all phases were interpreted and discussed as a whole.

Results: A majority (253/377, 67%) of participants showed low engagement, with 62% (158/253) never interacting with the intervention beyond receiving weekly SMS text messaging. Focus group discussions revealed 3 overarching categories influencing engagement: perceived importance of behavior change, user experiences, and environment of use. In total, 48% (121/253) of the low-engaged participants were represented by 1 of 3 configurations, which described participants' characteristics as unmotivated high-needers, motivated low-needers, and dissatisfied needers. Robustness tests confirmed the stability of the unmotivated high-needers configuration.

Conclusions: LIFE4YOUth (Linköping University) did not engage high school students with multiple risk behaviors who were content with their lives and did not consider healthy behaviors as very important. However, positive experiences of being both confirmed and encouraged may explain engagement among students engaged in a combination of health-risk and health-promoting behaviors. Future research could explore how tailoring the number of behaviors targeted by mHealth interventions for adolescents might increase engagement and, in turn, behavioral outcomes.

Introduction

Health-risk behaviors among adolescents, such as insufficient physical activity, poor diet, heavy episodic drinking, and cigarette smoking, call for effective strategies to increase adolescents' engagement in healthy behaviors [1-3]. Research shows that interventions that use mobile health (mHealth) technology have the potential to influence adolescents' health behaviors [4-6]. This finding is promising because it implies that many adolescents can be reached concurrently at low costs regardless of geographical location [7].

Despite the potential of mHealth to reach adolescents anytime and anywhere while preserving their integrity in relation to peers and professionals [8], evidence indicates that it is often challenging to engage adolescents with mHealth tools [9,10]. The mHealth engagement typically includes behavioral, cognitive, and emotional aspects of the interaction between the user (eg, adolescent) and the technical platform, such as a mobile phone health app. Although these dimensions of engagement interact [11], the behavioral aspect has received the most attention in the scientific literature to date [12,13]. For example, studies that rely on usage data combined with user demographic data to investigate factors associated with, and potentially predictive of, intervention usage in general [14] and effective engagement in particular [10,15,16].

However, aside from the limited number of empirical studies that seek to understand and explain engagement patterns from broader perspectives, including cognitive and emotional aspects of engagement, several important knowledge gaps remain. First, since the use of multiple behavior change approaches to tackle the co-occurrence of health risk behaviors is still in its infancy, there is limited knowledge about user engagement with mHealth interventions that target multiple behaviors simultaneously [17,18]. Second, the existing evidence on contextual factors associated with mHealth engagement is primarily based on adult populations [17,19,20], underscoring the need for studies focusing specifically on adolescents' engagement with mHealth behavior change interventions [13]. To address these gaps, studies have been conducted to examine design features associated with sustained engagement [21,22] and to identify effective strategies for increasing engagement among adolescent users of mHealth behavior change tools [23]. However, knowledge about what influences and explains engagement patterns among adolescents with access to an mHealth multiple behavior change intervention is still limited.

Consequently, this mixed methods study aimed to investigate explanations for engagement among high school students with access to an mHealth multiple behavior change intervention (LIFE4YOUth; Linköping University), with a specific emphasis on understanding low engagement. The following research questions (RQs) were examined:

- RQ1: What characterizes high school students' engagement with the LIFE4YOUth intervention during a 16-week intervention period?
- RQ2: What conditions are plausible explanations for high school students' engagement with the LIFE4YOUth intervention?
- RQ3: Which configurations of psychosocial and behavioral conditions may explain low engagement?

Methods

Study Design

This study was part of a project that overall aimed to evaluate the effects of a multiple behavior change mHealth intervention (LIFE4YOUth) targeting Swedish high school students [24]. A sequential 3-phased explanatory mixed methods design [25] with qualitative comparative analysis (QCA) [26] was used to understand engagement patterns. Integration occurred at each stage of the study. In phase 1 (RQ1), baseline and usage data were analyzed using descriptive statistics to give an overall idea of how high school students engaged with LIFE4YOUth during a 16-week intervention period. Results from Phase 1 were used to develop an interview guide and diagrams depicting engagement patterns for the sequential phase. In phase 2 (RQ2), high school students participating in focus groups were encouraged to interpret the depicted engagement patterns through discussion and reflection based on their experiences with LIFE4YOUth. An inductive approach of qualitative content analysis was used for analyzing the qualitative data [27]. Explanations for low engagement discussed among focus group participants were thereafter used to conceptualize and build the conditions that were further investigated in Phase 3. In phase 3 (RQ3), conditions revealed from phase 2 were systematically compared using QCA to identify combinations of conditions (ie, configurations) that specifically occurred among low-engaged participants. In line with the sequential explanatory mixed methods design, the qualitative and quantitative results were ultimately integrated and interpreted together to provide a comprehensive understanding of explanations for engagement among high school students with access to an mHealth multiple behavior change intervention (LIFE4YOUth). All procedures are reported in accordance with the COREQ (Consolidated Criteria for Reporting Qualitative Research) 32-item checklist [28] and the Good Reporting of A Mixed Methods Study (GRAMMS) checklist [29].

LIFE4YOUth Intervention

The LIFE4YOUth intervention was developed as part of the Mobile health Multiple lifestyle Behaviors Interventions across the Lifespan (MoBILE) research program, which designs and evaluates mHealth interventions tailored for different populations [30]. LIFE4YOUth was designed to promote healthy behaviors among Swedish high school students. Three intervention components were central: (1) a weekly screening and feedback feature; (2) a dashboard with factual information and exercises for all health behaviors; and (3) an SMS text messaging service that can be activated by end users that includes automatic SMS text messaging programs for each health behavior (physical activity, diet, alcohol consumption, and cigarette smoking), as described in detail elsewhere [24,31]. All content was tailored to the target group [32] and based on recommendations provided by the National Board of Health and Welfare in Sweden [33], previous studies [34,35], and health behavior theories [36,37]. The LIFE4YOUth trial indicated a potential of LIFE4YOUth to increase participants' weekly time

XSL•FO
RenderX

spent in moderate to vigorous physical activity after 2 and 4 months and to a small extent increase their short-term intake of fruit and vegetables. The effects on alcohol consumption and cigarette smoking were less convincing [31].

Phase 1: Characterizing Engagement Patterns (RQ1)

Data Collection

Quantitative data were collected from participants (n=377) in the intervention arm of the LIFE4YOUth trial [31]. The trial participants were recruited from high schools across Sweden, including vocational training and education preparing students for higher studies. The eligibility criteria were being a high school student, not meeting health recommendations for either physical activity, diet, alcohol consumption, or cigarette smoking, and owning a mobile phone. No exclusion criteria were applied. A total of 1398 students registered interest in the study, of whom 890 (64%) consented to participate, and 760 completed the baseline questionnaire, which was used to assess eligibility. Four (0.5%) students did not meet the eligibility criteria and were therefore excluded. All participants were enrolled in the trial between September 2020 and June 2023.

Engagement Measures

Three engagement measures were used to describe participants' engagement with LIFE4YOUth: (1) activation of the SMS text messaging program to support behavior change (yes or no), (2) the number of weeks completing the weekly screening assessment (1-16), and (3) the total number of sessions interacting with the content, defined as a continuous series of screen views initiated by actively clicking on symbols to navigate between dashboard content (zero to infinity). A new screen view after 30 minutes of inactivity was considered a new session [38].

Explanatory Measures

Explanatory measures referred to baseline variables that were assumed to influence participants' engagement with the intervention. These included 4 psychosocial and 7 health behavioral variables. The choice of psychosocial variables was based on common constructs in behavior change theories [36,37] assumed to mediate the effects of LIFE4YOUth [39]. Importance, confidence, and know-how were generally measured using the following questions: (1) "How important do you think it is to improve your lifestyle or sustain your healthy behaviors?"; (2) "How confident are you that you will be able to change your lifestyle or sustain your healthy behaviors?"; (3) "How well do you know how to change your health behaviors?" Responses were given on a 10-point Likert scale. As adolescents' satisfaction with life is also associated with their health behaviors [40,41], life satisfaction was also included as a psychosocial variable; and assumed to influence engagement. Life satisfaction was measured using Cantril's ladder [42]: (4) "Thinking about your own life and personal circumstances, how satisfied are you with your life as a whole?" Responses were recorded on an 11-point Likert scale ranging from 0 (not at all satisfied) to 10 (completely satisfied).

The behavioral variables assumed to influence engagement included (1) weekly time (minutes) spent in moderate to vigorous physical activity (MVPA); (2) number of daily portions (100 g) of fruit and vegetables; (3) number of weekly portions of candy or snacks; (4) number of weekly sugary drinks (33 cL) consumed; (5) monthly frequency of heavy episodic drinking (ie, ≥ 4 standard drinks at 12 g pure alcohol on one occasion); (6) number of weekly standard drinks of alcohol consumed; and (7) smoking any cigarette in the past week (yes or no). All variables except for smoking were measured numerically through self-reported data, as described in detail elsewhere [31].

Data Analysis

The k-means function in R (version 1.3.1073; R Core Team) was used to create 3 engagement clusters (high, medium, and low) based on participants' (1) activation of text-message programs, (2) the number of weekly screening assessments, and (3) the number of sessions interacting with the dashboard content. Two-sample *t* tests and chi-square tests were used to test for statistically significant differences between clusters with respect to baseline characteristics, using a significance level of 0.05. The k-means clustering was also used to identify crossover points for all psychosocial variables included in the QCA.

Phase 2: Identifying Conditions Explaining Engagement Patterns (RQ2)

Data Collection

High school students participating in the LIFE4YOUth trial [31] were invited to participate in a focus group interview. Two high schools in the region of Östergötland invited students to focus groups using a convenient sampling strategy [27]. The schools were chosen based on their different educational profiles and the fact that contact with staff was established. Students were recruited either by written information provided by the school nurse or by oral information from teachers. All students in 2 classes were invited to participate during school hours. Three students within these classes declined participation. A total of 3 focus groups and 2 individual interviews with a total of 20 high school students were conducted by AS (a female PhD candidate and experienced school nurse) and UM (a female senior associate professor with expertise in qualitative methodology). No one other than the students and moderators, who were not familiar with the participants, attended the focus groups.

Both interviews and focus groups, which involved 4-8 participants, were audio-recorded and conducted at the participants' school during school hours between February 2023 and April 2023. A semistructured interview guide with predefined themes was used to facilitate the focus groups. The discussions were initiated by showing participants diagrams illustrating engagement patterns (derived from Phase 1) and asking them to reflect on the factors that might explain each pattern based on their experiences with LIFE4YOUth. The duration of the sessions varied between 33 and 46 (mean 40, SD 6) minutes. Field notes were written directly after each session.

Data Analysis

The audio-recorded data were transcribed verbatim by professionals and analyzed inductively using qualitative content

XSL•FO
RenderX

analysis [27]. All transcripts were carefully read by AS and UM and checked for accuracy against the audio recordings (AS). The coding procedure was performed using the software (NVivo 12 Plus; QSR International Pty Ltd) to organize similar content in the data using preliminary labels (ie, codes; AS). After establishing a coding scheme, all transcripts were reread to systematically code all relevant text units (AS). Text extracts for each code were read and reread to get an idea of similarities and differences among data within codes and between codes. Codes with similar content were combined to create categories, which were checked against the transcripts to verify meaningfulness and to ensure that all relevant data were captured by the categories. UM was involved in all analytical procedures through repeated discussions until consensus was reached.

Phase 3: Identifying Combinations of Conditions Explaining Low Engagement (RQ3)

Building Integration Using QCA

A crisp set QCA [26,43] was conducted to explore whether the conditions derived from the qualitative findings helped explain the low-engagement cluster identified in Phase 1. Crisp sets were used because of our interest in exploring whether the presence rather than the degree (ie, fuzzy set) of a condition was related to engagement. While the qualitative findings from Phase 2 informed the selection and definition of conditions, k-means clustering was used to determine the crossover points used to calibrate each condition. All participants at or above the crossover point were coded as 1 (fully in the set), while cases below the crossover point were coded as 0 (fully out). For negatively framed conditions, the calibration was reversed: cases at or below the crossover point were coded as 1, and cases above the crossover point were coded as 0. A truth table [26,44] was constructed to obtain an overview of all possible combinations of conditions (ie, configurations) and their coverage in empirical data. The analysis also included configurations represented by only one participant, which is coherent with good practice of QCA [45,46]. An enhanced standard analysis [47] was carried out by logically minimizing the truth table. A consistency threshold at 0.75 was deemed enough to reveal descriptive patterns in the data. The minimization procedure, as with all other QCA procedures, was performed using the QCA packages (version 3.19) and SetMethods (version 4.0) in R (version 1.3.1073). The algorithm used to minimize the truth table starts at the upper row and systematically works through each truth table row with an outcome value of 1 to determine whether a condition can be eliminated from the configuration. The goal of this procedure is to find the briefest way to summarize all available information from the truth table, that is, the most parsimonious solution [26]. All configurations included in the most parsimonious solution indicate alternative pathways to low engagement. All configurations were interpreted holistically based on knowledge gained from the qualitative phase and were labeled to describe the overall characteristics conveyed by each pathway.

Robustness Tests

The analytical procedures were repeated using the negation of the outcome (not low engagement), in accordance with recommendations [45,46]. The model analytics included interpretation of consistency and coverage, evaluating the simplifying assumptions used in the logical minimization (ie, whether possible configurations that were not represented by data were used in the minimization), and assessing model ambiguity (ie, whether the minimization revealed more than one valid way of summarizing the truth table).

Following Oana and Schneider's approach [48], robustness was further assessed using a fit-oriented and case-oriented approach to measure how sensitive the solution was to analytical decisions. The obtained solution was tested against alternative solutions derived from the following analytical decisions using a consistency threshold of 0.8 instead of 0.75, not excluding participants with activated SMS text messaging programs from the low engagement outcome, and using 5 as a frequency threshold (ie, including configurations represented by at least 5 participants in the minimization of the truth table). The obtained solution was compared to the minimal test solution, which is the area where all possible solutions agree, and the maximal test solution, which is the entire area of possible solutions. This comparison was made to determine how much the 2 sets of solutions overlapped. Robustness was also assessed in terms of the proportion of participants that would remain in the alternative solution.

Ethical Considerations

Students were informed about the LIFE4YOUth intervention through printed advertisements distributed in high school settings. Before providing consent to participate in the study, all participants received written and oral information that briefly described the characteristics of the 16-week digital intervention, the purpose and design of the study, the types of data collected, how data will be handled, and that participation is voluntary and without any financial compensation. All participants were further informed that they were free to decide if, how, and when to use the digital intervention, and that they had the right to withdraw from the study at any point without consequences. When applicable, participants were informed about the role of the focus group moderators as part of the research team. Informed consent was collected from all participants (aged 15 years or older) but not from their guardians. All quantitative data were pseudoanonymized using a user identity, which only one co-author (MB) had access to. To further ensure privacy and confidentiality, only those involved in the collection and analysis of focus group data (AS and UM) had access to personal information linked to the data. The procedures to collect and use quantitative engagement data (Swedish Ethical Review Authority, Dnr 2019-03813, Dnr 2020-03538) and qualitative data (Dnr 2022-02493-02) were consistent with the ethical approval from the Regional Ethical Committee in Linköping, Sweden. No financial compensation was offered for participation.

Results

Overview

The characteristics of the study sample are presented in Table 1. The median age of participants was 17 years. Females were overrepresented (265/377, 70%).

[c]Assessed as "Please select the highest education for your mother and father."

[d]Not available.

[e]Assessed as "How would you describe the economic situation in your family?"

[f]Assessed as "Where were you/your parents born?"

[g]Cantril's ladder: "Thinking about your own life and personal circumstances, how satisfied are you with your life as a whole?" Responses were given on an 11-point Likert scale where 0 represents not at all satisfied.

[h]Defined as follows: Importance: "How important do you think it is to improve your lifestyle or sustain your healthy behaviors?" Confidence: "How confident are you that you will be able to change your lifestyle or sustain your healthy behaviors?" Knowledge: "How well do you know how to change your health behaviors?" Responses were provided on a 10-point Likert scale.

[i]MVPA: moderate to vigorous physical activity.

The majority were born in Sweden (324/377, 86%) with highly educated Swedish-born parents. An overview of participants' baseline characteristics across all engagement levels is provided in Table S1 in Multimedia Appendix 1.

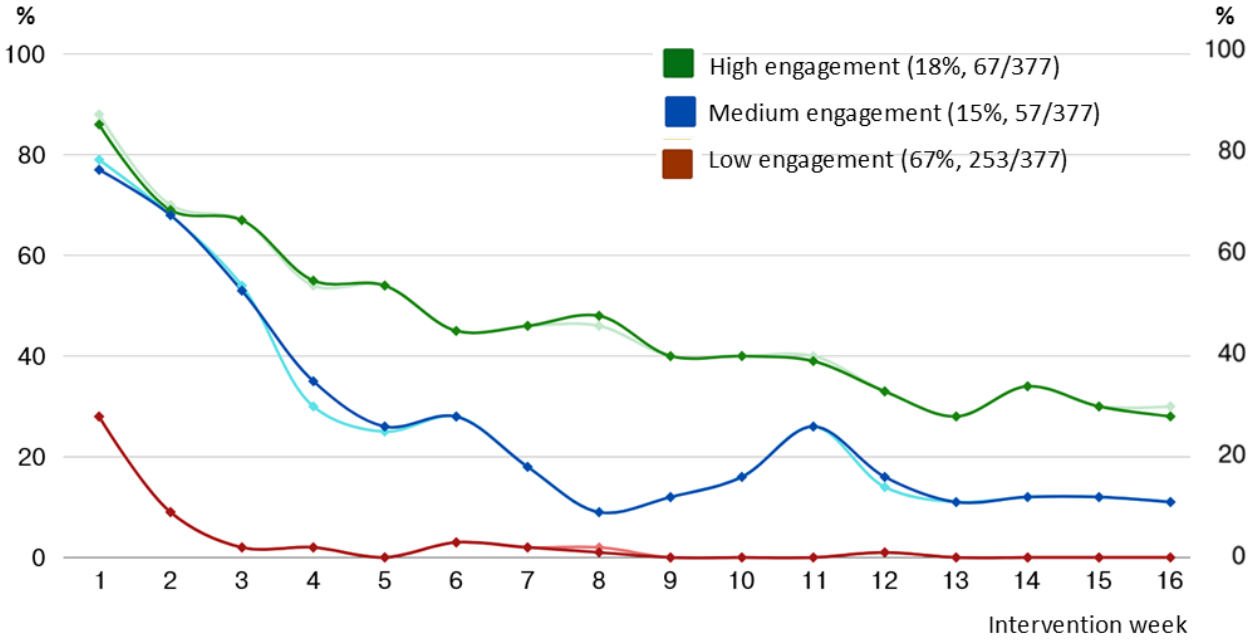
Phase 1: High School Students' Engagement With LIFE4YOUth (RQ1)

Defining Engagement Patterns

The results from this phase describe the characteristics of participants' engagement with the LIFE4YOUth intervention. The results from the k-means clustering (Table S2 in Multimedia Appendix 1) informed the thresholds used to define 3 engagement patterns. Low engagement was defined as 2 or fewer weeks (out of 16) of completing the weekly screenings, a maximum of 3 sessions of engagement with the dashboard content, and no activated SMS text messaging program. High engagement was defined as completing the weekly screening in at least 9 weeks, or by 12 or more engagement sessions during the intervention period, or by having activated at least one SMS text messaging program. Engagement between low and high was defined as a medium level of engagement.

Engagement With the LIFE4YOUth Intervention

Among participants who engaged with LIFE4YOUth at least once (219/377, 58%) during the 16-week intervention period, the weekly screening was completed on average in 4 (SD 4) weeks, and the dashboard content was accessed on average 5 (SD 5.5) sessions. The proportion of participants who completed the weekly screening assessment was almost identical to the proportion per week who engaged with the dashboard content. Twenty-one percent of participants (45/219) who engaged at least once activated one or more SMS text messaging programs focusing on physical activity, diet, alcohol consumption, or cigarette smoking. Table 2 presents an overview of engagement activities by engagement cluster.



In total, 18% (67/377) were defined as high-engaged, 15% (57/377) were defined as medium-engaged, and 67% (253/377) were defined as low-engaged (Figure 1). Sixty-two percent (158/253) of the low-engaged participants never engaged actively. At baseline, low-engaged participants reported significantly higher frequency of heavy episodic drinking, lower levels of perceived importance, and higher levels of knowledge of how to change their behaviors. These differences were investigated further in the subsequent phases to gain a better understanding of what explains engagement in general (Phase 2) and low engagement in particular (Phase 3). Engagement patterns were similar throughout the study period, with no statistically significant differences during or after the COVID-19 pandemic (Table S3 in Multimedia Appendix 1).

Table 2. Cluster-specific engagement measures.

Engagement measures	Low (n=253)	Medium (n=57)	High (n=67)
SMS text messaging programs, n (%)	0 (0)	0 (0)	45 (67)
Weekly screenings, mean (SD)	0.49 (0.69)	4.25 (1.66)	7.46 (5.28)
Session episodes, mean (SD)	0.54 (0.79)	5.35 (2.37)	9.75 (7.40)

Phase 2: Conditions Explaining High School Students' Engagement With LIFE4YOUth (RQ2)

Categories of Conditions That Overall Influence Engagement

The results from this phase describe conditions identified among a subset of participants (n=20) from phase 1 who took part in focus groups to provide insights and help interpret the previously identified engagement patterns. Three categories of plausible explanations for engagement with LIFE4YOUth were discussed among focus group participants: (1) perceived importance of health behavior change, (2) user experiences, and (3) environment of use. Descriptions of these categories are followed by suggestions regarding how these conditions were perceived to explain medium and high engagement as well as low engagement.

Perceived Importance of Health Behavior Change

Focus group participants considered the perceived importance of healthy behaviors as a product based on their interest, willingness, and intention to act to accomplish change. Experiences of problems, such as being dissatisfied with life or oneself, were considered reasons for being interested in behavior change. However, the components of willingness and intention were perceived to be influenced by students' beliefs about their ability to cope with the required efforts given the current circumstances in their lives. Thus, the perceived importance of health behavior change as a condition for engagement incorporates confidence in behavior change. Indeed, participants stressed that one can be both interested and have a desire to change something but lack the confidence to make changes, a constraint that impacts perceptions about the importance of a behavior change, as illustrated in the quotations below:

> *When one isn't doing well, one may easily think of oneself as incapable and avoid trying to establish new habits because being too busy thinking about other things and doesn't want any changes when one is at least somewhat happy.* [Female]

> *It's all about your attitude to change behaviors, [. . .] to notice the tips and acknowledge what they might do for you, you need to have a desire to be helped.* [Male]

> *Well, the first two times I used it [LIFE4YOUth], I browsed and read. After a while, I realized that there's nothing I want to actively change right now.* [Female]

User Experiences

The discussions among participants revealed that the experience of gaining something expected from the intervention—for example, gaining knowledge and adequate support—is critical for an overall positive user experience. The conditions the user experiences further include reactions elicited by the intervention, such as positive emotions of inspiration or negative emotions of defense. Emotions evoked can vary depending on current behaviors and social values. Indeed, some participants perceived that even study content that was not part of the intervention (eg, baseline weight question) elicited negative emotions:

> *It [study content] can be a reminder to always have to think about it, and when life struggles on and you know that 'yeah, I am aware about what I am doing may not be the best, but I don't have time to think about it'.* [Female]

> *Participant 1: I think that people always seek validation [. . .], it doesn't have to be something material, but as you said about feedback . . . Receiving feedback, such as grades or whatever, [. . .] is crucial, because if you do all the things and get nothing in return, then you will probably not . . . Participant 2: I also think that you want to gain something from it*

XSL•FO
RenderX

[the intervention]. Such as knowledge or, as you said, validation, and insights on how to improve oneself. [Male]

Environment of Use

The condition environment of use refers to social circumstances that influence when and how high school students engage with LIFE4YOUth. The participants emphasized that many things require high school students' attention that compete with how much time they spend with LIFE4YOUth. In fact, participants argued that it may be merely a lucky coincidence if a LIFE4YOUth SMS text messaging is received at a suitable time, which may slightly increase the likelihood of engaging with the intervention by clicking on the link in the SMS text messaging. On the other hand, receiving the SMS text messaging while busy means that the message will likely be forgotten:

Depending on when it is received [the LIFE4YOUth text message], one has a varied amount of time to actually respond to the questions. If I was studying at home and received a [LIFE4YOUth] text message, [. . .] I would likely take a break. But if you're with friends and get a text-message, it's not like, 'Yeah, chill, I should just respond to some questions.' [Male]

There are other [mobile-phone health] apps that only aims at smoking cessation [. . .], but this app [LIFE4YOUth] should aid . . . it serves several purposes. However, the other app may only have one function, and that is to make you stop smoking. [Female]

Suggested Explanations for Medium or High Engagement With LIFE4YOUth

Participants reasoned that when one is satisfied with life, one tends to be happier, more confident, curious, and interested in improving oneself. Satisfied people who are engaged in some behaviors considered healthy and in some behaviors considered risky can experience that LIFE4YOUth confirms their healthy behaviors and encourages them to avoid their risky behaviors. The experience of being validated and encouraged can spark ambitions and increase the likelihood of end users continuing to be engaged with LIFE4YOUth. Thus, positive reactions were considered a mechanism that explains engagement. Furthermore, the content provides tips for the adaptation of health-promoting behaviors. According to the participants, when experiencing the tips as desirable and helpful based on a learning need, end users may engage with LIFE4YOUth to a greater extent, indicating that meeting expectations also constitutes a mechanism that drives engagement.

Furthermore, participants thought that end users who are not very happy with their lives and want a change to feel better might consider LIFE4YOUth as a tool worth trying, even when not being convinced that a mobile phone app will help them. Under such circumstances, expectations regarding one's ability to improve health behaviors and the perceived helpfulness of LIFE4YOUth were lower than when the goal was to successfully change those behaviors. That is, the influence of confidence was perceived to be less meaningful in such situations.

Suggested Explanations for Low Engagement With LIFE4YOUth

Participants emphasized that end users with several health-risk behaviors are unlikely to want to be reminded of this on a regular basis. This was deemed to be stressful, that is, a negative reaction to LIFE4YOUth. In addition, participants believed that one may not agree with indicators about health behaviors being considered a health risk. Some participants underlined that behaviors vary from week to week and that their behaviors overall might be adequate. Furthermore, LIFE4YOUth addresses multiple health behaviors, and end users with limited knowledge, or who seek in-depth knowledge about a specific behavior, may find the content too broad. According to participants' reasoning, the risk of being disappointed increases as end users' expectations or needs increase. Higher needs can, for example, depend on current health behaviors or on overall circumstances that impact end users' capabilities to manage their situation.

Two additional explanations for low engagement were raised during the discussions. It was not assumed that end users experiencing life challenges possessed the necessary energy or interest to engage in behavior change. In fact, participants generally found it far too easy to disengage because no one pursued them or even encouraged them, as parents might with their schoolwork. When being satisfied with life, on the other hand, one may have no desire to change anything, and engagement with LIFE4YOUth might not be considered as worthwhile. Furthermore, the weekly SMS text messaging itself served as a reminder about health behaviors. Some participants did not believe that active engagement was therefore needed to benefit from the intervention.

Phase 3: Combinations of Conditions Explaining Low Engagement (RQ3)

Defining Conditions for the QCA

The integrated results from this phase describe how the conditions identified in phase 2 may help explain low engagement within the phase 1 sample (n=377). Based on the discussions among focus group participants, 5 conditions were selected, defined, and included in the QCA. These were (1) engagement in health-risk behaviors; (2) engagement in health-promoting behaviors; (3) being dissatisfied with life; (4) being high-skilled in how to change behaviors; and (5) considering healthy behaviors as very important.

Engagement in health-risk behaviors was defined as smoking ≥1 cigarette in the past week, or (if ≤18 years old) drinking any alcohol in the past week, or (if ≥18 years old) having consumed ≥10 standard drinks of alcohol in the past week, or engaging in heavy episodic drinking ≥1 time in the past month. Health-promoting behaviors were defined as ≥420 minutes of MVPA in the past week or ≥3 daily portions of fruit and vegetables in the past week, combined with either ≤4 portions of candy and cakes in the past week or ≤2 cans (33 cL) of sugary drinks in the past week. These cut-off points align with the thresholds used in the screening and feedback component of LIFE4YOUth. Dissatisfaction with life was defined based on the results of the k-means clustering (≤5 on a 11-point Likert scale). Being highly skilled in how to change health behaviors,

XSL•FO
RenderX

as well as considering healthy behaviors as very important, was defined as ≥8 on a 10-point Likert scale based on the k-means clustering.

Findings From the QCA

Table 3 shows an overview of all 32 possible combinations of conditions (ie, configurations) and their representation among participants in this dataset. The minimization of these configurations and their empirical representation assisted in identifying 3 configurations that contribute to explaining low engagement. No simplifying assumptions were applied to obtain the most parsimonious solution, and no model ambiguity occurred, meaning that none of the configurations associated with low engagement were also associated with non–low-engagement. The most parsimonious solution model was identical to the conservative and intermediate solution models, indicating a high degree of robustness in the identified configurations. The robustness test identified one configuration that remained stable across all tested changes, including participants who were not engaged in health-promoting behaviors but were engaged in health-risk behaviors, did not consider it important to change their health behaviors, and lacked knowledge of how to change them were likely to show low engagement with LIFE4YOUth. Details of the robustness tests are provided in Tables S4 and S5 in Multimedia Appendix 1.

The 26% raw coverage presented in Table 4 indicates that 26% (66/253) of all low-engaged participants demonstrated the configuration labeled unmotivated high needers. Within this configuration, participants engaged in health-risk behaviors but not in health-promoting behaviors, were not dissatisfied with their lives, and did not consider healthy behaviors to be very important. The consistency value of 0.83 means that, of all participants who were described by this configuration, 83% (69/80) were low-engaged. The configurations motivated low needers and dissatisfied needers to describe 2 additional pathways to low engagement. The first pathway reflects being engaged in health-promoting behaviors, considering healthy behaviors to be very important, and not being dissatisfied with life. The second pathway reflects being engaged in health-risk behaviors, not being very skilled in how to change behaviors, and being dissatisfied with life. In total, 48% (121/253) of all low-engaged participants in this dataset were described by one of these configurations, while 19% (29/151) of those described by the configurations were not low-engaged.

Discussion

Principal Findings

This mixed methods study aimed to deepen the understanding of the conditions that influence and explain high school students' engagement with an mHealth tool (LIFE4YOUth) targeting multiple health risk behaviors (physical activity, diet, alcohol consumption, and cigarette smoking). Overall, the majority of participants who were given access to the LIFE4YOUth intervention engaged to a low extent (Textbox 1). Participants' perceived importance of behavior change, their experiences with the intervention, and external circumstances that affected their ability to respond to prompts immediately may have influenced their level of engagement. By using participants' reasoning about explanations for low engagement as a basis for defining conditions in the QCA, the integrated results revealed 3 configurations associated with low engagement. These configurations constitute possible pathways for explaining why adolescents with access to a behavior change tool targeting multiple health-risk behaviors hardly ever interact with the tool. In the discussion that follows, these pathways are interpreted in relation to the findings obtained from the focus groups (phase 2) as well as theory and previous research.

Focus group participants suggested that having multiple risk behaviors—such as insufficient engagement in physical activity and unhealthy dietary behaviors alongside alcohol consumption and cigarette smoking—could explain low engagement among individuals who are content with their lives and do not consider behavior change to be important. This expectation was supported by the quantitative data through the configuration of unmotivated high needers. Indeed, 62% (157/253) of the low-engaged participants disengaged without being exposed to any intervention content other than the weekly SMS text messaging, which raises the question of why so many participants did not interact with the dashboard content even once. It is unlikely that this can be explained by participants' experiences of the LIFE4YOUth content. However, it is possible that low-engaged participants had no interest in changing their behaviors but enrolled in the trial for other reasons [49]. Therefore, it is possible that the characteristics shared by the low-engaged participants are similar to those of individuals who declined participation in the first place. Low interest in mHealth behavior change interventions can be understood from a novelty-complexity perspective, as suggested by Crutzen and Ruiter [50], who developed a conceptual model on mechanisms that are assumed to influence people's interest in such tools. People may be interested in behavior change interventions if they perceive the intervention to be novel and the level of complexity of end users' "problems" is neither too high nor too low. High-level complexity problems are thought to reduce people's self-efficacy and interest, whereas low-level complexity problems are thought to be simple enough to manage without the assistance of digital tools. Both scenarios can account for low interest in LIFE4YOUth among motivated low-needers, but also unmotivated high-needers and dissatisfied needers who may lack resources relative to their needs. Therefore, it is possible that focusing on multiple behaviors simultaneously within a single intervention became a barrier for some participants to even consider the idea of behavior change.

Although engagement in multiple health risk behaviors and dissatisfaction with life in combination with other explanatory conditions may explain low engagement in some cases, the reverse relationship may also apply. For example, Thornton et al [51] found no evidence of an association between the number of risk behaviors or psychological distress and adolescents' level of engagement with an app targeting multiple health risk behaviors. This finding is noteworthy, as it resonates with explanations discussed by participants in our focus groups, who suggested that experiencing poor mental well-being might spark interest in using mHealth tools to initiate positive change. This interpretation further aligns with the QCA results for the negated outcome (ie, medium or high engagement; Table S6 in Multimedia Appendix 1), which suggest that dissatisfaction with life, together with nonengagement in health-risk behaviors and other conditions, may be associated with continued engagement in LIFE4YOUth. Thus, adolescents who are struggling in some aspect of their lives may find mHealth lifestyle tools appealing. However, careful tailoring might be needed to empower individuals to believe in their ability to change.

XSL•FO
RenderX

The concept of response efficacy refers to the belief that the "problem" is manageable through the intervention, which is an essential mechanism that can drive continued engagement [50]. Our findings, as well as previous research [9,52,53], show that adolescents who overcome barriers and invest effort in mHealth lifestyle tools may experience these tools as encouraging and remain engaged over time. However, sustained engagement with mHealth tools is not a desired outcome itself [16]. Despite a large proportion of participants in the intervention group of the LIFE4YOUth trial engaging with the content only a few times over the 16-week intervention period, effect estimates [31] indicated positive effects on MVPA after 2 and 4 months and a small 2-month effect on fruit and vegetable intake. Given these effects, the overall level of engagement observed among participants in this study may have been adequate for gaining meaningful insights and reminders that influenced some health behaviors.

Our finding that a large proportion of adolescents engaged with the intervention only a limited number of times further aligns with previous research reporting high levels of nonusage attrition among adolescents using mHealth tools for health promotion [9,52,54]. Peuters et al [9,52] and Maenhout et al [54] explored reasons for engagement and nonengagement with an app targeting physical activity, diet, and sleep among adolescents aged 12-15 years and found that limited interest in behavior change contributed to low engagement. Consequently, it has been suggested that strategies are needed to first increase adolescents' awareness and motivation to change and thereafter integrate mHealth tools into their everyday lives [54,55].

Textbox 1. Joint display summarizing the results of each phase of this mixed methods study.

Summary of quantitative, qualitative, and integrated findings.

Quantitative findings (research question 1 [RQ1])

A total of 67% (253/377) of participants actively engaged with the intervention content ≤3 times over 16 weeks. Low-engaged participants were significantly more likely to report heavy episodic drinking (mean 1.47, SD 3.35; *P*=.01), lower perceived importance of behavior change (mean 6.45, SD 2.58; *P*=.03), and higher knowledge of how to change their behaviors (mean 6.99, SD 2.32; *P*=.05).

Qualitative findings (RQ2)

Three main categories described conditions influencing high school students' engagement with LIFE4YOUth: (1) perceived importance of health behavior change, (2) user experiences, and (3) environment of use. Low engagement was explained by pressure experienced by participants with poor health behaviors and dissatisfaction with life, or alternatively by high life satisfaction and no desire to change behaviors.

Integrated findings (RQ3)

Three configurations associated with low engagement were identified: unmotivated high-needers, motivated low-needers, and dissatisfied needers. These configurations accounted for 48% of all low-engaged participants. Unmeasured circumstances related to user experiences and the environment of usage may explain the remaining cases.

Implications

Our findings on possible explanations for low engagement as well as medium and higher levels of engagement may help other researchers interpret mHealth engagement data gathered from adolescents. Also, the results presented in this study may be useful in the design of future mHealth interventions aimed at promoting healthy behaviors in adolescents, as they indicate that the multiple behavior approach seemed less feasible for adolescents with the highest need for behavior change. On the other hand, many adolescents are engaged in a combination of health-risk and health-promoting behaviors [56], and our findings suggest that adolescents who experience being both confirmed and encouraged by the intervention may benefit from the multiple-behavior approach. To further examine participants' engagement with LIFE4YOUth, future research should investigate the quality of adolescents' engagement with intervention content in more depth, based on self-authored data as well as user-experience data collected from a larger sample of participants. Future research could explore how engagement levels relate to the effectiveness of multiple behavior change interventions in adolescents. It would also be valuable to understand the characteristics of adolescents who are not drawn to digital behavior change support and what types of health-promoting support, if any, they might prefer.

Strengths and Limitations

This study used a novel design to gain a more nuanced understanding of the conditions and mechanisms that influence and explain high school students' engagement with a stand-alone mHealth multiple behavior change intervention. The use of a mixed methods design with QCA for integration increased rigor and provided insights beyond those obtained from either quantitative or qualitative data alone, which is considered a strength. There are, however, several important limitations to consider. First, the use of self-reported data on health behaviors increases the risk of recall bias. Importance, confidence, and know-how were additionally measured using a general scale, which limited the ability to capture variability in these constructs across different behaviors [57]. Second, the convenience sampling [58] of the focus groups limited diversity in terms of, for example, socioeconomic status and educational background. The time since focus group participants accessed the intervention also varied, which may have resulted in more speculative statements rather than those based on participants' experiences. Furthermore, the choice of conditions for the QCA was limited to the data collected in the LIFE4YOUth trial. Several perspectives highlighted by focus group participants, including stress and LIFE4YOUth experiences, were therefore not included in the QCA. Nevertheless, this study was conducted iteratively, with methodological decisions based on the data rather than the reverse.

XSL•FO
RenderX

Finally, all data were collected within the context of a randomized controlled trial, which does not replicate naturalistic circumstances. Biases may have been introduced by the research setting due to research participation effects [59], and it is possible that high school students would have engaged with LIFE4YOUth differently if they had not been part of a research study. We believe, however, that the transparent reporting allows readers to assess whether the findings are valid and generalizable to other contexts.

Conclusions

Several conditions were identified that may influence and explain high school students' engagement with the multiple behavior change mHealth intervention (LIFE4YOUth). Low-engaged high school students were more likely to be described as unmotivated high-needers, motivated low-needers, or dissatisfied needers. Emotions and reactions evoked by the intervention, as well as perceptions of whether the intervention aligned with high school students' support needs, were suggested to explain engagement. In addition, the timing of SMS text messaging prompts was also considered an important condition influencing all levels of engagement. The findings from this study indicate that the multiple-behavior approach was a decisive factor for students with multiple risk behaviors not to remain engaged with LIFE4YOUth, whereas it may have been a better fit for students who felt both confirmed and encouraged by this approach. Future studies can build on these findings to investigate how tailoring the number of behaviors addressed by mHealth tools targeting adolescents may optimize engagement and behavioral outcomes.

Acknowledgments

We would like to express our gratitude to the high school students who participated in this study as well as staff at the schools for their assistance. We are also very grateful to all participants and experts at the International QCA Development Workshop 2023 in Antwerpen, who markedly contributed through insightful discussions and suggestions that improved the study.

The authors declare the use of generative AI in the research and writing process. According to the GAIDeT taxonomy (2025), the following tasks were delegated to generative artificial intelligence (GAI) tools under full human supervision:

1. The GAI tool used was Microsoft Copilot version number 2.20260101.44.0.

2. Responsibility for the final manuscript lies entirely with the authors.

3. GAI tools are not listed as authors and do not bear responsibility for the final outcomes.

4. Declaration submitted by the first author.

Funding

This research was funded by the Swedish Research Council for Health, Working Life and Welfare 2018-01410; ML. The funder had no involvement in the study design, data collection, analysis, interpretation, or the writing of the manuscript.

Data Availability

The data that support the findings of this study are available from the first author, but restrictions apply to the availability of these data to protect study participant privacy. However, pseudo-anonymized data are available upon reasonable request.

Authors' Contributions

AS, PH, KT, ML, MB, and UM performed conceptualization. AS performed data curation. AS and UM performed investigation. AS, PH, MB, and UM conducted formal analysis. AS, PH, KT, ML, MB, and UM contributed to interpretation of data. AS wrote the original draft. AS, PH, KT, ML, MB, and UM performed review and editing. All authors approved the final version of the manuscript.

Conflicts of Interest

MB owns a private company (Alexit AB) that maintains and distributes evidence-based lifestyle interventions to be used by the public and in health care settings. Alexit AB played no role in developing the intervention, study design, data analysis, data interpretation, or writing of this report.

Multimedia Appendix 1
Complementary analyses of engagement patterns, including the validity of the identified clusters, the influence of the COVID-19 pandemic on engagement, and the robustness of the results.

Abstract

Background: Pulse characteristics are well-established biomarkers of physical health; however, their relevance to psychological well-being remains insufficiently explored. A key barrier is the difficulty of acquiring pulse recordings and blood pressure measurements of adequate quality outside clinical or laboratory settings by using accessible measurement approaches.

Objective: This study aimed to examine the feasibility of using smartphone photoplethysmography to extract fingertip pulse-waveform features and to evaluate their associations with psychological measures. It further aimed to systematically compare time-, curvature-, and frequency-domain pulse-waveform features in relation to psychological variables.

Methods: A total of 127 students and university employees in Shenzhen, China, were recruited. Participants recorded repeated 4-minute fingertip videos by using a custom smartphone app while a fingertip oximeter simultaneously acquired reference pulse signals. Smartphone videos were converted into photoplethysmography signals, segmented into beat-to-beat intervals, and summarized into time-, curvature-, and frequency-domain features, with normalization for heart rate and stature. Psychological well-being and mental health were assessed using the Satisfaction With Life Scale, Subjective Vitality Scale, Positive and Negative Affect Schedule, Patient Health Questionnaire-9, Generalized Anxiety Disorder-7, and the Self-Assessment Manikin. Associations between pulse-waveform features and psychological measures were examined using univariate regression with participant-level aggregation and cluster-robust standard errors. Random forest models evaluated multivariate predictive performance by using participant-level cross-validation. Agreement between smartphone-derived and oximeter-derived waveform features was assessed using Bland–Altman analysis.

Results: Correlation analyses revealed strong within-domain associations among time-, curvature-, and frequency-domain pulse-waveform features, with comparatively weaker cross-domain correlations. A correlation-based feature-selection procedure reduced multicollinearity and yielded a final set of 7 features: estimated reflection index, crest time (CT), the third curvature minimum (F/A), the fourth curvature minimum (H/A), the first power spectrum density component, the baseline of Fourier decomposition (V0), and systolic blood pressure. Univariate regression analyses indicated that negative psychological states were primarily associated with time- and curvature-domain features. Depressive symptoms were significantly related to F/A, V0, and the estimated reflection index. Anxiety showed an association with F/A, and negative affect was associated with CT and F/A. In contrast, positive affect measures showed fewer and weaker associations. Valence was related to F/A and H/A, whereas arousal was associated with CT and H/A. Random forest models demonstrated statistically significant but modest predictive performance for negative mental health outcomes, with weaker performance for positive affect. Bland–Altman analyses indicated minimal systematic bias for outcomes with significant predictive correlations. Comparisons with an oximeter showed significant correlations and acceptable agreement, with time-domain features demonstrating greater robustness than reflection-based metrics.

XSL•FO
RenderX

Conclusions: Smartphone-based photoplethysmography can capture pulse-waveform features associated with psychological measures, particularly negative psychological states. However, predictive performance remains limited, and variability in signal quality from user-operated recordings poses a practical challenge.

Introduction

Assessing physiological health by monitoring pulse rhythm and waveforms has been practiced for millennia [1,2]. Through the analysis of pulse-waveform contours, clinicians gain insight into circulatory status and related physiological influences [3]. Numerous studies have associated waveform characteristics with factors including height, ethnicity [4], sex [5], respiration [6], and autonomic nervous system activity [7], and have used these features to predict medical conditions such as hypertension [8], heart failure [9], lipid metabolism disorders [3], renal disease [10], and diabetes mellitus [11].

The relationship between pulse waveforms and various health conditions can be explained by arterial stiffening. During ventricular systole, the left ventricle ejects oxygenated blood into the aorta, generating a forward pressure wave that travels through the arterial tree. The recorded pulse waveform reflects the superposition of this forward wave and the wave reflected from peripheral arterial sites [12] (Figure 1A) [8,13]. In healthy arteries, the compliant arterial walls transmit pulse energy more slowly, causing the reflected waves to arrive later, producing a waveform characterized by a pronounced systolic peak and a well-defined dicrotic notch (Figure 1B). With aging or pathological stiffening, often initiated by endothelial injury and atherosclerotic remodeling [14], arterial compliance decreases, causing the reflected wave to return earlier, which augments the forward wave, raises systolic pressure, and blunts the dicrotic notch [15] (Figure 1C). Thus, specific modifications in waveform morphology serve as indicators of cardiovascular aging and related pathologies [16].

Figure 1. (A) The reflected waves and the shape of the radial arterial pulse waveform (reproduced from Liu et al [13], which is published under Creative Commons Attribution-NonCommercial-NoDerivatives 4.0 International License [17]). (B) An illustration of the radial arterial pulse waveform of healthy young adults (adapted from Baruch et al [8], which is published under Creative Commons Attribution 2.0 Generic License [18]). (C) The pulse waveform of people with signs of arterial aging. The reflected wave arrives earlier, boosts the systolic blood pressure, and changes the pulse contour [12,19]. FW: forward wave; RW: reflected wave.

Because enduring psychological states and personality traits modulate physiological regulatory systems, particularly inflammatory pathways [20] and sympathetic nervous system activation [21], it is reasonable to assume that psychological factors also influence vascular waveforms. Empirical evidence has supported the assumption that individuals with psychological conditions, such as chronic stress [22], depression [23], bipolar disorder [24], anxiety [25], and panic disorder [26], frequently exhibit arterial stiffening. Consequently, maladaptive psychological states may be detectable via pulse waveform analysis. In support of this premise, early investigations have reported significant associations between pulse waveform characteristics and mental health issues, including depression [27], anxiety [18,28], affective states [29], chronic fatigue [30], and cognitive stress [31,32].

Although early studies have linked pulse waveform morphology to mental health, real-world applications remain limited. A key challenge lies in the cost and complexity of acquiring waveform features outside clinical environments. Most prior research has focused on aortic waveforms, obtained using invasive equipment and specialized personnel in hospital settings [33], thereby limiting scalability. More recently, a small number of pioneering studies have used photoplethysmography to capture peripheral arterial signals (eg, from radial or digital arteries) [34,35]. However, despite its lower technical requirements, photoplethysmography-based pulse analysis still typically relies on dedicated medical devices [36], which constrains its accessibility and widespread deployment.

To bridge the gap in the literature, this study has two primary objectives:

First, it proposes and validates an innovative technique for extracting fingertip (digital artery) pulse-waveform features pertinent to psychological evaluation using only a standard smartphone. Over the past decade, smartphone camera–based acquisition of cardiac signals has garnered substantial attention, and numerous investigations have demonstrated that heart rate (HR) and heart rate variability (HRV) derived from smartphone cameras can reflect alterations in psychological states [37]. This approach uses the phone's built-in camera to record subtle, cardiac-induced skin color fluctuations at the fingertip and

XSL•FO
RenderX

converts them into radial artery waveforms via photoplethysmography. However, the capacity of this technology to capture detailed pulse waveform morphology and its application to mental health assessment remains underexplored.

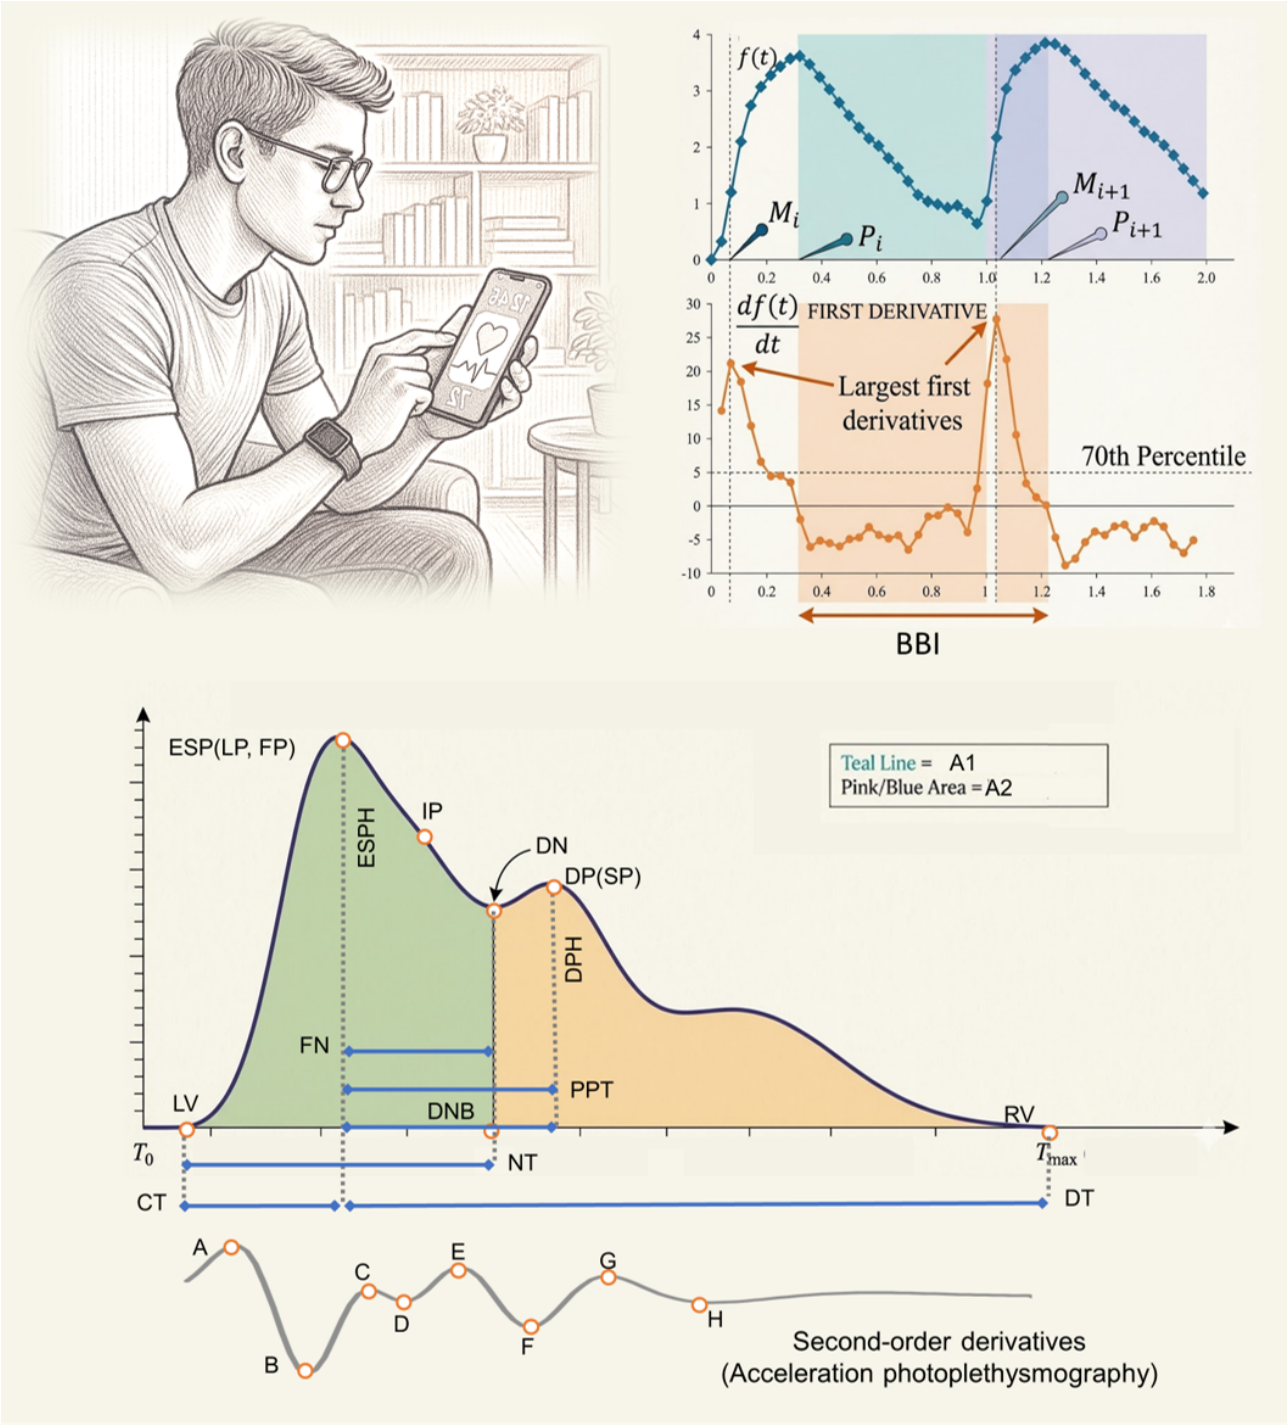
Second, existing studies have typically examined a limited number of pulse-waveform features in isolation, and comprehensive comparisons, particularly for digital pulse-waveform features, are largely lacking. Although prior research has explored associations between pulse-waveform characteristics and psychological states, it has focused almost exclusively on aortic indices, such as the augmentation index [38]. Therefore, evidence linking peripheral waveforms (eg, radial or digital artery signals) to mental health outcomes remains sparse. Given that peripheral waveform morphology differs substantially from aortic contours due to local anatomical and physiological factors [16], these signals warrant independent and systematic investigation. On the other hand, studies of radial or digital artery morphology have generally considered only a narrow subset of available features. To address these gaps, this study conducts an extensive examination of time-domain, frequency-domain, and curvature-domain pulse-waveform features, evaluates their interrelationships, and investigates their associations with psychological health.

Methods

Participant Recruitment

This study recruited a total of 127 participants, comprising university students and staff members, from the last author's affiliated institution in Shenzhen, China (72/127, 56.69% male; mean age 22.78, SD 1.97 years). Participants were recruited through on-campus posters and electronic posters distributed via student social media platforms. Eligibility was restricted to university students and staff, ensuring that all participants were at least 18 years of age and had access to university facilities. Participants were required to have no clinically diagnosed mental disorders or cardiovascular conditions. No additional exclusion criteria were applied.

Study Procedures and Data Collection



During data collection, participants were instructed to rest their arm on a table, hold a Mi 8 SE smartphone (Xiaomi) in their left hand, and place their index finger over the rear camera. Using the Heartily Happy app, developed by our team and publicly available on Google Play at the time of the study, participants recorded 7 fingertip videos, each lasting 4 minutes, at a resolution of 120×160 pixels. To further evaluate the accuracy and practical applicability of the proposed approach, participants were additionally instructed to place the index finger of their right hand on a US Food and Drug Administration–cleared fingertip oximeter (FDA 510(k): K082641; CMS50D, Contec Medical Systems Co Ltd) to simultaneously record pulse waveforms. This study is part of a broader research program examining the relationship between pulse waveforms and mental health. The same dataset has also been used in studies investigating blood pressure [13] and HRV [37].

Signal Processing

The Heartily Happy app used the smartphone's built-in flashlight to illuminate the fingertip and captured video at approximately 30 frames per second (Figure 2) [13,39]. Raw video frames, initially recorded in YUV format, were converted to red green blue color model for subsequent analysis. Waveform signals were extracted by computing a SD–weighted average across the 3 color channels.

Figure 2. Smartphone photoplethysmography data collection and feature extraction. BBI: beat-to-beat interval; CT: crest time; DN: dicrotic notch; DP: diastolic peak; DPH: diastolic peak height; DT: diastolic time; ESP: the early systolic left peak; ESPH: early systolic peak height; FN: the interval between first peak to notch; FP: first peak; IP: inflection point; LP: left peak; LV: left valley; NT: notch time; PPG: photoplethysmography; PPT: peak-to-peak time; RV: reflected wave; SP: second peak.

Following peak detection, both photoplethysmography and oximetry signals were segmented into beat-to-beat intervals (BBIs). Waveform features were calculated for each BBI, and the median value of each feature across all BBIs was used to represent the sample. Detailed signal-processing procedures are described in [13,39].

Because pulse waveform length is inversely related to HR, following a conventional, although controversial, practice in aortic blood pressure research, waveform features were normalized to a reference HR of 75 beats per minute to control for HR-related effects [40-42]. In addition, since the timing of reflected waves depends on vascular path length, which is associated with body height, waveform features are often further normalized by stature; for example, the stiffness index is defined as body height divided by peak-to-peak time (PPT) [43]. Therefore, in this study, waveform features were normalized to a reference height of 170 cm to reduce stature-related interindividual variability. Sex was not included as a separate normalization factor, as its effects on waveform morphology are largely mediated by differences in body height.

XSL•FO
RenderX

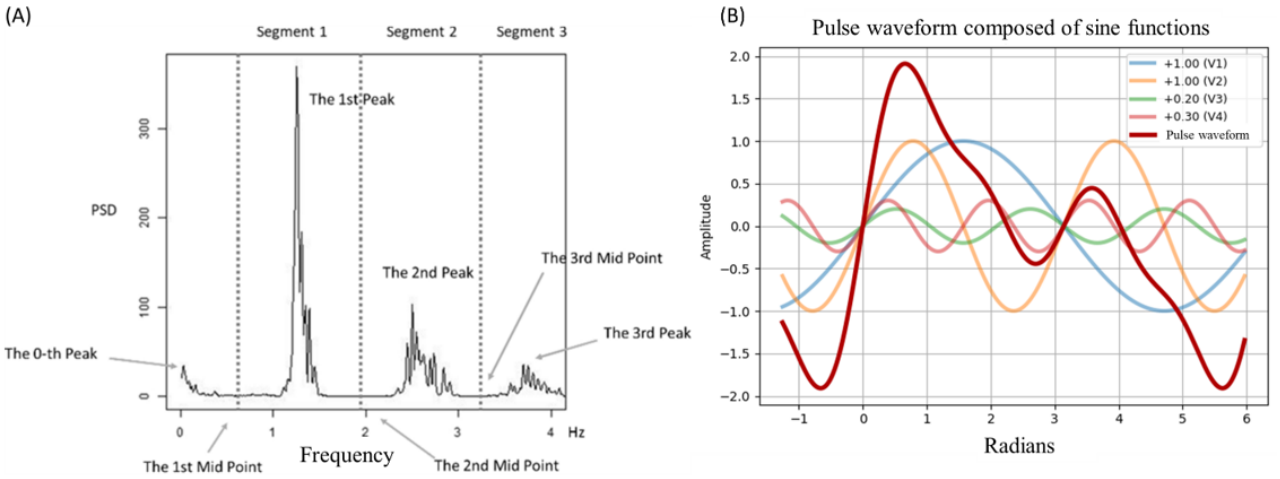
Waveform Metrics

This study considers 3 categories of waveform features commonly cited in pulse waveform analysis but underexplored in psychological research (Table 1 [13]). Time-domain indicators encompass measures of intervals between characteristic waveform points, amplitude differences among these points, and the total area under the waveform curve. Curvature-domain features are derived from the second derivative of the photoplethysmography waveform, often termed acceleration photoplethysmography, and quantify waveform contour and curvature [44]. Frequency-domain features are obtained via Fourier transform decomposition, with power spectral density functions characterizing the strength of each frequency component (Figure 3) [13].

XSL•FO
RenderX

Table 1. Waveform features (adapted from Liu et al [13]).

Name	Definition and calculation details
Time-domain features	
SI[a]	The ratio of body height to PPT[b] [45,46].
PPT	The interval between the ESP[c], (also known as the LP[d] or the FP[e]) and the DP[f]. The RV[g] is the lowest point in the BBI[h], and the preceding BBI's RV is termed the LV[i]. The DP or SP is the first point between ESP and RV with a zero first derivative and a negative second derivative. If no second peak exists between ESP and RV, indicating a consistently negative slope from LP to RV, the DP is identified as the point with the minimum second derivative between ESP and RV.
EPPT	Estimated PPT
RI[j]	The ratio of the DPH[k] to the estimated ESPH[l] is a critical measure in this analysis.
ERI[m]	Estimated RI. Since the initial findings indicated that the auto-exposure adjustment feature of smartphone cameras could result in waveforms that appear smoother than those predicted by theoretical models, this study incorporates the ERI, as proposed by [13]. The ERI, defined as the ratio between the second peak and the estimated early systolic peak, serves as a substitute for the widely used Reflection Index to account for these discrepancies.
ESI[n]	Estimated SI
CT[o]	The interval between the LV and ESP [47].
NT[p]	The IP[q] is defined as the last point before the second peak where the first derivative shifts from positive to negative. The lowest point between the end-systolic point (ESP) and the dicrotic peak DP[r] is called the DN[s]. NT is the interval from the LV to the DN. In cases where there is no obvious second peak, the IP is designated as the DN.
IPP[t]	The percentage of BBIs in a sample where there is no obvious second peak and the IP is designated as the DN.
DT[u]	The interval between ESP and the RV [48]
IS[v]	The slope of the curve at the inflection point.
RCA	The ratio of CT to NT.
RDA	The ratio of NT to the combined duration of CT and DT.
FN	The interval between the first peak to notch.
SR	The interval between the second peak to RV
NV	The interval between the notch to RV
NH	Notch height.
SPH	Second peak height.
A1	The area under the curve from LV to the DN [32,49,50]. When there is no obvious second peak, IP is used as a surrogate for the DN. Since calculating the actual area involves more complex methods, this study approximates A1 as the polygon formed by LV, ESP, DN, and the DNB.
A2	The area under the curve from DN to RV [49]. This study approximates A2 as the triangle comprising IP, DN, and RV.
Inflection point area (IPA)	A2/A1 [49].
Curvature-domain features (acceleration photoplethysmography)	
A	The first local maximum of the second derivative is determined by the point with the largest second derivative before ESP.
B	The first local minimum of the second derivative, determined by the point with the smallest second derivative before ESP.
C	The second local maximum of the second derivative is determined by the point with the largest second derivative, point B, and point E.
D	The second local minimum of the second derivative is determined by the point with the smallest second derivative between points B and point E.
E	The third local maximum of the second derivative is determined by the point with the largest second derivative between ESP and point F.
F	The third local minimum of the second derivative is determined by the point with the smallest second derivative between the ESP and RV.
G	The fourth local maximum of the second derivative is determined by the point with the largest second derivative between point F and point H.



XSL•FO
RenderX

Name	Definition and calculation details
H	The fourth local minimum of the second derivative is determined by the point with the smallest second derivative between point F and RV.
B/A, E/A, F/A, G/A, and H/A	|B/A|, |E/A|, |F/A|, |G/A| and |H/A|. Since B/A, F/A, and H/A were negative, we converted them to their absolute values for more intuitive interpretation. C/A and D/A were not used in this study due to difficulties in identifying points C and D under poor signal quality.
AI[w]	AI is typically defined as B/A – (C/A + D/A + E/A) [51]. However, in this study, AI is defined as the difference between B/A and E/A only, due to difficulties in identifying points C and D under poor signal quality, and because the values of C and D are close to zero.
Frequency-domain features	
PSDi[x]	The PSD function of the pulse waveform exhibits distinct peaks corresponding to fundamental sine-wave components and their harmonics. Traditional approaches often quantify harmonic strength by peak heights; however, this metric is vulnerable to random noise. To address this, the strength of the i-th harmonic (S) is defined as the area under the PSD curve between the midpoint separating the ith and (i + 1)th peaks and the subsequent midpoint. Each midpoint is located halfway between 2 consecutive spectral peaks. This interval-based integration reduces the influence of noise on individual peak amplitudes and yields a more robust estimate of harmonic strength by effectively averaging the PSD over each frequency band (Figure 3). Since the is influenced by signal quality, the value of S_0typically represents the average energy of the entire waveform, which is less relevant to the waveform contour. Additionally, the values of $S_i$for i>6 are usually very small. Therefore, the energy strength of the i-th harmonic (PSD_i) is normalized as: .
Vi	The weight of the i-th sinusoidal function that composes the waveform. Since any function can be decomposed into a Fourier series, Liu et al [39] proposed using the sum of sinusoidal functions to represent the waveform for further analysis. So, for each sample, f(t) can be decomposed as .
NHA[y]	[52]
IHAR[z]	(1-NHA)/IPA [52]

[a]SI: stiffness index.
[b]PPT: peak-to-peak time.
[c]ESP: early systolic peak.

Psychological Measures

To assess well-being, 3 self-report measures were administered: the Satisfaction With Life Scale (SWLS) [53], the Subjective Vitality Scale (SVS) [54], and the positive and negative affect schedule (PANAS) [55]. The SWLS comprises 5 items rated on a 7-point Likert scale ranging from "strongly disagree" to "strongly agree." The SVS comprises 7 statements scored on a 7-point scale from "not at all true" to "very true." The PANAS consists of 20 adjectives assessing positive and negative affect over the past week, with responses provided on a 5-point scale (1="very slightly or not at all," 5="extremely"). Separate scores for positive affect (PANAS-P) and negative affect (PANAS-N) were computed to enhance interpretability.

Common mental health measures included the Patient Health Questionnaire-9 (PHQ-9) [56] and the Generalized Anxiety Disorder-7 (GAD-7) scale [57]. The PHQ-9 includes 9 items rated from 0 ("not at all") to 3 ("nearly every day"), with total scores categorizing depressive symptom severity from minimal to severe. The GAD-7 comprises 7 items using the same response scale and classifies anxiety levels as normal, mild, moderate, or severe based on the summed score.

Momentary emotional states were captured using the Self-Assessment Manikin (SAM) [58], a nonverbal pictorial instrument representing affective valence and arousal. Participants selected the figure that best reflected their current level of pleasure (valence) and activation (arousal). The dominance dimension was omitted, as it was not directly relevant to the study's objectives. All questionnaires were completed before signal collection.

Data Analysis

Associations between individual pulse-waveform features and psychological measures were first examined using simple linear regression, which provides a transparent and interpretable baseline for evaluating feature–outcome relationships and facilitates comparison with prior psychophysiological studies relying on univariate analyses.

The data exhibited a nested structure: psychological scales were administered once per participant, whereas pulse-waveform features consisted of multiple repeated measurements per participant. Treating all observations as independent under standard ordinary least squares assumptions would therefore be inappropriate and could result in underestimated standard errors and biased statistical inference. To explicitly address this nonindependence, 2 complementary analytic strategies were implemented.

The first strategy involved participant-level aggregation, whereby waveform features were summarized for each individual using median values and were entered into ordinary least squares models. This approach mitigates within-subject dependence by aligning the unit of analysis for physiological features with that of the psychological measures. The second strategy applied cluster-robust standard errors at the original observation level, allowing statistical inference to account for repeated measurements within participants while preserving within-person variability.

From a theoretical perspective, participant-level aggregation may be more appropriate in this context, as cluster-robust standard errors can be less suitable when the dependent variable is constant across observations within the same cluster [59]. However, this aggregation approach necessarily entails a loss of within-participant information. Taken together, these 2 analytical strategies offer complementary protections against bias arising from nonindependent observations.

In addition, because multiple waveform features were tested following feature selection, statistical significance was evaluated using a Bonferroni-corrected threshold [60,61]. Although conservative, this correction was adopted to control the error rate, with the acknowledgment that it may exclude features of potential substantive relevance [62].

To evaluate predictive utility beyond univariate linear models, machine learning methods were further used to model psychological outcomes from multivariate pulse-waveform features. These methods are well-suited to this context because they can capture nonlinear relationships, complex feature

XSL•FO
RenderX

interactions, and high-dimensional structures that may not be adequately modeled using traditional regression. Model performance was assessed using 5-fold cross-validation to obtain stable estimates of generalization performance while maintaining sufficient training data in each fold. Among the evaluated algorithms, random forest (RF) models were selected due to their robustness to multicollinearity, resistance to overfitting in moderate sample sizes, and ability to model nonlinear associations without strong parametric assumptions.

In each fold, the RF model was trained on data from a subset of participants and evaluated on held-out participants. Performance was quantified using out-of-sample metrics, including mean absolute error and the correlation between predicted and observed values, averaged across folds. The RF models were implemented using the default hyperparameters provided by scikit-learn. No manual hyperparameter tuning was performed. Specifically, the number of trees was set to 100, node splitting used the mean squared error criterion, trees were grown to full depth (no maximum depth specified), and bootstrap sampling was enabled. Other parameters remained at their library default values.

To prevent data leakage and preserve independence between training and evaluation, all observations from a given participant were assigned exclusively to either the training or test set. For all data analyses, an IQR multiplier of 1.5 was applied for outlier removal.

Agreement between predicted and observed values was further assessed using Bland–Altman analysis. Unlike correlation-based metrics, this approach evaluates absolute agreement and identifies potential systematic bias between predictions and ground-truth values, providing a complementary assessment of model validity that is particularly relevant for evaluating practical predictive performance.

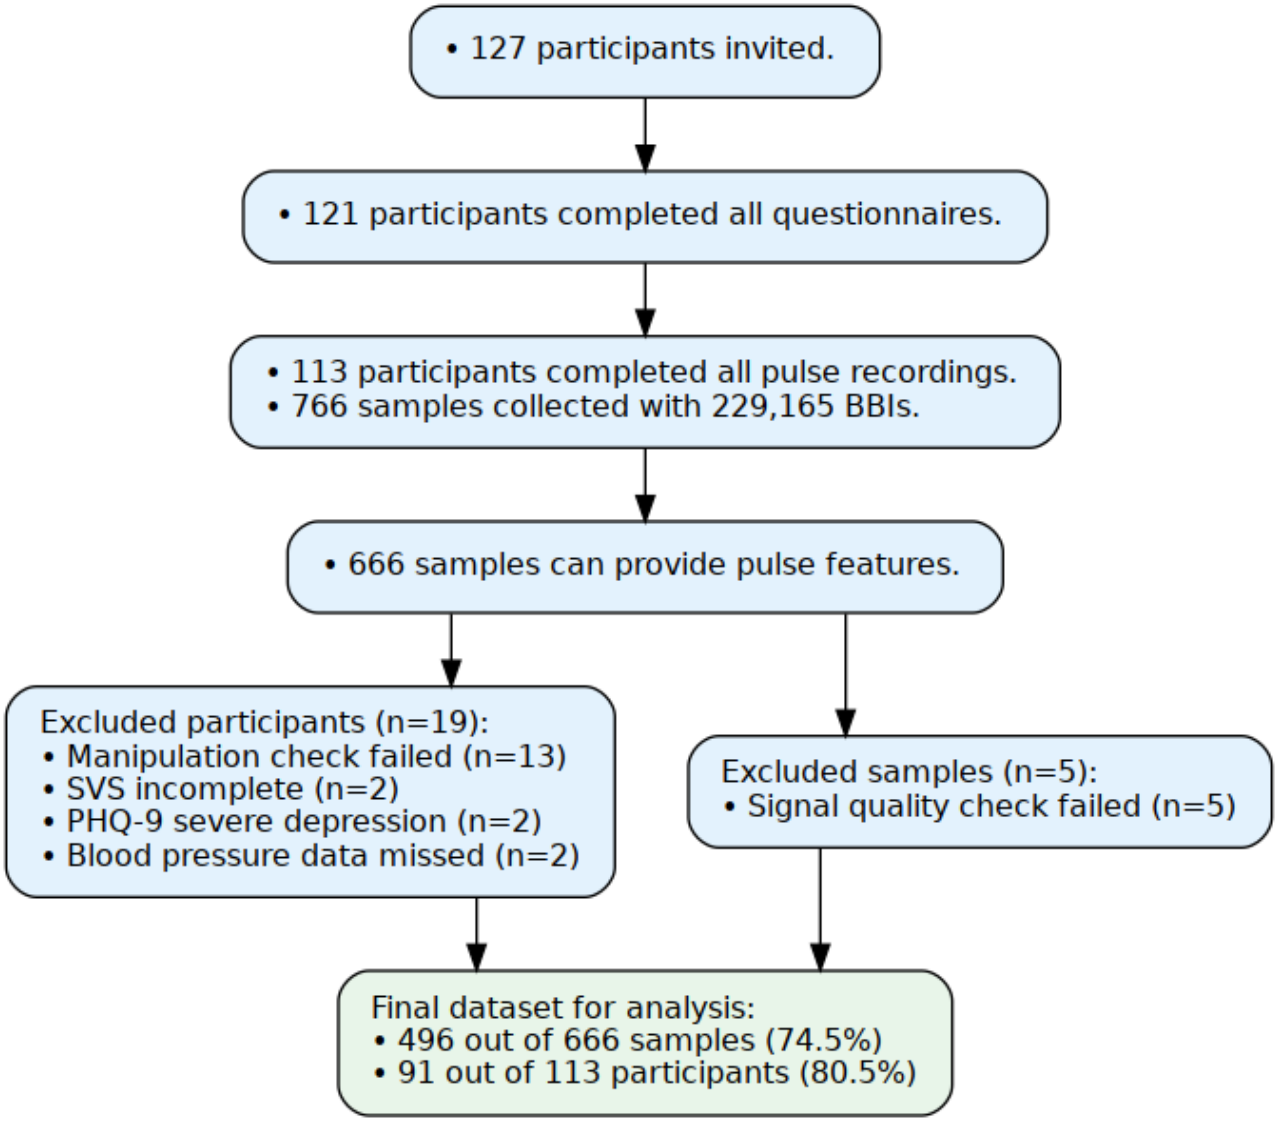
For oximeter-photoplethysmography agreement analysis, 3 time-domain pulse waveform features commonly reported in prior studies, RI, FN, and diastolic time, were selected as representative indicators. Pearson correlation analyses were conducted to assess the linear association between the 2 measurement systems for each feature. Because correlation does not imply measurement agreement or interchangeability, Bland–Altman analysis was additionally performed to evaluate method agreement by plotting the differences between measurements against their means, thereby visualizing systematic bias and the 95% limits of agreement. The mean difference indicates directional bias, whereas the limits of agreement define the expected range of measurement differences.

Agreement was considered acceptable when most observations fell within the limits of agreement without systematic trends across the measurement range. Together, correlation and Bland–Altman analyses enabled a comprehensive evaluation of both association strength and measurement agreement between the smartphone-based photoplethysmography system and the clinical-grade fingertip oximeter.

Ethical Considerations

The study protocol was approved by the Ethics Board of the Department of Psychology at Tsinghua University (number 201910). All study procedures were conducted in accordance with institutional and national ethical guidelines for human subjects research. Written informed consent was obtained from all participants prior to participation.Each participant received 50 renminbi (approximately US $7) as compensation for participation. Participants were informed about the study procedures and their right to withdraw at any time without penalty. All data were deidentified prior to analysis to protect participant privacy. Access to the original identifiable data were restricted to the first author, and no personally identifiable information was included in the analyses or reported results.

Results



Data Collection

Of the 127 participants recruited, 121 completed all questionnaires (71/121, 58.68% male; mean age 22.79, SD 1.87 years), and 113 of these participants completed the pulse-waveform recording (67/113, 59.29% male; mean age 22.74, SD 1.83 years). The 2 participants who exhibited severe depressive symptoms, as indicated by questionnaire assessments, were excluded at this stage.

From the remaining 113 participants, a total of 766 waveform samples were collected (mean 6.78 samples per participant), comprising 229,165 BBIs (BBIs; mean 299 BBIs per sample). Of these, 100 samples were excluded due to partial feature loss (666 remaining; 86.9%), primarily resulting from poor signal quality that prevented reliable peak and valley detection (eg, HR could not be computed), although all recordings were successfully completed. Additionally, 19 participants were excluded because of problematic questionnaire responses identified through manipulation checks or severe depressive symptoms, and 5 samples with a signal quality index below 0.5, as proposed by Liu et al [39], were removed. After all exclusions, 496 valid samples from 91 participants were retained for analysis (Figure 4).

Correlation Among Pulse Waveform Features

Features exhibited strong within-domain correlations across the time, curvature, and frequency domains, whereas cross-domain correlations were comparatively weak (Figure 5). To address high collinearity in the data, a systematic feature-selection procedure was applied prior to statistical modeling to reduce multicollinearity and improve model stability, parameter estimation, and inferential validity. Within each domain, feature pairs with absolute correlations exceeding a prespecified threshold of 0.5 were considered highly collinear and addressed through sequential elimination, after which the top 2 variables were retained for further analysis. Following this procedure, the final feature set used in subsequent analyses comprised estimated reflection index, crest time (CT), the third curvature minimum (F/A), the fourth curvature minimum (H/A), the first power spectrum density component (rPSD1), the baseline of Fourier decomposition (V0), and systolic blood pressure.

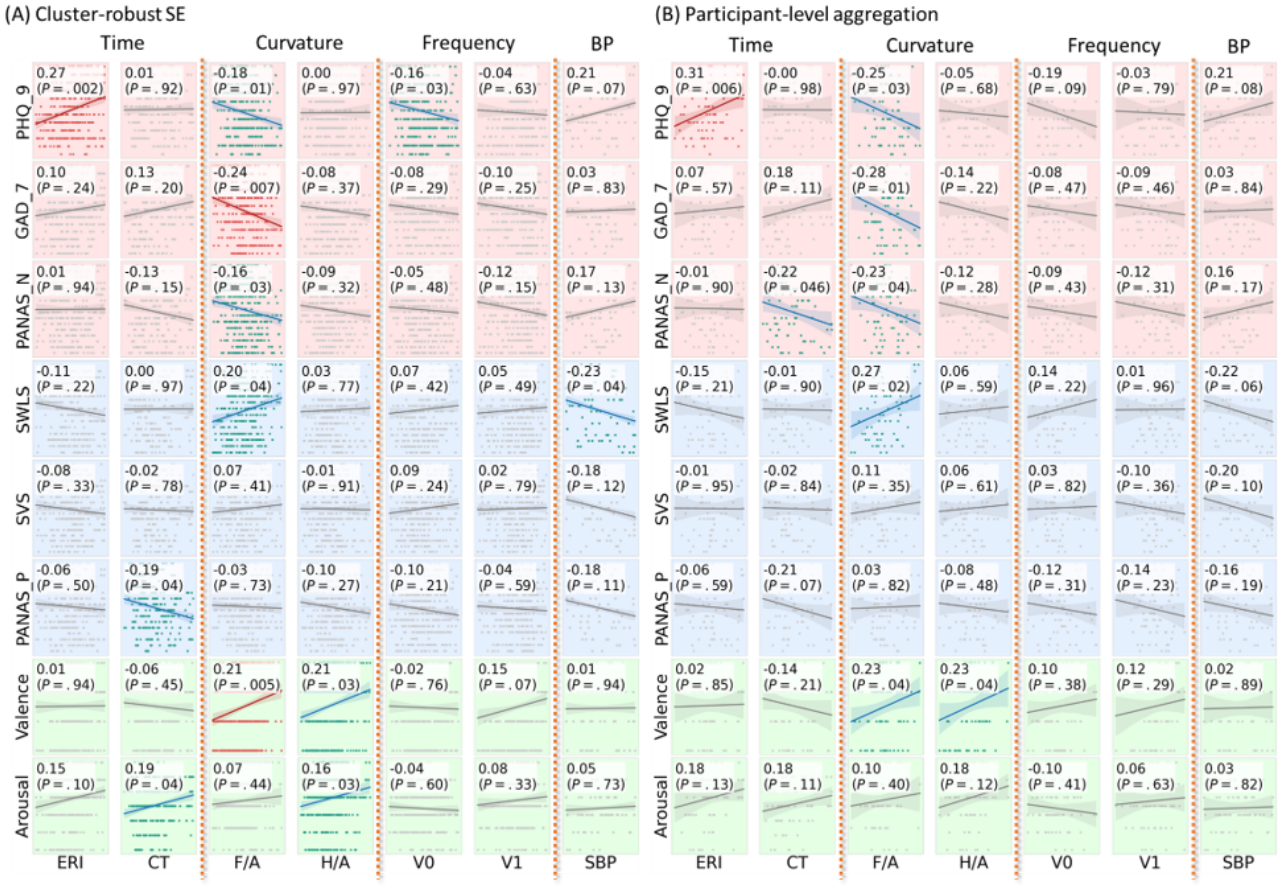
Figure 5. The correlation matrix of pulse waveform features. The orange boxes indicate the selected variables after correlation coefficient threshold filtering. DBP: diastolic blood pressure; DT: diastolic time; EPPT: estimated PPT; ERI: estimated reflection index; ESI: estimated SI; ESP: the early systolic peak; ESPH: early systolic peak height; IP: inflection point; IPA: inflection point area. (A2/A1); IPP: inflection point percentage; IS: inflection slope; NH: notch height; NT: notch time; NV: the interval between the second peak to right valley; PPT: peak-to-peak time; PSD: power spectrum density; RCA: the ratio of CT to NT; RDA: the ratio of NT to the combined duration of CT and DT; RI: reflection index; RV: right valley; SBP: systolic blood pressure; SI: stiffness index; SP: second peak; SPH: second peak height; SR: the interval between the second peak to right valley.



Linear Regression and Correlation Analysis

In univariate regression and correlation analyses, we examined associations among 8 psychological measures, 9 pulse waveform features, and blood pressure. The results indicated that negative psychological states were primarily associated with time- and curvature-domain waveform features (Figure 6). Depressive symptoms (PHQ-9) were significantly associated with F/A and V0, with the association between PHQ-9 and estimated reflection index remaining significant after Bonferroni correction. Generalized anxiety (GAD-7) also showed a Bonferroni-corrected significant association with F/A. Negative affect (PANAS-N) was associated with both CT and F/A.

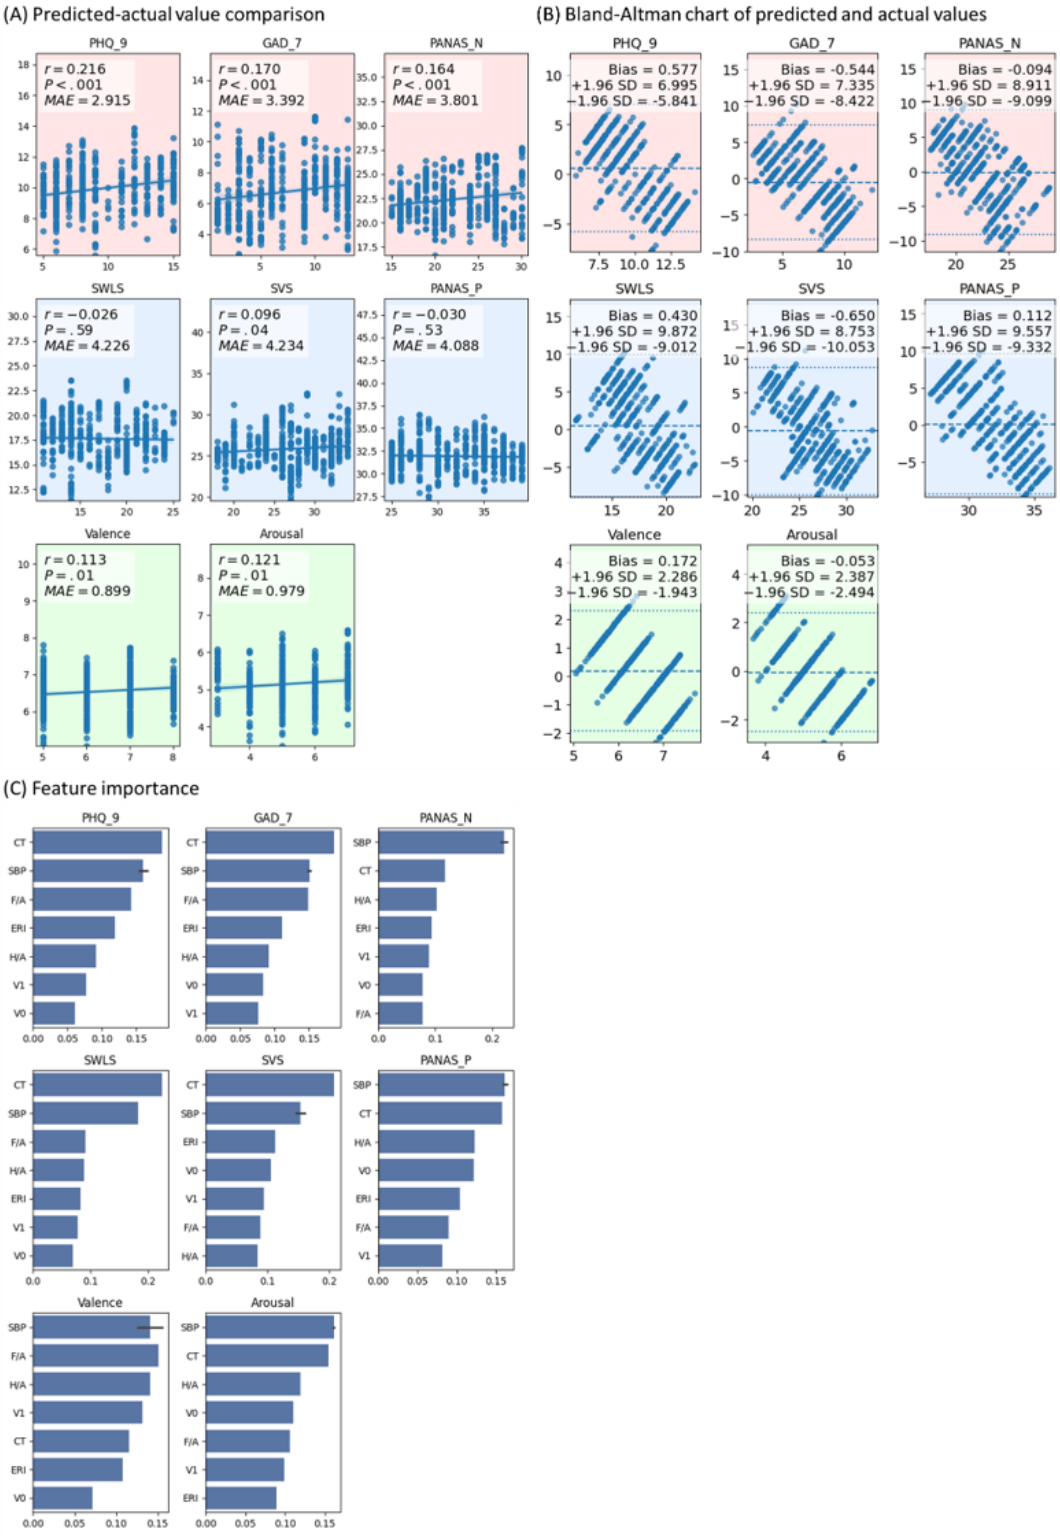
RenderX

Figure 6. Univariate relationships between each independent and dependent variable. Green markers and regression lines denote *P* value less than .05 and red markers denote *P* value less than the Bonferroni corrected criteria .05/9=.0056. CT: crest time; ERI: estimated reflection index; GAD-7: Generalized Anxiety Disorder-7; PANAS: positive and negative affect schedule; PANAS-N: negative affect; PANAS-P: positive affect; PHQ-9: Patient Health Questionnaire-9; SBP: systolic blood pressure; SVS: Subjective Vitality Scale; SWLS: Satisfaction with Life Scale.



In contrast, positive affect exhibited fewer significant associations with waveform features: SWLS was correlated with F/A, and PANAS-P was correlated with CT. Regarding momentary emotional states, valence was associated with F/A and H/A, whereas arousal was associated with CT and H/A.

Machine Learning

In this study, 9 features selected through feature engineering were used as inputs to predict mental health outcomes. The machine learning results (Figure 7) indicated that waveform-related features were effective in predicting mental disorders (*P*<.001 for PHQ-9, GAD-7, and PANAS-N), whereas predictive performance for positive emotional states was substantially weaker. With respect to short-term emotional fluctuations, heartbeat waveform features showed no clear association with valence but were evidently influenced by arousal. Bland–Altman analysis further demonstrated that, for outcomes with significant predictive correlations, the machine learning predictions exhibited slight but not substantial systematic bias. The 3 most important features identified by the RF models across all dependent variables were CT, F/A, and systolic blood pressure.

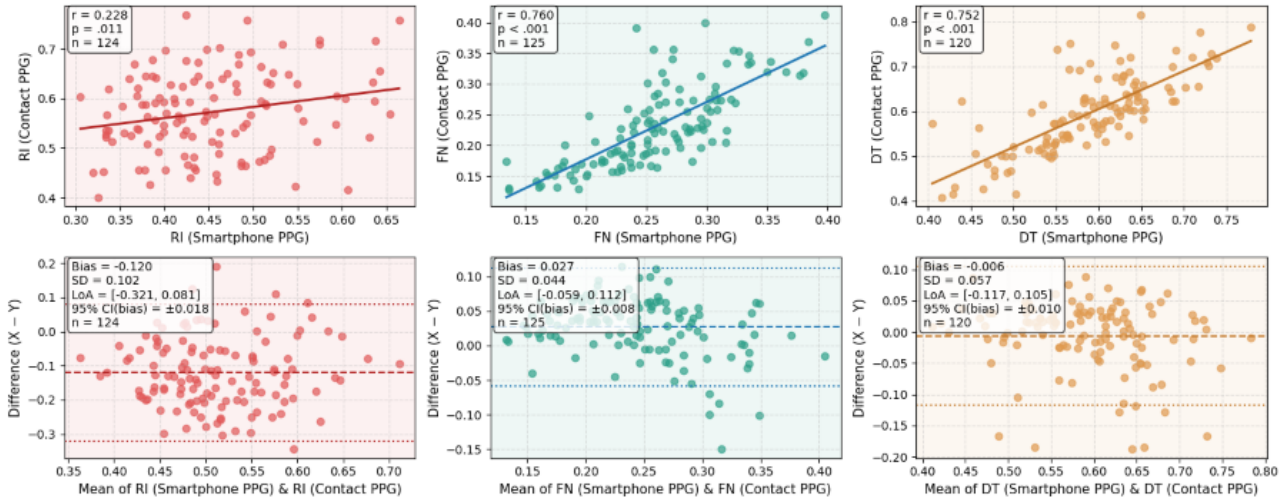
Figure 7. Machine learning results. GAD-7: Generalized Anxiety Disorder-7; MAE: mean absolute error; PANAS: positive and negative affect schedule; PANAS-N: negative affect; PANAS-P: positive affect; PHQ-9: Patient Health Questionnaire-9; SVS: Subjective Vitality Scale; SWLS: Satisfaction with Life Scale.



Oximeter Comparison

The results (Figure 8) indicate reasonable agreement between waveform features obtained from the oximeter and those derived from the smartphone-based photoplethysmography method. For all 3 features analyzed, correlation coefficients were statistically significant (P<.05), and Bland–Altman analyses revealed minimal systematic bias. However, consistent with the optical boundary effects inherent to smartphone photoplethysmography acquisition discussed in the waveform metrics section, the reflection index exhibited some degree of distortion. In contrast, time-related waveform features were largely unaffected by these optical limitations and showed more consistent agreement across the 2 measurement modalities.

Discussion

Principal Findings

Overall, the findings support the study's hypotheses and objectives by demonstrating that fingertip pulse-waveform signals recorded using a standard smartphone can be used to predict individual psychological health status. This work makes 3 principal contributions.

First, we introduce and validate a cost-effective, noninvasive approach that relies solely on a smartphone camera to capture subtle skin color variations, reconstruct digital arterial pulse waveforms, and infer mental health status. Across both univariate linear regression and multivariate machine learning analyses, waveform features showed consistent and statistically significant associations with psychological indicators. Beyond extending smartphone-based waveform analysis to psychological research, these findings provide additional empirical support for pulse-waveform–based psychological assessment more broadly [34,35], as well as for the use of smartphones in related physiological applications such as HRV and blood pressure analysis [63,64].

Second, our results reveal associations between pulse-waveform features and psychological variables across multiple feature domains. Consistent with findings reported by Kontaxis et al [34] and Celka et al [65], negative psychological conditions were strongly linked to waveform characteristics, suggesting that long-term psychological states may induce structural or functional changes in the arterial system. However, contrary to our initial expectations, these associations were primarily observed in curvature- and time-domain features rather than in the frequency domain. As one of the first studies to incorporate frequency-domain pulse-waveform features into mental health research, we suggest that such features may encode relevant information, although this was not supported by the present dataset.

The relatively weaker associations observed between positive affect and pulse-waveform features were also unexpected but appear reasonable in retrospect. Given the well-documented negative correlation between positive and negative affect and evidence that positive affect plays a protective role against adverse psychological states [66], we anticipated that positive affect would exhibit associations with waveform features comparable to those observed for negative affect. Although the observed relationships were directionally consistent with this hypothesis, they were generally weaker and less statistically robust. This pattern remains theoretically consistent with prior psychological research, which emphasizes that positive and negative affect are distinct, partially independent constructs that can co-occur within individuals despite their negative correlation [67]. Together, these findings suggest that both affective dimensions relate to cardiovascular functioning, but that negative affect exerts a more pronounced influence.

Short-term emotional fluctuations appear to exert limited influence on vascular wall properties. However, because arousal is closely linked to HRV [68], which directly affects the timing of cardiac contractions, it is reasonable that arousal was associated primarily with time-domain waveform features. This interpretation aligns with earlier work in affective computing by Healey and Picard [69], who demonstrated that physiological signals reliably capture arousal but are less effective at distinguishing affective valence. Although the present findings are supported by emerging evidence, further studies using higher-quality data and more controlled experimental designs are needed to confirm and extend these results.

Limitations and Future Directions

Despite the theoretical and practical innovations of this study, 3 limitations warrant cautious interpretation of the results.

First, although the machine learning models achieved significant predictive performance, the level of agreement between the proposed method and the target psychological measures remained limited. Similarly, comparisons between waveform features derived from the smartphone-based photoplethysmography method and those obtained from a reference oximeter demonstrated statistically significant associations, but the magnitude of agreement was insufficient for precise interchangeability. Taken together, these findings indicate that, while pulse waveform features are systematically

XSL•FO
RenderX

influenced by mental health status, the current models primarily capture correlational relationships rather than yielding predictions with practical accuracy.

Second, of the 766 waveform samples collected, 100 (13.1%) were classified as corrupted and excluded, a substantial loss rate that may undermine the study's validity. In uncontrolled, real-world settings, slight finger movement or fluctuations in ambient illumination can distort the photoplethysmography signals [70]. Future research can therefore use enhanced image capture protocols [71], integrate advanced signal processing and noise reduction algorithms [72], and implement quality filters to discard low-fidelity recordings [73]. Moreover, the limited and variable frame rates of smartphone cameras (typically 10-60 Hz) constrain temporal resolution compared with medical-grade devices sampling up to 1000 Hz [74]. Because smartphone camera frame rates are not fixed, this instability further exacerbates data-collection challenges [75]. The effects of reduced and unstable sampling rates on photoplethysmography signal integrity remain poorly understood and warrant further investigation [76].

Third, the sample consisted primarily of young adults with similar educational backgrounds, which may limit the generalizability of the findings. Because vascular changes associated with psychological factors often develop over time, associations between mental health and pulse-waveform morphology may be more pronounced in older adults or individuals with chronic conditions. Future studies should therefore include participants across broader age ranges and with more diverse health profiles. Additionally, the slight gender imbalance in the sample may have introduced bias in sex-specific waveform effects. Other potential confounders, such as sleep quality, smoking, diet, and medication use, were not controlled for and should be addressed in future research to reduce unexplained variance.

Conclusions

Pulse waveform analysis has traditionally been applied to the assessment of physical health, whereas its extension to mental health, via links between psychological states and vascular stiffness, remains relatively novel. Conventional waveform acquisition methods are often costly and inaccessible, which has limited their adoption in psychological research. This study uses smartphone-based photoplethysmography to analyze digital arterial waveforms, thereby providing a noninvasive and accessible approach for psychological assessment. The findings demonstrate significant associations between psychological variables and pulse-waveform features, particularly within the time- and curvature-domains, and thus contribute to the advancement of psychophysiological research grounded in hemodynamic principles. Nevertheless, technical limitations (eg, signal variability and low, unstable sampling rates) and sample-related constraints (eg, demographic homogeneity and uncontrolled confounders) should be addressed in future studies.

Abstract

Background: Total knee replacement (TKR) is a common surgery for end-stage knee osteoarthritis. Although reductions in pain and improvements in mobility occur after surgery, physical activity levels often do not change. Given the challenges of increasing physical activity in this population, targeting reductions in sedentary behavior may be a first step; however, no prior studies have examined the feasibility and effects of a sedentary reduction intervention after TKR.

Objective: This study examined the effects of a 2-month multicomponent mobile health sedentary reduction intervention (*NEAT!2*) on sedentary time in adults with TKR.

Methods: Adults (N=83; mean age 65.3, SD 9.4 years; mean BMI 32.7, SD 6.9 kg/m^2; 62/83, 74.7% female; 64/83, 77.1% White) with a TKR ≤1 year ago were randomized to the *NEAT!2* group (n=42, 50.6%) or the attention-matched control group (n=41, 49.4%). The *NEAT!2* intervention focused on reducing sedentary time via a smartphone app designed to interrupt prolonged bouts (≥30 minutes) of sedentary behavior and through 5 coaching calls emphasizing goal setting and problem solving. The control group focused on surgery recovery via an app or website and 5 educational calls. Sedentary time, total physical activity, physical function, and pain were measured at 2 and 5 months. Linear mixed-effects models examined intervention effects and differences between groups at each time point.

Results: Retention was 96% and 95% at 2 and 5 months, respectively, with no differences between groups. Participants in the *NEAT!2* group completed an average of 4.95 (SD 0.2) calls, used the app on an average of 40.3 (SD 13.8) days (out of 56 days), and received an average of 9.6 (SD 6.0) notifications per day. At 5 months, there was a significant increase in sit-to-stand transitions in the *NEAT!2* group and a substantial decrease in the control group, resulting in a significant difference between groups (mean difference 4.06, 95% CI 0.13-7.99; *P*=.04); however, the *NEAT!2* intervention did not result in significant effects on any of the other study outcomes at 2 or 5 months. Additionally, more days of app use were associated with greater increases in moderate-to-vigorous intensity physical activity (*r*=0.335; 95% CI 0.017-0.585; *P*=.04).

XSL•FO
RenderX

Conclusions: This study highlights the challenges of reducing sitting time in adults with TKR. Future studies should explore alternative behavior change techniques across different levels of influence (eg, environmental and social) to support interventions implemented within the first year after TKR.

Trial Registration: ClinicalTrials.gov NCT04482400; https://clinicaltrials.gov/ct2/show/NCT04482400

KEYWORDS

arthroplasty; sedentary behavior; mobile health; mHealth; physical activity

Introduction

Total knee replacement (TKR) is one of the most common surgical procedures performed in the United States, and its prevalence is expected to continue rising rapidly [1,2]. TKR is considered an effective treatment for severe knee osteoarthritis, with most patients experiencing reduced pain and improved physical function and quality of life following the procedure [3-5]. However, postoperatively, most adults struggle to increase physical activity [6], further increasing their risk of all-cause mortality, cardiovascular disease, and disability, with less than 5% of adults with TKR meeting physical activity guidelines [7]. Several interventions have been developed to target physical activity after TKR; however, most have had limited or modest success in increasing steps or moderate-intensity physical activity [8-10].

In addition to struggling to increase physical activity, adults with TKR continue to spend excessive time in sedentary behaviors [11,12]. Sedentary behavior is defined as any waking behavior in a seated or reclining position at ≤1.5 metabolic equivalents of task [13]. Among inactive adults, higher sedentary time is associated with an increased risk of all-cause mortality [14]. Given the low levels of physical activity after surgery, targeting reductions in sedentary behavior may be a more feasible first-step approach to increasing overall activity in this population. Sedentary reduction interventions tailored to other populations, such as office workers, have been shown to be effective [15,16], and a recent study demonstrated that multicomponent sedentary behavior interventions were well accepted and effective in older adults [17]; however, no prior studies have examined the effects of a sedentary reduction intervention after TKR.

The purpose of this study was to examine the effects of a multicomponent mobile health (mHealth) sedentary reduction intervention on sedentary time in adults with TKR at the end of the intervention (2 months) and following a 3-month maintenance period (5 months). Changes in physical activity, physical function, and pain were also examined at each time point. Additionally, this study examined the relationship between adherence to the mHealth program and changes in sedentary time, physical activity, physical function, and pain.

Methods

Study Design

This study was a randomized clinical trial, and full study details have been previously published [18]. Participants with TKR were randomized to either the mHealth sedentary reduction intervention (the *NEAT!2* group) or an attention control group. Outcomes were assessed at baseline, at the end of the intervention (2 months), and following a 3-month maintenance period.

Participants

Participants were recruited and enrolled between August 2020 and April 2024. Initially, participants were recruited at least 7 days prior to knee replacement and then started the program 4 weeks after surgery; however, due to recruitment challenges because of the COVID-19 pandemic, recruitment and eligibility criteria were modified in October 2021. Following the change, participants were eligible if they had a unilateral TKR within <1 year of the baseline assessment. Additional inclusion criteria included being aged 40 to 79 years, having a smartphone that was accessible and near them most of the day, being willing to download the study smartphone apps, self-reporting spending at least 7 hours a day sitting, and being English-speaking. Participants were excluded if they had any contraindications to activity, had a mobility-limiting comorbidity (eg, spinal stenosis), were scheduled for surgery (eg, TKR on the contralateral knee) within the next 6 months, or did not have ≥4 days of valid ActiGraph (ARCHIMED) accelerometer wear (≥10 hours/day) at baseline. There was no racial or gender bias in the selection of participants.

Participants were primarily recruited from orthopedic centers within a local health care system in Columbia, South Carolina. Study candidates were contacted via postcards, mailings, emails, or telephone calls. Additional recruitment strategies included flyers posted on the university campus or in local businesses or clinics, emails to university faculty and staff, and social media. All recruitment materials directed interested candidates to complete an online or telephone screening with study staff. Eligible candidates were invited to an in-person session to review complete study details and complete the written informed consent process if interested and eligible.

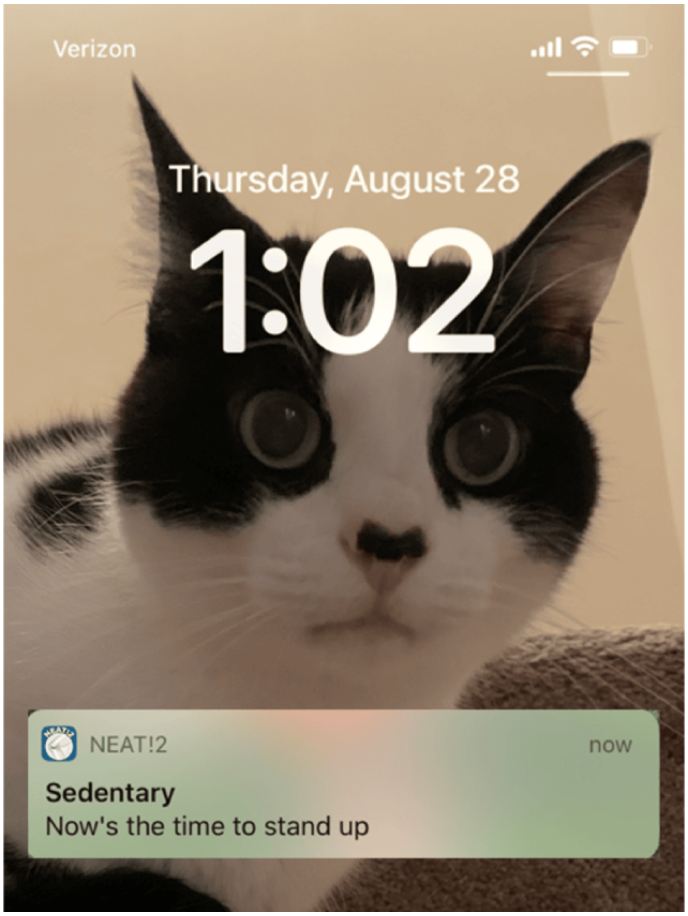
Randomization

After completing the baseline assessment and verifying accelerometer wear time, participants were contacted via telephone to remind them of the study details. Additionally, to promote retention and prevent differential attrition, the benefits and barriers to both general research study participation and specific study participation were reviewed, and participants were asked to discuss their personal perspectives on the pros and cons of being randomized to either study condition [19]. Participants who expressed continued interest in participating were randomized to one of two conditions: (1) *NEAT!2* or (2)

XSL•FO
RenderX

control. Randomization was created by the biostatistician, and participants were stratified by age (<65 years and ≥65 years). Participants were randomly assigned in a 1:1 ratio to either the *NEAT!2* group or the control group using permuted block sizes of 2 or 4.

Randomized Conditions



NEAT!2

Participants randomized to *NEAT!2* received the mHealth and coaching intervention guided by the Dual-Process Theory [20,21]. Participants were given goals to reduce sedentary time, starting with a reduction of 30 minutes per day and progressing every 2 weeks to a final goal of reducing sedentary time by 90 minutes per day. To help participants reach this goal, the *NEAT!2* app was turned on after randomization and displayed the overall daily goal. The app was designed to detect prolonged sedentary time using the accelerometer and activity recognition libraries on the participant's Android or iOS device. Specifically, when 30 minutes of continuous inactivity was detected, the app generated a sound or vibration and placed a notification on the participant's phone (Figure 1). The notifications varied in content, but each instructed participants to take a break from sitting, either by standing or walking for at least 2 minutes. The *NEAT!*2 prompts were designed to target automatic (implicit) processes.

In conjunction with the *NEAT!2* app, controlled (conscious) processes were targeted through goal setting, education, problem solving, and behavioral feedback. Participants received a coaching call every 2 weeks during the 2-month intervention (5 calls in total). Calls were intended to last 10 to 15 minutes and focused on app use, goal setting, and problem solving around reducing sedentary time, with coaches guided by semistructured call scripts. All coaches had a background in exercise science, psychology, public health, or a related field.

Between the 2- and 5-month assessments, participants received monthly phone calls from research staff members who did not conduct the coaching calls. These calls focused solely on surgery recovery and were designed to help with retention during the follow-up period. Participants were given the option to continue using the *NEAT!2* app during this period; however, use of the app or sedentary time was not discussed on calls.

Figure 1. Screenshot of an example NEAT!2 app notification.

Attention-Matched Control

Participants randomized to the control group received an attention-matched education program focused on surgery recovery, which included a smartphone app or website (My Knee Guide) and regular calls. Control participants were encouraged to use the app or website to plan recovery activities and read about others' experiences after TKR. Participants also received calls from the study coaches every 2 weeks (5 calls in total) to discuss surgery recovery and education after TKR (eg, dealing with fatigue, emotional self-care, and reducing injuries at home). If participants brought up unintended content (eg, sedentary behavior or physical activity), coaches were trained to redirect the conversation.

XSL•FO
RenderX

Similar to *NEAT!2* participants, control participants received monthly phone calls on surgery recovery between the 2- and 5-month assessments. Following the 5-month assessment, the control group was offered access to the *NEAT!2 app*.

Treatment Fidelity

For both groups, all coaching sessions were audiotaped, and a 15% sample of calls was rated every quarter. Fidelity assessments evaluated unintended and intended content based on randomized conditions. If fidelity fell below 80% or coaches discussed unintended content, coaches were retrained.

Measures

Assessments were completed either in an orthopedic clinic or a campus research center at baseline and at 2-month and 5-month follow-ups. Study assessors were blinded to group allocation and had undergone training on all assessment procedures. All questionnaires were completed online via REDCap (Research Electronic Data Capture) [22].

Outcomes

The primary outcome of the study was the percentage of time spent in sedentary behavior as assessed by ActiGraph at 2 months. Secondary outcomes included total physical activity time (light-, moderate-, and vigorous-intensity physical activity), physical function, and pain. Exploratory outcomes included sedentary time assessed by activPAL, knee symptoms, general health, sleep disturbance, and habit strength.

Sedentary Time and Physical Activity

At each assessment, participants were asked to wear an ActiGraph GT9X Link waist-worn accelerometer for 7 days during waking hours (except during water-based activities). A minimum of 4 days of valid wear time consisting of at least 10 hours/day was required for inclusion in analyses [23]. Nonwear time was defined as ≥90 minutes with 0 activity counts, allowing for up to 2 minutes of <100 counts/minute [24]. Sedentary time was defined as <100 counts/minute, and total activity as ≥100 counts/minute [23]. Average daily sedentary time (minutes/day), percentage of the waking day spent in sedentary time, and weekly total physical activity (light-, moderate-, and vigorous-intensity activity) were calculated within the ActiLife (version 6; Ametris) software.

In addition to ActiGraph monitors, the activPAL software (version 8; PAL Technologies) and Sedentary Time and Activity Reporting Questionnaire [25] were used as exploratory measures of sedentary time at each time point. The activPAL monitor was waterproofed and taped onto participants' thighs using waterproof tape. Participants were asked to wear the monitor for 24 hours a day during each 7-day period. A minimum of 4 days of valid wear time, defined as 24 hours, was required for inclusion in analyses. The time spent sitting or lying, standing, and walking; transitions; and step counts were determined using the activPAL. The Sedentary Time and Activity Reporting Questionnaire [25] was also administered and is a self-reported measure of habitual sedentary behavior. The average number of hours per day spent sitting on weekdays and weekends was calculated.

Physical Function

Physical function was assessed using the Chair Stand Test, Timed Up and Go test, and 6-minute walk test. All physical function tests were completed following the Osteoarthritis Research Society International–recommended procedures [26]. During the Chair Stand Test, participants were asked to complete as many chair stand repetitions as possible during a 30-second period. The Timed Up and Go test assessed the time, in seconds, taken to rise from a chair, walk 3 meters, turn, walk back to the chair, and sit down. The 6-minute walk test evaluated the maximal distance, in feet, that a participant could walk during a 6-minute period.

Patient-Reported Outcomes

Pain and related self-reported outcomes were assessed using the Western Ontario and McMaster Universities Osteoarthritis Index [27] and Knee Injury and Osteoarthritis Outcome Score [28]. The Western Ontario and McMaster Universities Osteoarthritis Index is a 15-item survey assessing pain, stiffness, and functional limitations over the last 48 hours on a 5-point Likert scale. Scores range from 0 to 20 for pain, 0 to 8 for stiffness, and 0 to 68 for physical function, with higher scores indicating more symptoms. The Knee Injury and Osteoarthritis Outcome Score assesses overall knee health and includes 5 subscales: pain, symptoms, activities of daily living, sport and recreation, and knee-related quality of life. Scores on each subscale range from 0 (no knee issues) to 100 (extreme knee issues). General health, sleep disturbance, and mobility were also assessed using Patient-Reported Outcomes Measurement Information System computer-adaptive tests via REDCap. Each survey generates a *t* score, where scores <50 indicate poorer outcomes, while scores >50 reflect better outcomes.

Habit strength was assessed with 4 items for sitting, stretching, and exercising from the Self-Report Habit Index [29]. Participants were asked to rate each behavior from 1 (strongly disagree) to 7 (strongly agree) on the following items: "I do automatically," "I do without having to consciously remember," "I do without thinking," and "I start doing before I realize I'm doing it." Higher scores indicate greater habit strength.

Demographics and Intervention Adherence

Demographics and medical history were obtained at baseline. Height (m) and weight (kg) were measured in light clothing and without shoes at each time point. BMI was subsequently calculated as kg/m^2.

Adherence to the *NEAT!2* intervention was assessed by the percentage of coaching calls completed (completed calls/5 total calls), the total days the *NEAT!2* app was used (56 possible days), and the response to *NEAT!2* notifications. Total days the *NEAT!2* app was used were determined as the number of unique days participants received notifications through the app. The response to *NEAT!2* notifications was determined by the percentage of notifications for which movement or activity was detected by the app within 5 minutes of notification delivery.

Adverse Events

Injuries and illnesses were assessed at each assessment, as well as during follow-up calls. All adverse events were monitored

XSL•FO
RenderX

and rated based on their severity, expectedness, and relatedness to the study.

Statistical Analysis

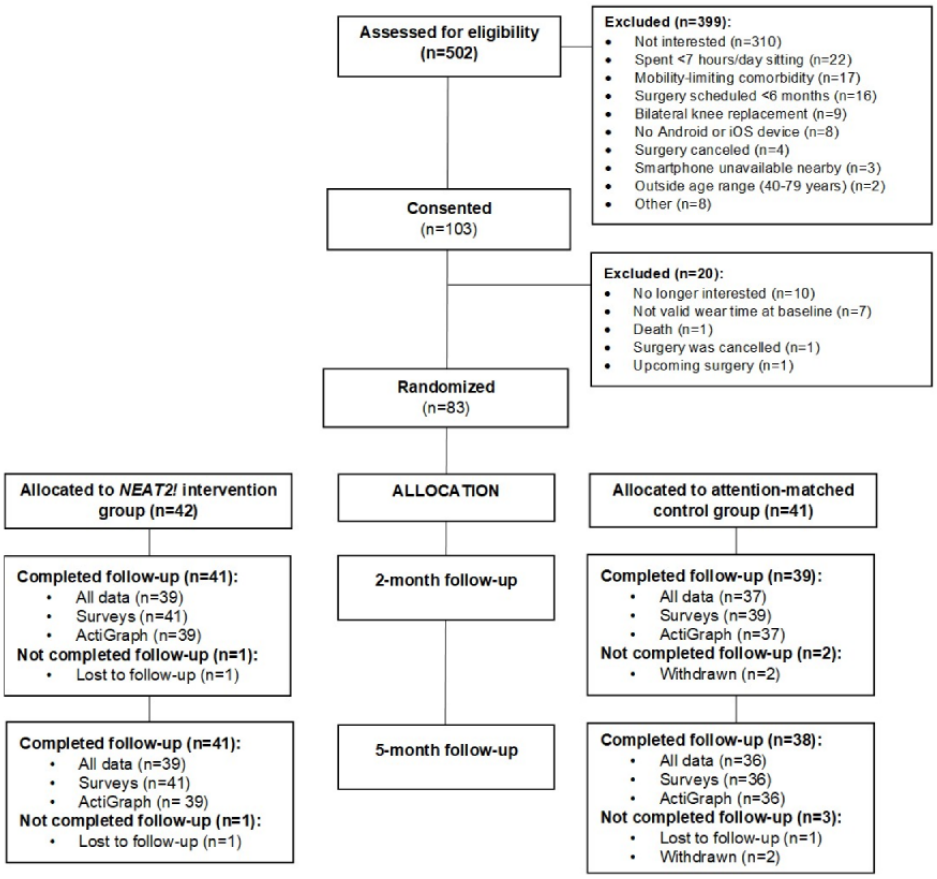
Descriptive statistics were used to describe participants' baseline characteristics. Mean (SD) for continuous variables and frequency (percentage) for categorical variables were reported. Linear mixed-effects models were used to evaluate whether the *NEAT!2* sedentary reduction intervention led to greater improvements in sedentary time (ActiGraph minutes/day and percentage of the day spent sedentary), physical activity, physical function, and pain than the control group at 2 and 5 months. Models included group (*NEAT!2* vs control), time (baseline, 2-month follow-up, and 5-month follow-up), and group×time interaction terms. Models accounted for repeated measures with a random intercept to allow for baseline differences. Estimated regression coefficients and corresponding 95% CIs were computed for each outcome. Potential confounders included age, sex, BMI, and comorbidities. ActiGraph total and moderate-to-vigorous intensity physical activity were adjusted for monitor wear time. To examine the association between adherence to the *NEAT!2* intervention and changes in outcomes (sedentary time, physical activity, physical function, and pain), bootstrap Spearman correlation coefficients and corresponding 95% Cis, accounting for the small sample size, were computed between adherence to the *NEAT!2* intervention and changes in outcomes. All hypothesis tests were 2-sided with statistical significance set at $P<.05$. No adjustments were made for multiple comparisons. All statistical analyses were performed in SAS (version 9.4; SAS Institute Inc).

The sample size calculations have been reported previously [18]. In brief, having 40 participants per group complete the 2-month and 5-month assessments would provide 90% power to detect a difference of 8.1% reduction in sedentary time (ie, effect size of 0.7) between participants in the *NEAT!2* and control groups. A reduction of 8% was chosen as it is approximately equivalent to a 90-minute reduction in sedentary time over the course of a waking day.

Ethical Considerations

All study procedures were approved by the University of South Carolina's Institutional Review Board (approval number Pro00092132) on September 19, 2019, and all procedures were conducted in accordance with the Helsinki Declaration of 1975. All participants provided written informed consent before participation. The trial was registered on Clinicaltrials.gov (NCT04482400). A CONSORT checklist is provided in Multimedia Appendix 1. Participants received US $15 for completing each follow-up assessment, and all research data were deidentified.

Results



Participant Characteristics, Retention, and Safety

Of the 502 individuals screened for eligibility, 103 (20.5%) were eligible and provided consent (Figure 2). The primary reasons participants were excluded were lack of interest (n=310, 77.7%), reporting sitting <7 hours/day (n=22, 5.5%), or having a mobility-limiting comorbidity (n=17, 4.3%). Following consent, 83 (80.6%) participants were eligible and underwent randomization (n=42, 50.6% to the *NEAT!2* group and n=41, 49.4% to the control group). Retention was 96% and 95% at 2-month follow-up and 5-month follow-up, respectively, with no differences between groups at either time point.

Participants in the *NEAT!2* and control groups had similar characteristics at baseline (Table 1). Participants had a mean age of 65.3 (SD 9.4) years, were primarily female (n=62, 74.7%) and White (n=64, 77.1%), and had an average BMI of 32.7 (SD 6.9) kg/m^2. Most participants (n=44, 53%) were employed full-time or part-time. The most common medical conditions included hypertension (n=48, 57.8%), depression or anxiety (n=27, 32.5%), sleep apnea (n=22, 26.5%), and diabetes (n=18, 21.7%). In total, 9 (10.8%) participants were recruited prior to surgery (mean 12.0, SD 3.5 days before surgery), and 74 (83.2%) participants were recruited a median of 213 (IQR 87-300.5, range 38- 351) days after surgery. During the study period, 32 adverse events (2 prior to randomization, 8 in the control group, and 22 in the *NEAT!2* group) and 6 serious adverse events (3 in the control group and 1 in the *NEAT!2* group) occurred. The serious adverse events included 1 death and 5 surgeries or hospitalizations. Only 1 adverse event (nerve entanglement in the back) was deemed possibly related to the intervention; all others were deemed unrelated to the study.

Intervention Effects on Primary and Secondary Outcomes

Valid ActiGraph data were provided by 82 (98.8%) participants at baseline (mean 6.6, SD 0.8 valid days), 76 (91.6%) participants at 2 months (mean 6.4, SD 0.9 valid days), and 75 (90.4%) participants at 5 months (mean 6.4, SD 0.9 valid days). Valid activPAL data were provided by 81 (97.6%) participants at baseline (mean 6.5, SD 0.7 valid days), 74 (89.2%) participants at 2 months (mean 6.2, SD 0.6 valid days), and 74 (89.2%) participants at 5 months (mean 6.2, SD 0.8 valid days). The intervention effects on sedentary behavior and physical activity outcomes are shown in Table 2. At baseline, the average percentage of the waking day spent in sedentary time was 73.26% (SD 7.47%) in the *NEAT!2* group and 74.13% (SD 6.17%) in the control group. At 5 months, ActiGraph-assessed moderate-to-vigorous physical activity (MVPA; mean difference −24.23, 95% CI −46.91 to −1.55; adjusted for weekly wear time; P=.04) and activPAL sit-to-stand transitions (mean difference 4.06, 95% CI 0.13-7.99; P=.04) were different between groups. The *NEAT!2* intervention did not result in statistically significant effects on any other sedentary behavior or physical activity outcomes at 2 or 5 months, and no other differences were observed between groups. The intervention effects on physical function and patient-reported outcomes are shown in Table 3. Exploratory outcomes are shown in

[b]WOMAC: Western Ontario and McMaster Universities Osteoarthritis Index (higher scores on WOMAC indicate more knee symptoms).

A sensitivity analysis was performed including covariates such as BMI, marital status, cancer, depression, and the interaction between baseline physical activity and BMI. Effect estimates were similar across all covariate specifications. Compared with the primary outcome of ActiGraph percentage of time sedentary (group × time interaction effect −0.02, 95% CI −2.36 to 2.33 at 2M; 1.78, 95% CI −0.57 to 4.14 at 5M), estimates from the model adjusted for BMI, marital status, cancer, and depression (0.01, 95% CI −2.34 to 2.35 at 2M; 1.82, 95% CI −0.54 to 4.17 at 5M) and the model accounting for interaction of baseline low physical activity and BMI (0.28, 95% CI −2.01 to 2.57 at 2M; 2.18, 95% CI −0.12 to 4.49 at 5M) did not change conclusions. After accounting for covariates, the *NEAT!2* intervention did not result in statistically significant improvement on any of the

XSL•FO
RenderX

other sedentary behavior or physical activity outcomes at 2 or 5 months.

Intervention Engagement

On average, participants completed an average of 4.8 (SD 0.6) calls of the possible 5 calls, with no difference between randomized groups. Average call times for *NEAT!2* participants (mean 13.0, SD 7.2 minutes) were greater than those for participants in the control group (mean 10.65, SD 4.8 minutes; $P<.001$). Participants in the *NEAT!2* condition used the app for an average of 40.3 (SD 3.82) days over the 56-day intervention, with participants receiving an average of 9.7 (SD 6.0) notifications per day. Participants responded to *NEAT!2* notifications (movement detected by the smartphone) on an average of 9.7% (SD 7.8%; range 2%-42%) of occasions, with an average time between notification and movement of 2.4 (0.4) minutes.

Association Between Intervention Adherence and Changes in Outcomes

A higher percentage of days of *NEAT!2* app use was associated with greater increases in MVPA ($r=0.335$; 95% CI 0.017-0.585; $P=.04$). There were no other significant relationships between adherence to call completion or response to *NEAT!2* notifications and changes in sedentary time, physical activity, physical function, and pain.

Discussion

This study examined the effects of a multicomponent mHealth sedentary reduction intervention (*NEAT!2*) on sedentary time in adults with recent TKR. Additionally, this study examined the dose-response relationship between adherence to the mHealth program and changes in each outcome. Despite high adherence to the program, the *NEAT!2* intervention only led to improvements in sit-to-stand transitions assessed by activPAL at 5 months. The intervention did not result in any other statistically significant changes in the study outcomes of sedentary time, physical activity, physical function, or pain. Results did not change even after adjusting for covariates. Although there were no between-group differences in outcomes, there was a positive association between adherence to the *NEAT!2* app and MVPA, suggesting that those who used the app more frequently had greater increases in MVPA.

Although some previous interventions have been effective in reducing sedentary time in non-TKR populations [15-17], the literature is mixed, particularly among older adults [30]. A recent systematic review by Chastin et al [30] highlighted the uncertainties regarding whether sedentary reduction interventions can effectively reduce sedentary time in older adults; however, the review only included 7 studies. The lack of changes in sedentary time in this *NEAT!2* mHealth intervention among adults <1 year after TKR is consistent with this review [30], highlighting the challenges of reducing sitting time in an older clinical population, as well as the need for more studies examining reductions in sedentary behavior in older adults.

This intervention was guided by the Dual-Process Theory [20,21] and targeted both automatic and conscious individual-level behaviors. The behavior change techniques implemented in this study included strategies, such as reminders to interrupt sedentary behavior (targeting automatic processes) and goal setting (targeting conscious processes), to target total sedentary time. Previously, mHealth interventions, including disruptive smartphone apps designed to interrupt sedentary behavior, have shown effectiveness in reducing total sedentary time among various populations, including individuals with overweight or obesity and diabetes [15,31]; however, these strategies may not have been sufficient to change daily sitting time in adults after TKR within this brief 2-month intervention. The intervention increased sit-to-stand transitions at 5 months, but to change total sedentary time, providing real-time feedback may be necessary, as this approach has been an effective behavior change technique for physical activity [32]. Unfortunately, there were no devices at the time, to our knowledge, that could accurately provide feedback on sitting time. Furthermore, many effective sedentary reduction programs have included environmental changes and the provision of standing desks, primarily for office workers [33]. Although this approach may work for working adults, approximately half of the participants in this study were retired or not working; thus, standing desks may not be an effective strategy for this population. Environmental strategies for retired adults could include modifying the home by adding standing-friendly spaces (eg, high tables or counters) for activities such as puzzles, rearranging furniture and living space to encourage standing and light movement, or incorporating visual cues or reminders (eg, notes near the television) to break up sitting time. Future interventions may need to increase the focus on environmental, as well as cultural and social factors that could be influencing sedentary behavior more than individual-level factors [30,34].

Potential postoperative and COVID-19 pandemic–related barriers faced by the current participants may have also reinforced sedentary behaviors [35] and prevented the intervention from being effective. Additionally, previous research has suggested that adults with TKR and osteoarthritis are unaware of the health benefits of light-intensity activity and often think that sedentary time should be replaced with moderate-intensity activity [34]. This intervention primarily promoted light-intensity activity such as standing or light walking; however, the results suggested that the more days the app was used, the greater the increase in MVPA. Despite coaches encouraging the replacement of sedentary time with light-intensity activity, participants may still have focused on replacing sedentary time with MVPA such as through brisk walk. Although increasing MVPA would provide substantial health benefits, it is unreasonable to think that all excess sedentary time could be replaced with MVPA. More effort is needed to raise awareness of the health consequences of excess sedentary time and the benefits of replacing sedentary time with activity of any intensity in older adults [36].

This study had several strengths. In addition to being one of the first studies to examine a sedentary reduction program after TKR, the use of multiple objective and subjective measurement tools provides further evidence of the challenges and

XSL•FO
RenderX

inconsistencies in measuring sedentary time in this population. However, this study has also had several limitations. The COVID-19 pandemic resulted in necessary changes to recruitment whereby some participants completed baseline testing before surgery, and others completed testing postoperatively. Although this was accounted for in the analyses, the COVID-19 pandemic may have had other effects on participants and outcomes in both the intervention and control groups. Additionally, the prevalence of depression and/or anxiety (32.5%) was higher than anticipated and may have affected adherence to the intervention. The sample size was smaller than anticipated, resulting in lower power to detect changes and there was potential for inter- and intraindividual variation in capturing habitual sedentary and physical activity behaviors, which may have influenced the results. Furthermore, there is likely an error in the determination of responsiveness to the *NEAT!2* notifications, as the determination of response was based on movement detected on the smartphone. It is possible that participants may have stood up or walked around but did not move their phone; thus, the app would not have been able to detect that response. Additionally, the ActiGraph activity monitor cannot distinguish sitting from standing. Future studies may need to consider using more innovative wearables that can detect postural changes.

A multicomponent mHealth sedentary reduction intervention led to changes at 5M in sit-to-stand transitions but was not effective in reducing sedentary time in adults who had undergone TKR; however, participants who used the app more frequently throughout the intervention had greater increases in MVPA. This study highlights the challenges of reducing sitting time in this population and presents direction for future studies, which should explore alternative behavior change techniques across different levels of influence (eg, environmental and social) within interventions during the first year after TKR.

Abstract

Background: Mobile health (mHealth) interventions are growing in popularity, but less research has focused on low-income families, particularly interventions integrating wearable devices with automated personalized messages.

Objective: We tested a preliminary wearable-integrated mHealth intervention with initial personalization elements among adults and youth from low-income urban communities, focusing on feasibility, acceptability, and preliminary evidence of physical activity behavior.

Methods: Participants were 83 adults and 31 youth recruited through community health events held in low-income urban communities. Using a single-arm pre-post design, participants were enrolled into a 7-week beta-version mHealth intervention that integrated a Garmin activity monitor with automated text messages. Messages were sent 4 days/week and focused on increasing step counts using theory-based behavior change techniques related to goal setting, self-monitoring, reinforcement, contextual factors, and self-efficacy. Most messages were personalized by including calculations based on the step-count and step-goal data, using branching logic, and using 2-way question-and-response messages. Feasibility measures included enrollment, retention, fidelity of message delivery, and adherence to wearing the Garmin device. Acceptability measures included survey items and engagement with responding to 2-way messages. Changes in daily steps were explored using mixed-effects linear regression.

Results: Enrollment and eligibility rates were 64% (84/132, adults) and 63% (31/49, youth), retention for physical activity measures was 84% (70/83) and 77% (24/31), and 99% (3910/3955) of the intended messages were delivered. Adults and youth adhered to wearing the Garmin on 82% (45/56) and 79% (44/56) of the study days, respectively. Overall acceptability ratings were 83% to 100%, with 97% (75/77) of adults and 100% (27/27) of youth indicating they would recommend the program. Adults and youth replied to a mean of 2.6 (SD 2.2) and 3.2 (SD 2.7) of the 7 text messages that asked for a reply, with higher engagement among adults who participated with their child. Pre-post changes in daily steps were β=240 (95% CI –387 to 866) for adults and β=413 (95% CI –877 to 1703) among youth, with larger changes observed among those in the highest tertile of engagement (adults: β=584, 95% CI –784 to 1952; n=19; youth: β=941, 95% CI –827 to 2709; n=11) and those who were meeting less than two-thirds of the physical activity guideline at baseline (adults: β=609, 95% CI –30 to 1247; n=47; youth: β=1406, 95% CI –94 to 2907; n=22).

Conclusions: Personalized mHealth physical activity interventions integrating wearable step trackers with automated text messaging appear to be feasible and acceptable among adults and youth from low-income communities. Step-count findings show

XSL•FO
RenderX

promise for the intervention's ability to support individuals who are further from meeting physical activity guidelines and warrant more research among parent–child dyads. Overall, findings support additional research to optimize and evaluate similar interventions within this population group using fully powered randomized controlled trials.

Trial Registration: ClinicalTrials.gov NCT05110508; https://clinicaltrials.gov/ct2/show/NCT05110508

Introduction

Increasing physical activity is central to the prevention and control of many diseases and promotion of general wellness for adults and youth [1]. Physical activity interventions are especially important for low-income population groups, which can be underresourced and have been shown to engage in less leisure-time physical activity and experience higher rates of related chronic diseases than other groups [2-5]. While behavior change interventions have been effective for increasing physical activity in multiple population groups [6,7], participation can be difficult because of burdensome protocols, times constraints, and scheduling conflicts, particularly for those from marginalized backgrounds [8-11]. Mobile health (mHealth) approaches have helped mitigate some of these barriers by providing greater flexibility for participants, which can improve the reach of behavior change interventions [12]. mHealth can also improve the reach and scalability of interventions through automation, such as delivering content through automated messages and/or website- or app-based platforms. Mobile technologies are now highly prevalent among low-income groups, with more than 84% of adults in low-income households having a smartphone [13].

mHealth interventions have been effective for increasing physical activity in multiple population groups, but there has been less research in low-income groups [14-19]. The few prior mHealth studies addressing physical activity among low-income groups have shown promise for this approach [20-23]. However, there is a need for more mHealth research among these groups, especially studies that include both adults and youth. This family-inclusive approach could improve reach by allowing parents/caregivers and children to enroll together and may extend physical activity support within family networks. Another gap in prior work among low-income groups is that while interventions have used wearables and websites or apps and content is often tailored to the focus population, the extent to which the content is personalized or individualized for each participant has been limited in many studies [12,20-23]. Personalization better addresses the real-life circumstances and contexts people experience and can be accomplished in multiple ways, including customizing delivery timing, using participant information within content/messages, and using participant or environmental information to select and/or customize goals, feedback, prompts, or other content based on decision trees, algorithms, or even artificial intelligence [14,24-28]. Wearable physical activity trackers are particularly useful for personalizing content on physical activity goal monitoring, although there is a need for more research in low-income groups to investigate the integration of physical activity wearables with automated, personalized messaging using text messages [20-23].

This pilot study aimed to help address gaps in prior research by exploring a personalized, wearable-integrated, family-inclusive physical activity mHealth intervention among both adults and youth from low-income communities. The study used a beta-version intervention to collect initial information on the intervention approach to inform a more robust version of the intervention and evaluation in a future randomized clinical trial. The beta-version incorporated basic elements of personalization through integration of step-count and adaptive step-goal information into messages, use of branching logic to select messages based on step counts and goal achievement, 2-way question-and-response messaging, and use of participant names in messages. The evaluation focused on feasibility and acceptability (primary outcomes) while exploring preliminary evidence of physical activity behavior change.

Methods

Ethical Considerations

The study protocol was approved by Children's Mercy Hospital's Internal Review Board on August 24, 2021 (IRB study number STUDY00001939), and participants were compensated up to US $95 for completing study assessments. Prior to receiving the Garmin monitor, all participants provided written informed consent or child assent, and parents provided written parental permission. All data were deidentified prior to data storage and analyses. Study reporting was aligned with the Transparent Reporting of Evaluations with Nonrandomized Designs statement [29]. The only deviation from the original clinical trials registration was that step counts, rather than both step counts and physical activity minutes, were used as the physical activity outcome measure, as detailed below.

Participants and Procedures

The study used a single-arm pre-post design, with all participants receiving the same active intervention, termed ActiveKC. Adults and youth were included, with those aged 8 years or older being eligible. Participants were required to be able to communicate in English and could be an adult, child, or parent–child dyad enrolled together. Either the participant or parent was required to have access to a smartphone. A priori eligibility criteria included that participants be insufficiently active, defined as not meeting step-count–based physical activity guidelines [30-32], because of the intervention's focus on helping move individuals toward meeting these guidelines. Interested adults and youth wore a step tracker (Garmin Vívofit 4; Garmin

XSL•FO
RenderX

International, Inc) for a 7-day run-in period and were excluded from the study if they averaged ≥7500 steps/day (adults) or ≥12,000 steps/day (youth). Individuals were also ineligible if they did not wear the Garmin device for ≥3 days during the run-in period because of perceived difficulty in their ability to receive the intervention content as intended, thus impacting internal validity. The selection of wear-time thresholds is detailed below.

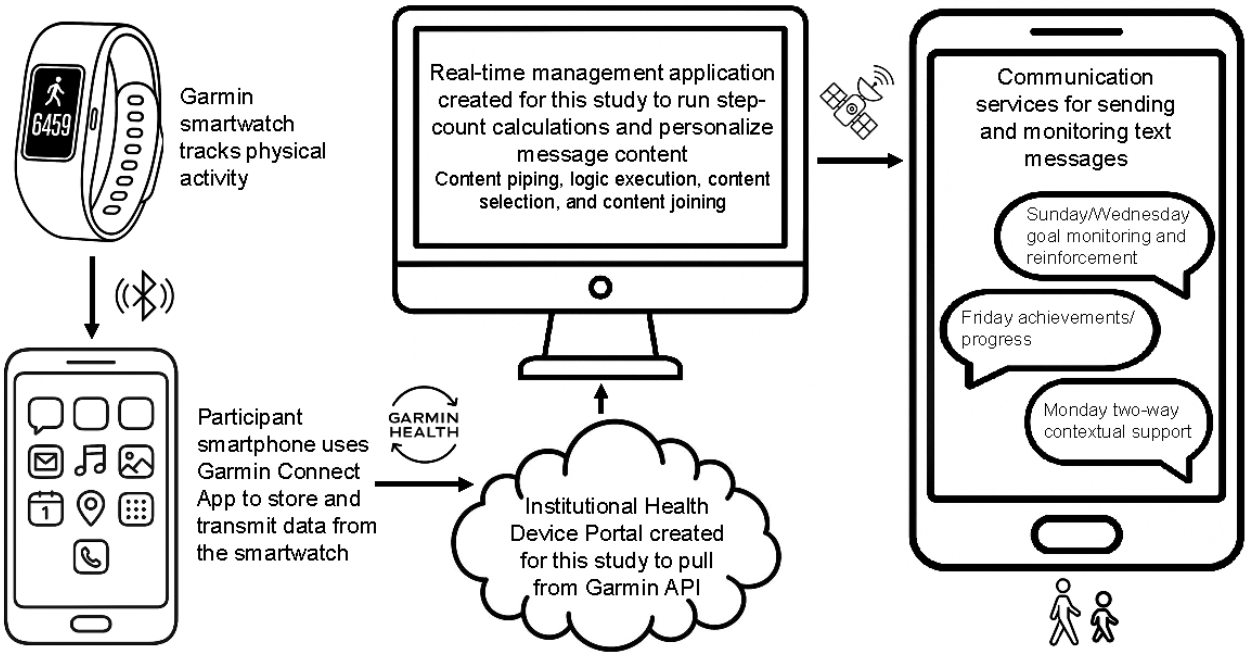
Participants were recruited from 6 zip codes within eastern Kansas City, Missouri, that were considered low income by the study team because of having the highest scores on the Centers for Disease Control and Prevention Social Vulnerability Index [33] among all zip codes within Kansas City, Missouri. Social Vulnerability Index scores for the 6 selected zip codes ranged from 0.67 to 0.95 on a range of 0 (lowest vulnerability) to 1 (highest vulnerability) based on measures of socioeconomic status, household composition/disability, minority status and language, and housing and transportation. The 6 zip codes also had a large population of Black residents, with 44% to 88% of the residents being Black individuals. Recruitment occurred at COVID-19 vaccination and health screening community events hosted by neighborhood, youth, business, faith-based, and health organizations in collaboration with university health professional schools, and during well-child visits within a large hospital-based pediatric primary care health system serving primarily uninsured and underinsured families from the same communities where the events were held. At the community events, the study team operated a study-information booth and distributed study fliers to event attendees. In the health care system, study team members used a recruitment flier and script to offer enrollment to families while they were waiting to see their provider or just after seeing their provider. For both recruitment approaches, individuals were enrolled on site during the event or clinic visit, except in a few circumstances when a separate enrollment appointment was warranted so that a family member who was not present could be included. These separate appointments occurred in community locations, the study team's office, or remotely over the telephone. Study enrollment occurred between September 2021 and February 2022.

Intervention

The beta-version ActiveKC intervention was informed by prior qualitative research conducted with parents and children from the same low-income Kansas City communities of focus in this study [34]. A primary objective of the ActiveKC pilot project was to obtain participants' input on design elements and intervention content while receiving a beta-version mHealth intervention. This participant input has been reported elsewhere.

ActiveKC was a 7-week mHealth physical activity intervention that integrated the Garmin Vívofit 4 with automated intervention text messages developed by the study team. The messages were sent to the participant's phone number using Microsoft Azure Communication Services and a real-time management application custom built for this project (Figure 1). For youth without a personal mobile phone, text messages were sent to the parent. Study staff helped set up the Garmin monitor, Garmin Connect smartphone app, and Garmin account; set the monitor to automatically synchronize with the Connect app; and demonstrated how to use the monitor and Connect app. Study staff monitored the data reports through the Garmin application programming interface (API) on a weekly basis and reached out to participants who did not have data within the prior 4 days. These participants were contacted via text message and phone call to provide technical assistance around synchronizing their Garmin watch with the Garmin Connect app on their smartphone (eg, because of problems with automatic synchronization). Participants could also request technical support from study staff.

The intervention focused on step counts because they are readily interpretable and preferred by many participants and because step counts and other measures of total physical activity have been consistently linked with health outcomes [35-40]. The intervention content used behavior change techniques [41] that were grounded in Social Cognitive Theory [42] and emphasized active living for building habitual physical activity into daily routines, including walking and movement throughout the day [43]. The automated text messages were sent 4 days/week and were personalized using the participant's Garmin data obtained through the Garmin API, using 2-way messaging starting with a question that was used to tailor the content of the second message, and using the participant's first name.



Step goals, monitoring, and reinforcement were core components of the intervention because of their grounding in Social Cognitive Theory [42] and because of consistent evidence showing their important role in behavior change [44]. The activity monitor tracked the participant's daily steps and step goal, and the text messages focused on weekly goals, with each week spanning Sunday to Saturday. The daily step goal was set by the activity monitor based on the participant's daily steps during their baseline week and adjusted each day using Garmin's adaptive algorithm that increased or decreased the goal based on the participant's step counts over the previous days. The weekly goal was the same for all participants: meeting their personalized daily goal on ≥4 days/week. Goal-monitoring messages were sent on Sundays (past-week review) and Wednesdays (midweek check-in). These messages were personalized based on step-count and goal-achievement data from the past week (past-week review; eg, "Congratulations Mallory, you met your step goal on 6 days this past week!") or prior days in the current week (midweek check-in; eg, "Mallory, there's still enough time to meet your step goal on 4 days this week. You just need 2 more days including today. You can do it!"). Conditional branching logic was used in these messages to include language that was reinforcing (eg, "You're a natural!") or encouraging (eg, "You can do it!") based on whether the goal was met or on track to be met [41]. The Sunday messages also included a success story from a fictional participant in the intervention, targeting self-efficacy through vicarious learning with a similar model [45]. The Wednesday messages included a new tip on incorporating habitual physical activity into daily routines (eg, "Weekly activity tip: Sitting too much is bad for us even when we meet our step goal. Stand up every 20-30 minutes and move around for a minute or two!"). Friday messages were also personalized using data from the wearable tracker, revealing the number of miles the participant had walked since the start of the intervention and referencing

XSL•FO
RenderX

an area or origin and destination with a similar distance (eg, the deepest part of the ocean). Throughout the study, participants were sent automated text messages to remind them to wear and/or synchronize the wearable tracker with the Garmin Connect app if data were not recorded on ≥3 consecutive days.

Each Monday, the participant received a 2-way message on a new topic related to multilevel contextual factors: knowledge, values, problem solving, planning, built environment, social support, and maintenance. The use of 2-way messaging allowed the system to send personalized information on the topic based on the participant's response to the first message. The first message comprised a multiple-choice assessment of the context the participant was currently experiencing in relation to the topic. For example, the message for the problem-solving topic asked the participant to choose the top physical activity barrier they were facing that day or week, and the second message provided behavioral support for problem solving the selected barrier (eg, "When your energy is low and being active sounds like a chore, start small. Stand up, wiggle your limbs, and walk at a low pace until you are re-energized!"). Participants were then sent a link to a study web page with more information on the topic and on the unselected response options. Participants had 48 hours to respond to each Monday message to receive a response from the system.

Figure 1. Overview of the ActiveKC Mobile Health System Architecture.

Measures

Sociodemographic Characteristics

Participant sociodemographic characteristics were collected via survey and included age, sex at birth, race/ethnicity, and adult or parent education (categorized as college degree or higher vs no college degree).

Feasibility

Enrollment and retention measures included the proportion of individuals who were enrolled out of all individuals who expressed interest and were assessed for eligibility, as well as the proportion of those enrolled who completed follow-up measurements (Garmin measures at the intervention midpoint and end point and survey measures at the intervention end point). Fidelity was based on the number of total messages per participant that were not received (eg, due to the participant's phone service being disconnected), which was recorded through the messaging services provider. Adherence to wearing the Garmin device was based on the number of days the Garmin was worn across the intervention. The number of participants whom staff needed to contact to provide technical support was also tracked.

Acceptability

The primary items used to capture overall acceptability were: "How difficult or easy was it to use the program?" ("very difficult," "somewhat difficult," "somewhat easy," or "very easy"); "How would you rate the frequency of the messages?" ("too few," "just right," or "too many"); "How much, if at all, did the program help you to be more active?" ("not at all," "somewhat," or "a lot"); and "Would you recommend that your family and friends use the program?" ("yes" or "no"). A total of 4 additional items had participants rate how helpful they perceived each of the primary 4 components of the intervention (step-tracker device, text-message content, ability to respond to messages, and web resources), with response options of "not at all," "somewhat," "very," and "extremely." Engagement with the text messages was captured as an additional indicator of acceptability based on text-message logs that tracked the number of times each participant responded to a 2-way message that asked for a reply, with up to 7 responses possible.

XSL•FO
RenderX

Physical Activity

Participants were asked to wear the Garmin Vívofit 4 step tracker throughout the intervention to facilitate intervention content and evaluation. Garmin step trackers have good validity for measuring step counts in adults and youth [46-48]. At the start of the screening period, study staff helped each participant set up a Garmin Connect account on their smartphone to facilitate automatic transfer of data into the Garmin API. Youth without a smartphone were connected to another device in the household (eg, tablet or parent's smartphone). In the present analyses, daily step counts were evaluated over a 1-week baseline prior to the start of the intervention (week 0, also referred to as the run-in period), the intervention midpoint (weeks 3 and 4), and the end of the intervention (weeks 6 and 7). An exception was that the baseline period could have been 5 or 6 days if the participant was enrolled on a Monday or Tuesday. To account for nonwear time, 15-minute periods with a maximum motion intensity of 0, indicating no movement of the watch, were considered nonwear. Participant-level estimates for each assessment period were based on only valid days, defined as having ≥8 hours of wear time and ≥100 total steps. Participant-level estimates were set to missing if the participant did not have ≥3 valid days during the assessment period. These wear time criteria aimed to capture habitual physical activity while minimizing missing data [49,50]. The outcome variable of interest was an average daily step count for the participant at each assessment period. Minutes of physical activity was explored. However, those results are not reported because the Garmin model that was used calculated physical activity based on step counts and the results were redundant with the step-count outcome. Participants' awareness of their physical activity levels was measured at baseline and at the end of the intervention with 1 item asking whether they generally knew how much physical activity or steps they obtained each day, with a 4-point response scale ranging from "strongly disagree" to "strongly agree."

Analysis

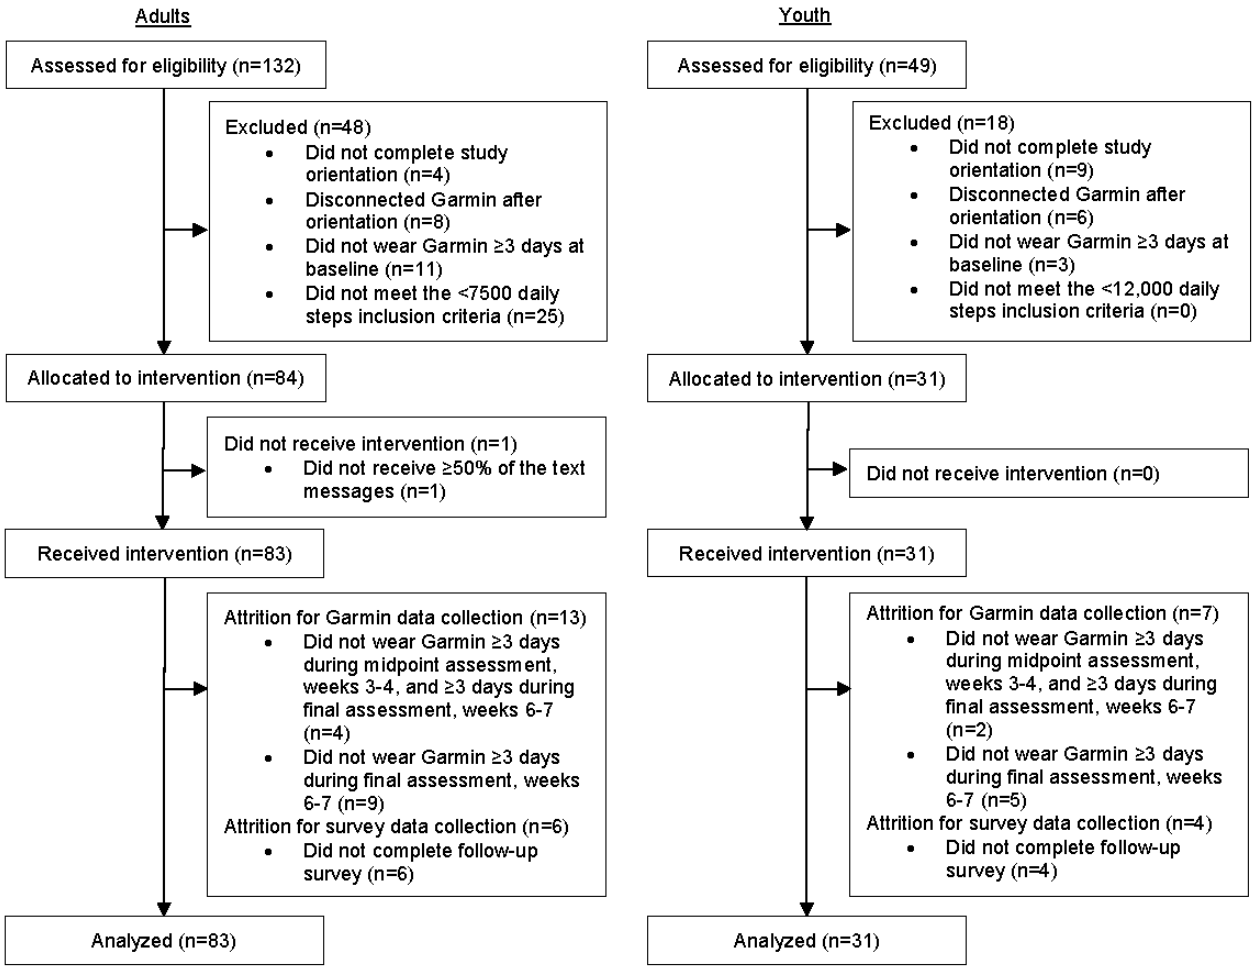
Descriptive statistics were summarized using frequencies, means, and SDs. Feasibility and acceptability benchmarks that were perceived to be reasonable targets in the current context were selected to help guide the interpretation of findings and were generally based on prior pilot behavioral and mHealth intervention studies [51,52]. These benchmarks included ≥60% for enrollment/eligibility, ≥80% for retention and fidelity, ≥70% for adherence, ≥80% for acceptability ratings, and ≥70% for engagement [51,52]. ANOVA and chi-square tests were used to investigate differences by eligibility/enrollment status, baseline physical activity, and level of engagement. Engagement as indicated by responses to messages was investigated as a categorical variable based on tertiles, which resulted in the following groups: replied to 0-1 messages, replied to 2-4 messages, and replied to 5-7 messages. We used 2-tailed *t* tests to investigate differences from preintervention to postintervention in participants' awareness of the amount of physical activity they engaged in. Changes in daily step counts over time were explored using mixed-effects linear regression models, with participant entered as the nesting variable and time entered as a categorical fixed effect (coded as 0=baseline, 1=midpoint, and 2=end point) to test differences at both the midpoint and end point. Models were adjusted for daily wear time (minutes/day), number of valid wear days, and proportion of valid wear days that were weekdays during each measurement period as time-varying fixed effects. These models were explored in the full adult and youth sample as well as post hoc by subgroup based on meeting less than two-thirds of the recommended daily steps at baseline based on the physical activity guidelines (<5000 steps/day for adults and <8000 for youth) [30-32], which is aligned with clinical trials that have focused on individuals with lower activity. These participants were of interest given the low levels of physical activity in the US population, particularly among low-income groups [5]. There is also greater potential for improvement among these individuals and a need for interventions that can help individuals move from low to moderate levels of physical activity [1,4,5]. The same models were also explored within subgroups based on level of engagement with the messages asking for a response, to capture dose-response and help inform whether observed increases in step counts were potentially attributable to greater exposure to intervention content. An intent-to-treat approach was used by including those lost to follow-up in the mixed-effects models and using restricted maximum likelihood estimation to account for the missing Garmin data. Effect sizes (Cohen *d*) were calculated by dividing the mean change in daily steps from baseline to the end of the intervention by the SD in this change. Given this pilot study was not powered to detect effectiveness, interpretations of the data were focused more on effect sizes than *P* values. All analyses were conducted separately for adults and youth using SPSS (version 27.0, SPSS Inc).

Results

Feasibility

Figure 2 presents study enrollment, exclusions, and retention information based on the CONSORT (Consolidated Standards of Reporting Trials) guidelines. Among adults, 64% (84/132) of those assessed for eligibility were enrolled into the intervention, although 1 participant did not receive most of the intervention text messages because of their phone being disconnected or because they changed phone numbers. Similar enrollment rates were observed for youth, with 63% (31/49) of those assessed for eligibility being enrolled. A total of 19% (25/132) of adults were ineligible because of the step-count criteria during the run-in period, whereas no youth were ineligible based on these criteria. No individuals who were screened for eligibility were ineligible because of lack of access to a smartphone.

The analytic sample comprised 83 adults and 31 youth. Among adult participants, 88% (73/83) were female, 84% (70/83) were Black or African American individuals, and the mean age was 50 years (range 19-88 years) (Table 1). A total of 77% (24/31) of the youth participants were female, 77% (24/31) were Black or African American individuals, and the mean age was 13 years (range 8-17 years). A total of 84% (26/31) of the youth participants had a parent who also participated. The eligible/enrolled (n=83) and ineligible/not enrolled (n=48) adults were similar with regards to age and race/ethnicity, although



XSL•FO
RenderX

enrolled adults were significantly (P<.05) more likely to have a college degree (30/80, 37% vs 7/46, 15%) and nonsignificantly more likely to be female (73/83, 88% vs 39/48, 75%; Table S1 in Multimedia Appendix 1). The eligible/enrolled (n=31) and ineligible/not enrolled (n=18) youth were similar with regards to age, although enrolled youth were significantly more likely to be female (24/31, 77% vs 4/12, 33%), significantly more likely to be Black individuals (24/31, 77% vs 9/17, 53%), and nonsignificantly more likely to have a parent with a college degree (6/29, 21% vs 0/12, 0%; Table S2 in Multimedia Appendix 1). For 48% (15/31) of the youth participants, messages were sent to the parent's phone. These youth were significantly younger than those whose messages were sent to their own phone (mean age 10.5, SD 1.9 years vs mean age 15.1, SD 1.9 years) and nonsignificantly more likely to have a parent with a college degree (4/14, 29% vs 1/14, 7%), although the 2 groups were similar with regards to sex, race/ethnicity, or parental education (Table S2 in Multimedia Appendix 1).

Retention rates were 95% (79/83) among adults and 94% (29/31) among youth for the step-tracker midpoint assessment, and 84% (70/83) among adults and 77% (24/31) among youth for the step-tracker end point assessment. Retention was 93% (77/83) among adults and 87% (27/31) among youth for the survey end point assessment. Across the 3955 messages that were sent, a total of 1.1% (45/3955) failed to be delivered, largely because of mobile phone numbers being inactive for a period of time. No participants experienced adverse events related to the intervention.

For adherence to wearing the step tracker, adults and youth had a mean of 46 (SD 13) valid wear days and 44 (SD 13) valid wear days, respectively, over the 54- to 56-day period spanning the 5- to 7-day baseline and 7-week intervention (ie, 45/56, 82% and 44/56, 79%). Wear time at each study assessment period is summarized in Table S3 in Multimedia Appendix 1. Study staff contacted 10 total participants to troubleshoot technical problems, all of which were related to a lack of recent Garmin data. Of these, 9 participants were documented as experiencing technical problems related to their Garmin monitor synchronizing with the Garmin app on their smartphone, while the other participant was believed to have disengaged from wearing the study monitor.

Table 1. Participant sociodemographic characteristics.

Characteristic	Adults (n=83)	Youth (n=31)
Age (years), range	19-88	8-17
Age (years), mean (SD)	49.6 (17.0)	12.9 (3.0)
Female, n (%)	73 (88)	24 (77)
Race/ethnicity, n (%)		
Black/African American	70 (84)	24 (77)
White non-Hispanic	11 (13)	6 (19)
Hispanic/Latino	0 (0)	0 (0)
Other	2 (2)	1 (3)
No college degree, n (%)[a]	50 (63)	23 (79)[b]

[a]Percentages were calculated based on nonmissing responses (3 and 2 participants had missing responses in the adult and youth columns, respectively).
[b]Refers to parent education.

Acceptability

Among adults, 88% (69/78) indicated the intervention was somewhat or very easy to use, 83% (65/78) rated the frequency of messages as just right, 99% (77/78) believed the program helped them be more active, and 97% (75/77) indicated they would recommend the program to family and friends (Table S3 in Multimedia Appendix 1). Among youth, 96% (27/28) indicated the program was somewhat or very easy to use, 93% (26/28) rated the frequency of messages as just right, 100% (28/28) believed the program helped them be somewhat or a lot more active, and 100% (28/28) indicated they would recommend the program to family and friends. The step tracker device was the highest rated component of the intervention, followed by the text message content and ability to respond to messages, and these results were similar for adults and youth (Table S3 in Multimedia Appendix 1).

Adults replied to a mean of 2.6 (SD 2.2) of the 7 text messages that asked for a reply within the allotted 48-hour response period. Youth replied to a mean of 3.2 (SD 2.7) messages. Among adults, those who had a child who also participated replied to more messages than those without a participating child (mean 3.3, SD 2.2 messages vs mean 2.4, SD 2.2 messages), although this difference was nonsignificant (2-tailed t_{81}=1.5; P=.12). Adults who replied to more messages were significantly (P<.05) more likely to be White non-Hispanic and have a college degree, and nonsignificantly more likely to be female and younger in age (Table S1 in Multimedia Appendix 1). Youth who replied to more messages, including those with messages sent to the parent's phone, were similar to those who replied to fewer messages with regard to age, sex, race/ethnicity, and parent education (Table S2 in Multimedia Appendix 1).

Physical Activity

Adults and youth had a mean of 4761 (SD 1719) daily step counts and 6618 (SD 2229) daily step counts at baseline, respectively. Adults and youth experienced small and nonsignificant increases in their daily step counts from baseline to the end of the intervention (weeks 6-7) of a mean of 240 (SD 1799; d=0.13) steps/day and 413 (SD 2698; d=0.15) steps/day, respectively, based on the regression analysis (Table 2).

Exploratory analyses suggested that participants with lower daily step counts at baseline experienced larger increases over the course of the intervention, with adults and youth who entered the study with a daily step count that was less than two-thirds of the recommended daily steps experiencing nonsignificant increases of a mean of 609 (SD 1534; d=0.40) steps/day and 1406 (SD 2445; d=0.58) steps/day by the end of the intervention, respectively (Table 2). This reflected increases of 18% and 26% over baseline. As shown in Tables S1 and S2 in Multimedia Appendix 1, both adults and youth with less than two-thirds of the recommended daily steps at baseline were similar to those with at least two-thirds of the recommended daily steps at baseline with regard to age, sex, race/ethnicity, and adult education.

Exploratory analyses also suggested that participants who had higher engagement with the intervention messages experienced larger increases over the course of the intervention, with adults and youth in the highest tertile of engagement experiencing nonsignificant increases of a mean of 584 (SD 1744; d=0.33) steps/day and 941 (SD 2465; d=0.38) steps/day by the end of the intervention, respectively (Table 2). This reflected increases of 12% (584/4838) and 15% (941/6321) over baseline. Among youth, data suggested that larger increases in daily steps were experienced by those whose parent was receiving messages about the child (mean 530, SD 2690 steps/day; d=0.20), rather than the child receiving the messages on their own mobile phone.

Increases were observed in participants' awareness of their physical activity levels, from a mean of 2.7 (SD 1.0) to 3.1 (SD 0.8) in adults (2-tailed t_{53}=–2.6; P=.01) and a mean of 2.6 (SD 0.7) to 2.9 (SD 0.7) in youth (2-tailed t_{16}=–1.8; P=.10).

Discussion

Overview

Findings generally supported high feasibility and acceptability of the beta-version mHealth intervention among adult and youth participants from marginalized, low-income communities. Most benchmarks were achieved for enrollment/eligibility, retention, fidelity, adherence, and acceptability, although level of engagement based on replies to messages was moderate overall and highly variable. The step-count data provided preliminary evidence in support of increased physical activity, particularly among those who had a low amount of physical activity at baseline (less than two-thirds of the daily recommendation) or who were more engaged in the intervention. The engagement and physical activity findings were most promising among

XSL•FO
RenderX

youth, particularly those who were younger and participated as part of a dyad whereby messages were sent to the parent. These findings warrant expansion of the beta-version intervention to further incorporate end-user preferences around content and personalized components along with rigorous evaluation using a randomized controlled trial design.

Feasibility

Feasibility was supported across all indicators for both adults and youth, including rates of enrollment/eligibility (31/49, 63% to 84/132, 64%), retention (24/31, 77% to 77/83, 93%), fidelity of message delivery (3910/3955, 99%), and adherence to wearing the step tracker (44/56, 79% to 46/56, 82% of days). All individuals screened had a smartphone, which reflects the growing ubiquity in smartphone use among low-income populations [13] and supports the potential for mHealth interventions to have high reach among this population group. The exclusion of 19% (25/132) of adults because of already meeting the physical activity guideline aligns with the low levels of physical activity in the US population and generally lower levels among low-income groups [4], although it was alarming that none of the youth who were screened were already meeting the physical activity guideline, highlighting the particular importance of efforts to increase physical activity among youth from these communities. The enrolled participants generally reflected the target population based on sociodemographic factors, although findings suggest a need to improve reach among boys, men, and adults with lower education. Engaging men in health behavior interventions is a known challenge and may warrant interventions tailored for adult men from specific population groups [53]. The low rate of enrollment among boys warrants further investigation and differs from other family-based interventions and interventions among children, which have generally had similar reach among boys and girls [54,55]. The retention rate in youth for the final physical activity assessment period warrants improvement, with potential strategies including incentivization tied to wearing the monitor for specific time periods and even using a separate monitor (eg, research-grade accelerometer) for baseline and end point evaluation measurement given the need to retain participants in assessments even if they disengage from the intervention.

The high level of adherence to wearing the step tracker among adults and youth can also be viewed as a marker of engagement in the intervention, supporting both feasibility and acceptability. Prior studies have observed similar levels of adherence during relatively brief (eg, 12-week) interventions, with poorer adherence over longer periods of time and at follow-up periods [56], indicative of the challenges with ongoing adherence to wearing step trackers. Adherence is especially important in wearable-integrated interventions that rely on activity data. Given the vast body of evidence supporting self-monitoring as one of the most important components in physical activity and behavior change interventions [44,57], there is a need for more research on longer-term adherence to consumer wearable trackers [58]. Future mHealth research should consider testing whether intermittent periods of wearing the tracker can provide benefits that translate to periods of nonwear and testing “back-up” strategies for supporting goal setting and monitoring during periods of nonwear.

Many participants experienced technical problems with the step tracker, primarily with the tracker failing to regularly synchronize with the Garmin app on their smartphone. This challenge has been documented across many prior studies and monitor brands and models and thus is a critical issue facing wearable-integrated mHealth research [59]. Study staff were able to work with many of these participants to achieve resolution, although anecdotal evidence that we were unable to quantify suggested that some problems were recurring and that some participants needed to regularly engage with their Garmin app to ensure proper synchronizing. The exact source of the problem could vary and was often unknown, and the process for implementing and testing solutions could vary somewhat across smartphone software type and version, requiring staff to develop detailed guidance protocols to capture the different scenarios encountered. Overall, there is a need for more research to guide effective and efficient technical support for wearable-based physical activity interventions to reduce missing data and prevent disruptions in delivery of tailored intervention content, particularly among population groups with less experience with technology.

Acceptability

The high overall acceptability ratings of the intervention among adults and youth (65/78, 83% to 28/28, 100%) show that participants generally enjoyed the automated intervention. The step tracker device was a favorite aspect of the intervention, especially among youth. This was likely attributable to the behavioral monitoring features it provided, given participants became more aware of their physical activity during the intervention and given the entry-level device had limited additional features (eg, no internet connectivity or text message alerts). The acceptability ratings suggested that participants liked the message frequency of approximately once per day on 4 days of the week, which is similar to the messaging frequency used in some prior physical activity interventions [15,20,60]. This somewhat frequent delivery of messages helps facilitate timely interaction and check-ins, allowing content to be personalized to experiences related to that day or even time of day. However, the acceptability ratings of the text messages were lower than the overall acceptability ratings for the intervention, and engagement based on replies to messages was moderate and highly variable across participants. These findings indicate a need for refined message content and potentially message types and targets. Qualitative research from this study sample, which is being reported elsewhere in more detail, suggested that participants generally preferred personalized messages over other messages, particularly the 2-way messages and the messages that were customized using their Garmin data, although present findings suggest that even these message types warrant further optimization. Future studies should use additional user-centered design strategies to collect participant input on specific messages and personalization components to optimize content, such as iterative prototyping and co-design activities [61-64]. There is also a need to explore additional approaches for personalization within this study population, such as integrating periodic questionnaires, ecological momentary assessments, location tracking, and/or meteorological monitoring [26-28]. Study designs such as

XSL•FO
RenderX

microrandomized and multifactorial trials allow for testing different types of messages and personalization elements and thus are ideal next steps for optimizing this and similar interventions [65].

Participant engagement with intervention content is a common concern in behavioral interventions, including those using mHealth [66]. The participant characteristics among those who were more likely to engage in responding to messages can help to inform the population groups that future versions of the intervention should focus on, although research is also needed to identify strategies for improving engagement among groups that may be more difficult to engage. The present engagement findings generally suggest that wearable-integrated, text message–based mHealth interventions may be most promising among youth and among younger adults, and that additional strategies are needed to support engagement among older adults, Black individuals, individuals with lower education, and men. Features that have been shown to increase engagement include personalization, which was a focus of this study but through basic initial elements, as well as gamification, social interaction, and live human integration (eg, coaching) [67,68]. Present findings also suggest that participating together as a parent–child dyad may result in higher engagement, which warrants more family-based research in this area. Theory-based frameworks such as Family Systems Theory [69] can guide family-based physical activity interventions and be used to inform personalized content, so their use should be investigated within this context to better address engagement from both the parent and child. It is also important to consider that, given the flexibility and scalability of mHealth tools, lower levels of engagement may be acceptable, especially if behavioral outcomes are still achieved.

The web-based content was rated as the least helpful aspect of the intervention, warranting more exploration of strategies for providing helpful behavior change content beyond what is provided in the text messages themselves. Through qualitative research in this study sample, we discovered that some participants were concerned about clicking on website links that were provided in the text messages, which may have impacted acceptability. Future studies should track website metrics such as visits by each participant, which we have had success doing in other studies through use of participant-specific URLs for each study web page. More research is needed to test strategies for increasing engagement in asynchronous intervention content, which could include personalization of content within web pages, enhancements to credibility, enhancement to aesthetics, multimedia content (eg, pictures, videos, and audio), gamification, peer-to-peer engagement, and/or reinforcing engagement [70,71].

Physical Activity

The magnitude of the changes in daily step counts was small and not likely to be meaningful in the full sample, although the changes appeared meaningful for participants who were more engaged in the intervention or who were further from meeting the recommended daily steps at baseline. The association between engagement and physical activity has also been observed in prior research [72] and suggests that the observed changes were more likely to be attributable to intervention participation than to an external or confounding factor. These exploratory findings were also useful in informing who may be more likely to benefit from future iterations of the intervention, pointing to those with low levels of activity (meeting less than two-thirds of the guideline) and parent–child dyads (ie, children with parent involvement). The approximately 500 steps/day to approximately 1400 steps/day changes in daily steps among these subgroups of youth are comparable to prior digital health interventions in youth from different population groups and to amounts recommended for health improvements, which reflect changes of approximately 1000 steps/day (reflecting approximately 10 minutes/day of moderate-to-vigorous physical activity [MVPA]) [24,30,73,74]. Similarly, the approximately 500 steps/day to approximately 600 steps/day changes in adults are comparable to prior studies in adults and are within the range of 500 steps/day to 600 steps/day (reflecting approximately 30-35 minutes/week of MVPA) that has been shown to produce clinically meaningful health improvements [1,15,16,31,32,75]. However, caution should be used when considering these changes alongside findings from prior studies given the pilot nature of this study and lack of a control group. Overall, the physical activity findings warrant additional research on mHealth physical activity interventions among low-income populations to focus on optimization and effectiveness testing in randomized controlled trials.

Strengths and Limitations

Study strengths and innovations included the focus on a population group that has been historically underrepresented in research and the integration of device-based physical activity data with automated messages that were personalized based on goal achievements. The inclusion of both adults and youth was a study strength given this approach can increase reach and allow families to participate together. However, the intervention content did not differ between adults and youth in this beta-version intervention, and qualitative data collected as part of this study (reported separately) suggest future iterations of the intervention should heavily tailor the content for different age groups (eg, children, adolescents, parents, and other adults). While the intervention content was informed through community engagement, more work is needed to refine the content through additional cocreation strategies to optimize its relevance for the population group. The study design did not support investigation of which intervention components or text messages had the greatest impact on engagement and physical activity. Since message frequency did not vary across weeks or across participants, we were not able to explore the impact of message frequency. We were unable to track whether participants viewed text messages or web pages, which are important aspects of engagement that should be assessed in future research. Survey measures generally relied on single-item ratings that did not have established psychometric properties and thus should be interpreted cautiously. The lack of a control group prevented the ability to distinguish the effects of the intervention from natural changes in physical activity that may have occurred over time and thus limited the ability to make causal inferences. Few of the daily step increases observed were statistically significant, which was likely due to the small sample size and wide CIs, so

XSL•FO
RenderX

results should be confirmed in larger samples. The step count data collected from the Garmin device did not provide insights into activity intensity, so we were unable to distinguish light activity from MVPA. Since the study focused on a low-income group, the results may not generalize to other population groups.

Conclusions

This study showed high feasibility and acceptability for using basic personalized mHealth physical activity intervention components that integrate wearable step trackers with automated text messaging among adults and youth from marginalized, low-income communities. More robust development and testing of this type of intervention appears particularly promising for children with low physical activity through involvement from a parent (ie, dyadic approach). The daily step increases associated with the brief beta-version intervention warrant larger-scale effectiveness research in randomized controlled trials. Given the importance of content personalization, future research is warranted to evaluate additional strategies for delivering highly personalized and engaging content for marginalized population groups.

Acknowledgments

The authors thank Shauna Kim, Maurice Miller, Amy Moran, Maddy Pilla, Shea Roy, and the study participants for their contributions to this work.

Figure 1 was created with assistance from the generative artificial intelligence tool Microsoft Copilot. Generative artificial intelligence was not used in any other portion of the manuscript writing.

Funding

Funding was provided by Jackson County, Missouri (contract number O.5506). Garmin Inc provided some of the monitors for this study. The funders had no role in the design or conduct of this study or in the interpretation or publication of findings.

Abstract

Background: Tobacco use remains a leading preventable cause of morbidity and mortality. Digital health tools and wearable technologies offer scalable opportunities for behavioral self-monitoring. However, real-world evidence characterizing long-term tobacco use trajectories and associated physiological changes during wearable adoption is limited.

Objective: This study aims to characterize longitudinal trajectories of self-reported tobacco use during the first 72 weeks of wearable adoption and to examine associations between tobacco use and wearable-derived cardiopulmonary and sleep measures.

Methods: We analyzed data from 12,678 new wearable members (18-79 years) who contributed up to 72 weeks of daily self-reported tobacco use and wearable-derived biometric data. Longitudinal trajectories of tobacco use were examined across prespecified 12-week quarters (Q1-Q6) using generalized linear mixed-effects models. Associations between tobacco use and wearable-derived nocturnal resting heart rate (RHR), heart rate variability (HRV), respiratory rate (RR), and sleep duration were evaluated using linear mixed-effects models that accounted for within- and between-person variation and adjusted for demographic and temporal covariates.

Results: Across 3,765,573 person-days, the estimated daily probability of tobacco use declined from 55.1% (95% CI 53.8-56.4) during Q1 to 27.2% (95% CI 26.1-28.3) during Q6, representing an absolute reduction of 27.9 percentage points (95% CI –28.4 to –27.4). Among tobacco users with end-of-follow-up data, over one-quarter (1404/4975, 28.22%) reported no tobacco use during Q6. Greater logging engagement was associated with larger reductions in tobacco use; each 10-percentage-point increase in engagement corresponded to a 0.92-percentage-point greater decline from Q1 to Q6 (95% CI –1.58 to –0.26). Following tobacco use days, RHR was 1.71 beats/minute higher (95% CI 1.70-1.73), HRV was 3.54 ms lower (95% CI –3.59 to –3.49), RR was 0.19 breaths/minute higher (95% CI 0.19-0.20), and sleep duration was 9.78 minutes shorter (95% CI –10.08 to –9.49) relative to nonuse days. Reductions in tobacco use over time were associated with directionally favorable changes in RHR (P=.001), RR (P=.002), and sleep duration (P=.02).

XSL•FO
RenderX

Conclusions: In this large-scale, observational, real-world study of wearable users, the probability of tobacco use declined over the first 72 weeks of adoption. Among participants with end-of-follow-up data, more than one-quarter reported no tobacco use during Q6. Tobacco use was consistently associated with less favorable cardiopulmonary and sleep measures, while reductions in tobacco use over time co-occurred with directionally favorable changes in these measures, although such changes may also reflect broader lifestyle or health changes. Overall, this study provides large-scale, longitudinal evidence that sustained reductions in tobacco use co-occur with favorable changes in physiological markers within a digital self-monitoring environment. As the findings derive from a single commercial ecosystem, independent replication in noncommercial, multiplatform settings will be needed to establish generalizability.

wearable technology; digital health; cigarettes; behavior change; cardiopulmonary

Introduction

Tobacco use remains a leading global cause of morbidity and mortality [1], largely due to its contributions to cardiovascular disease, cancer, and chronic respiratory disease [2]. Although age-standardized rates of tobacco-related mortality have declined over the past century, the absolute burden remains high. For example, in the 2019 Global Burden of Disease study [3], tobacco use was associated with an estimated 8.7 million deaths and 229.8 million disability-adjusted life years globally. Despite widespread awareness of health risks and strong motivation to quit among tobacco users, the habitual and addictive nature of tobacco use makes sustained cessation challenging [4]. A variety of pharmacological and behavioral cessation interventions have been developed to address this challenge, but these approaches vary widely in cost, effectiveness, and scalability [5].

Digital health technologies are increasingly recognized as promising tools for supporting behavior change across a range of health behaviors [6,7]. Prior work suggests that digital health platforms and self-monitoring tools may facilitate reductions in substance use through increased awareness, feedback, and habit formation [8]. Work in psychological control theory provides a potential explanation for this change, which posits that awareness of discrepancies between desired states and observed states may prompt behavior change [9]. Still, evidence for digital tobacco cessation interventions remains mixed. A recent systematic review reported potential benefits of digital health approaches but noted substantial heterogeneity in intervention design, participant characteristics, and outcomes [10]. Importantly, the evidence base is characterized by relatively modest sample sizes, raising questions about generalizability and persistence of observed effects. Indeed, a recent systematic review and meta-analysis reported that digital health interventions may be most effective in the short (<3 months) and medium term (3-9 months), with less certainty regarding longer-term maintenance of cessation [11]. Collectively, these findings highlight both the promise and limitations of existing digital tobacco cessation interventions and emphasize the need for scalable, real-world evidence examining how continuous self-monitoring may relate to changes in tobacco use over extended periods.

Leveraging a large real-world dataset, we examined longitudinal trajectories of self-reported tobacco use (ie, use of tobacco products as reported in a smartphone app) during the first 72 weeks of wearable membership and how trajectories differed by age, biological sex, baseline tobacco use frequency, and engagement with optional in-app goal setting. We also evaluated associations between tobacco use and wearable-derived measures, including resting heart rate (RHR), heart rate variability (HRV), respiratory rate (RR), and sleep duration, and assessed whether changes in tobacco use were associated with corresponding changes in these outcomes. We conducted these analyses using the WHOOP platform (WHOOP, Inc), which served 2 primary purposes in the study. First, it provided the combination of features required for this investigation: daily user-initiated self-reports of tobacco use, continuous nightly cardiorespiratory and sleep measures, and a recently onboarded member base of sufficient scale to support longitudinal analyses across 72 weeks. Second, it functioned as a digital self-monitoring environment in which users receive insights on their sleep, recovery, and strain; accordingly, this study characterizes tobacco use trajectories and associated physiological changes within this larger environment rather than any isolated platform feature. The platform has previously been leveraged for analogous real-world longitudinal characterization of health behavior trajectories [6,7,12], including a recent companion analysis of alcohol use [7].

Methods

Overview

We conducted a 72-week observational cohort study of WHOOP members who contributed daily self-reported tobacco use, and continuous wearable-derived cardiopulmonary and sleep measures. Participants self-reported tobacco use through a daily morning prompt within the WHOOP smartphone app, with the option to set tobacco-related goals at any point during the observation period. Detailed descriptions of the study population, wearable device and measures, self-reported tobacco use, and statistical analyses follow.

Study Population

We studied international adults aged 18-79 years who joined the WHOOP platform between January 2022 and June 2024 and met prespecified reporting criteria. Participants enrolled on a rolling basis and contributed up to 504 days (72 weeks) of data. Time was structured into consecutive, nonoverlapping 7-day weeks anchored to each participant's join date. Quarters

XSL•FO
RenderX

(Q1-Q6) were defined relative to each individual's join date as consecutive 12-week intervals.

Eligibility required at least 8 weeks with tobacco use reporting (≥10% of the 72-week observation window). Eligible weeks were defined as those with either complete reporting (ie, explicit "yes" or "no" entries for all 7 days) or at least 3 tobacco use entries to capture meaningful reporting even if all 7 days were not logged. These weeks did not need to be consecutive and could occur at any time during the observation period. These thresholds were selected a priori to balance adequate longitudinal coverage with retention of a broadly representative cohort rather than restricting analyses to only highly consistent reporters.

Ethics Considerations

All members consented to the use of their deidentified data for research purposes at account creation under WHOOP's Terms of Service. The study protocol was reviewed and approved under expedited procedures by an independent institutional review board (Salus Institutional Review Board; approval number 251121). The study is reported in accordance with the Strengthening the Reporting of Observational Studies in Epidemiology (STROBE) guidelines for observational cohort studies (Multimedia Appendix 1).

Wearable Device and Measures

WHOOP (WHOOP, Inc) is a subscription-based wearable platform consisting of a wrist-worn device and companion smartphone app used to derive sleep, recovery, and strain metrics that provide members with personalized insights and recommendations (Figure S1 in Multimedia Appendix 2). The WHOOP strap combines accelerometry and photoplethysmography to detect major sleep periods of at least 1 hour in duration. Within each detected sleep period, WHOOP classifies each 30-second interval into 1 of 4 stages: wake, light sleep, slow-wave sleep (SWS), and rapid eye movement sleep. Throughout each sleep period, the WHOOP device derives peak-to-peak heartbeat intervals from photoplethysmography to estimate HRV, calculated as the root mean square of successive differences. Beat-to-beat intervals, along with features derived from frequency transformations, are used to estimate RHR throughout the night. To generate nightly RHR and HRV values, WHOOP first filters out epochs identified as wake or as having low signal quality. The remaining epochs are then aggregated using a weighted average, in which epochs with a higher likelihood of SWS and epochs closer to the end of sleep are assigned greater weights. RR is calculated as the median respirations per minute derived from interbeat intervals throughout sleep. Sleep duration is defined as total sleep time (light, SWS, and rapid eye movement). WHOOP has undergone independent validation against gold-standard reference methods in peer-reviewed studies. Compared with electrocardiography, WHOOP-derived heart rate measures demonstrate 99% agreement, and compared with polysomnography, WHOOP demonstrates 86%-89% agreement for 2-stage sleep categorization [13,14].

Self-Reported Tobacco Use

Daily tobacco use was self-reported through the WHOOP smartphone app via the WHOOP Journal feature, a customizable morning prompt through which users confirmed behaviors from the prior day (Figure S1B in Multimedia Appendix 2). Users were prompted to indicate whether they used tobacco ("yes" or "no") and could optionally report the number of times they used tobacco that day (ie, tobacco use instances). These self-reported entries are user-initiated and configurable within the smartphone app; tobacco logging was not required for device use. Primary analyses included only days with explicit "yes" or "no" responses, whereas days with missing responses were used solely to calculate logging engagement, defined as the proportion of active days on the platform with a reported tobacco status.

Members could also set personalized tobacco-related goals within the app, which could range from abstaining entirely to limiting tobacco use on specific days. Goals could be created, modified, or abandoned at any time. Due to heterogeneity in goal types and because goals could be initiated at any point during follow-up, goal setting was analyzed as a fixed binary indicator of whether a member set any tobacco-related goal at any time during the 72-week observation window (any goal vs none). As this approach collapses a dynamic, heterogeneous behavior into a single time-invariant indicator, analyses involving goal setting should be interpreted as exploratory.

Statistical Analysis

Descriptive statistics are reported as means (SDs). Tobacco use frequency was modeled as the daily probability of tobacco use within each user-week using generalized linear mixed-effects models (GLMMs) with a binomial distribution and logit link. Weekly outcomes were specified as the number of tobacco use and nontobacco use days, allowing the binomial denominator to vary according to the number of completed tobacco use entries that week (range 3-7 days). Fixed effects included prespecified 12-week quarters (Q1-Q6), age, biological sex, season, total weeks contributed, and the proportion of days in each user-week that fell on a weekend (Saturday or Sunday entries, which reflect Friday or Saturday tobacco use), with participant-level random intercepts. Models were first fit in the overall sample, followed by evaluation of effect modification by biological sex, age group (young=18-39 years, n=10,248; middle=40-59 years, n=2294; and old=60-79 years, n=136), baseline tobacco use tertiles, and tobacco-related goal setting (goal setters vs nongoal setters). Estimated marginal means were computed on the response scale to obtain model-predicted daily tobacco use probabilities by quarter. Sensitivity analyses used inverse probability of censoring weighting (IPCW) to assess whether differential dropout biased the primary estimates. A logistic regression predicted quarter-to-quarter retention from quarter, age, sex, BMI, and the participant's mean tobacco use proportion in the current quarter. Each participant's IPCW weight was the inverse of their cumulative predicted retention probability across all prior quarter transitions, winsorized at the 1st and 99th percentiles. Weights were applied at the participant-quarter level in the GLMM. To assess the robustness of findings to incomplete tobacco use reporting, we conducted multiple imputation by chained equations under a

XSL•FO
RenderX

missing-at-random assumption. Of all active platform-days contributed by participants (ie, days the wearable was worn; N=4,436,523), 619,295 (13.96%) lacked an explicit yes/no tobacco use response. As the analytic sample additionally required ≥3 reported days per person-week, this day-level denominator exceeds the analytic person-day total. The imputation model included age, biological sex, BMI, weekday versus weekend, season, habitual tobacco use (ie, proportion of days with tobacco use), and the corresponding night's wearable-derived measures (RHR, HRV, RR, and sleep duration) decomposed into within- and between-person components. Tobacco use trajectory analyses were re-fit across imputed datasets and pooled using Rubin's rules [15]. Further sensitivity analyses were conducted among members contributing at least 1 week with complete tobacco use instances reporting (12,271/12,678, 96.79%). Weekly use instances were modeled using negative binomial GLMMs with a log link.

As a complementary descriptive analysis, we characterized the proportion of participants reporting tobacco use during Q1 who achieved sustained nonuse, defined as reporting zero tobacco use days during Q6, conditional on contributing at least 3 weeks in each quarter. We also examined whether logging engagement was associated with changes in tobacco use frequency. For each participant, logging engagement was defined as the proportion of their total active days on the platform during the observation period with a reported tobacco use status (yes/no). Linear models evaluated associations between logging engagement and change in tobacco use frequency from Q1 to Q6, adjusting for baseline (Q1) tobacco use, total platform days, age, sex, and BMI.

Associations between tobacco use and biometric and sleep outcomes over the observation period were evaluated using linear mixed-effects models that decomposed tobacco use into within-person (binary daily deviation from an individual's mean) and between-person (proportion of days with tobacco use) components. The between-person component was defined as each individual's mean across all days with a tobacco use entry over the full 72-week observation window. Outcomes included nightly RHR, HRV, RR, and total sleep duration. Additional analyses examined sleep onset time (bedtime) and the percentage of time in bed spent awake as complementary indicators of sleep continuity and quality. Models included random intercepts for participants and were adjusted for age, biological sex, BMI, weekday versus weekend, and season. For interpretability and visualization, models were fit with between-person tobacco use specified either as a continuous variable or as tertiles (low, medium, and high).

To evaluate whether changes in tobacco use were associated with changes in physiological outcomes, we used a change-score framework restricted to participants with data in Q1 and Q6 (n=5776). Quarterly averages were computed for each participant, and change scores were calculated as the difference between Q6 and Q1. Change in tobacco use was defined as the absolute percentage-point change between quarters. Models adjusted for baseline (Q1) tobacco use percentage, the baseline outcome value, age, biological sex, BMI, and Q1 season. Change in tobacco use was modeled both continuously and categorically in 5 prespecified groups: large increase (≥25 percentage-point increase; n=597), small increase (≥5 to <25 percentage-point increase; n=749), no meaningful change (>−5 to <5 percentage-point change; n=1643), small decrease (≤−5 to >−25 percentage-point decrease; n=1264), and large decrease (≤−25 percentage-point decrease; n=1523). These categorical thresholds were prespecified to facilitate interpretation of the change-score analyses and to distinguish meaningful behavior change from minor fluctuation. Absolute, rather than relative, change was used because it more directly reflects the magnitude of behavioral exposure relevant to physiological outcomes.

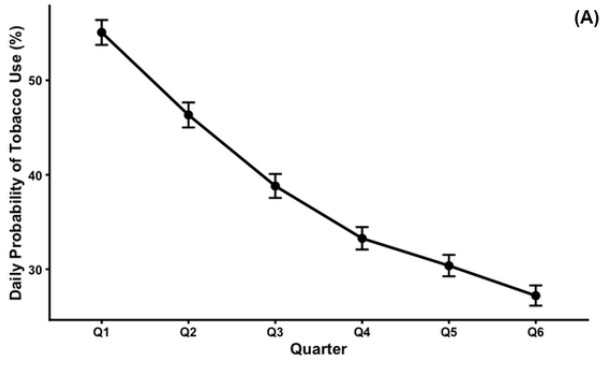
Across analyses, post hoc comparisons were adjusted for multiple testing as appropriate. Comparisons across quarters were evaluated relative to Q1 using Dunnett-adjusted contrasts, whereas Tukey-adjusted pairwise comparisons were used for categorical group comparisons. All analyses were conducted in R (version 4.4.2; R Foundation), with statistical significance set at α=.05.

Results

Sample Characteristics

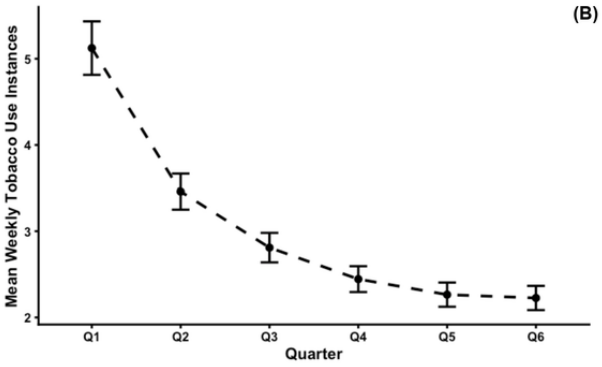
The final dataset included 12,678 participants (n=2678, 21.12%, females) and consisted of 3,765,573 person-days, aggregated into 596,589 person-weeks. The mean age was 32.4 (SD 8.9) years and the mean BMI was 25.7 (SD 4.3) kg/m^2. Participants contributed a mean of 47.1 (SD 18.2) weeks (median 48 weeks; range 8-72 weeks), with an average of 6.3 (SD 1.1) completed tobacco status ("yes" or "no") entries per week. The number of contributing participants declined from 12,626 in Q1 to 5804 in Q6 (Tables S1-S3 in Multimedia Appendix 2). A total of 52 participants met eligibility criteria through reporting that began after Q1, and therefore, are not represented in Q1 counts. Reporting engagement remained relatively high across follow-up, with a mean of 6.5 (SD 0.9) completed tobacco entries per week in Q1 and 6.1 (SD 1.2) in Q6.

Daily Tobacco Use Probability Declines Over 72 Weeks



The predicted probability of daily tobacco use declined over the 72-week observation window (Figure 1A), from 55.1% (95% CI 53.8-56.4) in Q1 to 27.2% (95% CI 26.1-28.3) by Q6, representing an absolute decrease of 27.9 percentage points (95% CI –28.4 to –27.4). Estimates were similar in a sensitivity analysis restricted to person-weeks with complete 7-day reporting (ie, 7 explicit "yes" or "no" entries), which included 374,497 of 596,589 (62.77%) person-weeks. In this restricted sample, the predicted daily probability of tobacco use declined from 54.9% (95% CI 53.4-56.4) in Q1 to 26.0% (95% CI 24.8-27.2) in Q6, corresponding to an absolute decrease of 28.9 percentage points (95% CI –29.5 to –28.3; data not shown).

To further test the robustness of these observations, additional sensitivity analyses were conducted. When analyses were restricted to users with all 72 weeks of follow-up (n=1049), results remained consistent (Figure S2 in Multimedia Appendix 2), with the daily probability of tobacco use declining from 66.9% (95% CI 62.1-71.4) in Q1 to 37.4% (95% CI 32.6-42.5) in Q6, a decrease of 29.5 percentage points (95% CI –30.4 to –28.6). Models incorporating IPCW produced estimates consistent with the primary analysis (Table S4 in Multimedia Appendix 2), with the IPCW-adjusted daily probability of



XSL•FO
RenderX

tobacco use declining from 55.3% (95% CI 53.9-56.6) in Q1 to 27.3% (95% CI 26.2-28.4) in Q6, a decrease of 28.0 percentage points (95% CI –28.4 to –27.5). Trajectory estimates derived from multiple-imputation analyses were similarly consistent (Figure S3 in Multimedia Appendix 2), with a Q1-to-Q6 decrease of 25.6 percentage points (95% CI –26.1 to –25.1). Results were also similar when analyses were restricted to weeks with complete 7-day tobacco instance data (ie, all "yes" entries specified the number of use instances, 321,925/596,589, 53.96%, person-weeks; Figure 1B); the model-estimated weekly number of tobacco use instances declined from 5.12 (95% CI 4.81-5.43) in Q1 to 2.23 (95% CI 2.09-2.37) in Q6, a decrease of 2.89 use instances per week (95% CI –3.14 to –2.65).

Figure 1. Adjusted tobacco use over 72 weeks. (A) Adjusted daily probability of tobacco use. (B) Adjusted mean weekly tobacco use instances. Marginal estimates from generalized linear mixed-effects models are shown for 6 sequential 12-week quarters (Q1-Q6). Points represent model-based estimates, and error bars indicate 95% CIs. Absolute changes from Q1 and corresponding Dunnett-adjusted *P* values are based on model contrasts. Panel A is based on a binomial model estimating the probability of a tobacco-use day, whereas Panel B is based on a negative binomial model estimating weekly tobacco use instances. Both models included quarter, age at activation, sex, season, proportion of weekend days, and total weeks contributed as fixed effects, with a random intercept for each participant. N/A: not applicable.

Quarter	Daily probability (%) (95% CI)	Absolute change vs Q1 (pp, 95% CI)	*P* value
Q1	55.1 (53.8 to 56.4)	N/A	N/A
Q2	46.3 (45.0 to 47.7)	–8.8 (–9.0 to –8.5)	<.001
Q3	38.8 (37.6 to 40.1)	–16.3 (–16.6 to –16.0)	<.001
Q4	33.3 (32.1 to 34.5)	–21.8 (–22.2 to –21.5)	<.001
Q5	30.4 (29.3 to 31.5)	–24.7 (–25.1 to –24.3)	<.001
Q6	27.2 (26.1 to 28.3)	–27.9 (–28.4 to –27.4)	<.001

Quarter	Weekly use instances (95% CI)	Absolute change vs Q1 (95% CI)	*P* value
Q1	5.12 (4.81 to 5.43)	N/A	N/A
Q2	3.46 (3.25 to 3.67)	–1.66 (–1.82 to –1.51)	<.001

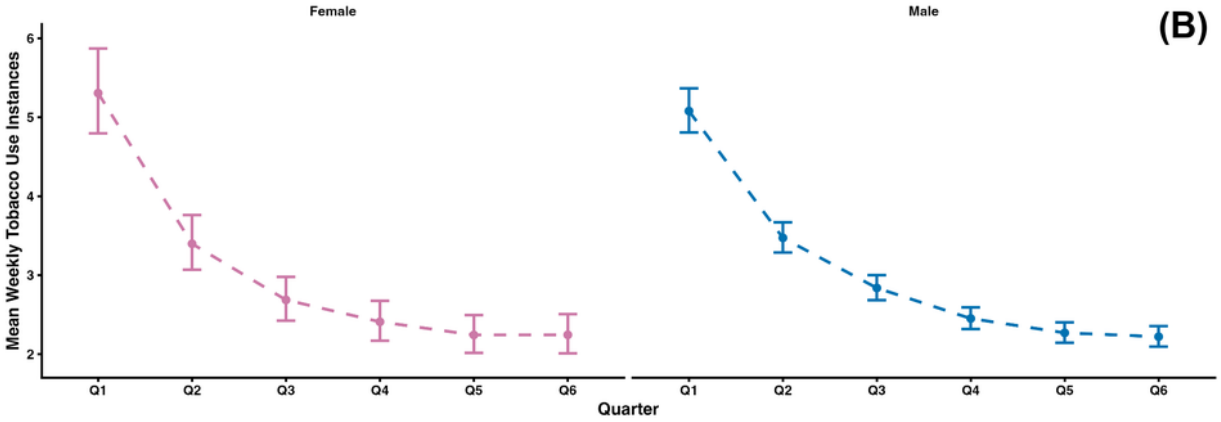
Females and Middle-Aged Adults Show Greater Relative Declines in Tobacco Use

The decline in use probability from Q1 to Q6 differed by biological sex (β=–.08 on the log-odds scale, 95% CI –0.12 to –0.05; *P*<.001), indicating a greater relative decline among females. From Q1 to Q6, decreases were 30.0 percentage points in females (95% CI –30.9 to –29.1) and 26.6 percentage points in males (95% CI –27.2 to –26.1; Figure 2A). Trends were similar in sensitivity analyses of tobacco use instances (Figure 2B), with decreases of 3.07 instances per week in females (95% CI –3.52 to –2.60) and 2.86 instances per week in males (95% CI –3.09 to –2.63).



Trajectories of tobacco use probabilities varied by age group (Figure 3A). Across follow-up, all age groups demonstrated declines in tobacco use probability, although the decline from Q1 to Q6 differed by age group (*P*s≤.001). Middle-aged adults showed greater relative declines from Q1 to Q6 than both younger adults (β=–.13 on the log-odds scale, 95% CI –0.17 to –0.09; *P*<.001) and older adults (β=–.19, 95% CI –0.32 to –0.07; *P*=.001), with no significant difference between younger and older adults (*P*=.49). From Q1 to Q6, the model-estimated daily probability of tobacco use decreased by 31.0 percentage points (95% CI –31.8 to –30.1) in the middle-aged group, compared with 27.1 percentage points (95% CI –27.6 to –26.5) and 26.8 percentage points (95% CI –29.9 to –23.7) in the youngest and oldest age groups, respectively. Decreases in weekly tobacco use instances were also observed across age groups (Figure 3B).

Figure 2. Adjusted tobacco use over 72 weeks, stratified by biological sex. (A) Adjusted daily probability of tobacco use. (B) Adjusted mean weekly tobacco use instances. Marginal estimates from generalized linear mixed-effects models with a quarter × sex interaction are shown for 6 sequential 12-week quarters (Q1-Q6), separately for males (blue) and females (pink). Points represent model-based estimates, and error bars indicate 95% CIs. Absolute changes from Q1 and corresponding Dunnett-adjusted *P* values are based on within-sex model contrasts. The quarter-by-sex interaction was assessed by comparing the Q6 versus Q1 contrast between sexes on the model scale (log odds for panel A and log instances for panel B). Panel A is based on a binomial model estimating the probability of a tobacco-use day, whereas Panel B is based on a negative binomial model estimating weekly tobacco use instances. All models included quarter, sex, their interaction, age at activation, season, proportion of weekend days, and total weeks contributed as fixed effects, with a random intercept for each participant. N/A: not applicable.

Figure 3. Adjusted tobacco use over 72 weeks, stratified by age group. (A) Adjusted daily probability of tobacco use. (B) Adjusted mean weekly tobacco use instances. Marginal estimates from generalized linear mixed-effects models with a quarter × age-group interaction are shown for 6 sequential 12-week quarters (Q1-Q6), separately for younger (18-39 years; green), middle-aged (40-59 years; orange), and older (60-79 years; purple) adults. Points represent model-based estimates, and error bars indicate 95% CIs. Absolute changes from Q1 and corresponding Dunnett-adjusted *P* values are based on within-age-group model contrasts. The quarter × age-group interaction was assessed by comparing the Q6 versus Q1 contrast across age groups on the model scale (log odds for panel A and log instances for panel B). Panel A is based on a binomial model estimating the probability of a tobacco-use day, whereas panel B is based on a negative binomial model estimating weekly tobacco use instances. All models included quarter, age group, their interaction, sex, season, proportion of weekend days, and total weeks contributed as fixed effects, with a random intercept for each participant.

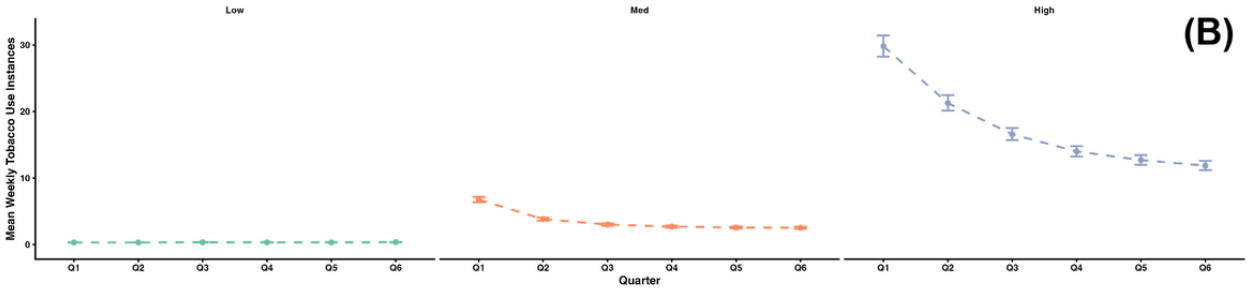
High Baseline Tobacco Users Show the Largest Declines



Longitudinal tobacco use trajectories differed by baseline tobacco use frequency (*P*<.001; Figure 4A), with progressively larger relative reductions in use across the low-, medium-, and high-use tertiles. Relative declines were greater in the medium-use tertile than in the low-use tertile (β=–1.08 on the log-odds scale, 95% CI –1.12 to –1.04) and greater in the high-use tertile than in the medium-use tertile (β=–2.96, 95% CI –2.99 to –2.92). From Q1 to Q6, the model-estimated daily probability of tobacco use increased by 3.1 percentage points (95% CI 2.8-3.4) in the low-use tertile but decreased by 13.7 percentage points (95% CI –14.2 to –13.1) and 39.3 percentage points (95% CI –40.8 to –37.8) in the medium- and high-use tertiles, respectively. Comparable trends were observed for the model-estimated mean weekly total number of use instances (Figure 4B).

Figure 4. Adjusted tobacco use over 72 weeks, stratified by baseline use tertile. (A) Adjusted daily probability of tobacco use. (B) Adjusted mean weekly tobacco use instances. Marginal estimates from generalized linear mixed-effects models with a quarter × tertile interaction are shown for 6 sequential 12-week quarters (Q1-Q6), separately for participants in the low (teal), medium (orange), and high (purple) tertiles. Points represent model-based estimates, and error bars indicate 95% CIs. Absolute changes from Q1 and corresponding Dunnett-adjusted *P* values are based on within-tertile model contrasts. The quarter × tertile interaction was assessed by comparing the Q6 versus Q1 contrast across tertiles on the model scale (log odds for panel A and log instances for panel B). Panel A is based on a binomial model estimating the probability of a tobacco-use day, with tertiles defined by the observed Q1 tobacco use proportion. Panel B is based on a negative binomial model estimating weekly tobacco use instances, with tertiles defined by the observed Q1 tobacco use instances. All models included quarter, tertile, their interaction, sex, age at activation, season, proportion of weekend days, and total weeks contributed as fixed effects, with a random intercept for each participant. N/A: not applicable.

Nongoal Setters Show Greater Relative Declines in Tobacco Use

A total of 1587 members set at least 1 tobacco-related goal during follow-up. Compared with members who did not set goals (n=11,091), goal-setting members were similar in age (mean 32.1, SD 8.8 years vs mean 32.4, SD 8.9 years; *P*=.13) but had lower BMI (mean 25.4, SD 4.1 kg/m^2 vs mean 25.8, SD 4.3 kg/m^2; *P*=.003). A greater proportion of goal-setting members were female (371/1587, 23.38% vs 2307/11,091, 20.80%; *P*=.02). The decline from Q1 to Q6 differed by goal-setting status (β=.20 on the log-odds scale; *P*<.001), indicating different longitudinal trajectories between groups. From Q1 to Q6, declines were 25.0 percentage points in goal-setting members (95% CI –25.9 to –24.0) and 28.2 percentage points in members who did not set goals (95% CI –28.8 to –27.7; Figure S4A in Multimedia Appendix 2). Declines in tobacco use instances were also observed among goal-setting and non-goal-setting members (Figure S4B in Multimedia Appendix 2).

Over One-Quarter of Participants Report Nonuse by Q6

Among participants contributing at least 3 weeks of data in both Q1 and Q6, slightly over a quarter (1404/4975, 28.22%) reported sustained nonuse by the end of follow-up, defined as zero tobacco use days during Q6. To assess potential attrition bias, baseline Q1 characteristics (tobacco use, logging frequency, sex, age, BMI, RHR, HRV, RR, and sleep duration) were compared between participants retained through Q6 and those lost to follow-up. Effect sizes were consistent with

XSL•FO
RenderX

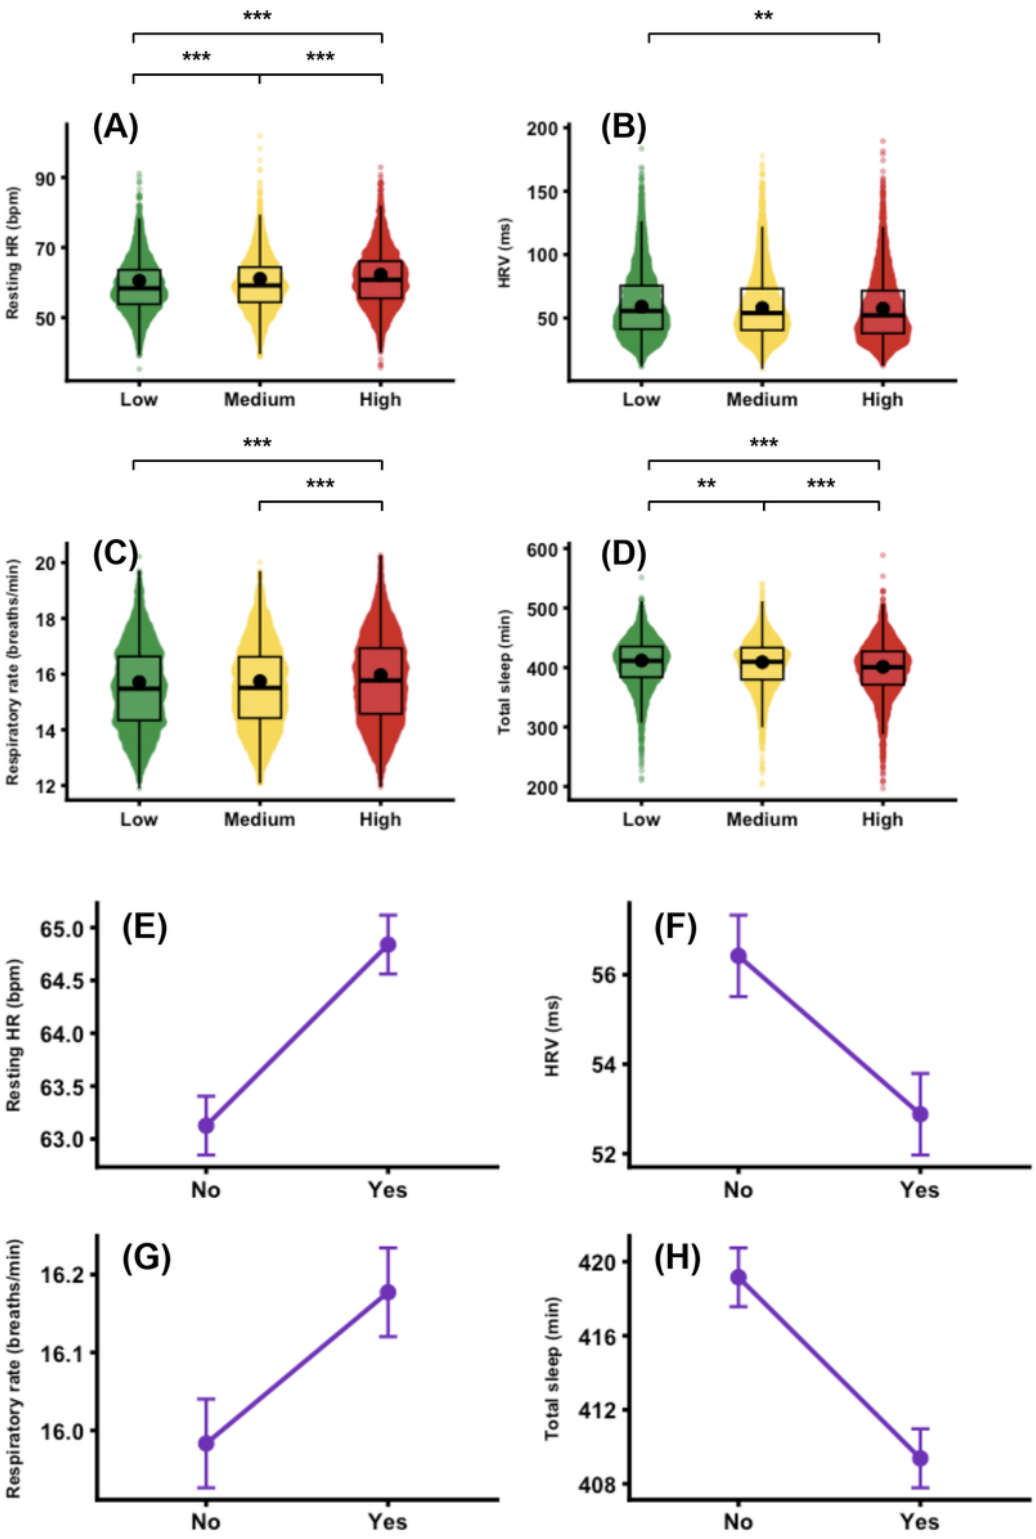
trivial-to-small differences (Cohen *d* range=0.02-0.22; Table S5 in Multimedia Appendix 2) [16].

The prevalence of sustained nonuse was similar by biological sex, occurring in 270 of 981 (27.5%) females and 1134 of 3994 (28.4%) males. However, participants in the lowest tertile of tobacco use probability exhibited the highest prevalence of self-reported nonuse (658/1552, 42.4%), followed by the medium- (386/1712, 22.5%) and high-use tertiles (360/1711, 21%).

In a sensitivity analysis restricted to participants with complete daily tobacco use reporting across all 12 weeks of both Q1 and Q6, the prevalence of sustained nonuse was similar (408/1623, 25.1%).

Logging Engagement Is Associated With Larger Reductions in Tobacco Use

In a complementary engagement analysis, we examined whether the proportion of days with completed tobacco logging was associated with a percentage-point change in tobacco use from Q1 to Q6. Heavier baseline (Q1) tobacco users had higher logging engagement (β=15.0; 95% CI 12.0-18.0). After adjustment for baseline tobacco use, total observed study days, age, biological sex, and BMI, logging engagement was independently associated with larger reductions in tobacco use (Figure S5 in Multimedia Appendix 2); each 10-percentage-point increase in engagement corresponded to a 0.92-percentage-point greater decline from Q1 to Q6 (95% CI –1.58 to –0.26).



Higher Tobacco Use Is Associated With Higher RHR, Lower HRV, Higher RR, and Shorter Sleep

In models that decomposed tobacco use into between- and within-person components, tobacco use was consistently associated with worse biometric and sleep measures. At the between-person level (Figure S6 in Multimedia Appendix 2), continuous models indicated that higher tobacco use was associated with increased RHR (0.22 beats/minute per 10 percentage-point increase in tobacco use days; 95% CI 0.18-0.26), reduced HRV (–0.19 ms per 10 percentage-point increase in tobacco use days; 95% CI –0.31 to –0.07), increased RR (0.03 breaths/minute per 10 percentage-point increase in tobacco use days; 95% CI 0.03-0.04), and reduced total sleep duration (–1.39 minutes per 10 percentage-point increase in tobacco use days; 95% CI –1.60 to –1.18). Consistent with these continuous associations, categorical models comparing tobacco use tertiles demonstrated significant differences in biometric and sleep measures (Figure 5A-D). Relative to the low-use tertile, individuals in the high-use tertile exhibited a 1.75 beats/minute higher RHR (95% CI 1.43-2.06, *P*<.001), a 1.58 ms lower HRV (95% CI –2.59 to –0.58, *P*=.006), a 0.25 breaths/minute higher RR (95% CI 0.19-0.31, *P*<.001), and a 10.55-minute shorter total sleep duration (95% CI –12.28 to –8.81, *P*<.001).

Within individuals, days with reported tobacco use were associated with acute adverse changes in overnight physiology and sleep measures compared with tobacco-free days (Figure 5E-H). On nights following tobacco use days, RHR was 1.71 beats/minute higher (95% CI 1.70-1.73), HRV was 3.54 ms lower (95% CI –3.59 to –3.49), RR was 0.19 breaths/minute higher (95% CI 0.19-0.20), and total sleep duration was 9.78 minutes shorter (95% CI –10.08 to –9.49) relative to nonuse days (*P*s<.001). Exploratory analyses suggested that these reductions in sleep duration were largely accompanied by later sleep onset, with tobacco use days associated with a 13.5-minute later bedtime (95% CI 13.0-14.0) but only a modest increase in the percentage of time in bed spent awake (0.20%; 95% CI 0.19-0.22).

RenderX

Figure 5. Associations of tobacco use with physiological outcomes. (A-D) Between-person associations of tobacco use frequency with physiological outcomes, stratified by overall tobacco use tertile. (E-H) Within-person associations of tobacco use on a given day with concurrent physiological outcomes. Outcomes included resting heart rate (HR; beats/minute), heart rate variability (HRV; ms), respiratory rate (breaths/minute), and total sleep duration (minutes), each modeled separately using linear mixed-effects models with a random intercept for participant and fixed effects for tobacco variables, biological sex, age at activation, BMI, season, and weekday versus weekend. In panels A-D, individual data points (quasi-random jitter) represent each participant's mean outcome value and are colored by tobacco use tertile: low (green), medium (yellow), and high (red). Boxplots summarize the distribution within each tertile. Black points with error bars represent estimated marginal means and 95% CIs; pairwise comparisons were adjusted using the Tukey method. In panels E-H, points represent model-based estimates of population-average outcome values for days without tobacco use (no) and days with tobacco use (yes), with continuous covariates held at their sample means and categorical covariates at their modal values. Error bars indicate 95% CIs. pp: percentage point. ***P*<.01, ****P*<.001.

RenderX

Reductions in Tobacco Use Are Associated With Favorable Changes in Biometrics and Sleep

Reductions in tobacco use between Q1 and Q6 were associated with directionally favorable changes in biometric and sleep measures. In continuous models (Figure S7 in Multimedia Appendix 2), reductions in tobacco use were associated with lower RHR, higher HRV, lower RR, and longer sleep duration. Categorical models reinforced these findings. For RHR (Figure 6A), participants with large decreases in tobacco use demonstrated a 0.25 beats/minute decrease (95% CI –0.46 to –0.04), which differed significantly from the changes observed among those with small (0.38 beats/minute; 95% CI 0.11-0.66, *P*=.001) or large increases (0.58 beats/minute; 95% CI 0.27-0.89, *P*<.001) in tobacco use. For HRV (Figure 6B), participants with large increases in tobacco use experienced HRV reductions of 1.57 ms (95% CI –2.46 to –0.68) that differed from the HRV changes observed among participants with small decreases in tobacco use (0.09 ms; 95% CI –0.54 to 0.73, between-group *P*=.01).

Regarding RR (Figure 6C), participants with large decreases in tobacco use demonstrated a 0.14 breaths/minute reduction (95% CI –0.16 to –0.11), which was significantly greater in magnitude than the reductions observed in all other groups (*P*<.001 vs the large-increase, small-increase, and no-change groups; *P*=.002 vs the small-decrease group). Total sleep duration increased across all groups (Figure 6D), but larger increases were observed among participants with large reductions in tobacco use (12.5 minutes; 95% CI 10.5-14.5) than among those with large increases in tobacco use (7.00 minutes; 95% CI 4.07-9.92; between-group *P*=.02). To investigate trajectories over time, visualizations of quarter-by-quarter tobacco-change-group interactions for each outcome were also constructed (Figure S8 in Multimedia Appendix 2).

Figure 6. Association between change in tobacco use frequency and change in physiological outcomes from Q1 to Q6. Model-based estimated marginal means (points) and 95% CIs (error bars) are shown for changes in each outcome across 5 categories of tobacco use change: large decrease (≤−25 percentage points [pp]), small decrease (−25 to −5 pp), no change (−5 to +5 pp), small increase (+5 to +25 pp), and large increase (≥+25 pp). Dashed horizontal lines indicate no change. Outcomes include resting heart rate (beats/minute; A), heart rate variability (ms; B), respiratory rate (breaths/minute; C), and total sleep duration (minute; D). Each outcome was modeled separately. Models included baseline tobacco use frequency, baseline outcome value, age, biological sex, BMI, and season as covariates. Pairwise comparisons between tobacco-use change categories were adjusted using the Tukey method.

Discussion

Principal Findings

In this 72-week study of more than 12,000 wearable device adopters, we examined longitudinal trajectories of tobacco use and their associations with cardiopulmonary and sleep-related biomarkers. Two principal findings emerged. First, daily tobacco use probability and total use instances declined over time at the population level, and more than one-quarter of participants who reported tobacco use at baseline achieved sustained nonuse by the end of follow-up. Second, tobacco use was consistently

associated with less favorable cardiopulmonary and sleep-related biomarkers at both the acute, within-person level (ie, days of use vs nonuse) and the habitual, between-person level (differences in overall use patterns). Importantly, reductions in tobacco use over time were accompanied by directionally favorable shifts in RHR, RR, and sleep duration.

Across the 72-week observation period, tobacco use probability declined substantially at the population level, with reductions robust to multiple sensitivity analyses, including IPCW and restriction to complete reporting. Prior wearable-based approaches to tobacco reduction have focused on real-time detection of smoking behavior using event-triggered feedback [17], with a recent 8-week randomized controlled trial reporting a reduction of 10 cigarettes per day and 11% of participants achieving 7-day biochemically confirmed abstinence [18]. By contrast, our study did not involve real-time tobacco use detection. Instead, participants engaged in active self-monitoring through daily tobacco use entries, a behavior independently shown to promote reductions in tobacco use [19], alongside continuous passive feedback on physiological responses to use. Such feedback on sleep and recovery may surface discrepancies between an individual's physiological state and desired state, consistent with a self-regulation framework; however, this study cannot establish whether, or to what extent, these elements contributed to behavior change. Furthermore, over a substantially longer follow-up period, we observed a reduction of approximately 3 tobacco use instances per week and a substantial proportion of participants achieving sustained nonuse (1404/4975, 28.22%), although fundamental differences in study design, outcome definitions, and follow-up duration preclude direct comparison. Nonetheless, these findings are consistent with the possibility that physiological self-monitoring may complement existing pathways to tobacco reduction. Future work evaluating the combination of real-time use detection and continuous physiological feedback is warranted.

Although declines in tobacco use were detected in all demographic subgroups, they were greater in females than in males, and middle-aged adults showed greater relative reductions than younger and older adults. Women and younger adults are more likely to enroll in digital tobacco cessation programs [20], yet women have historically demonstrated lower quit rates than men despite greater tobacco-related disease risk [21,22]. The reasons for sex differences remain unclear but do not appear to be fully explained by demographic, socioeconomic, or addiction-related factors [23], making the greater relative decline among females in this study notable. Although our observational design and modest number of female participants limit mechanistic interpretation, one plausible contributor is that women's smoking behavior is more strongly reinforced by nonnicotine, behavioral, and sensory cues than men's [24], such that behavioral feedback environments like the one studied here may be disproportionately associated with reductions in this group. Regarding age, it has been posited that differences in digital health engagement may contribute to differences in intervention efficacy. However, while younger adults are generally more likely to use technology, older adults are increasingly adopting digital health–related tools [25], with some evidence suggesting comparable outcomes across age groups [26]. Rather, we observed the greatest relative declines in tobacco use among middle-aged adults, in line with prior evidence from a systematic review and meta-analysis that used a cruder framework comparing individuals aged <40 and ≥40 years [11]. The factors driving greater reductions specifically among middle-aged adults represent an important area for future inquiry.

Declines in tobacco use were most pronounced among participants with the highest baseline use, whereas those in the low-use tertile showed modest increases over time. This pattern may reflect greater motivation for reduction among heavier users and is consistent with pharmacotherapy trials showing larger relative treatment effects among individuals with higher baseline nicotine dependence [27]. However, these observations should be interpreted cautiously, given the potential for regression to the mean [28].

A counterintuitive finding was that members who did not set tobacco-related goals exhibited greater relative reductions in tobacco use than those who did, which contrasts with the broader behavior change literature on goal setting. Notably, a similar pattern was observed in our recent companion analysis of alcohol use trajectories among WHOOP members [7]. Although the mechanisms underlying this finding cannot be resolved by our observational design, several nonmutually exclusive explanations warrant consideration. First, goal-setting members had a substantially higher baseline tobacco use probability, which may reflect greater nicotine dependence or longer use histories that could render reductions more difficult to achieve (ie, the hardening hypothesis) [29]. Second, members may self-select into goal setting precisely because they anticipate difficulty reducing use, such that group differences may reflect underlying addiction severity rather than an effect of goal setting, per se. Third, our binary indicator of goal setting captured any goal set at any point during the 72-week observation window. As goals could be set, modified, or abandoned over time, treating goal setting as a time-invariant exposure may introduce time-related bias. We accordingly interpret this exploratory finding as hypothesis-generating and suggest that future work examine goal type, timing, and persistence as time-varying exposures.

Participants with larger reductions in tobacco use exhibited directionally favorable changes in cardiopulmonary and sleep-related biomarkers, consistent with known acute and chronic physiological effects of tobacco exposure. Acute tobacco exposure reduces vagal-cardiac activity [30,31], reflected by increased RHR and reduced HRV, and nicotine exposure disrupts central nervous system regulation of sleep [32]. Meanwhile, real-world monitoring studies have shown lower RHR during periods of smoking abstinence [33]. These findings align with our within-person results, in which day-to-day tobacco use was associated with unfavorable changes in cardiopulmonary indices and shorter sleep duration. Notably, while associations between tobacco use reductions and population-level favorable shifts in cardiopulmonary and sleep-related measures were modest, changes were graded according to the degree of tobacco reduction. This dose-response pattern supports the interpretation that the observed associations are biologically meaningful rather than statistical artifacts of a

XSL•FO
RenderX

large sample. Moreover, because tobacco use is a chronic, repeated exposure, modest differences may compound over time and yield clinically relevant cumulative effects, particularly given that even small increases in RHR have been linked to elevated cardiovascular and all-cause mortality in large epidemiological cohorts [34].

At the between-person level, habitual tobacco use has been associated with higher RHR, lower HRV, and poorer sleep outcomes, with evidence of dose-response associations based on use frequency and intensity [35-37]. Consistent with these cross-sectional associations, we observed that reductions in tobacco use were associated with modest but statistically significant improvements in RHR, RR, and sleep duration. The relationship between tobacco use and HRV was more nuanced. Participants with large increases in tobacco use exhibited significant HRV reductions relative to those with small decreases in use, but HRV did not significantly improve among participants who reduced their tobacco use. Prior cessation studies suggest that HRV improvements may occur transiently following smoking cessation, peaking within the first week and attenuating thereafter [38]. Longer-term autonomic adaptations may also be influenced by concurrent metabolic changes following cessation, such as weight gain and reductions in insulin sensitivity that have been reported after tobacco cessation [39], which could counteract sustained HRV improvements. These findings suggest that cardiac autonomic function may follow a different temporal trajectory than other cardiopulmonary and sleep-related measures following reductions in tobacco use.

Implications

Our study has several potential implications for the broader mobile health (mHealth) community. First, this study highlights how wearables can combine data from free-living populations with long observation windows, complementing work conducted in more controlled environments. Second, these findings suggest that further investigation of the combined effects of continuous health measurement and behavioral logging in tobacco cessation programs may be particularly valuable. Third, the association between logging engagement and reductions in tobacco use suggests that future evaluations may benefit from including logging engagement as a covariate. Fourth, to support broader generalizability, it will be important to replicate these findings outside of a single commercial environment.

Limitations

Several limitations should be considered when interpreting these findings. First, tobacco use was self-reported and not biochemically verified, raising the possibility of recall error, underreporting, and social desirability bias, the degree of which cannot be quantified from the available data. However, the graded dose-response pattern between self-reported tobacco reduction and physiological change, with the largest reported reductions corresponding to the greatest favorable shifts in RHR, RR, and sleep duration, provides objective corroboration that these self-reports reflect meaningful behavior change. Second, participants were subscription-based wearable users and may have been more health conscious or had greater financial resources than the general population. The additional requirement for sustained reporting engagement (≥8 weeks) may have further enriched the sample with more motivated individuals, limiting generalizability. Relatedly, we lacked information on participants' tobacco use histories and concurrent use of cessation supports such as nicotine replacement therapy, pharmacotherapy, or behavioral counseling, any of which may have contributed to the observed reductions independent of the wearable platform. Third, tobacco exposure was assessed as daily use probability and the number of weekly use instances, without the ability to distinguish among tobacco products (eg, cigarettes, cigars, chewing tobacco), which may have heterogeneous physiological effects. Fourth, we were unable to account for a range of co-occurring behavioral and health factors that may independently influence cardiopulmonary physiology and sleep, including alcohol intake, caffeine consumption, physical activity, acute illness, medication use, and psychological stress. Fifth, without a control group, observed changes cannot be attributed causally to wearable adoption or self-monitoring and may reflect broader secular trends [40]. Although the 72-week follow-up represents a relatively long observation period compared with prior digital health studies, longer durations will be needed to evaluate the persistence of observed changes. Additionally, outcomes were limited to wearable-derived measures of RHR, HRV, RR, and sleep; future studies incorporating clinical end points such as blood pressure, body weight, or blood biomarkers would provide greater insight into the health implications of tobacco reduction. Finally, the study was conducted within a single wearable ecosystem (WHOOP), and several authors hold financial interests in the company. While analytic and editorial decisions were firewalled from commercial functions (see the "Conflicts of Interest" section), readers should consider this context when interpreting the findings. Nonetheless, these limitations are offset by several strengths, including the large sample size, real-world setting, extended follow-up, and high-frequency longitudinal assessment of tobacco use alongside continuous physiological monitoring.

Conclusions

In this 72-week observational study of more than 12,000 wearable device users, self-reported tobacco use declined substantially over time, with greater reductions among females, middle-aged adults, and individuals with medium-to-high baseline use. More than one-quarter of baseline tobacco users with data available in Q6 reported sustained nonuse by the end of follow-up. Tobacco use was consistently associated with less favorable cardiopulmonary and sleep-related measures, and reductions in use were accompanied by modest but directionally favorable changes in RHR, RR, and sleep duration. Although these findings cannot establish causality, they suggest that sustained reductions in tobacco use co-occur with favorable shifts in objective physiological measures over time. However, the observed physiological changes may also reflect broader lifestyle or health changes. Together, these results highlight the potential relevance of wearable technologies and digital health platforms as settings in which tobacco use reductions and associated physiological differences are observed.

Abstract

Background: Although machine learning has increasingly been used to predict mental health symptoms and maladaptive behaviors, real-world prediction of addiction-related risk remains limited. Emotional and temperamental vulnerabilities are established correlates of alcohol-related problems, yet few studies have integrated these factors with wearable-derived biosignals in alcohol-risk prediction models.

Objective: This study evaluated whether machine learning models could predict weekly high-risk drinking episodes among young adults with elevated alcohol-use risk by integrating wearable-derived health data with baseline emotional and personality vulnerability indicators.

Methods: In this prospective observational study, adults in their 20s completed weekly self-report surveys and wore Fitbit devices for 4 weeks. Features from week *t* were used to predict the Alcohol Use Disorders Identification Test-Korean version (AUDIT-K)–based high-risk drinking label at week *t*+1. Positive labels were defined using AUDIT-K high-risk drinking cutoffs, with scores of ≥20 for men and ≥10 for women. Extreme gradient boosting (XGBoost) and random forest models were evaluated across self-report-only, wearable-only, and integrated feature sets using 5-fold participant-level grouped cross-validation.

Results: A total of 206 participants contributed 620 week-level observations, of which 85 (13.7%) were labeled as positive high-risk drinking episodes. In participant-level grouped cross-validation, the integrated random forest model showed the most favorable sensitivity-oriented performance, with a mean accuracy of 0.617 (SD 0.078), recall/sensitivity of 0.653 (SD 0.144), area under the receiver operating characteristic curve (ROC AUC) of 0.681 (SD 0.079), and area under the precision-recall curve (PR AUC) of 0.255 (SD 0.090). The integrated XGBoost model achieved an accuracy of 0.670 (SD 0.089), recall/sensitivity of 0.399 (SD 0.174), ROC AUC of 0.651 (SD 0.089), and PR AUC of 0.228 (SD 0.074). Shapley additive explanations analyses indicated that both baseline vulnerability indicators and wearable-derived weekly summaries contributed to model predictions.

Conclusions: Integrating baseline emotional and personality vulnerability indicators with wearable-derived weekly health signals may provide useful information for week-ahead prediction of high-risk drinking episodes. These findings provide preliminary support for wearable-assisted alcohol-risk stratification, although the modest positive predictive performance indicates

XSL•FO
RenderX

that external validation and more proximal within-person measures are needed before real-world early-warning or just-in-time adaptive intervention applications.

Introduction

Background

According to the 2021 National Mental Health Survey conducted by the Ministry of Health and Welfare, the 12-month prevalence of alcohol use disorder among Korean adults was 2.6%, yet only 2.6% of those individuals reported receiving any treatment during the past year [1]. In addition, data from the Korea Community Health Survey [2] showed that monthly alcohol consumption increased from 53.7% in 2021 to 58.0% in 2023, a rise of 4.3 percentage points. The prevalence of high-risk drinking also increased from 11.0% in 2021 to 13.2% in 2023. Rising rates of alcohol use and high-risk drinking heighten the likelihood of early alcohol misuse and chronic alcohol dependence, underscoring an urgent need for targeted public-health strategies.

The COVID-19 pandemic further exacerbated alcohol-related problems. According to the 2020 Alcohol Industry Information Survey [3], the incidence of home drinking (72.2%) and drinking alone (74.9%) increased substantially. A twin study of adults also indicated that pandemic-related social restrictions increased stress and anxiety, which in turn led to greater alcohol consumption as a coping mechanism [4]. Collectively, these findings, combined with the limited accessibility of in-person treatment during the pandemic, have intensified the emphasis on digital interventions as an alternative means of addressing alcohol-related problems [5].

Research efforts have increasingly focused on addressing alcohol-related problems by leveraging widely accessible technologies such as smartphones and wearable devices, particularly in response to low treatment use, limited-service accessibility, and poor treatment awareness among individuals with alcohol problems [6-8]. Wearable technologies offer notable advantages by continuously monitoring individuals' behaviors and physiological states in real time, enabling timely and context-sensitive interventions [9]. Moreover, wearing such devices can enhance users' sense of empowerment, motivation, and accountability [6], suggesting that wearable-supported approaches may contribute positively to reducing alcohol use and improving outcomes among individuals at risk.

A growing body of research has attempted to predict alcohol-related problems at an early stage. One representative line of work uses smartphone sensors and machine learning to detect or forecast drinking and binge-drinking episodes among young adults. Prior studies have demonstrated the feasibility of classifying and predicting high-risk drinking using passively collected indicators, such as accelerometer data, call logs, and digital device use patterns [10]. More recent work has combined extreme gradient boosting (XGBoost)–based prediction models with artificial intelligence (AI) to anticipate same-day binge drinking 1 to 6 hours in advance, with the aim of enabling just-in-time adaptive interventions (JITAIs) [11]. Early studies further established the technical validity of detecting weekend nighttime drinking or heavy drinking using smartphone sensors with high accuracy [12].

In parallel, digital marker–based screening approaches have emerged, including models that estimate alcohol risk from Instagram images and text using neural network analysis [13]. In the neuroimaging domain, multimodal classifiers integrating structural, task-based, and resting-state connectivity data have demonstrated significant accuracy in distinguishing individuals with alcohol dependence [14]. Similarly, a model combining default mode network functional connectivity, neuropsychological indicators, and impulsivity features using random forest algorithms has been reported [15]. Deep-learning classification using electroencephalography signals has also shown high accuracy even with a limited number of channels and small sample sizes, highlighting the promise of noninvasive physiological markers [16].

Taken together, research across digital sensing, neuroimaging, physiological signals, and behavioral data demonstrates a growing potential for machine learning–based early detection and prediction of alcohol-related behaviors. These approaches collectively aim to balance measurement burden, real-time monitoring capability, and generalizability, thereby advancing the development of lightweight and scalable predictive models for use in real-world settings.

Despite their well-established relevance, emotional problems and personality vulnerabilities have been insufficiently explored in AI and machine learning research on alcohol use. Systematic reviews and empirical studies consistently show that psychological factors such as depression [17,18], anxiety [17,19], and stress [20,21], as well as personality-related vulnerabilities including emotional instability [22], harm avoidance [22-25], and impulsivity [22,26,27], are among the most robust predictors of alcohol dependence and problematic drinking. Exploring whether these emotional and personality vulnerabilities interact with real-world physiological rhythms to predict high-risk drinking at an early stage represents a meaningful and necessary research avenue.

Despite the growing body of international research, machine learning studies that use smartphones or wearable devices to predict alcohol-related problems are virtually absent in South Korea. Although national statistics indicate rising prevalence and increasing rates of hazardous drinking, treatment use, and service accessibility remain critically low. Developing machine learning models capable of detecting early indicators of problematic drinking in individuals' daily lives, therefore,

XSL•FO
RenderX

represents a highly significant public-health priority. Accordingly, this study aims to develop a predictive model for high-risk drinking episodes by passively and unobtrusively collecting real-world biodata through wearable devices and integrating these signals with individuals' emotional and personality vulnerability profiles. This approach seeks to estimate the onset of high-risk alcohol use in advance, enabling timely and personalized preventive intervention.

Objectives

This study aims to develop machine learning algorithms capable of predicting the risk of emerging alcohol-related problems among high-risk drinkers using easily accessible tools such as smartphones and wearable devices. To achieve this goal, we collected real-time health data (eg, heart rate, activity, and sleep) via a wearable device and gathered self-reported emotional and personality vulnerability measures through a smartphone interface. We then compared the predictive performance of machine learning models trained on (1) self-report psychological data alone, (2) wearable-derived health data alone, and (3) an integrated feature set combining both.

This approach aligns with prior machine learning research demonstrating that predictive accuracy for mental health outcomes, such as emotional distress, stress responses, and depressive symptoms, improves when physiological sensing data and psychological-behavioral data are jointly modeled [28-30]. Accordingly, this study aimed to develop and evaluate machine learning models for week-ahead prediction of Alcohol Use Disorders Identification Test-Korean version (AUDIT-K)–defined high-risk drinking episodes by comparing self-report-only, wearable-only, and integrated feature sets.

Methods

Participants

Participants were recruited through Kiwisurvey, an online panel platform operated by Korea Research International, where an announcement for a mobile-based health behavior monitoring study was posted. Individuals who expressed interest and met the eligibility criteria were screened for inclusion. Eligible participants were Korean adults aged 19-29 years residing in the Seoul or Gyeonggi metropolitan areas, with no visual or hearing impairments. To maintain gender balance, a 1:1 sex allocation strategy was applied during recruitment. Additionally, to ensure sufficient representation of high-risk drinkers, at least 30% of the sample was required to meet the AUDIT-K threshold for hazardous drinking (≥10 for men and ≥6 for women). This recruitment criterion was distinct from the prediction outcome label, which was defined using the AUDIT-K high-risk drinking threshold.

Two offline orientation sessions were held on June 24 and July 1, 2023, and participants were asked to attend one of the sessions. During these sessions, researchers provided detailed instructions regarding study procedures, wearable device setup, and informed consent requirements. A total of 209 individuals provided written informed consent and were enrolled in the study. Of these, 206 participants completed the full 4-week monitoring period and were included in the final analyses. Two participants withdrew consent, and one was excluded due to missing data. Participants received an incentive equivalent to approximately US $100 upon completing the 4-week follow-up period.

Measures and Procedure

After providing written informed consent, participants received a baseline survey link via their personal smartphones and completed a series of self-report questionnaires. Baseline assessments included sociodemographic characteristics such as gender, age, education level, monthly personal allowance, and residential status. Participants also completed the AUDIT-K at baseline and once weekly for 4 consecutive weeks to assess alcohol-use risk.

The AUDIT-K is a validated screening instrument based on the *International Classification of Diseases, Tenth Revision* diagnostic criteria that assesses alcohol use disorder risk and associated drinking problems. The Korean version consists of 10 items measuring drinking frequency and quantity, symptoms of dependence, and alcohol-related problems [31]. Validation studies have established AUDIT-K cutoff scores of ≥10 for men and ≥6 for women to classify hazardous drinking and ≥20 for men and ≥10 for women to classify high-risk drinking. In this study, the hazardous drinking cutoff was used only for recruitment enrichment, whereas the high-risk drinking cutoff was used to define the binary prediction outcome. The measure demonstrated excellent test-retest reliability in prior validation research (r=0.929). In this study, internal consistency at baseline was acceptable (Cronbach α=0.794).

Baseline and week-4 surveys included the Patient Health Questionnaire-9 (PHQ-9), the Generalized Anxiety Disorder scale (GAD-7), and the Perceived Stress Scale-10 (PSS-10). The PHQ-9 demonstrated excellent internal consistency at the time of development (Cronbach α=0.89) [32]. A Korean validation study [33] recommended a cutoff score of 9, reporting strong reliability (Cronbach α=0.95); in this study, internal consistency was acceptable (Cronbach α=0.845). The GAD-7 similarly showed high reliability in its original development (Cronbach α=0.92) [34]. The Korean validated version [35] also demonstrated strong internal consistency (Cronbach α=0.92), and reliability in this sample was high (Cronbach α=0.906). Both the PHQ-9 and GAD-7 assess subjective symptoms experienced over the past 2 weeks using a Likert scale ranging from 0 ("not at all") to 3 ("nearly every day"). Higher total scores indicate greater severity of depressive or anxiety symptoms, respectively.

We used the Korean validated version of the scale, which measures the degree to which individuals perceive their lives as stressful and comprises 2 factors, negative perception and positive perception, rated on a 5-point Likert scale [36]. Higher total scores indicate greater perceived stress, with possible scores ranging from 0 to 40. Established interpretive ranges categorize scores of 14-16 as mild stress, 17-18 as moderate stress, and ≥19 as severe stress. The original PSS-10 demonstrated strong internal consistency (Cronbach α=0.84-0.86), and reliability in this study was also high (Cronbach α=0.815).

XSL•FO
RenderX

Personality vulnerabilities were assessed using the Personality Vulnerability Scale, a measure developed by the Korean Psychological Association [37] based on transdiagnostic approaches. The scale was designed to identify and screen for dispositional psychological risk factors, including cognitive, emotional, and behavioral processes, that interact with stressful environments to trigger or maintain various mental health problems. The original instrument consists of 58 items rated on a 4-point Likert scale (0="not at all" to 3="very much"), organized into 3 overarching domains (emotional and impulse regulation, information processing, and interpersonal/social functioning) and 8 subcomponents.

For the purposes of this study, we extracted 3 subscales known to be closely associated with risky alcohol use: emotional instability, impulsivity, and harm avoidance. Internal consistency at baseline was high for all subscales (Cronbach α=0.891 for emotional instability, 0.808 for impulsivity, and 0.870 for harm avoidance). Reliability in the current dataset also demonstrated excellent internal consistency (Cronbach α=0.870, 0.759, and 0.851, respectively).

All questionnaire data, including baseline and follow-up assessments, were collected via a smartphone-accessible web-based survey platform. Physiological and behavioral data—such as sleep, heart rate, and step count—were passively and continuously recorded in real time using a wearable device (Fitbit Charge 5; Fitbit Inc).

Statistical Analysis

Supervised classification models were applied to predict a binary outcome variable aggregated at the weekly level. The dependent variable, weekly high-risk drinking episode, was defined using the AUDIT-K high-risk drinking cutoffs, with positive cases coded as ≥20 for men and ≥10 for women. Predictor variables consisted of self-report measures (depression, anxiety, stress, and personality vulnerabilities) and wearable-derived features (summarized metrics of heart rate, activity, and sleep). Missing data were handled according to predefined rules. The full list of features included in the analysis is presented in Table 1.

For psychological predictors in the primary models, only baseline scores of emotional and personality vulnerability indicators were included. These included depression, anxiety, perceived stress, emotional instability, impulsivity, and harm avoidance, and were treated as baseline vulnerability indicators rather than time-varying weekly predictors. Accordingly, these variables were interpreted as between-person vulnerability indicators, whereas week-to-week variation in the prediction task was primarily captured by wearable-derived weekly summaries.

Preliminary exploratory analyses examined whether adding repeated weekly self-report symptom scores improved week-ahead prediction. These weekly self-report scores referred to repeated PHQ-9, GAD-7, and PSS-10 assessments collected during follow-up and paired with the subsequent week's high-risk drinking label when available. These repeated weekly self-report models were treated as exploratory analyses and were not retained as the final primary modeling approach because they differed from the primary models in feature definition, available feature-label pairs, missing-data structure, and conceptual interpretation. In the primary models, self-report psychological and personality measures were conceptualized as baseline vulnerability indicators rather than rapidly changing weekly predictors. This decision was based on the theoretical nature and assessment time frames of the PHQ-9, GAD-7, PSS-10, and personality vulnerability measures, which are intended to capture symptom severity or relatively stable vulnerability profiles over specified recent periods rather than short-term week-to-week fluctuations. Therefore, the primary modeling framework fixed these self-report vulnerability indicators at baseline and focused on whether week-varying wearable-derived summaries could improve the prediction of the following week's high-risk drinking label. Because these exploratory models differed from the primary models in feature definition, available feature-label pairs, and missing-data structure, their performance estimates should not be directly compared with the primary model results reported in the Results section. Details are provided in Multimedia Appendix 1.

Wearable-derived features were constructed through a multistep aggregation process. Raw Fitbit-derived heart rate, activity, calorie expenditure, distance, and sleep data were first processed at their available sampling resolution and transformed into minute-level, hour-binned, daily, or sleep episode–level summaries, depending on the type of signal. These intermediate summaries were then aggregated to the weekly level to create the final model features. Thus, variables such as steps_mean and calories_mean represent weekly summaries of minute-level activity or energy-expenditure metrics, whereas variables such as avg_heart_rate_1hour and total_calories represent weekly summaries of hour-binned metrics. Sleep-related variables, such as total_sleep_duration_weekly_avg and sleep_fragmentation_weekly_avg, represent weekly averages of daily or sleep-episode-level sleep summaries**.** The resulting weekly wearable-derived features were paired with baseline psychological variables to predict the high-risk drinking label at week *t*+1 from characteristics observed during week *t*.

Table 1. Variables used in machine learning models for predicting weekly high-risk drinking episodes.

Category and variable	Description
Dependent variable	
y	Weekly alcohol episode (1=yes, 0=no; AUDIT-K[a]: male ≥20, female ≥10)
Psychometric data	
Emotional instability	Total score for emotional instability at baseline
Harm avoidance	Total score for harm avoidance at baseline
Impulsivity	Total score for impulsivity at baseline
PHQ[b]_mean	Mean score for depressive items at baseline
PHQ_std	Standard deviation for depressive items at baseline
GAD[c]_mean	Mean score for anxiety items at baseline
GAD_std	Standard deviation for anxiety items at baseline
PSS[d]_mean	Mean score for stress items at baseline
PSS_std	Standard deviation for stress items at baseline
Physiological data (wearable)	
heart_rate_mean	Weekly mean heart rate
heart_rate_std	Weekly standard deviation for heart rate
heart_rate_max	Weekly maximum heart rate
heart_rate_min	Weekly minimum heart rate
steps_mean	Weekly mean for minute-level step count
steps_std	Weekly standard deviation for minute-level step count
steps_max	Weekly maximum for minute-level step count
steps_min	Weekly minimum for minute-level step count
distance_mean	Weekly mean for minute-level distance (m)
distance_std	Weekly standard deviation for minute-level distance
distance_max	Weekly maximum for minute-level distance
distance_min	Weekly minimum for minute-level distance
calories_mean	Weekly mean for minute-level calories burned
calories_std	Weekly standard deviation for minute-level calories burned
calories_max	Weekly maximum for minute-level calories burned
calories_min	Weekly minimum for minute-level calories burned
avg_heart_rate_1hour	Weekly mean for hour-binned average heart rate
std_heart_rate_1hour	Weekly mean for hour-binned heart rate standard deviation
total_steps	Weekly mean for hour-binned total steps
total_distance	Weekly mean for hour-binned total distance
total_calories	Weekly mean for hour-binned total calories burned
active_minutes	Weekly mean for hour-binned minutes with active_rate ≥2
ratio_light_sleep	Weekly mean for hour-binned light-sleep ratio
ratio_sleep	Weekly mean for hour-binned total-sleep ratio
ratio_deep_sleep	Weekly mean for hour-binned deep-sleep ratio
movement_burst_count	Weekly count for ≥3-minute activity bursts within 10-minute windows
resting_duration	Weekly summary of the longest continuous resting duration with active_rate=1 (min)
step_zero_streak	Weekly summary for continuous inactivity duration with steps=0

XSL•FO
RenderX

Category and variable	Description
total_sleep_duration_weekly_avg	Weekly average for daily total sleep duration
sleep_fragmentation_weekly_avg	Weekly average number of daily sleep-stage transitions
max_hr_spike_weekly_avg	Weekly average number of ≥10 bpm heart-rate spikes per minute
hr_variability_window_weekly_avg	Weekly average for window-based heart rate variability (SD)
nighttime_hr_avg_weekly_avg	Weekly average for mean heart rate between 00:00 and 06:00
unexpected_activity_at_night_occurred	Weekly indicator of whether active_rate ≥3 occurred between 00:00 and 06:00
nocturnal_walking_occurred	Weekly indicator of whether steps or distance >0 occurred during sleep
resting_high_calorie_occurred	Weekly indicator of whether high calorie expenditure occurred during inactivity (steps=0 and active_rate=1)

[a]AUDIT-K: Alcohol Use Disorders Identification Test-Korean version.

[b]PHQ: Patient Health Questionnaire-9.

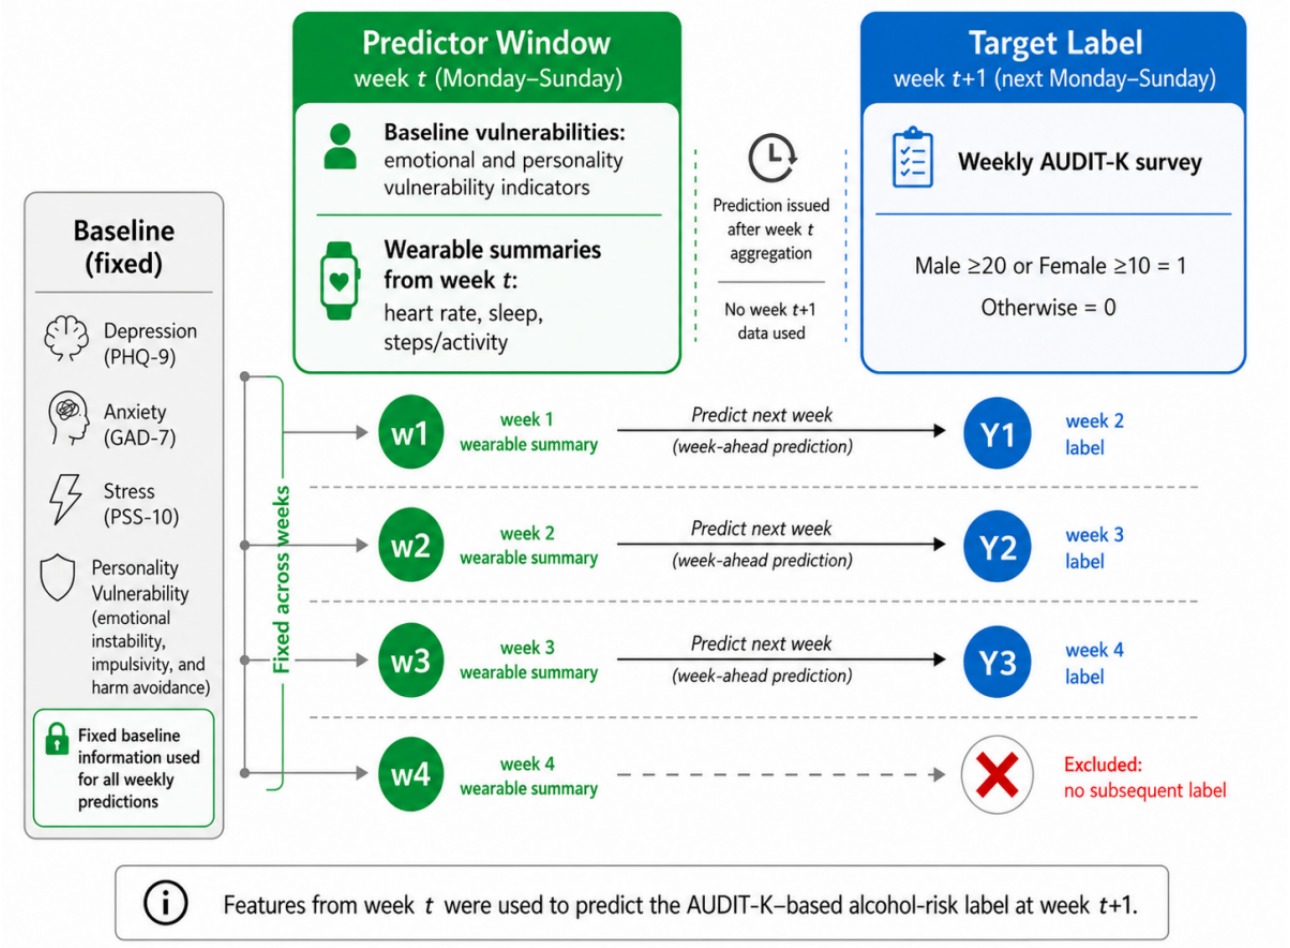
[c]GAD: Generalized Anxiety Disorder-7.

[d]PSS: Perceived Stress Scale-10.

To clarify temporal alignment, each participant's data were organized into Monday to Sunday calendar weeks. Wearable-derived signals collected during week *t* were aggregated only after the week *t* observation window was complete. Weekly survey responses were collected following each calendar week and were used to define the alcohol-risk label for that corresponding week. Prediction was conceptualized as occurring after week *t* feature aggregation but before week *t*+1 outcome information was available; therefore, no information from the target week was used to construct predictors for that target label. Figure 1 illustrates the temporal alignment used to construct week-ahead feature-label pairs. Model evaluation was conducted separately using participant-level grouped cross-validation. The analytical task was defined as a week-ahead binary classification problem in which features aggregated at week *t* were used to predict the positive label at week *t*+1. For each participant, week indices were chronologically ordered, and (t, t+1) feature-label pairs were generated only when the label for week *t*+1 was observed. Observations from the final week, for which no subsequent label existed, were excluded from model training and evaluation (Figure 1). Wearable signals and self-report indicators were summarized from daily raw data into weekly statistics, including means, SDs, quantiles, and proportional measures (eg, proportion of time spent in specific sleep stages). Temporal context variables, such as weekday/weekend indicators and the number of valid observation days per week, were also included in the feature set. Missing data were handled according to the nature and distribution of each variable. Weeks with insufficient within-week observations were excluded entirely, whereas simple imputation or model-tolerant missingness strategies were applied when appropriate. All scaling and imputation procedures were derived exclusively from statistics calculated within each training fold (eg, fold-specific mean and SD) to strictly prevent information leakage into validation folds.

Model comparisons were conducted across three feature configurations: (1) self-report features only, (2) wearable-derived health features only, and (3) an integrated feature set combining self-report and wearable-derived health data. Two supervised classifiers, XGBoost and random forest, were implemented. The primary model evaluation framework was a 5-fold participant-level stratified grouped cross-validation. Participant ID was used as the grouping variable, ensuring that all week-level observations from the same participant were assigned to the same fold and did not appear simultaneously in both the training and held-out folds. Label stratification was applied as far as possible to maintain a comparable distribution of positive high-risk drinking labels across folds. The cross-validation split was generated using a fixed random seed of 42, and fixed random seeds were also applied to stochastic model-training procedures to support reproducibility. This procedure was used to prevent subject-level information leakage arising from repeated weekly observations within individuals.

Within each cross-validation iteration, the held-out fold was used only for final performance estimation. All preprocessing steps, including missing-data handling, scaling where applicable, and any feature transformation, were fitted exclusively on the training portion of that fold and then applied to the held-out fold. Class imbalance was addressed within the training portion of each fold using algorithm-specific class weighting rather than oversampling or undersampling. For XGBoost, the positive-class weight was adjusted based on the ratio of negative to positive labels within the training portion of each fold. For random forest, balanced class weights were applied. No oversampling, undersampling, synthetic minority oversampling technique, or synthetic data generation was applied to the held-out fold. Hyperparameter tuning was conducted within the training portion of each fold using internal validation, and the held-out fold was not used for model selection or threshold determination. Details of the Optuna hyperparameter search spaces, number of trials, and key hyperparameter ranges are provided in Multimedia Appendix 2.



Because the intended use of the model was early detection of future high-risk drinking episodes, recall/sensitivity was prespecified as the primary performance metric. Threshold-dependent metrics were calculated using a sensitivity-oriented decision threshold of 0.20 to prioritize early detection while monitoring precision/positive predictive value (PPV). Precision/PPV, recall/sensitivity, negative predictive

XSL•FO
RenderX

value (NPV), and F_1-score were calculated at this operating point. Model discrimination was evaluated using the area under the receiver operating characteristic curve (ROC AUC) and the area under the precision-recall curve (PR AUC), which are threshold-independent metrics. Final performance estimates were reported as the mean and SD across the 5 participant-level grouped cross-validation folds. All analyses were conducted in Python using *scikit-learn*, *xgboost*, and *Optuna*.

To improve transparency and completeness of reporting, the Methods and Results sections were reviewed and revised with reference to the TRIPOD+AI (Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis Plus Artificial Intelligence) reporting guidance for prediction model studies using machine learning methods.

Ethical Considerations

All study procedures were conducted in accordance with the Declaration of Helsinki. The institutional review board of the College of Medicine, The Catholic University of Korea, approved this study (MC22OIDI0117). All participants attended an in-person orientation session, during which the study objectives and data collection procedures were fully explained, and written informed consent was obtained from all participants prior to enrollment.

To protect participant privacy and confidentiality, identifying information was stored separately from the research data. Online self-report data and wearable-derived biometric data were managed using study registration numbers after direct identifiers were removed. The linkage file connecting personal identifiers with study registration numbers was stored in encrypted form, and access was restricted to designated data-management personnel. Electronic files and computers were password-protected, and physical documents, including consent forms, were stored in double-locked storage at Korea Research International. Unauthorized access, viewing, or modification of the study data was not permitted under the study data management procedures.

Participants received a coffee voucher worth KRW 5000 (approximately US $3.24) after completing the orientation, consent forms, and baseline questionnaires. Participants who completed the study received KRW 100,000 (approximately US $64.71) as a single bank transfer. Consent for collecting bank account information for compensation payment was included in the informed consent form.

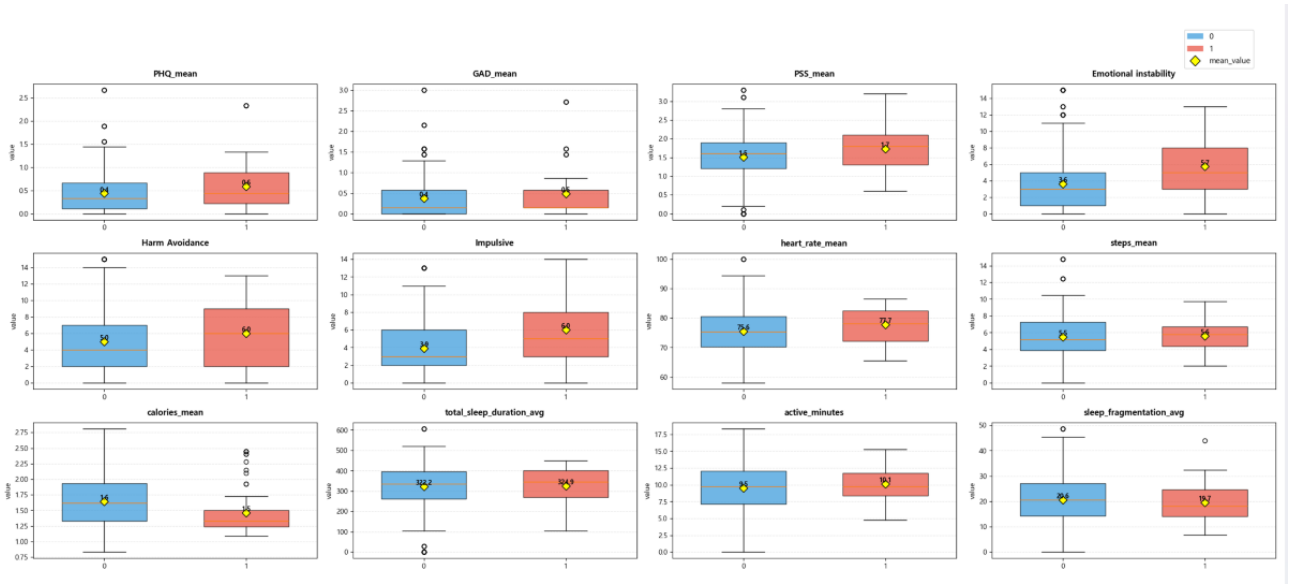
Results

Participant Characteristics

Table 2 summarizes the general characteristics of the 206 participants included in the analysis. The sample showed a balanced gender distribution, with 102 (49.5%) men and 104 (50.5%) women. Participants were primarily in their mid to late 20s: 129 (62.6%) individuals were aged 25-29 years, and 77 (37.4%) individuals were aged 19-24 years, with a mean age of 25.21 (SD 2.54) years. Regarding educational attainment, 118 (57.3%) participants had completed a university degree, 60 (29.1%) were currently enrolled as undergraduates, 7 (3.4%) were on a leave of absence, 12 (5.8%) held a graduate-level degree, and 9 (4.4%) had a high school education or below. Monthly personal allowance was ≤US $500 for 95 (46.1%) participants and US $501-US $1000 for 74 (35.9%) participants, with an average of US $783 (SD 558), assuming an approximate conversion rate of US $1=KRW 1000. In terms of living arrangements, 115 (55.8%) participants lived with their parents, 82 (39.8%) lived independently, 6 (2.9%) resided in dormitories, and 3 (1.5%) lived with relatives.

Table 2. General characteristics of participants (N=206).

Variable and category	Value
Gender, n (%)	
Male	102 (49.5)
Female	104 (50.5)
Age (years), n (%)	
19-24	77 (37.4)
25-29	129 (62.6)
Age (years), mean (SD)	25.21 (2.54)
Education level, n (%)	
High school or below	9 (4.4)
Undergraduate (enrolled)	60 (29.1)
Undergraduate (on leave)	7 (3.4)
Bachelor's degree	118 (57.3)
Graduate school or higher	12 (5.8)
Monthly personal allowance (US $)[a], n (%)	
≤500	95 (46.1)
501-1000	74 (35.9)
Monthly personal allowance (US $), mean (SD)	783 (558)
Housing type, n (%)	
Living independently	82 (39.8)
Parents' home	115 (55.8)
Dormitory	6 (2.9)
Relative's home	3 (1.5)



[a]Refers to the monthly allowance an individual uses for personal expenses (eg, transportation, eating out, and cultural activities). For convenience, US $1=KRW 1000 was used for conversion.

Figure 2 presents group comparisons between the nonepisode group (0) and the episode group (1) across psychological, personality, and wearable-derived physiological and behavioral indicators. The episode group showed higher levels of depressive symptoms (PHQ_mean), anxiety (GAD_mean), and perceived stress (PSS_mean), as well as higher scores on personality vulnerability traits, including emotional instability, harm avoidance, and impulsivity. These patterns suggest that individuals in the episode group were more emotionally vulnerable and exposed to greater negative affective states.

Clear differences were also observed in wearable-derived health metrics. The episode group exhibited a higher average heart rate (heart_rate_mean) but lower average daily steps (steps_mean) and calorie expenditure (calories_mean). Additionally, they demonstrated shorter total sleep duration (total_sleep_duration_avg) and greater sleep fragmentation (sleep_fragmentation_avg). Collectively, these findings indicate that the episode group experienced reduced behavioral stability, heightened physiological arousal, and disruptions in sleep-activity rhythms compared to the nonepisode group.

Data Overview

A total of 620 week-level observations were obtained from 206 participants across the 4-week monitoring period. Based on the AUDIT-K high-risk drinking thresholds (≥20 for men and ≥10 for women), 85 (13.7%) observations were labeled as positive high-risk drinking episodes, and 535 (86.3%) observations were labeled as negative episodes.

Model development and evaluation were conducted using 5-fold participant-level grouped cross-validation. All week-level observations from the same participant were kept within the same fold to avoid subject-level leakage. Therefore, model performance was estimated from held-out participants rather than from randomly split week-level observations. Within each fold, preprocessing, class-imbalance handling through algorithm-specific class weighting, hyperparameter tuning, and model fitting were performed using only the training portion, and the held-out fold was used exclusively for performance estimation. The overall modeling workflow is summarized in Figure 3. Accordingly, all primary performance estimates were derived from participant-level grouped cross-validation rather than from randomly split week-level observations.

Performance of High-Risk Drinking Episode Prediction Models

Table 3 summarizes model performance estimated using 5-fold participant-level grouped cross-validation. To prevent information leakage, all preprocessing procedures, class-imbalance correction, hyperparameter tuning, and model fitting were performed exclusively within the training portion of each fold; the held-out fold was used only for final performance estimation. Because the intended application was early detection of future high-risk drinking episodes, threshold-dependent metrics were calculated using a sensitivity-oriented decision threshold of 0.20, while ROC AUC and PR AUC were evaluated as threshold-independent discrimination metrics.

Across the evaluated models, the integrated random forest model showed the most favorable early-detection profile. This model achieved a mean accuracy of 0.617 (SD 0.078), precision/PPV of 0.209 (SD 0.069), recall/sensitivity of 0.653 (SD 0.144), NPV of 0.919 (SD 0.036), F_1-score of 0.315 (SD 0.097), ROC AUC of 0.681 (SD 0.079), and PR AUC of 0.255 (SD 0.090). The integrated XGBoost model showed higher accuracy but lower sensitivity, with a mean accuracy of 0.670 (SD 0.089), precision/PPV of 0.172 (SD 0.039), recall/sensitivity of 0.399 (SD 0.174), NPV of 0.880 (SD 0.059), F_1-score of 0.236 (SD 0.066), ROC AUC of 0.651 (SD 0.089), and PR AUC of 0.228 (SD 0.074).

For models trained on self-report features only, the XGBoost classifier achieved a mean accuracy of 0.396 (SD 0.225), precision/PPV of 0.128 (SD 0.044), recall/sensitivity of 0.630 (SD 0.356), NPV of 0.884 (SD 0.085), F_1-score of 0.203 (SD 0.076), ROC AUC of 0.603 (0.084), and PR AUC of 0.213 (0.023). The random forest classifier showed a mean accuracy of 0.491 (SD 0.057), precision/PPV of 0.150 (SD 0.044), recall/sensitivity of 0.607 (SD 0.221), NPV of 0.882 (SD 0.086), F_1-score of 0.234 (SD 0.061), ROC AUC of 0.569 (SD 0.137), and PR AUC of 0.226 (SD 0.080).

For wearable-derived health features only, the XGBoost model yielded a mean accuracy of 0.727 (SD 0.086), precision/PPV of 0.208 (SD 0.095), recall/sensitivity of 0.393 (SD 0.246), NPV of 0.888 (SD 0.069), F_1-score of 0.260 (SD 0.133), ROC AUC of 0.649 (SD 0.087), and PR AUC of 0.248 (SD 0.070). The random forest model achieved a mean accuracy of 0.601 (SD 0.056), precision/PPV of 0.185 (SD 0.061), recall/sensitivity of 0.581 (SD 0.147), NPV of 0.902 (SD 0.051), F_1-score of 0.278 (SD 0.086), ROC AUC of 0.610 (SD 0.076), and PR AUC of 0.264 (SD 0.107).

Overall, the integrated random forest model showed the highest recall/sensitivity and ROC AUC among the evaluated models, suggesting that combining baseline psychological vulnerability indicators with wearable-derived weekly summaries may improve sensitivity for detecting future high-risk drinking episodes. However, precision/PPV remained modest across models, indicating that the models should be interpreted as preliminary risk-stratification tools rather than stand-alone decision systems.

The confusion matrices and ROC curves for the integrated XGBoost and random forest models were generated from pooled out-of-fold predictions across participant-level grouped

Model Explainability Using Shapley Additive Explanations

We examined which features contributed most strongly to the performance of each machine learning model. Shapley additive explanations (SHAP) summary plots and bar plots visually illustrate the variables that contributed most to model predictions (Figures 6 and 7 and Table 4). Because SHAP values quantify feature contributions to model output rather than causal effects, the identified variables were interpreted as predictive correlates rather than physiological precursors or causal mechanisms.

[a]The table presents the top 15 features ranked by SHAP feature importance scores in the integrated models combining self-report and wearable-derived health features. SHAP feature importance scores were calculated as the average absolute SHAP values across observations for each feature and were used to rank the relative contribution of predictors within each model. SHAP values indicate relative feature contributions to model output and should be interpreted as predictive correlates rather than causal effects.

To interpret the integrated XGBoost model, we conducted SHAP analyses to assess feature importance and contribution patterns. Based on the SHAP summary plot and mean absolute SHAP values, the most influential features included mean calorie expenditure (calories_mean), impulsivity (Q66_11to15), emotional instability (Q66_1to5), active minutes, average heart rate per hour (avg_heart_rate_1hour), and mean heart rate (heart_rate_mean). These findings indicate that the integrated model relied on both baseline vulnerability indicators and wearable-derived weekly summaries when classifying next-week high-risk drinking labels.

Among baseline psychological indicators, impulsivity and emotional instability demonstrated prominent contributions to model predictions. Among wearable-derived features, calorie expenditure, active minutes, and heart-rate summaries

XSL•FO
RenderX

contributed prominently to the model output. This pattern suggests that baseline emotional and personality vulnerability indicators provided between-person risk information, whereas wearable-derived summaries contributed week-varying behavioral and physiological information. In the integrated XGBoost model, lower values of calorie expenditure tended to contribute positively to model output for high-risk classification, whereas higher values of impulsivity and emotional instability generally contributed toward higher predicted risk. These patterns should be interpreted as model-identified predictive correlates associated with the classification of subsequent high-risk drinking labels.

To interpret the integrated random forest model, we conducted SHAP analyses to identify the features that contributed most strongly to next-week predictions of high-risk drinking episodes. Based on the SHAP summary plot and rankings of mean absolute SHAP values, the most influential variables included impulsivity (Q66_11to15), total calories, maximum calories, minimum calories, active minutes, mean calories, emotional instability (Q66_1to5), maximum heart rate, mean heart rate, and average heart rate per hour.

The random forest model similarly showed that both baseline vulnerability indicators and wearable-derived activity, heart rate, sleep, or calorie-related summaries contributed to prediction outcomes. Among baseline psychological variables, impulsivity and emotional instability demonstrated consistent contributions. Among wearable-derived variables, calorie-related indices, active minutes, and heart rate indicators were prominent contributors. The integrated random forest model showed a particularly strong contribution of impulsivity, followed by calorie-related wearable features. These findings indicate that SHAP-identified features helped explain model classification patterns, but they do not establish causal pathways or temporally specific physiological mechanisms.

Because this was an observational sensing study, wearable-derived predictors may also reflect unmeasured contextual or behavioral factors, including physical activity routines, sleep debt, acute illness, academic or work schedules, weekend social activity, shift work, device wear time, and consumer-device estimation error. Therefore, SHAP-identified features should be interpreted as predictive correlates that require validation in future studies using more granular contextual, behavioral, and physiological data.

Discussion

Principal Findings

This study developed machine learning models that integrate psychological and personality vulnerability factors with wearable-derived physiological and behavioral signals to predict weekly high-risk drinking episodes among young adults. Several key findings emerged.

First, the integrated models combining biosignals and psychological-personality vulnerabilities showed a modest but meaningful early-detection profile under 5-fold participant-level grouped cross-validation compared with models using either feature set alone. The integrated XGBoost model achieved a mean accuracy of 0.670 (SD 0.089) and a mean ROC AUC of 0.651 (SD 0.089), while the integrated random forest model achieved a mean accuracy of 0.617 (SD 0.078) and a ROC AUC of 0.681 (SD 0.079). The corresponding PR AUC values were mean 0.228 (SD 0.074) for XGBoost and mean 0.255 (SD 0.090) for random forest. These cross-validated estimates suggest that the integrated models provided modest but useful week-ahead predictive information for high-risk drinking episodes under participant-level grouped validation. In particular, the integrated random forest model showed the most favorable sensitivity-oriented performance, with a mean recall/sensitivity of 0.653 (SD 0.144) and a mean NPV of 0.919 (SD 0.036). However, precision/PPV remained modest at a mean of 0.209 (SD 0.069), indicating that the model should be interpreted as a preliminary risk-stratification tool rather than a stand-alone decision system.

These findings are broadly consistent with previous machine learning and AI-based studies addressing alcohol dependence and substance-use risk. For example, a study detecting substance-use risk from Instagram images reported an ROC AUC of 0.65 [13], and a multimodal neuroimaging classifier for chronic alcohol dependence achieved an accuracy of 79.3% [14]. Research predicting high-risk drinking patterns among medical students reported an area under the curve of 0.738 [38]. Smartphone sensor–based studies forecasting heavy drinking showed a wider performance range, with accuracies from 94.3% to 96.6% [11,12]. However, direct comparison across studies should be made cautiously because prediction horizons, outcome definitions, data modalities, validation schemes, operating thresholds, and participant-level leakage controls differ substantially across studies.

In comparison, a distinctive strength of this study lies in its integration of behavioral biosignals with psychological and personality vulnerabilities that are theoretically and empirically central to alcohol-use problems. Rather than relying on a single modality or purely behavioral data, the present models incorporated emotional vulnerability, including depression, anxiety, and perceived stress, and personality traits such as emotional instability and impulsivity. This multimodal approach may improve week-ahead risk estimation by combining stable vulnerability profiles with week-varying physiological and behavioral information. The integrated model should therefore be interpreted as combining 2 distinct sources of predictive information: stable between-person vulnerability captured by baseline psychological and personality indicators, and week-varying behavioral and physiological information captured by wearable-derived summaries. Accordingly, the model's week-ahead performance does not necessarily imply that baseline psychological variables captured short-term within-person psychological change. Rather, these variables likely contributed to identifying individuals with higher underlying vulnerability, while wearable-derived weekly features provided the time-varying component of the prediction.

Examining the most influential predictors showed that both baseline vulnerability indicators and wearable-derived weekly summaries contributed to model prediction. In the integrated XGBoost model, the features with the highest mean absolute SHAP values included mean calorie expenditure, impulsivity,

XSL•FO
RenderX

emotional instability, active minutes, average heart rate per hour, and mean heart rate. In the integrated random forest model, the highest-ranking SHAP features included impulsivity, total calories, maximum calories, minimum calories, active minutes, mean calories, emotional instability, maximum heart rate, mean heart rate, and average heart rate per hour.

Across both integrated models, impulsivity and emotional instability emerged as prominent baseline vulnerability indicators, while calorie-related metrics, active minutes, and heart-rate summaries were consistently identified among the most influential wearable-derived features. This pattern suggests that the models combined relatively stable between-person vulnerability information with week-level behavioral and physiological summaries when estimating the likelihood of a subsequent high-risk drinking label. The convergence of feature rankings across the 2 algorithms also supports the relevance of integrating psychological vulnerability profiles with passive wearable signals for week-ahead alcohol-risk prediction. Although these SHAP-identified features helped explain the models' classification patterns, they should be interpreted as predictive correlates rather than causal mechanisms. Because this was an observational sensing study, activity-, calorie-, and heart rate–related features may also reflect broader contextual factors such as habitual physical activity, sleep debt, illness, academic or work schedules, weekend social activity, shift work, or device wear time. Future studies incorporating more granular contextual information and person-centered deviations from individual baselines will be needed to clarify which wearable-derived changes are most specific to alcohol-related risk.

These findings align with prior work using mobile sensor data, which demonstrated that increased physical movement—such as greater acceleration and travel distance—preceded binge-drinking episodes by 1-6 hours [11]. Other studies have similarly reported that fluctuations in activity levels serve as meaningful predictors of drinking behavior [10,12], supporting the relevance of activity-related digital signals as predictive features for drinking-related outcomes. Although this study focused on weekly episode prediction rather than immediate predrinking states, the finding that activity- and calorie-related wearable summaries contributed to model prediction is directionally consistent with previous work on sensor-based alcohol-risk prediction. However, these similarities should be interpreted cautiously because this study did not directly measure immediate predrinking states and cannot determine whether the observed wearable patterns reflected drinking-related processes or other contextual factors. Prior research has also shown that individuals who drink tend to be more physically active than nondrinkers [39], and population-based health surveillance data in Korea likewise indicate that among adults aged 20-39 years, higher levels of alcohol consumption are associated with greater physical activity [40].

A notable finding was that calorie-related variables contributed strongly to model predictions in both integrated models and differed between the high-risk episode and nonepisode groups. Unlike heart rate or step count, both of which largely reflect gross physical movement, calorie expenditure is a composite wearable-derived metric that may be influenced by sleep-wake rhythm, arousal level, metabolic factors, device estimation algorithms, and the intensity and quality of physical activity. However, this pattern should not be interpreted as evidence of altered metabolic efficiency or disrupted biological rhythms. Rather, it indicates that calorie-related wearable summaries were useful predictive features in this model. Although prior research has suggested that alcohol use may be associated with disruptions in biological rhythms [41], this observational sensing data cannot determine whether the observed calorie-related patterns reflected alcohol-related physiological processes or other contextual factors. Because calorie estimates from consumer wearables can be affected by activity type, device wear time, individual physiology, and algorithmic estimation error, this finding should be interpreted cautiously and validated in future studies using more granular contextual and physiological data.

Taken together, the findings suggest that integrating wearable-derived physiological signals with psychological and personality-based vulnerability factors may provide useful information for week-ahead prediction of high-risk drinking episodes. In particular, personality vulnerabilities such as impulsivity and emotional instability, together with activity-, calorie-, and heart rate–related wearable summaries, emerged as predictive correlates of subsequent high-risk drinking labels. These results provide preliminary support for risk-stratified digital monitoring approaches, while also indicating that this model is not yet sufficient as a stand-alone early-warning or intervention-triggering system. Future JITAI-oriented models may require more proximal within-person signals, such as ecological momentary assessment (EMA)–based affective states, individualized deviations from wearable baselines, and contextual data that can distinguish alcohol-related risk signals from broader daily-life variability.

From a translational perspective, these findings are best interpreted as supporting a preliminary risk-stratification approach rather than immediate deployment as a stand-alone early-warning system. A wearable-assisted prediction system of this kind could be most realistically implemented as part of a stepped-care workflow in which model-generated risk signals prompt low-burden self-monitoring feedback, brief motivational messages, or clinician review when elevated risk persists. In primary care, community mental health, university counseling, or addiction service settings, such a system could support clinicians, counselors, or care coordinators in identifying young adults who may benefit from closer monitoring or preventive intervention. This implementation pathway is consistent with evidence suggesting that practitioner-delivered alcohol interventions may have greater short-term effects than digitally delivered interventions alone, while digital interventions may still provide scalable benefits over time and at the population level [42]. Therefore, the model may be most useful when integrated into ongoing professional support or postintervention follow-up, where weekly risk estimates can help guide timely preventive feedback, brief intervention, or referral.

Even when predictive performance remains preliminary, low-burden digital risk feedback may have public health value if it helps individuals recognize periods of elevated vulnerability

XSL•FO
RenderX

and prepare preventive coping strategies before high-risk drinking occurs. This aligns with a precautionary public health perspective, in which early, proportionate, and low-risk preventive actions may be justified when potential harms are substantial, and the intervention burden is minimal [43]. However, responsible deployment would require higher and externally validated predictive performance, clear escalation pathways, user consent, transparent alert logic, and safeguards to prevent unnecessary alarm, stigma, or overintervention. In this regard, the model may be better suited to an institution- or service-mediated business to business to consumer–type model than to a stand-alone direct-to-consumer application [44]. In such a model, individuals would use the mobile app and wearable device in daily life, while health care providers, counseling services, public health agencies, university counseling centers, workplace mental health programs, or addiction care coordinators would provide oversight, interpret risk signals, and connect users to appropriate support when needed. In the South Korean context, this approach would also require careful attention to privacy, data minimization, secure storage, governance of sensitive behavioral and health data, regulatory classification, and clear rules regarding who is authorized to access and act on model-generated risk information.

Limitations

Despite the meaningful findings of this study, several limitations should be acknowledged. First, the sample consisted exclusively of young adults in their 20s, which constrains the generalizability of the results. High-risk drinking patterns are known to vary substantially across age groups, occupational contexts, and sociocultural environments; therefore, the predictive performance demonstrated in this cohort may not translate directly to older adults or clinical populations with more severe alcohol-related problems. Nevertheless, given the rising prevalence of problematic drinking among young adults in South Korea [1,2], early detection and intervention efforts targeting this age group carry important preventive value. Future studies should expand the model to a broader age range to evaluate its robustness across more diverse populations.

Second, this study developed prediction models using relatively short-term longitudinal data from 5 assessment time points over a 4-week follow-up period. As a result, the models were unable to capture long-term fluctuations in drinking behavior, seasonal or contextual influences, and broader temporal dynamics that may affect alcohol use risk. Future work should incorporate longer monitoring periods to more precisely characterize how changes in biosignal patterns interact with shifts in drinking risk over time. Although certain mental health conditions, such as mood or anxiety disorders, often show seasonal or cyclical patterns and therefore require extended longitudinal observation [28,30], such temporal regularity is not a defining feature of addictive behaviors. Indeed, prior studies have reported that using only 1-3 days of past smartphone sensor data was sufficient to enhance model performance for predicting drinking episodes [12]. From an implementation standpoint, accumulating excessively long digital histories may not be advantageous. In real-world mobile apps, storing and processing large volumes of behavioral and physiological data can impose substantial data usage burdens, reduce algorithmic efficiency, and negatively affect user adherence [45]. Thus, while long-term data collection can provide analytic benefits, it may conflict with the practical requirement for lightweight, low-burden, and scalable digital health solutions.

Third, psychological and personality vulnerability variables were measured only at baseline and were therefore modeled as time-invariant predictors. As a result, these variables likely captured between-person differences in underlying vulnerability rather than within-person psychological changes preceding a high-risk drinking episode. Although wearable-derived weekly summaries provided time-varying behavioral and physiological information, this model did not directly estimate individualized deviations from each participant's own psychological baseline. This distinction is important for interpreting the model as a week-ahead risk prediction tool. Emotional states and stress levels can fluctuate considerably on a week-to-week basis, and treating these variables as static may have influenced both predictive performance and interpretability. The findings suggest that stable vulnerability profiles can improve risk stratification when combined with weekly wearable signals, but they should not be interpreted as demonstrating that baseline psychological variables function as proximal early-warning signals.

However, the psychological measures used in this study, including depression (PHQ-9), anxiety (GAD-7), perceived stress (PSS-10), and personality vulnerability indicators, were originally developed to capture relatively stable symptom severity or vulnerability profiles rather than rapid state-level changes [32,34,46]. Consequently, although repeated weekly self-report symptom scores may provide additional predictive information, they differ conceptually from the baseline vulnerability indicators used in the primary models. The primary modeling framework, therefore, treated psychological and personality measures as baseline vulnerability indicators and focused on whether week-varying wearable-derived summaries could contribute to the prediction of the following week's high-risk drinking label.

Nevertheless, research using EMA for affective disorders has demonstrated that negative affect often shows substantial moment-to-moment fluctuation, whereas positive affect tends to exhibit dampened diurnal variation [47,48]. Emotional states also react strongly to daily stressors [49]. Therefore, future models should incorporate EMA-based affective states, repeated brief affect measures, or person-centered deviation features to better capture within-person changes that may be more actionable for JITAI delivery.

Fourth, because this was an observational sensing study, wearable-derived predictors may have been influenced by unmeasured contextual and behavioral factors. For example, physical activity routines, sleep debt, acute illness, academic or work schedules, weekend social activity, shift work, device wear time, and other daily-life contexts may affect heart rate, sleep, step count, and calorie estimates independently of alcohol-risk processes. Therefore, SHAP-identified features should be interpreted as predictive correlates rather than causal mechanisms or physiological precursors. Future studies should incorporate contextual measures, EMA-based state assessments,

XSL•FO
RenderX

and person-centered deviation features to better distinguish alcohol-related risk signals from broader daily-life variability.

Fifth, the prediction model in this study defined weekly high-risk drinking episodes using a binary threshold based on the AUDIT-K. Because AUDIT-K scores rely on self-reported information, they are subject to recall bias and social desirability bias, which may limit the precision of the outcome labels. It is possible that the model's predictive performance would differ if more granular event-level drinking assessments or biosensing-based alcohol detection technologies were used.

At the same time, many machine learning and AI studies aiming to predict substance use or alcohol-related risk rely on self-reported labels for the outcome variable [10-12,28,30,50]. Although the reliability of such outcome labels may be debated, they remain the most practical and widely adopted approach in real-world digital phenotyping research. Nonetheless, future studies will benefit from incorporating passive and low-burden outcome measurement tools—such as continuous biosensing devices or ecological momentary detection of drinking events—which may enhance labeling accuracy and further improve predictive performance.

Sixth, although participant-level grouped cross-validation was used to reduce subject-level leakage, the number of positive high-risk drinking episodes within each held-out fold was relatively small. This may have contributed to variability in sensitivity and precision estimates across folds. In addition, the sensitivity-oriented operating threshold improved detection of positive episodes but resulted in modest precision/PPV, indicating that the model may generate false-positive alerts if applied as a stand-alone early-warning tool. Therefore, this model should be interpreted as a preliminary risk-stratification approach rather than a clinically deployable decision system.

Finally, the predictive modeling in this study was limited to 2 tree-based algorithms, XGBoost and random forest. These models were chosen to balance interpretability and predictive performance, particularly given our focus on identifying the likelihood of entering the high-risk drinking category in the following week. However, tree-based models have only limited capacity to capture temporal dependencies or long-range sequential patterns inherent in week-to-week behavioral fluctuations. Future research should incorporate more advanced time-series deep learning approaches, such as long short-term memory networks, temporal convolutional networks, or transformer-based architectures, which may better model temporal dynamics and improve prediction accuracy as longer-term longitudinal data become available.

Conclusions

This study developed machine learning models integrating emotional and personality vulnerability factors with wearable-derived physiological and behavioral signals to predict weekly high-risk drinking episodes among young adults. The findings suggest that combining stable baseline vulnerability indicators with week-level wearable summaries may provide useful information for week-ahead risk estimation. Activity-, sleep-, heart rate-, and vulnerability-related features contributed to model prediction, although these features should be interpreted as predictive correlates rather than causal mechanisms or proximal physiological precursors.

Importantly, this work provides preliminary evidence for the feasibility of wearable-assisted risk stratification for alcohol-related risk in South Korea. Rather than establishing a fully deployable early-warning system, these findings offer an initial basis for future digital monitoring approaches. Future studies involving broader age groups, longer-term longitudinal data, more proximal within-person measures, and external validation will be essential to enhance the generalizability, clinical use, and JITAI relevance of prediction models for high-risk drinking.

Acknowledgments

We extend our deepest gratitude to all members of the research team who have worked tirelessly over a long period to achieve optimal model performance.

Data Availability

The datasets generated and analyzed during this study contain sensitive personal health and behavioral information and are therefore not publicly available. Deidentified data may be made available from the corresponding author upon reasonable request and with appropriate institutional approval.

Funding

This research was supported by a grant from the Korea Health Technology R&D Project through the Korea Health Industry Development Institute (KHIDI), funded by the Ministry of Health & Welfare, Republic of Korea (grant RS-2022-KH125882).

Authors' Contributions

JSK, SJJ, HKL, JHK, SJK, YK, and HL designed and conceptualized the study. JSK and SJJ developed the methodology and contributed to writing the manuscript. JSK was responsible for project administration and visualization. JHK curated and processed the data and supported data analysis. HKL provided funding acquisition, supervision, and resources. SJK and YK contributed to conceptualization and provided resources. HL performed data curation, investigation, and software implementation. Abstract

Background: Adolescents with depressive symptoms are at increased risk of social functional impairment and are more likely to develop major depressive disorder. Digital interventions offer advantages, such as high accessibility, especially for adolescents. However, evidence on the effectiveness of web-based psychological interventions in alleviating depressive symptoms among adolescents remains limited.

Objective: This study aims to develop a brief web-based psychological intervention tailored to the developmental and psychological characteristics of Chinese adolescents and to evaluate its effectiveness and influencing factors.

Methods: In a 2-arm randomized controlled trial, adolescents aged 12 to 18 years with depressive symptoms were recruited from high schools in China. Eligible participants were randomly assigned in a 1:1 ratio to the intervention group (n=212) or the control group (n=224). Participants in the intervention group received a 4-week brief web-based emotional cognitive training program, whereas those in the control group received a web-based psychoeducation program. Nonprofessional helpers provided minimal support through text messages or phone calls. The primary outcome was depressive symptom severity. Secondary outcomes included the depressive symptom remission rate, changes in anxiety symptoms, suicidal ideation, and resilience. Data were collected at baseline (T0), postintervention (T1), and at 1- and 3-month follow-ups (T2 and T3). Statistical analyses included analysis of covariance (ANCOVA), logistic regression analysis, and mediation analysis.

Results: Two-way repeated-measures ANCOVA revealed a significant time effect ($F_{3,1461}$=82.515; P<.001; η^2_p=0.140) on depressive symptom severity, with significantly lower scores at T1, T2, and T3 than at T0. No significant group effect ($F_{1,1461}$=1.039; P=.31; η^2_p=0.001) or time-by-group interaction ($F_{3,1461}$=2.424; P=.06; η^2_p=0.005) for depressive symptom severity was observed. Post hoc exploratory analysis showed that among adolescents with anxiety symptoms, the intervention group exhibited a higher depressive symptom remission rate at T1 than the control group (adjusted odds ratio 1.39, 95% CI 1.05-1.85; P=.02; number needed to treat=7). Additionally, the intervention group showed significantly greater improvements in the interpersonal support dimension of resilience at T1 (least squares mean difference=1.79, 95% CI 0.53-3.06; Cohen d=0.37, 95% CI 0.11-0.63; P=.006; false discovery rate–adjusted P=.04). Exploratory mediation analysis identified a significant indirect effect between the intervention and depressive symptom remission via the interpersonal support dimension of resilience at T1 (indirect effect=0.08, 95% CI 0.02-0.14; P=.009).

XSL•FO
RenderX

Conclusions: The brief web-based psychological intervention showed no significant difference from web-based psychoeducation in reducing depressive symptoms across the 3-month follow-up period. Post hoc exploratory analyses detected a potential between-group difference in depressive symptom remission among adolescents with comorbid anxiety symptoms, with interpersonal support showing a significant mediating association. These exploratory findings may provide new insights into identifying the target population suitable for brief web-based psychological interventions and inform the development of tailored interventions in the future.

KEYWORDS

adolescents; brief web-based psychological intervention; depressive symptoms; randomized controlled trial; RCT; web-based psychoeducation

Introduction

Major depressive disorder (MDD) is a prevalent mental disorder among the general population and has ranked fourth in the global burden of disease in recent years [1]. Evidence suggests that 19% of MDD cases first emerge during adolescence [2]. Given that adolescents are in a critical developmental period characterized by emotional and cognitive growth [3], they are particularly susceptible to various life events that may trigger depressive symptoms and potentially lead to the onset of MDD [4]. The global prevalence of depressive symptoms among adolescents during the COVID-19 pandemic was 25.2% [5]. Adolescents with depressive symptoms may experience impairments in academic and occupational functioning [6,7], and they remain at elevated risk of developing MDD compared with healthy individuals [8-10]. Therefore, psychological interventions targeting adolescents with depressive symptoms represent a critical approach for the early prevention and early intervention of depression.

Cognitive behavioral therapy (CBT) has been widely recommended as a standard intervention for adolescents with depressive symptoms or mild depressive disorders across many countries [11-14]. Although research suggests that CBT is the most evidence-based psychological intervention for depressive symptoms [15], several barriers hinder its widespread implementation, including high intervention costs, substantial time investment from therapists, and limited accessibility [16-18]. School-based CBT interventions can cost up to GBP £43 (US $32) per student [16]. During a full course of CBT treatment, therapists typically spend between 5 and 24 hours providing direct guidance to each participant [17]. Approximately 75% of adolescents with mental health problems have not accessed mental health services [18]. This reluctance to seek help is primarily attributed to a lack of accurate knowledge about mental disorders, high levels of stigma, significant economic burdens, and the inherent inaccessibility of psychotherapy itself [19].

Recent advances in psychotherapy have revealed that specific functional modules within effective interventions demonstrate significant therapeutic value in reducing symptoms [20]. Previous studies have demonstrated that behavioral activation, whether delivered alone or in combination with cognitive restructuring [21,22], as well as psychoeducation [23], mindfulness, relaxation training [24], and peer support modules, can effectively reduce depressive symptoms [25]. Digital therapeutics integrated with internet technology, as well as web-based psychological interventions derived from traditional psychological approaches, have increasingly attracted attention in the field of psychotherapy [26]. Indeed, recent studies have demonstrated that brief web-based psychotherapy provides significant therapeutic effects on depressive symptoms [27-29]. These interventions offer several advantages, including shorter treatment durations, reduced constraints of time and space, high accessibility, and strong scalability. For example, the World Health Organization has released a brief web-based psychological intervention called “Step-by-Step” for adult depressive symptoms [30]. Evidence indicates that “Step-by-Step” can effectively reduce depressive symptoms in both adults and university students, with effects maintained for up to a 3-month follow-up period [31,32].

For adolescent depressive symptoms, studies have demonstrated the efficacy of brief web-based psychological interventions in reducing depressive symptoms. A randomized controlled trial (RCT) involving 128 female adolescents with mild to moderate depressive symptoms evaluated a web-based social cognitive training program. Results showed that the intervention group exhibited significantly lower symptom severity than the blank control group at the 3-month follow-up [33]. A systematic review indicates that most current brief web-based interventions for adolescent depression incorporate psychoeducational components, whereas control groups are typically assigned to waitlist or blank controls [34]. Such designs may introduce placebo effects and overstate the ability to assess the specific therapeutic benefits of the interventions. Therefore, it is essential to implement psychoeducation as an active control condition within an RCT framework to more rigorously evaluate the efficacy of brief CBT-oriented web-based interventions.

This study aims to examine whether a brief web-based psychological intervention can reduce depressive symptoms in Chinese adolescents aged 12 to 18 years and assess the efficacy and sustainability of the intervention effects over a 1- to 3-month follow-up period. Additionally, this study seeks to explore the potential factors influencing the effectiveness of the intervention, such as resilience.

Methods

Ethical Considerations

The study protocol was approved by the Ethics Committee on Biomedical Research at West China Hospital, Sichuan University (approval number 2024-1225), and registered in the Chinese Clinical Trial Registry (ChiCTR2400090235). This study was reported in accordance with the CONSORT-EHEALTH checklist (Multimedia Appendix 1). All participants and their parents provided informed consent. Participants received US $15 for completing each of the 1-month and 3-month follow-up assessments. Participants were not compensated for engaging in the intervention. All data were deidentified before analysis to ensure participant confidentiality.

Study Design

This study used a 2-arm RCT design. From October 2024 to January 2025, eligible adolescents were recruited from 2 junior high schools and 1 senior high school in Chengdu. A total of 457 participants were initially enrolled, and 436 completed randomization and received the assigned interventions. The inclusion criteria were as follows: (1) age between 12 and 18 years; (2) a score of ≥10 on the Patient Health Questionnaire-8 (PHQ-8). Given the sensitivity of items related to "suicide" and "self-harm" in school-based universal screening, the final item of the PHQ-9 was omitted, and the PHQ-8 was used for screening; and (3) all adolescent participants volunteered to take part in the study, and both the participants and their parents provided written informed consent. Outcome assessments were conducted at 4 time points: baseline (T0), postintervention (T1), 1-month follow-up (T2), and 3-month follow-up (T3).

Procedure

From October 2024 to January 2025, adolescents aged 12 to 18 years with depressive symptoms were recruited from schools to participate in this study. A total of 457 participants were recruited, and 436 underwent randomization. A dedicated researcher stratified the participants by age, gender, school, and depressive symptom severity using a random number generator and subsequently allocated them to either the intervention group or the control group in a 1:1 ratio. Participants in both groups received their assigned interventions and completed outcome assessments at 4 time points. Participants and outcome assessors were not informed of their assigned group or the intervention content delivered to the comparator arm; however, formal verification of blinding status was not conducted during the trial.

Interventions

Participants in the intervention group received a 4-week, once-weekly web-based psychological intervention through a WeChat mini-program accessible via mobile phone or computer (a screenshot is provided in Figure S1 in Multimedia Appendix 2), whereas those in the control group received web-based psychoeducation with the same frequency and delivered via the identical platform. More details of the intervention modules are provided in Table S1 in Multimedia Appendix 2. Each participant was provided a unique login account and password. Participants were not informed about the content of the other group's intervention. Four postgraduate students majoring in psychology or psychiatry without medical licenses served as nonprofessional helpers, providing minimal support for platform access and login issues via text messages or phone calls. They did not perform any clinical assessment or therapeutic intervention. The average time commitment per participant was 15 minutes per week for both arms.

Safety Monitoring

All participants completed the PHQ-8 and the Beck Scale for Suicide Ideation–Chinese Version (BSI-CV) at screening and throughout the intervention period via the online platform. A licensed psychiatrist supervised the risk assessment. An automated alert system was activated when participants scored ≥6 on the BSI-CV to flag suicide risk for psychiatrist review. Based on this review, the psychiatrist determined final study eligibility and decided whether clinical referral was warranted. If a participant explicitly reported worsening depressive symptoms, expressed suicidal ideation, or asked for professional help, the nonprofessional helpers documented the participant's exact words and escalated the case within 2 hours to the supervising psychiatrist via a secure channel. The psychiatrist then contacted the participant directly, assessed the need for referral, and, if necessary, withdrew the participant from the study to arrange appropriate care.

Outcome Measurements

Overview

Data were collected via the same online platform used for the interventions, with participants completing self-report questionnaires at 4 time points (T0, T1, T2, and T3).

PHQ-8

The primary outcome was depressive symptom severity measured by the PHQ-8 [35]. A total score of ≥10 is considered clinically significant and suggests the presence of depressive symptoms [35]. In this study, remission of depressive symptoms was defined as a score of <10 [36]. Score changes were defined as follows: T1–T0 (postintervention minus baseline), T2–T0 (1-month follow-up minus baseline), and T3–T0 (3-month follow-up minus baseline).

Generalized Anxiety Disorder-7

Anxiety symptom severity was assessed using the Generalized Anxiety Disorder-7 [37]. A total score of ≥10 is considered indicative of clinically significant anxiety symptoms and may suggest the presence of an anxiety disorder [37].

BSI-CV

Suicidal ideation severity was assessed using the BSI-CV [38]. A total score of ≥6 demonstrates the highest classification accuracy for predicting future suicidal behavior [39].

Adolescent Resilience Scale

Resilience was evaluated using the Adolescent Resilience Scale [40]. It is a self-report instrument comprising 27 items organized into 5 dimensions: emotion regulation, interpersonal support, family support, positive cognition, and focused targeting. Higher

XSL•FO
RenderX

total scores reflect greater resilience and a stronger capacity to cope with stress and adversity.

Difficulties in Emotion Regulation Scale

Emotional regulation difficulties were assessed using the Difficulties in Emotion Regulation Scale [41]. It is a self-report measure consisting of 36 items organized into 6 dimensions: lack of emotional awareness, lack of emotional clarity, nonacceptance of emotional responses, impulse control difficulties, difficulties engaging in goal-directed behavior, and limited access to emotion regulation strategies. Higher total scores indicate greater difficulties in emotion regulation.

Adolescent Social Support Rating Scale

Social support levels were assessed using the Adolescent Social Support Rating Scale [42]. It is a self-report measure consisting of 17 items organized into 3 dimensions: subjective support, objective support, and support utilization. The average total score reflects the overall level of perceived social support, with higher scores indicating greater availability and more effective use of social support resources.

Socioeconomic Status Index

The socioeconomic status (SES) index was calculated using Ren's method [43], which used principal component analysis to generate standardized scores for parents' educational level, parents' occupation type, and family monthly income. Factor loadings were used as weights and multiplied by the corresponding *Z* scores; these weighted values were then summed and divided by the eigenvalue of the first principal component: $SES = (\beta_1 \times Z_{\text{parents' education level}} + \beta_2 \times Z_{\text{parents' occupation type}} + \beta_3 \times Z_{\text{family monthly income}})/f$. In this equation, β_1, β_2, and β_3 represent factor loadings, while f denotes the eigenvalue. The final derived formula in this study is: $SES = (0.84 \times Z_{\text{parents' education level}} + 0.84 \times Z_{\text{parents' occupation type}} + 0.68 \times Z_{\text{family monthly income}})/0.62$.

Acceptability and Adverse Events

Regarding the acceptability of the brief web-based psychological intervention program, we analyzed completion rates for both the intervention and control groups at T1, T2, and T3. Additionally, qualitative feedback regarding user experience and suggestions was collected from a subset of students. Technical issues encountered during implementation were reported by the backend developers.

Adverse events, including suicide attempts, self-harm, physical discomfort, and symptom deterioration, were systematically monitored and documented through reports from participants, guardians, or school personnel. Students who reported severe adverse events, such as suicide attempts or self-harm, were followed up and received appropriate psychological or medical support as necessary.

Statistical Analysis

The sample size was determined using G*Power software (version 3.1). Based on effect size data from a previous RCT, the between-group difference in postintervention depressive symptom scores assessed by the PHQ-9 scale yielded a Hedges *g* of 0.35 [31]. In that trial, the intervention group received a brief web-based psychological intervention, whereas the control group was offered brief web-based psychoeducation and referrals to local mental health services for professional assistance [31]. The statistical power analysis assumed a 2-tailed significance level of α=.05, a desired power of 80% (β=0.20), and a 1:1 allocation ratio between groups, yielding a minimum required sample size of 130 participants per group and a total of 260 participants for the study. To account for anticipated participant attrition, we applied a conservative dropout rate of 40%, informed by a pooled attrition rate of 35.5% estimated from a meta-analysis of smartphone-delivered psychological interventions [44]. The adjusted sample size was set at 217 participants per group, resulting in a target total sample size of 434. Eventually, 457 adolescents with depressive symptoms were initially recruited, and 21 participants withdrew before randomization, leaving a final sample of 436 randomized participants.

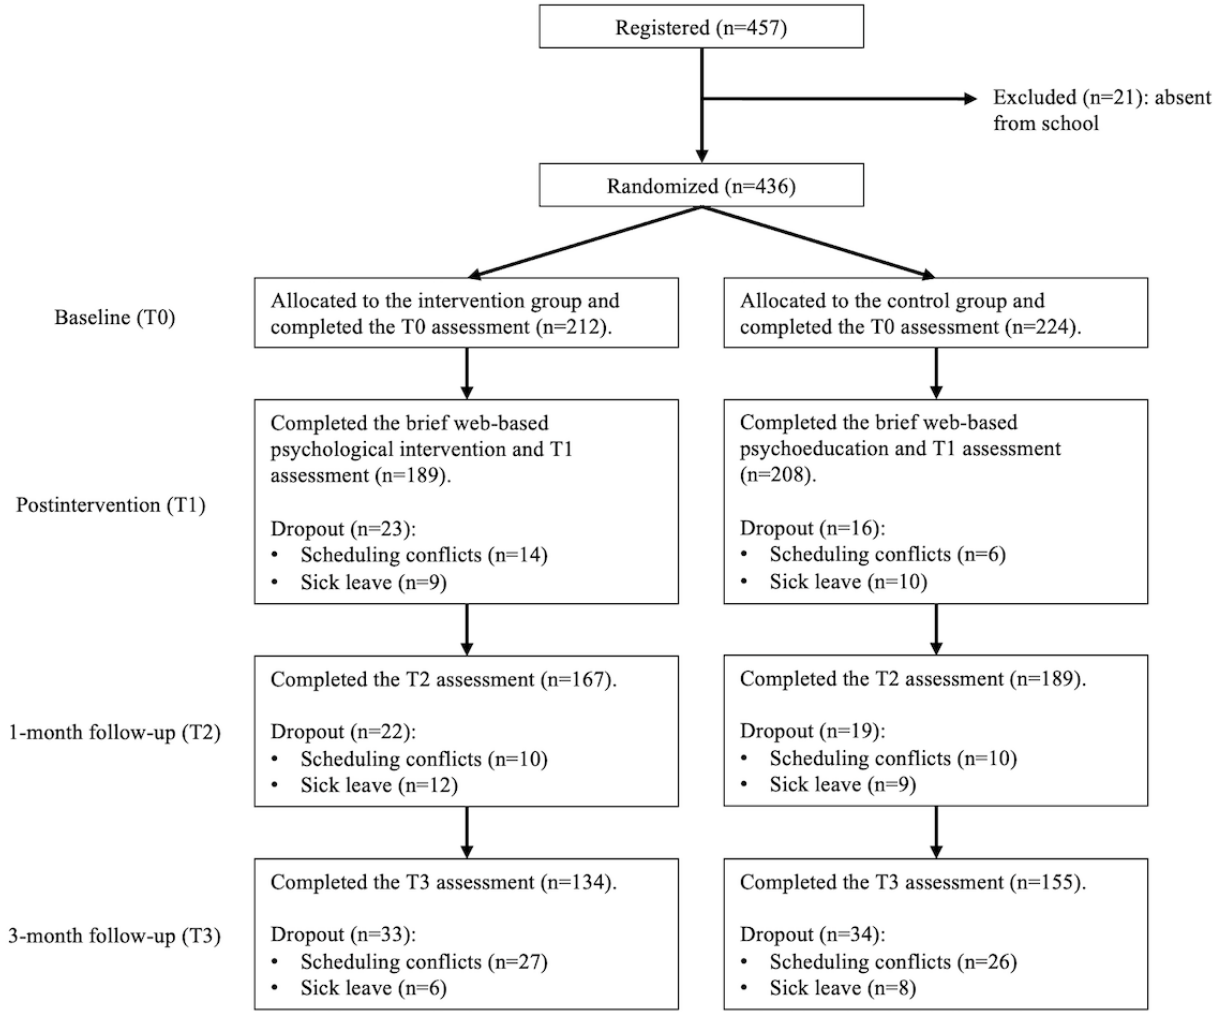
To assess whether the achieved sample size provided adequate power to detect the effect size observed in this trial, we performed a post hoc sensitivity analysis. Given the final sample of 436 participants (intervention group=212 and control group=224), a 2-tailed independent-samples *t* test with α=.05 and power (1–β)=0.80 could detect a minimum standardized mean difference of Cohen *d*=0.27, computed using the R (version 4.5.1; R Foundation for Statistical Computing) *pwr* package (version 1.3-0). This sensitivity analysis indicates that the trial could reliably identify small effects above Cohen *d*=0.27, whereas true treatment effects smaller than this threshold could not be statistically distinguished from 0.

Data were organized and analyzed using R, including the *lme4* (version 1.1-37) and *lmerTest* (version 3.1-3) packages, SPSS (version 25.0; IBM Corp), and Mplus (version 8.3; 2012-2018 Muthen & Muthen) software. Demographic characteristics and baseline outcome measures were compared between the intervention and control groups via 2-tailed independent-samples *t* tests and chi-square tests. For data with multiple time points (scale scores of depressive symptoms or other outcome indicators), 2-way repeated-measures analyses of covariance (ANCOVAs) were used, with time (T0, T1, T2, and T3), group (intervention vs control) effects, and the time-by-group interaction as independent variables. Baseline values of the outcome indicators, age, gender, educational stage, only-child status, family structure, and SES index were included as covariates. For change scores in depressive symptoms or other outcome indicators, 1-way ANCOVAs were used, with group as the independent variable and baseline values of the outcome indicators, age, gender, educational stage, only-child status, family structure, and SES index as covariates. Effect sizes for main effects and interactions were evaluated using η^2_p, with 0.01, 0.06, and 0.14 representing small, medium, and large effects, respectively [45]. Between-group effect sizes were calculated via least squares mean differences (LSMDs) and Cohen *d*, along with corresponding 95% CIs. Cohen *d* effect magnitudes were interpreted using conventional thresholds: small (*d*=0.20), medium (*d*=0.50), and large (*d*=0.80) [45]. Logistic regression analyses were conducted to examine the association between group assignment and depressive symptom

XSL•FO
RenderX

remission rates at each assessment time point (T1, T2, and T3), adjusting for baseline PHQ-8 score, age, gender, educational stage, only-child status, family structure, and SES index. Number needed to treat (NNT) and odds ratios (ORs) with 95% CIs were derived from the adjusted models [45]. A *P* value of <.05 was considered statistically significant throughout the study. To control for inflated type I error from multiple comparisons, we adopted stratified Benjamini-Hochberg false discovery rate (FDR) correction for indicators in between-group comparisons [46,47]. FDR correction was applied to scores and score changes of anxiety symptoms and suicidal ideation, as well as total and subscale scores and corresponding score changes for resilience, difficulties in emotion regulation, and social support.

To explore potential influencing factors of the intervention and the underlying psychological mechanisms, outcome variables with significant between-group differences were selected as mediators. With group assignment as the independent variable and outcome scores or rates as the dependent variable, we adjusted for age, gender, and baseline levels of each outcome. Mediation analyses were performed using maximum likelihood estimation and 1000 bootstrap resamples to evaluate the significance of indirect effects [48].



Results

Participants

From October 2024 to January 2025, adolescents aged 12 to 18 years with depressive symptoms were recruited from schools to participate in this study. A total of 457 participants were recruited, and 436 underwent randomization. Dropout rates differed across time points (Figure 1). For the intervention group (n=212), the rates were 10.9% (23/212) at T1, 10.4% (22/212) at T2, and 15.6% (33/212) at T3. For the control group (n=224), the corresponding rates were 7.1% (16/224) at T1, 8.5% (19/224) at T2, and 15.2% (34/224) at T3. Among the full sample of 436 participants, the mean age was 15.02 (SD 1.49) years. In terms of demographic characteristics, 75.2% (328/436) of participants were female, and 24.8% (108/436) were male; 30.7% (134/436) were junior high school students, while 69.3% (302/436) were high school students. Additionally, 27.3% (119/436) of participants were only children. Regarding family structure, 67% (292/436) of participants came from 2-parent families (residing with both biological or adoptive parents), 9.4% (41/436) from single-parent families (residing with only 1 parent), 6.4% (28/436) from stepfamilies (residing with 1 biological parent and a stepparent), and 17.2% (75/436) did not live with either parent but resided with grandparents or other relatives instead. The SES index ranged from –5.18 to 9.41, with a mean value of 0 (SD 2.99). The mean baseline PHQ-8 score in the full sample was 14.43 (SD 3.02), ranging from 10 to 24. No significant differences were found between the intervention and control groups regarding age, gender, educational stage, only-child status, family structure, SES index, and any outcome indicators (all $P \geq .05$; Table 1).

Objective support	3.25 (1.03)	3.34 (1.07)	–0.842 (434)[a]	.40
Support utilization	2.86 (1.06)	3.04 (1.20)	–1.660 (432.06)[a]	.10

[a]Indicates 2-tailed independent-samples *t* test.

[b]Indicates chi-square test.

[c]Family structure was classified into 4 types. 2-parent family: residing with both biological or adoptive parents; single-parent family: residing with only 1 parent; stepfamily: residing with 1 biological parent and a stepparent; no parent present: not living with either parent but staying with grandparents or other relatives.

[d]The criteria for determining the presence of anxiety symptoms were as follows: a total score of ≥10 on the Generalized Anxiety Disorder-7 indicates the presence of anxiety symptoms, whereas a score of <10 indicates the absence of anxiety symptoms.

Main Results

For all participants, Table 2 presents the ANCOVA-adjusted estimated means and standard errors of each continuous outcome indicator at each time point for the intervention and control groups. The primary outcome (depressive symptom severity, measured by the PHQ-8 score) demonstrated a significant time effect through 2-way repeated-measures ANCOVA ($F_{3,1461}$=82.515; P<.001; η^2_p=0.140), but the group effect ($F_{1,1461}$=1.039; P=.31; η^2_p=0.001) and time-by-group interaction ($F_{3,1461}$=2.424; P=.06; η^2_p=0.005) were not significant. Post hoc comparisons revealed that depressive symptom severity at T1, T2, and T3 was significantly lower than that at T0 in both the intervention and control groups (T1–T0: Cohen d=–0.91, 95% CI –1.05 to –0.77; T2–T0: Cohen d=–0.90, 95% CI –1.05 to –0.76; T3–T0: Cohen d=–0.89, 95% CI –1.05 to –0.74). Significant time effects were also observed for almost all secondary outcomes (P_s<.05; Table S2 in Multimedia Appendix 2). Following FDR correction for multiple testing, none of the secondary outcomes exhibited a statistically significant group effect or time-by-group interaction (all FDR-adjusted P≥.05; Table S2 in Multimedia Appendix 2).

[a]At baseline, postintervention, 1-month follow-up, and 3-month follow-up, the intervention group included 212, 189, 167, and 134 participants, respectively, while the control group included 224, 208, 189, and 155 participants, respectively.

Furthermore, a significant between-group difference was observed in the change score for the interpersonal support dimension of resilience from T0 to T1 (intervention group: mean change 2.03, SD 0.53; control group: mean change 0.64, SD 0.52; LSMD=1.39, 95% CI 0.42-2.35; Cohen *d*=0.29, 95% CI 0.09-0.49; *P*=.005; FDR-adjusted *P*=.03) through 1-way ANCOVA (Table S3 in Multimedia Appendix 2). Moreover, there was no significant difference in the depressive symptom remission rate between the groups at any time point through logistic regression analysis (Table S4 in Multimedia Appendix 2).

In terms of acceptability, completion rates for both the intervention and control groups across all time points are presented in Table 3. Chi-square tests revealed no significant between-group differences at any assessment point (all *P*≥.05). Furthermore, some participants reported that the visual and textual content was engaging. However, participants reported difficulty finding a quiet environment for audio playback, and the password reset process was troublesome when they forgot their credentials. The backend developers resolved the network latency issue during intervention delivery and shortened the password reset procedure to improve user experience.

No severe adverse events, such as suicide attempts or self-harm behaviors, were reported during the intervention or follow-up period. In this trial, 3 participants withdrew because of self-reported worsening depressive symptoms that required clinical referral. No physical discomfort related to program use was reported.

Table 3. Comparison of completion rates between the intervention and control groups across different time points.

Time points	Intervention group (n=212), n (%)	Control group (n=224), n (%)	Chi-square (*df*)	*P* value
Postintervention	189 (89.2)	208 (92.9)	1.837 (1)	.18
1-month follow-up	167 (78.8)	189 (84.4)	2.281 (1)	.13
3-month follow-up	134 (63.2)	155 (69.2)	1.748 (1)	.19

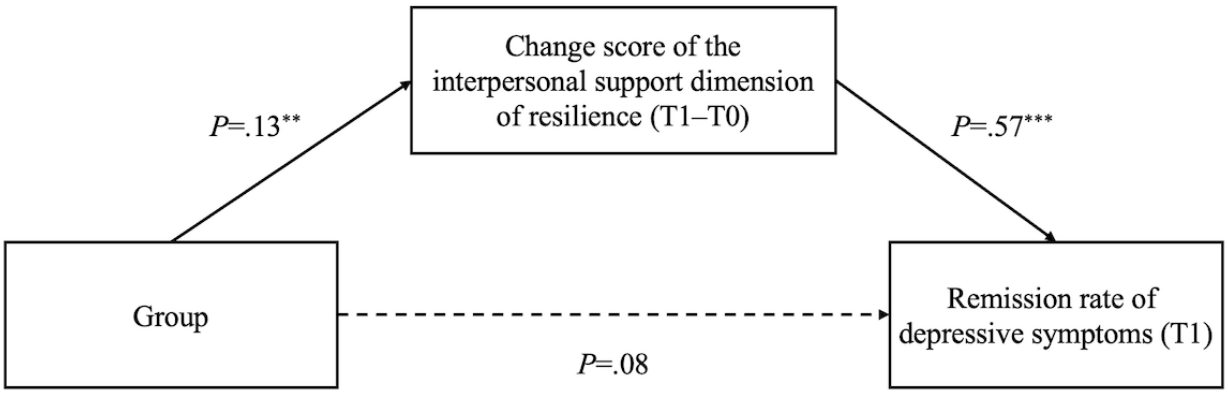
Post Hoc Exploratory Analysis Results

Adolescents with depressive symptoms may exhibit substantial individual heterogeneity, and intervention effects may differ between those with and without anxiety symptoms. Therefore, participants were divided into 2 subgroups (with anxiety symptoms vs without anxiety symptoms), and the statistical analyses were performed separately within each subgroup. Results are reported in the subsequent section. Demographic characteristics and baseline scale score differences between the intervention and control groups within each subgroup are presented in Table S5 in Multimedia Appendix 2.

Among adolescents with anxiety symptoms, logistic regression analyses indicated a significantly higher depressive symptom remission rate at T1 in the intervention group relative to the control group (intervention: 53/123, 43.1%; control: 39/128, 30.5%; adjusted OR=1.39, 95% CI 1.05-1.85; *P*=.02; NNT=7; Figure 2 and Table S4 in Multimedia Appendix 2). No significant between-group differences were detected in raw scores or changes in depressive symptom severity at any time point in this subgroup (all *P*≥.05; Tables S6-S8 in Multimedia Appendix 2). One-way ANCOVA further showed that the intervention group exhibited substantially greater improvements in the interpersonal support dimension of resilience from T0 to T1 (intervention group: mean change 2.75, SD 0.69; control group: mean change 0.96, SD 0.64; LSMD=1.79, 95% CI 0.53-3.06; Cohen *d*=0.37, 95% CI 0.11-0.63; *P*=.006; FDR-adjusted *P*=.04; Table S8 in Multimedia Appendix 2).

Figure 2. The number of individuals with remission and no remission of depressive symptoms in the intervention and control groups among adolescents with anxiety symptoms at postintervention. Remission of depressive symptoms is defined as a Patient Health Questionnaire-8 (PHQ-8) score of <10 (below the clinical cutoff point). **P*<.05; ***P*<.01; ****P*<.001.



Building on these findings observed among adolescents with anxiety symptoms, we constructed an exploratory mediation model. The analysis revealed a statistical association between group assignment and changes in the interpersonal support dimension of resilience from T0 to T1 (β=0.13, 95% CI 0.03-0.23; *P*=.008). In turn, changes in interpersonal support were associated with depressive symptom remission at T1 (β=0.57, 95% CI 0.41-0.69; *P*<.001). A significant indirect effect was observed across the sequence: group → changes in interpersonal support from T0 to T1 → depressive symptom remission at T1 (β=0.08, 95% CI 0.02-0.14; *P*=.009; Figure 3). The proportion mediated was 49.8% (95% CI 15.5%-169.5%). The upper bound exceeding 100% reflects sampling variability and the instability of ratio-based mediation metrics when the total effect is not statistically significant. We therefore focus on the indirect effect as the primary evidence for mediation.

Among adolescents without anxiety symptoms, no significant between-group differences were found in depressive symptom severity, any other outcome measures, or depressive symptom remission rates (all *P*≥.05; all FDR-adjusted *P*≥.05; Tables S4, S6, S9, and S10 in Multimedia Appendix 2).

Figure 3. The mediating mechanism on remission of depressive symptoms. The group is a binary categorical variable, with the "intervention group" coded as 1 and the "control group" coded as 0. T0 and T1 refer to the baseline and postintervention time points, respectively. *P<.05; **P<.01; ***P<.001.

Discussion

Principal Findings

This study reveals that both the brief web-based psychological intervention and web-based psychoeducation are associated with short-term reductions in adolescent depressive symptoms, with improvements sustained from postintervention to the 1- to 3-month follow-up period. No significant between-group differences were observed in any outcome measures. However, unplanned, hypothesis-generating post hoc exploratory analyses among adolescents with anxiety symptoms indicated that the intervention group exhibited a higher depressive symptom remission rate and greater improvement in the interpersonal support dimension of resilience at T1 relative to the control group. Additionally, the association between the intervention and depressive symptom remission was partially explained by improvements in interpersonal support. Given that these findings came from unplanned post hoc analyses, they should be interpreted cautiously and require further validation in rigorous trials.

Both groups exhibited significant reductions in depressive symptom severity up to the 3-month follow-up, which aligns with prior studies of web-based psychological interventions for youth. RCTs have shown that when the control group receives web-based psychoeducation or supportive therapy, both the intervention and control groups exhibit significant decreases in depressive symptom scores, with effects lasting up to the 1- to 3-month follow-up [49,50]. These findings align with the present results, suggesting that web-based psychoeducation alone may relieve depressive symptoms via emotion recognition, regulation training, and social skills modules, which may help adolescents build self-confidence and improve emotional well-being, thereby reducing depressive symptoms. Consistent with several previous trials, we found no group differences in depressive symptom severity when the control group received web-based psychoeducation [51,52]. By contrast, when the control group received treatment as usual or a blank control, the intervention group showed significantly lower depressive symptom scores postintervention or at the 3- to 6-month follow-up [33,53,54]. Notably, significant between-group differences were observed in several subdimensions of resilience and social support. However, these differences did not survive after multiple-comparison correction (Tables S2 and S3 in Multimedia Appendix 2), indicating that they should be interpreted as exploratory rather than confirmatory. Nonetheless, the observed trend toward improved adolescent resilience and social support following web-based psychological intervention aligns with prior evidence [55,56]. This may be attributed to the combined effects of identifying personal strengths within the psychoeducation module of the brief web-based psychological intervention, as well as the skill modules of behavioral activation, cognitive restructuring, peer support, mindfulness, and relaxation training [57-59]. In summary, the brief web-based intervention showed no advantages over web-based psychoeducation in reducing depressive symptoms across all assessed time points. Future work should extend follow-up to 6 to 12 months to evaluate long-term effects and add a blank control group to identify the specific components of psychoeducation that contribute to its effectiveness.

Among adolescents with anxiety symptoms, post hoc analyses revealed a higher postintervention depressive symptom remission rate in the intervention group, whereas no group difference was found in overall depressive symptom changes from baseline to postintervention and the 1- to 3-month follow-ups. Previous studies have reported contradictory findings regarding effects on depressive symptom severity and remission rate. Two RCTs with larger sample sizes (n=160 and n=187) yielded results similar to those of this study, showing significantly higher depressive symptom remission rates in the intervention group but no significant between-group differences in depressive symptom scores [60,61]. In contrast, an RCT with a smaller sample size (n=34) reported the opposite results: significant differences in depressive symptom severity but not in depressive symptom remission rate [50]. In these studies, the control groups received either web-based psychoeducation or treatment as usual, and criteria for depressive symptom remission were both defined as a score less than the clinical cutoff on the depression scales. These findings suggest that larger sample sizes may be more likely to detect significant differences in depressive symptom remission rates. Notably, using a PHQ-8 cutoff of 10 for both enrollment and remission may lead to biased classification due to mean regression. To address this concern, we excluded participants with baseline PHQ-8 scores of 10 to 11 (full sample: 39/436, 8.9%; subgroup

XSL•FO
RenderX

with anxiety symptoms: 17/275, 6.2%) and reconducted sensitivity analyses for all significant outcomes. The results remained statistically significant, demonstrating that our main findings are relatively robust (Multimedia Appendix 2).

Both the full sample and the subgroup with anxiety symptoms showed small but statistically significant between-group differences in changes in the interpersonal support dimension of resilience from baseline to postintervention (full sample: Cohen *d*=0.29, 95% CI 0.09-0.49; subgroup with anxiety symptoms: Cohen *d*=0.37, 95% CI 0.11-0.63). Despite statistical significance, the small effect size suggests limited clinical practicality, as such minor changes are unlikely to improve daily functioning or clinical outcomes. This exploratory result can only serve as a preliminary reference for intervention design, rather than evidence of robust clinical efficacy. Mediation analyses further revealed that improved interpersonal support partially mediated the association between the intervention and depressive symptom remission in the anxiety subgroup. As a core component of adolescent resilience, interpersonal support reflects the ability to seek comfort and express emotions through social connections [40]. The peer support module in our intervention may have strengthened this capacity, helping adolescents access more psychological resources, cope better with stress, and recover from distress [62]. A prior RCT involving 91 adolescents with MDD found that higher baseline levels of resilience predicted lower depressive symptom levels after receiving CBT [63]. These findings indicate that the interpersonal support dimension of resilience not only serves as a protective factor against depressive symptoms before intervention but may also predict better postintervention outcomes. Therefore, future web-based psychological interventions should prioritize resilience-building strategies. Unfortunately, these benefits were not maintained at the 1- to 3-month follow-ups, highlighting the need for longer follow-up assessments to evaluate long-term efficacy.

Compared with adolescents with anxiety symptoms, adolescents without anxiety symptoms showed no significant between-group differences in any outcome measures, which is consistent with previous research. In an RCT involving 151 adults with MDD, participants in the intervention group received traditional face-to-face cognitive therapy, whereas those in the control group received interpersonal psychotherapy. The study found that anxiety symptoms positively predicted greater reductions in depressive symptoms in the cognitive therapy group at postintervention [64]. Another RCT including 268 adults with persistent depressive disorder found that participants receiving face-to-face CBT exhibited significantly lower depressive symptom scores and a higher remission rate among those with comorbid anxiety disorders than among those without comorbid anxiety disorders [65]. The co-occurrence of depressive and anxiety symptoms during adolescence is relatively common [66]. Another study showed that among youth with anxiety disorders receiving self-guided CBT, the subgroup exhibiting severe depressive and anxiety symptoms, poor sleep quality, and high levels of negative emotion experienced greater alleviation of both depressive and anxiety symptom severity following intervention [67]. Multiple large-scale epidemiological studies in China have reported a comorbidity rate of depression and anxiety of 11.3% among adolescents [68]. Compared with individuals presenting with either depressive or anxiety symptoms alone, those with both depressive and anxiety symptoms may experience more severe impairments in social functioning, underscoring the need for targeted interventions in this population [69]. The observed intervention effects exhibited considerable heterogeneity within the adolescent population. Future research should aim to refine intervention protocols and develop more tailored psychological intervention strategies to enhance treatment outcomes for specific subgroups.

In terms of intervention acceptability, the overall completion rate reached 89.2% at postintervention, comparable to the average rate of 88.3% reported in similar web-based psychological interventions [70]. We summarized participants' reasons for withdrawal: some dropped out because of academic conflicts, for which we coordinated with teachers to adjust schedules and facilitate participation; others withdrew because of technical failures, which were resolved promptly by the technical team. Future improvements should optimize intervention content, technical delivery, and implementation based on withdrawal patterns. No severe adverse events, such as suicide attempts or self-harm behaviors, occurred during the trial.

Limitations

First, this study lacked a no-intervention blank control group. Both the web-based psychological intervention and psychoeducation reduced adolescents' depressive symptoms, yet no significant differences were found between the 2 interventions. Adding a blank control group in future research will help identify the effective components of psychoeducation. Second, no formal clinical diagnostic assessments were conducted, so the intervention efficacy among adolescents with diagnosed depression remains unknown. Standard diagnostic procedures are needed in future studies to stratify participants accurately and design targeted interventions. Third, data on family-level factors, including siblings' mental health and parental physical or psychiatric illness, were not collected. These factors influence the development of adolescent depression and intervention responses [71-74]. Systematic assessment of family characteristics is warranted to explore how family dynamics interact with online interventions. Fourth, rigorous allocation concealment was implemented during randomization to prevent predictable group assignment prior to enrollment. Nevertheless, we did not conduct formal checks to confirm whether participants and outcome assessors remained unaware of group allocation after randomization, which may introduce performance bias and detection bias. Future trials should strictly enforce and verify blinding protocols. Fifth, a post hoc sensitivity analysis revealed that, given the final sample size (n=436), the study could detect only between-group differences of Cohen $d \geq 0.27$. All observed effect sizes for the primary outcome were below this threshold. Therefore, the study was underpowered to detect the true effect size achievable when comparing 2 active interventions, which may partly explain the nonsignificant group effects and interactions. Future trials should consider larger sample sizes or alternative designs to detect small but potentially meaningful effects. Finally, follow-up was limited to 1 and 3 months after the intervention. Extended

XSL•FO
RenderX

follow-up of 6 to 12 months is necessary to assess the long-term outcomes of this intervention.

Conclusions

In this RCT comparing a brief web-based psychological intervention with an active web-based psychoeducation control among adolescents with depressive symptoms, the intervention showed no superior effects relative to the active control in reducing depressive symptom severity at any follow-up time point. However, in exploratory subgroup analyses among adolescents with comorbid anxiety symptoms, the intervention suggested a possible improvement in depressive symptom remission at postintervention, which was partially mediated by improvements in the interpersonal support dimension of resilience at that time point. These findings suggest that future studies should strengthen the peer support components, optimize intervention content to deliver targeted psychological support tailored to adolescents with and without anxiety symptoms, and extend the follow-up period to assess the long-term effects of the intervention on depressive symptom reduction.

Abstract

Background: Young adults experience disproportionately high levels of stress, creating significant health challenges. This demographic often underuses traditional stress management methods due to perceived ineffectiveness, inconvenience, or stigma. Given these challenges, mobile virtual reality (VR) offers a novel, engaging, and accessible alternative stress management tool that may be more appealing to young adults.

Objective: This pilot randomized controlled trial (RCT) evaluated the preliminary effects of MindCo Relief (MR), a mobile VR-based stress management app, accompanied by online coaching, on perceived stress, resilience, anxiety, depressive symptoms, and quality of life (QoL).

Methods: Young adults aged 18 to 29 years were recruited to participate in the study. A total of 70 participants with moderate-to-high stress levels at baseline were randomized to an intervention (n=34) group and a control (n=36) group. Moderate-to-high stress was defined as a sum score of 14 or more on the Perceived Stress Scale–10 (PSS-10). The intervention group completed an 8-week VR mindfulness program with access to in-person coaching, while the control group received no intervention. The primary outcome was self-reported perceived stress (PSS-10). Secondary measures included resilience (measured by the Connor-Davidson Resilience Scale–2), anxiety (measured by the Generalized Anxiety Disorder–7 scale), depressive symptoms (measured by the Patient Health Questionnaire–9), and QoL (measured by the General Well-Being Schedule). Primary analyses used linear mixed-effects models to assess the intervention effect over the 8-week study period. Secondary analyses examined whether the percentage of program modules completed and the number of coaching sessions attended were associated with changes in the primary and secondary outcomes.

Results: The mean age of the participants was 23 (SD 3.41) years, and they were predominantly female (n=52, 74%), students (n=46, 66%), and insured (n=63, 90%). No significant differences were observed between the intervention and control groups in terms of sex (*P*=.89), student status (*P*=.56), insurance status (*P*=.68), race and ethnicity (*P*=.18), or age (*P*=.32). Linear mixed-effects models showed a significant interaction between time and intervention, with the intervention group showing greater reductions in stress (β=−3.84, SE 1.37; *P*=.007), anxiety (β=−3.21, SE 0.97; *P*=.002), and depressive symptoms (β=−3.13, SE 1.13; *P*=.007) and a greater increase in QoL (β=9.99, SE 2.92; *P*=.001). No significant interaction was found for resilience

XSL•FO
RenderX

(β=0.83, SE 0.43; *P*=.06). In the secondary analyses, neither the percentage of modules completed nor the number of coaching sessions attended was significantly associated with changes in the primary or secondary outcomes.

Conclusions: This study provided preliminary evidence that mobile VR can help reduce stress among young adults by providing immersive environments that promote relaxation and adaptive stress responses. The findings support further exploration of VR's role in mental health care. Future research should examine the efficacy and long-term effects of this mobile VR software using larger, more diverse samples. Strategies to sustain VR engagement are also warranted.

KEYWORDS

virtual reality; stress management; young adults; mindfulness; randomized control trial

Introduction

Young adults aged 18 to 29 years in the United States experience disproportionately high levels of stress, making them one of the most vulnerable groups for mental health disorders [1-3]. Several often co-occurring challenges of young adulthood, such as pressures to succeed in school, establish a career, maintain relationships, and manage finances, contribute to higher stress levels in this age group than among older adults [2,4]. Repeated exposure to social comparisons and expectations from frequent use of social media and other digital technologies may further exacerbate feelings of stress [5,6].

Stress can have a profound impact on both mental and physical health. Studies have shown that prolonged stress is a precursor to severe psychiatric conditions, such as major depressive disorder, bipolar disorder, and posttraumatic stress disorder (PTSD) [7]. Furthermore, adverse psychological health conditions, including stress, anxiety, and depression, are considered risk factors for neurological, metabolic, and cardiovascular diseases (CVDs) [8,9]. The psychological effects of frequent stress and the perception of daily stress may disrupt short-term stress responses and hinder healthy adaptation. Consequently, these disruptions can increase the risk of chronic diseases such as CVD [10].

For young adults, the consequences of untreated stress extend to diminished academic and occupational performance and reduced overall quality of life (QoL), highlighting the urgent need for accessible and effective interventions [11]. Despite studies showing that physical activity is positively associated with mental well-being, only a quarter of US adults meet the National Physical Activity Guidelines [9,12,13]. Although traditional methods such as cognitive behavioral therapy (CBT) and mindfulness-based stress reduction therapy have also been shown to be effective for managing stress and anxiety, the uptake of these treatments among young adults is often hindered by perceptions that such care is ineffective or inconvenient [14-16]. Studies have also shown that stigma is a major barrier to mental health help seeking among college students, as they feel embarrassed and fear being labeled "crazy" by others [17,18]. Young adults also lack knowledge about mental health services and have difficulty identifying symptoms of mental illness. Consequently, they often continue to normalize their elevated distress and prefer self-reliance over professional help [3,18-20]. Moreover, traditional therapeutic approaches often lack personalization and do not resonate or align with young adults' individual needs and lifestyles [20].

Given these challenges, innovative stress management interventions that are flexible, accessible, and appealing to young adults are needed. Virtual reality (VR) is a novel and promising stress management tool, providing an immersive and engaging experience that can be more appealing than traditional approaches to many individuals [21]. VR technology uses computer modeling to generate interactive 3D visual environments, with additional auditory and haptic feedback also possible [22-24]. VR allows users to experience and interact with the generated environment as if they were physically present, setting it apart from other non-VR apps, websites, and video-based relaxation programs [25]. Compared to imagery and 2D technologies, VR triggers stronger emotional engagement and physiological responses, making it a more efficient medium for immersive experiences [26]. By fostering a strong sense of presence in a calming, controllable environment, VR can support short-term emotion regulation, which in turn may improve subjective well-being and QoL [27]. Mobile VR operating on smartphones can enhance VR's accessibility and portability, making it a potential solution for addressing stress on a larger scale [20].

Despite the growing interest in VR apps, there is limited research on the effectiveness of VR in stress reduction and management, particularly among young adults. Some studies have shown promising results, indicating that VR is associated with stress reduction [28-30]. However, most of the literature to date on VR therapy focuses on addictions or severe mental health conditions, such as social anxiety disorder, obsessive-compulsive disorder, and PTSD [20,22,31]. Although mobile technology has evolved rapidly over the past 5 years, studies examining VR use for stress remain scarce [27].

This pilot study used MindCo Relief (MR), a smartphone VR app designed for stress reduction, as the intervention in a randomized controlled trial (RCT) to test whether this mobile VR behavior change program would reduce perceived stress among young adults aged 18 to 29 years. We hypothesized that after the 8-week intervention period, use of the MR app would be positively associated with decreases in perceived stress, depressive symptoms, and anxiety and increases in resilience and QoL.

Methods

Study Design

This study was an 8-week pilot RCT conducted to examine the feasibility and preliminary impact of MR on stress reduction among young adults. Block randomization by sex was used to ensure a balanced distribution between male and female participants. The random allocation sequence was generated using a computer-based random number generator, with a block size of 2. Participants were assigned sequentially to the intervention or control group according to the generated allocation sequence. Enrollment occurred from October 2023 to January 2024. The first participant began the trial in October 2023, and the last completed the study in May 2024. This study was reported in accordance with the CONSORT (Consolidated Standards of Reporting Trials) checklist, which can be found in Multimedia Appendix 1.

Participants

Study participants were screened for eligibility using an online REDCap-based survey (Vanderbilt University) [32,33]. Eligibility criteria included being aged 18 to 29 years, having a moderate or high level of perceived stress at baseline, having access to a smartphone running the Android or iOS operating system, and being able to install and run the MR app. Perceived stress was measured using the Perceived Stress Scale–10 (PSS-10) [34,35]. Individuals participating in other stress reduction programs or with photosensitive epilepsy were excluded. Moderate stress was defined as a PSS-10 score of at least 14 but no more than 26, and high stress was defined as a score of 27 or greater. Participants were recruited primarily through online postings (on university websites and social media platforms) directed at individuals residing in New York City. Recruitment materials emphasized stress management and targeted college students and young adults meeting the inclusion criteria. After enrollment, participants were required to visit our study site to complete randomization.

Intervention Details

Participants in the intervention group received access to the MR smartphone app and a smartphone-compatible VR headset, both developed by MindCo Health [36]. All participants in the intervention group received VR headsets directly from the research team at our study site. The app contained a stress reduction program that comprised a structured sequence of 76 modules designed to be completed over 8 weeks. Each module was designed to be completed in approximately 7 minutes and had to be completed before progressing to the next module. Forty modules used VR. In these modules, participants placed their personal smartphones running the MR app in the VR headset, and the smartphone provided all the audiovisual content. All other modules used smartphones without the VR headset.

The program was grounded in a CBT framework and integrated mindfulness-based stress reduction principles with structured psychoeducation and immersive natural environments [37-39]. VR modules served 2 complementary functions. First, educational VR sessions placed participants in a simulated therapy office environment where a prerecorded clinician delivered CBT-based psychoeducational content focused on stress physiology, cognitive appraisal, maladaptive thought patterns, and coping strategies. This immersive format was designed to enhance attentional engagement and contextual encoding of therapeutic material. Second, mindfulness-based VR sessions transported participants to simulated natural environments (eg, forests and beaches), where guided practices such as breath awareness, body scan, muscle relaxation, and compassion exercises were delivered within biophilic settings to promote attentional stabilization and relaxation.

VR module completion was automatically tracked through the app backend. To initiate immersive playback, participants were required to grant gyroscope and rotation permissions, activating head-tracking mode. VR videos could not be fast-forwarded, and module completion status was recorded only after full playback duration. Progression to subsequent modules required completion of prior modules. Backend logs captured the playback duration and activation of immersive mode. As is typical in remote digital health interventions, direct verification of sustained headset wear or continuous visual attention was not feasible. Self-reflective journaling modules reinforced the integration of psychoeducational and mindfulness content by prompting participants to identify stress triggers, bodily sensations, and cognitive responses.

In addition to the structured program, the app provided access to 30-minute online coaching sessions. Each participant in the intervention group was allowed to schedule up to 3 sessions during the 8-week participation period. Coaches were non–US-licensed psychologists based in Argentina, trained in CBT, and followed a protocol developed to support the MR intervention. The protocol promoted engagement with the MR modules aligned with the participants' needs at the time of the coaching session. The control group received no active intervention throughout the study period.

Primary and Secondary Outcomes

The primary study outcome was perceived stress, measured by PSS-10, a widely used, validated, and easy-to-use questionnaire [34,40,41]. The PSS-10 includes 10 questions, each scored from 0 to 4. A sum score is calculated as the total PSS score, with a higher score indicating a higher stress level. Secondary outcomes were also collected via surveys, including resilience, anxiety, depression, and QoL. Resilience was measured using the Connor-Davidson Resilience Scale–2 (CD-RISC2), with a total score ranging from 0 to 8, where higher scores indicate greater resilience [42]. Anxiety symptoms were assessed using the Generalized Anxiety Disorder-7 scale (GAD-7), and depressive symptoms were measured using the Patient Health Questionnaire–9 (PHQ-9). Both instruments evaluated symptom frequency over the past 2 weeks using a 4-point scale with answer options as follows: 0="Not at all," 1="Several days," 2="More than half the days," and 3="Nearly every day." Total scores range from 0 to 21 for the GAD-7 and 0 to 27 for the PHQ-9, with higher scores indicating greater symptom severity [43-46]. QoL was measured using the General Well-Being Schedule (GWS), which comprises 18 items assessing psychosocial well-being; higher scores indicate better overall

XSL•FO
RenderX

QoL [47-49]. All measures have demonstrated good reliability and validity in adult populations and have been widely used in young adults of the study cohort [41,50-52]. Assessments for all outcomes were conducted at baseline and again at 8 weeks after the conclusion of the intervention.

Covariates

Demographic variables were collected from the participants at study enrollment, including age, sex (male vs female), race and ethnicity (Asian, Black, other, Hispanic, or White), student status, and health insurance status (public, private, or none). Age and student status were examined to account for potential differences in digital program use, as recent systematic reviews have indicated that these factors significantly influence adherence to digital health interventions [53,54]. Additionally, race and ethnicity were explored to assess potential differences in intervention outcomes. Reports and studies have shown that mental health outcomes and stress exposure differ across racial and ethnic groups in New York City, with structural and environmental inequities contributing to higher psychological distress among Black and Latino adults [55-57]. A previous study has also indicated that insurance status may affect mental health conditions [57].

Statistical Analysis

Demographics were summarized by treatment group, and chi-square tests were used to examine differences in categorical variables by intervention status. A 2-tailed *t* test was used to compare age between the intervention and control groups. Additional comparisons were conducted between individuals who enrolled in the study and those who were eligible but did not participate, as well as between participants who completed the follow-up assessment and those who were lost to follow-up.

Linear mixed-effects models with repeated measures were used to regress primary and secondary outcomes on time, intervention, and the interaction between time and intervention. The models also included fixed effects for sex, as sex was used for block randomization. With 2 waves of data collection, a compound symmetry covariance structure was used. Other covariates that were balanced between the 2 groups were not included in the model.

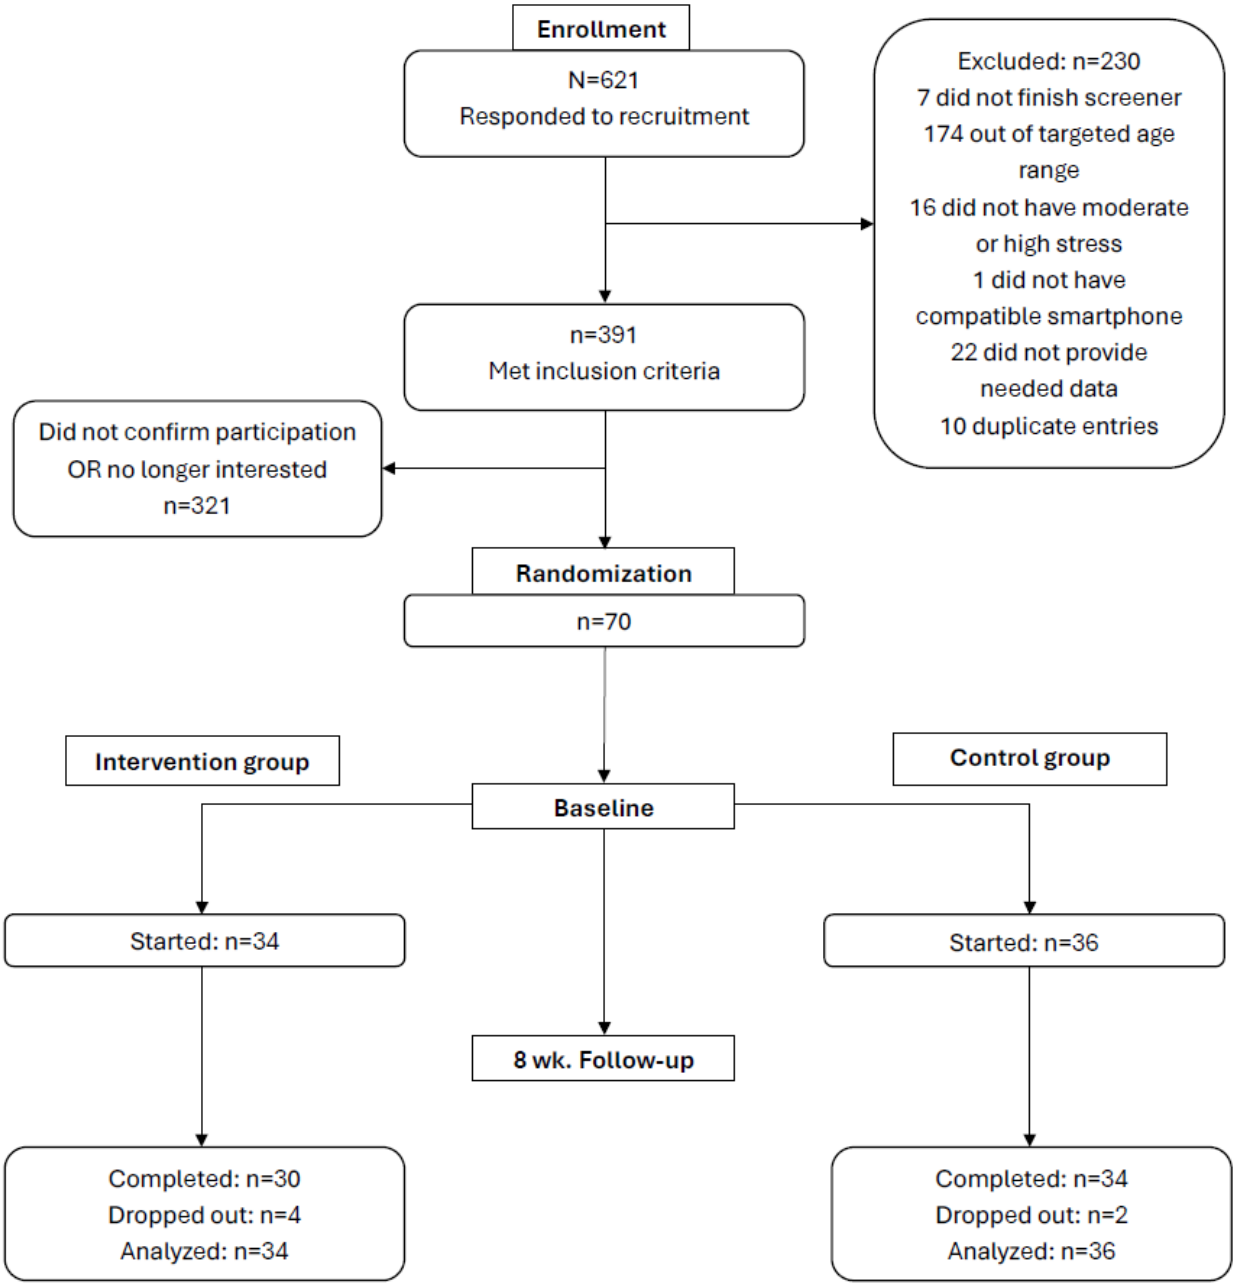
In the secondary analysis, we also examined whether program engagement was associated with improvements in outcomes. Changes in scores for the primary and secondary outcomes were first calculated as the difference between follow-up and baseline measurements and then modeled as a function of program engagement. Program engagement was assessed by the percentage of module completion and the number of in-person coaching sessions attended. Both variables were analyzed as continuous and categorical variables, with each specification evaluated in a separate regression model. When analyzed as categorical variables, the percentage of module completion was divided into quartiles, and the number of coaching sessions was dichotomized as <2 sessions vs ≥2 sessions.

The primary analysis was conducted on an intention-to-treat (ITT) basis. No participants with relevant observed data were excluded, and the analysis followed the participants' assigned group, regardless of the actual treatment or dose received. The secondary engagement analysis, which modeled change scores as a function of the dose received, was restricted to participants with both baseline and follow-up measurements. Statistical analyses were performed using R (version 4.4.1; R Foundation for Statistical Computing) [58,59]. The α level was set at .05.

Ethical Considerations

The study was approved by the City University of New York Institutional Review Board (2023-0338-PHHP), which determined the study to be of minimal risk. This study was registered at ClinicalTrials.gov (NCT06970652). All participants were provided with detailed information regarding the study's purpose, procedures, potential risks and benefits, data confidentiality, and their rights as research participants. Informed consent was obtained electronically through REDCap prior to study participation.

Participation was entirely voluntary, and participants were informed that they could withdraw at any time without penalty. To protect privacy and confidentiality, data were deidentified before analysis, and only the research team had access to the final analytic dataset. Personally identifiable information was stored separately from study data on secure, password-protected servers. Participants who completed all 8 weeks of the study and provided postintervention data were compensated with a US $50 electronic gift card.



Results

Sample Characteristics

A total of 621 individuals responded to the online recruitment, of whom 230 were excluded based on the study's inclusion and exclusion criteria. Among the remaining respondents, 283 individuals completed the consent form, and 70 enrolled in the study and were randomized to either the intervention or control group. Figure 1 shows the sampling flowchart. Demographic comparisons between participants who enrolled and those who were eligible but did not enroll are shown in Table S1 in Multimedia Appendix 1.

XSL•FO
RenderX

Figure 1. CONSORT flow diagram.

Of the 70 enrolled participants, 34 were randomized to the intervention group and 36 to the control group. The mean age was 23.4 (SD 3.41) years, and the majority were female (n=52, 74%). Forty-six participants were college students, and 63 reported health insurance coverage, either private (n=24) or public (n=39). We found no significant differences in demographic variables between the intervention and control groups at baseline (all $P>.05$; Table 1). Six participants dropped out of the study and failed to provide postintervention data (n=4 in the intervention group; n=2 in the control group). Additional comparisons showed no demographic differences between those who were lost to follow-up and those who provided follow-up data (Table S2 in Multimedia Appendix 1).

Table 1. Demographic characteristics of study participants (n=70).

Characteristics	Overall	Control group (n=36)	Intervention group (n=34)	*P* value
Sex, n (%)				.89
Male	18 (26)	9 (25)	9 (26)	
Female	52 (74)	27 (75)	25 (74)	
Student status, n (%)				.56
Not a student	24 (34)	14 (39)	10 (29)	
Student	46 (66)	22 (61)	24 (71)	
Insurance status, n (%)				.68
Public	39 (56)	22 (61)	17 (50)	
Private	24 (34)	11 (31)	13 (38)	
None	7 (10)	3 (8)	4 (12)	
Race and ethnicity, n (%)				.18
Asian	24 (34)	12 (33)	12 (35)	
Black	9 (13)	4 (11)	5 (15)	
Hispanic	22 (31)	12 (33)	10 (29)	
White	11 (16)	8 (22)	3 (9)	
Other	4 (6)	0 (0)	4 (12)	
Age (years), mean (SD)	23.36 (3.41)	23.75 (3.51)	22.94 (3.30)	.32

Overall, the sample showed moderate levels of stress (PSS-10: mean 25.87, SD 4.84; 23/70, 33% with high stress), moderate resilience (CD-RISC2: mean 4.52, SD 1.50), moderate anxiety (GAD-7: mean 11.41, SD 4.61), moderate depression (PHQ-9: mean 11.99, SD 6.26), and severe distress (GWS: mean 55.66, SD 13.23). There were no significant differences between the intervention and control groups in perceived stress, anxiety, depressive symptoms, resilience, or QoL at baseline (all *P*>.05).

Primary Outcome

The intervention group showed a decrease in average stress scores from 25.92 (SE 1.03) at baseline to 18.21 (SE 1.03) after the intervention. Linear mixed-effects regression showed a significant interaction between the intervention group and time for PSS-10 (β=−3.84, SE 1.37; *P*=.007; Table 2).

Table 2. Mean scores for primary and secondary outcomes at baseline and follow-up (n=70)[a].

Outcomes	Control group (n=36), mean (SE)		Intervention group (n=34), mean (SE)		Interaction, β (SE)	*P* value
	Baseline	Follow-up	Baseline	Follow-up		
Perceived Stress Scale–10	25.25 (0.96)	21.38 (0.98)	25.92 (0.98)	18.21 (1.03)	−3.84 (1.37)	*.007* [b]
Connor-Davidson Resilience Scale–2	4.68 (0.28)	4.81 (0.27)	4.33 (0.27)	5.29 (0.29)	0.83 (0.43)	.06
Generalized Anxiety Disorder–7 scale	11.43 (0.84)	9.68 (0.85)	10.98 (0.85)	6.02 (0.89)	−3.21 (0.97)	*.002*
Patient Health Questionnaire–9	12.15 (1.14)	10.42 (1.15)	11.78 (1.16)	6.93 (1.20)	−3.13 (1.13)	*.007*
General Well-Being Schedule	55.31 (2.53)	59.72 (2.56)	56.65 (2.57)	71.05 (2.67)	9.99 (2.92)	*.001*

[a]Reported means and interaction estimates were derived from linear mixed-effects models that included intervention, time, sex, and the time×intervention interaction.

[b]Italicized *P* values indicate statistical significance.

Secondary Outcomes

The intervention group showed significant reductions in GAD-7 and PHQ-9 scores and significant increases in CD-RISC2 and GWS scores from baseline to follow-up. Significant interactions were also observed for GAD-7 (β=−3.21, SE 0.97; *P*=.002), PHQ-9 (β=−3.13, SE 1.13; *P*=.007), and GWS (β=9.99, SE 2.92; *P*=.001), but not for CD-RISC2 (β=0.83, SE 0.43; *P*=.06). Detailed results from the sex-adjusted models are shown in Table 2, and results from the unadjusted models are provided in Table S3 in Multimedia Appendix 1.

XSL•FO
RenderX

Intervention Use

At the end of the intervention period, participants in the intervention group completed an average of 35% of the MR program. When examining the relationship between changes in outcomes and the percentage of modules completed, we did not find a significant interaction between time and the percentage of modules completed. Module completion was also not a significant predictor of changes in outcomes when examined by quartile. The average number of assisted coaching sessions used by participants in the intervention group was 1.3 out of a maximum of 3. Among individuals who attended any coaching sessions, the average number of sessions used was 2.2. No associations were found between the number of coaching sessions and changes in the primary and secondary outcomes. Study participants reported no harmful or unintended consequences.

Discussion

Principal Findings

This pilot study aimed to explore the feasibility of mobile VR technology as a potential tool for reducing stress and managing anxiety among young adults. The results showed that after 8 weeks of using a VR-based mindfulness program, the intervention group had significant reductions in stress, anxiety, and depressive symptoms and an increase in QoL.

Our findings are consistent with those of the limited previous studies demonstrating that VR technology, particularly mobile VR, is effective in reducing stress and managing mental health challenges. Gao et al [28] found that the use of mobile VR led to a reduction in stress. Similar findings were reported by McGarry et al [60], who found that mobile VR reduced psychological stress and was perceived as a useful and effective strategy for stress management by young adults aged 18 to 25 years. These 2 studies, however, did not have an active control group. In contrast, a mixed methods study with a control group that examined the short-term pre-post intervention effect on psychological well-being also reported a large decrease in stress, anxiety, and sadness in the intervention group [30]. These findings should be interpreted cautiously, as all 3 studies were limited to sample sizes of <20 participants and brief VR exposures ranging from a single session to a maximum of 14 days. Furthermore, these studies focused on generic VR apps that used scenery for relaxation, whereas our study used an integrated app designed for stress reduction through a CBT-based structured protocol.

Despite the positive findings from our study, participant engagement remains an important area for improvement. The average completion rate of VR sessions was 35% in this 8-week, 76-module intervention. Although modest, this level of completion is consistent with adherence patterns observed in multiweek, self-directed digital mental health programs, where attrition over time is common and full completion rates often fall within similar ranges (reported ranges of 0.5% to 28.6%), particularly in the absence of performance-based incentives [61]. Digital mindfulness and CBT interventions frequently demonstrate a progressive decline in engagement across sequential modules, especially in young adult populations [30,62]. In the present study, the requirement to complete modules sequentially and, for 40 modules, to set up immersive VR hardware may have introduced additional user burden relative to purely smartphone-based apps. Although monthly coaching sessions were incorporated to support adherence, the frequency of support may not have been sufficient to fully counteract typical digital attrition. Future iterations may benefit from increased personalization, adaptive pacing, or gamification strategies to enhance sustained engagement.

Our study did not find a dose-response relationship. In the regression models examining the preintervention and postintervention changes as a function of module completion, there was a trend in which participants in the highest quartile had the greatest reduction in PSS-10, GAD-7, and PHQ-9 scores compared to those in the lowest quartile. However, the differences did not reach statistical significance. Although dose-response relationships have been observed in VR interventions for other conditions such as PTSD and chronic pain, there is a lack of consensus regarding such relationships in VR-based stress management [63,64]. Future studies should explore effective engagement strategies and dose-response effects to strengthen VR-based stress management programs.

The ways in which VR reduces stress and anxiety are likely to be multifaceted. VR creates an immersive environment that can transport users to calm, relaxing settings, and this immersion can help redirect users away from real-world stressors and promote relaxation [65,66]. The VR app used by our participants incorporated guided imagery and relaxation techniques, such as deep breathing exercises and mindfulness practices. In addition, the program also facilitated psychoeducational content grounded in CBT. These techniques help users build coping skills, reduce stress responses, and achieve relaxation [65].

Unlike the significant findings for stress, we did not find a significant improvement in resilience associated with MR. Resilience, defined as the ability to adapt to adversity, is a critical component of mental health and well-being [67]. However, resilience may be influenced by a broader range of factors beyond the scope of our intervention, such as long-term life experiences, social support, and personality traits, which may require more extended or targeted interventions to observe measurable changes. There is a limited body of research examining resilience as an outcome of VR-based stress interventions, but given the potential of resilience to buffer against a poor ability to cope with stress, further research in this area is warranted.

An important observation from our study is the improvement in self-reported QoL following the intervention. QoL is a multifaceted construct of well-being, encompassing physical, psychological, and social dimensions [68]. Stress and anxiety are known to be negatively associated with QoL, contributing to emotional instability, cognitive difficulties, and possibly impaired social interactions [69]. Studies have shown that interventions aimed at reducing stress can improve QoL [27]. This study provides further evidence supporting the relationship between stress and QoL. Unlike generic relaxation VR, which typically consists solely of passive, scenery-based relaxation audiovisual components without targeted educational or skill

XSL•FO
RenderX

training content, the intervention used in this study was designed for stress management with structured techniques and guided practices. This targeted approach may be more effective than generic relaxation VR in improving psychological well-being and stress management. Future research should explore how integrating adaptive content and personalized engagement strategies can further optimize VR interventions for sustained improvements in QoL.

As VR technology continues to evolve, its integration into mental health care systems offers more possibilities. Mobile VR solutions, in particular, are advantageous due to their high accessibility and portability, making them widely available and suitable for individuals regardless of location [70]. Furthermore, the increasing prevalence of telehealth provides an opportunity to complement remote therapy with VR-based interventions, offering individuals accessible tools for managing psychological distress at home. The feasibility and cost-effectiveness of integrating VR into existing mental health care services will be an important next step toward maximizing VR's potential impact.

Strength and Limitations

Although this study used an RCT design, several limitations remain. First, our study had a small sample size and a relatively short study duration, limiting the ability to assess the intervention's long-term effects. Participants were not blinded due to the nature of the VR intervention, which may introduce expectancy effects in both the intervention and control groups. Although we observed significant reductions in stress, anxiety, and depressive symptoms over the trial period, the duration of these effects remains uncertain. Additionally, all outcomes were measured using self-reported surveys, which may be subject to reporting bias. The generalizability of our findings is also limited by the self-selected nature of our sample, which consisted primarily of young adults in New York City. The inclusion criteria were necessary to account for confounders but may have inadvertently excluded individuals who would benefit from the intervention in real-world settings. Although many eligible individuals did not proceed to randomization, this attrition occurred between screening and in-person equipment collection, suggesting that logistical requirements may have posed a barrier to study participation. Further research with larger, more diverse samples and extended follow-up periods is necessary to determine the sustained benefits of VR-based stress management interventions over time.

Conclusions

This study provides preliminary evidence supporting the use of mobile VR technology to reduce stress, anxiety, and depressive symptoms and to improve QoL among young adults. Given that this study had a moderate sample size, a low program completion rate, and a sample that was predominantly female, self-selected, and mostly urban, the generalizability of the study's results should be approached with caution. Future research should examine the efficacy of this VR app with larger, more diverse samples to assess its long-term mental health impact.

Acknowledgments

The authors thank all study participants who devoted their time to this study. The authors declare that no generative AI tools were used in the writing of this manuscript, and only the writing tool, Grammarly (Grammarly Inc) was used to suggest language improvements.

Conflicts of Interest

EG, NR, and CW are cofounders of MindCo Health, a start-up company that developed the MindCo Relief app used in this study. TH is affiliated with an investment fund that holds an equity interest in MindCo Health.

Editorial Notice

This randomized study was retrospectively registered. The authors noted that the registration was conducted retrospectively due to administrative oversight. The editor granted an exception from ICMJE rules mandating prospective registration of randomized trials, because the risk of bias appears low and the study information registered with authors' ethics committee matches the trial reporting. However, readers are advised to carefully assess the validity of any potential explicit or implicit claims related to primary outcomes or effectiveness, as retrospective registration does not prevent authors from changing their outcome measures retrospectively.

Abstract

Background: Prediabetes is highly prevalent and increasing globally, yet lifestyle interventions remain underused. AI-driven mobile health (mHealth) tools can help scale diabetes prevention efforts, but the key factors driving their success are not well understood.

Objective: This post hoc secondary analysis of a randomized controlled trial (RCT) aimed to characterize the most valued features and the role of user engagement in outcomes of a fully automated mHealth intervention for diabetes prevention.

Methods: Data from 151 participants with prediabetes and overweight or obesity who were assigned to an AI-based diabetes prevention program (Sweetch) in a parent RCT (NCT05056376) were analyzed. Engagement (defined as the total number of days the app was used) was categorized into tertiles (low, medium, and high). Baseline characteristics were compared across engagement groups using ANOVA, Kruskal-Wallis, and chi-square tests, and regression models assessed the association between engagement and achievement of diabetes risk reduction outcomes (≥5% weight loss, ≥4% weight loss with ≥150 min/week of physical activity, or ≥0.2 percentage point reduction in hemoglobin A_{1c} [HbA_{1c}] at 12 months). Perceived usefulness of intervention features was surveyed at 12 months.

Results: Median engagement was 98 (IQR 34-232) days. Older age (P<.001) and lower baseline BMI (P=.04) were significantly associated with higher engagement. Compared with low engagement, high engagement was associated with greater odds of achieving the composite diabetes risk reduction outcome (odds ratio [OR] 2.59, 95% CI 1.11-6.01; P=.03), ≥5% weight loss (OR 3.31, 95% CI 1.16-9.42; P=.03), and ≥0.2 percentage point reduction in HbA_{1c} (OR 3.57, 95% CI 1.19-10.75; P=.02). Participants most frequently rated weight tracking, physical activity tracking, and the digital body weight scale as the features that were most helpful for achieving their health goals.

Conclusions: Higher engagement with an AI-driven intervention requiring no human intervention was associated with improved diabetes risk reduction. Contrary to concerns about lower digital literacy, older adults engaged with the intervention more than younger adults. Features related to weight and physical activity tracking were most valued by patients in the program.

Introduction

Background

Mobile health (mHealth) technologies offer a promising modality for delivering diabetes prevention interventions at scale, with the potential to reach large populations at significantly lower costs than traditional, human-based interventions [1,2]. Various digital health tools, including mobile apps, web-based platforms, SMS text messaging, telemedicine, activity monitors, and voice calls, have been used to support diabetes prevention and weight management. These tools have yielded promising results in previous studies [3-5], and consequently, the Centers for Disease Control and Prevention (CDC) has recognized asynchronous, digital diabetes prevention programs (DPPs) within the National DPP framework [6].

Despite demonstrated efficacy in controlled settings, mHealth interventions have not translated into sustained real-world impact in diabetes prevention. Even with the availability of digital DPPs, which lower barriers to access compared with in-person programs, fewer than 1% of eligible adults participate in a DPP [7]. Engagement in intensive behavioral interventions is influenced by the perceived relevance, timing, and personalization of intervention content. With the emergence of AI, mHealth platforms have the potential to address these limitations by dynamically tailoring content delivery, feedback, and behavioral prompts to individual users at scale [8]. Unlike rule-based or static digital programs, AI-driven systems can adapt to user behavior over time, a capability that may enhance long-term engagement and increase participation. At the same time, skepticism persists regarding user willingness to engage with fully automated AI-based health interventions [9]. Concerns regarding trust and the perceived lack of human support raise important questions about whether AI-driven programs can sustain meaningful engagement over extended periods.

One such platform is Sweetch, an AI-driven, fully automated mHealth intervention that delivers personalized recommendations to promote physical activity and weight loss. A prior pilot study demonstrated the feasibility, acceptability, and short-term effectiveness of the Sweetch platform in adults with prediabetes [10]. A follow-up randomized, noninferiority clinical trial demonstrated that Sweetch was noninferior to the human coach–based DPP in reducing diabetes risk among patients with prediabetes [11]. However, beyond its clinical performance, the patterns, determinants, and perceived drivers of program engagement have not yet been examined. In addition, given the multicomponent nature of the Sweetch intervention, it remains unclear which features were perceived as most important in achieving these outcomes. Identifying these features may help inform the design and scaling of digital DPPs in the early stages of development [6].

Study Objectives

We conducted a post hoc secondary analysis of a randomized controlled trial (RCT) to evaluate engagement with and perceived feature-specific usefulness of the AI-driven DPP over a 12-month period. The objectives of this study were to (1) characterize longitudinal engagement with an AI-driven DPP and identify participant characteristics associated with higher engagement, (2) evaluate the association between engagement and clinical outcomes, and (3) assess participants' perceived usefulness of individual intervention features at the end of the intervention period. By elucidating how users interact with a fully automated AI-based DPP in real-world conditions, this study aims to inform the design, optimization, and scaling of future AI-driven diabetes prevention interventions.

Methods

Study Design and Population

The parent study was a multisite, pragmatic, parallel-group, 1:1 randomized noninferiority trial comparing a fully automated, AI-based DPP with a standard human-coached DPP over 12 months. Participants were randomized to either referral to an AI-powered DPP delivered through a mobile app and Bluetooth-enabled digital scale or referral to a CDC-recognized, human coach–led DPP delivered remotely over 12 months. The AI-led intervention provided personalized behavioral recommendations, educational content, self-monitoring tools, and adaptive push notifications without human coaching, whereas the comparator consisted of trained lifestyle coaches delivering the CDC PreventT2 curriculum through an initial core phase of 16 weekly sessions, followed by a maintenance phase of biweekly to monthly sessions. Both interventions were delivered independently of the study team after referral. The present study is a post hoc secondary analysis restricted to participants randomized to the AI-led DPP arm. The protocol and primary outcomes of the parent trial have been described elsewhere [11,12].

The parent trial was conducted from October 11, 2021, to December 16, 2024, with a planned 12-month follow-up for all participants. The 368 participants enrolled in the parent trial had laboratory-confirmed prediabetes and a race-specific BMI in the overweight or obese range (≥25 kg/m^2 or ≥23 kg/m^2 for Asian individuals). Exclusion criteria included a prior diagnosis of diabetes, severe cardiovascular conditions, factors affecting accuracy of hemoglobin A_{1c} (HbA_{1c}), cognitive or psychiatric barriers to participation, and conditions or medications expected to substantially affect body weight or blood glucose.

In the parent trial, eligible participants were randomized in a 1:1 ratio to the AI-based or human coach–led DPP using centrally administered REDCap (Vanderbilt University) software. Randomization was stratified by recruitment site and baseline HbA_{1c} (≤6% vs 6.1%-6.4%) using randomly permuted block sizes of 2, 4, and 8. The allocation sequence was

XSL•FO
RenderX

concealed from research coordinators responsible for participant enrollment and assignment until randomization occurred. Participants continued to receive routine medical care throughout the study. To minimize potential confounding, participation in other structured lifestyle interventions targeting nutrition, weight management, or diabetes prevention was not permitted, and medications expected to substantially influence body weight or glycemic control were prohibited during follow-up.

For this single-arm analysis, participants were included if they (1) were assigned to the AI arm of the trial and (2) had available outcomes data at 12 months. Participants were excluded from this analysis if they initiated any medications that could impact study outcomes during the intervention period, including antihyperglycemic agents, weight loss medications, or systemic steroids. No separate sample-size calculation was performed for this post hoc secondary analysis.

The clinical trial was conducted at 2 sites in the United States: Johns Hopkins Hospital, an urban tertiary academic medical center in Baltimore, Maryland; and Reading Hospital (Tower Health) in Reading, Pennsylvania, which serves a mixed urban, suburban, and rural population. The parent trial was prospectively registered at ClinicalTrials.gov (NCT05056376).

Outcomes

The parent trial prespecified a primary composite outcome assessed at 12 months, defined as maintenance of HbA_{1c} <6.5% throughout follow-up and achievement of at least 1 of the following: (1) ≥5% weight loss, (2) ≥4% weight loss plus ≥150 minutes/week of moderate-to-vigorous physical activity (MVPA), or (3) an absolute HbA_{1c} reduction of ≥0.2 percentage points. Secondary end points were the individual components of the composite primary end point; attainment of CDC-recommended weekly physical activity levels at 12 months; and continuous changes in body weight, HbA_{1c}, and average weekly physical activity over 12 months.

This secondary analysis focused on identifying factors associated with participant engagement and evaluating whether engagement level was associated with achieving end points related to weight loss, physical activity, and HbA_{1c} reduction. Thus, engagement served as the primary exposure variable, and the outcomes corresponded to the original end points from the parent trial.

Although the intervention incorporated Bluetooth-enabled devices and smartphone-derived data to support personalized recommendations, study outcomes were assessed independently. Body weight and HbA_{1c} were measured during study visits by trained research coordinators, and physical activity outcomes were derived from ActiGraph wrist monitors (Signant Health) worn for 7 consecutive days each month.

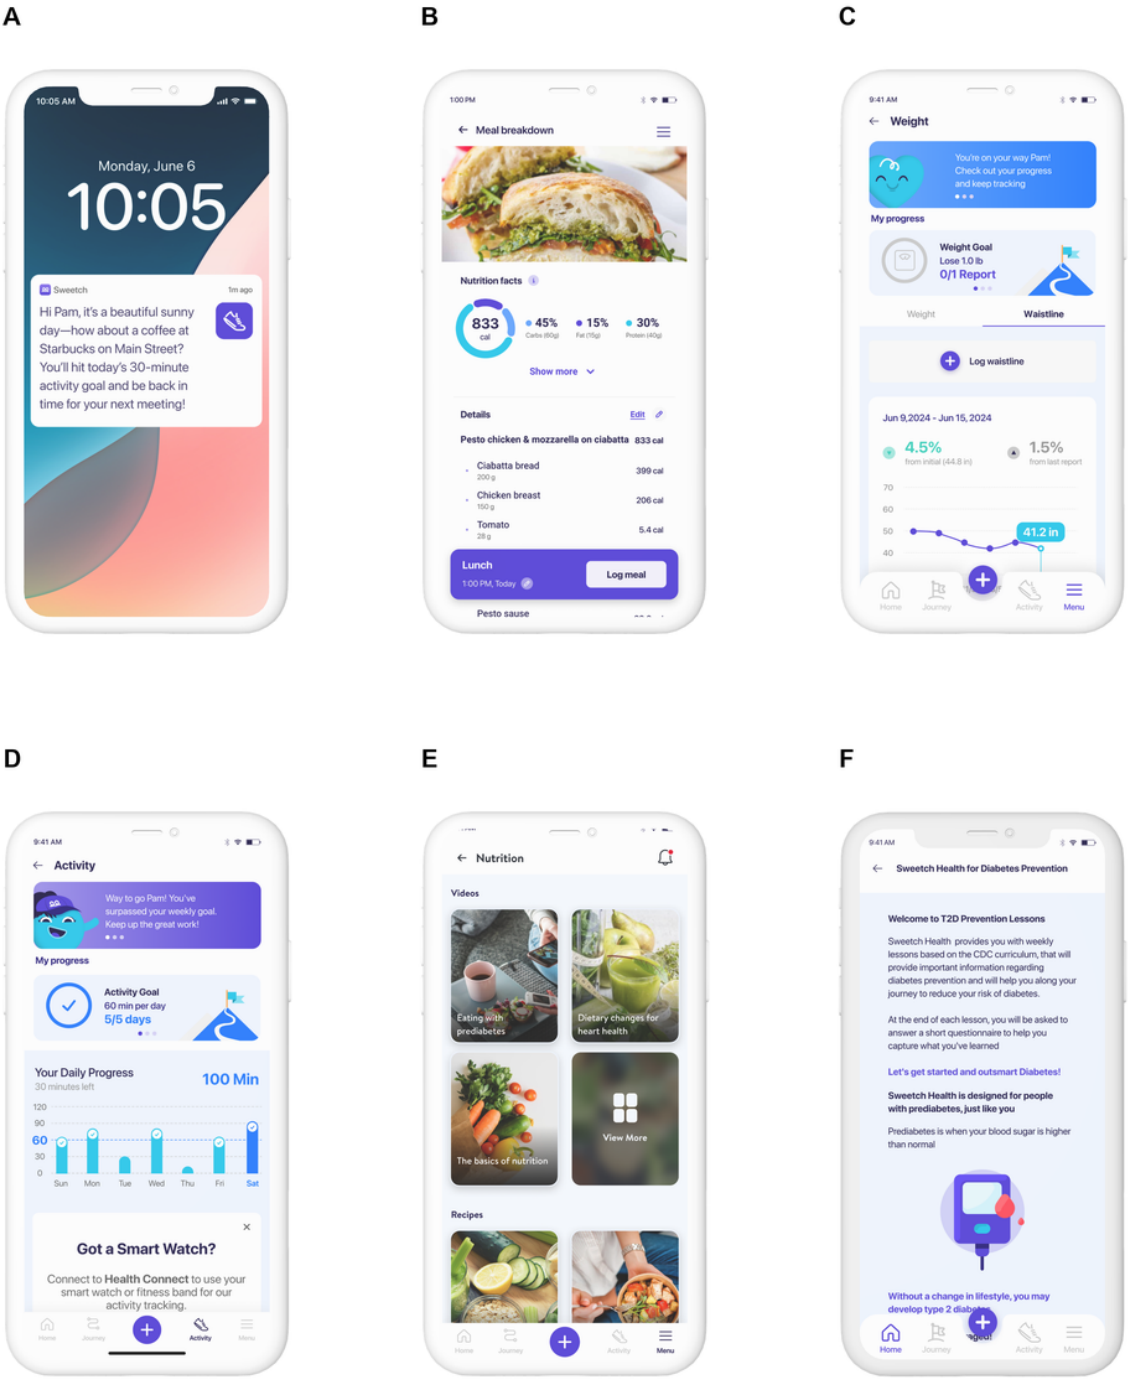
Engagement Definition and Data Collection

Engagement definitions were not prespecified because engagement data were collected passively by the manufacturer's platform, and the research team did not have access to these data until after trial completion. Participant engagement was automatically tracked by the Sweetch app (Sweetch Health Ltd) during months 1 to 11 of the trial and transferred to the research team after trial completion. Engagement was defined as the number of days over the course of the trial on which the Sweetch app was opened, and participants were categorized into tertiles based on cumulative use. Passive background processes (eg, automatic sensor data collection or data synchronization without opening the app) were not counted as engagement days. Engagement during month 12 was not included because participants completed their final study visits on different dates, resulting in unequal observation periods during the final month. Restricting engagement analyses to months 1 through 11 ensured a comparable exposure period for all participants before assessment of the 12-month outcomes. In addition, the number of days on which the app was opened in each month of the intervention period was assessed. Baseline characteristics were compared between engagement groups.

REDCap electronic data capture tools were used to collect participant baseline data and follow-up measures [12]. Baseline data were collected by trained research coordinators and included point-of-care HbA_{1c} measurements, height, weight, and demographics. Follow-up assessments at 6 and 12 months included repeat HbA_{1c} measurements, body weight, and surveys of perceived usefulness of intervention features. Physical activity was measured using ActiGraph wrist monitors worn for 7 consecutive days each month from randomization through month 11. MVPA was derived from raw accelerometer data using the Montoye wrist-worn cut point (≥3941 counts/min) [13]. Weekly MVPA was estimated as the mean across 11 monitoring periods.

Intervention Description

The AI-based DPP used in this study was Sweetch. Participants received a health kit from Sweetch Health Ltd within 8 to 12 days after randomization. The kit included a Bluetooth-enabled digital body weight scale and instructions for app registration and synchronization. To simulate real-world conditions, research staff did not intervene in participants' initiation or ongoing engagement with the app.



The intervention was fully automated, meaning that it was delivered without human coaching or scheduled human support after enrollment. Personalized recommendations and behavioral prompts were generated automatically by the AI-based platform, and use of the platform's features (eg, tracking tools and the health education library) was driven solely by the participants themselves.

The manufacturer was permitted to implement updates to the intervention during the study period (refer to Multimedia Appendix 1 for details on the timing and content of these updates).

The key features of the Sweetch intervention are displayed in Figure 1 and are summarized here.

XSL•FO
RenderX

Figure 1. Features of the Sweetch intervention. (A) Just-in-time adaptive push notification, (B) meal-logging screen with a nutrition breakdown, (C) weight-tracking dashboard showing trend and goal progress, (D) physical activity module summarizing daily and weekly activity, (E) nutrition content library featuring videos and recipes, and (F) educational lesson on type 2 diabetes prevention.

Push notifications enable personalized, real-time nudges promoting adherence to physical activity, weight management, and dietary goals (Figure 1A). These notifications are generated based on both active data inputs (eg, body weight and meal logging) and passive data inputs (eg, geolocation, smartphone accelerometer data, and calendar) and use a reinforcement learning algorithm that iteratively adapts its recommendations by assigning rewards or penalties based on user behavior [14,15].

Nutrition tracking allows structured meal logging, including options for manual entry using a food library and automated photo-based meal detection. This feature replaced self-rated meal quality assessments in previous versions of the app (Figure 1B).

Weight tracking tracks weight trends over time through a Bluetooth-enabled digital scale, manual entries, or synchronization from third-party platforms. Visual graphs and logs allow users to monitor progress, while seamless integration

XSL•FO
RenderX

with the Bluetooth-enabled scale ensures accurate, up-to-date data (Figure 1C).

Physical activity tracking automatically monitors users' daily activities using smartphone accelerometers or integrated wearable devices (eg, Apple Health and Google Fit; Figure 1B). Users can also manually log activities such as Pilates, yoga, and swimming. The app provides insights into activity levels and sets adaptive, personalized goals to encourage gradual improvement (Figure 1D).

An educational content library provides evidence-based resources and lessons on type 2 diabetes (T2D) prevention, accessible within the app interface (Figures 1E and 1F)

"My Achievements" tracks user progress by displaying milestones and rewarding positive behaviors, offering visual motivation to continue healthy habits

"My Challenges" presents tailored health goals for users to complete, fostering resilience and a sense of accomplishment with each task achieved

"My Competitions" introduces friendly competition by allowing users to compare progress with peers, enhancing motivation and accountability through engaging contests

"My Leaderboard" displays user rankings based on activity and achievements, promoting motivation and community engagement through visible progress tracking

Assessment of Perceived Feature Usefulness

After the intervention period (12 months), participants completed a survey assessing the perceived usefulness of specific app features in helping them achieve their health goals. The survey administered to participants is provided in Multimedia Appendix 1. Participants rated the following features on a 5-point Likert scale (1="strongly disagree" to 5="strongly agree"): push notifications, My Achievements, My Challenges, My Competitions, My Leaderboard, T2D prevention lessons, physical activity tracking, weight tracking, and the digital body weight scale. Four features were either discontinued before the trial (My Supporter and My Habits) or added during the intervention period (nutrition tracking and the educational content library) after survey finalization and were therefore not included in the feature usefulness assessment.

Statistical Analysis

Baseline characteristics were summarized using medians and IQRs for continuous variables and frequencies with percentages for categorical variables. Differences in baseline characteristics across engagement categories (low, moderate, and high tertiles of total app use days) were assessed using 1-way ANOVA for normally distributed continuous variables, Kruskal-Wallis tests for nonnormally distributed continuous variables, and the Pearson chi-square tests for categorical variables. Monthly engagement patterns were examined descriptively across engagement groups.

To evaluate associations between engagement and study outcomes, logistic regression models were used for binary end points, including the primary composite end point and its individual components (eg, ≥5% weight loss, ≥0.2 percentage point reduction in HbA_{1c}, and ≥4% weight loss combined with ≥150 minutes per week of physical activity), and linear regression models were used for continuous outcomes, including changes in body weight, HbA_{1c}, and mean physical activity from baseline to 12 months. As an additional analysis, engagement was modeled as a continuous exposure, defined as total app-open days over the 330-day study period and scaled per 10-day increase for interpretability. For all analyses evaluating HbA_{1c} change at 12 months, models were restricted to participants with a baseline HbA_{1c} in the prediabetes range (5.7%-6.4%).

We performed a targeted sensitivity analysis adjusting for baseline BMI, baseline HbA_{1c}, and baseline physical activity because these baseline measures correspond directly to the outcomes being evaluated (weight loss, HbA_{1c} reduction, and achievement of physical activity targets) and therefore could influence participants' likelihood of achieving the study outcomes. Additional adjustment for age, sex, race, education, and study site was not performed because the limited number of outcome events would have resulted in low events-per-variable ratios and an increased risk of model overfitting and unstable coefficient estimates.

Missing data were handled using a complete-case approach. Participants without 12-month outcome data were excluded from the analytic cohort. Analyses of perceived feature usefulness included only participants who completed the 12-month follow-up survey. There was no missing engagement data for any participant, as these data were collected continuously and automatically. No imputation of missing data was performed for this secondary analysis.

All statistical tests were 2-tailed, and a significance threshold of $P<.05$ was used.

Due to the post hoc nature of the study, these analyses were exploratory, and the findings are presented as hypothesis generating.

Ethical Considerations

The parent RCT (ClinicalTrials.gov; NCT05056376) was conducted in accordance with the Declaration of Helsinki and approved by the institutional review boards at Johns Hopkins Hospital and Reading Hospital (Tower Health). All participants provided written informed consent before randomization, and the original informed consent form and institutional review board approval permitted secondary analyses of the study data without additional participant contact or consent. This secondary analysis used deidentified data collected as part of the approved parent trial and did not require additional participant contact or consent. Participants received compensation for study-related assessments, as specified in the parent trial protocol [11,12]. No additional compensation was provided for this secondary analysis.

Results

Participants

Figure 2 illustrates participant flow from randomization through exclusions, resulting in 151 participants included in the final analytic sample; baseline characteristics are shown in Table 1. Participants were predominantly female and White, with high educational attainment and most being married or partnered. Recruitment occurred across 2 health systems. The median BMI was 32.3 (IQR 28.2-35.9) kg/m^2, and the mean HbA_{1c} at baseline was 5.8% (SD 0.3%).

Engagement Patterns During the Intervention Period

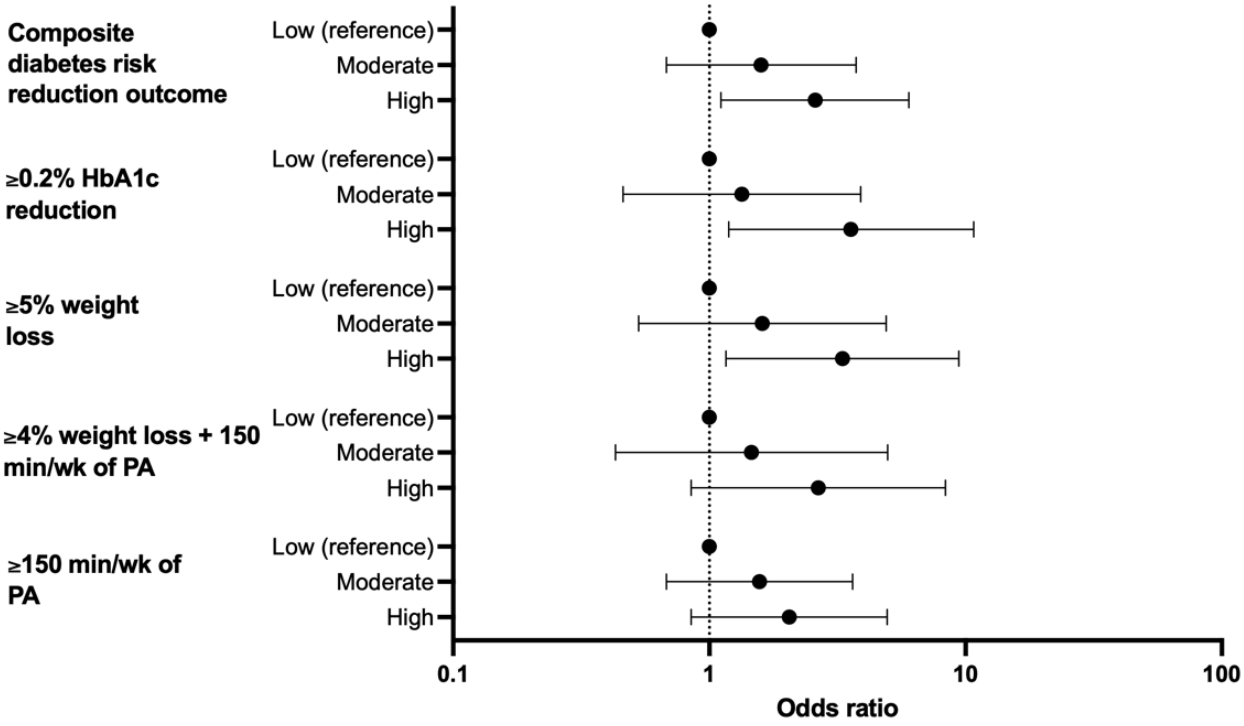
Table 2 shows the distribution of total days engaged throughout the trial. Median engagement was 98 (IQR 34-232) days. The distribution was roughly bimodal, and engagement tertiles were defined as low (≤49 open days), moderate (50-175 open days), and high (>175 open days). The median number of days engaged per month among the cohort was 9 (IQR 3-21) days. Monthly engagement patterns (showing the median number of days engaged each month among the cohort) revealed a gradual decrease in app engagement over time (Figure 3).

Table 2. Distribution of total days engaged during the trial period (N=151).

Days engaged during trial period	Participants, n (%)
0	22 (14.6)
30	23 (15.2)
60	20 (13.2)
90	13 (8.6)
120	11 (7.3)
150	10 (6.6)
180	4 (2.6)
210	8 (5.3)
240	9 (6)
270	8 (5.3)
300	9 (6)
330	14 (9.3)

Figure 3. Engagement with the intervention during the study period. The median monthly engagement trajectory for all participants is shown over the intervention period.

Factors Associated With Increased Engagement



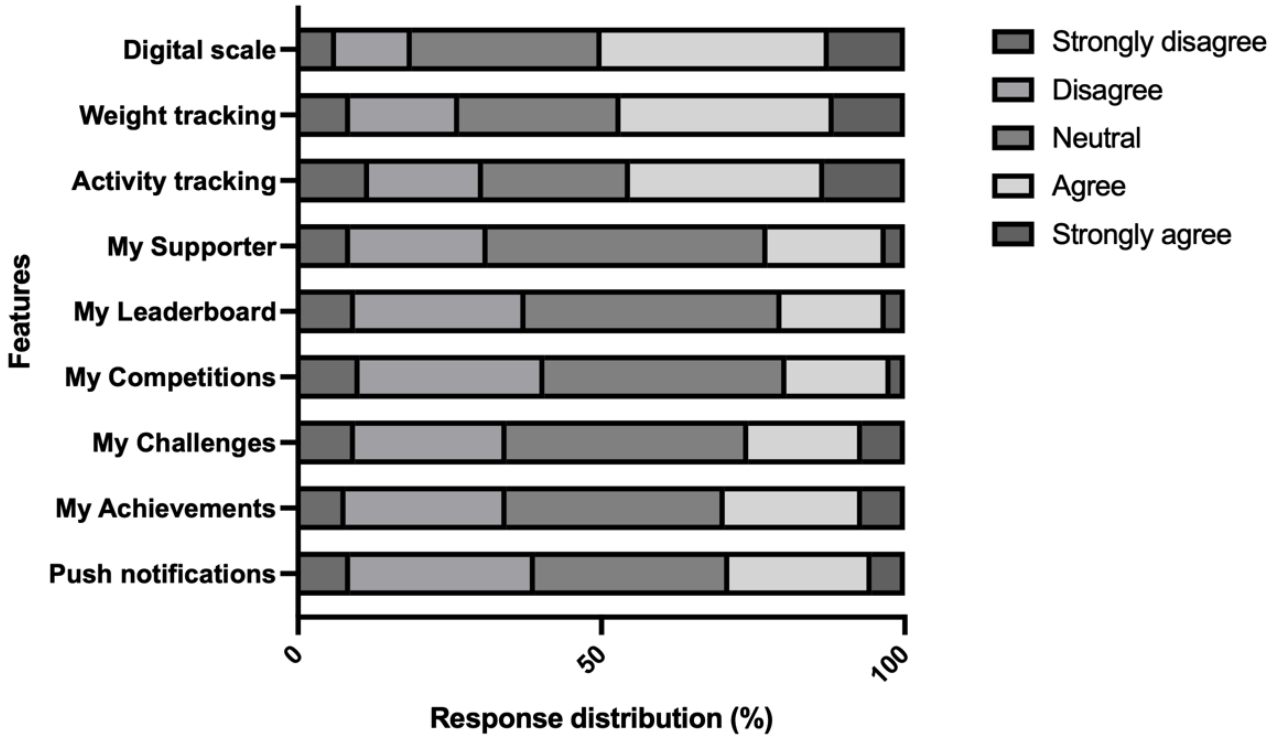
Several baseline factors were associated with engagement level. Participants in the low engagement group were significantly younger (median 52, IQR 42-63 years) than those in the moderate (median 63, IQR 55-68 years) and high (median 65, IQR 58-70 years) engagement groups (P<.001). They also had a higher median BMI (33.5, IQR 30.4-37.6 kg/m^2) than those in the high engagement group (30.8 kg/m^2, IQR 27.5-34.0; P=.04). There were no significant differences across engagement levels by sex, race, educational attainment, physical activity, or diet quality (Table S1 in Multimedia Appendix 1).

XSL•FO
RenderX

Association Between Engagement and Outcomes

Higher engagement was associated with greater odds of achieving the composite diabetes risk reduction benchmark (odds ratio [OR] 2.59, 95% CI 1.11-6.01; *P*=.03), ≥5% weight loss (OR 3.31, 95% CI 1.16-9.42; *P*=.03), and a ≥0.2 percentage point reduction in HbA_{1c} (OR 3.57, 95% CI 1.19-10.75; *P*=.02) compared with low engagement (Figure 4). Moderate engagement was not significantly associated with any outcome. Engagement level was not significantly associated with achieving ≥4% weight loss combined with 150 minutes per week of physical activity or with meeting the physical activity threshold alone. The sensitivity analysis of the primary composite outcome, adjusting for baseline BMI, baseline HbA_{1c}, and baseline physical activity, yielded results consistent with the primary analysis (Table S2 in Multimedia Appendix 1).

Figure 4. Odds ratios (ORs) for clinical outcomes at 12 months by engagement level. OR and 95% CI are shown for each engagement category, with low engagement as the reference group. Engagement categories represent tertiles based on the cumulative number of days the app was opened during the trial. HbA1c: hemoglobin A1c; PA: physical activity.



In linear regression analyses of continuous outcomes, high engagement was associated with greater weight loss at 12 months, whereas no significant associations were observed for changes in HbA_{1c} or physical activity (Table S3 in Multimedia Appendix 1). When engagement was modeled as a continuous variable, higher engagement was associated with modest increases in the odds of achieving the composite diabetes risk reduction outcome, ≥0.2 percentage point reduction in HbA_{1c}, and ≥5% weight loss, with no significant associations observed for physical activity outcomes (Table S4 in Multimedia Appendix 1).

User Preferences After 12 Months of Intervention

Survey data were available for 128 of 151 (84.8%) participants included in the analytic sample. Participants' perceptions of whether individual app features helped them achieve their goals are summarized in Figure 5, with corresponding raw counts and percentages reported in Table S5 in Multimedia Appendix 1. For several features, a neutral response was the most frequently selected among the 128 participants, including achievements (n=46, 35.9%), challenges (n=51, 39.8%), competitions (n=51, 39.8%), leaderboard (n=54, 42.2%), and T2D prevention lessons (n=59, 46.1%).

XSL•FO
RenderX

Figure 5. Perceived usefulness of features in the intervention. The horizontal stacked bar chart shows the percentage distribution of responses to survey items assessing whether each app feature helped participants achieve their goals. Responses were recorded on a 5-point Likert scale ranging from "strongly disagree" to "strongly agree." Each bar represents 1 feature and sums to 100% of responses (n=128 per item).

In contrast, tracking-oriented features elicited more favorable perceptions. For activity tracking, 58 (45.3%) participants reported agreeing or strongly agreeing, compared with 39 (30.5%) reporting disagreeing or strongly disagreeing. Similar patterns were observed for weight tracking, with 60 (46.9%) participants reporting agreeing or strongly agreeing. The digital scale demonstrated the most positive response distribution overall, with 64 (50%) participants agreeing or strongly agreeing.

For push notifications, among the 128 participants, 39 (30.5%) indicated disagreement, 41 (32%) were neutral, 30 (23.4%) indicated agreement, and 7 (5.5%) indicated strong agreement.

Discussion

Principal Findings

In this secondary analysis of an RCT, engagement (ie, greater amounts of app use) with an AI-led DPP was associated with achieving the CDC's diabetes risk reduction benchmark and recommended thresholds for weight loss and HbA_{1c} reduction. These findings reinforce app engagement as an important mechanism through which mHealth interventions may exert clinical benefit and extend prior digital health literature by demonstrating this relationship in the context of a fully automated AI-based program delivered over a year-long intervention period [3,16-18].

Factors Associated With Engagement

Engagement varied by participant characteristics. Older participants demonstrated higher levels of engagement, challenging assumptions that older adults engage less with digital health interventions [19,20]. This may reflect greater health motivation, more available time, or a stronger perceived need among older users. Participants with higher baseline BMI engaged less with the intervention, which may be a result of greater physical, behavioral, or psychological barriers to sustained self-monitoring and physical activity. Because participants with higher baseline BMI are at greater metabolic risk, lower engagement in this subgroup raises the possibility that additional tailoring, support, or re-engagement strategies may be needed to ensure that fully automated DPPs do not inadvertently widen disparities by preferentially benefiting individuals at lower metabolic risk.

Engagement with the intervention declined over time, which may reflect a natural waning of novelty, behavior change fatigue, and/or a perceived decline in the app's ongoing value. Alternatively, it may indicate that users acquired the knowledge or behavioral reinforcement they needed early on, reducing their reliance on the app over time. The Hawthorne effect, whereby initial behavior changes are driven by awareness of being observed, may also explain early spikes followed by tapering engagement [21]. The observed decline in engagement highlights the need for future work to identify strategies to maintain or re-engage users over time, particularly in longer-term prevention programs.

Interpretation of the Engagement-Outcome Association

This exploratory analysis identified an association between higher engagement with the intervention and a greater likelihood of achieving diabetes risk reduction outcomes. However, several alternative explanations should be considered. Participants who engaged with the app more frequently may have differed

XSL•FO
RenderX

systematically from those with lower engagement in ways not captured by measured baseline characteristics, including motivation, self-regulation, or readiness for behavior change. Reverse causality is also possible, as participants who experienced early weight loss or other positive reinforcement may have become more engaged over time rather than engagement itself driving these improvements. Consequently, the observed associations should not be interpreted as causal, and residual confounding cannot be excluded.

Notably, the engagement metric used in this analysis may not fully capture all aspects of intervention engagement. Some components of the Sweetch intervention, including meal logging, weight tracking, educational content, and progress monitoring, require active interaction with the app. In contrast, the AI-generated push notifications were designed to deliver personalized behavioral support passively and could influence participants without requiring the app to be opened. Furthermore, the lifestyle behaviors targeted by the intervention occur outside the app, meaning that behavior change initiated through either active or passive intervention components may be sustained without ongoing app interaction.

Perceived Usefulness of Features

Weight tracking, physical activity tracking, and use of the digital scale were more frequently endorsed as helpful in achieving health goals than social or gamified features, such as leaderboards and competitions, which were often rated as neutral. This aligns with findings from a large-scale evaluation of the NHS digital DPP, which found that participants most frequently engaged with tracking features, while peer support was rarely used [22].

Push notifications, which serve as the primary application for AI-driven personalization and are intended to approximate aspects of human coaching, were not perceived as among the most useful features, whereas participants more frequently endorsed self-monitoring features that do not rely directly on AI (eg, weight tracking, physical activity tracking, and the connected digital scale). These findings suggest that the contribution of AI-driven personalization to user engagement and clinical benefit remains uncertain and highlight the need for future studies to better define the most effective role of AI within digital DPPs.

In the context of the parent trial's demonstration of noninferiority to a human-coached DPP, these findings raise the possibility that comparable clinical benefit may have been achieved through mechanisms distinct from human support, with advanced, low-burden self-monitoring capabilities playing a central role. Other programs, such as Lark [23], have similarly adopted AI-based personalization through chatbot interfaces, reflecting a broader trend toward individualized digital experiences. However, the relative value of these features remains uncertain from the user perspective. As digital DPPs continue to scale, the findings from this study underscore the need to better understand how users interact with individual components and suggest that refining core tracking functionality may be as important as, or potentially more impactful than, expanding complex personalization systems.

Strengths

This study has strengths. It draws on prospectively collected data from a RCT with a 12-month follow-up period and high retention. Unlike prior studies that report engagement descriptively without treating it as a formal research end point, this study prospectively measured engagement, analyzed its association with clinical outcomes, and examined use patterns over time [24]. The pragmatic nature of the trial, specifically the absence of prompts from research staff to engage with the intervention, allowed participant behavior to more closely reflect real-world dynamics. The multisite design and diverse participant demographics enhance generalizability, and the use of validated, policy-relevant outcomes for diabetes risk reduction and objectively measured physical activity data strengthen the reliability of the findings.

Limitations

Our study has limitations. Because the research team did not have access to the engagement data structure until after trial completion, engagement definitions and analytic thresholds could not be prespecified. Consequently, this post hoc secondary analysis should be considered exploratory and hypothesis generating, and the observed associations warrant confirmation in prospectively designed studies. Residual confounding by measured baseline factors (eg, sex, age, race, and education) and unmeasured baseline characteristics (eg, health status, motivation, and readiness for behavior change) cannot be excluded. Given the limited number of outcome events, adjusted multivariable models were not constructed because of potential overfitting and unstable coefficient estimates. Engagement was defined solely by the number of days the app was opened, which may not capture the quality or type of user interaction, although this is a commonly used metric for measuring engagement in mHealth interventions [24]. Engagement was categorized using sample-dependent tertiles due to the lack of accepted criteria for thresholds of meaningful or adequate use, limiting interpretability and comparability across studies. Consequently, the definitions of low, moderate, and high engagement used in this study may not generalize to other digital interventions or real-world populations. In addition, feature usefulness was assessed only at the 12-month follow-up and may therefore not reflect the perspectives of participants who disengaged previously and did not complete the survey. Iterative updates to the Sweetch platform during the study period could have influenced user experience, engagement patterns, and participants' perceptions of individual intervention features, as not all participants were necessarily exposed to identical versions of the app throughout the study. Finally, the trial was conducted during the COVID-19 pandemic, which may have affected participants' health behaviors or ability to engage with the app.

Conclusions

In summary, this study found that higher engagement with a fully automated, AI-driven DPP was associated with clinically meaningful diabetes risk reduction outcomes. Engagement was notably higher among older adults and individuals with lower BMI, challenging assumptions about digital literacy barriers and suggesting possible differences in motivation or perceived

XSL•FO
RenderX

need. Among the app's features, integrated tracking tools, such as weight and activity monitoring, were rated most positively. Future research should further investigate the relative value of specific features within digital DPPs, particularly in fully automated platforms, and explore how such programs perform in broader real-world settings beyond the trial environment. As digital health interventions continue to expand, identifying the most effective and user-preferred components will be essential for designing scalable, cost-effective, and sustainable tools for diabetes prevention.

Acknowledgments

The authors thank the participants in this trial, particularly for their participation during the challenging period of the COVID-19 pandemic. The members of the AI-DPP Study Group are Nestoras N Mathioudakis, MD, MHS; Benjamin Lalani, BS; Mohammed S Abusamaan, MD, MPH; Adrian Dobs, MD, MHS; Jeromie Ballreich, PhD, MHS; Nisa Maruthur, MD, MHS; John McGready, PhD; Kristin Riekert, PhD; Amal Wanigatunga, PhD; Brian Kane, MD; Aliyah Shehadeh, BS; Defne Alver, BS, MHS; Benjamin Ringham, BS, MS; Fatima Vandi, BS, MS; Daniel Zade, BS; Pamela Morrero, CCRP; Amy Schiller, BS; Mary (Ellie) Alderfer, MSN, RN; Nae-Yuh Wang, PhD; Seth Martin, MD, MHS; and Sara Benjamin-Neelon, PhD, JD, MPH. The authors also thank the program directors and lifestyle coaches from the participating human coach-based diabetes prevention programs who implemented the intervention and provided attendance data to the coordinating center: Amanda Kulp, Chris Yocom, and Debbie Zlomek (Pottstown Medical Specialists Inc DPP); Dawn Batman, Tray Flynn, and Doreen Hespell (Montgomery County DPP); Megan Brown, Nicole Cronin, and Sahirmayi Chalimila (Brancati Center DPP); Mary Jane E Vaeth, Alexandra Morán, Dylan Blough, and Angela Ginn-Meadow (University of Maryland Medical Center DPP). The authors further acknowledge the team at Sweetch Health Ltd for their vision and successful delivery of the AI-led DPP: Yossi Bahagon, Miri Mishor-Goldenberg, Jennifer Meller, Noam Diamant, Bar Harpazi, Roy Sonnenberg, and Dana Chanan. None of these acknowledged individuals received direct compensation for their contributions. Generative AI (ChatGPT version 5.5; OpenAI) was used solely for ideation and brainstorming during manuscript preparation. It was not used to generate scientific content, interpret study findings, or draft the final manuscript. All final writing, revisions, and editorial decisions were completed and verified by the authors.

Data Availability

As of the time of this submission, the authors do not have institutional review board (IRB) approval to share this dataset. However, the consent language used in the study may permit the data to be submitted to a controlled-access repository (eg, Vivli) following deidentification and IRB approval of a change in research.

Funding

This study was funded by the National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK; grant R01DK125780). This study was also supported by the Johns Hopkins Institute for Clinical and Translational Research (ICTR), which is funded in part by a grant from the National Center for Advancing Translational Sciences (NCATS; grant UL1TR001079), a component of the National Institutes of Health (NIH), and the NIH Roadmap for Medical Research. The funders had no role in the study design, data collection, data analysis, interpretation of the results, writing of the manuscript, or the decision to submit the manuscript for publication.

Abstract

Background: Relaxation-based mobile health (mHealth) interventions hold strong potential to address perioperative anxiety and pain management in a scalable manner. However, there is limited research on how surgical patients engage with these interventions and what aspects may be most helpful.

Objective: This study had 3 goals: (1) explore how users interact with a relaxation-based mHealth intervention during the perioperative period; (2) understand how user performance and perceptions relate to perceived benefits; and (3) identify design considerations to enhance user engagement and behavior change outcomes in mHealth interventions.

Methods: We conducted a prospective longitudinal cohort, mixed methods study to evaluate user engagement with MiCarePath, a relaxation-based mHealth intervention. A total of 19 perioperative patients (mean age 41.3 years; 14/19, 74%, female) undergoing elective surgery and reporting sometimes-to-always anxiety were enrolled using 3 recruitment methods. Participants used the app from 10 days before surgery to 4 weeks after surgery. We collected quantitative data on video engagement metrics (eg, duration of watching, response rate to video prompts) and ecological momentary assessments of anxiety and pain. Concurrently, we conducted semistructured, data-prompted interviews at 3 time points to assess user perceptions. These data were integrated using descriptive statistics, repeated-measures ANOVA, and qualitative thematic analysis to examine the relationship between user performance and perceived benefits.

Results: Eleven participants reported developing or improving relaxation-based self-management strategies (high benefit), whereas 8 reported little benefit from the intervention. The high-benefit group showed significantly greater total watching time (difference 223.8 minutes, 95% CI 95.54-366.46 minutes, P<.001), higher adherence to video prompts (73.45% vs 34.60%, P<.001), and greater perceived helpfulness of the content (79.80% vs 25.50%, P<.001) compared with the low-benefit group. A significant group-by-time interaction effect was observed for engagement ($F_{1,17}$=17.02, P<.001). No difference was observed in delay in response to video prompts. However, within each group, participant perceptions were not fully reflected in performance. Some participants in the high-benefit group showed decreased video watching after surgery but still reported feeling engaged with the intervention. Interview data revealed that “intentional use” behavior—where users actively seek content to manage

XSL•FO
RenderX

symptoms independent of prompts—distinguished these participants. Those who developed intentional use were able to practice relaxation techniques without the app and resume app engagement following contextual disruptions.

Conclusions: This study explored user engagement with a relaxation-based mHealth intervention for perioperative care, advancing the literature by integrating user perceptions and performance for digital anxiety and pain management. Results indicate that perceived benefit may not always be reflected in user performance. Intentional use emerges as a promising indicator of effective mHealth engagement in perioperative care. Future designs should aim to foster intentional use through features such as reflection prompts and adaptive notifications. Future work should also develop computational models to detect intentional use and evaluate adaptive interventions in larger cohorts.

mHealth intervention; perioperative anxiety; pain management; user engagement; relaxation; mindfulness

Introduction

Background

Preoperative anxiety is common and closely intertwined with pain experiences both before and after surgery. It affects a significant proportion of individuals across different ages and health conditions, with estimates suggesting that up to 50% of patients experience heightened anxiety in anticipation of surgery [1]. Some studies report even higher rates, with up to 80% of patients across different surgical fields experiencing anxiety due to elevated stress and fear of surgery [2]. The experience of preoperative anxiety, if not addressed in a timely and appropriate manner, often extends throughout the entire perioperative period. Greater preoperative anxiety is associated with adverse outcomes, including increased patient-reported pain, prolonged opioid use, and postoperative misuse [3-6]. These interrelated challenges pose a substantial clinical burden, increasing both clinical workload and patient morbidity [7]. Despite the severity of the problem, managing both anxiety and pain throughout the perioperative period remains a critical challenge. Unlike general chronic disease populations, perioperative patients often face unique, acute stressors that complicate self-management. These include physical mobility restrictions, the cognitive load of managing new medication regimens (eg, opioids), and the emotional burden of anticipated surgical outcomes, all of which significantly complicate recovery for patients undergoing surgery [3,8].

In recent years, mobile health (mHealth) interventions have been shown to promote well-being through personalized care and behavioral support [9-11] and have the potential to improve perioperative outcomes by delivering interventions that support healthy behaviors [10,12]. With integrated educational and psychological strategies delivered via an mHealth platform, patients can receive support without the need for additional clinical appointments or programs [13,14], allowing more time to build resilience and receive behavioral support before and after surgery [15]. Some interventions focus on behavioral pain management and self-regulation, helping patients actively participate in their recovery and pain control [16,17]. A growing number of intervention apps have adopted a relaxation-based approach, leveraging evidence-based mind-body techniques to alleviate perioperative anxiety and pain [18]. These include guided mindfulness, breathing exercises, meditation [19], progressive muscle relaxation [20], and music-based interventions delivered via digital devices [21]. Emerging evidence suggests that these technologies show promise in supporting patients' emotional and physical well-being in a scalable manner during the perioperative period.

Research Gap

While mHealth interventions show promise for managing preoperative anxiety and pain, sustained user engagement remains a major challenge in this and most mHealth settings [22-26]. User engagement refers to interaction with and use of mHealth tools and can be measured by user perceptions and performance [22,23]. The effectiveness and desired outcomes of mHealth interventions are often hindered by poor uptake [27], early attrition [28], significant declines in adherence over 4-8 weeks of an intervention [29], intentional nonadherence to the intervention [30], and even abandonment [23] (eg, [29,31,32]). While broader mHealth studies have examined engagement, there is a scarcity of studies examining both user performance and perceptions in relaxation-based interventions for surgical patients [15,20,33]. Prior work often focused on general populations or chronic conditions, lacking the specific context of the acute perioperative phase and longitudinal data tracking usage from presurgery to recovery. Consequently, the intersection of objective usage metrics and subjective user experience remains underexplored in the perioperative patient population.

Given the acute stress of surgical anticipation, significant time constraints, and the physical burden of postoperative pain, these patients often navigate competing medical priorities that may limit their capacity to engage with digital tools [34,35]. Consequently, prior research on digital interventions for pain and anxiety management in surgical settings has reported low uptake and high attrition due to substantial time demands and emotional burden [16,34]. However, existing studies have relied heavily on quantitative metrics (eg, system usage data) to assess these challenges, often neglecting the affective and cognitive dimensions of the user experience [35]. Taken together, only a few studies have examined both user performance and perceptions through a longitudinal lens specifically within the acute perioperative phase, as most research focuses on general wellness or chronic conditions. This gap is particularly significant for perioperative patients, whose unique stressors and needs may shape their interaction with mHealth interventions for anxiety and pain management. Thus, a comprehensive understanding of the relationship between

XSL•FO
RenderX

objective usage and subjective experience remains underexplored in this population.

To address this gap, we investigated perioperative patient engagement with a relaxation-based mHealth intervention, MiCarePath. MiCarePath was designed to provide perioperative patients with low-cost, engaging education and relaxation-based exercises to help reduce both anxiety and pain. It includes 3 short educational videos about surgery in general (eg, what to expect, pain as a normal part of healing), the role of anxiety in the experience of pain, the use of opioids and other strategies to mitigate surgical pain, and the potential benefits of learning behavioral skills to reduce anxiety and pain. MiCarePath also includes self-directed, evidence-based relaxation exercises, such as guided imagery meditation videos and deep breathing training, which have been demonstrated to reduce perioperative anxiety and pain [3,4]. In addition, MiCarePath incorporates ecological momentary assessments of anxiety and pain, as well as questionnaires to measure health and behavioral outcomes (eg, pain, anxiety, self-management strategies) at different time points during the study.

Regarding user performance, we primarily focused on the length of interaction with different videos, the delay in responding to video prompts, and the response rate to video prompts. To examine user perceptions, we conducted semistructured interviews informed by the data-prompted interview approach [36] both before and following surgery. We used video engagement data, momentary anxiety and pain levels, and feedback related to the relaxation videos to probe participant decision-making and actions in response to video prompts. Findings from this study will inform the design of relaxation-based interventions for perioperative anxiety and pain management and enhance understanding of user perceptions and performance with such interventions.

Objective

We aimed to better understand perioperative patients' engagement with a relaxation-based mHealth intervention. We examined both user perceptions and performance during the pre- and postsurgical periods. This understanding is critical for designing more effective, patient-centered interventions that promote adherence and improve clinical outcomes. We conducted a mixed methods analysis to address the following research questions: (1) How do patients act on video prompts and engage with relaxation exercise videos during the perioperative period? (2) How can user perceptions and performance be aligned with an intervention to better understand user engagement? and (3) How might mHealth interventions be better designed to enhance user engagement and ultimately improve behavioral outcomes?

Methods

Intervention Design: The MiCarePath App

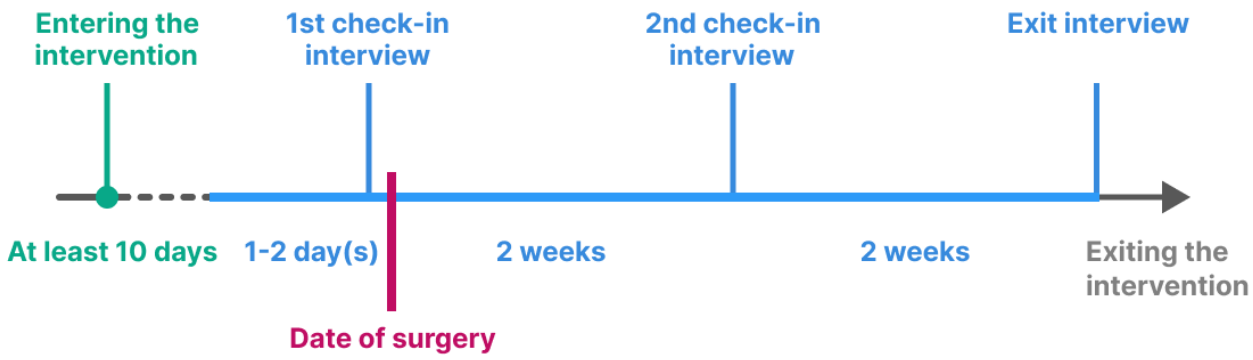
The MiCarePath app was designed to help surgical patients manage perioperative anxiety and pain through education and the teaching of relaxation skills. The app was built using MyDataHelps [37], a research platform that enables survey data collection and the delivery of mHealth interventions. The MiCarePath intervention included 5 components: (1) 3 surgery-related educational videos assigned to participants at the start of the intervention, covering expectations for surgery, safe opioid use, and the benefits of learning anxiety and pain self-management strategies; (2) relaxation exercise videos for day-to-day pain and anxiety management, including guided imagery meditation videos and a deep breathing pacer; (3) push notifications that provide reminders to watch relaxation exercise videos; (4) mindfulness-related behavioral suggestions; and (5) ecological momentary assessments of anxiety and pain (1 item each).

Prior literature shows that the timing of intervention delivery affects user receptivity and engagement with intervention content [12,25,26]. While we did not aim to evaluate the effectiveness of the intervention in a fully randomized controlled trial setting, we recognized the importance of randomizing the timing of video prompts to examine user experience. This approach allowed us to explore context-specific variations in user decision-making and actions in response to different video prompts. Accordingly, each day, the app delivered a video prompt at a random time within 1 of the following 4 time frames: (1) morning: 9:00 AM-noon; (2) early afternoon: noon-3:00 PM; (3) late afternoon: 3:00-6:00 PM; and (4) evening: 6:00-9:00 PM. Similar to the video prompts, participants completed momentary assessments of pain and anxiety 4 times per day, prompted within the same time frames. Considering the capabilities of MyDataHelps, we randomly generated 3 unique prompting schedules (ie, when to deliver a relaxation exercise video and ecological momentary assessments) and randomly assigned participants to one of these schedules, forming 3 groups. Participants within the same group received intervention prompts and self-report questions at the same time.

The primary intervention content of the MiCarePath app was the relaxation exercise videos, which were presented to participants once per day and were also the focus of this study. The videos, ranging from approximately 10 to 15 minutes in length, immerse users in various relaxation and meditation scenarios, such as a forest, seaside, or garden. These videos were developed and produced specifically for the MiCarePath app. Participants could switch to a different video or watch multiple videos, and they also had the option to proactively watch a video without being prompted. After completing relaxation exercises, the app prompted them to answer 3 or 4 questions designed to collect user feedback, including whether the video was watched, the perceived helpfulness of the video (helpful, neutral, or not helpful), activities before responding to the prompt, and reasons for nonadherence (if relevant). To monitor users' anxiety and pain levels, we implemented ecological momentary assessments using two 10-point single-item rating scales (ie, "From 1-10, what is your level of anxiety/pain right now?") [37].

To preliminarily assess the major outcomes of the MiCarePath intervention, the app collected data on participants' pain, anxiety, and any self-management strategies used over the course of the intervention. These measures were completed at study entry and for 2 weeks following surgery. The small sample size precluded analysis of the intervention's effectiveness;

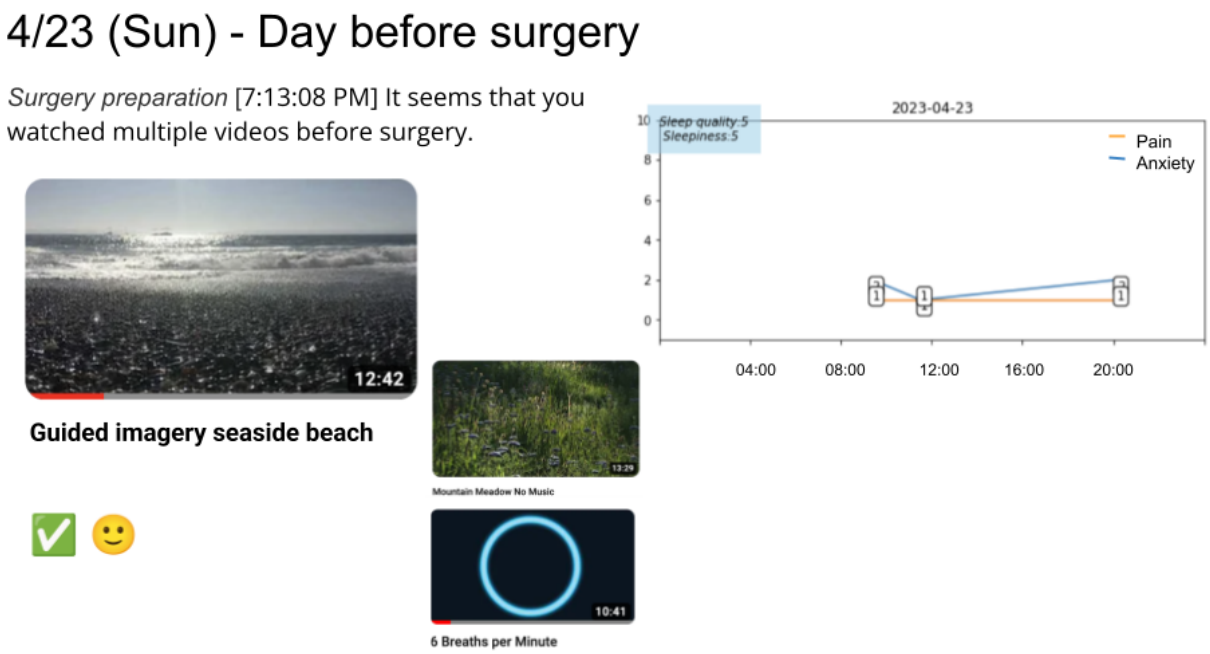
XSL•FO
RenderX



instead, we examined participants' user experience over time to explore intervention engagement.

Study Procedures

The study team first invited individuals to participate. The study used a fully remote design, with participant coordination conducted via email. Individuals who indicated interest were screened for eligibility criteria, consented, and then provided with instructions to download and install the MiCarePath project within the MyDataHelps app. The intervention period for each participant lasted approximately 40 days; participants began using the app at least 10 days before surgery and were encouraged to continue for 1 month following surgery. This timeline allowed participants to become familiar with the intervention, as well as to learn and practice relaxation techniques in preparation for surgery and during recovery. We conducted 3 qualitative interviews (each approximately 15-20 minutes): (1) before surgery (1-2 days prior); (2) 2 weeks after surgery; and (3) upon study completion (4 weeks following surgery, approximately 30 minutes). These interviews, conducted at multiple time points over the course of the intervention, allowed us to examine changes in participant perceptions and experiences. Figure 1 presents the study timeline. Additionally, participants were asked to complete questionnaires at these time points, including measures of anxiety and pain levels, self-management strategies, and medication use.



Interviews were informed by a data-prompted interview approach, which helps researchers gain rich insights into participants' in-the-field experiences by using collected data to guide conversations [38-40]. Two authors (XY and RB), both graduate researchers trained in human-computer interaction, developed the interview guide and conducted the interviews remotely via Zoom (Zoom Communications). During each interview, the research investigator first introduced the purpose of the interview and their background, and began with general questions about health and surgical status. We then presented data visualizations to participants displaying information about their actions in response to video prompts (ie, whether they chose to watch the video or not, or switched to a different video), video engagement (eg, completion of a video), momentary anxiety and pain, and activities before watching a video. Interview materials were presented using Google Slides (Google LLC; see Figure 2 for an example). Specifically, we probed user actions when (1) the participant chose not to watch a video; (2) the participant appeared to watch a video at an atypical time or in a unique context; and (3) the participant expressed an attitude that differed from their usual perceptions of the videos. When presenting the visualizations, the researcher described the data and asked participants to recall their experiences around the time they responded to a video prompt. Follow-up questions were used to explore possible reasons underlying participant decision-making and actions. We concluded the interviews by asking participants about other techniques or behavioral support they received during that period.

Figure 1. Study timeline. Participants attended 2 check-in interviews and 1 exit interview.

XSL•FO
RenderX

Figure 2. Example of the visualization shown during interviews. Text indicated when participants received a video prompt and their subsequent actions (eg, watching the video). A video screenshot was used to prompt recall of past experiences, and same-day pain and anxiety scores were displayed. Icons indicated video completion and perceived helpfulness.

Participant Recruitment

Participants were recruited using 3 sampling methods: study posts on a university-based research study site, snowball sampling of clinical providers' patient contacts, and review of surgical schedules for patients undergoing elective surgery. We used multiple recruitment methods to maximize enrollment of a diverse cohort of end users. Eligible participants were (1) at least 18 years of age; (2) fluent in English; (3) undergoing elective surgery at least 10 days after the consent date (to provide sufficient time to engage with the app); (4) willing to participate in surveys through 4 weeks after surgery; (5) able to access a device (smartphone or tablet, such as an iPad; Apple Inc) to use the MyDataHelps platform for completing anxiety and pain assessments and engaging with the MiCarePath intervention content; and (6) endorsing surgery-related anxiety, as indicated by a response of 3-5 to the following statement: "I feel anxious when thinking of my upcoming surgery (1=never, 2=rarely, 3=sometimes, 4=often, and 5=always)." We focused on patients who reported surgery-related anxiety, as these patients may be more interested in learning relaxation techniques and motivated to do so before surgery. The enrollment process commenced in October 2022 and concluded in July 2023. We aimed to enroll 15-25 participants to achieve thematic saturation and allow for subgroup comparisons [41,42]. The final sample size (N=19) is consistent with prior mixed methods and feasibility studies examining mHealth engagement in clinical contexts [29,43]. Given the exploratory aim of identifying engagement patterns and intentional use behaviors, this sample size was deemed sufficient to support thematic analysis and descriptive quantitative comparisons rather than hypothesis testing.

Ethical Considerations

Ethics approval was obtained in 2022 from the University of Michigan, Ann Arbor Institutional Review Board (approval number IRBMED HUM00217162). Individuals who contacted the study team were screened for eligibility, and those who were eligible provided e-consent before enrollment in study activities. Participants were instructed to install the MyDataHelps app during a brief onboarding session and were provided with a 1-page user manual for reference.

To ensure participant data confidentiality, all collected data were deidentified and replaced with unique participant codes. Interviews were audio-recorded, and no images of participants were obtained or reported in the manuscript. The document linking these codes to personally identifiable information was stored separately from the study data on a secure, firewalled university server, with access strictly restricted to the research team. Regarding data security, the MyDataHelps platform uses industry-standard encryption protocols. It is built on the HIPAA (Health Insurance Portability and Accountability Act)–compliant HIEBus platform, which securely handles protected health information in accordance with clinical standards.

Participants were compensated up to US $60 for completing surveys and interviews. They were not compensated for their engagement with video prompts to mitigate potential intervention effects related to incentives.

Data Analysis

Characterization of Perceived Benefit and Mixed Methods Integration

As the key aim of the MiCarePath intervention is to introduce relaxation techniques to perioperative patients and encourage

XSL•FO
RenderX

them to adopt or maintain relaxation as a self-management strategy, we used participant-reported use of strategies at week 2 after surgery—a multiple-choice question framed as follows: "Do you currently use strategies to decrease anxiety? (check all that apply)."—and frequency of use as criteria to assess perceived benefit from the intervention (ie, whether patients learned and developed a new self-management strategy as intended). We categorized participants into 2 groups based on their reported benefit from the intervention: a high-benefit group, comprising those who reported developing a new self-management strategy or maintaining relaxation techniques, and a low-benefit group, comprising those who did not report these outcomes. Our focus was on identifying commonalities within each perceived benefit group (high vs low) and differences between the 2 groups to identify phenomena indicative of users' perceived benefit. We first followed a sequential explanatory strategy [43,44], using the collected data to inform the check-in and exit interviews. During the data analysis phase, researchers applied a concurrent triangulation approach to conduct qualitative and quantitative analyses simultaneously and then integrated both sets of results for interpretation. When discrepancies were identified, we used participants' interview data to interpret changes in perceptions and performance.

Quantitative Data Analysis

We analyzed 4 key video engagement metrics: (1) average length of video engagement per week (in minutes), (2) response rate to video prompts (defined as whether a participant opened the notification), (3) response delay (measured in seconds from notification to video engagement), and (4) reported helpfulness of videos (categorized as helpful, neutral, or not helpful). These measures served as proxy indicators of user interest and depth of engagement with different relaxation videos [45]. User interaction data were collected using Google Analytics 4 and Google Tag Manager [46], which recorded time-stamped events such as video start and stop times, video content type, and engagement duration. Weekly engagement data (eg, postoperative week 1, week 2) were treated as a categorical within-participant variable to enable temporal comparisons. Missing data resulting from participant dropout were handled using listwise deletion, as analyses focused on within-participant trends rather than population-level inference. Given the exploratory nature of the study and small sample size, analyses were interpreted descriptively rather than as confirmatory tests. We began with descriptive statistical analyses to summarize trends in video engagement and perceived helpfulness. We then applied mixed-design analysis of variance (mixed ANOVA) to examine weekly video viewing time and response delay between the 2 groups. Before conducting ANOVA, we assessed the assumptions of normality and sphericity. When the Mauchly test indicated a violation of sphericity, we applied the Greenhouse-Geisser correction. Given the exploratory nature of the study, we did not apply corrections for multiple comparisons. All statistical analyses were conducted in Python (version 3.8.7; Python Foundation) using Jupyter Notebook.

Qualitative Data Analysis

We conducted a 2-stage thematic analysis of interview data, drawing on data-prompted interview analysis practices [38-40]. Interviews were audio-recorded and transcribed using auto-generated transcripts, which were subsequently proofread by the first author (XY) for accuracy. Researchers first reviewed participants' transcripts and annotated critical incidents, a widely used technique in qualitative research in which researchers focus on participants' recalled events (eg, how they responded to an intervention prompt) to reconstruct past behaviors and identify notable behavioral patterns [47]. Data visualizations presented during the interviews (eg, engagement trends) were used to contextualize participant responses and anchor incidents during analysis. In the first stage, 2 researchers (XY and RB) engaged in memo writing [48] to summarize each participant's key characteristics (including prior meditation experience and coping strategies for anxiety and pain management) and general experience with the intervention (including development of new self-management strategies and overall attitudes toward the intervention). Using a spreadsheet, researchers conducted a deductive analysis guided by the study's research questions, focusing on key experiential domains such as perceptions, reported behaviors, and changes before and after surgery. The spreadsheet format allowed for flexible categorization, efficient organization, and filtering of quotes by contextual variables (eg, timing relative to surgery, user group). Drawing on participants' objective engagement data, the researchers examined alignment between perceptions and performance, particularly across the 2 user groups. Check-in interview data were used to help explain changes in engagement over time. This triangulation process allowed us to contextualize subjective experience with objective intervention engagement patterns, specifically examining alignment between user perceptions and performance across the 2 user groups.

Researchers then applied in vivo coding [49,50] to uncover emergent themes grounded in participants' language through an iterative codebook development process. They collaboratively coded around 20% of the transcripts (4/19, 21%), establishing intercoder reliability through discussion and alignment on code definitions. Once a consistent agreement was reached, the remaining transcripts were independently coded using the finalized codebook. The broader research team, including senior members (NEC and MWN), held regular debriefing meetings to review and refine emerging themes. Data saturation was assessed through ongoing review of new transcripts and was considered achieved when no substantial new codes or themes emerged.

To ensure the quality and transparency of our mixed methods approach, this study followed the GRAMMS (Good Reporting of a Mixed Methods Study; Multimedia Appendix 1) framework [51] and the COREQ (Consolidated Criteria for Reporting Qualitative Research; Multimedia Appendix 2) guidelines [52].

Results

Overview

A total of 22 participants were enrolled in this study. Of these, 19 participants successfully completed the study; 1 participant

XSL•FO
RenderX

dropped out before surgery, and 2 dropped out after surgery. Sixteen participants completed all 3 interviews, while 3 were either unavailable due to physical therapy or remained unresponsive to the research team's phone calls or emails. Table 1 presents demographic characteristics, with a focus on prior experience and whether participants developed or maintained relaxation as a self-management strategy upon completing the intervention, which was used as the criterion to differentiate users' perceived benefit.

Based on participant responses to the self-management strategy survey items and the reported frequency of use in the baseline and exit surveys, participants were categorized into 2 groups: a high-benefit group (n=11) and a low-benefit group (n=8). In the high-benefit group, 7 participants incorporated relaxation as a new self-management strategy, and 4 reported increasing the frequency of its use. By contrast, participants in the low-benefit group reported that they did not develop a new strategy.

Table 1. Demographic characteristics of the participants (N=19) who completed this study.

Did not develop a new strategy	8

Comparing User Perceptions and Performance Between High- and Low-Benefit Groups

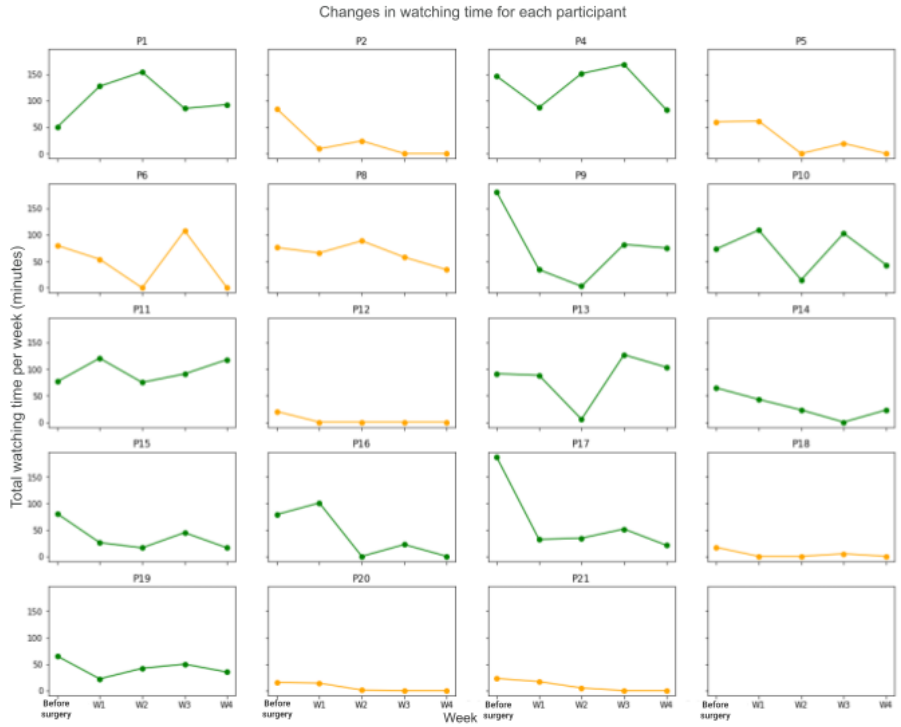
User Performance

All participants viewed the 3 educational videos upon entering the intervention. Table 2 presents the average total watching time, response rate to video prompts, delay in responding to a video prompt, and perceived helpfulness of the videos. Overall, results showed that, except for the average delay in responding to a video prompt, participants in the 2 groups exhibited significant differences in average total watching time (P <.001) and average response rate to video prompts (P<.001; also see Tables 2 and 3; Figures 3 and 4). The average weekly watching time and CIs of both high- and low-perceived benefit groups are presented in Table 3.

Before surgery, participants in the high-benefit group generally adhered to video prompts, with a mean nonadherence rate of only 11% (14/127). Four participants reported intentionally choosing their preferred relaxation exercises at least once, despite being recommended a different one. Three participants from the high-benefit group reported that they sometimes watched more than 1 video when prompted. In comparison, participants who perceived little or low benefit initially tried relaxation exercises before surgery, with an adherence rate of 55% (53/97) to video prompts, but most did not finish viewing the entire video. After surgery, 4 of 8 participants in the low-benefit group rarely attended to any video prompts.

A mixed ANOVA was conducted to examine changes in watching time across 5 perioperative time points (T1: before surgery; T2-T5: week 1 to week 4 after surgery) between the 2 groups. The data showed that, in the high-benefit group, the average weekly watching time started at 99.6 (95% CI 70.9-128.2) minutes at baseline (T1) and was maintained at 55.4 (95% CI 31.7-79.1) minutes by the end of the study (week 4, T5). Although there was a nominal reduction of 44.2 minutes, high interparticipant variability across the 5 time points resulted in a nonsignificant main effect of time (P=.10).

By contrast, participants in the low-benefit group exhibited a significant decline in watching time after surgery ($F_{4,28}$=19.76, P<.001). While they began with moderate engagement at baseline (mean 47.0 minutes; 95% CI 25.6-68.4 minutes)—approximately half the watching time of the high-benefit group, the average weekly watching time in the low-benefit group had dropped to only 4.3 (95% CI 0.0-12.6) minutes. At baseline (T1), there was already a significant difference in watching time between the high- and low-benefit



XSL•FO
RenderX

groups ($F_{1,17}$=21.62, P<.001), suggesting that participants in the low-benefit group were not initially engaged with the intervention. Moreover, preliminary analyses indicated an interaction effect between perioperative time and participants' perceived benefit level. The high-benefit group sustained 55.6% (55.4/99.6) of their baseline engagement by week 4 (maintaining a mean of 55.4 minutes), whereas the low-benefit group exhibited a significantly greater decline in watching time over time than the high-benefit group ($F_{1,17}$=17.02, P<.001). Conversely, no significant difference in video responsiveness was observed between the 2 groups (P=.81). The average delay in attending to video prompts was comparable between high-benefit (5.54 hours) and low-benefit (5.15 hours) participants.

Table 2. The average total watching time, average response rate to video prompts, average delay in attending to a video prompt, and the rate of perceiving videos as helpful from the ecological momentary assessment. Except for the delay in attending to a video prompt, participants in the high-benefit group acted significantly more engaged with the intervention as opposed to the low-benefit group.

Group variable	High-perceived benefit (H) (n=11), mean (SD); 95% CI	Low-perceived benefit (n=8), mean (SD); 95% CI	*P* value
Total watching time on average (minutes)	340.8 (152.3); 238.5-443.1	117 (115.5); 20.4-213.6	<.001
Average response rate to video prompts (%)	73.45 (15.36); 63.13-83.78	34.60 (18.26); 19.35-49.90	<.001
Average delay in attending a video prompt (hours)	5.54 (4.02); 2.84-8.24	5.15 (3.42); 2.29-8.01	.81
Rate of perceiving videos as helpful (%)	79.80 (9.25); 73.18-86.42	25.50 (14.76); 13.20-37.80	<.001

Table 3. The average weekly watching time and CIs of both high- and low-perceived benefit groups.

Time point	High-perceived benefit (n=11), mean; 95% CI	Low-perceived benefit (n=8), mean; 95% CI
T1 (before surgery)	99.6; 70.9-128.2	47.0; 25.6-68.4
T2 (week 1)	71.8; 47.8-95.9	25.8; 5.6-46.1
T3 (week 2)	48.7; 15.9-81.5	14.3; 0.0-35.9
T4 (week 3)	65.3; 39.5-91.2	23.2; 0.0-50.7
T5 (week 4)	55.4; 31.7-79.1	4.3; 0.0-12.6

User Perceptions

High-Benefit Group (n=11)

All participants in the high-benefit group reported incorporating relaxation practices as a new self-management strategy or reinforcing their previous experience with relaxation. Participants with prior experience continued to engage with the videos, viewing at least one video per week during the intervention. For example, P4 had over 20 years of meditation experience and told us, "The meditation videos in this app were good because they were new to me. So it gave me a fresher feeling." Among participants without prior experience (7/11), individuals gradually became familiar with relaxation techniques and appreciated having a tool to cope with anxiety and pain. Their positive experience with the intervention appeared to stem from 1 or more helpful relaxation exercises. For example, P9 tried garden imagery meditation for the first time and appreciated that the video offered less instruction and greater flexibility for imagination: "There's a little bit less instruction. The video does not talk as much, but it will give good ideas of going through the (garden) path and everything, and then just sitting down and relaxing. There's a little bit of freedom just to do whatever. And sometimes I like to imagine lots of flowers, or sometimes I just relax, and it's nice." Similarly, P11 gradually became more engaged with the relaxation videos, and increased interaction reinforced continued use of the intervention: "I did some meditation sometimes, but on and off. But with this [intervention], it's helping me to remind me to keep meditating and relaxing."

Low-Benefit Group (n=8)

As noted in user performance, participants who perceived low benefit were not engaged with the intervention from the outset. Most participants in this group reported that they felt it was less necessary to incorporate the intervention into their self-care, owing to satisfaction with existing self-management strategies. For example, P6 reported being satisfied with his current strategy: "As long as I am just sitting in this massage chair, it's not too painful, and I just watch television or read....This is the first time I really ever even thought about it [meditation] or seen anything about it." For several participants, although they completed the educational videos (including the rationale for learning relaxation techniques) upon entering the intervention, they remained unreceptive to relaxation exercises and intentionally ignored video prompts, as reported by P5: "I'm also very busy with work, and I don't have time [to use the

XSL•FO
RenderX

intervention app]. If I have time, I'll be relaxing and thinking about the surgery, and then I'll get the notification. And I have to think about it again. It's not that stressful, but sometimes I feel like I have one more thing to do now."

Discrepancy Between Participants' Performance and Perceptions

As previously noted, for most participants, those who derived the most benefit from the intervention exhibited significantly higher quantity and quality of video engagement with the MiCarePath app (ie, average total watching time, $P<.001$; average response rate to video prompts, $P<.001$; and rate of perceiving videos as helpful, $P<.001$). However, when aligning each participant's performance data with their perceptions of the app obtained from interviews, we observed variability within both groups. Briefly, a few participants in the high-benefit group showed lower video engagement at certain points during the intervention than some participants who reported little benefit. Additionally, although these participants appeared to perceive benefit from the MiCarePath app, their video engagement fluctuated throughout the intervention and occasionally showed signs of disengagement (eg, P14, P20, P21; see Figure 3). Conversely, 2 participants in the low-benefit group exhibited higher adherence rates before surgery, despite reporting that they did not perceive any benefit from using the intervention.

High-Perceived Benefit With Low Intervention Engagement After Surgery

Five participants in the high-benefit group reported reduced use of the intervention after surgery, while others reported maintaining a similar level of use as before; this was also confirmed by their performance data. However, these 5 participants still reported that the videos were helpful and that they derived benefit from the relaxation exercises. Notably, all 5 participants refrained from using the intervention for at least one week during the postoperative period (1 participant did not use the intervention in week 1 after surgery, and 4 in week 2 after surgery). From the interviews, one possible explanation was that these participants were prescribed other treatments or therapy after surgery and therefore, felt less able to attend to the video prompts. Nevertheless, they expressed satisfaction whenever they engaged with a relaxation video. In P17's case, he was proactively engaged with the videos before surgery to cope with abrupt, severe back pain, resulting in an average of 18 minutes of watching time per day: "That [the back pain] was a big thing. I was dealing with the pain and the anxiety that it might affect my heart surgery." He reported a positive experience with the app: "For most of the videos, I ended up closing my eyes. I pictured some places as depicted by the video." After surgery, P17 reported being busy and less attentive to video prompts (adherence rate dropped from 100% before surgery to 34% in weeks 1-2 after surgery). Although the frequency of relaxation practice decreased, he reported becoming more adapted to "imagining my own vision while watching videos." Consistent with P17's experience, other participants reported continued benefit from the app by gradually grasping relaxation techniques (eg, "learned a lot from the app"), although resumption of regular responsibilities after surgery (eg, work) limited their availability to engage in relaxation practice as before.

Low-Perceived Benefit Despite High Engagement With The Intervention

Adherence Without Perceived Benefit in the Low-Benefit Group

Regarding the low-benefit group's experience, 2 participants (P6 and P8) showed high adherence to video prompts and short response delays, often demonstrating better adherence than some participants in the high-benefit group. During the first interview before surgery, both P6 and P8 expressed doubt about the value of relaxation exercises. However, because both were retired, they had greater availability and could respond quickly to video prompts. For example, P6 told us: "If I saw there was a notification, I would just open it and play the video, sometimes doing other tasks." As noted, they typically played the recommended video in the background but were not fully engaged with the content. After surgery, because P6 and P8 did not perceive benefit, they became less compliant with video prompts and mostly chose not to engage with the videos. For the remaining participants who perceived low benefit, although they sometimes complied with video prompts, they did not report a positive experience or develop a routine of practicing relaxation. Interview data indicated that these participants either had difficulty finding time to watch the videos or watched them without full engagement. For example, P18 watched a video before sleep but did not perceive sufficient benefit: "On that day, I just happened to do the breathing exercises when I went to bed. It set the stage for sleep, but certainly not worth that much focus of time."

Overall, by aligning individual participants' performance data with their perceptions of the intervention, we found that user engagement with the intervention videos (eg, length of video engagement, delay in attending to a video prompt) may not fully reflect their perceived engagement or ability to derive benefit.

Intentional Use as a Key Phenomenon to Differentiate the 2 Groups

As presented above, participants' performance was largely aligned with perceived benefit from the intervention; however, in some cases, we observed discrepancies between performance and perceptions of the intervention. By triangulating user performance data, self-reported video helpfulness, and interview insights—particularly from participants who showed such discrepancies—we identified intentional use of the intervention content as a key factor in the interview data. We defined "intentional use" as using the intervention content purposefully for desired health-related effects, namely, managing anxiety and pain in our research context. This phenomenon can be considered a qualitative dimension of user engagement that differed between participants who perceived high benefit and those who perceived little benefit.

Participants Developed Intentional Use of the Intervention (n=7)

Participants in the high-benefit group reported that they would actively engage in relaxation exercises using the MiCarePath

XSL•FO
RenderX

app when feeling anxious or in pain, even without prompts. P16, for example, reported experiencing anxiety symptoms for years and being aware of her anxiety patterns. With the intervention, she became more conscious of using it to address her specific patterns of anxiety: “I'm usually already relaxed in the morning, but more at a higher anxiety state in the afternoon. So as long as I had time to watch the videos, I would open the app and practice mindfulness.”

Some participants with little prior experience with relaxation exercises appeared to shift in their engagement with the intervention, from more compliance-based to more intention-driven. For example, P10 reported that she initially responded to prompts to watch relaxation videos before surgery. After surgery, she became more intentional about practicing relaxation to cope with postoperative pain and avoid opioid use: “I was doing it as soon as I got the alerts, but then I learned that I could do them [do meditation exercises] later on. Sometimes it alerted me when I was in the middle of working. This was before my surgery. But now it's like I try to do it at times when I know that I'm stressed, to really get the full effect of it.” P15 gradually developed a habit of intentionally choosing a short relaxation video to address unexpected anxiety episodes, as expressed in the exit interview: “I think, it was going to be the difference between watching or not watching the video, [less about which video to watch]. So sometimes when I felt anxious, I would open the app and pick the shorter one because my goal was just to address my anxiety at that moment.” P19 also reported actively using the intervention; interestingly, she noted that the videos tended to be more helpful when she was more relaxed: “If I do it when I’m more relaxed, I actually pay more attention and the videos will actually help me better more. So I tried to watch them when I felt calm.”

Although some participants perceived little benefit from the intervention, they occasionally reported actively engaging with relaxation exercises without prompts, albeit without developing a clear intention or habit. For example, P8 recalled waiting at a doctor’s appointment and thinking of the intervention. He tried a relaxation exercise during that stressful moment and, for the first time, perceived the video as helpful. He told us, “The (doctor) appointment reminded me of the app so I pulled it up while waiting at the doctor’s place. Other than that, I haven’t experienced [anxiety] a lot, so I could not tell the difference [in my anxiety change before and after watching a video].” Compared with P8, although P5 exhibited low engagement and perceived little benefit from the intervention, she liked the 2-minute diaphragmatic breathing video and actively tried it on 1 occasion when she had time: “A week or 2 before surgery like I said, I was busy preparing like with work and with my house. But I thought about trying the 2-min video (6 breaths per minute), it’s kind of telling you how to do it....But it’s hard to start a habit [practicing relaxation].”

Participants Applied Relaxation Techniques Without Using the App (n=5)

A subset of participants (n=5) in the high-benefit group learned and remembered scripts of the relaxation exercises and were able to practice meditation without using the app. This may partly explain why these participants, despite subjectively feeling engaged with the intervention, showed lower engagement with relaxation videos (eg, shorter or less frequent use). For example, P10 watched her preferred meditation video multiple times and was able to remember parts of the instructions, which were “replayed” in her mind when she felt anxious. She told us, “I feel like I’ve been able to learn and remember different parts of the video [meditation instructions] even if I did not listen to it. I can still think myself through some of the stuff to relax and to get myself out of a stressful moment. So that’s pretty cool. It’s a skill that I’ve built up over time that I didn’t have at the beginning of all of this [this intervention].” Similarly, P17 preferred the short breathing pacer exercise and actively applied the learned skill over time: “[While practicing deep breathing], you just focus on your breathing, and you don’t think about ‘oh, my heart is racing’. So I could apply this when I felt overwhelmed.”

Moreover, there were situations in which participants intended to watch a video but were unable to interact with the app due to contextual constraints. As a result, some participants applied relaxation techniques without using the app. For example, P11 became capable of proactively using deep breathing techniques when feeling overwhelmed, even when her anxiety was unrelated to surgery, as expressed in the second check-in interview: “I am a contract-based teacher and every time I get a different teaching task. I can be anxious. During the day with my students in the classroom, I couldn’t play the video, so I just reminded myself to take deep breaths when it was overwhelming.”

Participants With Intentional Use of the Intervention Could Resume Engagement After Experiencing Disruptions

Surgery is considered a major life disruption that requires time, can prompt significant anxiety, and may require additional therapy for recovery. Along with surgery, other contextual disruptions (eg, going on vacation) can lead to temporary or sustained disengagement from mHealth interventions, as reported in prior work [42]. Based on responses from the check-in interviews, several participants in the high-benefit group appeared able to resume engagement after experiencing contextual disruptions to their daily routines. P13 learned to practice deep breathing through the app and was able to intentionally apply the technique when feeling stressed, noting, “I think it benefits me even right now, as I am talking about it. I am slowing down my breathing a little bit.” In week 3 after surgery, she did not use the app at all due to a family trip. Upon returning, she resumed use and achieved a level of video engagement similar to before (127 minutes over the 2 weeks after the trip, compared with 91 minutes before surgery; see Figure 3). By contrast, P2 (low perceived benefit) initially complied with video prompts before surgery but did not find it easy to integrate the meditation exercises into her routines after surgery (eg, “I was not quite engaged,” “Maybe it might help to watch videos right before sleep.”). Following recovery, she reported physical and mental fatigue that disrupted her routine and led to continued disengagement (eg, total watching time was 35 minutes over 4 weeks after surgery).

Discussion

Principal Findings

We report data from an exploratory field study of 19 perioperative patients on their experience with and use of a relaxation-based mHealth intervention, MiCarePath, designed to target perioperative anxiety and pain management. Findings indicate 2 distinct user groups: those who perceived high benefit from the intervention (n=11) and those who perceived little to no benefit (n=8). Participants in the high-benefit group remained more engaged with relaxation exercises before and after surgery, showing significant differences in interaction duration with videos (P<.001), average response rates (P<.001), and rate of perceiving videos as helpful (P<.001) compared with participants who reported limited or no benefit. However, for some participants, video engagement did not fully reflect perceived benefit, suggesting a discrepancy between user performance and perceptions of the intervention. Interview data indicated that this discrepancy may be attributed to 2 factors: (1) although participants' use of the intervention decreased after surgery, they were still able to apply relaxation techniques learned from the videos when needed, even without rewatching them; and (2) participants may have adhered to video prompts without feeling genuinely engaged in the activities, leading to gradual disengagement over time. To characterize this discrepancy, we propose intentional use of the intervention content as an important phenomenon that may distinguish participants who derive high benefit from those who do not. Intentional use can be considered a qualitative dimension of engagement, shifting the focus from the quantity of interaction (eg, amount, frequency, duration) to its quality. This concept complements quantitative measures by capturing whether user interaction with intervention content stems from motivation and intention, thereby distinguishing between passive adherence to intervention delivery and the strategic application of intervention strategies in daily life [53,54]. In this study, participants demonstrating intentional use were able to resume engagement with the intervention after experiencing contextual disruptions to their daily lives.

Theoretical Implications: Intentional Use and Behavioral Change Frameworks

Our interview data suggest that intentional use of an intervention involves 2 key factors: (1) belief in its ability to alleviate anxiety and pain, and (2) the capacity to schedule and integrate practice into daily routines. These findings align with the Health Action Process Approach (HAPA) [55,56] and the Theory of Planned Behavior (TPB) [57], both of which emphasize intention as central to behavior formation. More specifically, intentional use maps onto key constructs within these frameworks. Participants' belief in the effectiveness of relaxation techniques parallels outcome expectancies in HAPA and attitudes in TPB, while their ability to apply these techniques within daily routines reflects task self-efficacy in HAPA and perceived behavioral control in TPB. HAPA divides behavior change into 2 stages: the preintentional phase, in which intentions are formed, and the postintentional phase, in which intentions are enacted [55,56]. Within this framework, intention is shaped by task self-efficacy, outcome expectancies, and risk perception [55]. Our study suggests that participants who developed intentional use behaviors may be transitioning into the postintentional phase, actively engaging with the intervention rather than passively receiving content. The identified factor of outcome expectancies reflects participants' belief in achieving desired outcomes (eg, reduced anxiety or pain), which may explain why some repeatedly watched the same video, driven by anticipated benefits. TPB similarly links intention to attitudes, subjective norms, and perceived behavioral control [57]. Here, attitudes are shaped by the perceived effectiveness of the behavior [57], consistent with participants' belief in the value of relaxation techniques. Perceived behavioral control extends beyond self-efficacy to include external factors such as time, resources, and environment [58], aligning with participants' ability to apply relaxation techniques in real-life contexts. Thus, we suggest that intentional use arises when users believe in the effectiveness of the intervention and feel capable of incorporating it into their routines, consistent with facilitators identified in prior work as central to engagement with digital health interventions [54,59].

Furthermore, our findings show that even participants who perceived high benefit may temporarily "disengage" from the intervention, as they may be prescribed additional treatments after surgery. The perioperative context introduces acute stressors—such as surgical anticipation, postoperative pain, and competing clinical demands [60-62]—that can temporarily disrupt observable engagement without necessarily undermining user intention. Our findings suggest that intention may remain stable even when actions on intervention content through the app fluctuate, indicating a decoupling between system-recorded engagement and the underlying behavior change process. This aligns with Yardley's model, which outlines 4 phases of user engagement with digital behavior change interventions: initial engagement with the intervention only (phase 1), intervention-mediated behavior change (phase 2), sustained behavior change independent of the platform (phase 3), and potential reengagement if needed (phase 4). This model suggests that users may disengage from an intervention platform (eg, an app) while remaining engaged in the behavior change process [63]. Similarly, Perski et al [64] defined engagement as both the extent of usage and a subjective experience, specifically a user's attention, interest, and affect related to the intervention.

Taken together, user engagement with an intervention—particularly effective engagement—reflects the intervention-mediated behavior change process [63,65]. To better connect the design of mHealth interventions with behavior change theories, designers need to consider the desired type and level of behavior change mediated by the intervention. This perspective aligns with prior agenda-setting work in behavior change and digital health intervention design [66,67]. Such consideration is critical, as the user's behavior change process may not be entirely driven by the intervention or easily detectable [68]. Furthermore, our research offers a perspective that extends behavioral frameworks by emphasizing contextual disruption as a moderating factor in intention enactment, rather than as a failure of engagement. In this respect, our findings contribute to a more nuanced understanding of user engagement

XSL•FO
RenderX

that is sensitive to an individual's short-term self-care trajectory. Given the variability in users' motivation, needs, prior skills, and changing contexts, the target level of engagement can be tailored to individual status (eg, existing skills and strategies) and evolving contexts (eg, before and after surgery), rather than defined by uniform expectations of intervention use.

Design Implications: Supporting Intentional Use in Perioperative mHealth Interventions

Overview

In this section, we discuss design implications centered on the concept of intentional use. These implications include (1) accounting for both user performance and perceptions in understanding perioperative patients' engagement; (2) considering intentional use in the evaluation of mHealth interventions; and (3) designing mHealth interventions to support and shape intentional use.

Accounting for Both User Performance and Perceptions in Understanding Perioperative Patients' Engagement With an Intervention

Assessing user engagement with mHealth interventions requires both objective performance measures and subjective user perceptions, as relying solely on objective metrics may misrepresent engagement by prioritizing frequency over quality [69]. Our study with perioperative patients revealed a potential discrepancy between performance with relaxation videos and perceived benefits. While several low-benefit users consistently followed video prompts with minimal delay, they did not report meaningful benefits. By contrast, intentional use—where users actively incorporate relaxation as a self-management strategy—emerged as a potentially valuable indicator of "effective engagement" and behavior change [63]. This suggests that engagement is not solely driven by system reminders (eg, push notifications), but also by users' growing recognition of when and how to use the intervention to achieve desired outcomes. As prior research highlights varying definitions and measures of engagement, the concept of "effective engagement"—interactions that lead to meaningful behavioral outcomes [70]—offers a more appropriate lens for evaluation. Given the importance of intentional use in shaping user engagement and behavior change, future mHealth interventions should integrate this factor into system design to enable better personalization and optimization in alignment with behavioral theories.

Considering Intentional Use to Evaluate mHealth Interventions

Findings from our study show that participants who benefited most from the app were able to intentionally engage with the intervention content at preferred and needed moments. However, in practice, it remains unclear how to leverage this insight to better understand user experience with mHealth interventions and to optimize intervention algorithms for adaptive interventions. In our study, check-in interviews—through which we learned about participants' gradual development of intentional use behaviors over time—proved useful. This suggests that periodic assessment of intentional use behavior, as well as progress in developing such behavior, may be valuable for inferring user engagement and determining whether desirable behavioral outcomes (eg, learning a new self-management strategy) are likely to occur.

Indeed, measuring user intention is challenging due to its subjective nature, highlighting the need to develop appropriate measures in future research. Intervention designers may consider using self-report methods to periodically assess intention in using preferred intervention content (eg, new skills, health behaviors) and associated contextual conditions (eg, before sleep, before a doctor's appointment). One caveat is the potential user burden associated with manual data collection, which may negatively affect overall adherence to the intervention [71]. Furthermore, it remains unclear whether users can accurately express their perceptions and reflect on their intent, particularly when they are in an intermediate stage of intentional use (ie, not fully aware of their intent but gradually developing the inclination to use the intervention) [72]. Future work should continue to explore factors that may influence or indicate intentional use. For example, prior research suggests that engaging with intervention content at a consistent time may indicate higher engagement [73]. In this direction, it would be valuable to explore how to computationally characterize the trajectory of developing intentional use, enabling digital tools to adapt intervention strategies accordingly.

Designing to Shape Intentional Use With mHealth Interventions

Our study highlights the potential to shape intentional use of an intervention to achieve behavioral goals. At present, it remains unclear how different system features, such as user onboarding or a feedback dashboard, may support the development of intentional use. Our interview findings suggest that intentional use may involve a belief in the intervention's ability to produce desired benefits. Accordingly, intervention systems could encourage users to reflect on the benefits they experience [74]. For example, after a relaxation exercise, the app could prompt a simple reflection question: "How do you feel after watching this?" This may help users recognize positive effects over time and reinforce belief in the intervention's benefits. As intentional use develops—for instance, as users gain a better understanding of when to proactively engage with intervention content—systems could introduce features such as implementation intentions, prompting users to specify actions (eg, engaging with the intervention) and associated conditions (eg, needed moments) [75]. Additionally, interventions could prompt users to reflect on and actively plan future activities based on their detected intentions (eg, [76,77]). For example, a lightweight planning feature might ask, "Would you like to schedule a time for your next relaxation session?" and synchronize with users' calendars to provide timely nudges [76]. Overall, these design strategies align with behavioral theory by reinforcing self-efficacy and autonomy, rather than promoting compliance with fixed intervention schedules [78].

XSL•FO
RenderX

Closing Remarks: Practical and Theoretical Implications

Theoretical Implications

Intentional, self-initiated use of the intervention—without reliance on system notifications—emerges as a key behavior distinguishing high-benefit users. This finding underscores the theoretical importance of autonomous engagement in mHealth interventions.

Practical Implications for the Design and Assessment of mHealth Interventions

Given the potential discrepancies between user performance and perceptions, it is important to consider both aspects when assessing user engagement. When examining user perceptions, priority should be given to self-reported intention, such as perceived behavioral control [79]. Future research should explore the development of assessment methods that effectively capture users' intentions. When evaluating intervention effectiveness, systems should account for user behaviors that occur outside the system but are reinforced by in-system engagement, to support a more holistic view of users' progress in the behavior change process. With this perspective, intervention designers should consider incorporating reflective features that promote intentional use or implementation intentions—for example, by prompting users to specify actions and contextual conditions. Looking ahead, future research could investigate gamified meditation exercises to strengthen user intention, alongside visual progress trackers (eg, integrating in-system and off-system activities) to reinforce habit formation.

Limitations

Although this exploratory study revealed important insights into perioperative patient engagement with a relaxation-based intervention, several limitations should be noted.

First, the study was conducted with a small sample of perioperative patients. As participants were expected to use the intervention around the surgical period, recruitment was subject to strict timing constraints. Despite employing 3 recruitment approaches, we encountered difficulties enrolling participants, primarily due to limited availability and high levels of preoperative stress. These recruitment constraints may have introduced selection bias, as individuals who chose to participate may have been more motivated, more comfortable with technology, or more open to relaxation-based approaches than the broader perioperative population. Nevertheless, we were able to obtain insights from participants with varying levels of intervention engagement, which helped inform refinement of the intervention design and evaluation of its effectiveness.

Second, the study sample was relatively homogeneous, with participants predominantly female and all fluent in English. The predominance of female participants may reflect prior findings that meditation apps tend to be more favored and well-received by females than males [80]. This homogeneity may limit the generalizability of the findings to more diverse populations, including individuals from different cultural backgrounds, non–English-speaking patients, and those with varying levels of health literacy and access to technology. Future work should intentionally recruit more diverse samples to examine how cultural, linguistic, and sociodemographic factors shape engagement with relaxation-based mHealth interventions.

Third, the current intervention does not offer adaptive or personalized tailoring. Findings from this study highlight the importance of facilitating intentional use of interventions. Building on this direction, there is an opportunity to implement a just-in-time adaptive intervention system for perioperative patients and to explore approaches that enhance user proactivity and intentional use over time. Fourth, we conducted multiple check-in interviews during the intervention, which may have been perceived as intrusive and could have influenced user perceptions and experiences. To mitigate this, unless participants asked about a feature in the app, we did not prompt them to engage with the intervention or evaluate their performance. Nevertheless, some participants may have inferred the study's desired outcomes and, as a result, expressed more favorable views of the intervention during interviews. Accordingly, interview questions were designed to focus on eliciting detailed accounts of participants' experiences in context. Participants may also have had difficulty recalling details of their engagement with the intervention, leading to potential recall bias. To minimize this, we used a data-prompted interview approach, presenting participants with their anxiety and pain scores, along with screenshots of relaxation videos, to support recall. Finally, several participants dropped out during the postoperative period due to unavailability or recovery, and they may have lacked interest in the intervention; however, we were unable to collect their feedback.

Conclusions

This exploratory study examined perioperative patients' engagement with a relaxation-based mHealth intervention (ie, the MiCarePath app) by jointly considering user performance, subjective perceptions, and retrospective perceptions over 3 weeks. Our findings highlight the importance of understanding how patients interpret and apply intervention content within the constraints of the perioperative context. By integrating user engagement data with interview data, this work demonstrates that observable interaction with an intervention may not fully capture perceived value or its role in supporting patients' self-management during the perioperative period.

A central contribution of this study is the identification of intentional use as a qualitative dimension of engagement that helps explain discrepancies between performance and perceived benefit. Participants who reported greater benefit were not necessarily those with consistently high levels of interaction with intervention content, but rather those who developed the ability to intentionally use relaxation strategies to manage anxiety and pain—including outside the app and after disruptions such as surgery or competing care demands. This finding extends the existing literature on user engagement by emphasizing the quality and purpose of interaction, particularly in short-term, high-burden clinical settings where sustained adherence may be difficult to achieve.

These insights have important implications for the design and evaluation of relaxation-based mHealth interventions in perioperative care. Interventions that support the development

of intentional use may better promote nonpharmacological anxiety and pain management, complement clinical care, and reduce reliance on intensive in-person support or medication-based approaches. Future research should explore how intentional use can be fostered and detected over time, as well as how adaptive intervention strategies can be integrated into perioperative care pathways to support scalable, patient-centered outcomes.

Abstract

Background: Peripheral artery disease (PAD) is prevalent in hemodialysis (HD) patients but remains difficult to diagnose due to unreliable ankle-brachial index (ABI) measurements caused by vascular calcification. We hypothesized that monitoring foot temperatures and their changes during HD, provoked by hemodynamic shifts, could serve as a novel diagnostic tool for detecting severe PAD.

Objective: This study aims to evaluate the diagnostic utility of intradialytic foot temperature monitoring using wearable mobile health (mHealth) sensors for detecting severe PAD in patients undergoing HD.

Methods: In this prospective observational study, we recruited 109 patients undergoing chronic maintenance HD. Skin temperatures were monitored continuously at the instep and sole during HD sessions using wearable sensors (Temp Pal, iWEECARE Co, Ltd), which are wireless, nanochip-based mHealth thermometers with ±0.05 °C accuracy. The diagnostic performance of temperature parameters, specifically the temperature difference between the wrist and foot at the end of HD, was evaluated against vascular duplex ultrasound (DUS). Severe PAD was defined as abnormal (monophasic or absent) flow in the distal posterior tibial artery (PTA) or anterior tibial artery (ATA).

Results: Patients with abnormal tibial flow on DUS exhibited significantly different temperature gradients between the wrist and foot at the end of dialysis compared to those with normal flow. Receiver operating characteristic (ROC) analysis demonstrated that the wrist-foot temperature difference at the sole effectively discriminated abnormal ATA flow (area under the curve [AUC] 64.5%, 95% CI 57.8% - 70.9%) and abnormal PTA flow (AUC 62.0%, 95% CI 55.2% - 68.5%). Notably, an instep wrist-foot temperature difference cutoff of –2.2 °C or less yielded a specificity of 97.6% (95% CI 94.0%-99.3%) for detecting abnormal PTA flow.

Conclusions: Intradialytic foot temperature monitoring, particularly the temperature gradient between the wrist and foot, significantly correlates with severe tibial artery flow abnormalities. This method offers an accessible, noninvasive screening adjunct to the ABI for detecting severe PAD in the HD population. These findings indicate an association rather than a standalone diagnostic test; given the modest discriminative ability, external validation is warranted.

Introduction

Patients with end-stage renal disease (ESRD) are at elevated risk of multivascular cardiovascular disease, including coronary artery disease (CAD), cerebrovascular disease, and peripheral artery disease (PAD) [1,2], compared to the general population. In addition, the presentation of PAD in patients undergoing dialysis manifests a worse prognosis than that in patients without ESRD, with greater risk of major adverse limb events, including amputation or hospitalization for chronic limb-threatening ischemia (CLTI), and mortality [3-6]. Indeed, patients with ESRD receiving dialysis are at even higher risk of PAD and adverse limb outcomes than those in earlier stages of chronic kidney disease. As with most diseases, earlier detection is pivotal to the optimal management of these patients. However, diagnosis of PAD remains challenging in the hemodialysis (HD) population for several reasons. First, symptoms are often mild, atypical, or even absent in this group due to limited ambulation or concomitant neuropathy [7]. Second, the severe vascular calcification that is commonly seen in patients with ESRD often leads to falsely elevated ankle-brachial index (ABI) measurements due to noncompressible vessels [8]. Third, the presence of below-the-ankle disease in renal-diabetic foot ulcers is associated with higher risk of treatment failure [9] but is less likely to be detected using conventional ABI or vascular duplex measurements in the tibial arteries. Several noninvasive modalities are used to assess PAD, including the ABI, toe-brachial index, Doppler waveform analysis, duplex ultrasonography, and computed tomographic or magnetic resonance angiography [10]. Infrared thermography, which maps skin-temperature variation as a surrogate for perfusion, has also been applied to identify ischemic changes, although it requires dedicated cameras and is sensitive to ambient conditions [11,12].

Foot temperature monitoring has previously been advocated as a means of surveillance for the development of diabetic foot ulcers [13-15]. This was based on the rationale that inflammation usually precedes overt ulceration in neuropathic ulcers, which can be detected by an increase in local foot temperature. However, for ischemic ulcers seen in PAD, temperatures are usually low. We previously demonstrated that an increase in foot temperature of 2 °C or greater after endovascular therapy (EVT) for chronic foot ulcers in the absence of active infection was associated with better wound healing compared to those with a foot temperature increase of less than 2 °C after EVT [16]. As yet, how temperatures relate to outcomes in asymptomatic patients is uncertain. We hypothesized that foot temperatures in asymptomatic patients also relate to the degree of ischemia and may provide significant diagnostic value. In addition, in patients with ESRD whose ABIs are often falsely negative due to noncompressible vessels, foot temperatures may have higher sensitivity in diagnosing PAD than conventional ABIs and offer greater accessibility than vascular duplex ultrasound (DUS).

Because symptoms related to PAD often manifest in patients with ESRD during their HD sessions due to the significant fluid shifts and hemodynamic changes, we initiated a prospective study that investigated the associations among ABI, DUS measurements, and intradialytic foot temperatures. Our goal was to explore the diagnostic value of intradialytic foot temperatures in identifying severe PAD, potentially offering a readily accessible means of early detection in this vulnerable patient group.

Methods

Study Cohort

This prospective, observational cohort study was conducted at 2 tertiary centers in Taiwan: National Taiwan University Hospital, Hsinchu Branch, and Shin Kong Wu Ho-Su Memorial Hospital. Patients with ESRD undergoing maintenance HD were screened for inclusion. Exclusion criteria included age under 20 years, prior lower-limb amputations (minor or major), and refusal to provide informed consent. Each lower limb was evaluated as an independent unit. Following enrollment, data on participant characteristics, biochemical profiles, and ABI measurements were collected. The presence of severe PAD was confirmed using DUS as the gold standard, defined by monophasic or absent flow in the distal posterior tibial artery (PTA) and distal anterior tibial artery (ATA) at 5 cm above the ankle.

Ethical Considerations

This study was approved by the Institutional Review Board (IRB) of both the National Taiwan University Hospital, Hsinchu Branch (IRB number 111 - 105-E), and Shin Kong Wu Ho-Su Memorial Hospital (IRB number 20230702D); written informed consent was obtained from all participants.

Data Collection

Following study enrollment, a systematic review of electronic medical records and baseline clinical assessments of the participants was conducted. Demographic information, including age and sex, and a detailed history of comorbid conditions such as hypertension, diabetes mellitus (DM), hyperlipidemia, CAD, congestive heart failure, and prior cerebrovascular or myocardial events were recorded. Current medication profiles were also documented, specifically the use of erythropoietin, vitamin D analogs, antihypertensive agents, and iron supplements. Comprehensive laboratory data were gathered, including complete blood counts, serum albumin, and markers of dialysis adequacy such as predialysis and postdialysis blood urea nitrogen and Kt/V. Additionally, we recorded metabolic indicators including fasting blood glucose, lipid panels, and bone mineral markers such as calcium, phosphorus, and intact parathyroid hormone levels. As part of the initial vascular screening, the ABI was measured for each limb.

Foot Temperature Measurements

To record skin temperatures, contact thermometers were placed on the instep and sole of both feet, as well as the wrist of the nonaccess arm (Figures 1 and 2). The instep (dorsal midfoot) overlies the anterior tibial and dorsalis pedis angiosomes, whereas the sole reflects the posterior tibial angiosome; monitoring both sites therefore samples the 2 principal tibial-artery territories assessed by DUS, and these acral sites are among the earliest to display perfusion-related thermal

XSL•FO
RenderX

changes. We used Temp Pal (iWEECARE Co Ltd), a wireless, mobile health (mHealth)–based thermometer system that allows for simultaneous, multisite continuous monitoring. Five devices were paired via Bluetooth to a single iOS mobile device running the Temp Pal app, which captured and uploaded continuous temperature data to a cloud-based server for export. This system uses an autocalibration algorithm to ensure a high degree of measurement reliability, maintaining accuracy and precision within ±0.05 °C. Baseline body temperature was measured at the start and end of each HD session using an infrared ear thermometer, with simultaneous readings obtained from the skin sensors. Throughout the entire procedure, skin temperatures at the wrist and both feet were monitored continuously to capture fluctuations related to intradialytic hemodynamic shifts. Furthermore, clinical parameters, including dialysate temperature, blood pressure, and heart rate, were systematically recorded during the session.

Figure 1. Schematic of foot temperature monitoring using Temp Pal nanochip-based thermometer.

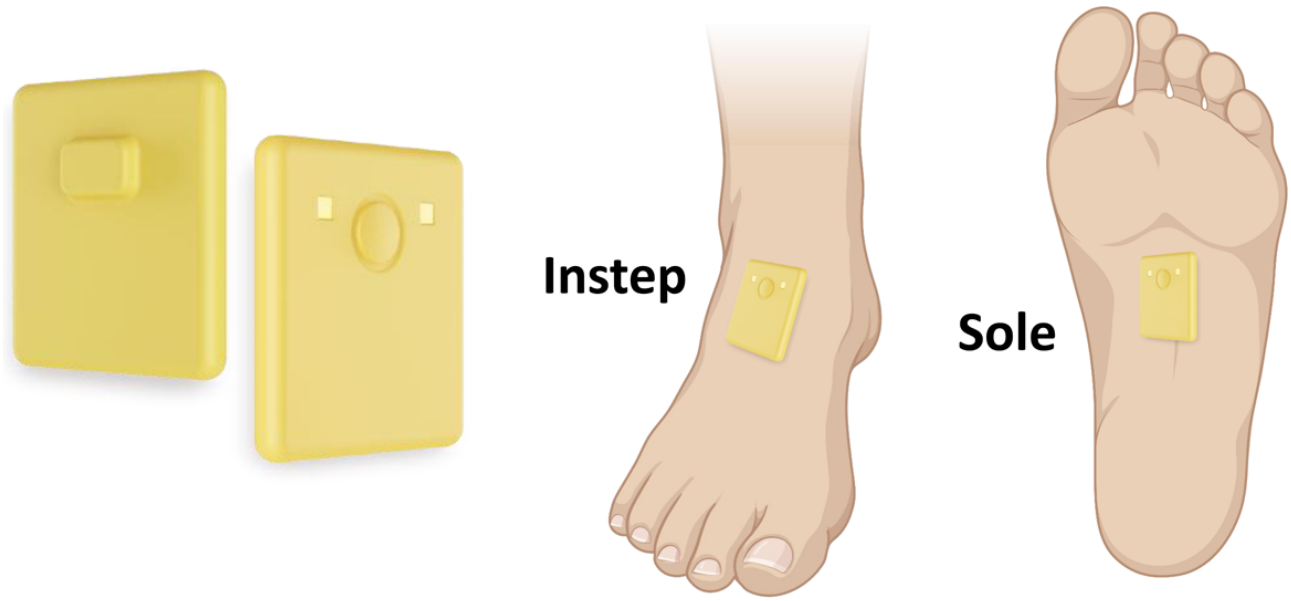

Figure 2. Example photos showing intradialytic foot and wrist temperature monitoring with Temp Pal nanochip-based thermometer.

Vascular DUS Measurements

To evaluate the presence and severity of PAD, all participants underwent DUS performed by experienced technicians. DUS served as the gold standard for this study, specifically focusing on flow patterns in the tibial arteries. Measurements were obtained from the distal PTA and ATA at a standardized location 5 cm above the ankle. Severe PAD was defined by the identification of monophasic or absent flow in either the distal PTA or ATA. These flow patterns were contrasted with normal (triphasic or biphasic) flow to categorize the limbs for comparative analysis of intradialytic temperature shifts.

Statistical Analysis

Inferential analyses were conducted at the limb level; 109 patients contributed 218 limbs eligible for analysis. Temperature parameters were compared between limbs with normal vs abnormal distal PTA/ATA flow using generalized estimating equation (GEE) with a normal distribution and an identity link, accounting for the intrapatient correlation between the 2 limbs of the same individual by using robust (empirical) standard errors. We further performed multivariable GEE analyses to investigate the independent associations of each temperature parameter and ABI value with abnormal distal PTA/ATA flow. The models were adjusted for age, DM, CAD, congestive heart failure, Kt/V (Daugirdas formula), and calcium × phosphorus product. We intentionally limited the adjustment to 6 confounding variables to avoid model overfitting, given that the number of events was 51 for abnormal distal PTA flow and 48 for abnormal distal ATA flow.

Discriminative performance of abnormal distal PTA/ATA flow was evaluated using receiver operating characteristic (ROC) curve analysis, with area under the curve (AUC) calculated as

XSL•FO
RenderX

the primary metric. The 95% CI for the AUC was derived using DeLong nonparametric method. When the AUC was statistically significant (ie, the 95% CI did not include 0.5), the optimal cutoff was determined using the Youden index to balance sensitivity and specificity. To determine if temperature monitoring offers incremental diagnostic value beyond the ABI, the statistical significance of differences between the respective AUC values was assessed via DeLong test. Statistical significance was defined as a 2-sided *P* value of less than .05. All analyses were conducted with MedCalc Statistical Software (version 20.019; MedCalc Software).

Results

Baseline Characteristics of the Study Cohort

The study included 109 patients with ESRD undergoing maintenance HD. The mean age of the participants was 65.2 (SD 11.9) years, and 56.9% (n=62) were male participants. Comorbid conditions were highly prevalent in this cohort, with hypertension (n=89, 81.7%) and DM (n=61, 55.9%) being the most frequent, followed by gout (n=29, 26.6%), CAD (n=26, 23.9%), and congestive heart failure (n=25, 22.9%). A smaller proportion of patients had a history of malignancy (n=6, 5.5%), cerebrovascular accidents (n=4, 3.7%), and myocardial infarctions (n=2, 1.8%). Regarding pharmacological management, the majority of patients were receiving erythropoietin (n=97, 88.9%) and iron supplements (n=84, 77.1%), while 58.7% (n=64) were on antihypertensive medications. Laboratory assessments revealed a mean hemoglobin of 11.6 (SD 1.2) g/dL and mean albumin of 3.99 (SD 0.37) g/dL. Dialysis adequacy was reflected by a mean Daugirdas Kt/V of 1.62 (SD 0.21). Biochemical markers related to bone and mineral metabolism showed a mean calcium of 8.92 (SD 0.98) mg/dL, mean phosphorus of 5.03 (SD 1.35) mg/dL, and median intact parathyroid hormone level of 290.7 (IQR 106.1-570.8) pg/mL. Iron status was characterized by a mean transferrin saturation of 27.9% (SD 11.8%) and median ferritin level of 567 (IQR 333-738) ng/mL. Detailed demographic, clinical, and biochemical data are summarized in Table 1.

Foot Temperature Parameters and ABI in Limbs With and Without Severe PAD

A total of 218 limbs were evaluated to analyze the relationship between distal arterial flow and various physiological parameters (Table 2). The parameters analyzed comprised the ABI and the temperature parameters, namely, wrist-to-foot and ear-to-foot temperature differences at the end of HD and absolute foot temperature before and at the end of HD. Limbs with abnormal flow in either the distal PTA or ATA exhibited significantly lower ABI values compared to those with normal flow (mean 0.90, SD 0.26 vs mean 1.13, SD 0.20 for PTA; mean 0.89, SD 0.27 vs mean 1.13, SD 0.200 for ATA; both $P<.001$). However, it is noteworthy that despite these significant differences, limbs with confirmed severe PAD still exhibited mean ABI values as high as 0.89 (SD 0.27) to 0.90 (SD 0.26), which border the clinically normal range and highlight the limitations of ABI in representing disease severity in this population.

Foot temperature at the end of the HD session	30.23 (2.60)	30.84 (2.63)	30.05 (2.58)	.04	31.20 (2.36)	29.96 (2.61)	.02

[a]HD: hemodialysis.

Regarding intradialytic temperature dynamics, the temperature difference between the wrist and the foot at the end of the HD session was significantly smaller in limbs with abnormal flow (Table 2). Specifically, at the sole, the wrist-foot temperature difference was mean 1.05 (SD 3.05) °C in the abnormal PTA group compared to mean 2.23 (SD 2.57) °C in the normal group (*P*=.02). A similar pattern was observed at the instep, reaching statistical significance for ATA flow (*P*=.046) but showing only a borderline association for PTA flow (*P*=.051). While foot temperatures before the HD session did not differ significantly between groups, the foot temperature at the end of the session tended to be higher in limbs with abnormal ATA flow compared to those with normal flow (mean 31.41, SD 2.55 °C vs mean 30.48, SD 2.46 °C at the instep; *P*=.08; mean 31.20, SD 2.36 °C vs mean 29.96, SD 2.61 °C at the sole; *P*=.02).

Additionally, a multivariable GEE model, adjusting for age, DM, CAD, congestive heart failure, Kt/V (Daugirdas formula), and the calcium × phosphorus product, revealed that an increased ABI was significantly associated with a reduced risk of abnormal distal PTA flow (odds ratio [OR] 0.73, 95% CI 0.63 - 0.83) and ATA flow (OR 0.71, 95% CI 0.59 - 0.85; Table 3). Moreover, wrist-to-foot temperature differences at the end of the HD session, evaluated at the instep and sole, respectively, were significantly associated with abnormal distal PTA flow at the sole (OR 0.81, 95% CI 0.68 - 0.97), with a borderline, nonsignificant association at the instep (OR 0.84, 95% CI 0.70 - 1.003), and with abnormal distal ATA flow at both the

XSL•FO
RenderX

instep (OR 0.84, 95% CI 0.71 - 0.99) and sole (OR 0.81, 95% CI 0.70 - 0.95). A similar pattern of results was observed for foot temperature at the end of the HD session.

Table . Associations of each temperature parameter and the ankle-brachial index (ABI) with abnormal distal posterior tibial artery (PTA)/anterior tibial artery (ATA) flow using a generalized estimating equation model[a].

Variable	Distal PTA flow		Distal ATA flow	
	OR[b] (95% CI)	*P* value	OR (95% CI)	*P* value
ABI (n=203)	0.73 (0.63 - 0.83)	<.001	0.71 (0.59 - 0.85)	<.001
Instep				
Temperature difference between the wrist and foot at the end of the HD[c] session	0.84 (0.70 - 1.003)	.053	0.84 (0.71 - 0.99)	.04
Temperature difference between the ear and foot at the end of the HD session	0.86 (0.75 - 0.995)	.04	0.83 (0.71 - 0.98)	.03
Foot temperature before the HD session	1.10 (0.93 - 1.31)	.27	1.06 (0.89 - 1.26)	.53
Foot temperature at the end of the HD session	1.16 (0.99 - 1.35)	.07	1.21 (1.02 - 1.44)	.03

Diagnostic Performance of Foot Temperature Parameters in Discriminating an ABI Value of Less Than 0.9

The diagnostic utility of intradialytic temperature monitoring was evaluated for its ability to predict an ABI value of less than 0.9 (Table 4). ROC analysis revealed that the temperature difference between the wrist and foot at the end of the HD session was the most effective parameter for this purpose. At the instep, this gradient achieved an AUC of 64.5% (95% CI 57.5% - 71.0%). Similarly, the gradient measured at the sole demonstrated a significant AUC of 64.2% (95% CI 57.2% - 70.8%; Figure 3). For the instep measurement, an optimal cutoff of 1.25 °C or less yielded a sensitivity of 63.2% (95% CI 46.0% - 78.2%) and a specificity of 60.0% (95% CI 52.1% - 67.5%). At the sole, a cutoff of 2.83 °C or less provided a higher sensitivity of 81.6% (95% CI 65.7% - 92.3%) but lower specificity of 42.4% (95% CI 34.8% - 50.3%). Other parameters, including absolute foot temperatures before or after HD and the ear-foot temperature gradient, did not reach statistical significance in discriminating limbs with an ABI value of less than 0.9 (Table 4).

Diagnostic Performance of Foot Temperature Parameters in Predicting the Presence of Severe PAD

ROC analysis was performed to further evaluate the diagnostic utility of various temperature parameters for identifying severe PAD (Table 5). The temperature difference between the wrist and the foot at the end of the HD session emerged as a significant indicator of arterial flow abnormalities. Specifically, for the detection of abnormal distal PTA flow, the wrist-foot temperature difference at the sole yielded an AUC of 62.0% (95% CI 55.2% - 68.5%; Figure 4). At the instep, this parameter showed an AUC of 59.1% (95% CI 52.3% - 65.7%). Notably, using a cutoff value of –2.2 °C or less for the wrist-foot difference at the instep provided a high specificity of 97.6% (95% CI 94.0% - 99.3%) for identifying abnormal PTA flow. The temperature parameters demonstrated even greater discriminative power for abnormal distal ATA flow. The wrist-foot temperature difference at the end of dialysis showed an AUC of 64.5% (95% CI 57.8% - 70.9%) at the sole and 62.0% (95% CI 55.2% - 68.5%) at the instep (Figure 5). Furthermore, absolute foot temperature at the end of the HD session was also a significant indicator of abnormal ATA flow, with an AUC of 64.5% (95% CI 57.7% - 70.8%) at the sole and 61.5% (95% CI 54.7% - 68.0%) at the instep. According to Youden index, a sole temperature cutoff of greater than 30.44 °C at the end of HD yielded a sensitivity of 70.8% (95% CI 55.9% - 83.0%) and a specificity of 58.2% (95% CI 50.4% - 65.7%) for detecting abnormal ATA flow (Table 5).

[e]Not applicable

Lastly, we performed DeLong test to examine whether the addition of temperature monitoring yields incremental diagnostic value over the baseline ABI (Table 6). Regarding abnormal distal PTA flow, temperature parameters at both the instep and sole failed to offer incremental diagnostic value over an ABI value of less than 0.9. Conversely, relatively stronger diagnostic utility was observed for abnormal distal ATA flow. For the instep measurements, although the improvements did not achieve statistical significance, the ΔAUC values increased by roughly 1% (95% CI –5.5% to 7.5%) to 4% (95% CI –2.1% to 10.1%). Notably, for the sole measurements, the wrist-to-foot temperature difference at the end of dialysis yielded a significant increase in AUC (ΔAUC 5.6%, 95% CI 0.2%-11.0%). Additionally, a potential trend toward improved AUC was noted for foot temperature at the end of the HD session (ΔAUC 5.1%, 95% CI –1.0% to 11.2%).

Discussion

Principal Findings

In this prospective cohort study of patients with ESRD undergoing maintenance HD, we explored the diagnostic potential of intradialytic foot temperatures for detecting severe PAD. First, we found that in this population, where arterial calcification is prominent, the ABI may remain near-normal despite the presence of severe PAD as confirmed by DUS. Second, absolute foot temperatures at the end of the dialysis session were significantly higher in patients with severe ATA disease compared with those without. Finally, the temperature gradient between the wrist and foot served as a significant predictor of severe ATA or PTA disease, achieving an AUC of up to 64.5% (95% CI 57.8%-70.9%) for abnormal ATA flow. These results suggest that monitoring foot temperatures during HD provides an accessible and noninvasive means of screening for PAD in the vulnerable ESRD population. Nonetheless, the discriminative ability of these temperature parameters was modest (AUCs of approximately 0.59 - 0.65), and because all estimates were derived and tested within the same cohort without internal or external validation, these findings should be interpreted as demonstrating an association rather than establishing a standalone diagnostic tool.

The diagnosis of PAD in patients with ESRD remains a significant clinical challenge due to the inherent limitations of conventional screening tools. The ABI, while widely used as a first-line diagnostic test, frequently yields falsely elevated or "normal" results in the HD population [17,18]. This is due to extensive arterial calcification, which renders the crural vessels noncompressible and prevents the accurate measurement of distal blood pressure [8]. This leads to a high rate of underdiagnosis in a population that is otherwise at extreme risk for CLTI and amputation. Furthermore, renal insufficiency is frequently associated with a more distal, crural distribution of atherosclerosis, which further complicates pressure-based assessments that are more sensitive to proximal disease. In our cohort, limbs confirmed to have severe PAD via DUS still exhibited mean ABI values as high as 0.89 (SD 0.27) to 0.90 (SD 0.26), suggesting that relying on ABI alone would have missed a substantial proportion of patients with severe tibial artery disease. We also demonstrated the feasibility of detecting severe PAD through the temperature gradient between the wrist and foot at the end of the HD session. For example, an instep wrist-foot temperature difference cutoff of –2.2 °C or less achieved a remarkable specificity of 97.6% (95% CI 94.0%-99.3%) for detecting abnormal flow in the PTA. By leveraging the hemodynamic stress during the dialysis process, this method provides a functional assessment of perfusion that is independent of vessel wall compressibility. Intradialytic thermography offers a potential screening adjunct, identifying high-risk patients who would otherwise be cleared by traditional, yet possibly less reliable, pressure-derived measurements.

Based on the established relationship between thermodynamics and hemodynamics, the use of skin temperature during HD as a proxy for arterial perfusion provides a novel physiological entry point for detecting PAD in patients with ESRD. Skin temperature has been previously recognized as an indicator of cutaneous blood flow, with infrared thermography and contact sensors being used to map ischemic zones in high-risk populations [19-21]. Prior studies have demonstrated that abnormal skin temperatures in the feet correlate significantly with reduced ABI values and abnormal limb arterial ultrasonography [20,22]. Our team previously reported that a significant postprocedural increase in foot temperature serves as a robust predictor of wound healing after EVT [16], reinforcing that thermal changes can directly reflect perfusion. However, interpretation of foot temperatures varies in different settings and can be challenging. In patients with DM, focal increases in foot temperatures are predictive of ulceration [15,23], while globally warmer feet suggest autosympathectomy related to diabetic neuropathy, with subsequent arteriovenous shunting and increased blood flow to the skin [19,22]. Thus, absolute foot temperature alone may be confounded and insufficient to reflect PAD severity. Similar to the use of myocardial stress testing to unmask underlying CAD, this present study advances this diagnostic concept by leveraging HD as a "thermal stress test" for the peripheral vasculature. To ensure diagnostic precision, the temperature at the wrist of the nonaccess arm served as a proximal, well-perfused reference. This approach allowed for the isolation of local thermal changes elicited specifically by vascular stress, thus controlling for systemic temperature fluctuations related to the dialysate itself. We found that while baseline temperatures before dialysis were similar between groups, the temperature at the end of the session significantly differentiated those with severe PAD. Specifically, the wrist-foot difference at the sole effectively discriminated abnormal flow in both the PTA and ATA. Interestingly, it is a lack of temperature decrease during HD that identifies severe PAD in our cohort (ie, those with severe PAD have higher foot temperatures). This paradoxical finding conforms with literature [18,19], suggesting disrupted vasoconstriction mechanisms in these patients. Our study demonstrates that wearable mHealth sensors provide a physiological foundation for future research into the underlying mechanisms of PAD in patients with ESRD.

Socioeconomic disparities significantly delay the diagnosis of PAD, leading to higher amputation rates in underserved populations [24]. Patients with ESRD, in particular, are frequently overlooked, with limited access to specialized care due to ambulatory difficulties and socioeconomic disadvantages [7]. Traditional screening for PAD via ABI or DUS is often limited by accessibility, resulting in a reactive approach where referral is initiated only after ulcers or gangrene appear. Intradialytic foot temperature monitoring offers a solution to overcome these barriers by using the Temp Pal, a wearable mHealth thermometer system that provides high-fidelity, continuous monitoring with minimal overhead. While studies have demonstrated the feasibility of smart-socks [21,25], such specialized apparel is unavailable in many regions, including Taiwan. In contrast, cutaneous thermometers are significantly cheaper, highly accessible, and reusable, making them a more practical choice for global implementation. More importantly, integrating this monitoring method into routine dialysis sessions allows patients to undergo screening without additional travel or time commitments, ensuring accessibility to those with limited mobility or resources. Our ultimate goal is to mitigate

XSL•FO
RenderX

health disparities within the high-risk population with ESRD, thereby improving both the trajectory of vascular disease and long-term survival. These potential benefits, improved screening access, reduced disparities, and earlier identification, were not evaluated in the present study and remain hypotheses to be tested in future implementation and outcome studies.

Limitations

While this study offers a novel approach to PAD screening, several limitations must be acknowledged. First, the sample size of 109 patients is relatively small and was recruited from 2 tertiary centers within a single geographic region. As our cohort consisted exclusively of an East Asian population in Taiwan, the generalizability of our findings to other ethnic groups remains uncertain. Given that racial and socioeconomic disparities significantly influence the presentation and progression of CLTI, further research in more diverse populations is necessary to validate our findings. Second, we used DUS flow patterns at 5 cm above the ankle as our gold standard for defining severe PAD. Although DUS is a clinically standard and reliable tool for assessing arterial patency, it primarily evaluates macrovascular flow. We did not incorporate other perfusion markers, such as transcutaneous oxygen tension or skin perfusion pressure, which might have provided a better understanding of how intradialytic temperature shifts correlate with actual tissue oxygenation. Finally, the sensitivity of intradialytic temperature monitoring for detecting severe tibial artery flow abnormalities varied considerably across parameters and measurement sites, with a reciprocal trade-off in specificity. In addition, this study was not designed to assess long-term outcomes. Although early detection is critical in PAD, there is a lack of evidence that this screening method leads to improved limb salvage rates or survival benefits. Future longitudinal studies are required to determine if initiating early interventions based on these thermal warning signs can successfully reduce major adverse limb events, major adverse cardiovascular events, or mortality associated with PAD in the population with ESRD. In addition, as most patients were asymptomatic and were screened irrespective of symptoms, formal clinical PAD staging (eg, Fontaine or Rutherford categories) was not performed; disease severity was instead defined objectively by DUS flow patterns. Moreover, several factors may have affected the accuracy of our temperature measurements: the ambient temperature of the dialysis unit was not systematically recorded, the access (fistula) arm was not measured, and a single nonaccess arm was used as the wrist reference for both legs, which could introduce bias if that reference limb itself had impaired perfusion.

Conclusions

This study demonstrated that intradialytic foot temperature monitoring is a potential diagnostic adjunct for detecting severe PAD in patients with ESRD. We found that in patients with ESRD, the ABI can remain near-normal despite severe disease, whereas the wrist-foot temperature difference at the end of the HD session was significantly associated with abnormal tibial flow, although sensitivity and specificity varied considerably across temperature parameters. Temperature monitoring with mHealth devices during HD may provide an accessible, low-cost screening solution that mitigates health disparities in patients with ESRD. Further longitudinal studies are required to confirm the survival benefits of this novel method. Because the observed discriminative ability was modest and has not yet been externally validated, intradialytic temperature monitoring should be regarded as a complementary adjunct to, rather than a replacement for, established vascular assessments such as the ABI.

Abstract

Background: AI-based tools for oral cancer screening have shown promising performance in curated image datasets, but their performance in real-world mobile community screening workflows remains less clear.

Objective: This study evaluated the prospective field performance of a parameter-locked, mobile AI-assisted oral lesion triage system embedded in a human-supervised community oral cancer screening workflow.

Methods: We conducted a prospective community-based field evaluation in eastern Taiwan from June 17 to December 31, 2025. Trained nonspecialist personnel acquired standard white-light intraoral images using handheld mobile devices during routine screening. The AI system incorporated on-site image quality assessment and lesion-level risk stratification into green, yellow, and red triage categories. Technically inadequate images after repeated acquisition attempts were classified as ungradable and excluded from performance analysis. Three board-certified oral and maxillofacial specialists established an operational clinical reference standard through structured image review and consensus adjudication. The primary outcome was lesion-level identification of high-risk lesions requiring specialist referral, defined as red versus nonred triage. Diagnostic performance was estimated with Wilson 95% CIs; precision-recall performance and preconsensus specialist agreement were also assessed.

Results: Among 602 screened participants, 4283 interpretable intraoral images were included in expert adjudication and lesion-level analysis. The AI system flagged 68 red lesions; 12 (17.6%) were confirmed as high risk, and 4 additional high-risk lesions were identified during expert review, yielding 16 high-risk events for the primary red-triage analysis. For high-risk lesion identification, sensitivity was 75% (12/16; 95% CI 50.5%-89.8%) and positive predictive value was 17.6% (12/68; 95% CI 10.4%-28.4%); specificity, negative predictive value, and accuracy were 98.6% (3928/3984), 99.9% (3928/3932), and 98.5% (3940/4000), respectively. Area under the receiver operating characteristic curve values were 0.957 for red, 0.931 for yellow, and 0.964 for green triage; precision-recall analysis showed area under the precision-recall curve values of 0.8235, 0.9052, and 0.9476, respectively. Preconsensus specialist agreement was high, with a Fleiss κ of 0.921 and a Gwet AC1 of 0.981.

Conclusions: This mobile AI-assisted oral lesion triage system was feasibly integrated into a real-world community screening workflow operated by trained nonspecialist personnel. In this low-prevalence field setting, red triage showed moderate sensitivity and modest positive predictive value, supporting its use as human-supervised referral-prioritization support rather than autonomous diagnosis. Further multicenter studies with blinded assessment, participant-level outcomes, workflow-efficiency measures, and longitudinal follow-up are needed before clinical impact and scalability can be determined.

Introduction

Oral cancer (OC) remains a substantial global public health burden and is associated with considerable yet often underrecognized socioeconomic consequences. Major risk factors include tobacco use, excessive alcohol consumption, and betel quid chewing, with a subset of cases associated with human papillomavirus infection [1]. Malignant transformation

XSL•FO
RenderX

commonly develops along a continuum of precursor conditions collectively referred to as oral potentially malignant disorders (OPMDs), which encompass clinical and histopathologic alterations of the oral mucosa and carry variable risks of subsequent progression to cancer [2]. Although surgical resection with or without adjuvant therapy remains the cornerstone of treatment, the overall 5-year survival rate for OC has remained approximately 40% to 50% [3]. These observations underscore the importance of early detection and risk-stratified referral, particularly in community screening settings where subtle oral mucosal lesions may be encountered before specialist evaluation.

In Taiwan, a nationwide OC screening program targeting high-risk populations, including individuals with tobacco, alcohol, or betel quid use, has been implemented for more than two decades, reflecting the recognized clinical and public health value of early detection. Nevertheless, the effectiveness of population-level screening remains challenged by the subtle and heterogeneous appearance of early oral mucosal lesions, as well as variability in lesion recognition among frontline screening personnel. These challenges may be amplified in remote community-based screening settings, where access to specialist oral oncology expertise is limited and screening is often performed under field conditions rather than in specialist clinics. Consequently, misclassification or underrecognition of OPMDs remains a long-standing issue [4]. These workflow-level constraints highlight the need for scalable, mobile-compatible tools that can support image acquisition, lesion risk stratification, and referral prioritization while preserving specialist oversight.

With advances in AI and deep learning, image-based tools for detecting oral mucosal lesions have progressed from proof-of-concept classification models toward clinically oriented screening support. Prior studies have shown that AI systems can identify OPMDs and OC from intraoral images with favorable classification or detection performance across diverse datasets [5-13]. Smartphone-based and mobile digital platforms have also been explored as accessible approaches for OC screening in community or resource-limited settings [14,15]. In addition, recent work has incorporated multimodal imaging, lesion segmentation, and risk-based triage frameworks to improve lesion detection, boundary delineation, and referral decision support [16-19]. However, most existing evidence remains focused on model development, internal validation, retrospective datasets, or clinic-based populations, which may not fully capture deployment-related factors such as image acquisition variability, low-prevalence predictive values, and reference standard uncertainty. Prospective evidence on how mobile AI-assisted triage performs when embedded in real-world community screening workflows, particularly with trained nonspecialist image acquisition and on-site quality assurance and expert oversight, remains limited.

To address these clinical and workflow needs, our group previously developed a deep learning system capable of simultaneously identifying multiple coexisting oral mucosal lesions from standard white-light intraoral images collected through Taiwan's population-based screening program [20]. Unlike approaches centered on single-disease classification, this system was designed to reflect the clinical complexity of routine oral examinations, in which benign lesions, OPMDs, and highly suspicious lesions may coexist within the same individual. In internal validation, the model demonstrated favorable diagnostic performance, supporting further prospective evaluation of its potential role as triage support for community-based screening. However, model performance in curated or development datasets does not necessarily translate into reliable operation in mobile field settings. In community screening workflows, image quality, operator experience, oral cavity exposure, lighting conditions, and lesion prevalence may differ substantially from those observed in controlled datasets. Therefore, prospective evaluation within routine screening workflows is needed to determine whether AI-assisted oral lesion triage can operate reliably under real-world conditions and support referral prioritization without replacing specialist oversight.

Although recent multicenter and clinically oriented studies have reported robust performance of AI systems for OPMD-related detection and classification tasks, much of the existing evidence has been generated from controlled image datasets or clinical populations rather than prospective community screening workflows [21,22]. Direct evidence remains limited regarding how mobile AI-assisted oral lesion triage performs when integrated into real-world field screening, particularly when images are acquired by trained nonspecialist personnel using handheld mobile devices. In this study, we evaluated the prospective field performance of a previously developed, parameter-locked AI-based oral lesion triage system embedded within routine community OC screening. Rather than focusing on model development or diagnostic classification alone, we assessed a human-supervised mobile health workflow that incorporated on-site image quality assurance; green, yellow, and red lesion-level triage; and structured expert adjudication.

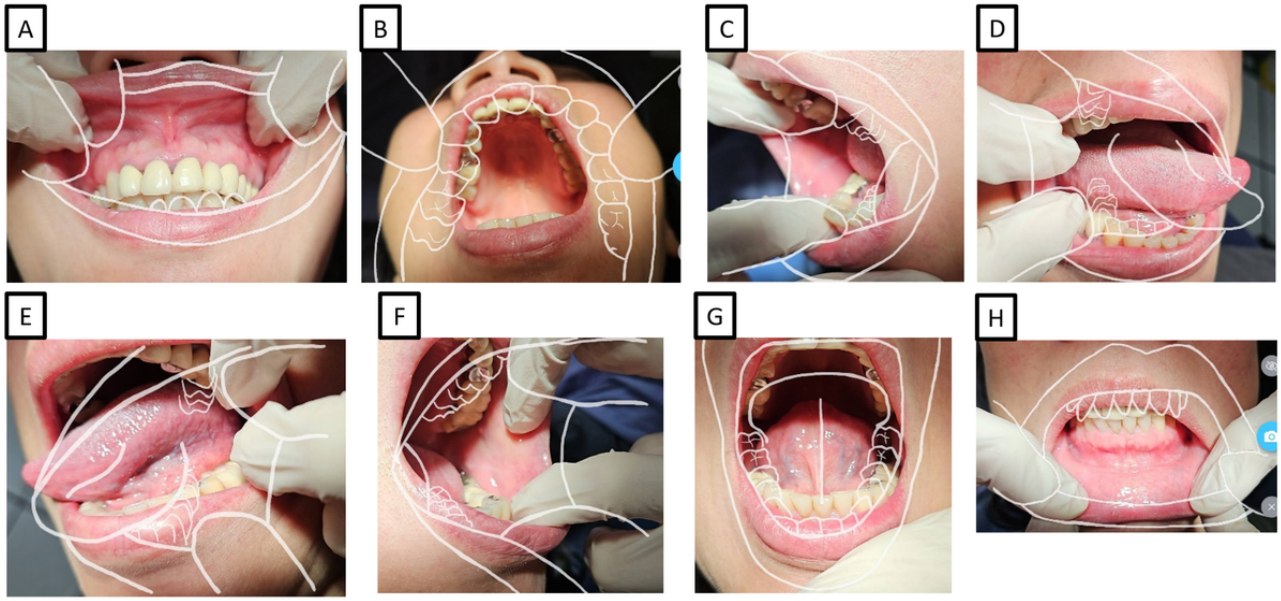
Methods

Study Design and Setting

This prospective, community-based field evaluation study assessed a previously developed and parameter-locked AI-assisted oral lesion triage system within routine OC screening workflows. The system was deployed from June 17, 2025, to December 31, 2025, during community screening activities in eastern Taiwan, a region with a relatively high OC burden and limited access to specialist oral oncology services. This study was designed to evaluate workflow-integrated performance rather than model development; no retraining, optimization, or post hoc threshold adjustment was performed during the study period. No formal sample size calculation was performed; the sample size reflected all eligible participants screened during the prospective field deployment period. Screening procedures followed the standard operating protocols of Taiwan's national OC prevention program and were conducted by trained nonspecialist personnel to reflect frontline community practice. Intraoral image acquisition using handheld mobile devices, automated on-site image quality assessment, and AI-generated triage outputs were performed concurrently at screening sites under routine field conditions. Representative images of the

XSL•FO
RenderX

community screening environment are provided in Figure S1 in Multimedia Appendix 1.



Participants and Recruitment

Community residents aged 18 years or older who voluntarily participated in routine OC screening activities were eligible for inclusion. Participants were recruited from community-based screening events rather than specialist referral clinics, thereby reflecting a frontline screening population with a low expected prevalence of high-risk oral lesions. Exclusion criteria were refusal to undergo intraoral imaging, persistently inadequate image quality despite repeated acquisition attempts, or a history of OC treatment resulting in substantial postsurgical anatomic alteration that precluded standardized mucosal assessment. In accordance with Taiwan's national OC screening protocols, each participant underwent standardized intraoral photographic documentation as part of the screening workflow. Screening-related clinical and imaging data were collected prospectively at the screening sites to reflect real-world community-level heterogeneity. Individual-level demographic variables and behavioral risk factors, including age, sex, tobacco use, alcohol use, and betel quid use, were not collected in the analytic dataset.

Mobile Image Acquisition and On-Site Quality Assurance

Intraoral images were acquired during routine community screening by trained nonspecialist personnel using handheld mobile devices. Each participant underwent standardized photographic documentation of the oral cavity according to Taiwan's national screening protocols, with images obtained from predefined mucosal regions to support comprehensive visual assessment (Figure 1). Image acquisition was performed under real-world field conditions without specialized photographic equipment, thereby preserving variability in illumination, patient positioning, oral opening, and operator technique encountered in frontline community screening practice.

Figure 1. A standard oral photograph sample using augmented reality lines to guide the correct angles and positions for examining different parts of the oral mucosa.

Immediately after acquisition, each image was assessed on-site by the AI-based image quality assurance module. The module evaluated whether the image provided adequate focus sharpness, illumination, mucosal visibility, and absence of motion artifacts for downstream lesion assessment. Images that failed to meet predefined quality criteria triggered immediate repeat acquisition, with up to 3 attempts permitted for each target view. Images that remained inadequate after repeated acquisition attempts were classified as ungradable and were excluded from AI triage output and subsequent performance analysis. This quality assurance step was incorporated into the mobile screening workflow to reduce the impact of technically inadequate images while preserving the practical constraints of community-based image acquisition.

AI Triage System and Field Deployment Workflow

The AI system evaluated in this study was a previously developed oral lesion triage model trained on 8336 clinical intraoral images collected between 2021 and 2024 at a tertiary medical center. Before field deployment, the model architecture, parameters, and triage thresholds were fixed, and no retraining, fine-tuning, or post hoc threshold adjustment was performed during the study period. The system was designed to identify multiple coexisting oral mucosal lesions within standard white-light intraoral images and generate lesion-level bounding box annotations with risk-based triage outputs to support screening workflow decisions.

For field deployment, the system incorporated 2 sequential modules within the mobile screening workflow. The first was an automated image quality assurance module, which assessed whether acquired images were technically adequate for lesion evaluation and triggered immediate repeat acquisition when predefined quality criteria were not met. The second was a multi-lesion detection and risk stratification module, which classified screening findings into 3 clinically actionable triage

XSL•FO
RenderX

categories: green, indicating no actionable lesion or no evident malignant potential; yellow, indicating lesions requiring structured follow-up; and red, indicating lesions requiring specialist referral because of high-risk clinical features. AI-generated outputs were produced on-site as triage support and were not used as autonomous diagnostic decisions. Representative AI-generated outputs for the green, yellow, and red triage categories are provided in Figure S2 in Multimedia Appendix 1. Additional technical details of model development, internal validation, and comparative training outcomes are provided in Table S1 in Multimedia Appendix 1.

Operational Clinical Reference Standard

The reference standard in this study was defined as an operational clinical reference standard established through structured expert adjudication, reflecting decision-making in community-based OC screening rather than definitive histopathologic diagnosis. Three board-certified oral and maxillofacial specialists independently reviewed the complete intraoral image set for each participant. Reviewers assessed the appropriateness of the AI-generated triage classification and evaluated the presence, location, and risk category of clinically relevant lesions across the full image set.

Reviewers were aware of the AI-generated triage outputs, including green, yellow, and red classifications, during the evaluation process. This design reflected the workflow-integrated nature of the field evaluation and, therefore, constituted an unblinded operational reference standard rather than a blinded diagnostic validation reference standard. In addition to assessing AI-flagged findings, reviewers were instructed to comprehensively examine all original images to identify clinically significant lesions that may not have been detected by the AI system, thereby incorporating potential false-negative findings into the reference standard. Initial independent assessments were recorded for all cases and were used to calculate preconsensus interrater agreement among the 3 specialists. When all reviewers agreed, the concordant classification was adopted. For cases with disagreement, a formal adjudication meeting was conducted, and the final consensus decision was established as the operational clinical reference standard.

Histopathologic examination remains the definitive standard for confirming oral malignancy and epithelial dysplasia. However, systematic biopsy of all lesions or all screened participants is not feasible or ethically appropriate in population-level community screening. In routine screening practice, referral and follow-up decisions are commonly based on clinical visual assessment by experienced specialists, with biopsy reserved for lesions considered clinically suspicious or requiring diagnostic confirmation. Furthermore, in the context of multifocal and heterogeneous OPMDs, localized biopsy sampling may not fully represent overall lesion risk because of inherent sampling limitations [23]. Because this study evaluated AI-assisted triage within a screening workflow rather than final disease diagnosis, structured expert consensus was used to determine clinically relevant risk categories for performance evaluation. This study was designed and reported in accordance with the STARD (Standards for Reporting of Diagnostic Accuracy Studies) 2015 reporting guidelines, and the completed checklist is provided in Checklist 1.

Outcome Measures

The primary outcome was the lesion-level performance of the AI system for identifying high-risk oral mucosal lesions requiring specialist referral, corresponding to the red triage category. For the primary analysis, each AI-detected or expert-adjudicated lesion was classified using a red vs nonred framework, and lesion-level 2 × 2 contingency tables were constructed using expert adjudication as the comparator. Given the low expected prevalence of high-risk lesions in community screening, interpretation of the primary red triage outcome emphasized sensitivity and positive predictive value (PPV).

Secondary outcomes included category-specific lesion-level performance for the yellow and green triage categories, image-level agreement between AI outputs and expert adjudication where applicable, and discriminative performance based on AI detection confidence using receiver operating characteristic (ROC) and precision-recall analyses. The 3 triage categories were defined according to clinical actionability and were informed by previously reported gradients of malignant transformation risk in OPMDs [24-28]. In this framework, red indicated lesions requiring specialist referral because of high-risk clinical features; yellow indicated lesions requiring structured follow-up because of low to intermediate risk features; and green indicated no actionable lesion or findings without evident malignant potential.

For category-specific analyses, each triage level was evaluated using a one vs the rest framework, with red compared with nonred categories, yellow compared with nonyellow categories, and green compared with nongreen categories. False-negative cases in the red category were further reviewed descriptively to characterize potential failure patterns relevant to real-world mobile screening deployment.

Statistical Analysis

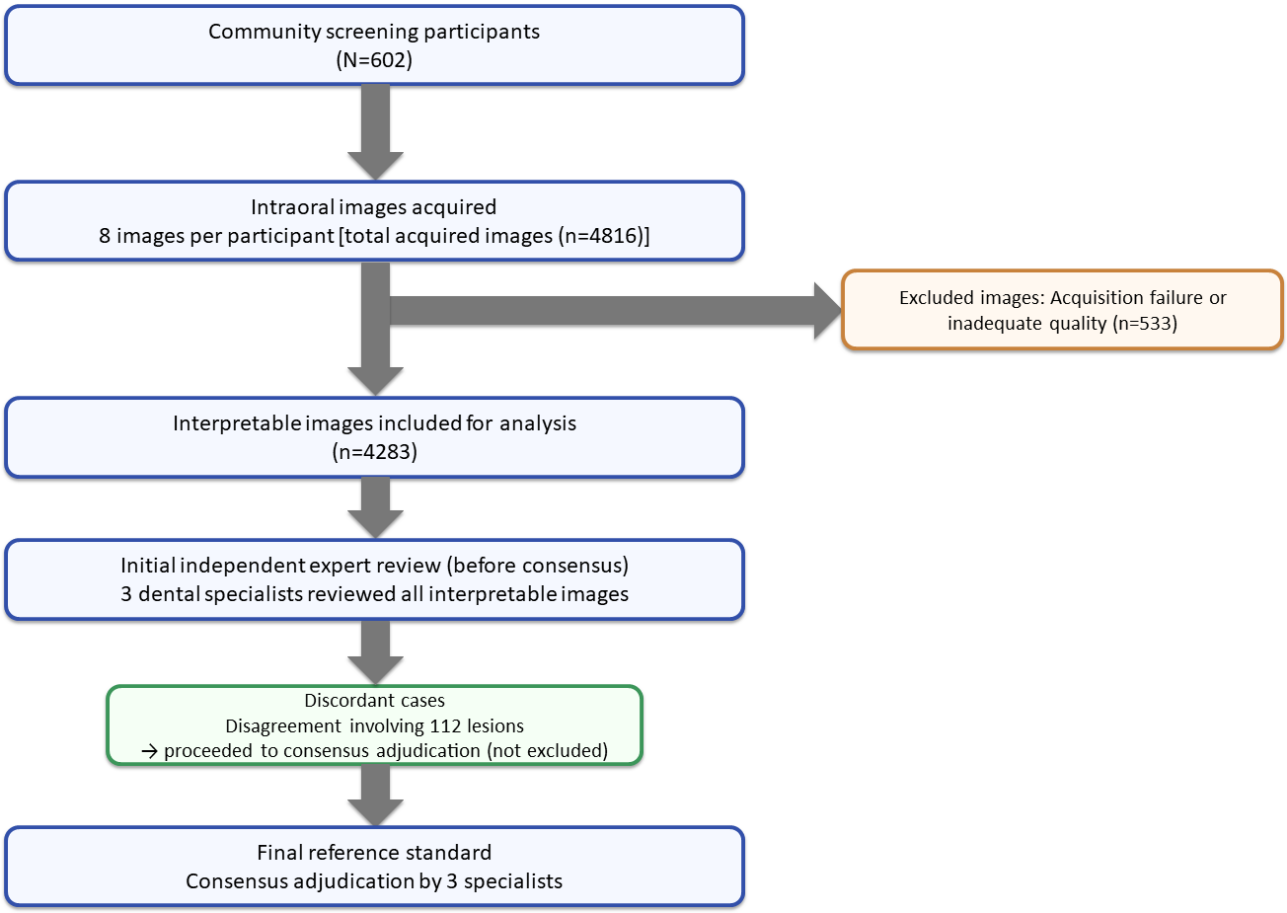
All analyses were conducted according to the predefined outcome framework. The primary analysis evaluated lesion-level performance of the AI system for identifying high-risk oral mucosal lesions requiring specialist referral using the expert-adjudicated lesion-level classification as the comparator. Secondary analyses included category-specific lesion-level performance for the yellow and green triage categories, as well as image-level agreement between AI outputs and expert adjudication where applicable.

For each analysis, diagnostic performance metrics, including sensitivity, PPV, specificity, negative predictive value (NPV), and overall accuracy, were calculated with corresponding 95% CIs using the Wilson method. Discriminative performance was further assessed using ROC curves and the area under these curves (ROC-AUC) based on AI detection confidence scores for each triage category. Precision-recall curves and the area under these curves (PR-AUC) were also generated to evaluate positive triage performance in the low-prevalence screening setting. Preconsensus interrater agreement among the 3 specialists was summarized using the complete agreement rate, average pairwise observed agreement, Fleiss κ, and Gwet AC1.

XSL•FO
RenderX

All analyses were descriptive in nature, and no formal hypothesis testing was performed. Given the prospective field evaluation setting and the exploratory objective of workflow-integrated assessment, statistical comparisons between groups were not prespecified. Analyses were conducted using the Python software (version 3.11; Python Software Foundation) with standard scientific computing libraries.

Ethical Considerations



This study was approved by the Research Ethics Committee of National Taiwan University Hospital (approval number NTUH 202504075 RIND). All procedures were conducted in accordance with local regulations and the principles of the Declaration of Helsinki. Screening-related clinical and imaging data were deidentified before analysis and stored in secure institutional systems. Participation was voluntary, and informed consent was obtained according to the approved study protocol. No financial compensation was provided to participants.

Results

Participant and Image Flow

Between June 2025 and December 2025, a total of 602 participants underwent community-based OC screening. In accordance with the standardized screening protocol, multiple intraoral images were acquired for each participant, with a mean of approximately 8 images per participant. Of 4816 acquired intraoral images, 533 (11.1%) were excluded because of acquisition failure or inadequate quality, leaving 4283 (88.9%) interpretable images for expert adjudication and lesion-level performance analysis. The participant and image flow is summarized in Figure 2.

Figure 2. STARD (Standards for Reporting of Diagnostic Accuracy Studies)–consistent participant and image flow diagram.

Expert Adjudication and Final Analysis Set

All interpretable images were initially reviewed independently by 3 board-certified oral and maxillofacial specialists without discussion. During this initial review, cases for which all 3 specialists reached the same initial classification were summarized as a preconsensus process measure, as shown in Table 1. Preconsensus lesion-level agreement among the 3 specialists was high, with a complete agreement rate of 97.5%, a Fleiss κ of 0.921, and a Gwet AC1 of 0.981. This preconsensus summary was used to describe the initial concordant expert review process and was not used as the primary outcome analysis. Among these concordant initial assessments, 91% (3898/4283) of the images were classified as showing no detectable lesion.

XSL•FO
RenderX

Table . Lesion-level performance based on concordant initial independent expert assessments before consensus adjudication.

	TPs[a], n	FPs[b], n	FNs[c], n	TNs[d], n	Sensitivity (%; 95% CI)	Specificity (%; 95% CI)	PPV[e] (%; 95% CI)	NPV[f] (%; 95% CI)	Accuracy (%; 95% CI)
Red	10	12	4	3898	71.4 (45.4-88.3)	99.7 (99.5-99.8)	45.5 (26.9-65.3)	99.9 (99.7-100)	99.6 (99.3-99.7)
Yellow	240	16	9	3898	96.4 (94.0-98.1)	99.6 (99.3-99.7)	93.8 (90.1-96.2)	99.8 (99.6-99.9)	99.4 (99.2-99.6)

[a]TP: true positive.

[b]FP: false positive.

[c]FN: false negative.

[d]TN: true negative.

[e]PPV: positive predictive value.

[f]NPV: negative predictive value.

Disagreement among the 3 specialists was identified for 112 lesions, indicating that a subset of oral mucosal findings remained clinically equivocal during independent expert assessment. These discordant lesions subsequently underwent formal consensus adjudication to establish the final operational clinical reference standard. After consensus adjudication, all interpretable images, including those with initial discordance, were incorporated into the final lesion-level analysis. In the final adjudicated dataset, 91.7% (3928/4283) of the images were confirmed as not containing detectable lesions, and the final adjudicated performance is shown in Table 2.

Table . Final adjudicated lesion-level performance after expert consensus.

	TPs[a], n	FPs[b], n	FNs[c], n	TNs[d], n	Sensitivity (%; 95% CI)	Specificity (%; 95% CI)	PPV[e] (%; 95% CI)	NPV[f] (%; 95% CI)	Accuracy (%; 95% CI)

[a]TP: true positive.

[b]FP: false positive.

[c]FN: false negative.

[d]TN: true negative.

[e]PPV: positive predictive value.

[f]NPV: negative predictive value.

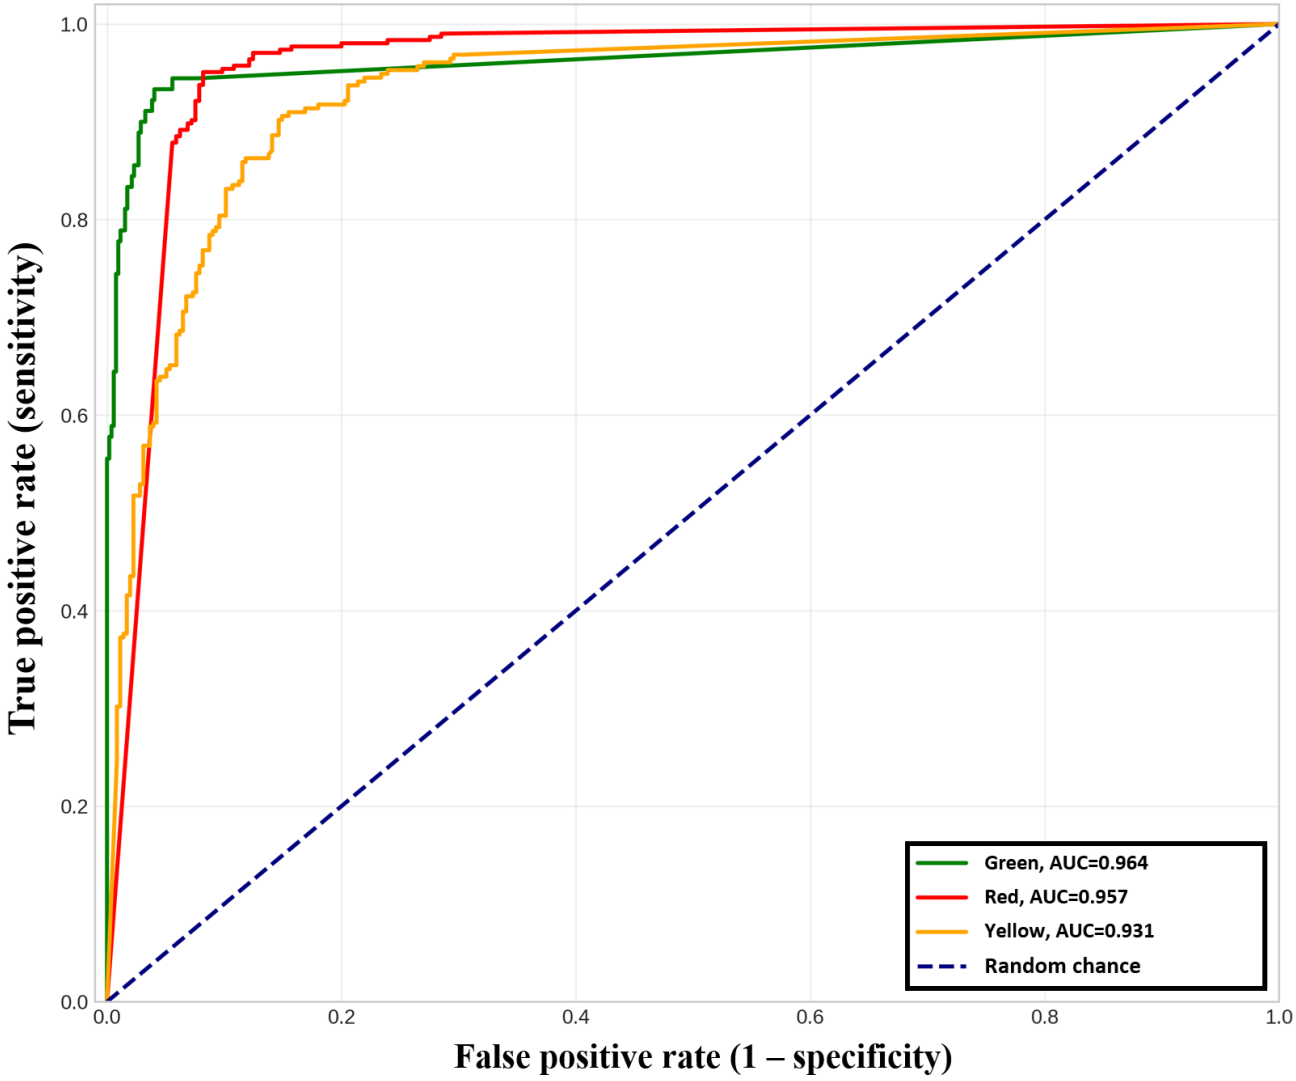
Primary Outcome: High-Risk Red Triage Categorization Performance

For the primary lesion-level analysis of high-risk lesions corresponding to the red triage category, the AI system flagged 68 lesions during screening. Following expert consensus adjudication, 17.6% (n=12) of these lesions were confirmed as true high-risk lesions. In addition, 4 lesions not initially classified as red by the AI system, including 2 lesions not detected by the model and 2 lesions classified as yellow or green, were adjudicated as high risk, yielding 16 high-risk lesions for the primary red triage category analysis.

In the final adjudicated analysis, sensitivity for high-risk lesion identification was 75.0% (95% CI 50.5%-89.8%), and PPV was 17.6% (95% CI 10.4%-28.4%). Specificity, NPV, and overall accuracy were 98.6% (95% CI 98.2%-98.9%), 99.9% (95% CI 99.7%-100%), and 98.5% (95% CI 98.1%-98.8%), respectively (Table 2). In operational terms, the red triage category generated 68 flags among the 4283 interpretable images, corresponding to 15.9 red flags, 2.8 true-positive red flags, and 13.1 false-positive red flags per 1000 interpretable images.

Secondary Outcomes: Yellow and Green Triage Categorization Performance

In secondary lesion-level analyses based on the final adjudicated reference standard, category-specific performance was evaluated for the yellow and green triage categories. For the yellow category, sensitivity was 92.7% (95% CI 89.3%-95.2%), and PPV was 81.4% (95% CI 77.0%-85.2%); specificity, NPV, and overall accuracy were 98.4% (95% CI 98.0%-98.7%), 99.4% (95% CI 99.2%-99.6%), and 98.0% (95% CI 97.5%-98.4%), respectively. For the green category, sensitivity was 82.2% (95% CI 77.1%-86.3%), and PPV was 94.4% (95% CI 90.7%-96.7%); specificity, NPV, and overall accuracy were



XSL•FO
RenderX

99.7% (95% CI 99.4%-99.8%), 98.8% (95% CI 98.4%-99.1%), and 98.6% (95% CI 98.1%-98.9%), respectively (Table 2).

Discriminative Performance Based on Detection Confidence

To evaluate discriminative performance across lesion risk categories, ROC curves were constructed using AI detection confidence scores. The expert-adjudicated classification served as the operational clinical reference standard for ROC analysis. For each triage category, a one vs the rest analysis was performed, with the target category treated as positive and all other categories combined as negative. ROC-AUC values were 0.957 for red, 0.931 for yellow, and 0.964 for green (Figure 3). Precision-recall analysis yielded PR-AUC values of 0.8235 for red, 0.9052 for yellow, and 0.9476 for green. The corresponding precision-recall curves are shown in Figure S3 in Multimedia Appendix 1.

Figure 3. Receiver operating characteristic curves for AI-based oral lesion risk stratification showing the discriminative performance of the AI system for green, yellow, and red risk categories using the expert-adjudicated operational clinical reference standard. The diagonal dashed line represents random classification. AUC: area under the curve.

Discussion

Principal Findings

In this prospective community-based field evaluation study, we assessed a previously developed, parameter-locked, mobile AI-assisted oral lesion triage system within a routine community OC screening workflow. Under field conditions, including image acquisition by trained nonspecialist personnel using handheld mobile devices, on-site image quality assurance, AI-assisted lesion-level risk stratification, and expert adjudication, the system was feasibly integrated into the screening workflow and provided preliminary lesion-level performance estimates for the high-risk red category. The primary red triage category analysis was based on 16 high-risk lesions and showed moderate sensitivity with modest PPV, reflecting the low-prevalence structure of community screening. Unlike model development or retrospective validation studies, this study evaluated how an AI-assisted triage system functioned when embedded in a real-world mobile screening workflow, where image quality, operator experience, lesion distribution, and expert interpretation reflect frontline community practice. These findings suggest that mobile AI-assisted oral lesion triage may help bridge the gap between algorithmic validation and practical field evaluation. The system should therefore be understood not as an autonomous diagnostic tool but as human-supervised triage

XSL•FO
RenderX

support within a digital health workflow designed to assist risk stratification and referral prioritization while preserving expert oversight.

Interpretation in the Context of Community Screening

Community-based OC screening differs fundamentally from the controlled image datasets commonly used in AI research. Prospective field evaluation can therefore reveal deployment-related constraints, including acquisition variability, low-prevalence predictive values, and reference standard uncertainty, that may not be fully captured in model development or retrospective validation studies [29,30]. More broadly, recent clinical AI evaluation commentaries have similarly emphasized that aggregate metrics or direct output-only evaluation may be insufficient to assess workflow-level reliability, interpretability, and deployment safety [31,32]. In routine mobile screening workflows, intraoral images are acquired on-site by trained nonspecialist personnel under variable lighting, positioning, oral opening, and operator conditions. In addition, the prevalence of high-risk lesions within community screening populations is low, resulting in a predominance of normal or nonspecific findings and a markedly imbalanced risk distribution. In this study, despite high overall preconsensus interrater agreement, disagreement among the 3 independent specialists was observed for 112 lesions before consensus adjudication, underscoring that a subset of oral mucosal findings remained clinically equivocal even under expert review. The contrast between the preconsensus summary and the final adjudicated analysis illustrates the clinical uncertainty inherent in field screening and supports the need for structured expert adjudication when evaluating AI-assisted triage systems. Within such workflows, image quality assurance is a central deployment requirement because reliable risk stratification depends not only on model performance but also on the quality and consistency of field-acquired images.

Interpretation of Predictive Values in Low-Prevalence Screening

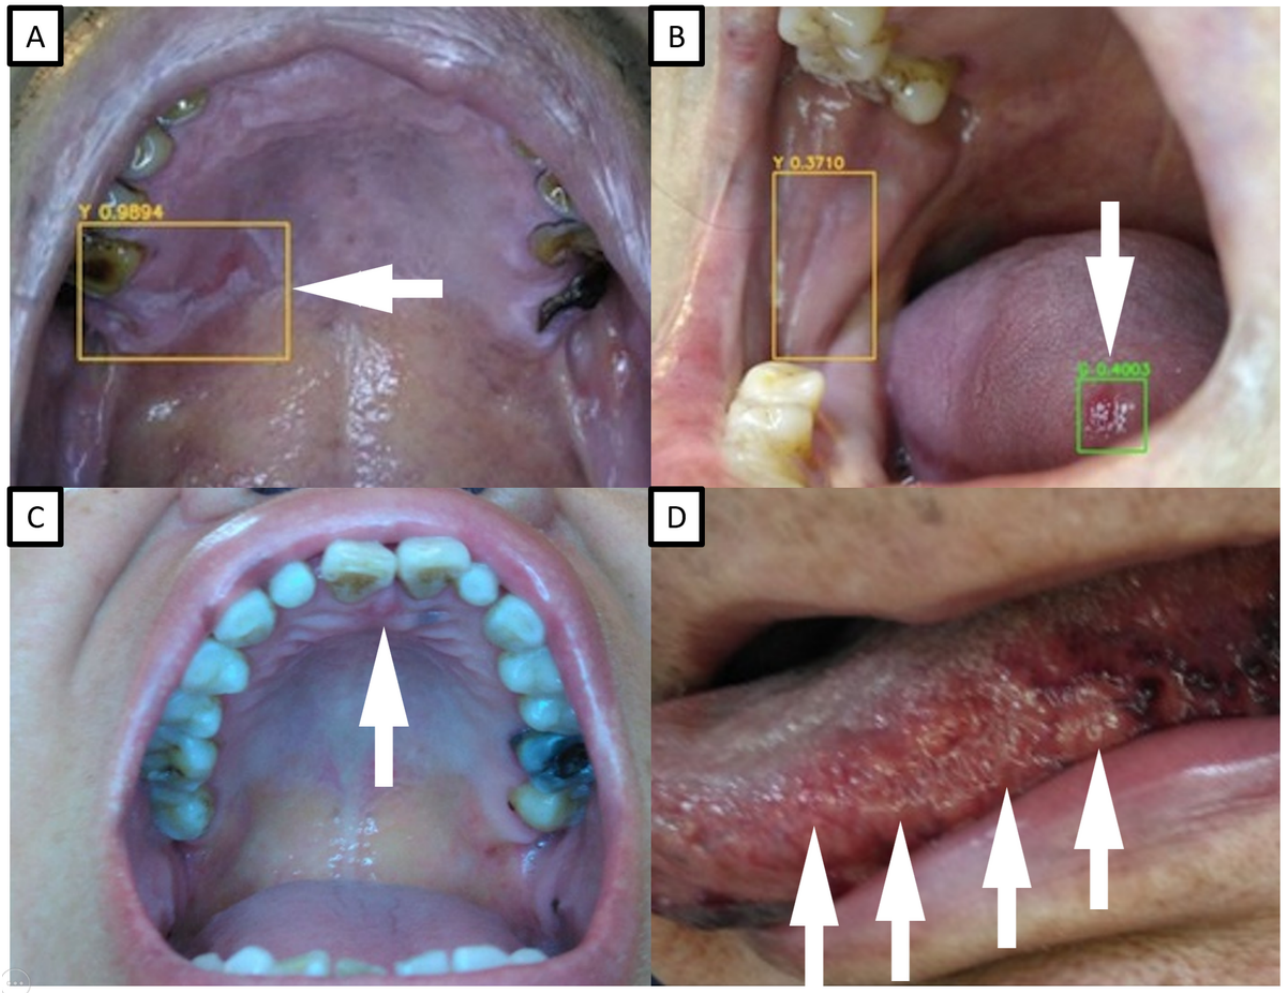
The high-risk red triage category showed moderate sensitivity and modest PPV despite high specificity and NPV. This finding should be interpreted within the epidemiologic structure of community-based OC screening. Population-based studies from Taiwan have reported that the prevalence of highly suspicious or referral-requiring oral lesions in community screening settings is approximately 0.9% to 2.2% [26-28]. In such low-prevalence settings, even screening tools with high sensitivity and specificity may yield constrained PPVs because predictive values are strongly influenced by baseline disease prevalence [33,34]. Therefore, the PPV observed for the red triage category should not be interpreted as a stand-alone diagnostic measure. It should also not be interpreted as an operational measure of positive triage yield and expert review burden. Rather, it should be considered in relation to the intended role of AI-assisted triage: prioritizing a smaller subset of lesions for further specialist evaluation while preserving human oversight in a predominantly low-risk screening population [35-37].

Contextual Risk Enrichment and Quality Management Relevance

As an exploratory contextual analysis, PPV lift was used to describe the degree of risk enrichment achieved by the red triage category relative to the expected baseline event rate in the screened population. Using reported baseline prevalence estimates for high-risk oral lesions in Taiwanese community screening populations and the observed red category sensitivity and specificity, the estimated PPV lift suggested that AI-assisted triage may concentrate high-risk findings within the red category [38-40]. PPV has also been used as a quality management indicator in Taiwan's oral mucosal screening program, although such benchmarks were developed for program-level screening evaluation rather than lesion-level AI triage assessment [41,42]. Although direct comparison is limited by differences in outcome definitions, analysis level, and reference standards, the lesion-level PPV of 17.6% observed for AI red triage may be viewed as a contextual signal of risk enrichment under low-prevalence community screening conditions. Because the present analysis did not directly measure participant-level referral yield, specialist workload, cost-effectiveness, or downstream clinical outcomes, this finding should be interpreted as a potential prioritization signal within a supervised triage workflow rather than direct evidence of clinical benefit.

Human-Supervised Triage and Expert Oversight

The structured expert adjudication process also provides insights into how AI outputs were incorporated into the screening workflow. Prior studies have cautioned that AI-driven decision support may introduce automation bias or anchoring effects if clinicians overrely on model outputs, particularly when explainability alone is insufficient to ensure appropriate clinical interpretation [43]. In the present study, the presence of 112 discordant lesions before consensus adjudication and the identification of 4 AI-missed high-risk lesions during expert review suggest that expert review included active assessment beyond AI-flagged outputs; however, because reviewers were aware of AI outputs, the process remains susceptible to AI-related review or incorporation bias. Instead, discordant or equivocal findings were subjected to formal consensus adjudication, and additional high-risk lesions not classified as red by the AI system were incorporated into the final operational clinical reference standard. This process helped maintain a practical distinction between AI-generated triage suggestions and expert-derived clinical reference decisions within the workflow. These findings are consistent with broader recommendations that medical AI systems should support rather than replace clinical judgment, with appropriate oversight and accountability maintained throughout deployment [44-46].



Failure Patterns and Field Deployment Implications

The 4 lesions adjudicated as high risk but not initially classified as red by the AI system provide clinically informative examples of deployment-relevant limitations under mobile field screening conditions. These cases included lesions with borderline visual characteristics, such as mixed erythematous and leukoplakic appearances, lesions located near image margins, and lesions with limited local contrast or incomplete visibility. These findings suggest that subtle morphology, partial lesion capture,

XSL•FO
RenderX

peripheral lesion location, and low contrast may reduce model sensitivity for high-risk triage in field-acquired images. From a workflow perspective, these failure patterns underscore the importance of maintaining human oversight, comprehensive image review, and structured expert adjudication in AI-assisted community screening, particularly for lesions that fall along a continuum of clinical risk. Representative examples are shown in Figure 4.

Figure 4. Representative false-negative cases in the high-risk (red) triage category during AI-based oral cancer screening (n=4): (A) a borderline lesion with mixed erythematous and leukoplakic appearance that was initially classified by the AI system as low risk (yellow) and subsequently reclassified as high risk (red) following expert consensus; (B) a lesion (green) located near the image margin that was not flagged as high risk by the AI system, where proximity to the image boundary may have influenced model detection; and (C and D) lesions not identified by the AI system that were subsequently recognized by experts upon case-by-case image review at the locations indicated by the white arrows and classified as high risk.

Practical Implications for Community Screening

The findings of this study support the potential value of AI-assisted oral lesion triage in remote community screening settings, where access to specialist oral oncology expertise may be limited. By combining on-site image quality assurance, risk-stratified AI outputs, and expert adjudication, this mobile screening workflow may support referral prioritization under specialist oversight rather than directly establishing improved diagnostic performance by frontline personnel. Because the fixed red triage operating point yielded modest PPV and measurable false positive review burden, future implementation studies should evaluate whether alternative operating points could better balance sensitivity, PPV, and specialist workload. Within Taiwan's existing national OC screening program, such systems could serve as adjunctive tools for referral prioritization rather than replacements for clinical judgment. This approach may be particularly relevant for high-risk or geographically underserved populations, where scalable triage support could help bridge gaps between community screening and specialist evaluation. Further studies are needed to determine whether mobile AI-assisted triage can improve referral efficiency, specialist workload, cost-effectiveness, and downstream clinical outcomes.

Limitations

Several limitations warrant consideration. First, the primary performance analysis was conducted at the lesion level rather than as a participant-level clinical outcome analysis. Although this approach was aligned with the lesion-level AI outputs and expert adjudication used in the present workflow, future studies should evaluate participant-level referral decisions, referral completion, and downstream clinical outcomes. Second, histopathologic confirmation was not systematically obtained for all lesions or screened participants. Expert consensus therefore served as an operational clinical reference standard

XSL•FO
RenderX

for triage evaluation rather than a definitive diagnostic gold standard. Third, expert adjudication was not blinded to AI outputs, reflecting the workflow-integrated design of this study but introducing potential AI-related review or incorporation bias. This unblinded operational reference standard may have influenced expert classification and may have overestimated agreement between AI triage and expert adjudication. Fourth, the number of high-risk lesions was limited, with only 16 high-risk lesions in the primary red triage category analysis. This was consistent with the low-prevalence structure of community screening but constrained the precision of sensitivity and PPV estimates. Fifth, performance analysis was restricted to interpretable images. Images that remained technically inadequate after repeated acquisition attempts were excluded, which may have introduced selection bias and may underestimate the practical burden of image acquisition in field screening. Sixth, this was a single-region field evaluation, and mobile device characteristics, operator training, acquisition conditions, local screening infrastructure, and population risk profiles may affect generalizability to other settings. Individual-level demographic variables and behavioral risk factors were not collected in the analytic dataset, precluding subgroup analyses by age, sex, tobacco use, alcohol use, or betel quid use. Finally, this study did not include a usual care comparator arm; direct evaluation of nonspecialist diagnostic performance; or formal measurement of acquisition time or repeat acquisition rate, specialist workload, cost-effectiveness, or longitudinal outcome linkage. Future multicenter studies incorporating blinded assessment, workflow efficiency metrics, registry linkage, and longitudinal follow-up will be needed to evaluate generalizability, clinical impact, and scalability.

Conclusions

In this prospective community-based field evaluation, a parameter-locked mobile AI-assisted oral lesion triage system was integrated into a routine OC screening workflow operated by trained nonspecialist personnel. Under field conditions characterized by mobile image acquisition, low prevalence of high-risk lesions, and variability in image quality and lesion presentation, the system provided preliminary lesion-level evidence of red triage categorization performance, with moderate sensitivity and modest PPV for high-risk lesion identification. These findings suggest that mobile AI-assisted triage may support referral prioritization within a human-supervised community screening workflow while preserving the need for expert oversight. Further multicenter studies with blinded assessment, participant-level outcome evaluation, workflow efficiency measures, and longitudinal follow-up are needed to determine the clinical impact and scalability of AI-assisted OC screening in real-world practice.

Acknowledgments

The authors thank the community screening personnel and participating residents for their contributions to this field evaluation. They also thank the oral and maxillofacial specialists involved in expert image review and consensus adjudication. Generative AI tools were used to assist with language editing and drafting during manuscript revision. All scientific content, analyses, interpretations, and final manuscript text were reviewed, verified, and approved by the authors. No generative AI tool was listed as an author.

Funding

This study was supported by an investigator-initiated clinical research program of National Taiwan University Hospital: “Application and validation of a mobile device–based deep learning system for assisting the screening of oral potentially malignant lesions and oral cancer” (NTUH 202504075 RIND). The funder had no role in the study design, data collection, data analysis, data interpretation, manuscript preparation, or the decision to submit the manuscript for publication.

Data Availability

The datasets generated and analyzed during this study are not publicly available because they contain clinical images and screening-related information that may compromise participant privacy and are subject to institutional data governance restrictions. Deidentified data may be available from the corresponding author on reasonable request, subject to institutional approval and applicable data-use agreements.

Abstract

Background: Discriminating mild cognitive impairment (MCI) from subjective cognitive decline (SCD), and healthy controls (HC) remains challenging. Digital tools may overcome paper-and-pencil screening's limitations.

Objective: This study evaluated the diagnostic accuracy and usability of CogniPaz (Daniel Blanco), an ecologically oriented, mobile health (mHealth), gamified cognitive assessment tool exploring memory and executive functions, in discriminating MCI (particularly amnestic phenotypes [aMCI]) from SCD, and HC.

Methods: This prospective observational study recruited a convenience sample of consecutive patients with cognitive complaints and HC at La Paz University Hospital Cognitive Disorders Unit from April 2025 to January 2026. Demographic and clinical characteristics, and Montreal Cognitive Assessment (MoCA) scores were collected. An evaluator blinded to the MoCA scores oversaw the automated, self-administered CogniPaz assessment. Participants were classified into HC (no cognitive complaints, MoCA score≥26), SCD (cognitive complaints, MoCA score≥26), and MCI (cognitive complaints without functional impairment, MoCA score<26, subdivided into amnestic [aMCI] and nonamnestic phenotypes). Receiver operating characteristic (ROC) analyses using age-adjusted models, the DeLong test, and bootstrap validation evaluated diagnostic accuracy across groups. The correlation between MoCA and CogniPaz scores was assessed using Spearman rank correlation. Participants with available biomarker data underwent exploratory analysis of CogniPaz's ability to detect biologically confirmed any-cause neurodegeneration (bND). Usability was tested using an ad hoc Likert questionnaire (1 - 9 points).

Results: The participants (n=84, 57.1% female; median age 72.0, IQR 62.5-77.0 years) included 27 HC, 17 with SCD, 22 with aMCI, and 18 with nonamnestic MCI. The aMCI group was older than the SCD group (age: median 76.5, IQR 70.8-78.8 vs median 59.0, IQR 50.0-69.0 years; Kruskal-Wallis/Dunn, *P*=.003). CogniPaz scores correlated with MoCA scores (ρ=0.81, 95% CI 0.75 - 0.89; *P*<.001). CogniPaz showed good concurrent accuracy, independently of age: MCI vs HC (area under the curve [AUC]=0.880, 95% CI 0.798 - 0.961), MCI vs SCD (AUC=0.915, 95% CI 0.841 - 0.990), aMCI vs HC (AUC=0.910, 95% CI 0.830 - 0.990), and aMCI vs SCD (AUC=0.943, 95% CI 0.878 - 1.000). At the provisional <28.5 cutoff point, sensitivity ranged from 85.0% (34/40, 95% CI 70.2 - 94.3) to 90.9% (20/22, 95% CI 70.8 - 98.9) and specificity from 74.1% (20/27, 95% CI 53.7 - 88.9) to 82.4% (14/17, 95% CI 56.6 - 96.2) across comparisons. CogniPaz suggested capacity to detect bND (AUC=0.810, 95% CI 0.661 - 0.958), with potential incremental value over MoCA and age (odds ratio [OR]=0.78, 95% CI 0.60 - 0.94; *P*=.02). Median administration time was 9.39 (IQR 7.53 - 11.38) minutes with 100% (84/84) completion. User satisfaction was high (median score 8.4/9, IQR 7.9 - 8.6; Cronbach α=0.84).

Conclusions: CogniPaz is an innovative, user-friendly mHealth tool that addresses classical cognitive screening tools' limitations through a brief, multidomain, minimally supervised gamified format, with high patient acceptance. It correlates with MoCA scores, shows good concurrent capacity to differentiate MCI, particularly aMCI, from SCD and HC, and appears promising for identifying bND. Pending external longitudinal validation, these findings support CogniPaz as a candidate for early cognitive screening in primary care.

Introduction

Mild cognitive impairment (MCI) is a transitional clinical state between normal aging and dementia, characterized by objective cognitive decline with largely preserved functional independence [1]. Within MCI, amnestic forms (aMCI) are associated with an increased risk of progression to dementia in Alzheimer disease (AD) [2]. Subjective cognitive decline (SCD) refers to a self-perceived, persistent decline in cognitive capacity, typically involving memory, despite normal performance on standard cognitive tests, and is now considered a risk state for future MCI and dementia [3]. Differentiating aMCI from SCD is clinically relevant but challenging because complaints and even subtle performance differences frequently overlap, and early deficits may be masked by cognitive reserve. Early and accurate identification of individuals at increased risk for neurodegenerative disease is essential to guide monitoring, risk factor management, and potential disease-modifying interventions.

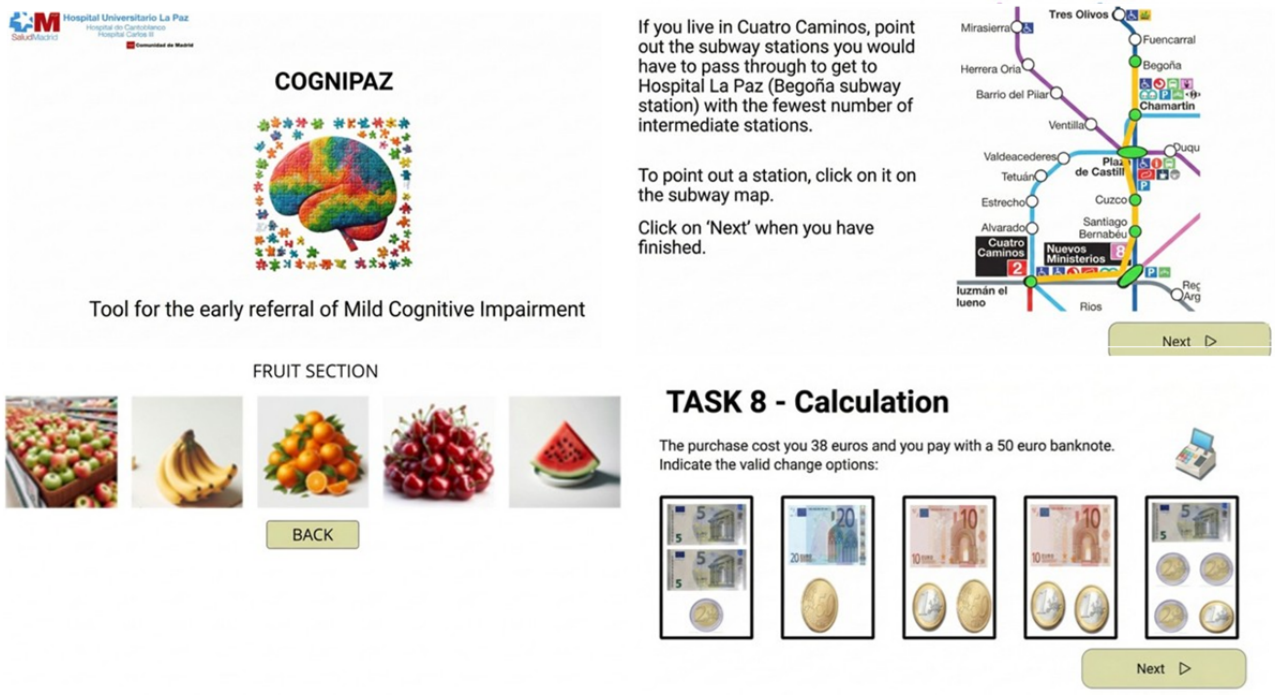
Traditional paper-and-pencil screening tools, such as the Mini-Mental State Examination (MMSE) and the Montreal Cognitive Assessment (MoCA), have important roles but can exhibit ceiling effects, limited sensitivity to early changes, and constraints in repeated administration [4,5]. These limitations have prompted a rapid shift toward digital tools for cognitive assessments. Recent narrative and systematic reviews indicate substantial growth in digital cognitive tools for detecting MCI and dementia, including web-based batteries, tablet-based neuropsychological platforms, and smartphone apps [6-9]. Digital assessments can improve standardization, capture reaction times, automate scoring, and facilitate remote or high-frequency testing. Moreover, the scalability of these tools makes them ideal candidates to meet the growing demand for screening in aging populations [5]. Indeed, the integration of emerging digital technologies is increasingly recognized as a crucial strategy for developing scalable algorithms that facilitate early AD diagnosis and provide globally accessible screening guidance [10-12]. Meta-analytic evidence suggests that digital cognitive tools generally achieve good sensitivity and specificity for MCI and dementia detection, but performance varies by domain, platform, and comparison group [13-16].

However, important limitations remain. Recent reviews show that although digital cognitive assessment for older adults has expanded quickly, validation remains uneven: across web-, tablet-, and smartphone-based tools, construct validity and robust normative data are still incompletely documented [5,17]. Usability and implementation barriers remain a recurring problem, including difficulties navigating software, unstable connectivity, lengthy assessment times, and limited adaptability for people with less education and lower digital literacy [18,19].

These gaps support the development of brief, user-friendly tools that can be deployed in real-world pathways. Many digital tools have been validated primarily to distinguish dementia or global cognitive impairment from normal cognition, rather than to separate SCD from MCI in real-world memory clinic populations [5,20]. Ecological validity and user engagement, particularly among older patients and patients with anxiety, are often underreported, and the integration of digital tests into existing pathways for specialized care is still evolving [5,14,19,20]. Moreover, there is a paucity of tools capable of exploring executive functions alongside episodic memory in a brief, gamified format that can be administered easily by nonspecialist personnel [21]. In this regard, incorporating principles from adaptive mobile health (mHealth) systems, which use human-centered design to dynamically adjust to the user's needs and have proven effective in improving engagement and usability [22,23], offers a valuable framework for developing cognitive tools tailored to older adults.

To address these needs, we developed CogniPaz (Daniel Blanco), an ecologically oriented, tablet-based, gamified digital cognitive screening tool designed for rapid administration by nonspecialist clinicians (eg, general physicians or nurses) as a screening tool to identify MCI in patients consulting for SCD. Accordingly, the primary objectives of this prospective study were to evaluate the diagnostic accuracy of CogniPaz in discriminating MCI, particularly aMCI, from SCD and healthy controls (HC), to examine its correlation with MoCA scores, and to assess its feasibility and usability. In a secondary exploratory analysis, we also evaluated whether CogniPaz could identify biologically confirmed any-cause neurodegeneration (bND) in a subset of participants with available biomarker data.

Methods



Instrumentation

CogniPaz was designed as a digital cognitive battery test. The study version of CogniPaz was implemented as an Android tablet app using Ionic/Angular and Capacitor. The protocol comprised 9 tasks, yielding a maximum total score of 38 points (Figure 1).

The device automatically provided the initial instructions to the participants before they began the tasks. To ensure accessibility, the platform featured an intuitive visual interface with minimal text to reduce linguistic bias, large font sizes for mild visual impairment, and an integrated audio guide for clear instructions. The assessment is structured as follows:

XSL•FO
RenderX

Figure 1. Examples of tasks included in the CogniPaz cognitive screening tool (English translation). The complete battery, in its original Spanish version, is provided in Multimedia Appendix 1.

Attention and Orientation (16 Points)

Task 1: Verbal Attention With Visual Input-Encoding

The participants encoded a list of 6 words (salmón [salmon], hamburguesas [hamburgers], azúcar [sugar], leche [milk], plátanos [bananas], and lejía [bleach]) presented sequentially in full-screen mode at 2-second intervals. This task was performed across 2 trials; after each presentation, participants verbally recalled the items using the tablet microphone; speech was processed transiently, and the resulting text was scored automatically by the app (6+6 points).

Task 3.1: Verbal Attention With Auditory Input-Encoding

The participants listened to a simulated TV news broadcast regarding a fire. Immediately after, they were required to manually type 3 specific details regarding the news story, including the number of victims, the distance in meters from the fire station, and the time of the event. They were also explicitly instructed to memorize these details, as they would be asked about them again later in the session (3 points).

Task 3.2: Orientation

The participants were asked to input the current date (day, month, and year) using the digital interface (1 point).

Attention and Working Memory (1 Point for Each Subtask, 3 Points)

Tasks 4 and 5: Forward and Backward Digit Span

The participants listened to and repeated increasingly long sequences of numbers, first in the same order, and then in reverse order.

Task 6: Visuospatial Sequencing

The participants were required to observe and replicate a sequence of changing colored circles by tapping them in the correct order.

Executive Function (4 Points)

Task 2: Planning

A metro route map was displayed; participants had to analyze the map and select the specific path that contains the fewest stations between 2 designated points (1 point).

Task 8: Calculation

In a simulated functional task, participants were presented with a total purchase costing €38 (US $42.02; €1=US $1.1057 as of April 4, 2025) and must calculate and select all the necessary currency denominations to provide the correct change from a €50 bill (US $55.29; 3 points).

Memory Domains (15 Points)

Task 7: Verbal Memory With Visual Input-Delayed Recall

This task evaluated the retrieval of the shopping list. It consists of a delayed free recall phase (Task 7.1), in which participants had to recall the original items (6 points). If free recall was incomplete, a facilitated cued recall phase (Task 7.2) was triggered to differentiate retrieval from storage deficits. A digital map of a supermarket was displayed, organized into various product sections (eg, bakery and butchery). When the participant tapped on a section, the interface displayed images of products in that category. The participant then had to identify and select the correct items from the original list (6 points). In both phases, the scoring algorithm applied a one-point penalty for each incorrect response. If a participant achieves a perfect score of

XSL•FO
RenderX

6 points in the free recall phase (Task 7.1), the facilitated cued recall phase (Task 7.2) was not administered, and the maximum score of 6 points for that phase was automatically awarded. The combined maximum for Task 7 is 12 points.

Task 9: Verbal Memory With Auditory Input—Delayed Recall

To assess long-term retrieval of the news broadcast, participants had to provide the 3 specific details previously encoded (3 points).

Tasks were scored based on the number of correctly recalled elements (1 point per item for Tasks 1, 3.1, 7, 9), on a dichotomous pass/fail basis (1/0 points for Tasks 2, 3.2, 4, 5, 6), or per correct denomination (1 point per item for Task 8). A total CogniPaz score was computed by summing the task scores; higher scores indicate better cognitive performance. Domain-specific scores for episodic memory and executive function were also generated. A full video demonstration in Spanish is available in Multimedia Appendix 1.

To ensure accurate and standardized quantification, CogniPaz used a deterministic rule-based scoring algorithm. For speech-based verbal recall tasks, the system transiently processed textual hypotheses returned by the native speech-recognition service, applying uppercase conversion and Spanish accent normalization. Target matching was then executed using a Levenshtein distance threshold of ≤1 to tolerate minor articulation, spelling, or speech-recognition variations. Further details on software architecture, data flow, and task-level scoring rules are provided in Multimedia Appendix 2.

A sanitized source-code artifact of the CogniPaz app is provided in Multimedia Appendix 3. This artifact is not intended to serve as a production deployment package or a fully executable clinical system. End-to-end execution requires a separately configured institutional REDCap (Vanderbilt University) backend project with matching fields, authorized private credentials, and institutionally approved deployment settings.

Upon completion, participants completed a custom-designed satisfaction questionnaire rated on a 9-point Likert scale (1=minimum; 9=maximum). This ad hoc, nonvalidated instrument covered 7 dimensions in total (general perception, ease of use, information clarity, task clarity, adequate time, task ease, and perceived utility), and was designed to capture aspects specific to a gamified, minimally supervised tablet-based assessment that are not fully covered by generic instruments. It was also evaluated for internal consistency using Cronbach alpha, which was computed among responders, alongside item-rest correlations and alpha-if-item-deleted statistics to assess the coherence of the construct.

Conditions and Design

This was a single-center, prospective observational study of patients with cognitive complaints and HC presenting to the Cognitive Disorders Unit of La Paz University Hospital (Madrid, Spain), a tertiary referral unit specializing in cognitive neurodegenerative diseases. In accordance with nonexperimental, observational designs, the participants' cognitive conditions were naturally observed, and no experimental manipulation was performed. This study was reported in adherence to the 2015 STARD (Standards for Reporting of Diagnostic Accuracy Studies) guidelines, with the completed checklist provided in .

Inclusion and Exclusion

The general inclusion criteria were patients with no diagnosis of dementia presenting with cognitive complaints. The comparison group of HC consisted of companions of the patients and other healthy volunteers recruited at the hospital who were age-matched to the patient group. The exclusion criteria were (1) established dementia, defined as significant functional impairment that compromised independence in instrumental activities of daily living (Clinical Dementia Rating [CDR] global score ≥1); (2) sensory or motor deficits (eg, severe visual impairment and upper limb paresis) precluding the use of a tablet; or (3) a significant language barrier or inability to communicate proficiently.

Participant Characteristics

Participants were classified into 3 diagnostic groups (HC, SCD, and MCI) based on a comprehensive clinical assessment integrating medical history, neurological examination, and standard neuropsychological testing. For subgroup analyses, the MCI group was further stratified into 2 phenotypes: aMCI and nonamnestic MCI. The MoCA, a widely validated instrument with established reliability and validity in the Spanish population [24], was used as the reference standard due to its sensitivity for MCI screening [25,26], and its potential value in predicting underlying AD pathology [27].

The MCI group was defined according to established clinical criteria [4,28]. Participants reported a persistent decline in cognitive capacity relative to their previous level of functioning, unrelated to an acute event, and this decline was corroborated by an informant. This was accompanied by objective impairment in at least one cognitive domain (MoCA <26, adjusted for education), while maintaining largely preserved independence in functional abilities (CDR global score of 0.5). For subgroup analyses, the aMCI subgroup was defined by predominant episodic memory impairment, whereas nonamnestic patients with MCI exhibited impairments in other cognitive domains [29].

The SCD group was defined according to the SCD-initiative framework [30]. Participants reported analogous subjective concerns regarding persistent cognitive decline but, in contrast to the MCI group, exhibited normal performance on standardized cognitive tests (MoCA ≥26, adjusted for education) and independence in functional abilities (CDR global score of 0).

HC were participants with an absence of active neurological or psychiatric disorders, no significant subjective cognitive concern, and performance within normal limits on screening (MoCA ≥26, adjusted for education).

Sampling Procedures

Participants were recruited using a consecutive convenience sampling procedure during scheduled clinical visits between April 2025 and January 2026. During this period, all consecutive patients and their accompanying individuals attending new

XSL•FO
RenderX

clinical consultations were systematically assessed for eligibility and recruited accordingly by the attending clinical and research staff to minimize selection bias. Potential candidates were provided with a detailed explanation of the study procedures prior to obtaining written informed consent. No financial compensation or other incentives were provided for participation.

Sample Size, Power, and Precision

No formal sample size calculation was performed because no previous data were available to estimate the expected effect sizes and because of the exploratory nature of the study. Therefore, a convenience sample was used based on feasibility criteria, including the expected recruitment capacity and available resources.

Measures and Covariates

Major demographic and clinical characteristics (including age, sex, education level, family history of AD, and MoCA scores) were collected and compared across the diagnostic groups (HC, SCD, MCI, aMCI, and nonamnestic MCI) to assess baseline differences. Structural neuroimaging (magnetic resonance imaging [MRI]), fluorodeoxyglucose positron emission tomography (FDG-PET), amyloid-PET, and cerebrospinal fluid (CSF) biomarkers (amyloid beta 42 [Aβ42], amyloid beta 42/40 ratio [Aβ42/40], phosphorylated tau [p-tau], and total tau [t-tau]) [31] were also reviewed in participants who had undergone these procedures, based on the routine clinical judgment of the attending physician. The primary investigational measures derived from the CogniPaz platform included the total cognitive score (ranging from 0 to 38) and the total administration time. Feasibility covariates included the completion rate, technical malfunctions, and the frequency of required external assistance. User satisfaction was measured using the 9-point ad hoc Likert scale questionnaire.

Data Collection

Participants completed the assessments during a single, in-person session in a quiet room at the cognitive disorders unit. To reflect routine clinical workflow, the order of administration was fixed (MoCA followed by CogniPaz). CogniPaz was administered on a 9-inch touchscreen device (Lenovo Tab M9, Android 12), and performance metrics (including correct responses, error counts, and completion times) were automatically captured by the software. To ensure secure data gathering, the tablet front end transmitted structured assessment data securely via HTTPS POST requests to a REDCap-compatible API. The app used an automated offline contingency mechanism (Ionic Storage) to temporarily queue data locally and prevent loss during Wi-Fi interruptions in the clinical environment. The research team recorded any technical malfunctions, data loss incidents, and the frequency and nature of required external assistance. Upon completion of the cognitive tasks, participants filled out the satisfaction questionnaire.

Quality of Measurements

To ensure standardization and enhance the quality of measurements, the research team attended an introductory training session prior to the study. To minimize interrater variability during data collection, the majority of the CogniPaz administrations were overseen by a single trained investigator. Supervision was minimal, limited strictly to technical support or task clarification to prevent administration bias.

Masking

Routine clinical assessment and MoCA administration were performed by neurologists blinded to the participants' CogniPaz scores. Subsequently, the self-administered, automated CogniPaz assessment was overseen by researchers who were entirely blinded to the participants' clinical diagnosis and MoCA results.

Data Diagnostics

A predefined protocol was established to manage data integrity prior to inferential testing. Post-data-collection exclusion criteria were set to disqualify sessions with incomplete data tracking resulting from technical disruptions or participant withdrawal. No missing data imputation methods were planned; instead, a complete-case analysis approach was prespecified for any incomplete records. In case of missing data, the Little test of missing completely at random (MCAR test) was performed to determine if missing data were missing completely at random. We also compared participants who completed the satisfaction questionnaire ("responders") with those who did not ("nonresponders") across demographic and clinical variables, using Welch *t* test for continuous variables and Fisher exact test for categorical variables, to assess whether noncompletion was associated with participant characteristics. Statistical outliers in continuous variables were defined using the IQR method. The normality of continuous-variable distributions was systematically evaluated using the Shapiro-Wilk test to guide the selection between parametric and nonparametric inferential strategies. Data transformations were not anticipated, as nonparametric methods were preferred to robustly handle potential skewness in neurocognitive metrics and session administration times.

Data Analysis

Continuous variables were presented as medians and IQR if nonnormal distribution and heterogeneity of variances were observed. Between-group comparisons of continuous variables were conducted using the Kruskal-Wallis test, run separately across the 3 primary diagnostic groups (HC, SCD, and MCI) and, within MCI, across its 2 subtypes (aMCI and nonamnestic MCI). Significant global results were followed by Dunn post hoc pairwise comparisons with Bonferroni correction.

Categorical variables were analyzed based on the distribution of expected frequencies. The chi-square test was used for variables meeting the assumption of expected cell counts ≥5 (sex and education level). Fisher exact test was used for variables with sparse data violating these assumptions (family history of dementia) and for all post hoc pairwise comparisons to ensure robustness against small subgroup sizes.

Correlations between CogniPaz global scores and MoCA indices were evaluated using Spearman rank coefficients. The 95% CIs for these correlation coefficients were derived using bootstrap resampling with 5000 replications. Diagnostic accuracy of CogniPaz was examined using receiver operating characteristic (ROC) curve analyses for the following four comparisons: (1)

XSL•FO
RenderX

MCI vs SCD, (2) MCI vs HC, (3) aMCI vs SCD, and (4) aMCI vs HC. For the secondary exploratory subanalysis, ROC analysis evaluated the tool's capacity to discriminate between biologically confirmed versus nonconfirmed ND. For each analysis, the area under the curve (AUC) with 95% CIs was calculated.

The Youden Index was initially used to identify the mathematically optimal threshold for each diagnostic comparison. To optimize the tool for clinical screening, a unified provisional threshold strategy was then applied, prioritizing high sensitivity to minimize false negatives. At the provisional, hypothesis-generating, unified cutoff point, we reported sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV), and overall diagnostic accuracy, each with 95% Clopper-Pearson CI. Additionally, positive and negative likelihood ratios (LR and LR-) were computed, with 95% CI derived using the log-normal method, to provide prevalence-independent measures of diagnostic performance. To characterize performance around each cutoff and support its interpretation as provisional, we calculated a threshold-performance table showing all metrics with 95% CI across a grid of candidate cutoffs (24.5, 26.5, and 28.5) for every comparison. It should be noted that MoCA scores contributed to the diagnostic group; accordingly, the primary diagnostic accuracy analyses constitute concurrent criterion validity assessment and are subject to potential incorporation bias.

To evaluate whether the tool's performance was influenced by demographic factors, we compared unadjusted models (CogniPaz score alone) against adjusted models incorporating those variables that showed significant baseline differences between groups. Using the DeLong test for correlated ROC curves, we assessed whether the inclusion of these variables significantly improved diagnostic accuracy or if the tool's performance remained independent of demographic characteristics. Furthermore, to quantify the specific explanatory power of the tool, we estimated the proportion of variance explained by each model using McFadden pseudo-R^2. The unique variance attributable to CogniPaz was calculated as the absolute increase in explained variance (incremental R^2) observed when adding the total score to the base model containing the confounding variables.

Internal validation was performed using bootstrap resampling with 1000 iterations to assess the robustness of diagnostic estimates. Optimism-corrected AUCs, sensitivities, and specificities were derived, with corresponding 95% CIs. Leave-one-out cross-validation (LOOCV) was conducted to confirm the stability of the results.

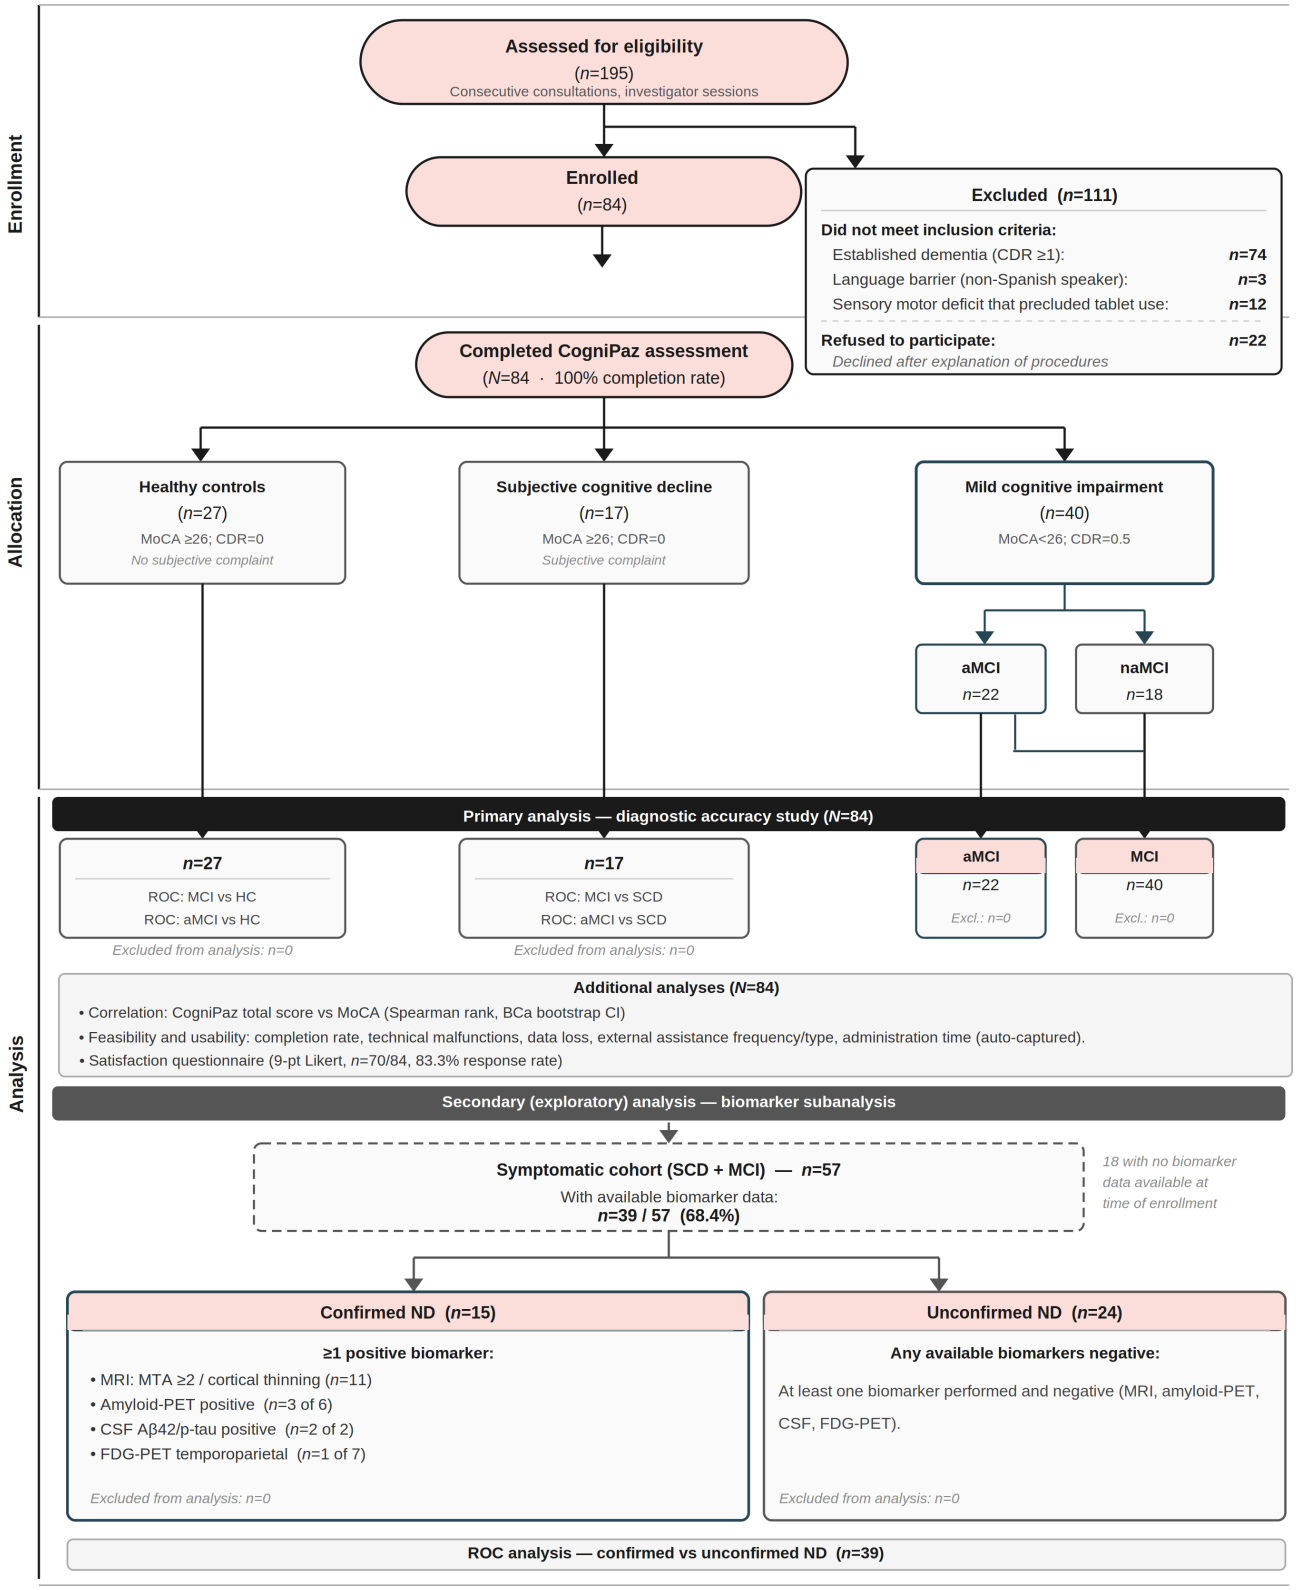
To assess the added value of CogniPaz relative to conventional cognitive screening, we conducted a secondary analysis restricted to the biomarker-confirmed subsample with a concurrently administered MoCA. CogniPaz and MoCA discrimination for confirmed bND were compared using the DeLong test for 2 correlated ROC curves, given that both measures were obtained in the same patients. To evaluate the potential incremental value of CogniPaz beyond MoCA and age, we fitted 2 nested logistic regression models predicting confirmed status: a base model including MoCA total score and age, and a full model additionally including the CogniPaz total score. Model improvement was assessed with a likelihood-ratio test. Effect estimates for CogniPaz in the full model were reported as adjusted odds ratios (ORs) with 95% CIs.

The 4 primary ROC comparisons, the secondary bND subanalysis, and the grid of candidate cutoffs were prespecified in the analysis plan. Dunn post hoc pairwise comparisons were Bonferroni-corrected; no further correction for multiplicity was applied across the prespecified primary comparisons, and the bND subanalysis and threshold-performance grid are reported as exploratory and hypothesis-generating. Reported *P* values should be interpreted accordingly.

Statistical analyses were performed using R software (version 4.4.2; R Foundation for Statistical Computing). All tests were 2-tailed, and a P value <.05 was considered statistically significant.

Ethical Considerations

The study protocol adhered to the principles of the Declaration of Helsinki and was approved by the Clinical Research Ethics Committee of La Paz University Hospital (HULP Code: PI-6915) on January 22, 2025 (Acta No. 02/2025). All participants provided written informed consent prior to enrollment. All data were deidentified at the source and stored in compliance with the General Data Protection Regulation (GDPR; EU 2016/679) and Spanish Organic Law 3/2018 on secure servers at the IdiPAZ Research Institute. No participant audio recordings or raw speech-recognition strings were stored or transmitted. No individual-level identifiable data or images of individual participants are reported. No financial compensation was provided to participants.



Results

Participants

A total of 195 consecutive individuals were assessed for eligibility. Of these, 111 (56.9%) were excluded, primarily due to established dementia (74/111, 66.7%) or refusal to participate (22/111, 19.8%). A total of 84 (43.1%) participants provided informed consent, met all criteria, and were formally enrolled. The test completion rate among enrolled participants was 100% (84/84), with no missing data or dropouts during the assessment. The complete participant flow, including detailed reasons for exclusion, allocation to primary diagnostic groups, and patients included in the exploratory biomarker subanalysis cohort, is depicted in Figure 2.

XSL•FO
RenderX

Figure 2. Participants flowchart, adapted from JARS-Quant guidelines. Aβ42: amyloid beta 42; aMCI: amnestic mild cognitive impairment; CDR: clinical dementia rating; CSF: cerebrospinal fluid; FDG-PET: fluorodeoxyglucose positron emission tomography; HC: healthy controls; MCI: mild cognitive impairment; MoCA: Montreal cognitive assessment; MRI: magnetic resonance imaging; MTA: medial temporal atrophy; naMCI: nonamnestic mild cognitive impairment; ND: neurodegeneration; PET: positron emission tomography; p-tau: phosphorylated tau; ROC: receiver operating characteristic; SCD: subjective cognitive decline.

Sample Characteristics

The study cohort comprised 84 participants. Final diagnoses were 27 (32.1%) HC, 17 (20.2%) SCD, and 40 (47.6%) MCI. Within the MCI group, 22 (55.0%) participants were classified as having aMCI and 18 (45.0%) as nonamnestic MCI. Detailed demographic and clinical characteristics are summarized in Table 1.

[a]HC: healthy control.

[b]SCD: subjective cognitive decline.

[c]MCI: mild cognitive impairment.

[d]aMCI: amnestic mild cognitive impairment.

[e]naMCI: nonamnestic mild cognitive impairment.

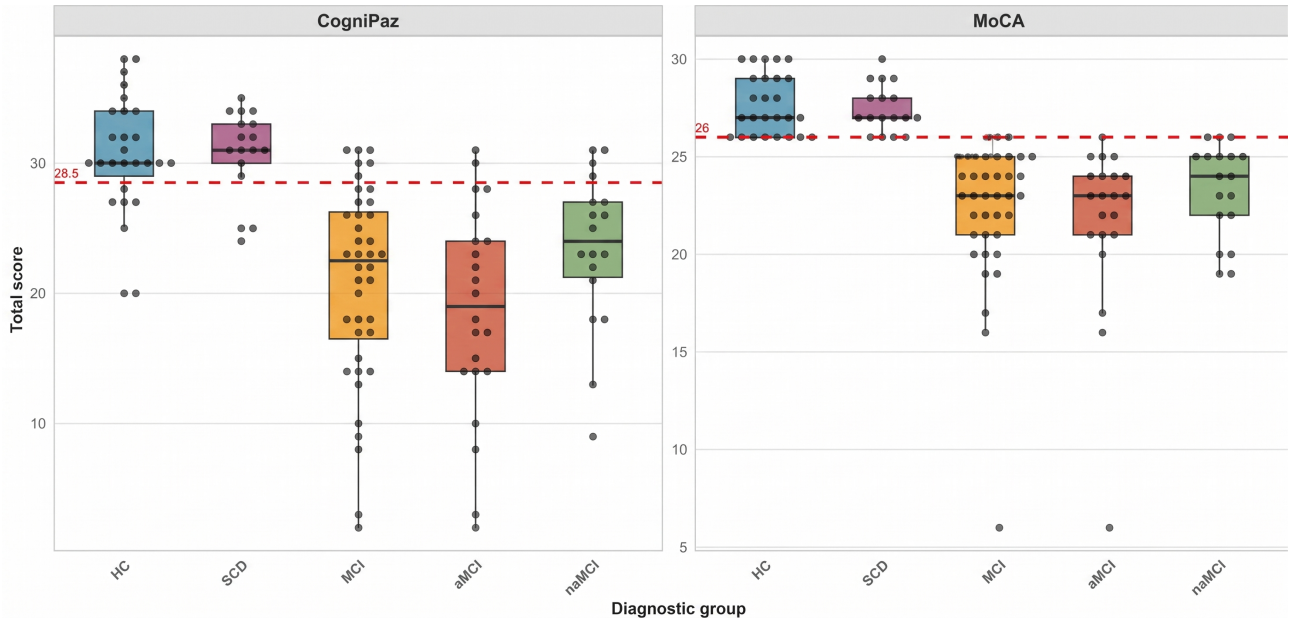
[f]*P* values correspond to the global comparison across 4 diagnostic groups: HC, SCD, aMCI, and naMCI.

[g]Kruskal-Wallis test.

[h]Chi-square test.

[i]MoCA: Montreal Cognitive Assessment.

[j]Fisher exact test.



For significant continuous variables, post hoc pairwise comparisons were performed using the Dunn test (Bonferroni-adjusted), run separately for the 3 primary groups (HC, SCD, and MCI) and for the 2 MCI subtypes (aMCI and nonamnestic MCI). Significant differences ($P<.05$) were found for age (MCI vs SCD, $P=.02$; aMCI vs SCD, $P=.003$); family history (HC vs MCI; $P=.006$); MoCA score (MCI and aMCI vs HC and SCD, all $P<.001$); and CogniPaz score (MCI and aMCI vs HC and SCD, all $P<.001$).

The median age of the cohort was 72 years. Significant age differences were observed between groups, primarily driven by SCD group being younger than those with MCI ($P=.02$) and aMCI ($P=.003$). Sex distribution and educational levels were well-balanced across all diagnostic categories. A family history of AD was significantly more prevalent in the clinical groups compared to the control group; specifically, in patients with MCI ($P=.006$).

Figure 3 illustrates the significant differences in MoCA and CogniPaz scores observed across diagnostic groups.

XSL•FO
RenderX

Figure 3. Distribution of baseline CogniPaz and Montreal Cognitive Assessment (MoCA) total scores across diagnostic groups. Boxplots show the median and IQR, and dots represent individual participants. aMCI: amnestic mild cognitive impairment; HC: healthy controls; MCI: mild cognitive impairment; naMCI: nonamnestic mild cognitive impairment; SCD: subjective cognitive decline.

MoCA scores were comparable between HC and SCD, confirming the objective normality of the SCD group on standard testing. In contrast, MCI and patients with aMCI showed significantly lower scores, with pairwise comparisons confirming significant (P<.001) differences compared to both HC and SCD groups. Similarly, CogniPaz total scores differed significantly between groups. While HC and SCD participants maintained preserved performance, with no significant differences between them, MCI—and particularly the aMCI subgroup—exhibited lower scores. Pairwise comparisons confirmed that patients with aMCI scored significantly lower than both HC (P<.001) and SCD (P<.001) participants, supporting the tool's ability to discriminate objective deficits in the target population.

MoCA scores displayed a ceiling effect in the HC and SCD groups and revealed no significant differences between aMCI and nonamnestic MCI phenotypes (P=.23). In contrast, CogniPaz scores exhibited a wider distribution. While aMCI participants obtained numerically lower scores than nonamnestic MCI cases, this difference did not reach statistical significance (P=.07).

Feasibility and Administration Time

All recruited participants completed the 9 CogniPaz tasks, achieving a 100% (84/84) task completion rate across all clinical sessions, with no indeterminate results, technical failures, software crashes, or data synchronization losses due to application malfunction reported during the study; thus, all recruited participants who completed the protocol were included in the final analysis. Regarding administration time, the total sample followed a nonnormal distribution. The median total administration time was 9.39 minutes (IQR 7.53 - 11.38). Notably, when stratified by diagnosis, the individual subgroups displayed normal distributions. This difference suggests that the global nonnormality is driven by a distinct performance clustering between groups. As illustrated in Figure 4 and detailed in Table 2, both HC and SCD groups completed the assessment significantly faster than participants with MCI.

XSL•FO
RenderX

Figure 4. Distribution of CogniPaz administration times across diagnostic groups. Violin plots represent the distribution density of administration times (minutes), embedded boxplots show the median and interquartile range, and dots represent individual participants. aMCI: amnestic mild cognitive impairment; HC: healthy controls; MCI: mild cognitive impairment; naMCI: nonamnestic mild cognitive impairment; SCD: subjective cognitive decline.

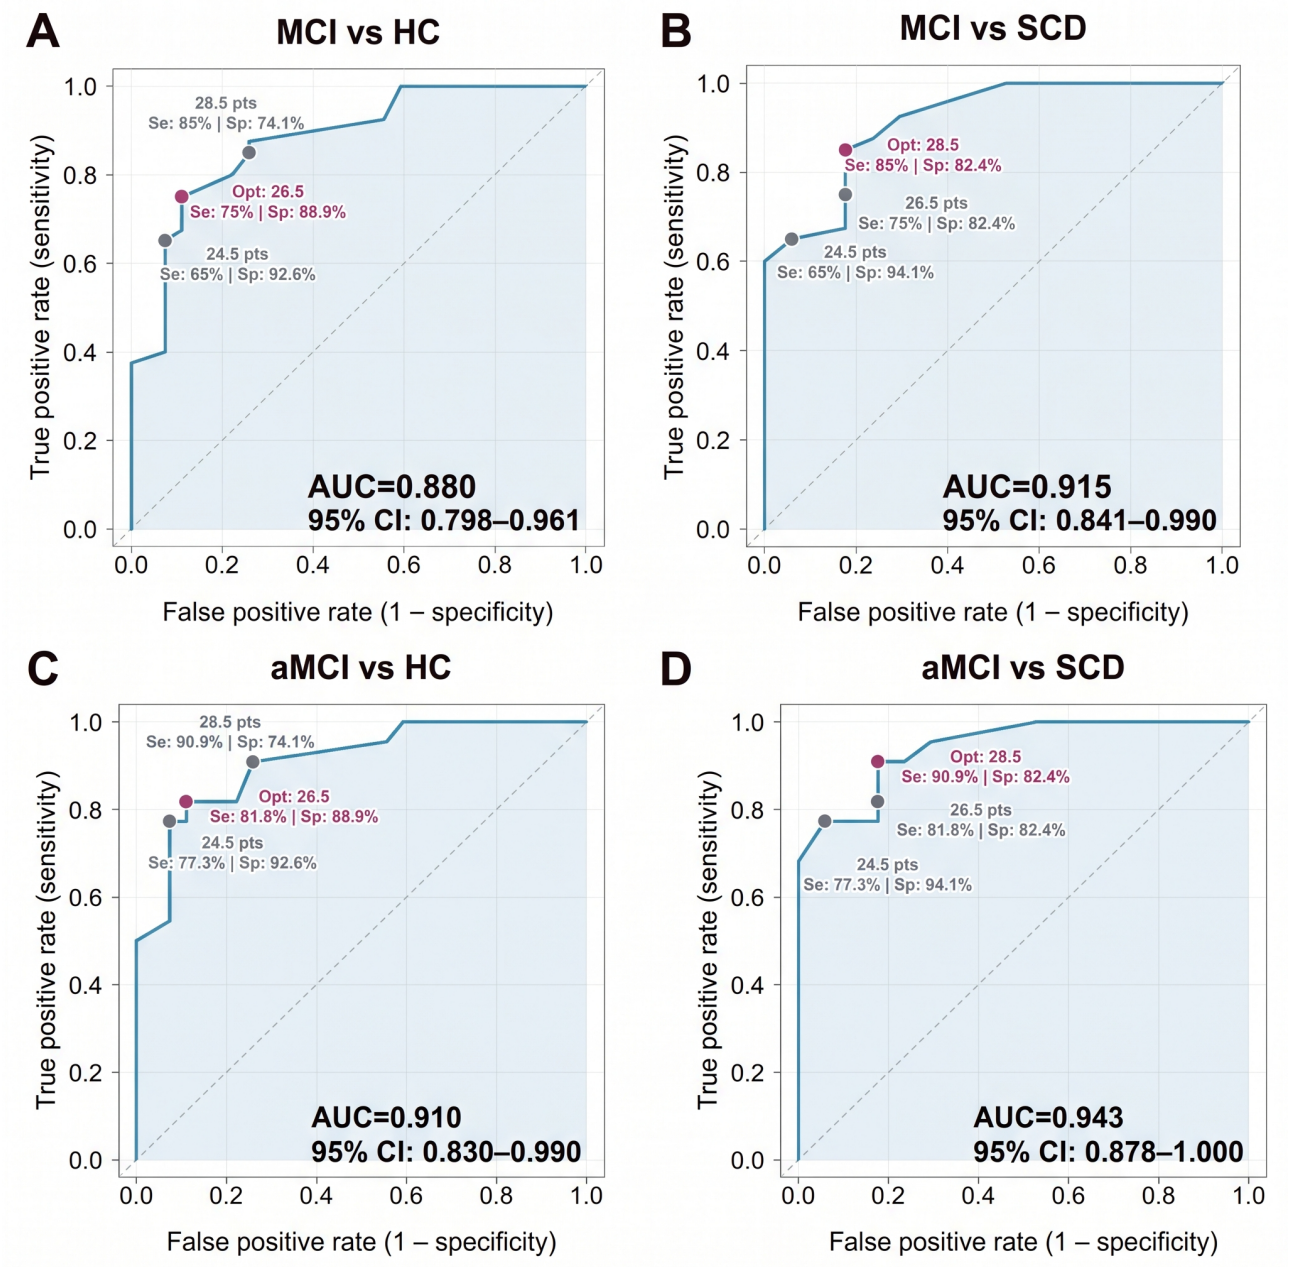
Correlation Between CogniPaz Scores and MoCA Scores

The CogniPaz total score exhibited a strong positive correlation with the MoCA total score (Spearman ρ=0.81, 95% CI 0.75 - 0.89; $P<.001$). Furthermore, domain-specific validity was supported by high correlations between the memory-related CogniPaz tasks and the corresponding MoCA memory indices (ρ=0.61-0.68; $P<.001$), suggesting that the digital metrics accurately capture the targeted cognitive constructs.

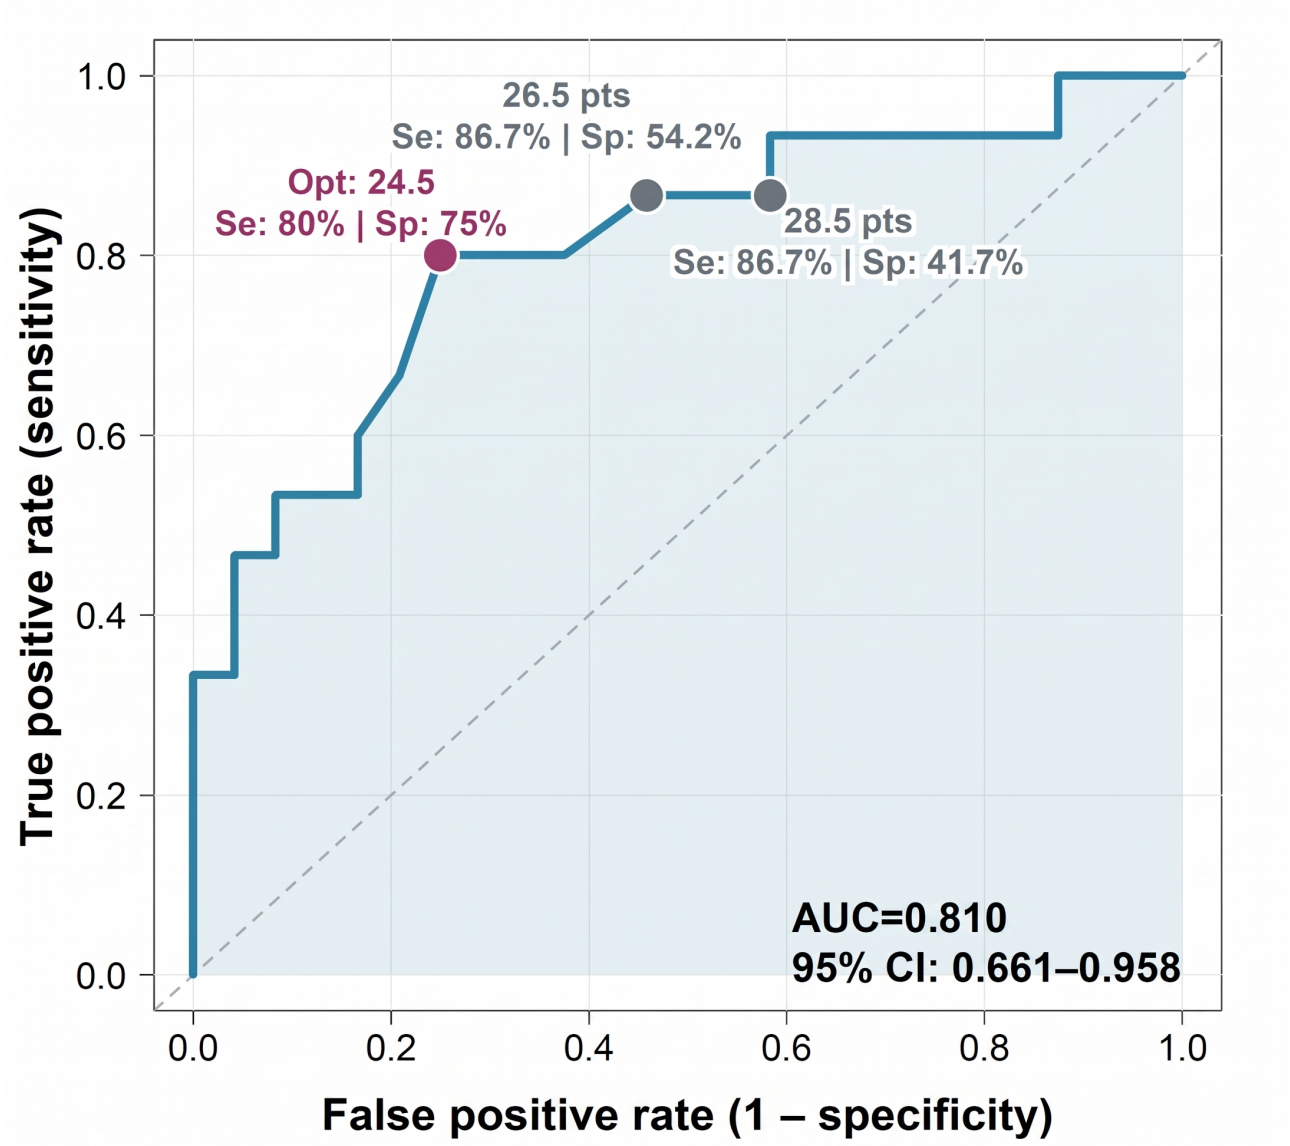
Diagnostic Accuracy



CogniPaz discriminated between MCI and HC and between MCI and SCD, with numerically higher accuracy for the amnestic MCI subgroup than for the overall MCI group. Figure 5 presents the ROC curve analyses for all diagnostic

XSL•FO
RenderX

comparisons. Because aMCI is a subset of MCI, the corresponding AUCs are not statistically independent, and relative performance across these comparisons should be interpreted descriptively rather than as formally tested differences.



We further conducted a prespecified secondary exploratory subanalysis to evaluate the tool's capacity to identify underlying bND within patients in the symptomatic cohort (SCD + MCI). Among patients with available biomarker data (n=39; 68.4% of the 57 symptomatic participants), 15 (38.5%) had confirmatory data, and 24 (61.5%) did not. The confirmed group included patients with hippocampal atrophy (medial temporal atrophy [MTA] score ≥2) and/or a reduced cortical thickness in the precuneus, entorhinal cortex, and posterior cingulate regions (11/37 MRIs performed, 29.7%), positive amyloid-PET (3/6, 50.0%), positive CSF biomarkers (2/2, 100.0%), or suggestive FDG-PET hypometabolism, defined as a temporoparietal pattern (1/7, 14.3%); the remaining cases showed nonspecific, patchy frontoparietal (2/7, 28.6%) or parietal (1/7, 14.3%) patterns, or were entirely normal (3/7, 42.9%) [32]. In this specific subsample, the tool achieved an AUC of 0.810 (95% CI 0.661 - 0.958) for discriminating both categories. ROC curve analyses are presented in Figure 6.

Figure 5. Receiver operating characteristic (ROC) curves showing the diagnostic performance of CogniPaz for identifying mild cognitive impairment (MCI) and amnestic mild cognitive impairment (aMCI) in the study population. (A) MCI versus healthy controls (HC). (B) MCI versus subjective cognitive decline (SCD). (C) aMCI versus HC. (D) aMCI versus SCD. The highlighted point in red indicates the optimal cutoff determined using the Youden index. Sensitivity and specificity at the 24.5-, 26.5-, and 28.5-point cutoffs are displayed for each comparison. The diagonal dashed line represents chance-level discrimination. aMCI: amnestic mild cognitive impairment; AUC: area under the curve; HC: healthy controls; MCI: mild cognitive impairment; Opt: optimal cutoff; Pts: points; Se: sensitivity; Sp: specificity.

Figure 6. Receiver operating characteristic (ROC) curve showing the diagnostic performance of CogniPaz for identifying biologically confirmed any-cause neurodegeneration among symptomatic participants (subjective cognitive decline and mild cognitive impairment) with available biomarker data recruited from a tertiary memory clinic. The highlighted point in red indicates the optimal cutoff determined using the Youden index. The diagonal dashed line represents chance-level discrimination. Sensitivity and specificity at 24.5, 26.5, and 28.5 cutoffs are shown, highlighting the optimal threshold. AUC: area under the curve; Opt: optimal cutoff; Pts: points; Se*:* sensitivity; Sp: specificity.

To formally address the added value of CogniPaz over conventional screening of neurodegenerative etiology, we analyzed the biomarker-available subsample (n=39; 15 confirmed bND, 24 not confirmed bND). CogniPaz showed higher discrimination than MoCA for confirmed bND (AUC=0.810, 95% CI 0.661 - 0.958, vs AUC=0.661, 95% CI 0.471 - 0.851; DeLong Z=1.97; P=.05). In multivariable analysis, adding the CogniPaz total score to a model including MoCA and age significantly improved model fit (likelihood-ratio test: χ^2_1=7.46; P=.006), with each additional CogniPaz point associated with lower odds of confirmed bND independently of MoCA and age (adjusted OR=0.78, 95% CI 0.60 - 0.94; P=.02).

To account for the significant differences in age identified in the baseline characteristics, we analyzed unadjusted and age-adjusted regression models. The inclusion of age did not yield a statistically significant improvement in diagnostic accuracy for any comparison, as detailed in Table 3.

XSL•FO
RenderX

Table . Comparison of diagnostic accuracy between unadjusted and age-adjusted CogniPaz models across the diagnostic subgroup comparisons.

Diagnostic comparison	Unadjusted AUC[a] (95% CI)	Age-adjusted AUC (95% CI)
MCI[b] vs HC[c]	0.880 (0.798 - 0.961)	0.901 (0.828 - 0.974)
MCI vs SCD[d]	0.915 (0.841 - 0.990)	0.921 (0.847 - 0.995)
aMCI[e] vs HC	0.910 (0.830 - 0.990)	0.924 (0.855 - 0.994)
aMCI vs SCD	0.943 (0.878 - 1.000)	0.943 (0.878 - 1.000)
Confirmed ND vs Unconfirmed ND[f]	0.810 (0.661 - 0.958)	0.811 (0.660 - 0.961)

[a]AUC: area under the curve.

[b]MCI: mild cognitive impairment.

[c]HC: healthy controls.

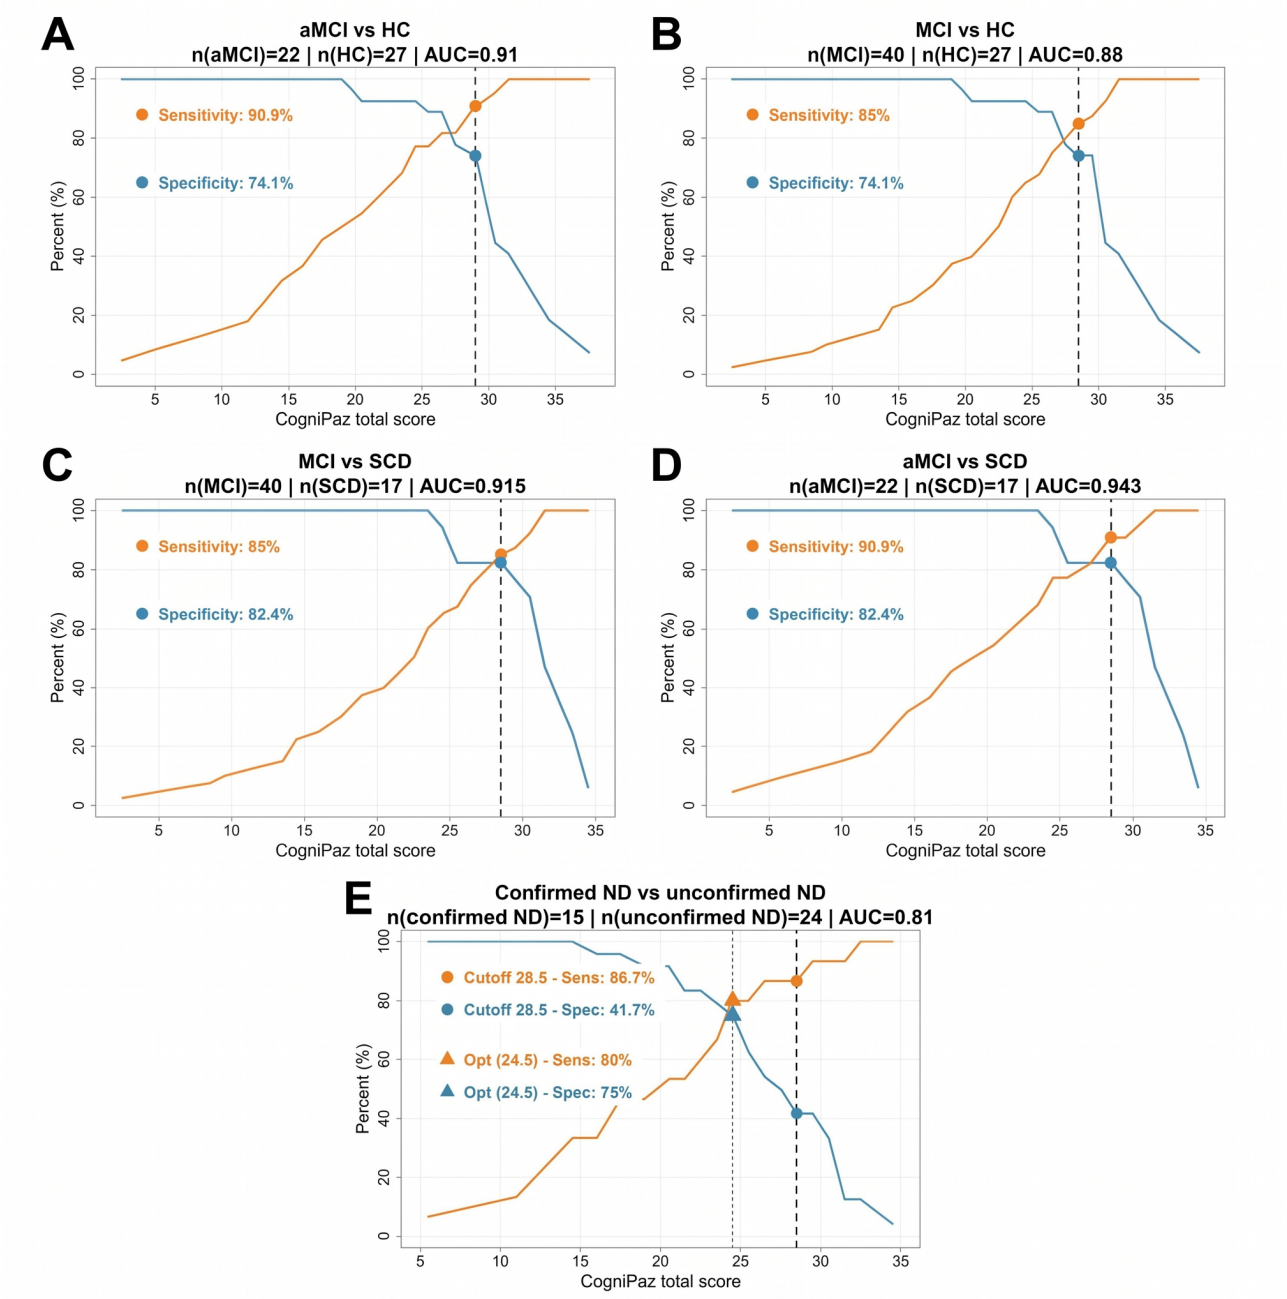
[d]SCD: subjective cognitive decline.

[e]aMCI: amnestic mild cognitive impairment.

[f]ND: neurodegeneration.

The analysis of explained variance demonstrated that CogniPaz accounted for a substantial proportion of the unique variance in diagnostic classification (20.9% - 38.8%), whereas age contributed only marginal additional variance (1.4% - 2.9%). These findings suggest that the discriminative ability of the tool may reflect disease-specific cognitive impairment rather than age differences between the diagnostic groups.

To optimize clinical utility, we evaluated the most discriminative cutoff point of CogniPaz scores based on the Youden index, which identified the optimal threshold according to the balance between sensitivity and specificity depending on the comparison group. To distinguish MCI from HC, the optimal threshold was identified at 26.5 points. At this cutoff, CogniPaz demonstrated a sensitivity of 81.8% and specificity of 88.9% for aMCI vs HC (PPV: 85.7%, NPV: 85.7%) and a sensitivity of 75.0% and specificity of 88.9% for MCI vs HC (PPV: 90.9%, NPV: 70.6%). Conversely, to distinguish MCI from SCD, the optimal threshold shifted to 28.5 points, as shown in Figure 5.



Since the primary objective of CogniPaz is to serve as an effective screening instrument, we prioritized sensitivity to minimize the risk of missing cases by establishing a provisional unified cutoff of 28.5 points (scores below this threshold indicate cognitive impairment). The shift from 26.5 to 28.5 resulted in an improvement in sensitivity for both aMCI vs HC (from 81.8% to 90.9%) and MCI vs HC (from 75.0% to 85.0%). This gain in sensitivity came with a trade-off in specificity, which decreased from 88.9% to 74.1% for both MCI vs HC and aMCI vs HC, as depicted in Figure 7.

In the subanalysis of bND, although the 28.5-point cutoff maintained good sensitivity (86.7%), this came at the cost of lower specificity (41.7%). The optimal 24.5 threshold provided a more balanced performance for identifying bND, increasing specificity to 75.0% and overall accuracy to 76.9% vs 59.0% at the 28.5 cutoff. The 95% CIs for all metrics at every candidate cutoff are provided in Table S1 in Multimedia Appendix 4.

At this level, 81.0% of the total cohort (68/84 participants) was correctly classified. Table 4 presents the final performance metrics at the provisional 28.5-point cutoff for the clinical comparisons and, separately, at the 24.5-point cutoff for the exploratory bND subanalysis; the complete threshold-performance table across all candidate cutoffs (24.5, 26.5, and 28.5), with 95% CIs for every metric, is provided in Table S1 in Multimedia Appendix 4.

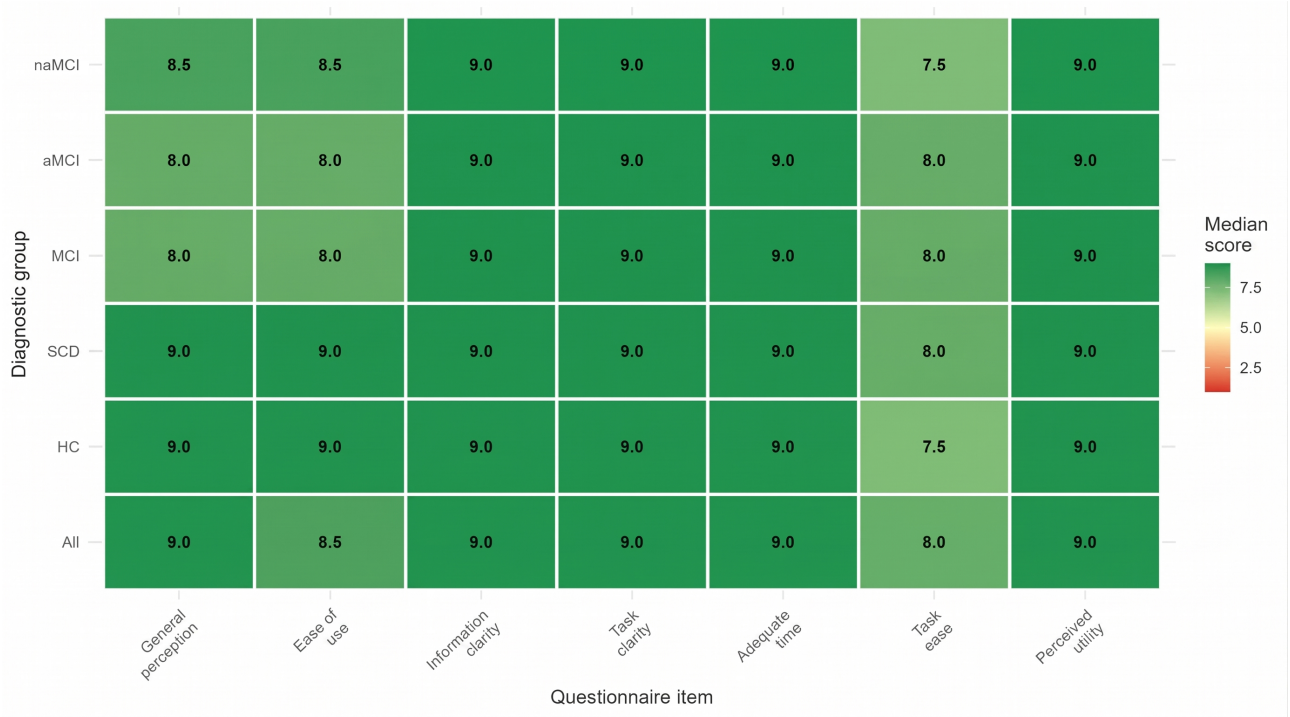
Internal validation using 1000 bootstrap resamples confirmed the robustness of these diagnostic estimates. The optimism-corrected AUCs were virtually identical to the apparent values for all comparisons (eg, aMCI vs SCD: apparent AUC=0.943 vs optimism-corrected AUC=0.942; 95% CI 0.866 - 0.989). Sensitivity and specificity at the 28.5 cutoff remained stable after correction (aMCI vs SCD: sensitivity 90.9% vs 90.7%; specificity 82.4% vs 82.5%), indicating minimal overfitting and supporting the generalizability of the findings within the target population (see Table S2 in Multimedia Appendix 5 for complete bootstrap results). LOOCV yielded consistent results, further reinforcing the stability of the model.

Usability and Satisfaction



Of the 84 participants, 70 (83.3%) completed the usability questionnaire and 14 (16.7%) did not. Responders and nonresponders did not differ significantly in age, sex, diagnostic group, or MoCA score. Nonresponders more frequently required assistance with the tablet during testing (69.2% vs 41.2%; *P*=.08). Nonresponders also had a significantly higher prevalence of first-degree family history of AD (57.1% vs 25.4%; *P*=.03). The Little MCAR test applied to the 7

XSL•FO
RenderX

questionnaire items alone did not reject the null hypothesis of data missing completely at random (χ^2_6=8.86; *P*=.18); however, when age, sex, family history, need for tablet assistance, and MoCA score were included, the test rejected MCAR (χ^2_{49}=69.77; *P*=.03), in line with the association between nonresponse and family history noted above. Missingness in this questionnaire was therefore better characterized as missing at random (MAR), conditional on observed covariates, rather than missing completely at random. The 7-item questionnaire showed good internal consistency (Cronbach α=0.84, 95% CI 0.78 - 0.89), with all item-rest correlations ≥0.46 and no item improving reliability if removed.

Overall usability ratings were high, with a median score of 8.43 (IQR 7.86 - 8.57) on a 9-point scale. Item-level analysis indicated high ratings across domains, with median scores of 9.0 for “Perceived Utility,” “Information Clarity,” “Task Clarity,” and “Adequate Time“ (all IQR 8.0 - 9.0) across all diagnostic groups. “Tasks Ease“ yielded the lowest median score (median 8.0, IQR 6.25 - 9.0), as illustrated in Figure 8.

Figure 8. Median satisfaction scores by diagnostic group and item. Heatmap colors and cell values represent the median score for each questionnaire item on a 1 - 9 scale. “ALL” indicates the overall study population. aMCI: amnestic mild cognitive impairment; HC: healthy controls; MCI: mild cognitive impairment; naMCI: nonamnestic mild cognitive impairment; SCD: subjective cognitive decline.

While HC and SCD participants reported high and homogeneous satisfaction scores (HC: median 8.50, IQR 8.00-8.61; SCD: median 8.43, IQR 8.29-8.57), the MCI subgroups exhibited wider IQR, reflecting a much broader dispersion in user experience. Specifically, the aMCI subgroup showed a median satisfaction score of 8.17, but with a wider dispersion (IQR 7.29-8.57) compared to the groups with no cognitive impairment; similarly, the nonamnestic MCI phenotype presented a median satisfaction score of 8.00 (IQR 7.61-8.61). Statistical analysis confirmed no significant correlation between age and satisfaction scores (Spearman ρ=–0.16; *P*=.20).

Moreover, the use of the tool required minimal supervision: 54.3% of the cohort completed the protocol with zero assistance, while the remaining participants required only minor guidance (limited to 1 - 2 interventions), which primarily involved assistance with microphone usage or clarification of the task instructions. However, the rate of independent use varied significantly by group: 87.5% for SCD, 69.2% for HC, and only 30.8% for the MCI group (ie, most patients required some support). A significant negative correlation was found between the frequency of assistance and total CogniPaz scores (*r*=–0.505; *P*<.001). Participants requiring guidance achieved significantly lower global scores (mean 21.51, SD 8.44) compared to those who were fully autonomous (mean 29.48, SD 5.17; *P*<.001). No systematic adverse reactions (eg, frustration and fatigue) were reported.

Discussion

Principal Findings

In this study, CogniPaz showed good, concurrent capacity to differentiate MCI, particularly the amnestic phenotype, from HC and SCD. It also exhibited a strong correlation with MoCA and proved feasible for routine clinical use, achieving good user satisfaction and requiring minimal supervision. Finally, the tool suggested a preliminary capacity to identify underlying bND among symptomatic patients.

Related Work

Different digital tools aimed at assessing cognitive disorders are available, with varying degrees of validation [5,6,15]. Established computerized batteries, such as the Cogstate Brief Battery (CBB), which focuses on processing speed and learning, have demonstrated moderate accuracy for discriminating MCI

XSL•FO
RenderX

from cognitively unimpaired participants (AUC≈0.75), achieving improved performance (AUC up to 0.93) only when biomarker-defined prodromal AD is considered [33]. Similarly, BrainCheck (BrainCheck, Inc), a multidomain battery, has reported sensitivities and specificities between 77% and 88% for MCI and dementia classification [34], while Philips IntelliSpace Cognition (ISC) offers tablet-based versions of conventional tests, with evidence of measurement equivalence [35].

Beyond the mere digitization of traditional assessments, recent diagnostic approaches have incorporated automated analysis of process-based metrics and machine learning algorithms to refine early detection [5,6,15,16]. A linear support vector model using digital metrics from the "What was where?" Oxford Memory Task (OMT) has shown high diagnostic accuracy across the AD continuum. This tablet-based tool achieved an AUC of 0.82 in discriminating between HC and those with SCD and an even higher AUC of 0.92 for distinguishing SCD from MCI. While its performance in classifying MCI versus AD dementia was lower (AUC=0.75), the tool's identification accuracy was a top predictor of hippocampal atrophy, performing as effectively as standard neuropsychological screenings [36]. Mobile-based solutions like the Digital Assessment of Cognitive Impairment (DACI) have achieved AUCs around 0.87 - 0.90 in identifying cognitively impaired older adults, with administration times under 5 minutes [37], while ALTOIDA-iADL (Altoida Inc), using augmented reality to simulate instrumental activities of daily living, demonstrated robust diagnostic accuracy (AUC≈0.78) in distinguishing nondegenerative MCI from prodromal AD in patients characterized by cerebrospinal fluid biomarkers [38]. Other emerging digital solutions include remote episodic memory composites, unsupervised paired-associate learning tasks, and app-based screeners such as digiDEM-SCREEN (digiDEM Bayern project, Friedrich-Alexander-Universität Erlangen-Nürnberg) [9,39].

Expanding into self-administered and remote solutions presents both opportunities and trade-offs regarding diagnostic certainty. The Geras Solutions Cognitive Test (GSCT) proved viable for unsupervised screening (AUC=0.740 for MCI vs SCD, AUC=0.960 for detecting dementia) [40,41], while the remote, unsupervised Cambridge Neuropsychological Test Automated Battery (CANTAB) Paired Associates Learning (PAL) demonstrated feasibility in the Brain Health Registry, despite modest accuracy (AUC=0.66 - 0.68 for self-reported MCI) compared to supervised versions [42]. In parallel, the digitalization of the "gold standard" MoCA has evolved from the eMoCA (which established measurement equivalence with the paper version; concordance correlation coefficient=0.84; mean difference <2 points [43]) to self-administered solutions like MoCA Solo [44] and MoCA XpressO. However, recent validation of XpressO highlights the complexity of unassisted screening: while effective at extremes, it yielded an "indeterminate range" (scores 43 - 71) where diagnostic certainty is reduced, achieving good sensitivity and specificity only outside this broad window [45].

Finally, this digital transformation is exemplified by large-scale initiatives aiming to democratize early detection. Prominent examples include SCAP-AD (Cognitive Screening and Personalized Approach for Alzheimer's and other Dementias, Fundación CIEN) [46], a research-driven project focused on developing screening algorithms for AD in the general population, and industry collaborations, such as "The Mind Guardian" (Samsung) [47], which promotes accessibility and cognitive monitoring.

From a digital health and implementation science perspective, CogniPaz should be considered a minimally supervised mHealth cognitive-assessment device rather than a standalone diagnostic algorithm. As highlighted in recent mHealth literature, the successful adoption of digital systems relies heavily on human-centered design, proof-of-concept validation, and thorough usability assessment [23]. The novelty of CogniPaz lies in applying these core mHealth design principles to a screening environment. Consequently, its primary value proposition is not based on diagnostic superiority alone but on how it overcomes practical implementation barriers. By integrating a multi-domain evaluation into an ecological and gamified format, the brief assessment can be entirely self-administered. As demonstrated in our feasibility analysis, these characteristics allow for minimal oversight from nonspecialist personnel, such as general nurses or accompanying family members, offering a highly scalable triage solution that may help mitigate administrative bottlenecks in real-world clinical settings.

Beyond these tools, CogniPaz offers several advantages based on its unique clinical and design features. While most published digital tools primarily contrast MCI or dementia with normal cognition or examine biomarker-defined AD stages [5,6,13-15,17,20,48], CogniPaz demonstrates good accuracy in distinguishing aMCI—the primary target for early interventions—from SCD, thus allowing identification of clinically relevant early cognitive deficits. Early cognitive deficits represent a diagnostic challenge frequently encountered in specialized settings but are less often studied in digital validation. In this regard, CogniPaz displays good accuracy, identifying a provisional threshold that maximizes sensitivity. While digital adaptations of traditional scales like eMoCA or MoCA XpressO can be hampered by broad 'indeterminate ranges' where diagnostic confidence drops [43,45], CogniPaz provides a provisional threshold for classification. With its good sensitivity and specificity for detecting aMCI versus SCD, it makes it a more practical instrument for rapid clinical triage. Specifically, the tool's likelihood ratios indicate that, while a positive result provides moderate evidence for confirming aMCI, a negative result offers evidence for ruling it out—a particularly valuable combination for clinical decision-making in memory clinic settings. Our findings suggest that CogniPaz may assist in establishing a clinical suspicion of bND versus nonneurodegenerative etiologies, a capability rarely available in brief, digital screening tools. In particular, its preliminary performance in identifying bND etiology suggests a high rule-out capacity that could be useful in clinical triage. Within this biomarker-confirmed subsample, CogniPaz showed higher point-estimate discrimination than the MoCA, and its addition to a model already containing MoCA score and age significantly improved model fit, a pattern that may suggest potential incremental value beyond conventional screening.

XSL•FO
RenderX

Our data indicate that CogniPaz scores are not biased by age, a limitation of many computerized batteries—such as CBB, CANTAB, BrainCheck, and Philips ISC—that require the use of complex, age-stratified normative databases to distinguish pathology from normal aging [6,17]. Since the tool's discriminative power appears to be driven by disease-specific deficits rather than age-related slowing, it allows for direct clinical interpretation without the need for lookup tables. This makes CogniPaz inherently more practical for rapid screening in diverse older adult populations.

Compared to other digital tools that emphasize episodic memory or processing speed [5,6,13-15,17,20,48], CogniPaz integrates memory and executive tasks for simultaneous assessment of memory and executive functions. Its strong correlation with the MoCA suggests that it effectively captures overall cognitive functioning, while its multidomain approach may enhance sensitivity to the early dysexecutive changes often observed in prodromal neurodegenerative syndromes. Notably, CogniPaz provides a more granular evaluation of episodic memory than traditional screens; for instance, while the MoCA uses a 5-word recall task, CogniPaz uses a 6-word list, presented through dual modalities—verbal memory with visual and auditory input. Despite this increased depth and the inclusion of multimodal assessments, the tool remains efficient. With a brief administration time, CogniPaz is competitive with existing digital batteries and shorter than many paper-based screens, successfully balancing diagnostic precision with the brevity required for routine clinical use.

The tool's gamified and ecologically oriented design ensures high user acceptance, a critical requirement for digital health interventions highlighted by previous research [5,6,13-15,17,20,48], especially for older adults and individuals with lower educational levels. In our sample, user satisfaction was high across all domains, and no major usability issues were reported. While some participants acknowledged the inherent difficulty of certain tasks—likely reflecting the subjective challenge associated with objective performance deficits in cognitively impaired individuals—high ratings in "perceived utility" across all diagnostic groups indicate that patients recognized and valued the tool's clinical relevance. Such intuitive and engaging interfaces may mitigate test anxiety and promote long-term engagement, thereby facilitating repeated or longitudinal assessments.

Limitations

Several limitations must be acknowledged. The sample size, particularly for the SCD group, was modest, and confidence intervals around AUC estimates (as well as around LRs) remain relatively wide. This low level of precision reflects the exploratory nature of the study of a novel tool with a modest sample size, broadly comparable to other early-stage digital cognitive assessment-tool validation studies [19,34,39,44]. Nevertheless, the robustness of these preliminary findings is supported by the study's prospective design and its execution within a real-world clinical setting. That said, larger, multicenter, prospective validation studies are necessary to confirm these findings and ensure their generalizability across more diverse populations and clinical environments.

Consistent with real-world clinical demographics, MCI participants were significantly older than SCD participants. While age differences can theoretically confound cognitive performance, statistical comparison of ROC curves demonstrated that adding age to the predictive models did not affect accuracy for any comparison. Furthermore, analysis of explained variance revealed that CogniPaz scores accounted for most of the predictive power, whereas age contributed marginally. This supports the tool's validity as a disease-detection instrument, independent of demographic confounders.

Regarding clinical characterization, we acknowledge a lack of systematic quantification of potential confounders. Unlike explanatory trials with strict exclusionary criteria, our study did not exclude patients with common comorbidities, such as depressive symptoms, vascular pathology, or sensory deficits, nor did we grade their severity using standardized scales. While this decision preserves the ecological validity of a "real-world" clinical cohort, it limits our ability to determine the extent to which these nonneurodegenerative factors—rather than incipient neurodegeneration—may have contributed to performance variability, particularly in the SCD group.

Biomarker data (eg, amyloid/tau PET and CSF markers) were not systematically available for the entire cohort, as this was not the primary aim of the study. This limitation reflects the real-world setting of a tertiary memory clinic, where many participants were patients with mild symptoms, attending their first specialist consultation, at which point invasive or expensive confirmatory tests had not yet been performed. Consequently, our preliminary biological validation represents an exploratory subanalysis. While we identified a subset of bND cases with good sensitivity, the small sample size limits the statistical power and generalizability of these findings. This may have resulted in an underestimation of the tool's diagnostic accuracy in this group, as the "unconfirmed" group may include individuals with latent neurodegenerative pathology who had not yet undergone definitive testing. These preliminary findings warrant future studies with systematic biomarker profiling before establishing CogniPaz as a digital proxy for bND and should be regarded as hypothesis-generating rather than conclusive evidence of added value.

The composite bND outcome combined heterogeneous biomarker modalities (MRI, amyloid-PET, CSF, and FDG-PET) that were obtained through routine clinical judgment rather than a uniform protocol. Participants were not verified with the same set of tests, and the modalities differ in their sensitivity and specificity for detecting neurodegeneration, so the "confirmed" and "unconfirmed" labels may not represent a fully consistent construct across participants.

The usability questionnaire used was an ad hoc, nonvalidated instrument rather than a standardized tool integrating both researcher and patient perspectives, allowing a more comparable, reproducible appraisal [49]. The 7-item scale nonetheless showed good internal consistency, supporting its interpretation as a coherent construct within this study. Furthermore, a minority of participants did not complete the questionnaire. While responders and nonresponders did not differ significantly on most measured demographic or cognitive variables, the Little

XSL•FO
RenderX

MCAR test formally rejected the assumption of data missing completely at random, indicating that nonresponse was systematically related to observed participant characteristics rather than occurring purely by chance. This reinforces the need for caution when interpreting aggregate usability scores. Future iterations of CogniPaz should incorporate a validated usability instrument administered with strategies to minimize missing data, particularly among participants at higher risk of non-response.

We also did not include longitudinal follow-up in this initial, preliminary validation. Consequently, we were unable to estimate the test-retest reliability of the CogniPaz battery, and we cannot yet determine the prognostic value of CogniPaz scores for predicting conversion from SCD to MCI or from MCI to dementia. Longitudinal digital assessments, including remote or home-based administration to formally assess test-retest reliability and clinical trajectories, could be considered for future work.

We acknowledge a potential incorporation bias, as the MoCA test was utilized as one of the operational criteria for defining the aMCI group. Theoretically, validating a new tool against a standard that forms part of the diagnosis could inflate diagnostic accuracy estimates. However, the clinical classification of aMCI was not determined by MoCA cutoffs alone but through a comprehensive clinical adjudication process involving the CDR, functional history, and expert neurological consensus. Therefore, the strong relationship observed between CogniPaz and MoCA should be interpreted as evidence of solid concurrent validity against the current standard of care, demonstrating that our digital tool successfully captures the same cognitive constructs as traditional, paper-based screening, without being solely a statistical artifact of the inclusion criteria. Beyond incorporation bias in the statistical sense, the index test and the reference standard tap partially overlapping cognitive constructs by design: both CogniPaz and the MoCA assess verbal word-list recall, and aMCI is itself defined by predominant episodic memory impairment. Part of the observed correlation and of the discriminative accuracy for aMCI may therefore reflect shared method rather than fully independent validity.

The optimal cutoff score of 28.5 points was derived and tested within the same cohort, introducing a risk of overfitting. Although internal validation using bootstrap resampling suggested stability of the estimates, this does not replace external validation. Consequently, this threshold should be considered provisional and hypothesis-generating, and its generalizability to other populations and clinical settings remains unproven. The enrollment design presents an inherent risk of spectrum bias. Because this study was conducted within a tertiary memory clinic, the clinical spectrum of our cohort may not fully mirror that of general community or primary care populations where digital screening tools are frequently deployed. Using a convenience sample of accompanying individuals as HC could artificially amplify the contrast between typical aging and cognitive impairment. The relationship of each control to a study patient (eg, spouse, other relative, or unrelated volunteer) was not systematically recorded, so shared lifestyle, socioeconomic, or genetic factors within this group could not be assessed in more detail. This may be partly mitigated by the study's focus on differentiating subtle cognitive states, such as aMCI from SCD, rather than extreme phenotypes. Independent confirmation of both the cutoff and the tool's generalizability in larger, multicenter cohorts spanning primary care and community settings is therefore an essential prerequisite before clinical implementation can be recommended.

We were unable to calculate the word error rate (WER) or perform a post hoc inter-rater agreement analysis between the automated system and manual transcriptions. To prioritize participant privacy and satisfy regulatory constraints, the application was architected to fully discard all audio recordings and raw speech-recognition text strings immediately after task execution. While this design prevents retrospective acoustic or linguistic auditing, the platform demonstrated reliable technical feasibility during clinical evaluation, with zero technical failures or data losses. Potential automatic speech recognition (ASR) errors were mitigated in real time through live user-interface safeguards (including real-time word visualization, the ability to manually delete misrecognized items, and the option to retry the task), requiring only minimal examiner supervision. Nevertheless, future iterations of the platform should incorporate prospective, item-level logging alongside parallel manual validation protocols to formally quantify ASR diagnostic accuracy.

Finally, this study focused on supervised administration in a specialized hospital setting; we did not examine unsupervised or remote use, which is increasingly relevant for population-level screening and monitoring [17]. In our study, the need for external support was not attributable to interface complexity but was strongly driven by the participants' cognitive status. Collectively, these findings suggest that requests for assistance reflect the executive and memory deficits inherent to the MCI condition, rather than limitations in the clarity or usability of the CogniPaz platform. Additional work is needed to determine whether the gamified interface of CogniPaz translates into consistent performance under remote conditions and how best to adapt or simplify tasks, if needed.

Future Directions

Future research on CogniPaz should pursue several lines. First, larger normative datasets stratified by age, education, and culture are necessary to refine cutoffs and ensure fair interpretation across populations. Furthermore, longitudinal validation through repeated assessments in SCD and MCI cohorts will help determine whether CogniPaz scores and trajectories predict clinical progression or stability. Integrating these digital metrics with multimodal biomarkers—including neuroimaging, fluid and serum markers, and genetic risk profiles—may further enhance early detection and allow for the derivation of composite risk scores. Finally, evaluating CogniPaz in nonspecialized settings is a critical next step to establish its utility as a first-line triage tool; to this end, future validation studies will be extended to the primary care settings within the La Paz University Hospital health area to assess the tool's effectiveness and feasibility as a scalable screening instrument in real-world community practice.

RenderX

Conclusions

CogniPaz is an innovative mHealth tool for early screening of cognitive impairment, designed as a multidomain, gamified, and ecologically oriented framework that includes multimodal memory and executive tasks. It differs from traditional screening tools by offering a brief, self-administered format that requires minimal supervision, makes use of the inherent advantages of digital platforms, and targets the clinically demanding aMCI-versus-SCD boundary. In doing so, it brings to the field a practical, user-friendly instrument capable of addressing shortcomings of classical screening tools. CogniPaz shows good concurrent capacity to distinguish MCI, particularly the amnestic phenotype, from SCD and HC, alongside high user acceptance. Additionally, it showed preliminary, hypothesis-generating capacity to identify bND. These results require further external, multicenter, longitudinal validation to confirm the diagnostic capacity and prognostic value of the tool in daily practice. If validated, this digital approach may provide more efficient pathways for cognitive assessment in primary care and earlier triage of patients with cognitive decline to specialized care.

Generative AI Use

The authors declare the use of generative AI in the research and writing process. According to the GAIDeT taxonomy (2025), the following tasks were delegated to GenAI tools under full human supervision: literature search and systematization, writing the literature review, code generation, code optimization, creation of algorithms for data analysis, data curation and organization, data analysis, text generation, proofreading and editing, summarizing text, formulation of conclusions, translation, reformatting, bias analysis and potential discrimination assessment, ethical risk analysis, monitoring compliance with ethical standards, quality assessment, trend identification, identification of limitations, recommendations, and publication support.

The GenAI tools used were Claude (Anthropic, Sonnet 4.6), DeepSeek (R1), ChatGPT (OpenAI, 4.1), and Gemini (Google, flash, pro).

Responsibility for the final manuscript lies entirely with the authors.

GenAI tools are not listed as authors and do not bear responsibility for the final outcomes.

Abstract

Background: Depressive symptoms are common yet often underrecognized in routine care, underscoring the need for scalable screening approaches beyond episodic self-report assessments. Wearable actigraphy can passively and continuously capture daily activity and 24-hour rest–activity rhythms associated with depressive symptom burden. However, the performance of artificial intelligence (AI) models that leverage actigraphy data for depressive symptom screening remains insufficiently established.

Objective: This study aimed to develop and evaluate AI-based models for passive screening of depressive symptoms from daily wrist actigraphy data.

Methods: We analyzed actigraphy recordings from 1160 Hispanic/Latino adults in the Hispanic Community Health Study/Study of Latinos who completed the 10-item Center for Epidemiologic Studies Depression scale (CESD-10), a self-reported depressive symptom screening scale. Multichannel actigraphy data, including activity counts, light exposure, and wake status, were used as inputs to 5 deep learning architectures to classify CESD-10–defined depressive symptom groups, comparing mild and higher symptoms with the normal group.

Results: Actigraphy-derived behavioral markers differed across depressive symptom groups, showing lower daytime activity and altered circadian rest–activity organization with increasing symptom burden. Among the 5 deep learning architectures evaluated, the long short-term memory model consistently demonstrated the strongest overall discrimination. In held-out testing, the long short-term memory model achieved a macro-averaged area under the receiver operating characteristic curve of 0.80, with the strongest discrimination observed for the higher depressive symptom group (area under the receiver operating characteristic curve 0.889). These findings indicate improved model discrimination with increasing symptom severity, although false-positive rates remained notable across both classification tasks.

Conclusions: Our study suggests that actigraphy-derived data can support AI-based classification of depressive symptoms. An actigraphy-based AI model may serve as a scalable, passive, and noninvasive complementary signal to aid early screening alongside traditional depressive symptom assessments before clinical diagnosis.

Introduction

Depression is a highly prevalent and debilitating psychiatric condition globally, with its burden increasing steadily in recent decades [1]. Despite its substantial impact on individuals and society, the mechanisms underlying depression remain complex and incompletely understood. Clinically, depression encompasses a broad spectrum of psychological, behavioral, and somatic symptoms, such as fatigue, sleep disturbances, persistent low mood, changes in appetite, anhedonia, and weight changes, impaired concentration, low self-esteem, and suicidal ideation [2,3]. These manifestations can markedly impair daily functioning, interpersonal relationships, and self-care [4].

XSL•FO
RenderX

Depression nevertheless remains underdiagnosed and undertreated in routine clinical practice, representing a critical gap in mental health care [2]. Many individuals are not identified during standard assessments, and screening is reported to occur in only 4.2% of adults without a prior diagnosis [5]. The nonspecific nature of depressive symptoms, which frequently overlap with somatic complaints such as fatigue or pain, can lead to misdiagnosis or attribution to other medical conditions [6,7]. Consequently, a substantial proportion of affected individuals remain untreated, increasing the likelihood of persistent symptoms and long-term functional impairment.

Given these challenges, there is increasing interest in objective behavioral markers that can complement traditional self-report tools [8]. Sedentary behavior, reduced physical activity, and sleep disruption have been consistently linked to depressive symptoms [9]. However, many studies rely primarily on self-reported measures, which are susceptible to subjectivity and limitations in memory accuracy. In contrast, wearable devices can passively and continuously monitor activity and sleep, providing an objective approach to capturing behavioral changes relevant to depressive symptoms [10].

Passive monitoring modalities differ in their technical characteristics, the type of behavioral information captured, and their degree of standardization. Consumer wearables, such as Fitbit devices [11] or the Apple Watch [12], rely on proprietary, closed-source algorithms that limit methodological transparency and reproducibility. Smartphones capture behavior indirectly through usage-based proxies, such as screen time, GPS mobility [13], and call logs [14], which are susceptible to device heterogeneity and user-specific confounds. Research-grade actigraphy, by contrast, uses validated, open-standard triaxial accelerometry with well-characterized signal processing pipelines, making it particularly suitable for controlled cohort studies and systematic architectural model comparison.

Actigraphy, based on wrist-worn triaxial accelerometers, provides an unobtrusive and continuous method for monitoring physical activity, rest-activity cycles, and light exposure over extended periods [15]. It can reliably estimate sleep-wake patterns and behavioral rhythms, enabling the characterization of reduced activity levels, increased sedentary time, and irregular sleep-wake schedules commonly observed among individuals with elevated depressive symptoms [16]. Evidence from meta-analyses indicates that depressive symptoms are associated with lower overall activity, poor sleep efficiency, longer sleep-onset latency, greater wake after sleep onset, and attenuated circadian amplitude compared with the normal group [17]. Collectively, these actigraphy-derived measures complement questionnaires and clinical interviews by providing a quantitative representation of circadian dysregulation and reduced activity. They may also support more effective screening of depressive symptoms than self-report alone [18].

Recent advances in artificial intelligence (AI) have expanded the utility of actigraphy for screening depressive symptoms [19]. Prior work has ranged from conventional machine learning models trained in manually engineered features, such as step-derived activity summaries and circadian indices, to end-to-end deep learning approaches [20]. While feature-based methods, including gradient-boosted ensembles, can yield moderate performance, they may be less effective at capturing time-resolved structure in actigraphy signals and can be susceptible to overfitting when many correlated predictors are included [21]. Accordingly, deep learning models have been applied directly to raw or minimally processed actigraphy sequences. Existing work has examined convolutional and recurrent architectures [22], including long short-term memory (LSTM) and gated recurrent unit (GRU) models, alongside transformers, Gramian angular field–based convolutional neural networks (CNNs), and mixed-input frameworks that incorporate sleep-stage features or questionnaire data, reporting area under the curve (AUC) values ranging approximately between 0.68 and 0.94 [20]. However, many studies have relied on small or selected samples, focused on extreme symptom groupings, or required additional clinical inputs, limiting generalizability and scalability [23]. Moreover, most studies evaluate a single architecture, which restricts comparative insight into sequence-modeling strategies [24]. Therefore, systematic comparisons of end-to-end deep learning models trained on multichannel actigraphy in large, ethnically diverse cohorts using validated self-report screening tools remain needed.

Despite these advances, actigraphy-based approaches for depressive symptoms have shown modest and variable performance, with reported accuracy and AUC values spanning a wide range across studies [25]. Much of the prior work has been developed using relatively small or demographically narrow samples, which increases the risk of overfitting and may limit the generalizability of findings to broader populations. Moreover, both machine learning and deep learning models can be difficult to interpret, particularly when complex architectures or extensive feature engineering are used, making it challenging to relate predictions to meaningful behavioral or physiological patterns [26]. Limited interpretability can hinder clinical uptake, as clinicians may be reluctant to act on algorithmic outputs without a clear connection to recognizable patterns in patients' daily activities and sleep. Accordingly, there is a need for actigraphy-based screening models that achieve robust discrimination, with transparency and clinical interpretability identified as important directions for future development [27].

We developed and evaluated an AI-based screening approach that leverages wrist-worn actigraphy to identify depressive symptoms, using the 10-item Center for Epidemiologic Studies Depression scale (CESD-10) as the reference screening tool. We trained and compared 5 deep learning architectures on 7 days of multichannel actigraphy time series to classify CESD-10 depressive symptoms. We hypothesized that a higher symptom burden would be reflected in characteristic behavioral signatures, including reduced overall activity and disrupted rest-activity rhythms, which sequence models could learn from raw actigraphy patterns. This study evaluates whether daily actigraphy-based AI models can support objective and unobtrusive screening for depressive symptoms.

Methods

Study Design and Participants

The Hispanic Community Health Study/Study of Latinos (HCHS/SOL) is a multicenter, population-based cohort study that enrolled 16,415 noninstitutionalized Hispanic/Latino adults aged 18 to 75 years across 4 US field centers in Miami, San Diego, the Bronx, and Chicago. Baseline examinations from 2008 to 2011 included standardized assessments of sociodemographic characteristics, lifestyle factors, medical comorbidities, and cardiometabolic biomarkers [28]. The Sueño ancillary study recruited 2087 adults aged 18 - 65 years from the parent cohort for actigraphy-based assessment of sleep and circadian rhythms (Figure 1A).

Figure 1. Overview of the methodological framework for screening depressive symptoms using actigraphy-derived data. (A) Study design and participants, (B) data processing and feature extraction, (C) artificial intelligence–based models, and (D) output. AI: artificial intelligence, Bi-LSTM: bidirectional long short-term memory, CNN: convolutional neural network, GRU: gated recurrent unit, LSTM: long short-term memory.

In the parent HCHS/SOL Sueño study, exclusion criteria included pregnancy, cognitive dysfunction affecting reliable self-report or informed consent, and severe mobility limitations such as hemiparesis or quadriparesis. Actigraphy was collected over 7 days using an Actiwatch Spectrum device (Philips Respironics) worn on the nondominant wrist to continuously record activity counts, multiwavelength light exposure, and sleep-wake status. After standardized quality-control procedures that excluded recordings with prolonged off-wrist intervals or implausible signal patterns, valid actigraphy data were available for 1887 participants. We then excluded 217 participants with missing demographic or psychometric data, yielding 1670 participants eligible for propensity score matching. Using a 1:1 propensity score matching approach matched on age, sex, and BMI, we derived a final analytic cohort of 1160 participants (71.4% female, aged 18 - 65 years, BMI 21.9-41.2 kg/m²), comprising 580 participants with normal depressive symptom scores and 580 with depressive symptoms. The depressive symptom group was further classified into mild and higher subgroups based on CESD-10 scores (Figure S1 in Multimedia Appendix 1).

All dataset partitioning and model evaluation were performed at the participant level. The matched cohort was then partitioned into training (70%, n=812), validation (10%, n=116), and test (20%, n=232) sets, with no participant appearing in more than one split. A fixed hold-out design was selected over cross-validation because the sequential, time-structured nature of actigraphy data makes random k-fold partitioning susceptible to temporal leakage across participants. The large number of

XSL•FO
RenderX

epoch-level training samples (>17 million) per channel further mitigates overfitting risk despite the moderate participant count. Epoch-level counts for each channel are provided in Table 1 for descriptive purposes only; all model development and performance evaluations were conducted at the participant level.

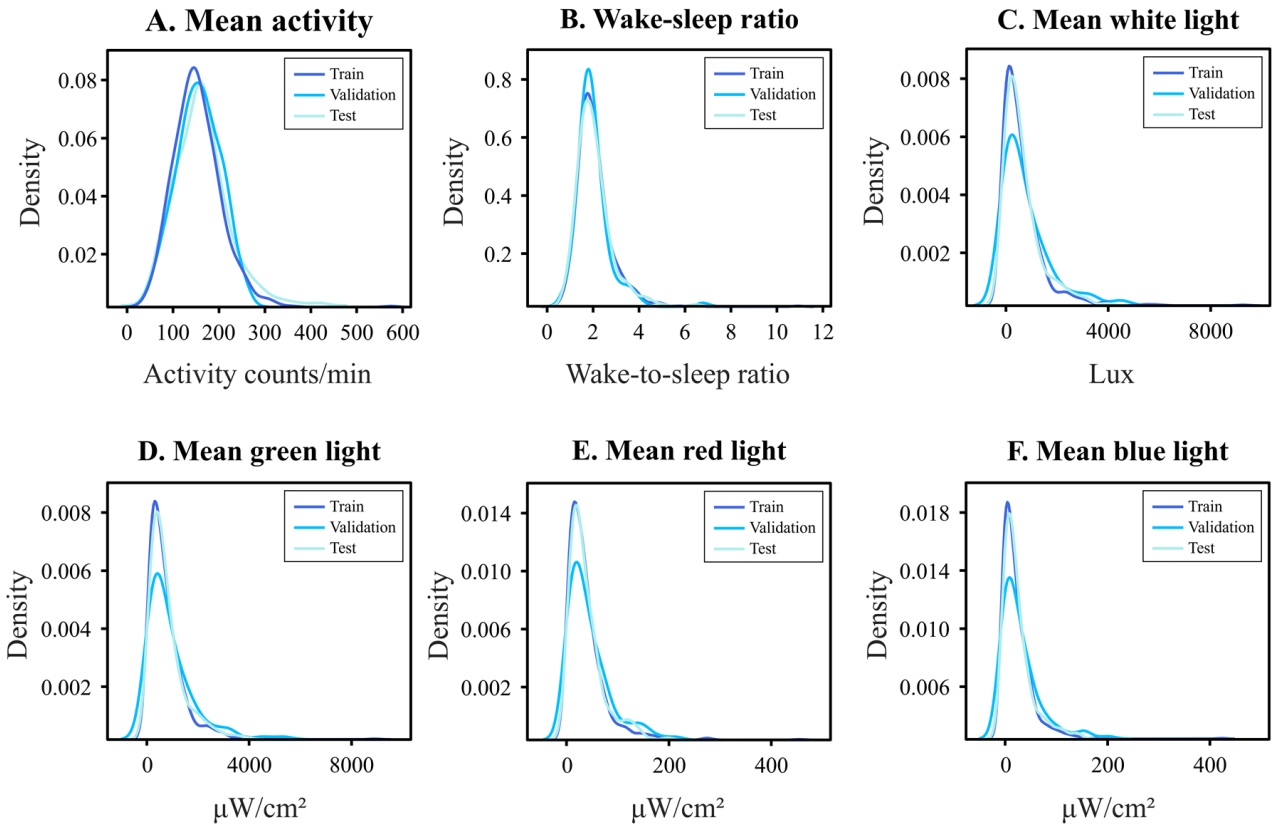
Data access, documentation, and governance were provided through the National Sleep Research Resource (NSRR) under a controlled-access data use agreement. Institutional review board approvals were in place at all participating sites, and written informed consent was obtained from all participants.

Table . Total epoch counts for each actigraphy channel across the training, validation, and test splits.

Features	Training set	Validation set	Test set	Total
Activity	17,336,985	2,487,580	4,898,740	24,723,305
Wake	17,325,681	2,486,083	4,895,117	24,706,881
White light	17,335,426	2,487,011	4,898,349	24,720,786
RGB[a] light	17,336,985	2,487,580	4,898,740	24,723,305
Total	69,335,077	9,948,254	19,590,946	98,874,277

[a]R: red, G: green, and B: blue light channels have an equal number of epochs.

Depressive Symptoms Assessment



Depressive symptoms were measured using the CESD-10, a validated self-report screening tool widely used in epidemiologic and community-based studies [29]. Items are rated on a 4-point response scale from 0 to 3, yielding a total score from 0 to 30, with higher scores indicating greater depressive symptom burden over the past week [30]. Following prior HCHS/SOL analyses, participants with CESD-10 scores of 10 or higher were classified as having elevated depressive symptoms [31]. For the present analyses, CESD-10 scores were further categorized into three groups to capture graded symptom burden: 0 to 9 (normal), 10 to 14 (mild), and ≥15 (higher depressive symptoms). These categories were used to describe baseline characteristics and to evaluate trends in sociodemographic, behavioral, and clinical factors across increasing symptom severity. CESD-10 has demonstrated good psychometric properties across diverse populations, supporting its use as a community-based screening measure for depressive symptoms [32].

Data Processing and Feature Extraction

Raw wrist actigraphy recordings were preprocessed to support downstream model development and evaluation. For each participant, signals were segmented into 30-second epochs containing activity counts, binary wake status, and light exposures in the white, red, green, and blue channels. Epochs flagged as invalid or off-wrist under the HCHS/SOL quality control criteria were removed before analysis. After data cleaning, the remaining time series were standardized using *z* score normalization. To prevent information leakage, the mean and SD were estimated using the training set only and applied unchanged to the validation and test sets for consistent scaling across splits (Figure 1B). The normalized sequences were segmented into nonoverlapping windows of 2000 consecutive epochs, corresponding to approximately 16.7 hours, providing fixed-length inputs for the deep learning architectures. The resulting inputs comprised the following six synchronized channels: activity (Figure 2A), wake status (Figure 2B), white light exposure (Figure 2C), green light exposure (Figure 2D), red light exposure (Figure 2E), and blue light exposure (Figure 2F). Across the training, validation, and test splits, this yielded approximately 24 to 25 million 30-second epochs per channel in total (Table 1). Minor differences in epoch counts across channels reflect channel-specific quality-control exclusions applied independently during preprocessing. Overall epoch proportions across splits remained consistent with the participant-level 70/10/20 allocation. This segmentation approach provided a large and representative set of training samples while maintaining consistent preprocessing across datasets and minimizing the risk of distributional shifts introduced by data handling.

XSL•FO
RenderX

Figure 2. Density distributions of *z* score–normalized actigraphy features across dataset splits. Kernel density curves for the training, validation, and test sets show substantial overlap, indicating comparable feature distributions across splits and supporting consistent data representation during model development and evaluation. (A) Mean activity, (B) wake-to-sleep ratio, (C) mean white light, (D) mean green light, (E) mean red light, and (F) mean blue light.

To assess consistency across dataset splits, we examined the distributions of key actigraphy-derived features within the training, validation, and test sets (Figure 2). The *z* score–normalized distributions showed substantial overlap, indicating comparable feature profiles across splits and supporting the appropriateness of the partitioning. This consistency helps preserve statistical comparability between datasets and strengthens the reliability of model development and evaluation.

In addition to the raw actigraphy time series used for deep learning, we computed summary measures to describe 24-hour rest–activity rhythms for descriptive analyses and between-group comparisons. For each valid day, mean activity counts were calculated within eight 3-hour clock-time intervals spanning midnight to 2:59 AM through 9 PM to 11:59 PM and then averaged across monitoring days. Using the 30-second activity signal, we quantified circadian rhythm metrics, including intradaily variability, interdaily stability, and relative amplitude derived from the most active 10-hour window (M10) and the least active 5-hour window (L5), along with the onset times of M10 and L5. We also fit a 24-hour cosinor model to each participant's activity profile to estimate the midline statistic of rhythm, log-transformed amplitude, and acrophase. For each metric, values were aggregated across valid days to obtain a participant-level estimate, which was compared across CESD-10 depressive symptom categories.

AI-Based Models

We implemented 5 deep learning architectures to classify depressive symptoms using multichannel wrist actigraphy data, including a GRU [33], LSTM [34], bidirectional LSTM (Bi-LSTM) [35], 1-dimensional convolutional neural network–long short-term memory (CNN-LSTM) [36], and attention-LSTM [37] (Figure 1C). These architectures were selected to represent diverse sequential modeling strategies, ranging from conventional recurrent networks to bidirectional and hybrid designs, thereby enabling a systematic comparison of their ability to capture temporal dependencies in multichannel actigraphy data. Each model leveraged different modeling strengths, from local feature extraction and long-range temporal dependency learning to bidirectional sequence modeling, enabling identification of the most effective approach for classifying depressive symptom severity from wrist-worn sensor data.

All models received input sequences of 2000 time steps with 6 synchronized channels, including activity counts, wake status, and multiwavelength light exposure (white, red, green, and blue), and produced a 3-class probability distribution through a softmax activation function. A dropout rate of 0.3 was selected based on prior LSTM-based studies [34] and preliminary validation experiments comparing rates of 0.2, 0.3, and 0.5, with 0.3 yielding the best validation performance. The final class prediction was determined by selecting the class with the highest softmax probability (Table 2).

[a]BN: batch normalization.

[b]AI: artificial intelligence.

[c]LSTM: long short-term memory.

[d]Bi-LSTM: bidirectional long short-term memory.

[e]CNN-LSTM: convolutional neural network–long short-term memory.

[f]GRU: gated recurrent unit.

Single AI Models

The GRU, LSTM, and Bi-LSTM models were implemented using 4 stacked recurrent layers with 60 - 120 hidden units, followed by batch normalization and a fully connected output layer (Table S2 and Figures S2-S3 in Multimedia Appendix 1). GRU and LSTM models use different gating formulations but are both widely applied to sequential physiological signals. In contrast, the Bi-LSTM processes each sequence in both forward and backward directions, allowing the model to integrate information from both earlier and later time points within the same window (Table S3 and Figure S6 in Multimedia Appendix 1).

Hybrid AI Models

The CNN-LSTM model consisted of three 1D convolutional blocks with filter sizes of 32 - 128, each followed by rectified linear unit activation and max-pooling, and 2 LSTM layers with 64 hidden units (Table S4 and Figure S7 in Multimedia Appendix 1). The attention-LSTM extended this architecture with a single-head attention module before the LSTM layer (Table S5 and Figure S8 in Multimedia Appendix 1).

Model Training

All models were trained for up to 150 epochs using a mini-batch size of 32, with early stopping applied for 30 consecutive epochs. A Cosine Annealing Warm Restarts learning rate scheduler was applied to facilitate convergence. Hyperparameters, including learning rate (3×10^{-4}), hidden units, and dropout rate, were selected through a structured manual search over predefined ranges, with final configurations chosen to maximize validation AUC. To further optimize classification performance, threshold calibration was performed on the validation set using the Nelder-Mead optimization method to maximize macro F_1, with calibrated thresholds applied during test set evaluation.

Class Imbalance

The training cohort reflected moderate class imbalance, with 580 participants classified as normal, 318 as mild, and 262 as higher depressive symptoms (Figure 1D). This was addressed using a combination of 3 strategies. First, sequence-level oversampling was applied to the training set, augmenting minority class samples with Gaussian jitter and random scaling until each class reached 65% of the majority class size (target ratio=0.65). Second, weighted random sampling was applied during mini-batch construction to further balance class representation. Third, focal loss with class-specific weights (mild: 1.8×, higher: 2.0× relative to normal) was used to penalize misclassification of minority classes during training.

Experiments and Evaluations

All experiments were implemented in Python (version 3.11.4; Python Software Foundation), with model development and training carried out using the Keras API within TensorFlow 2.x [38]. Statistical analyses were carried out using SciPy (version 1.8.1; SciPy developers) [39], and machine learning metrics were computed using scikit-learn (version 1.1.2; scikit-learn developers) [40].

Training and evaluation were performed on a Windows 11 workstation equipped with an NVIDIA GTX 1080 Ti GPU. For efficient computation, the dataset was divided into minibatches of 256 samples. Model parameters were updated using gradient accumulation after each minibatch.

XSL•FO
RenderX

Model performance on the test set was summarized using standard classification metrics, including precision, specificity, sensitivity, accuracy, F_1-score, and the area under the receiver operating characteristic curve (AUROC). To assess the robustness of model performance, 95% CIs for AUROC were estimated using bootstrap resampling (1000 iterations) on the test set. All metrics were computed from the test-set confusion matrix. Metric definitions are provided below [41]:

Precision = TP / (TP + FP)

Specificity = TN / (TN + FP)

Sensitivity (Recall) = TP / (TP + FN)

Accuracy = (TP + TN) / (TP + TN + FP + FN)

F_1-score = 2 × (Precision × Recall) / (Precision + Recall)

For multi-class classification, accuracy was computed within a one-versus-rest framework, in which each depressive symptom group was designated as the positive class, and the remaining two groups were combined as the negative class. Per-class accuracy thus reflects the proportion of correctly classified instances, both true positives and true negatives, within each binary classification setting.

Here, TP represents depressed participants correctly classified as depressed, and TN represents nondepressed participants correctly classified as nondepressed. FP refers to nondepressed participants misclassified as depressed, whereas FN indicates depressed participants misclassified as nondepressed.

Ethical Considerations

This study was a secondary analysis of deidentified wrist-worn actigraphy and associated covariate data from the HCHS/SOL, obtained through the NSRR. The original HCHS/SOL study received institutional review board approvals at all participating field centers (University of North Carolina at Chapel Hill, Albert Einstein College of Medicine, University of Illinois at Chicago, University of Miami, and San Diego State University), and written informed consent was obtained from all participants. The dataset analyzed in this study was deidentified before release in accordance with the Health Insurance Portability and Accountability Act and contained no direct or indirect personal identifiers. This study involved secondary analysis of existing deidentified data and did not involve recruitment of participants, interaction with participants, intervention, or access to identifiable private information. Because this study used only deidentified secondary data and did not involve human participants as defined under applicable institutional and national research ethics regulations, additional institutional review board approval and informed consent were not required for this secondary analysis. Data were accessed under an approved Data Access and Use Agreement with Brigham and Women's Hospital through the NSRR (NHLBI R24 HL114473). No attempt was made to identify or reidentify any participant. All data were fully deidentified; no identifiable participant information was accessed, and no identifying details appear in this study.

Results

Demographic Characteristics

A total of 1160 participants with valid baseline actigraphy and CESD-10 data were included. Based on CESD-10 scores, 580 (49.1%) participants were classified into the normal group (CESD-10 <10), 318 (27.9%) into the mild symptom group (CESD-10 =10 - 14), and 262 (23%) into the higher symptom group (CESD-10 ≥15). Higher depressive symptom burden was associated with a greater prevalence of being unmarried, currently unemployed, and current smoking (all P<.001; Table 3).

[a]*P* values reflect between-group comparisons based on the tests described above.

[b]HS: high school.

[c]GED: general educational development.

In contrast, demographic characteristics and cardiometabolic comorbidities were comparable across depressive symptom groups, with no statistically significant differences observed in age, sex, education, BMI, alcohol use, diabetes, hypertension, cerebrovascular disease, chronic kidney disease, coronary heart disease, or dyslipidemia (all *P*>.05). In this community-based cohort, higher depressive symptom burden was more strongly associated with sociodemographic and behavioral factors, particularly marital status, unemployment, and smoking, than with cardiometabolic comorbidity. Specifically, unemployment exceeded two-thirds in the higher symptom group, and current smoking increased across depressive categories (Table 3).

Daily Light Exposure and Rest Activity

Actigraphy-derived light exposure and rest-activity characteristics by depressive symptom groups are provided in Table 4. Time spent above 500 and 1000 lux did not differ significantly across groups, although values were numerically lower among participants with depressive symptoms. In contrast, mean daytime white-light exposure was reduced in the higher symptom group compared with the normal group.

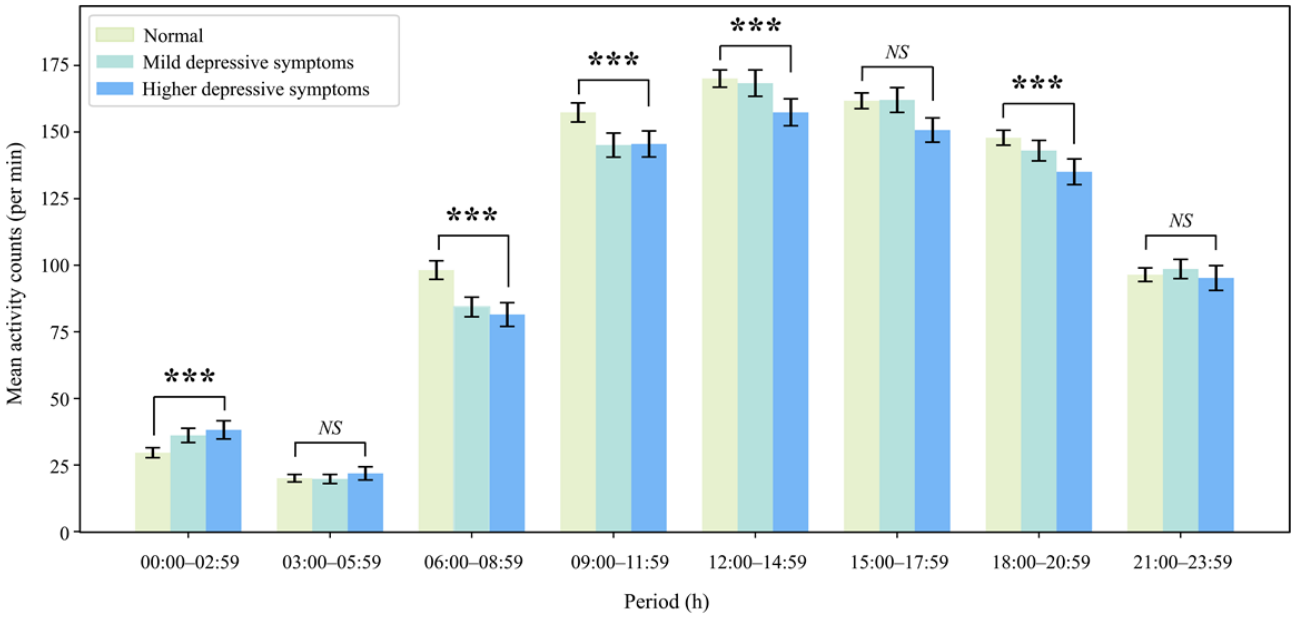
[a]*P*=.05: statistically significant.

[b]M10: average activity within the most active 10-h period of the day.

[c]Average activity within the least active 5-h period of the day.

[d]MESOR: midline estimating statistics of rhythm.

Across nonparametric rest-activity measures, higher depressive symptom burden was associated with lower M10 activity and higher L5 activity, consistent with attenuation of the 24-hour rest-activity amplitude. M10 and L5 onset times were also shifted in symptomatic groups, indicating a modest change in the timing of the most and least active periods. Cosinor-derived metrics showed concordant patterns, with midline estimating statistics of rhythm and log-transformed amplitude decreasing from the normal to the higher depressive group, while acrophase occurred slightly earlier in participants with greater symptom burden. In contrast, interdaily stability and intradaily variability differed minimally between groups, suggesting that day-to-day regularity and fragmentation were largely preserved despite lower overall activity and reduced rhythmic amplitude.



Time-of-Day Activity

Across the 24-hour day, mean activity declined as depressive symptom burden increased, with the largest separations observed

XSL•FO
RenderX

during daytime periods (Figure 3). The higher-symptom group showed lower activity in the morning (6 AM-8:59 AM and 9 AM-11:59 AM), midday (noon to 2:59 PM), and early evening (6 PM-8:59 PM) relative to the normal group. In contrast, late-evening activity (9 PM-11:59 PM) and several late-night intervals differed only modestly between groups. Notably, activity between midnight and 2:59 AM was slightly higher in the higher-symptom group, suggesting a small redistribution of activity toward the nighttime period.

Figure 3. Mean activity counts across 3-h intervals by depressive symptom group. *P* values were calculated using unpaired 2-tailed student *t* tests (NS: not significant; ***$P<.001$).

AI Model Performance for Depressive Symptom Screening

Across the 5 deep learning architectures, we evaluated classification performance on the test set, with 95% CIs (Table 5). Among all models, discrimination was consistently higher for the higher depressive symptom group than for the mild group, suggesting that actigraphy-derived behavioral patterns may better differentiate higher symptom burden from normal. LSTM demonstrated the strongest overall performance, achieving the highest AUROC of 0.640 (95% CI 0.526 - 0.736) for the mild depressive symptom group and 0.889 (95% CI 0.829 - 0.942) for the higher depressive symptom group, followed by Bi-LSTM with a comparable AUROC of 0.881 (95% CI 0.817 - 0.939). Model performance across the training, validation, and test sets is provided in Table S1 in Multimedia Appendix 1.

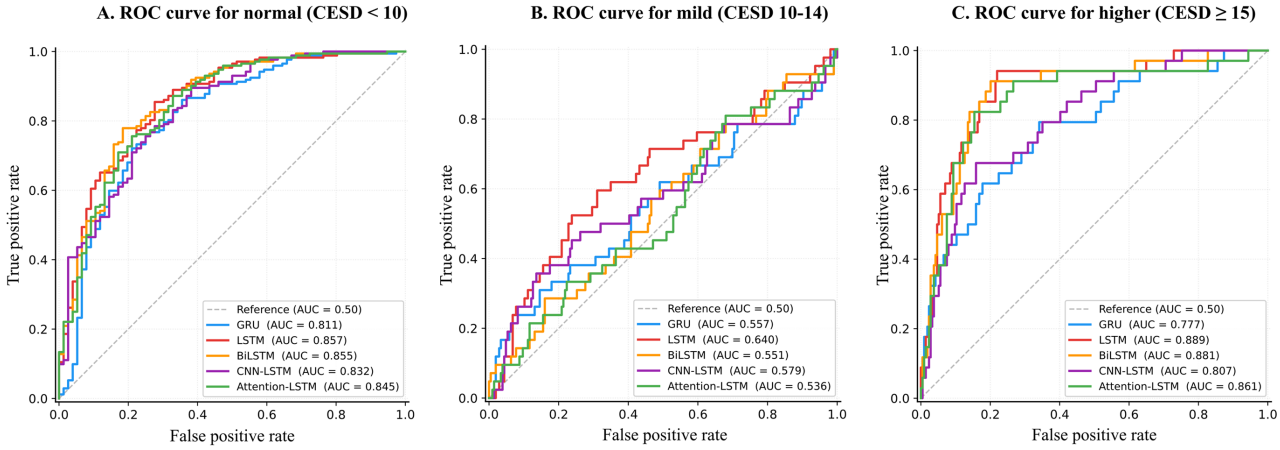
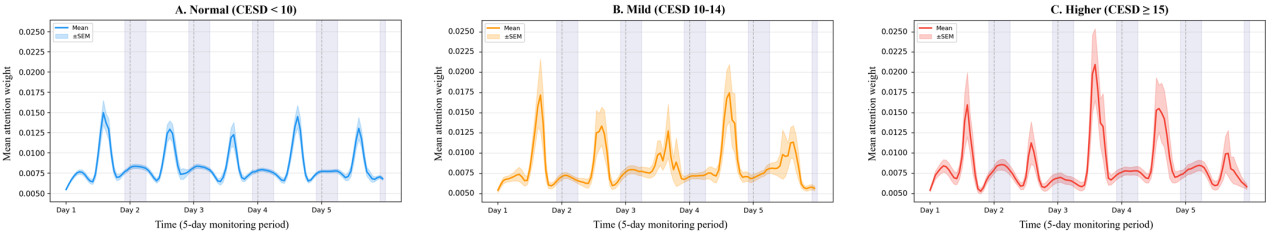
The confusion matrices summarize test-set classification outcomes across 3 depressive symptom groups—normal, mild, and higher—for 5 deep learning models: GRU (Figure 4A), LSTM (Figure 4B), Bi-LSTM (Figure 4C), CNN-LSTM (Figure 4D), and Attention-LSTM (Figure 4E). Recall for the mild symptom group was comparatively limited across all models, with recall ranging from 41% to 51.3%, reflecting frequent misclassification into adjacent categories. For the higher depressive symptom group, CNN-LSTM achieved the highest recall at 68.7% (22/32), followed by Bi-LSTM at 65.7% (21/32) (Figures 4C and 4D). Across all models, misclassification was most prevalent in the mild depressive symptom group, while higher depressive symptoms were least likely to be misclassified as normal across all models.



XSL•FO
RenderX

Figure 4. Confusion matrices for depressive symptom classification on the test set. Models evaluated include (A) gated recurrent unit (GRU), (B) long short-term memory (LSTM), (C) bidirectional long short-term memory (Bi-LSTM), (D) convolutional neural network–long short-term memory (CNN-LSTM), and (E) attention-LSTM.

XSL•FO
RenderX



We further evaluated model discrimination using receiver operating characteristic curves across 5 deep learning models (Figure 5). For the normal group, all models achieved strong discrimination, with AUC values ranging from 0.811 to 0.857 (Figure 5A). In contrast, for the mild depressive symptom group (Figure 5B), discriminative performance was substantially lower across all models, with AUC values ranging from 0.536 to 0.640, with LSTM achieving the highest AUC of 0.640, reflecting the inherent challenge of classifying mild depressive symptoms. For the higher depressive symptom group (Figure 5C), models showed improved performance with AUC values ranging from 0.777 to 0.889, with LSTM achieving the highest AUC of 0.889, followed by Bi-LSTM at 0.881 and attention-LSTM at 0.861.

Figure 5. Receiver operating characteristic (ROC) curves for multiclass classification of depressive symptoms across 5 artificial intelligence models (gated recurrent unit [GRU], long short-term memory [LSTM], bidirectional long short-term memory [Bi-LSTM], convolutional neural network–long short-term memory [CNN-LSTM], and attention-LSTM) using a one-versus-rest framework. ROC curves are presented for each depressive symptom group: (A) normal (Center for Epidemiologic Studies Depression scale [CESD] <10), (B) mild (CESD 10-14), and (C) higher (CESD ≥15). Each curve represents the trade-off between the true positive rate (sensitivity) and false positive rate (1 − specificity) for a given model, with the dashed diagonal line indicating reference-level discrimination (area under the curve [AUC]=0.50).

The attention-LSTM model consistently assigned higher attention weights to daytime periods across all depressive symptom groups throughout the 5-day monitoring period. The normal group demonstrated stable (Figure 6A), rhythmic daily peaks, whereas the mild group showed more variable patterns with pronounced spikes at days 1, 3, and 4 (Figure 6B). The higher group exhibited the largest attention weight peaks, particularly at days 3 and 4, with wider SE of the mean (SEM) bands indicating greater interindividual variability (Figure 6C). Heatmap visualization further confirmed the concentration of attention weights between 12 hours and 16 hours (Figure S9 in Multimedia Appendix 1). To further quantify these patterns, peak attention timepoints were identified for each group (Table S6 and Figure S10 in Multimedia Appendix 1). The normal group peaked at day 1, 14 hours (mean 0.0150, SD 0.0197), the mild group at day 4, 15 hours (mean 0.0175, SD 0.0230), and the higher group showed concentrated peaks on day 3 between 13 hours and 15 hours (mean 0.0181, SD 0.0210), with all 3 peaks occurring within the same day, indicating sustained afternoon behavioral disruption as a key discriminative feature for severe depressive symptoms.

Figure 6. Mean attention weights of the attention-LSTM model across a 5-day monitoring period by depressive symptom group. Mean attention weights are plotted over the 5-day monitoring period for each depressive symptom group. (A) Normal (Center for Epidemiologic Studies Depression scale [CESD] <10), (B) mild (CESD 10-14), and (C) higher (CESD ≥15). Solid lines represent the group-level mean attention weight, and shaded regions indicate ±1 SE of the mean (SEM). Navy-shaded vertical bands denote approximate nighttime periods. The attention-LSTM model consistently assigned higher weights to daytime periods across all groups, reflecting the importance of active-hour behavioral signals in depressive symptom classification.

Discussion

Principal Findings

This study systematically compared 5 deep learning architectures using multichannel wrist-worn actigraphy to screen for CESD-10–defined depressive symptoms in a propensity score–matched HCHS/SOL cohort. Across both symptom-burden comparisons, discrimination was consistently higher for the higher depressive symptom group than for the mild group. In the mild depressive symptom comparison, LSTM achieved the strongest overall discrimination, with a test-set AUROC of 0.640. In the higher depressive symptom comparison, LSTM also showed the best performance, achieving

XSL•FO
RenderX

a test-set AUROC of 0.889, followed closely by Bi-LSTM with an AUROC of 0.881 (Table 5). The confusion matrix findings further indicated fewer missed cases in the higher symptom burden comparison, whereas false-positive classifications remained substantial in both settings (Figure 4). Collectively, these findings suggest that actigraphy-based sequence models may better distinguish higher symptom burden from typical behavioral patterns than mild symptoms. This difference may reflect the more heterogeneous and subtle behavioral signatures associated with mild depressive burden.

From a clinical and public health perspective, these findings support actigraphy-based deep learning as a scalable, passive approach for depressive symptom screening rather than a diagnostic test. In settings where depressive symptoms are underrecognized during routine care, model outputs could complement self-report screening by providing objective, longitudinal behavioral information that may prompt follow-up assessment, particularly among individuals with higher symptom burden.

Clinical Utility and Implementation Considerations

Classification threshold selection is a key consideration for real-world deployment. In this study, threshold calibration using the Nelder-Mead method on the validation set yielded model-specific optimal thresholds that maximized macro-F_1 performance. Lower thresholds may be preferred in population-level screening to prioritize sensitivity and reduce missed cases, whereas higher thresholds may be more appropriate in resource-limited settings to improve specificity and reduce unnecessary follow-up. As illustrated by the receiver operating characteristic curves (Figure 5), operating points can be adjusted to reflect these trade-offs; however, the optimal threshold should ultimately be determined empirically through prospective validation in the target population.

The confusion matrices (Figure 4) further illuminate the practical implications of these classification outcomes. For the mild depressive symptom group, the attention-LSTM produced 61 false positives and 23 false negatives (Figure 4E), reflecting a greater burden of overidentification than missed cases. For the higher depressive symptom group, despite CNN-LSTM achieving the highest recall, the Bi-LSTM yielded 11 false negatives with a false-positive rate of 12.5% (n=25), suggesting a more favorable trade-off between sensitivity and specificity (Figure 4C). These findings highlight a key characteristic of screening-oriented models: while sensitivity can be improved, false-positive rates may remain substantial, especially for the mild depressive symptom group.

In real-world clinical settings, false-positive predictions may increase patient burden, clinician workload, and health care costs. To address this, we propose a stepped implementation pathway in which a positive actigraphy-based screen is followed by a low-burden secondary assessment, such as a validated Patient Health Questionnaire-9 (PHQ-9) [42], rather than immediate referral for specialist evaluation. Repeating actigraphy-based screening over time may further help confirm persistent behavioral patterns before clinical referral. Individuals who screen positive across both stages could then be prioritized for formal clinical assessment by a mental health professional. The proposed model is not intended to replace clinical diagnosis but to function as a complementary screening signal within existing care pathways, enabling earlier identification in settings where depressive symptoms remain underrecognized during routine care.

Comparison With Prior Work

Prior studies using smartphones and consumer wearables have reported predictive value for depressive outcomes; however, as discussed in the Introduction section, these modalities differ fundamentally from research-grade actigraphy in sensor standardization, algorithmic transparency, and signal continuity, limiting direct comparisons. Among smartphone-based approaches, Saeb et al [13] demonstrated that GPS-derived features, including location variance and circadian movement, were significantly correlated with PHQ-9 depressive symptom severity ($|r| \geq 0.43$). Ikäheimonen et al [14] showed that smartphone behavioral features, including screen-off events, communication patterns, and location data, classified depressive states with an accuracy of 82% (95% CI 80% - 84%) in a clinically diagnosed sample. Consumer wearable studies have leveraged heart rate variability and circadian rhythm features for depressive symptom screening; for instance, Rykov et al [11] used Fitbit-derived features and reported an accuracy of 0.80, though performance varied across subgroups, reflecting the influence of population characteristics and feature selection on model generalizability.

Beyond modality, this study also differs from prior actigraphy work in its modeling approach. Incorporating multi-wavelength light exposure alongside activity and wake status offers a richer behavioral representation than studies relying on activity alone. Performance differences across model architectures were not uniform, suggesting that model selection should align with the intended screening target and the acceptable trade-off between missed cases and false alarms.

Table 6 summarizes representative studies that differ in outcome definitions, populations, and input features. Notably, all prior studies employed binary classification frameworks, whereas the present study simultaneously classified three depressive symptom groups, which inherently increases task complexity and limits direct performance comparison. Nonetheless, these studies provide useful context, as the present results extend prior evidence that AI models can support passive screening of depressive symptoms from wearable data. Specifically, Vahedifard et al [23] presented engineered actigraphy-based activity features using XGBoost for 4-class classification of inpatient adolescents with bipolar disorder. Price et al [24] applied a Gramian angular field CNN approach and highlighted the informativeness of nighttime motor patterns, although sensitivity was comparatively lower, potentially reflecting differences in feature scope and labeling strategy.

[m]Values represent macro-averaged one-versus-rest performance metrics across three classes.

Prior work has evaluated deep learning approaches for depression screening using either actigraphy as a stand-alone modality or in combination with complementary modalities (Table 6). Lee et al [26] implemented a mixed-input framework integrating actigraphy-derived step counts with sleep stage information and survey measures, reporting an AUC of 0.94. Price et al [27] presented transformer-based architectures to model long-range temporal dependencies in actigraphy sequences, yielding an AUC of 0.89. Jacobsen et al [43] used CNN-based models to distinguish individuals with and without depression, reporting an accuracy of 0.73.

Additional studies have incorporated transfer learning and real-world wearable platforms. Ghate et al [45] proposed a real-time screening pipeline using transfer learning on Fitbit data, achieving 79% accuracy with leave-one-out cross-validation in a small sample. Rykov et al [11] evaluated an XGBoost (Extreme Gradient Boosting)–based machine learning model using wearable-derived digital biomarkers, such as circadian rhythm regularity and nighttime heart rate variation, for binary classification of depressive symptom status in a contrasted subsample, achieving an AUC of 0.75.

Strengths and Limitations

Unlike studies that rely primarily on engineered features or small-sample transfer-learning settings, we trained 5 deep learning models directly on raw multichannel actigraphy signals in a large, ethnically diverse Hispanic/Latino community cohort (n=1160), a population that remains underrepresented in actigraphy-based mental health research. All models used relatively lightweight architectures ranging from 86,817 to 518,065 parameters, supporting computational feasibility for real-world deployment. We further characterized symptom burden across three depressive symptom groups and reported complementary discrimination and error-profile metrics to quantify trade-offs between missed cases and false alarms. The use of 6 synchronized actigraphy channels, including activity counts, wake status, and multiwavelength light exposure, provided a richer behavioral representation than studies relying on single-channel inputs.

Several limitations should be considered. First, depressive symptom status was defined using the CESD-10, a self-reported screening tool rather than a structured clinical diagnosis;

XSL•FO
RenderX

therefore, our models estimate symptom burden, not clinician-diagnosed major depressive disorder. Second, actigraphy nonwear and missing segments may introduce residual measurement noise despite quality-control procedures. Third, external validation in independent cohorts is needed to establish transportability across diverse populations. Fourth, attention weight patterns in the attention-LSTM reflect selective temporal weighting rather than formal clinical explanations; individual-level attribution methods, such as Shapley Additive Explanations–based approaches, represent an important direction for future work.

Future Research

Future studies should validate these findings using clinically adjudicated outcomes across diverse subgroups and comorbid conditions. Longitudinal monitoring designs should be explored to assess whether actigraphy-derived behavioral signatures can track symptom trajectories and detect early relapses or recovery patterns. Additionally, the generalizability of models trained on research-grade actigraphy to consumer wearables and smartphone-based platforms warrants investigation. Establishing interpretable and externally validated models will be essential for translating actigraphy-based screening into real-world mental health workflows.

Conclusions

In a matched Hispanic/Latino community-based cohort, deep learning models trained on multichannel wrist-worn actigraphy demonstrated stronger discrimination for higher depressive symptoms than for mild depressive symptoms, with LSTM achieving the strongest overall performance and a macro-averaged AUROC of 0.80. These findings suggest that actigraphy-derived data can support AI-based passive screening of depressive symptoms; however, false-positive rates remain notable, and external validation and improved interpretability are needed before clinical deployment. An actigraphy-based AI model may serve as a scalable, passive, and noninvasive complementary signal to aid early screening alongside traditional depressive symptom assessments.

Abstract

Background: Knee pain affects 22.9% of individuals aged 40 years and over globally and is associated with body function, activity, environmental, and personal factors described in the *International Classification of Functioning, Disability and Health* (ICF) model. Most prior studies examined isolated risk factors using conventional regression.

Objective: This study aimed to examine self-reported knee pain in community-dwelling older adults by combining machine learning and partial-correlation network analysis with smartphone-based physical performance measurement.

Methods: This cross-sectional study included 852 adults aged 60 years and older. Baseline assessment of 38 variables across 7 ICF-aligned domains was reduced to 21 predictors using prespecified, rule-based criteria (events per variable=14.95). Walking speed, sit-to-stand, gait knee flexion, and gait asymmetry were measured using a validated vision-based smartphone app. Missing data were addressed by multiple imputation (m=5) with Rubin rules. Six algorithms (logistic regression with elastic-net penalty as baseline, k-nearest neighbors, random forest, Extreme Gradient Boosting, Light Gradient Boosting Machine, and support vector machine) were trained using nested 5×5 cross-validation, and the best model was interpreted using Shapley Additive Explanations and partial dependence plots. Partial-correlation network analysis examined the 10 top-ranked features and the knee-pain node, with bootstrap stability assessment and a sensitivity analysis excluding EuroQol 5-Dimension (EQ-5D) Pain/Discomfort.

Results: Knee pain prevalence was 36.9% (314/852). Pooled area under the receiver operating characteristic curve values ranged from 0.692 to 0.723, with random forest highest (area under the receiver operating characteristic curve=0.723, 95% CI 0.689 - 0.757). The top Shapley Additive Explanations features were EQ-5D Pain/Discomfort, EQ-5D Utility, and house estate. In the 11-node network, only EQ-5D Pain/Discomfort (partial correlation=0.260) and house estate (0.158) had direct edges with knee pain. Sit-to-stand showed the highest strength centrality (0.679) without a direct edge, acting as a hub linking body function, body structure, mental health, and activity variables. Shapley Additive Explanations importance and network strength were weakly correlated (ρ=0.018). The sensitivity analysis preserved the pattern (best area under the receiver operating characteristic curve=0.724).

Conclusions: Knee pain in older adults was associated with variables spanning 7 ICF domains, with EQ-5D Pain/Discomfort and housing environment (lower-income rental estate residence) as direct correlates and sit-to-stand as a network hub. Combining machine learning and partial-correlation network analysis may inform multidisciplinary biopsychosocial assessment, pending confirmation in prospective and externally validated studies.

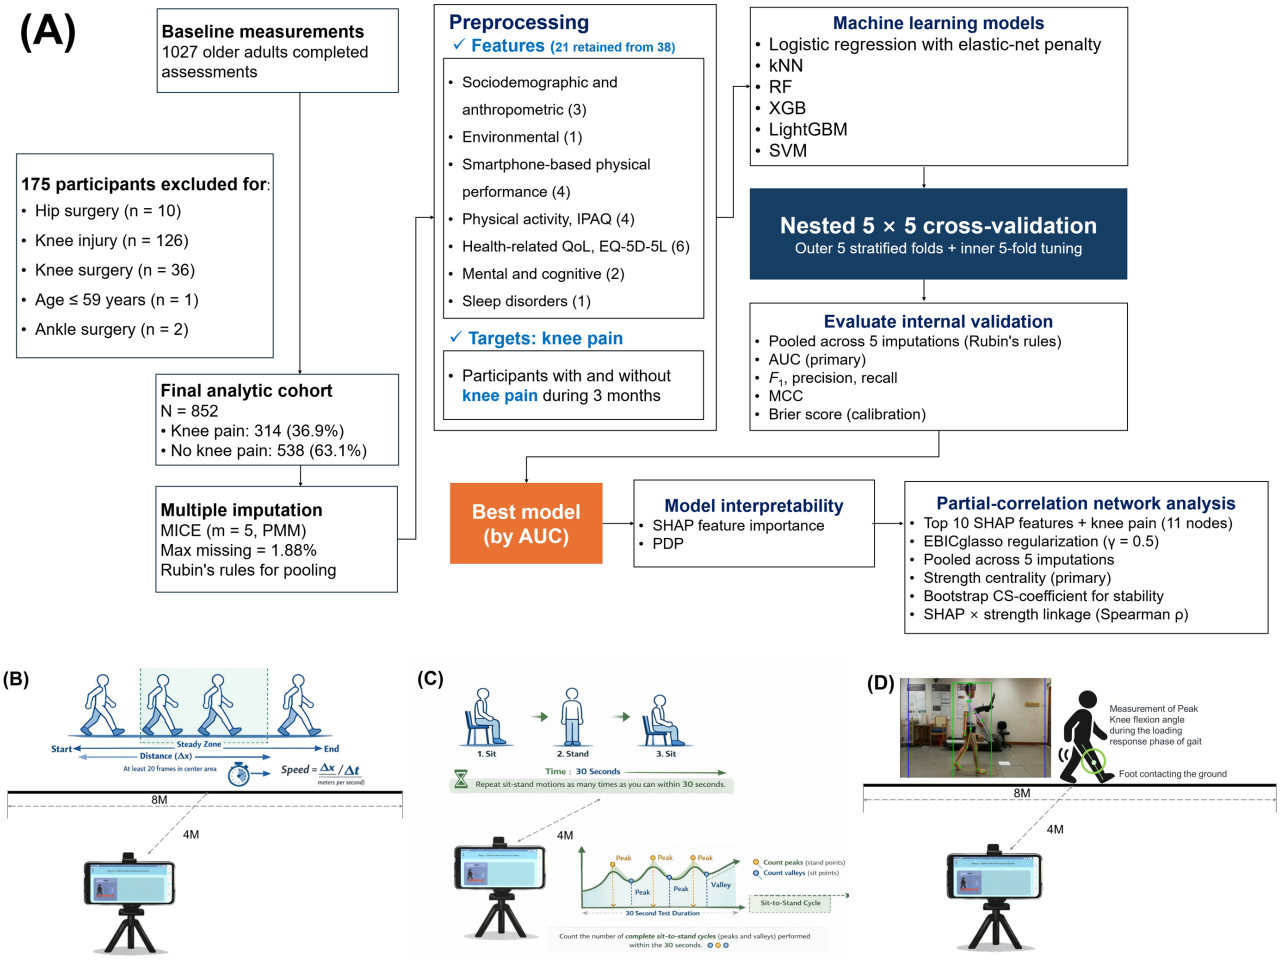
Introduction

Self-reported knee pain is one of the most common musculoskeletal complaints among community-dwelling older adults and a leading contributor to disability, reduced physical activity, and impaired quality of life [1,2]. The Global Burden of Disease 2021 study estimated that 595 million people worldwide were living with osteoarthritis in 2020, corresponding to 7.6% of the global population, with knee being the most common site; compared with 2020, the number of cases of knee osteoarthritis is projected to increase by 74.9% by 2050, alongside continued increases in population aging and obesity prevalence [3,4]. Identifying which factors are associated with self-reported knee pain in community settings, before structural disease and clinical referral, is therefore a continuing research priority.

Knee pain in older adults is conceptualized as multidimensional. The *International Classification of Functioning, Disability and Health* (*ICF*) framework, built on the biopsychosocial model, organizes health into interacting domains spanning body functions and structures, activities and participation, and environmental and personal factors [5-7]. In knee osteoarthritis populations, physical performance, psychological status, sleep, and environmental context each carry independent associations with pain experience and functional limitation [8-10]. The *ICF* specifies that health outcomes such as knee pain arise from a structure in which some variables show direct associations with the outcome and others act through intermediate variables. Although this direct-versus-indirect distinction is part of the framework, prior studies of knee pain have not quantitatively separated the two types of association in a single analysis. As a result, it remains unclear which domains carry direct associations with knee pain in older adults and which contribute through other variables in the multidimensional structure.

Two analytical paradigms have been applied to multidimensional pain data, but they answer different questions and have typically been used in isolation. Machine learning (ML) classification with Shapley Additive Explanations (SHAP)–based explanation quantifies the marginal predictive importance of each feature, capturing potentially nonlinear contributions that traditional regression may miss [11,12]. Recent reviews of ML applications in knee osteoarthritis highlight the rapid growth of this methodology across clinical, structural, and surgical endpoints, while also noting that most studies focus on imaging-based outcomes and that few have addressed self-reported pain or nonimaging multidimensional determinants in older adults [2,3]. Partial-correlation network analysis characterizes the conditional dependency structure among variables, with centrality indices summarizing how each variable connects to the broader system after controlling for all others [13,14]. When the two paradigms are reported jointly on the same data, it becomes possible to determine whether a variable's contribution to the model output is mirrored by a direct conditional dependency with the outcome, or whether that contribution is accounted for by other variables in the network. This joint use operationalizes the direct and indirect pathways described by the *ICF*, but applications of this combined analysis to knee pain remain limited [8,15]. Mobile health measures of physical performance, such as smartphone-based gait and sit-to-stand assessments [16], need to be integrated with questionnaire-based body function and environmental variables within a single *ICF*-aligned analysis.

The aim of this study was to characterize how variables across seven *ICF*-aligned domains, including smartphone-derived physical performance, are associated with self-reported knee pain in community-dwelling older adults, and to distinguish those that show direct conditional dependencies with knee pain from those whose contribution is accounted for by other variables in the multidimensional structure. We hypothesized that the seven *ICF* domains would show heterogeneous patterns of association with knee pain, with some domains contributing through direct conditional dependencies and others through indirect pathways involving other variables, in line with the multidimensional structure described by the framework.



Methods

Study Design and Participation

A total of 1027 community-dwelling Hong Kong residents aged 60 years or older were recruited for the study. Eligible participants were those living independently in housing estates, able to walk independently for at least 8 meters, and capable of providing informed consent. Exclusion criteria included (1) severe cognitive impairment preventing informed consent; (2) inability to communicate in Cantonese or read Traditional Chinese; (3) history of hip surgery, knee surgery, or ankle surgery within the past 12 months; (4) recent knee injury (within the past 6 mo); and (5) diagnosed neurological diseases including Parkinson disease, stroke, multiple sclerosis, or other conditions. Of the 1027 participants initially screened, 852 participants (83%) met all inclusion criteria and completed the comprehensive baseline assessment protocol. Study flowchart and participant characteristics are presented in Figure 1 and Table 1, respectively. Reporting follows the Transparent Reporting of a multivariable prediction model for Individual Prognosis Or Diagnosis + AI statement for prediction model studies using AI and ML [17], consistent with the *Journal of Medical Internet Research*–recommended guidelines for ML predictive models in biomedical research [18].

Ethical Considerations

This study was conducted in accordance with the Declaration of Helsinki and was approved by the Institutional Review Board of The Hong Kong Polytechnic University (HSEARS20220628001). All participants provided written informed consent before data collection, after the nature and possible consequences of the study were explained. Video recordings captured during the smartphone-based assessments were transmitted to institutional servers for automated pose-estimation analysis; all data were deidentified before analysis and stored in a password-protected database accessible only to the research team. No identifiable participant information is presented in this paper or its supplementary materials. As part of the wider project, participants who completed the exercise program and achieved a predefined fitness criterion at the 12-month follow-up received a health hamper valued at HKD 200 (approximately US $26).

Knee Pain Outcome

The primary outcome was the presence of self-reported knee pain experienced within the preceding 3 months, ascertained through structured interviewer-administered questionnaires conducted by trained research assistants. Knee pain was defined as any ache, discomfort, or pain sensation experienced in one or both knees during this 3-month period [1]. Participants were classified as having knee pain (Yes) or not (No) based on this question.

Data Collection and Measurements

Overview

Comprehensive baseline assessment included variables organized under seven domains aligned with the *ICF* framework: sociodemographic and anthropometric characteristics, environmental factors, smartphone-based physical performance, physical activity, health-related quality of life, mental and cognitive functioning, and sleep. All instruments used validated Traditional Chinese versions with established psychometric properties in older adult populations.

Sociodemographic and anthropometric measures comprised age, sex, and BMI (calculated from measured height and weight). Housing type (elderly housing vs rental estate) was used as an environmental indicator. The Hong Kong Housing Society operates a spectrum of estates serving different income groups, with rental housing estates serving lower-income households and senior (older) housing serving middle- to higher-income groups; in this cohort, rental estate residence therefore reflects a relatively lower socioeconomic position. Health-related quality of life was assessed using the EuroQol 5-Dimension 5-Level (EQ-5D-5L) instrument [19], confirming scores for five dimensions (Mobility, Self-care, Usual Activities, Pain/Discomfort, and Anxiety/Depression), the visual analog scale, and the Hong Kong–specific utility index. Aging expectations were assessed using the 12-item Expectations Regarding Aging questionnaire total score [20]. Mental health–related quality of life was assessed using the Recovering Quality of Life total score [21]. Sleep was assessed using the Sleep Disorders Questionnaire covering six categories (insomnia, periodic limb movement, circadian rhythm disorder, movement disorder, parasomnia, and sleep apnea); a total disorder count from 0 to 6 was used for analysis [22]. Physical activity was assessed using the International Physical Activity Questionnaire (IPAQ), from which we derived sitting time (minutes per day) and metabolic equivalent of task (MET) minutes per week for walking, moderate, and vigorous activities [23].

Smartphone-Based Physical Performance Assessment

Physical performance assessment was performed at community-dwelling centers using a research prototype smartphone-based digital health system that used computer vision pose estimation algorithms for mobility evaluation (Figure 1) [16]. Correlation analyses of the smartphone measurement system showed agreement for walking speed measurements (r=0.975) and knee flexion assessments (r=0.907 to 0.923), with test-retest reliability values (intraclass correlation coefficient=0.86 to 0.94) and no significant systematic bias detected following algorithm calibration [16]. The experimental setup involved positioning an Android (Google LLC) smartphone equipped with a single camera on a 0.9-meter height stand, placed 4 meters perpendicular to the midpoint of an 8-meter walkway within the dwelling centers. The smartphone was installed with a vision-based gait analysis app that uses pose estimation technology to detect and track anatomical landmarks throughout movement sequences. The app connects to a backend infrastructure featuring cloud-based processing capabilities through an Nginx load balancer (F5, Inc.) capable of handling multiple simultaneous connections. Video data is transmitted frame-by-frame in real-time to a Flask framework for pose detection [16]. Processed data, including raw video files and numerical results, are stored in a MySQL (Oracle Corporation) database with web-based researcher portals providing access to results.

For walking speed (m/s) [24,25], participants walked naturally across a standardized 8-meter walkway while being recorded using smartphone cameras positioned perpendicular to the walking path. The analysis system used human detection followed by pose estimation to track 17 key anatomical landmarks, including head, thorax, pelvis, and bilateral extremity joints with subpixel accuracy. Spatial calibration was applied by matching the median-detected human height across all frames with participant-reported height, enabling conversion from pixel coordinates to real-world measurements without external reference objects. The system automatically identified steady-state walking zones by tracking pelvis position along the trajectory, requiring consistent walking velocity within a predefined spatial range (1/5 to 4/5 of walkway length) for a minimum of 20 consecutive frames to exclude acceleration and deceleration phases. Walking speed was computed as the change in pelvis horizontal position divided by elapsed time within identified zones, with median values calculated across multiple segments and temporal smoothing applied using a 5-frame median filter.

Sit-to-stand performance was assessed through automated movement cycle counting using pose-based motion analysis over 30 seconds [26,27]. The system tracked pelvis vertical position and bilateral knee flexion angles, with hip height

XSL•FO
RenderX

changes serving as the primary indicator for transitions supplemented by knee angle verification. Complete cycles were identified using peak and valley detection in hip trajectories with dynamic thresholds established based on movement range (25th to 75th percentile of hip height range) to accommodate individual differences. Each detected peak required a corresponding valley for cycle validation, counting only complete cycles within the time window from the first detected movement. Quality control included 5-frame smoothing filters and automatic switching to knee flexion angle-based analysis using predefined thresholds (110 to 160 degrees range) when hip height detection showed inconsistencies.

Bilateral knee flexion angles were measured during early stance phase using three-point angular calculations incorporating hip, knee, and ankle joint centers [28,29]. The algorithm computed angles between thigh and shank segments using arctangent-based trigonometric calculations, with early stance phase automatically identified through ankle crossing patterns and calf angle peaks. The system detected when the contralateral ankle passed the ipsilateral ankle, followed by identification of maximum calf angle relative to vertical, indicating early stance initiation. Measurements were direction-adjusted based on walking trajectory, analyzing right leg early stance for rightward walking and left leg for leftward movement. Peak knee flexion angles were identified across multiple gait cycles with median values calculated to represent typical performance while minimizing outlier influence.

Statistical Analysis

All ML analyses were conducted using R statistical software (version 4.5.3; R Core Team). Baseline characteristics of the analytic cohort were compared between participants with and without self-reported knee pain using independent 2-tailed *t* tests (continuous variables) or χ^2 tests (categorical variables).

Premodeling Variable Reduction

To address events-per-variable (EPV) constraints raised in the literature for prediction model development [30,31], we applied a prespecified, rule-based variable reduction prior to modeling. The 38 candidate predictor variables were reduced to 21 based on conceptual and statistical overlap (Table S1 in Multimedia Appendix 1): six Sleep Disorders Questionnaire items were collapsed into a single sleep-disorder count (0 to 6); bilateral knee flexion was averaged into one variable, with absolute bilateral asymmetry retained as a separate gait-quality measure; redundant IPAQ frequency or duration counts were dropped in favor of four MET-summary variables (sitting, walking, moderate, and vigorous); the EQ-5D visual analog scale was excluded because it overlaps with the five dimensions and the utility index; and Expectations Regarding Aging subscale scores were collapsed into the Expectations Regarding Aging-12 total. With 314 self-reported knee-pain events in the 852 analytic cohort, this supported an EPV of 14.95, exceeding the conventional threshold of 10 or greater for stable prediction model estimation [31]. Data-driven variable selection was not applied, and the rule-based reduction was conducted before any outcome-aware modeling step.

Multiple Imputation

Across the 21 retained variables, the maximum item-level missingness was 1.88%, with a median of 1.17% (IQR 0.47%-1.29%; Table S2 in Multimedia Appendix 1). Missing values were addressed using multiple imputation by chained equations with predictive mean matching, m=5 imputed datasets, and 30 iterations per chain. Convergence was inspected using trace plots (Figure S1 in Multimedia Appendix 1). All subsequent analyses were conducted on each of the 5 imputed datasets, and results were pooled using Rubin's rules. The class distribution (knee pain "Yes" [314/852] 36.9%, "No" [538/852] 63.1%) constituted mild imbalance, addressed through imbalance-aware metrics (area under the receiver operating characteristic curve [AUC], F_1-score, and Matthews correlation coefficient [MCC]) rather than algorithmic resampling.

Nested Cross-Validation and Comparison With Logistic Regression Baseline

Six classification algorithms were compared: logistic regression (LR) with elastic-net penalty (LR; clinically interpretable baseline), k-nearest neighbors, random forest (RF), Extreme Gradient Boosting (XGB), Light Gradient Boosting Machine (LightGBM), and support vector machine (SVM) with radial basis function kernel. Performance was estimated using nested 5×5 cross-validation: 5 stratified outer folds for unbiased performance estimation, with an inner 5-fold cross-validation within each outer training fold for hyperparameter grid-search tuning (Table S3 in Multimedia Appendix 1). Continuous predictors were centered and scaled within each fold. This procedure was repeated independently on each of the 5 multiply-imputed datasets, and pooled estimates with 95% CIs were obtained via Rubin rules. For each algorithm, we report pooled AUC, F_1-score, precision, recall, Matthews correlation coefficient [MCC], accuracy, and Brier score with 95% CIs.

SHAP-Based Marginal Importance and Partial Dependence

Each variable's marginal contribution to the model output was quantified using SHAP values computed with the fastshap package and 50 Monte Carlo permutation samples on the best-performing caret-compatible algorithm [11]. SHAP values were computed within each imputation and averaged. We report mean absolute SHAP for global ranking and beeswarm plots for per-participant distributions. To visualize the marginal model–implied relationship between each top-ranked feature and the predicted probability of knee pain, partial dependence plots (PDPs) were generated for the top 9 SHAP features using the iml package with a 30-point grid. PDPs are model-dependent visualizations that do not establish causal effects or constitute clinical thresholds; we therefore frame all PDP-derived patterns as exploratory.

Partial-Correlation Network Analysis With Paradigm Concordance and Pathway Decomposition

To characterize the conditional dependency structure among predictor variables and the outcome, we estimated partial-correlation networks using graphical LASSO with extended Bayesian information criterion (EBICglasso) regularization, Spearman correlations to accommodate

XSL•FO
RenderX

nonnormal distributions, EBIC tuning parameter gamma of 0.5, and edge thresholding [32]. Network nodes comprised the top 10 SHAP-ranked features plus the binary knee pain outcome (n=11). This prespecified threshold was chosen to keep the node count compatible with stable EBICglasso estimation at our sample size, to focus the network on the predictors carrying the most model-relevant information, and to preserve interpretability; the sensitivity analysis confirmed a consistent network structure. One prespecified rule was applied: when EQ-5D Utility appeared in the top 10 alongside one or more individual EQ-5D dimensions, Utility was excluded (because it is a deterministic weighted combination of the dimensions) and replaced with the next-ranked SHAP feature. Networks were estimated separately on each imputation, and partial-correlation matrices were averaged. Three centrality measures were computed (strength, closeness, and betweenness); strength was prespecified as the primary measure, as closeness and betweenness are known to be unstable in cross-sectional networks of modest size. Centrality stability was assessed using case-dropping bootstrap (1000 resamples, first imputation), with the correlation-stability (CS) coefficient reported [33].

To examine paradigm concordance, we prespecified the Spearman rank correlation between SHAP importance and each centrality measure across the 10 network feature nodes (excluding the knee-pain node) as a quantitative test. We additionally decomposed each variable's contribution into a direct pathway, operationalized as the absolute partial correlation with the knee-pain node, and an indirect pathway, operationalized as the residual SHAP magnitude after subtracting the direct edge contribution. This decomposition is descriptive, not causal: it characterizes whether a variable's contribution to the model's output corresponds to a direct conditional dependency with the outcome or is instead accounted for by conditional dependencies with other variables in the network.

Sensitivity Analysis for Outcome-Feature Conceptual Overlap

EQ-5D Pain/Discomfort is a self-rated pain item that shares conceptual content with the outcome. To examine whether model results depended on this overlap, we conducted a prespecified sensitivity analysis excluding EQ-5D Pain/Discomfort from the feature set (n=20 variables; EPV=15.7). The full pipeline was repeated unchanged, and results are reported in Table S4 in Multimedia Appendix 1.

Results

Baseline Characteristics

Of the 852 participants, 314 (36.9%) reported knee pain in the preceding 3 months and 538 (63.1%) did not. Baseline characteristics by knee pain status are presented in Table 1. The two groups were comparable in age (2-tailed t_{693}=1.27; P=.21), with a small difference in the proportion of female participants (χ^2_1=5.08; P=.02). Participants with knee pain had higher BMI (t_{613}=−3.22; P=.001), were more frequently rental estate residents (χ^2_1=35.57; P<.001), and showed slower walking speed (t_{702}=2.41; P=.02) and fewer sit-to-stand repetitions (t_{713}=3.85; P<.001). They reported more sitting time (t_{635}=−3.81; P<.001), less walking-related (t_{816}=4.61; P<.001), and vigorous physical activity (all P<.001), poorer health-related quality of life across multiple EQ-5D dimensions, lower mental health scores (t_{640}=2.74; P=.006), and a higher count of sleep disorder categories (t_{553}=−4.88; P<.001). The largest between-group difference was observed for EQ-5D Pain/Discomfort (Cohen d=−0.73), followed by EQ-5D Utility (Cohen d=0.57) and EQ-5D Mobility (Cohen d=−0.39).

Model Performance

Pooled performance metrics for the six classification algorithms are presented in Table 2 and Figure 2. AUC values clustered within a narrow range from 0.692 (95% CI 0.661-0.724) for LightGBM to 0.723 (95% CI 0.686-0.760) for RF. The LR baseline showed a pooled AUC of 0.721 (95% CI 0.691-0.751), placing it within 0.002 of RF and 0.001 of SVM. F_1-score, recall, and MCC were modest across all algorithms (MCC range 0.252-0.328), and LR produced the lowest Brier score (0.200), indicating the best calibration. Performance was stable across the 5 imputations, with within-imputation variation in mean AUC less than 0.02 for every algorithm (Figure 2D). The discrimination performance of all six algorithms was effectively comparable; RF was retained as the best-performing algorithm by pooled AUC for SHAP analysis.

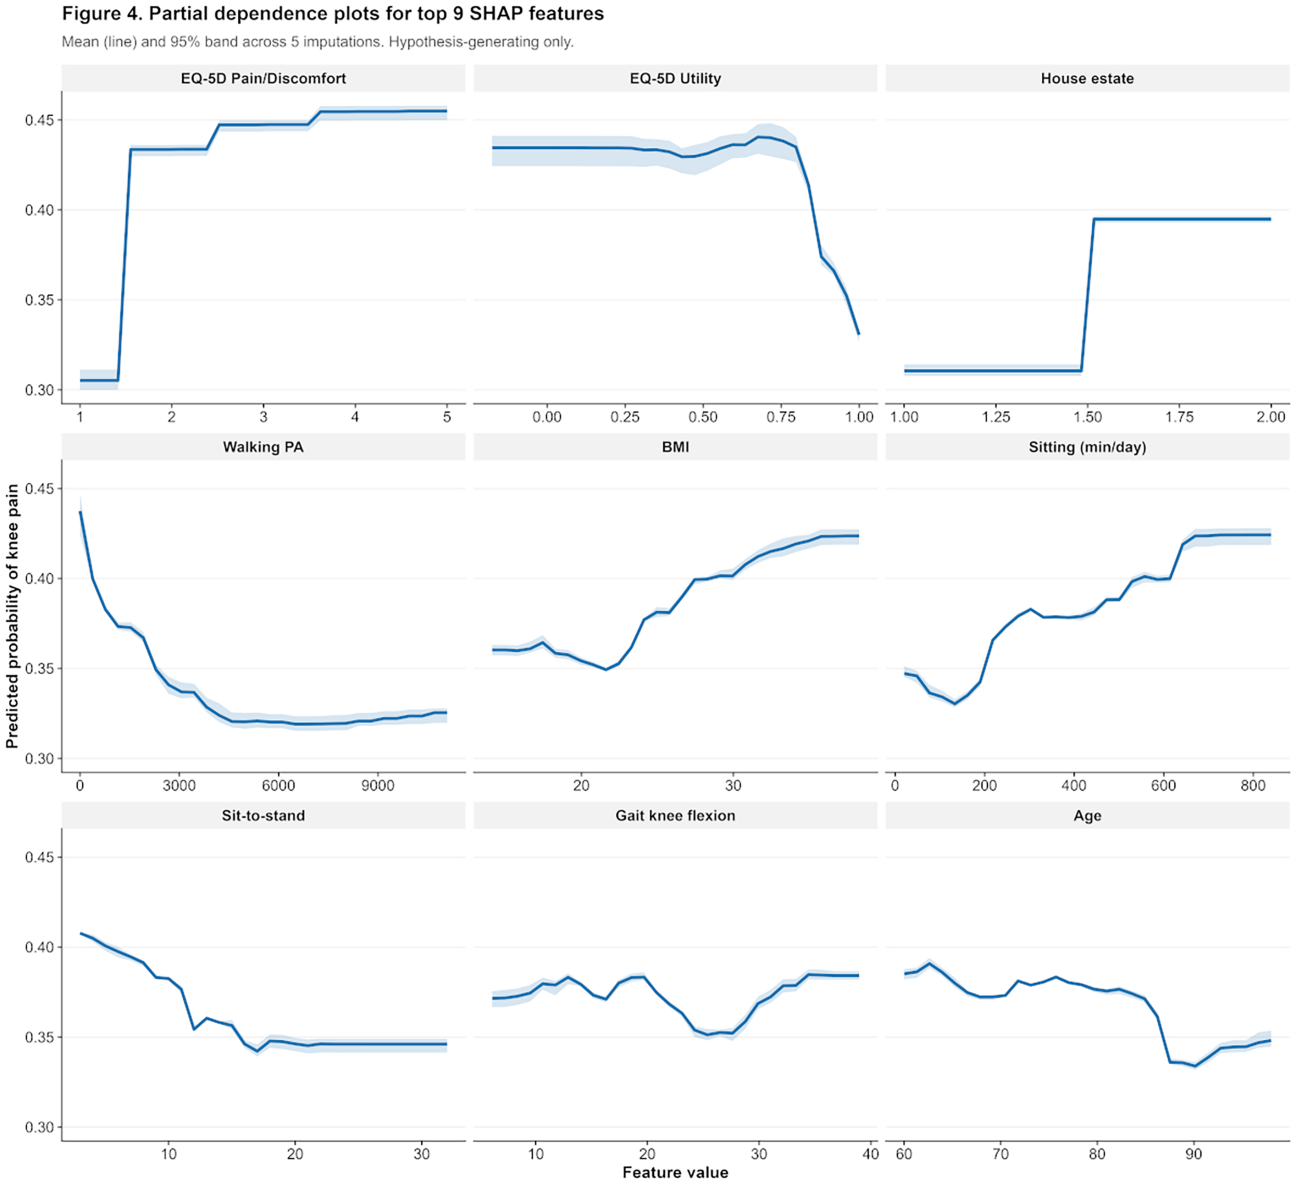
Values are pooled estimates (95% CI) across five multiply-imputed datasets, obtained via Rubin's rules from nested 5×5 cross-validation. Algorithms are ordered by pooled AUC.

Pooled performance of six classification algorithms (LR with elastic-net penalty, k-nearest neighbors, RF, XGB, LightGBM, and SVM with radial basis function kernel) estimated using nested 5×5 cross-validation on five multiply-imputed datasets and pooled via Rubin rules.

SHAP-Based Marginal Contribution

Pooled SHAP-based feature importance for the RF model is presented in Figure 3, with values for all 21 variables in Table S5 in Multimedia Appendix 1. The three highest-ranked features were EQ-5D Pain/Discomfort (mean |SHAP|=0.064), EQ-5D Utility (0.038), and house estate (0.034). Subsequent features clustered at substantially lower magnitudes (|SHAP| range 0.013-0.019) and included physical activity, anthropometric, smartphone-based physical performance, and mental and sleep variables. The SHAP value distributions in Figure 3 characterized the direction of each association: higher EQ-5D Pain/Discomfort scores, lower EQ-5D Utility, rental estate residence, lower walking physical activity and sit-to-stand repetitions, higher BMI and sitting time, and higher sleep disorder counts were each associated with increased predicted probability of knee pain, consistent with the group differences observed in Table 1.

Figure 3. SHAP-based feature importance for knee pain classification. (A) Feature importance for mean absolute SHAP value for the top 15 features; (B) SHAP value distribution per feature (beeswarm plot). ERA: Expectations Regarding Aging; EQ-5D: EuroQol 5-Dimension; SHAP: Shapley Additive Explanations; BMI: body mass index; PA: physical activity.



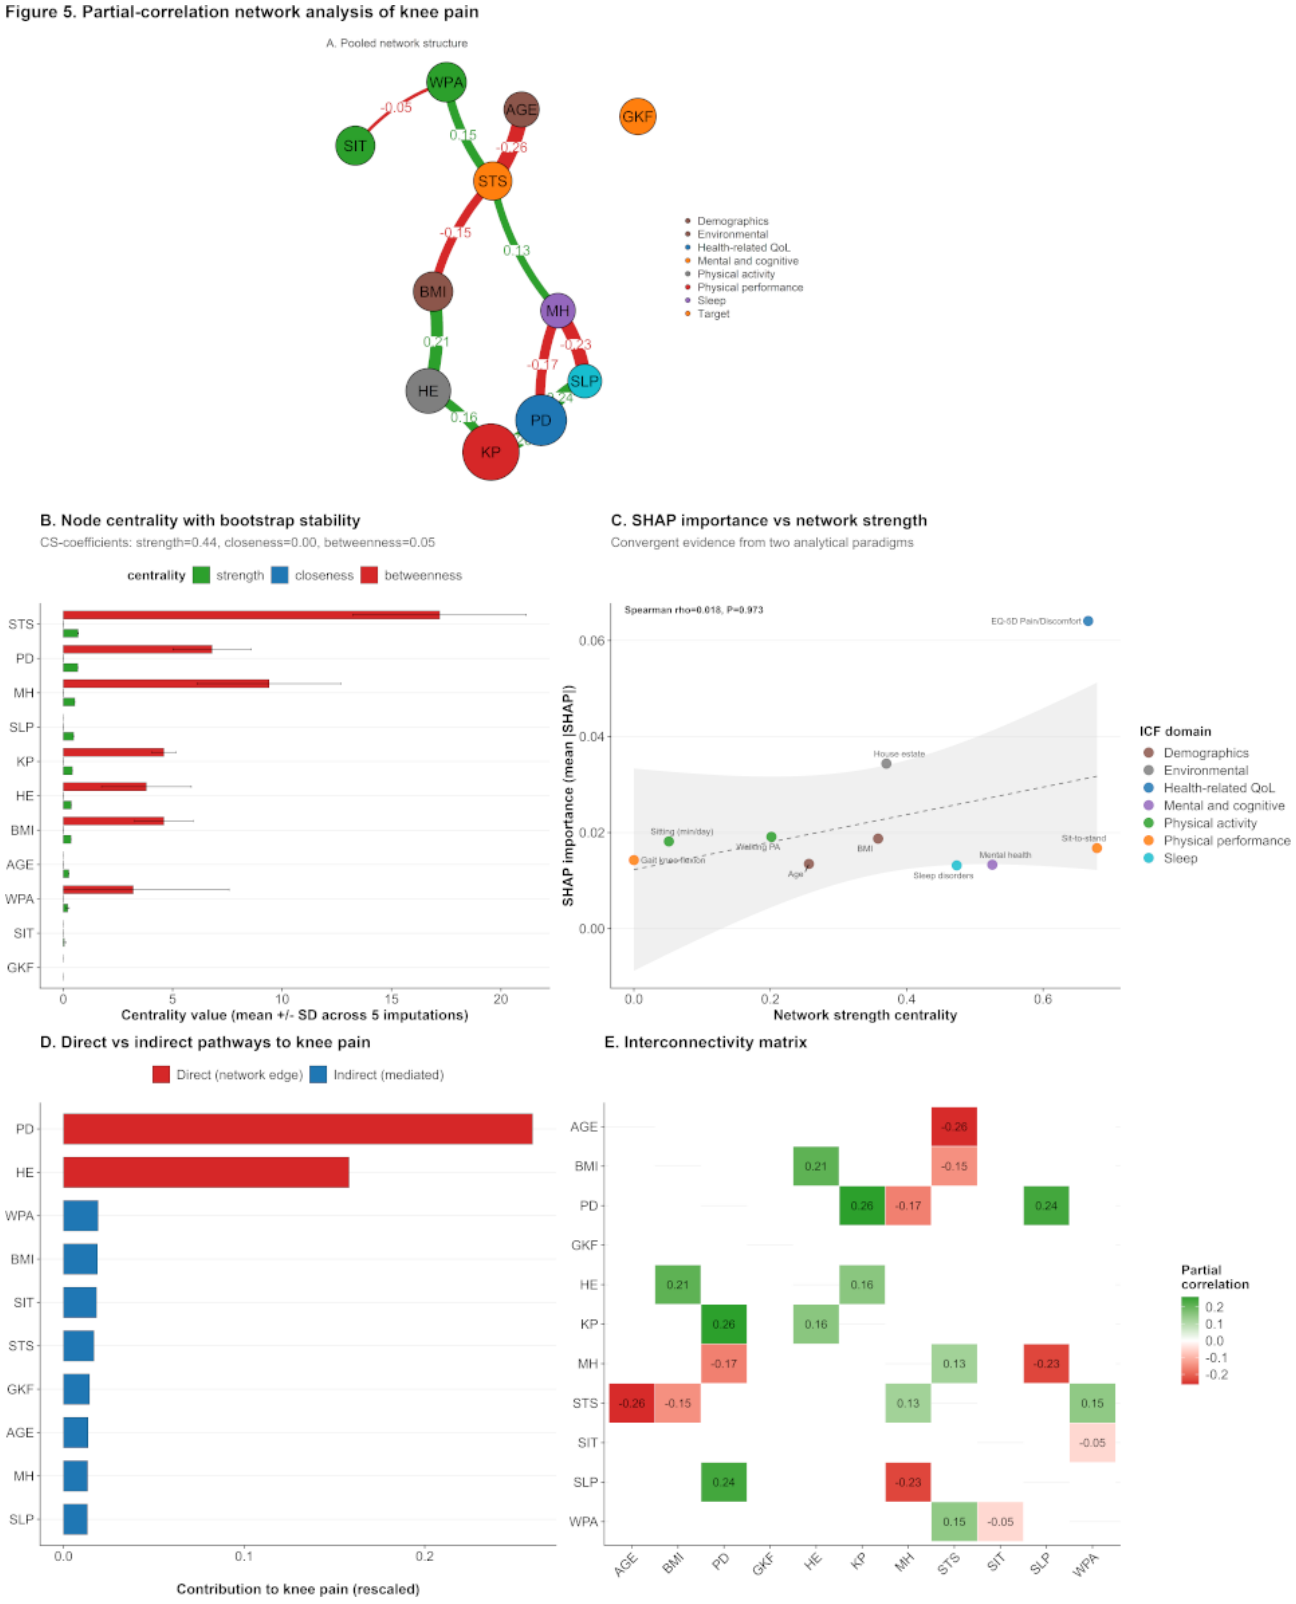
Partial Dependence Plots

PDPs for the top 9 SHAP-ranked features are shown in Figure 4. The model-implied probability of knee pain rose sharply between EQ-5D Pain/Discomfort scores of 1 and 2 (from approximately 0.31 to 0.43), reaching a plateau near 0.45. The relationship for EQ-5D Utility was relatively flat across most of the range and decreased steeply at utility values above approximately 0.85. House estate showed a step function consistent with its binary coding. For continuous features, the model-implied probability of knee pain decreased with higher walking physical activity and sit-to-stand repetitions and increased with higher BMI and sitting time. Gait knee flexion and age showed comparatively flat partial dependence functions. These patterns describe model-implied marginal relationships and are presented as exploratory; they do not establish causal effects or clinical thresholds.

XSL•FO
RenderX

Figure 4. Partial dependence plots for the top 9 SHAP-ranked features. Features are arranged in descending order of SHAP importance: EQ-5D Pain/Discomfort, EQ-5D Utility, house estate, walking physical activity, body mass index, sitting time, sit-to-stand repetitions, gait knee flexion, and age. EQ-5D: EuroQol 5-Dimension 5-Level; PA: physical activity; SHAP: Shapley Additive Explanations.

Network Structure, Paradigm Concordance, and Pathway Decomposition



The pooled partial-correlation network for the 11 nodes is shown in Figure 5A, with the full pooled partial-correlation matrix in Table S6 in Multimedia Appendix 1. After EBICglasso regularization and edge thresholding, 11 conditional dependencies survived. The highest strength centrality values were observed for sit-to-stand (0.679), EQ-5D Pain/Discomfort (0.666), and mental health (0.526), with the knee pain node ranking 5th of 11 (0.418; Figure 5). The case-dropping bootstrap CS-coefficient was 0.36 for strength (acceptable stability), and 0.00 and 0.05 for closeness and betweenness, respectively.

Two direct edges connected the knee pain node to the predictor set: a positive edge with EQ-5D Pain/Discomfort (partial correlation=0.260) and a positive edge with house estate (0.158). The remaining nine network edges represented conditional dependencies among the predictors after controlling for all others. The prespecified Spearman rank correlation between SHAP importance and network strength centrality across the 10 feature nodes was ρ=0.018 (*P*=.97), indicating no monotonic association between the two paradigms (Figure 5).

The decomposition of each variable's contribution into direct and indirect pathways (Figure 5D) showed a clear binary pattern. EQ-5D Pain/Discomfort and house estate carried their contributions entirely through direct conditional dependencies, with edge magnitudes (0.260 and 0.158) larger than their corresponding mean absolute SHAP values (0.064 and 0.034). The remaining eight predictors had no direct edge to knee pain after regularization (Figure 5), indicating that their contributions to the model output were accounted for by their conditional dependencies with other variables in the network. This pattern of two variables with direct dependencies and eight contributing only through indirect pathways is consistent with the multidimensional structure described by the *ICF* framework.

RenderX

Figure 5. Partial-correlation network, centrality, paradigm concordance, and pathway decomposition. (A) Pooled network structure, (B) node centrality with bootstrap stability, (C) linkage between SHAP importance and network strength centrality, (D) direct versus indirect pathways to knee pain, and (E) interconnectivity matrix. CS: correlation-stability; EBICglasso: graphical LASSO with extended Bayesian information criterion regularization; GKF: gait knee flexion; HE: house estate; *ICF*: *International Classification of Functioning, Disability and Health*; KP: knee pain; LASSO: Least Absolute Shrinkage and Selection Operator; MH: mental health; ML: machine learning; PD: EQ-5D-5L Pain/Discomfort dimension; SHAP: SHapley Additive exPlanations; SIT: sitting timea; SLP: sleep disorders; STS: sit-to-stand; WPA: walking physical activity; QoL: quality of life.

Sensitivity Analysis

Excluding EQ-5D Pain/Discomfort (n=20 variables; EPV=15.7) preserved the qualitative pattern of findings (Table S4 in Multimedia Appendix 1, Figures S1 and S2 in Multimedia Appendix 1). The pooled best AUC was 0.724 for SVM (ΔAUC =+0.001 vs main analysis; Figure S1 in Multimedia Appendix

XSL•FO
RenderX

1). The top SHAP feature shifted from EQ-5D Pain/Discomfort to EQ-5D Utility, but the next-ranked variables (house estate, walking physical activity, and BMI) remained the same (Figure S2 in Multimedia Appendix 1). House estate retained a direct conditional dependency with knee pain (partial correlation=0.20). The Spearman correlation between SHAP importance and network strength remained close to zero (ρ=−0.10; *P*=.78), and the CS-coefficient for strength was 0.44. The principal findings, including the modest discrimination performance, the predominance of indirect pathways from physical performance and mental health variables to knee pain, and the divergence between SHAP and network rankings, did not depend on inclusion of EQ-5D Pain/Discomfort.

Discussion

Principal Findings

This study examined self-reported knee pain in 852 community-dwelling older adults in Hong Kong using ML and partial-correlation network analysis. Based on the *ICF* model, knee pain in older age is associated with body function and structure, activity, participation, environmental, and personal factors [6,9,34]. These findings support this multidimensional view. Across the 21 predictors covering seven *ICF* domains, no single variable was dominant, and the model output reflected a distributed contribution from the health-related quality of life, environmental, physical performance, physical activity, mental health, and sleep domains. These results agree with the biopsychosocial view of knee pain in older adults [35], and with the projected rise of knee osteoarthritis to 595 million prevalent cases globally by 2050 [4,36]. Combining SHAP and network analysis allowed the assessment of which variables relate to knee pain and how those variables relate to one another.

The six classification algorithms showed similar discrimination, with pooled AUC ranging from 0.692 to 0.723. LR (AUC 0.721, 95% CI, 0.691–.751) was within 0.002 of RF and 0.001 of SVM, and showed the lowest Brier score (0.200) among the six algorithms. These results agree with prior reports that ML did not outperform LR in clinical prediction studies [37], and with recent recommendations that adequate sample size and prespecified variable selection, rather than algorithmic complexity, are the main determinants of stable AI-based prediction [38]. The discrimination level (best AUC 0.723) was comparable with prior ML models for knee pain or knee osteoarthritis in older adults, in which reported AUCs ranged from 0.70 to 0.80 [39-41]. With mild class imbalance (36.9% vs 63.1%), algorithmic resampling can degrade calibration without improving discrimination [42]; imbalance-aware metrics (AUC, F_1-score, MCC, and Brier score) were therefore used [43]. The convergence of LR and ML performance suggests that, when EPV is 14.95 and the predictor set is conceptually prespecified, the benefit of more flexible algorithms over a regularized LR is small in cross-sectional knee pain classification.

SHAP-based importance and PDPs showed the model-implied association of each variable with the predicted probability of knee pain. The three highest-ranked features were EQ-5D Pain/Discomfort (mean |SHAP|=0.064), EQ-5D Utility (0.038), and house estate (0.034). The remaining features clustered at lower magnitudes (mean |SHAP| range, 0.013 - 0.019) and included variables from the physical activity, sociodemographic, smartphone-based physical performance, mental health, and sleep domains. The SHAP-derived directions of association agreed with the baseline comparisons: lower walking-related physical activity and sit-to-stand repetitions, higher BMI and sitting time, lower mental health scores, and a higher count of sleep disorder categories were each associated with an increased predicted probability of knee pain. These patterns agree with prior reports linking reduced gait speed and lower-extremity capacity to musculoskeletal pain in older adults [44], and with the bidirectional association between sleep disturbance and chronic musculoskeletal pain [45]. Because PDPs show model-implied marginal associations rather than causal effects, the inflection points described below are reported as hypothesis-generating and require prospective validation. The predicted probability of knee pain rose sharply between EQ-5D Pain/Discomfort scores of 1 and 2 (0.31 to 0.43) and declined above an EQ-5D Utility of 0.85, while for the modifiable variables it declined steeply with walking physical activity up to 3000 MET·minutes/week, with sit-to-stand performance up to 15 repetitions, and rose above a BMI of 22 kg/m² and above a sitting time of 150 minutes/day. These patterns are consistent with prior reports linking sedentary behavior, low physical activity, higher BMI, and reduced lower-extremity capacity to musculoskeletal pain in older adults, but the exact values should not be treated as clinical cutoffs.

Network analysis showed how variables relate to one another after adjusting for the rest of the network. In the pooled 11-node network, only two predictors had direct edges with the knee pain node after EBICglasso regularization: EQ-5D Pain/Discomfort (partial correlation=0.260) and house estate (0.158). The remaining nine edges were among predictors. The Spearman correlation between SHAP importance and network strength centrality across the 10 feature nodes was ρ=0.018, indicating that the two analyses ranked variables differently and captured distinct facets of the multidimensional structure. Sit-to-stand showed this difference clearly. Although its marginal SHAP magnitude was modest (mean |SHAP|=0.0168; rank 7 of 21) and no direct edge to knee pain survived regularization, sit-to-stand showed the highest strength centrality (0.679). Sit-to-stand therefore acted as a central physical performance hub whose conditional dependencies extended across multiple *ICF* domains, including body structure and function (BMI, partial correlation = −0.146; age, −0.260), mental and cognitive function (mental health, +0.128), and activity (walking physical activity, +0.150). This pattern is consistent with the role of the sit-to-stand test as an integrative measure of lower-extremity power, balance, and global physical capacity in older adults [46,47]. Sit-to-stand therefore appears not as a direct correlate of knee pain, but as a multidimensional hub that links body function, body structure, activity, and mental health variables, which agrees with the biopsychosocial pathways described in the *ICF* model [15,48,49]. The direct edge between house estate and knee pain reflects rental estate residency as an indicator of lower socioeconomic position in Hong Kong, and is consistent with the well-documented inverse association between socioeconomic status and chronic pain [50], and with

XSL•FO
RenderX

reports that public rental housing in Hong Kong is associated with poorer health-related behaviors and chronic disease outcomes [51]. Beyond reflecting socioeconomic position, the housing categories in this cohort were defined primarily by income level rather than by physical or care-related features, so the mechanisms underlying the association with knee pain remain uncertain and warrant further study. The direct edge between EQ-5D Pain/Discomfort and knee pain partly reflects conceptual overlap, as both capture self-reported pain; however, the two are distinct constructs (general pain or discomfort versus knee-specific pain), and a sensitivity analysis excluding EQ-5D Pain/Discomfort preserved the qualitative pattern of findings, indicating that our conclusions do not depend on this predictor.

Several implications for clinical practice and future research are noted. First, the multidimensional pattern across *ICF* domains supports multidisciplinary, biopsychosocial assessment for older adults with knee pain, rather than the use of isolated impairment-based measures [34,35]. Second, the central network position of sit-to-stand, despite its weak direct association with knee pain, indicates that this measure was conditionally connected to body structure, mental health, and activity domains within the observed cross-sectional network, in which sit-to-stand was simultaneously connected to BMI and age, mental health, and walking physical activity. Sit-to-stand performance was therefore associated with multiple *ICF* domains in this network, a pattern that would be missed by considering its marginal SHAP rank alone and that prospective studies should test directly. This relationship is consistent with reports linking sit-to-stand power to functional outcomes in advanced knee osteoarthritis [26], and with the general role of sit-to-stand as a functional vital sign in geriatric assessment [46]. Third, the smartphone-based digital health system used in this study, validated for walking speed (r=0.975), knee flexion (r=0.907 - 0.923), and test-retest reliability (intraclass correlation coefficient=0.86 - 0.94) [16], provides a feasible method for measuring *ICF* body function and activity domain variables in community settings. Because these inferences are hypothesis-generating, independent external validation in separate cohorts is a necessary next step before any clinical implementation, alongside prospective longitudinal studies.

This study had several limitations. First, the cross-sectional design did not allow causal inference; the direct and indirect pathways describe conditional dependencies and model-implied associations, not mechanistic effects. Second, knee pain was measured by a single self-report item covering the preceding 3 months and did not distinguish etiology (osteoarthritis, rheumatoid arthritis, meniscal injury, or referred pain), severity, or laterality; medical diagnoses and medication use for knee pain (such as oral or topical nonsteroidal anti-inflammatory drugs, duloxetine, or intra-articular injections) were not ascertained and could not be included in the modeling. These omissions limit the clinical interpretability of the outcome and may contribute to the modest discrimination observed. Third, participants were recruited from eleven Hong Kong Housing Society estates by convenience sampling and were predominantly female (77.5%); generalizability to other regions, ethnicities, sex distributions, and socioeconomic strata is therefore limited. Fourth, no external validation was performed; nested 5×5 cross-validation provided unbiased internal estimates but not external transportability. Fifth, strength centrality showed acceptable bootstrap stability (CS-coefficient=0.36), but closeness and betweenness were unstable; these two measures were therefore not interpreted further. Sixth, the interpretive tools have inherent limits: PDPs show model-implied marginal associations, not clinical thresholds; SHAP values are model-dependent and may split importance among correlated predictors; and centrality metrics, especially closeness and betweenness, can be unstable in modest cross-sectional networks, which is why strength was pre-specified as the primary measure. Finally, the smartphone-based assessment used a research-prototype application that is not commercially available, and broader translation will require additional regulatory and engineering work. Future prospective and longitudinal studies with larger and more diverse cohorts, severity-graded outcomes, and independent external validation are required to test the hypotheses generated by this work.

Conclusions

This study combined ML and partial-correlation network analysis to examine self-reported knee pain in community-dwelling older adults within the *ICF* framework. The six classification algorithms showed pooled AUC values ranging from 0.692 to 0.723, indicating modest discrimination across the predictor set. Network analysis showed that only EQ-5D Pain/Discomfort and house estate had direct edges with knee pain, while sit-to-stand acted as a central hub linking body function, body structure, mental health, and activity variables. These cross-sectional, hypothesis-generating findings may inform multidisciplinary biopsychosocial assessment, but not causal or intervention conclusions, pending prospective external validation.

Acknowledgments

We would like to thank all participants in our study for their active participation and cooperation.

Abstract

Background: Poststroke cognitive impairment (PSCI) is a common and disabling complication after stroke; however, early screening remains challenging due to limited access to neuropsychological testing and the high cost of neuroimaging. Portable, tablet-based eye-tracking technology may offer a scalable, low-cost solution for early PSCI detection.

Objective: This study aimed to evaluate the clinical utility of a tablet-based, AI-driven eye-tracking system for early screening of PSCI at 3 months after acute ischemic stroke. We sought to quantify oculomotor-cognitive associations and develop a practical nomogram for individualized risk prediction.

Methods: We prospectively enrolled 142 hospitalized patients with acute cerebral infarction between May 2023 and October 2024, of whom 122 completed the 3-month follow-up and were included in the final analysis, along with 20 healthy community-dwelling controls. All patients underwent tablet-based eye tracking (visual paired comparison and antisaccade tasks) during the acute phase, as well as baseline and 3-month neuropsychological assessments. PSCI was defined using validated cutoffs. Multivariable logistic regression was used to identify independent predictors, and a nomogram was constructed. Internal validation was performed using bootstrap resampling (1000 samples).

Results: At 3 months, out of 122 patients, 47 (38.5%) met PSCI criteria. Compared with patients with non-PSCI (n=75), patients with PSCI showed significantly prolonged correct saccade latency (median 322.96, IQR 209.45-445.59 ms vs 194.55, IQR 141.50-299.75 ms; Z=−4.03, P<.001), increased uncorrected error rate (median 30.00%, IQR 15.00%-42.00% vs 5.00%, IQR 0.00%-28.00%; Z=−4.24, P<.001), and reduced novelty preference ratio (median 1.44, IQR 0.97-1.70 vs 2.12, IQR 1.27-4.56; Z=−3.44, P=.001). Multivariable analysis identified 4 independent predictors of 3-month PSCI: older age (odds ratio [OR] 1.067 per year, 95% CI 1.009 - 1.129; P=.02), lower education level (OR 0.841 per year, 95% CI 0.708 - 0.999; P=.049), higher NIHSS (National Institutes of Health Stroke Scale) scores (OR 1.557 per point, 95% CI 1.075 - 2.256; P=.02), and prolonged correct saccade latency (OR 1.004 per ms, 95% CI 1.000 - 1.007; P=.04). A nomogram incorporating these 4 factors achieved good discriminative performance (area under the receiver operating characteristic curve 0.86, 95% CI 0.793 - 0.927) with satisfactory calibration.

Conclusions: Age, education, admission NIHSS, and correct saccade latency were identified as possible independent predictors of 3-month PSCI in this cohort. The tablet-based eye-tracking system, when combined with clinical variables, may represent a feasible approach for early PSCI screening. A nomogram based on these variables demonstrated high accuracy and potential clinical utility for early PSCI identification. This approach may facilitate early identification of high-risk patients and enable timely, personalized interventions in resource-limited settings.

Introduction

Globally, stroke ranks as the second leading cause of mortality and frequently induces lifelong disabilities, including motor, cognitive, linguistic, and psychological impairments [1]. Among these sequelae, poststroke cognitive impairment (PSCI) constitutes a prevalent and debilitating neurological complication. PSCI is clinically defined as a syndrome fulfilling diagnostic criteria for cognitive impairment manifesting within 6 months post stroke. Formal neuropsychological assessment at 3 to 6 months post stroke is typically required for diagnosis [2]. This condition manifests clinically as deficits in memory, language comprehension, perceptual processing, visuospatial reasoning, and executive functioning [3]. Despite advances in acute stroke management, PSCI persists as a highly prevalent and debilitating condition [4], associated with elevated 5-year mortality and depression risks [5], thereby substantially contributing to long-term disability and reduced quality of life [6].

Early identification and management of PSCI represent critical clinical priorities [7]. Conventional tools such as the Mini-Mental State Examination (MMSE) and Montreal Cognitive Assessment (MoCA) exhibit limitations, including susceptibility to age, education, and emotional confounders, alongside significant time and resource requirements [8]. In recent years, mobile health (mHealth) technologies have shown great potential in enhancing the accessibility and scalability of medical assessments [9-11]. The integration of eye tracking into portable tablet devices allows for standardized, low-cost cognitive screening outside traditional clinical settings [12,13]. This approach aligns with growing emphasis on digital biomarkers and decentralized health care models, particularly in neurology and rehabilitation [14].

AI technology has gained substantial research interest owing to its objectivity and efficiency. AI-enhanced eye tracking quantitatively records ocular movements and gaze positions temporally and across task conditions. For target image projection and maintenance on the retinal fovea, coordinated eye movements are essential, assessed through saccadic, smooth pursuit, fixation, and visual search tasks [15]. As a noninvasive technique, eye tracking can identify cognitive impairment, monitor disease progression, and elucidate underlying cognitive processes [16]. Evidence suggests visual processing deficits may precede memory impairment in mild cognitive impairment (MCI), manifesting in altered eye movement patterns [17,18]. Patients with MCI frequently demonstrate elevated saccadic error rates, prolonged latency, and inverse correlations between erroneous saccade frequency and neuropsychological test performance [19]. In smooth pursuit tasks, patients with Alzheimer disease (AD) exhibit increased pursuit latency, reduced acceleration and gain, and frequent compensatory saccades correlating with cognitive decline [20].

These oculomotor abnormalities are not random; they directly reflect the functional state of the underlying neural circuits [21]. Precision eye tracking enables real-time parameter quantification, facilitating objective cognitive assessment [22]. Thus, AI-enhanced eye tracking captures millisecond-level ocular dynamics, offering an objective, quantifiable methodology for cognitive impairment evaluation.

Building on this evidence, researchers have recently extended eye tracking to stroke populations. Recent studies have applied eye tracking in stroke populations for various purposes, including augmenting stroke diagnosis [23], recognizing stroke through free viewing of faces [24], assessing the impact of poststroke fatigue on saccadic control [25], and evaluating memory-guided saccades in patients with subacute and chronic stroke [26]. These works confirm the feasibility of eye tracking in stroke-related conditions; however, none address early cognitive impairment. Regarding PSCI prediction, Zhou et al [27] built a nomogram using clinical and inflammatory markers. However, that model did not include oculomotor biomarkers. More recently, Chen et al [28] applied AI-assisted eye tracking with gait measurements to detect cognitive impairment in cerebral small vessel disease, directly supporting the utility of AI-driven oculomotor assessment in cerebrovascular disorders. A systematic review has further confirmed the diagnostic potential of eye tracking for AD and MCI, strengthening the rationale for applying oculomotor paradigms to cognitive screening [29]. Similarly, Maldonado-Díaz et al [30] used eye tracking to assess visual attention during virtual reality balance training in older adults with mild to moderate cognitive impairment, further illustrating the applicability of oculomotor measures across different cognitive impairment severities.

Despite these advances, no study has yet integrated a tablet-based, AI-enhanced eye-tracking system into a practical nomogram specifically for early PSCI screening. This gap motivated this study.

This study uses a noninvasive eye-tracking technology developed by Neuro Weave Ltd, which utilizes standard smartphone or tablet cameras to track subtle dynamic eye movements. By performing visual paired comparisons (VPCs) and antisaccade tasks on a tablet device, the assessment can be completed within minutes, significantly reducing time and labor compared to traditional paper-based scales. A study using this technology in patients with AD demonstrated a sensitivity of 82% and specificity of 91%, indicating high discriminative ability and low misdiagnosis risk in screening for AD [12]. Similarly, using the same tablet-based AI-driven eye-tracking technology, Wei et al [13] validated its performance in a large community-based cohort in China, achieving an area under the receiver operating characteristic curve (AUC) of 0.80 for detecting cognitive impairment and a high negative predictive value (87.2%), supporting its feasibility for population-level screening in resource-limited settings.

In summary, early warning and risk identification for PSCI are crucial. This study aims to explore the clinical utility of AI-based eye-tracking technology implemented on a tablet platform for screening early PSCI. By analyzing the relationship between eye movement characteristics and cognitive function in patients with stroke, we seek to develop and validate an AI eye-tracking model for early PSCI screening. The study hopes to provide an economical, convenient, and objective auxiliary diagnostic tool for early PSCI detection, thereby supporting clinical intervention

and rehabilitation strategies to improve long-term prognosis and quality of life for patients with stroke.

Methods

Participants

We prospectively recruited 142 patients with acute cerebral infarction who were admitted to the Department of Neurology at the Second Hospital of Hebei Medical University between May 2023 and October 2024. Of these, 122 completed the 3-month follow-up assessments and were included in the final analysis, along with 20 healthy community-dwelling controls. Inclusion criteria for patients with stroke were as follows: (1) age 18 to 80 years; (2) within 14 days after symptom onset; (3) fulfilling the American Heart Association/American Stroke Association diagnostic criteria for stroke [31]; (4) capacity to undergo neuropsychological testing, physical examination, and brain magnetic resonance imaging (MRI); (5) corrected visual acuity sufficient for testing; and (6) provision of informed consent. Exclusion criteria included the following: (1) significant aphasia; (2) pregnancy, active malignancy, major organ failure, or life expectancy less than 1 year; (3) prestroke dementia or neurodegenerative disorders (eg, Lewy body dementia, AD, or secondary dementias); (4) Informant Questionnaire on Cognitive Decline in the Elderly score ≥4; and (5) congenital intellectual disability or severe neuropsychiatric conditions. Control participants were recruited using the following criteria: (1) age 18 to 80 years, (2) capacity to undergo neuropsychological testing, (3) corrected visual acuity sufficient for testing, and (4) provision of informed consent. Exclusion criteria included the following: (1) history of cognitive disorders, congenital intellectual disability, or other severe neuropsychiatric comorbidities; (2) history of stroke; or (3) current cognitive impairment defined as below-threshold scores on either MMSE or MoCA. Potentially eligible participants were identified based on admission records and clinical diagnosis. A purposive sampling strategy was used.

Ethical Considerations

This study was approved by the Research Ethics Committee of the Second Hospital of Hebei Medical University (reference number 2023-C023) on March 31, 2023. All procedures followed the Declaration of Helsinki. Before enrollment, the researchers explained the study objectives in detail to the participants and their legal guardians, and written informed consent was obtained from the participants themselves or their guardians. All participants were informed that they could withdraw from the study at any time without penalty. Participant data were anonymized and deidentified before analysis; no personal identifiers are reported. No compensation was provided to participants for their involvement in this study.

Neuropsychological Assessment

All participants completed cognitive and mood assessments, including the MMSE, MoCA, Self-Rating Anxiety Scale, and Self-Rating Depression Scale. Patients with stroke underwent repeated assessments at 3 months post stroke. PSCI diagnosis required meeting either criterion: MMSE score <17 (illiterate), <20 (1‐6 y education), or <24 (≥7 y education) or MoCA score <22 (validated cutoff demonstrating optimal sensitivity/specificity) [32,33]. Patients were stratified into PSCI and non-PSCI (NPSCI) subgroups based on 3-month cognitive performance. All assessments were administered by neurologists certified in standardized neuropsychological testing protocols. The neurologists who administered the 3-month neuropsychological assessments were blinded to the patients' baseline eye-tracking results and the initial clinical assessments.

Eye-Tracking Technology Task

Eye-tracking data were acquired during the acute phase of cerebral infarction using a Xiaomi Pad 5 Pro 12.4 Android tablet (12.4-inch display, 2560×1600 resolution, 60 Hz refresh rate) with a front-facing camera capable of recording 1080p video at 30 frames per second, running a proprietary research software developed by Shanghai Neuroweave Technology Co, Ltd, for Android 8.0+ devices. This software is a research tool rather than a commercial retail product. Its validity for cognitive screening has been demonstrated in previous studies [12,13]. The system initiated recording upon task start, transmitting videos to Alibaba Cloud for processing via an AI eye-tracking model that integrated computer vision and deep learning architectures for facial landmark detection, head pose estimation, pupil tracking, and gaze vector calculation. Demographic data were input preassessment via user interface, followed by head pose calibration requiring participants to position within an on-screen virtual frame to standardize distance and minimize motion artifacts. The 6-minute protocol comprised (1) pretask calibration optimizing device-specific tracking, (2) VPC phase 1: five 5-second image sets for memorization, (3) antisaccade task (~3 min): central fixation with rapid gaze shifts to contralateral space upon peripheral red dot appearance, and (4) VPC phase 2: ten 6-second sets (1 familiar/1 novel image per set) where participants viewed novel stimuli while camera-recorded videos underwent cloud-based processing to extract quantitative eye movement-related parameters. After processing the video, a series of eye movement–related parameters were established, as shown in Table 1. An example diagram of the eye-tracking task is shown in Figure 1.

Table . Oculomotor parameters quantified during eye-tracking assessment.

Parameter	Definition	Unit/formula
Antisaccade task		
Latency	Time delay for saccade initiation after target onset	ms
Correct saccade latency	Latency of the first directionally accurate saccade	ms
Error rate	Percentage of initial saccades with incorrect direction	%
Peak velocity (horizontal)	Maximum horizontal velocity during saccades	Pixels/ms
Correction latency	Delay in generating corrective saccades after erroneous initial saccades	ms
Uncorrected error rate	Percentage of trials where corrective saccades remained directionally inaccurate	%
Corrected saccade latency	Latency of the first accurate saccade post correction	ms
Presaccadic fixation count	Number of fixation events before target onset	Count
Postsaccadic fixation count	Number of fixation events after target onset	Count
Fixation stability	Number of fixation clusters prior to target appearance	Count
Blinks during fixation	Fixation events contaminated by blinks	Count
Initial saccadic gain	Horizontal displacement amplitude of the first saccade	Pixels
Terminal saccadic gain ratio	Ratio of horizontal distance: Δ (first saccade end point → initial fixation)/Ref (final presaccade fixation → target)	Δ/Ref (unitless)
VPC[a] task		
Novelty preference ratio	Dwell time ratio (novel image/familiar image)	Ratio (unitless)
Total fixation duration	Summed duration of all fixation events	ms
Fixation events with blinks	Fixation epochs interrupted by blinks	Count

[a]VPC: visual paired comparisons.

XSL•FO
RenderX

Figure 1. The visual paired comparisons (VPC) and antisaccade task.

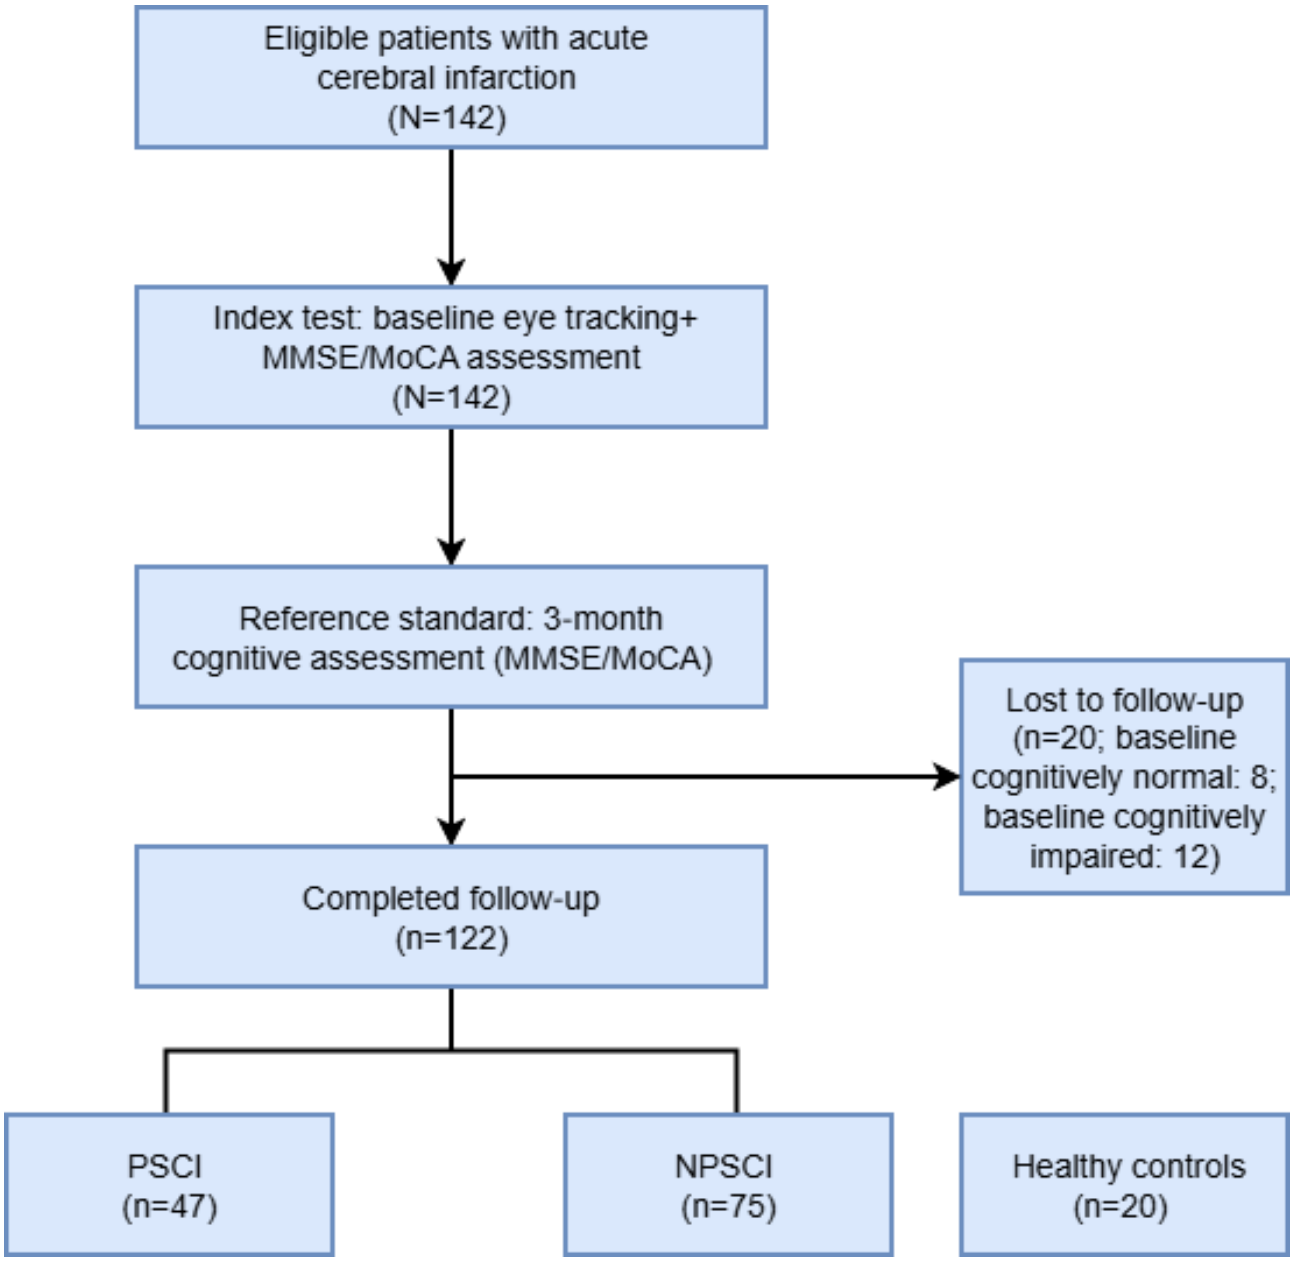
All tests were conducted in an inpatient setting, in a dedicated examination room to ensure a quiet and controlled environment. No other patients were present during testing. Patients remained seated during the test. The tablet was mounted on a stand and placed on a desk at a comfortable viewing distance. A single investigator who had undergone standardized protocol training administered the test. Before the test started, the investigator used a pre-prepared script to explain the procedure to the patient. Once the test began, the software provided voice guidance (on-screen text and narration) to instruct the patient through each step.

Head pose calibration required the patient to align their face within an on-screen virtual frame. The adjustment process typically took about 3 seconds; once the patient's head was correctly positioned, calibration was completed immediately. If the initial alignment failed, the investigator gently reminded the patient to stay still, and the patient readjusted within another few seconds. This process did not cause noticeable fatigue, even in patients with hand tremors. The complete testing procedure (including calibration, VPC, and antisaccade tasks) took approximately 6 minutes per participant, which was well tolerated.

Statistical Analysis

As the index test comprised multiple continuous oculomotor parameters, no single test positivity cutoff was predefined. Instead, a multivariable logistic regression model was constructed to combine these metrics with clinical variables for PSCI risk prediction. The model's performance was evaluated using AUC, sensitivity, and specificity at the optimal probability threshold derived from the receiver operating characteristic curve. All statistical analyses were performed using IBM SPSS 27.0 and R software (v4.2.2; R Foundation for Statistical Computing). The sample size was determined based on feasibility (all eligible patients enrolled during the study period); no formal sample size calculation was performed. Continuous variables with normal distribution were expressed as mean (SD) and compared using independent *t* tests or one-way ANOVA. Nonnormally distributed continuous variables were reported as median (IQR) and analyzed using Kruskal-Wallis *H* tests or Mann-Whitney *U* tests. Categorical variables were described as frequencies (%) and compared via chi-square tests or Fisher exact tests. Variables with $P<.05$ in univariate logistic regression analyses for PSCI were incorporated into multivariate binary logistic regression using stepwise selection to construct a PSCI risk prediction model. Model performance was validated internally. Statistical significance was defined as $P<.05$. Missing data on the 3-month follow-up were handled by complete case analysis; only patients with complete data were included in the final analysis.

Results



General Clinical Data Analysis of the Patients

This study enrolled 142 patients with acute cerebral infarction who met the inclusion/exclusion criteria, all of whom underwent baseline neuropsychological assessments during hospitalization. Of these, 122 completed 3-month follow-up evaluations, comprising the study cohort. PSCI developed in 47 patients (38.5% incidence), with 75 classified as NPSCI (Figure 2; see Checklist 1). Compared to patients with NPSCI, the PSCI group had a significantly higher proportion of females (18/47, 38% vs 14/75, 19%; $\chi^2_1=5.76$, $P=.02$), older age (mean 64.23, SD 8.95 vs mean 56.68, SD 10.42; $t_{120}=-4.11$, $P<.001$), lower education level (6.00, IQR 6.00 - 9.00 vs 9.00, IQR 6.00 - 12.00; $Z=-3.68$, $P<.001$), and elevated admission neurological severity scores (NIHSS [National Institutes of Health Stroke Scale]=3.00, IQR 2.00 - 6.00 vs 2.00, IQR

Analysis of Eye-Tracking Metrics

Analysis of eye-tracking metrics revealed that patients with PSCI exhibited markedly prolonged saccadic processing, demonstrating significantly higher saccade latency (Z=−4.77, P<.001), correct saccade latency (Z=−4.03, P<.001), uncorrected error rate (Z=−4.24, P<.001), and corrected saccade latency (Z=−4.62, P<.001) compared to NPSCI controls. Conversely, the PSCI group showed significantly reduced oculomotor efficiency, characterized by lower peak horizontal velocity (Z=−2.01, P=.04), diminished postsaccadic fixation count (Z=−2.20, P=.03), impaired terminal saccadic gain ratio (Z=−2.97, P=.003), and decreased novelty preference ratio (Z=−3.44, P=.001). However, fundamental visuomotor integration remained intact between groups, with no significant differences in error rate, correction latency, presaccadic fixation count, fixation stability, blinks during fixation, initial saccadic gain, total fixation duration, or VPC fixation events with blinks (all P>.05; Figure 3; see Multimedia Appendix 1 for exact P values). These findings suggest that executive-attentional deficits in PSCI selectively disrupt higher-order saccadic control and novelty processing, while preserving basic oculomotor functions.

Comparative Analysis of Demographic and Eye-Tracking Metrics Between Healthy Controls and NPSCI Groups

To investigate whether oculomotor performance in patients with NPSCI aligns with neurologically intact individuals, we compared quantitative eye-tracking metrics between 20 age-matched healthy control (HC) and the NPSCI cohort. Comprehensive analysis demonstrated no statistically significant differences in any eye-tracking parameters (all $P>.05$; Figure 3; see Multimedia Appendix 2 for exact P values), including saccade latency, novelty preference ratio, and fixation stability metrics, confirming that oculomotor function in patients with NPSCI remains within normative ranges despite cerebrovascular pathology. These findings suggest preserved visuomotor network integrity in patients living with stroke without cognitive impairment.

Logistic Regression Analysis of Eye-Tracking Metrics in Patients With PSCI

Binary logistic regression analysis identified significant predictors of PSCI, with demographic factors including sex (male vs female, with female as the reference; OR 0.370, 95% CI 0.162 - 0.845; $P=.02$), advanced age (OR 1.084, 95% CI 1.038 - 1.132 per year; $P<.001$), and lower education level (OR 0.801, 95% CI 0.710 - 0.904 per year; $P<.001$), alongside clinical indicators of higher admission NIHSS (OR 1.463, 95% CI 1.202 - 1.781 per point; $P<.001$) and elevated mRS scores (OR 1.701, 95% CI 1.220 - 2.373 per point; $P=.002$). Critically, oculomotor metrics independently predicted PSCI risk: prolonged saccade latency (OR 1.005, 95% CI 1.003 - 1.007 per ms; $P<.001$), increased correct saccade latency (OR 1.004, 95% CI 1.002 - 1.006 per ms; $P=.001$), elevated uncorrected error rate (OR 1.043, 95% CI 1.021 - 1.066 per %; $P<.001$), extended corrected saccade latency (OR 1.005, 95% CI 1.003 - 1.007 per ms; $P<.001$), reduced postsaccadic fixation count (OR 0.949, 95% CI 0.903 - 0.998 per count; $P=.04$), and diminished novelty preference ratio (OR 0.686, 95% CI 0.532 - 0.884 per unit; $P=.004$). These findings demonstrate that oculomotor dysfunction significantly contributes to PSCI pathogenesis beyond traditional clinical factors (complete models in Table 3).

Table . Univariate logistic regression analysis.

Variable	*B* (SE)	Wald	*P* value	OR[a] (95% CI)
Sex (male vs female)[b]	−0.995 (0.422)	5.565	.02	0.370 (0.162-0.845)

[c]NIHSS: National Institutes of Health Stroke Scale.

[d]mRS: Modified Rankin Scale.

Multivariate logistic regression analysis was performed after excluding variables with variance inflation factors greater than 5 to mitigate multicollinearity, retaining significant predictors from univariate screening. The final validated model demonstrated that advanced age (OR 1.067, 95% CI 1.009 - 1.129 per year; $P=.02$), lower education level (OR 0.841, 95% CI 0.708 - 0.999 per year; $P=.049$), higher NIHSS scores (OR 1.557, 95% CI 1.075 - 2.256 per point; $P=.02$), and prolonged correct saccade latency (OR 1.004, 95% CI 1.000 - 1.007 per ms; $P=.04$) independently predicted PSCI development. Clinically, each 1-year age increase elevates PSCI risk by 6.7% (OR 1.067), while each additional education year reduces risk by 15.9% ($1/0.841\approx1.189$). A 1-point NIHSS increase confers 55.7% higher PSCI probability, and critically, every 100-ms increase in correct saccade latency nearly doubles PSCI likelihood (OR 1.49, 95% CI 1.00 - 2.22, calculated as 1.004^{100}). These results establish eye-tracking metrics as novel predictors complementing traditional stroke severity indices (complete models in Table 4).

Development of a Multivariable Predictive Model for PSCI Incorporating a Risk Nomogram

Based on the multivariate logistic regression analysis, advanced age, lower education level, higher NIHSS scores, and prolonged correct saccade latency were identified as independent predictors of PSCI in patients with acute ischemic stroke. These factors were integrated into a clinically actionable point-based nomogram (Figure 4) for individualized PSCI risk estimation at 3 months post stroke. The nomogram operates through three sequential steps: (1) variable scoring: assign points for each predictor (age, education, NIHSS, and latency) using the top axis scale. (2) Total points calculation: sum all individual scores to determine aggregate risk points. (3) Probability conversion: map total points to the bottom probability axis, directly indicating PSCI likelihood. For example, a 70-year-old (50 points) with 6 years of education (35 points), NIHSS=4 (23 points), and correct saccade latency=500 ms (35 points) would have 143 total points, corresponding to 70% PSCI probability. This visual tool enables rapid risk stratification at bedside without computational tools, demonstrating how oculomotor metrics enhance traditional clinical prediction.

Validation of the PSCI Risk Nomogram: Discriminatory Accuracy and Calibration Performance

The discriminative ability of the PSCI risk prediction model was evaluated using the concordance index (C-index), which is mathematically equivalent to the AUC. The model achieved a C-index of 0.860 (95% CI 0.793 - 0.927, sensitivity=93.3%, and specificity=66.0%; Figure 5A). Internal validation with 1000 bootstrap resamples yielded a calibrated C-index of 0.860. Both values significantly exceeded the reference threshold of 0.75, indicating robust discriminative performance (Figure 5B).

Figure 5. Performance and validation of the nomogram model. (A) The model achieved a concordance index (C-index) of 0.860 (95% CI 0.793 - 0.927). (B) Internal validation with 1000 bootstrap resamples yielded a calibrated C-index of 0.860. (C) Calibration was assessed via a calibration plot comprising 3 characteristic curves: the apparent curve representing raw model predictions, the bias-corrected curve reflecting bias-adjusted predictions, and the ideal curve denoting perfect prediction; both the raw and bias-corrected curves demonstrated close alignment with the ideal trajectory, confirming satisfactory model calibration. (D) Calibration curve with internal validation. AUC: area under the receiver operating characteristic curve.

Calibration was assessed via a calibration plot comprising 3 characteristic curves: the apparent curve representing raw model predictions, the bias-corrected curve reflecting bias-adjusted predictions, and the ideal curve denoting perfect prediction. Both the raw and bias-corrected curves demonstrated close alignment with the ideal trajectory, confirming satisfactory model calibration (Figure 5C). The apparent performance line, bias-corrected performance line, and ideal line also show close alignment during internal model validation using bootstrap resampling (Figure 5D).

Comparative Analysis of Neuroimaging Metrics in PSCI vs NPSCI Cohorts

The analysis of admission brain MRI scans revealed a significantly higher prevalence of frontal lobe infarcts (16/47, 34% vs 11/75, 15%; χ^2_1=6.29, *P*=.01), temporal lobe involvement (13/47, 28% vs 6/75, 8%; χ^2_1=8.49, *P*=.004), larger infarct volumes (χ^2_2=11.27, *P*=.004), and more severe white matter hyperintensities (WMHs; Fazekas grade ≥2: 22/47, 47% vs 15/75, 20%; χ^2_2=10.00, *P*=.007) in patients with PSCI vs NPSCI (Table 5). No significant intergroup differences (*P*>.05) were observed in anterior/posterior circulation distribution or moderate-to-severe large vessel stenosis/occlusion (see Table 5 for exact *P* values). These findings implicate frontal-temporal lesions and white matter disruption as neuroanatomical substrates for PSCI.

Quantitative Correlation Analysis Between WMHs and Eye-Tracking Parameters

These stratified analyses were exploratory and not prespecified. Stratified by Fazekas grades on admission brain MRI, the 122 patients with cerebral infarction were categorized into grade 0 (n=41), grade I (n=44), and grade≥II (n=37) cohorts. Significant intergroup differences emerged in terminal saccadic gain ratio (H=6.35, P=.04) and novelty preference ratio (H=11.78, P=.003), while other oculomotor metrics showed no statistical significance (all P>.05; see Multimedia Appendix 3 for exact P values). Post hoc analyses revealed that for terminal saccadic gain ratio, grade≥II demonstrated a 33% reduction vs grade 0 (0.27, IQR 0.17-0.49 vs 0.40 IQR 0.33-0.51; Z=19.94, P=.04; Figure 6A), but no differences between grade≥II vs I (Z=13.20, P=.28) or grade I vs 0 (Z=6.74, P>.99). For novelty preference ratio, grade≥II showed 39% and 18% reductions vs grade 0 (1.43, IQR 1.00-1.63 vs 2.33, IQR 1.27-4.71; Z=25.57, P=.004; Figure 6B) and grade I (1.43, IQR 1.00-1.63 vs 1.74, IQR 1.28-3.76; Z=21.88, P=.02), respectively, with no grade 0-I difference (Z=3.69, P>.99). This dose-dependent impairment pattern indicates that severe WMHs (Fazekas≥II) selectively disrupt visuospatial calibration and novelty detection, implicating compromised comprehension and executive function and significant memory decline.

XSL•FO
RenderX

Figure 6. Stratified comparative analysis of eye-tracking metrics by white matter hyperintensity (WMH) severity and infarct volume strata. (A) Comparison of terminal saccadic gain ratio across different WMH severity grades. (B) Comparison of novelty preference ratio across WMH severity grades. (C) Comparison of uncorrected error rate across stroke infarct volume strata.

Quantitative Correlation Analysis Between Infarct Volumes and Eye-Tracking Parameters

These stratified analyses were exploratory and not prespecified. Stratified by cerebral infarct volume on admission MRI, the 122 patients were categorized into lacunar infarction (<1.5 cm, n=83), small infarction (1.5 - 3 cm, n=21), and large infarction (>3 cm, n=18) cohorts. Statistical analysis revealed significant intergroup differences exclusively in uncorrected saccadic error rate (H=6.22, P=.045; Figure 6C), while other oculomotor metrics showed no significance (all P>.05; see Multimedia Appendix 4 for exact P values). Post hoc comparisons demonstrated patients with large infarction exhibited 18.0% higher uncorrected error rates vs lacunar infarction (28.00, IQR 15.00-44.00 vs 10.00, IQR 0.00-32.00; Z=−22.21, P=.04), but there were no significant differences between large vs small infarction (Z=−13.90, P=.65) or small vs lacunar infarction (Z=−8.30, P>.99). The dose-dependent trend (large>small>lacunar) further suggests that infarct volume thresholds may dictate cognitive-motor integration failure.

Discussion

Principal Findings

PSCI represents a prevalent disabling sequela of stroke, characterized by an insidious onset that frequently delays diagnosis until 3 to 6 months post event. This diagnostic window highlights the urgent need for early detection tools, as untreated PSCI leads to irreversible cognitive decline, severely impacting quality of life and imposing substantial health care system burdens [34]. Current diagnostic limitations such as neuroimaging costs, psychometric scale inaccuracies in patients with aphasic/hemiparetic, and delayed assessment prompted our development of an accessible eye-tracking predictive model.

Among 122 patients with acute ischemic stroke, we observed a 3-month PSCI incidence of 38.5% (47/122), consistent with established epidemiological data [35]. Multivariable regression analysis identified key independent predictors of PSCI: demographic factors, including female sex, advanced age, and lower education level; clinical indicators of higher admission NIHSS score and elevated mRS score; and the oculomotor biomarker of prolonged correct saccade latency. Significantly, eye-tracking biomarkers differentiated PSCI from patients with NPSCI, demonstrating increased saccade latencies and error rates alongside decreased peak velocity, terminal saccadic gain, and novelty preference ratio, while patients with NPSCI exhibited normative oculomotor profiles indistinguishable from HCs. This specificity supports the validity of our integrated nomogram as a rapid, cost-effective tool for acute-phase PSCI risk stratification, facilitating timely interventions during the period of peak neuroplasticity.

Prediction Model for PSCI Combining AI Eye Tracking and Clinical Demographics

Advanced age and lower educational attainment represent nonmodifiable risk factors for PSCI, consistent with established epidemiological evidence [36,37]. A multicenter cross-sectional study demonstrated escalating PSCI incidence with age, demonstrating 1.887-fold elevated risk in patients ≥75 years compared to younger cohorts [1]. Furthermore, PSCI prevalence exhibits a socioeconomic gradient, disproportionately affecting individuals with lower education and income. The neurobiological mechanisms of education-cognition relationships are explained by 2 conceptual frameworks: the cognitive reserve hypothesis posits that advanced education enhances neural resilience against age-related decline, while the compensatory plasticity model suggests that higher education enables functional reorganization through preserved cognitive domains compensating for impaired functions [38].

NIHSS and mRS scores, which are validated measures of stroke severity, constitute robust predictors of long-term functional outcomes. Higher scores correlate with increased disability and

XSL•FO
RenderX

mortality and, specifically, predict the development of PSCI (adjusted OR 1.56 per NIHSS point increase in our cohort) [39]. Pathophysiologically, elevated NIHSS scores reflect more extensive neuroanatomical damage, heightening vulnerability to cognitive domain impairment.

Although female patients showed higher PSCI prevalence in our cohort (18/47, 38% vs 14/75, 19% in NPSCI), it was not an independent predictor in multivariate modeling. This observation aligns with reports of poorer poststroke functional outcomes in women, including greater activity limitations, reduced quality of life, and higher depression rates [40,41]. Notably, while PSCI incidence is compared between sexes, cognitive phenotypes differ: female patients demonstrate predominant deficits in attention, executive function, and language domains, while male patients display greater impairment in verbal memory [40]. Screening tool performance also varies by sex, with MMSE showing higher sensitivity but lower specificity for PSCI detection in women and MoCA exhibiting sex-dependent psychometric properties. These findings necessitate sex-stratified interpretation of cognitive screening instruments to reduce diagnostic inaccuracies.

Strong neuroanatomical connections exist between higher-order cognition and core oculomotor systems. Abstract cognitive tasks engage oculomotor circuits in primates, as manifested through cognitively modulated microsaccades [42]. Observed disparities in eye-tracking metrics between PSCI and NPSCI cohorts reflect multidimensional cognitive dysfunction encompassing attentional control, memory consolidation, and executive processing. Within the antisaccade paradigm, saccadic latency, the interval between stimulus onset and saccade initiation, reflects premotor decision-making processes. Primate neurophysiological studies confirm that saccade programming activates decision-related neurons in frontal eye fields and superior colliculi, wherein saccadic accuracy correlates with neuronal discharge patterns in oculomotor-integration zones [43-45]. Parameters, including latency, amplitude, peak velocity, and positional error, provide quantifiable proxies for decision accuracy and temporal processing [45].

Compared to prosaccades, antisaccades require heightened attentional and executive resources. This task recruits the dorsolateral prefrontal cortex, anterior cingulate cortex, supplementary eye field, and parietal eye field, with increased frontal activation correlating with enhanced antisaccade performance [28]. In our cohort, prolonged saccadic latency in patients with PSCI indicates impaired executive-attentional network function, consistent with frontoparietal dysfunction delaying stimulus-response integration [12,46,47]. Crucially, corrected saccade latency, requiring directional error correction, was identified as an independent PSCI predictor, indicating sensitivity to disrupted feedback monitoring in prefrontal-basal ganglia circuits [48,49]. During the VPC task, reduced novelty preference ratio in patients with PSCI indicated hippocampal-dependent memory impairment. Patients with NPSCI exhibited preserved familiarity discrimination, whereas patients with PSCI allocated equivalent dwell times to novel and familiar images, suggesting declarative memory consolidation failure. Notably, patients with NPSCI demonstrated normative eye-tracking profiles indistinguishable from HCs, confirming stroke-specific cognitive pathology rather than global oculomotor disruption. These oculomotor signatures provide direct windows into disrupted cortical-subcortical circuitry in PSCI.

Current evidence supports the diagnostic utility of eye tracking across neurodegenerative disorders: AD (AUC=0.91) [12], Parkinson dementia, and schizophrenia. Our integrated PSCI prediction model demonstrated comparable discriminative capacity (AUC=0.86, sensitivity=93.3%, and specificity=66.0%). Independent predictors included advanced age, lower education, higher NIHSS scores, and prolonged correct saccade latency, establishing this framework as a rapid biomarker-based stratification tool.

Correlations Between Neuroimaging Markers and Quantitative Eye-Tracking Metrics

These behavioral patterns implicate underlying neural substrates, which were validated through structural neuroimaging analyses. Neuroimaging analysis confirmed significant associations between PSCI and frontal/temporal lobe infarcts, larger infarct volumes, and severe WMH (Fazekas grade ≥ II). Frontal lesions disrupt attention-executive networks [50], while temporal infarcts impair hippocampal memory consolidation and language processing [35,51]. Moderate-to-severe WMH are established risk factors for PSCI [52,53], likely through the disruption of neuronal networks subserving cognitive reserve. Notably, left anterior thalamic radiation WMH specifically correlates with attention/executive dysfunction, whereas occipital callosal radiation lesions predominantly affect processing speed [54]. Larger infarct volumes predict greater cognitive vulnerability through extensive neocortical involvement. Thus, infarction location/size and WMH severity collectively contribute to cognitive decline.

These oculomotor biomarkers reflect underlying neuroimaging pathology. Significant oculomotor correlates were identified: WMH severity is inversely associated with terminal saccadic gain and novelty preference ratios, while infarct volume is positively correlated with uncorrected saccadic error rates (significantly higher in large vs lacunar infarcts). Mechanistically, reduced terminal gain indicates visuospatial-executive impairment; diminished novelty preference reflects declarative memory deficits; and elevated uncorrected errors signify attentional monitoring dysfunction [45]. These findings establish oculomotor metrics as structural pathology surrogates. Reduced terminal gain/novelty preference indicates severe WMH, while elevated uncorrected errors associate with large infarct volume. For patients contraindicated for neuroimaging, eye tracking provides a clinically feasible alternative for domain-specific cognitive assessment.

Implementing accessible methodologies for early cognitive impairment prediction is paramount in stroke care. Eye-tracking technology offers distinct clinical advantages by integrating audiovisual task instructions, including on-screen text, subtitles, and voice-over narration, to ensure accessibility across varying levels of literacy and physical ability. By relying on gaze-based responses, the method eliminates the need for verbal or manual interaction, making it particularly suitable for patients with aphasia or dominant-hand paresis. As a mobile screening tool,

XSL•FO
RenderX

it enables efficient cognitive phenotyping through quantitative oculomotor biomarkers, delivering actionable clinical insights promptly.

Furthermore, integrated within mHealth platforms, tablet-based eye tracking supports scalable, low-cost screening beyond traditional clinical settings. This approach facilitates real-time data acquisition and seamless telehealth integration, promoting equitable access to follow-up care—especially for individuals in remote or underserved regions. Beyond accelerating clinical decision-making, this mHealth-enabled paradigm allows decentralized longitudinal monitoring of disease progression and treatment response, including remotely administered home assessments.

This study pioneers the multidisciplinary integration of eye-tracking analytics with clinical demographics to develop a predictive model for PSCI. We established neurobiological correlations between oculomotor signatures and structural neuroimaging markers, thereby expanding the repertoire of neurobehavioral biomarkers while offering a cost-effective framework for stratifying post-stroke cognitive risk.

Limitations

Several limitations of this study should be acknowledged. First, the sample size was relatively modest (122 patients with complete follow-up, along with 20 HCs) and derived from a single center, which may limit statistical power and generalizability of the findings. Future multicenter studies with larger cohorts are needed to validate and refine our predictive model. Second, the follow-up period was limited to 3 months, which may not capture later-onset cognitive decline or the long-term trajectory of PSCI. Extended follow-up (eg, 6 or 12 mo) would provide a more comprehensive understanding of the evolution of cognitive impairment and the stability of eye-tracking biomarkers. Third, as an observational diagnostic study with a relatively small sample size, our findings should be considered exploratory rather than confirmatory. Prospective randomized controlled trials with adequate sample size and appropriate blinding are required to further validate the diagnostic sensitivity and specificity of this tablet-based eye-tracking tool, particularly if it is to be considered as a software-as-a-medical-device for regulatory or clinical registration purposes. Fourth, the oculomotor battery was restricted to VPC and antisaccade tasks. Although these tasks are well-established for assessing executive function and memory, incorporating additional paradigms such as smooth pursuit, free viewing, or memory-guided saccades could offer a more complete assessment of the spectrum of cognitive deficits in PSCI. Fifth, our study focused exclusively on acute cerebral infarction; therefore, the findings may not directly generalize to other stroke subtypes (eg, hemorrhagic stroke) or to diverse ethnic and demographic populations. Validation across different stroke types and settings is warranted. Sixth, while we correlated eye-tracking metrics with WMH severity and infarct volume, we did not integrate more advanced neuroimaging biomarkers (eg, diffusion tensor imaging or resting-state functional MRI). Future studies linking oculomotor impairments to structural and functional connectivity measures would further strengthen the neurobiological basis of our findings. Seventh, the study employed a purposive (nonprobability) sampling strategy, which may introduce selection bias and limit the representativeness of the sample. Eighth, there was heterogeneity in acute stroke treatments among participants (eg, intravenous thrombolysis and endovascular thrombectomy), which could influence cognitive outcomes; although we adjusted for baseline NIHSS and mRS scores, residual confounding cannot be excluded.

Conclusions

Age, educational level, admission NIHSS score, and correct saccade latency were identified as independent predictors of 3-month PSCI and were incorporated into a nomogram model. The model demonstrated robust performance, achieving high predictive accuracy (AUC=0.86), strong discriminative capacity, and clinically useful interpretability. This tool demonstrates potential for early identification of patients with high-risk PSCI, thereby enabling timely and personalized interventions. Its integration into standard clinical pathways—particularly through mHealth platforms—may significantly enhance strategic decision-making and improve long-term outcomes for vulnerable populations.

Acknowledgments

The authors sincerely thank Shanghai Neuroweave Technology Co, Ltd, for the provision of eye-tracking instrumentation and Huashan Hospital, Fudan University, for institutional support of this investigation. The authors declare the use of generative AI (GAI) in the research and writing process. According to the GAIDeT taxonomy (2025), the following tasks were delegated to GAI tools under full human supervision: proofreading and editing. The GAI tool used was DeepSeek-V3.2. Abstract

Background: Colorectal cancer (CRC) incidence and mortality rates continue to be elevated even though effective screening methods are widely available. To increase CRC screening in primary care practices, our team developed a tablet-based digital health program (mPATH) designed to identify patients needing CRC screening, provide education, and empower patients to request a screening test via the program.

Objective: This study aimed to qualitatively assess facilitators of and barriers to implementing and maintaining mPATH in primary care clinics.

Methods: In a pragmatic implementation trial, clinics were randomized to receive only in-person training and technological support via phone or email (low touch) or added levels of support, such as at-elbow support during launch, regular check-ins, memos, and reports (high touch). After implementation and data collection were concluded, we conducted telephone interviews with health care providers, clinic managers, and front desk and nursing staff recruited from 8 primary care clinics of varying sizes and with varying degrees of implementation of mPATH. The interviews were designed to collect perceived facilitators of and barriers to using mPATH. All interviews were administered via telephone by a single project staff member with no prior contact with participants. Interviews were audio-recorded, and 2 study team members independently coded each interview transcript and developed a codebook to identify meaningful categories in the dataset. The coders met periodically to resolve discrepancies. Data within each category were abstracted and synthesized into themes. Themes were determined inductively by prevalence and salience in the data per the principles of thematic analysis.

Results: A total of 33 interviews were completed between September 2021 and April 2023 with health care providers (n=8, 24.2%), clinic managers (n=9, 27.3%), nursing staff (n=8, 24.2%), and front desk staff (n=8, 24.2%). Interviews averaged 26.7 (SD 4.9) minutes. Barriers and facilitators identified varied among clinic sites and by clinic role. Overall, the primary factors supporting the implementation of mPATH were health care provider and staff buy-in, perceived potential time savings, and workflow improvement. The primary barriers identified were perceived lack of need for the program and technical issues. There was no significant indication that clinic size or randomization to low- or high-touch training and support played a role in the decision to continue or stop using the program.

XSL•FO
RenderX

Conclusions: Implementation of a tablet-based CRC screening tool in primary care practices is feasible with health care provider and staff buy-in and validation of potential time savings and workflow improvements but may be limited by perceived lack of need for the program and technical issues.

Introduction

Colorectal cancer (CRC) is the third most common cancer diagnosed among men (15.1/100,000) and women (10.7/100,000) in the United States, and it is the second leading cause of cancer-related death [1,2]. In 2025, an estimated 154,000 Americans will be diagnosed with CRC, and more than 52,000 will die from CRC [1]. The US Preventive Services Task Force recommends that average-risk adults be screened for CRC starting at the age of 45 years using any of several efficacious tests [3]. Unfortunately, although CRC screening rates have increased in recent decades, they remain relatively low [4] at approximately 70% and fall below the goal of 80% in every community promoted by the American Cancer Society National Colorectal Cancer Roundtable [5].

Multilevel barriers contribute to low CRC screening rates. Some patients are unaware of screening methods, and those aware of stool-based screening may be reluctant to provide stool samples [6,7]. For colonoscopy, patients report difficulty completing the preparation and may have other barriers such as cost, the need to take time off work, and arranging for transportation [8]. Decision aids have been developed and tested for prostate cancer, lung cancer, and CRC screening to assist health care providers and patients in identifying suitable screening methods [9-12], but primary care clinicians report that they lack the time needed for shared decision-making [13-16].

With the goal of creating a decision aid that addresses the patient, health care provider, and system barriers to CRC screening and requires minimal time from health care providers to implement, our group developed and tested a tablet-based app (mPATH) that identifies patients overdue for CRC screening, provides education, and allows them to request a screening test via the program. In a prior randomized controlled trial conducted in community-based primary care practices, mPATH doubled the proportion of patients who completed CRC screening [17].

To determine the optimal strategy for implementing the app in routine care, we then conducted a pragmatic cluster randomized type III hybrid implementation-effectiveness trial in 18 community-based primary care practices to evaluate a “low-touch” vs “high-touch” bundle of implementation strategies [18]. Low-touch clinics received an on-site training session on use of the app and access to ongoing technical support. High-touch clinics received the same support plus at-elbow support on the day the program was launched in the clinic, as well as periodic coaching calls throughout the 6-month implementation period and regular audit and feedback reports on program use. We observed initial moderate use of the program, which decreased over time with no difference by implementation strategy [19-21]. We also observed variation in use of the program across practices and staff. To identify and better understand the factors that led to higher or lower use of the program, we conducted in-depth interviews with clinicians and staff who participated in the trial.

Methods

Overview of the mPATH Program

On the basis of formative research with clinical staff and health care providers [18], the mPATH app was divided into 2 separate tablet programs: mPATH-CheckIn and mPATH-CRC. mPATH-CheckIn was provided to patients by front desk staff at check-in to be completed in the waiting room. mPATH-CheckIn included the health system’s mandated screening items for depression, fall risk, and intimate partner violence. An application programming interface connection to the electronic health record (EHR) imported CRC screening history. For age-eligible patients with no record of current CRC screening, mPATH-CheckIn asked additional questions to determine whether screening had been completed outside the health system and whether the patient had risk factors that would change screening recommendations. Those patients indicated as eligible or due for screening on mPATH-CheckIn were then provided with a separate tablet (mPATH-CRC) by nursing staff when they transitioned from the waiting room to an examination room, which displayed a screening decision aid video and closed by allowing patients to request a screening test, either a fecal immunochemical test or a colonoscopy. mPATH-CRC then immediately sent an EHR in-basket message to the health care provider, alerting them that the patient had used the program and summarizing the outcome. When the health care provider arrived in the examination room, a pop-up alert let the provider order the requested CRC screening test with minimal clicks.

Recruitment

We intentionally selected 8 primary care clinics from the 18 enrolled in the randomized trial described previously [20], varying by practice size, participant group, and degree of mPATH adoption, with the aim to conduct interviews with a representative sample of the primary care clinics in our randomized trial. Our sample included 3 small (1-3 health care providers) and 5 large (>3 health care providers) clinics. The sample included clinics that continued use of mPATH throughout the 6-month implementation period and those that discontinued use. Characteristics of the 8 clinics selected for interviews are shown in Table 1.

Table 1. Clinic characteristics.

Clinic	Size	High or low touch	Number of clinical personnel	Used mPATH for 12 months	Discontinued mPATH use before 12 months
A	Large	High	26	✓	
B	Small	High	8	✓	
C	Large	High	23	✓	
D	Large	High	14		✓
E	Small	Low	12	✓	
F	Large	Low	16		✓
G	Large	Low	16		✓
H	Small	Low	12		✓

Interview Development

Semistructured interview guides were developed by the investigators and pretested to ensure clarity. Separate interview guides were developed for (1) front desk or administrative staff and (2) clinical personnel or practice managers. Because the front desk and administrative staff did not interact with the mPATH-CRC program, their interviews only asked about mPATH-CheckIn, whereas the clinical personnel and practice manager interviews included questions about both mPATH-CheckIn and mPATH-CRC. The interview guides were designed to collect descriptive data on the interviewee and explore the following constructs: (1) overall assessment of the effectiveness of mPATH-CheckIn for screening for depression, fall risk, and home safety and effectiveness of mPATH-CRC for CRC screening; (2) perceived barriers and facilitators as related to mPATH and clinic flow; (3) impact of mPATH on screening and clinic operations; (4) resources or training that were provided to the practice to support implementation; (5) program champion and leadership functioning; and (6) scale-up and dissemination. Because the trial took place during the COVID-19 pandemic, all interviewees were also asked how COVID-19 affected the implementation of mPATH.

Data Collection, Management, and Analyses

Study personnel identified potential interviewees in collaboration with each practice's clinic champion, a clinical staff member who served as the primary contact and was responsible for promoting mPATH internally and encouraging its adoption. Because we had previously conducted extensive usability testing of the app with patients, this study focused on health care providers and clinic staff [18]. To avoid influencing the randomized trial results, interviews were conducted after 1 year of implementation data collection was completed or after they stopped using the program, if earlier. All interviews were conducted via telephone by a single independent project staff member with no prior contact with participants. Interviews were audio-recorded, transcribed, deidentified, and reviewed. Transcripts were imported into ATLAS.ti (Scientific Software Development GmbH) to store and manage the data. Two study team members (AR and MC) inductively developed a codebook to identify meaningful categories in the dataset. Each transcript was independently coded by the 2 study team members, who met periodically to resolve discrepancies and revise the codebook as needed. Response saturation was identified when interview responses were repetitive rather than providing new information. The interview data were analyzed, and differences among participant groups (health care providers, nursing staff, clinic managers, and front desk staff) were labeled. Data within each category were abstracted and synthesized into themes. Themes were determined inductively by their prevalence and salience in the data per the principles of thematic analysis.

Ethical Considerations

The Wake Forest University School of Medicine Institutional Review Board approved this study with a waiver of signed informed consent (IRB00048919). This study was also approved by the University of Kentucky Office of Research Integrity under a reliance agreement. Participants were provided with a study information sheet at the time of interview scheduling describing the purpose of the study and their rights to participate; risks and benefits and financial disclosures were declared. Participants provided verbal consent at the beginning of the interview to proceed and have their responses recorded. Interviews were conducted in private offices for confidentiality, and any participant or staff identifiers that were used in the interview discussion were removed from the transcripts. All interviewees were offered a US $50 gift card as compensation for their time.

Results

Overview

A total of 33 interviews were completed between September 2021 and April 2023 with health care providers (n=8, 24.2%), clinic managers (n=9, 27.3%), nursing staff (n=8, 24.2%), and front desk staff (n=8, 24.2%). Interviews averaged 25 minutes in length. Study staff identified the most prevalent facilitators of and barriers to mPATH implementation according to the methods described above. While some implementation facilitators and barriers were common to both mPATH-CheckIn and mPATH-CRC, there was some divergence of opinions on the 2, as described below.

Implementation Facilitators

Staff and Health Care Provider Buy-In

Staff buy-in was identified as a significant factor in the success of mPATH implementation. Clinic staff were initially hesitant about implementing a new program and new workflows to

XSL•FO
RenderX

accommodate mPATH, but this concern was alleviated with experience using the program:

> *I think that the biggest challenge would be, people worried about their workflow, and doctors are like everybody else. They do a lot of things just because that's the way they do it. Implementing anything new maybe makes everyone a little nervous, but I think in general, everybody felt the way I did, that it didn't disrupt workflows any significant way, so it was probably scary at the beginning, and didn't prove to be much trouble, and once you do a new thing for a little while, you are okay.* [Clinic A; health care provider]

> *I think the number one most important factor was the—for lack of a better term—buy-in by the docs and the staff. Initially, folks were very enthusiastic about it.* [Clinic D; health care provider]

Buy-in from front desk staff was noted as important in mPATH-CheckIn because they were responsible for cleaning, storing, charging, and distributing mPATH-CheckIn tablets; instructing patients on use; answering patient questions; and preparing the tablets for each patient. Health care provider buy-in was also very important for the implementation of mPATH-CRC as they felt responsible for CRC screening in their eligible patients. Nursing staff bridged both mPATH-CheckIn and mPATH-CRC implementation workflows, and buy-in from them was important for smooth implementation and transition between both apps. mPATH-CheckIn had the most impact on nursing staff because it improved their workflow by conducting the required check-in screening, which, in turn, increased their buy-in to the program.

Training and Support

Interviewees found the in-clinic training sessions to be effective, especially the "hands-on" aspect of being able to test the tablets:

> *Yes, when we got trained on it, it was, basically, real-time training, and so she [mPATH research team staff member] would come in and help us on a day when we had patients. She walked through one patient with us, and just be there, step by step.* [Clinic E; management]

Leadership Support and Champion

Before implementation, each clinic identified a champion to lead implementation efforts. The practice manager or clinical coordinator was often identified as the champion. Staff recognized the importance of the clinic champion role and felt that mPATH implementation was well supported at the clinic leadership level.

Efficiency, Workflow, and Time Savings

Interviewees agreed that mPATH-CheckIn was a significant time saver and improved workflow during patient check-in and rooming, as patients answered questions directly into the tablet and answers were transferred from the tablet directly into the EHR:

> *Oh, 'cause it saves so much time between them already answering them, and they just pull it over into our system. Versus me going through each question myself and having to put those answers in. I just pull it over in there, and I didn't have to go into any of those questions and open it up and ask.* [Clinic G; nurse]

Interviewees agreed that mPATH-CheckIn standardized and automated the assessment process and allowed more patients to be screened for depression, fall risk, and household violence than with previous workflows:

> *I do feel like it's made the screening part much easier and faster, and we've been able to screen more patients...Typically, we wouldn't get the chance to ask the questions just because of time and things like that. Typically, now they just do it in the waiting room when they're checking in. I feel like a large majority of our patients are getting screened now.* [Clinic E; health care provider]

Patient Openness

Patient openness was noted by a significant number of interviewees as an important benefit of mPATH-CheckIn, specifically regarding depression questions. Staff perceived that asking depression questions on the tablet instead of verbally helped patients be more open and forthcoming with their answers. On the basis of interview responses, more patients with depression symptoms were identified through the tablet-based depression questionnaire than through previous procedures:

> *I think it actually helps the patient sometimes. It's easier for them just to answer the question on the [tablet] rather than verbalize it 'cause sometimes they're embarrassed to verbalize it to someone in-person. I think it's easier for them just to answer it on the [tablet].* [Clinic C; nurse]

Patient Knowledge

Interviewees overall felt that the mPATH-CRC module with its educational video improved patient knowledge of CRC screening and the screening options available. It helped clarify the importance of screening, generate questions, and open the discussion when the health care provider entered the examination room:

> *I think that the content behind...[mPATH-CRC]...of giving our patients a visual, kind of audio/video on education with colon cancer screening, why they should be screened, and how they can do that is really helpful because I do that education with my patients, but some people learn better in a different manner, so that gives them a more visual or auditory way to learn. Then, they have, of course, the opportunity to ask more questions.* [Clinic F; health care provider]

Potential Impact on CRC Screening

Interviewees expressed that they believed that mPATH-CRC helped increase CRC screening or at least had the potential to increase screening:

XSL•FO
RenderX

> *I think the people that were on the fence of doing any type of screening, I think it did help do some screening. I think before our people said, nope, I'm not doing that—and I think after the mPATH, more people were open toward it.* [Clinic C; health care provider]

Implementation Barriers

Analysis of the interviews also identified barriers to implementing mPATH in the clinics.

COVID-19 Pandemic–Related Barriers

Interviewees acknowledged that there were intervals of time when they did not use mPATH due to the pandemic or that there were protocols for disinfecting the mPATH tablets that slowed implementation:

> *...some of the patients, especially with COVID, would complain that they didn't want to touch it (the tablet), so for a while, we could not use it at all, but now that we've added it back, some patients like it, and some patients absolutely refuse to do it.* [Clinic A; management]

However, not all clinics reported being affected by the pandemic:

> *I don't think it affected it a whole lot. We sterilize our live stuff anyway. The only extra thing was more sterilization, but COVID really didn't affect it a lot. We don't really give the iPad to sick patients. None of those sick visits get the iPads, so it really didn't affect it as much. Now, of course, patient volume was down during COVID, so we didn't use it as often but other than that.* [Clinic C; management]

Technical Issues and EHR Limitations

Although, overall, interviews indicated that mPATH-CheckIn improved workflow, several interviewees (clinics B and G) voiced concerns about occasional data transmission errors between mPATH-CheckIn and the EHR:

> *There seemed to be an intermittent problem with the Medicare wellness visit when we used the mPATH for check-in. It would pull in some erroneous values. We weren't able to figure out if that was part of mPATH or something else...* [Clinic G; health care provider]

Typically, when an issue arose where data were missing, staff would revert to their previous workflow of asking patients the mPATH-CheckIn questions verbally and then manually entering the data into the EHR.

There was also a perception that mPATH failed to recognize patients who received CRC screening outside the health system. Two clinics (A and F) with high numbers of patients who received screening outside the health system reported issues with mPATH-CRC properly identifying patients' CRC screening status:

> *...almost all of our people are screened with outside of [University] system, and mPATH can't see it. mPATH almost always tells me my patient hasn't had a screen, and I just have to look anyway and see that they have, and then I have to make sure that it's documented in a way that's acceptable to our system, but being on the periphery like this, I don't think mPATH stops me from basically having to do that same process and look. It always tells me they don't have it, and most of them do. If our patients were getting it through a [University] gastroenterologist and it was in our [EHR], I think that would be different, but it doesn't seem to identify the ones of ours that are done in community clinics, outside of our network.* [Clinic A; health care provider]

This added to staff burden as the health care provider or nurse had to double-check or verify the screening status of each patient before giving the patient the mPATH-CRC tablet.

Lack of Need or Demand for the Program

Specific to mPATH-CRC, while interviewees were generally positive about the potential of the program to improve patient knowledge and potentially help increase screening rates, most reported that they infrequently used mPATH-CRC, primarily due to patient eligibility factors. Clinics reported that many of their patients were outside of screening age or were up-to-date with CRC screening due to a colonoscopy within the previous 10 years.

Efficiency, Workflow, and Time Barriers

There were some barriers noted that impacted workflow, specifically the transition between the mPATH-CheckIn and mPATH-CRC apps. As patients were given mPATH-CheckIn in the waiting room and then mPATH-CRC after they were taken back to an examination room, any delays at the front end of the workflow had the potential to carry over to the back end. This particularly occurred with patients with limited technical skills who required more time with the tablets:

> *I feel like, for our patients that were more technologically inclined, it, in some cases, was able to help facilitate that data gathering more quickly. For other patients that were less technologically inclined, we found that often they hadn't made it through or had only partially made it through the questionnaire. Then the MAs [medical assistants] would go back in and redo the process.* [Clinic G; health care provider]

For mPATH-CRC specifically, several clinics said that the 5-minute screening decision aid video was too long and had a negative impact on workflow, especially health care provider workflow:

> *Because I personally liked that they can watch the video, but some of our providers do not like it, because it obviously delays them going into the room a little bit. That's the main hiccup that we've had is just the providers have to wait however many minutes. I don't remember how many minutes the video is, but they haven't wanted to do that.* [Clinic A; nurse]

XSL•FO
RenderX

Overall Recommendation for mPATH

Health care providers and staff from 4 clinics reported that they were still using mPATH at the time of their interviews, whereas 1 clinic reported continuing use of mPATH-CheckIn only. Interviewees from 3 clinics reported that they had discontinued use of the program at the time of their interviews. However, those who had discontinued the program reported that they liked it and would have continued using it if it were up to them individually. The decision to discontinue the program was often made by other clinic leadership who were not interviewed or was a group decision among health care providers and staff as a whole. All interviewees were positive about recommending that other clinics at least try mPATH to determine whether it was a good fit for them.

Discussion

Principal Findings

We found that the opinions of the clinical staff and health care providers about implementing the tablet-based screening program were impacted by staff buy-in, how well the program was incorporated into existing workflows, and the additional value it delivered. Concern related to technical issues was the main barrier described by interviewees. Those interviewed considered mPATH-CheckIn to be beneficial as a time saver and as a means to streamline and improve efficiency in the patient data collection process at check-in by providing an easy-to-use technology for increasing their quality metrics for depression, fall risk, and household violence and abuse. These factors seemed to serve as motivators for clinics to use mPATH, especially the clinical staff.

While the clinic staff interviewed expressed appreciation for the concept of mPATH-CRC "in theory," it was challenging to implement due to a variety of factors. Health care providers were most opinionated about mPATH-CRC compared to nursing staff, perhaps due to health care providers expressing their feelings of "ownership" and "responsibility" for ensuring that their patients were up-to-date with CRC screening. The nursing staff interviewed had a very limited or peripheral role in the CRC screening process—primarily reviewing patient screening history and notifying health care providers if the patient was due for screening. The health care providers interviewed seemed more resistant to changing their current workflows to accommodate mPATH-CRC and often indicated that "they do what mPATH-CRC does anyway," seeing it as a duplication or add-on to their existing preferred process. Another major factor in implementing mPATH-CRC was the belief that most patients were already up-to-date with CRC screening and did not need mPATH-CRC. Finally, mPATH-CheckIn was intended to be used with every patient aged >18 years, and mPATH-CRC was intended to be used just with those patients aged >50 years who were due for screening, reflecting screening guidelines in place at the start of the study. The need to differentiate patients by age may have impacted clinics' comfort level with the mPATH-CRC program as it was not routinely used for all adult patients.

Our findings are consistent with those of other trials that have reported difficulty implementing digital health interventions in primary care environments. In a hybrid implementation-effectiveness study of a digital health program to support patients with substance use disorders in federally qualified health centers, the program was offered to fewer than 10% of eligible patients [22]. Mei and Vaez [23] implemented electronic screening for substance use and mental health in a community-based university health system–affiliated primary care practice; although screening completion increased, the absolute improvement was modest at 9%. Similarly, Yakovchenko et al [24] implemented an automatic SMS text messaging program to help with hepatitis C virus medication adherence in Veterans Health Administration primary care clinics, with fewer than 20% of approached patients progressing to active use of the system.

Despite being conducted in markedly different health system contexts (federally qualified health centers, the US Department of Veterans Affairs health system, and a university-affiliated primary care practice), all 3 studies reported similar barriers to implementation, including workflow disruptions, technical challenges, and increased clinician burden. Each study also identified perceived time savings, leadership support, and staff engagement as important facilitators of adoption. Consistent with these findings, published literature reviews have repeatedly identified workflow integration as one of the strongest determinants of digital health implementation, with tools perceived to save time more likely to be adopted and those perceived to add burden less likely to be used [12,25-27].

Our study extends this literature by highlighting the importance of routinization. Participants specifically mentioned that the mPATH-CRC program was less likely to be used because it was only administered to age-eligible patients who needed screening. In contrast, the mPATH-CheckIn program was seen as easier to administer because it was designed to be used with every patient at every visit. In addition, because our study was conducted during the COVID-19 pandemic, our findings yielded unique insights into how public health concerns can affect implementation. Approximately half of the interviewees reported that patients were concerned about germs and touching the tablets. Although clinics used antibacterial tablet cases and implemented cleaning protocols that were communicated to patients, these reassurances were not always adequate to allay concerns. In addition, pandemic-related workflows, such as restricted tablet distribution to patients who were well, limited implementation in some clinics.

Limitations

The program was implemented in clinics all within the same health system and the same EHR system, which may have impacted opinions, perceptions, and technical issues regarding connectivity and integration. While we sought candid interview responses by ensuring confidentiality and using an external interviewer, social desirability bias may have affected responses. The fact that the study was conducted in the same health system to which the research team is affiliated may have also impacted responses. As stated previously, we conducted interviews after all quantitative implementation outcome data were collected, which was 1 year after program launch. This time delay may have impacted respondents' memories and perceptions of the

XSL•FO
RenderX

initial training and implementation activities. Finally, because we previously found that the program had excellent patient usability [13,15], and as staff were responsible for administering the program, we did not include patients in our interviews. Patient-level factors not identified by clinical staff may have affected implementation.

Conclusions

When implementing tablet-based digital health programs in primary care clinics, demonstrating the programs' ability to improve care, fit into usual workflows, and ideally save time is critical. Providing hands-on training before or at the start of implementation and identifying a suitable clinic champion can help increase buy-in and comfort with the program. For decision aids related to cancer or other health screenings, the demand for the program should be weighed against potential barriers to ensure that the program can be implemented and sustained effectively. Review of potential implementation facilitators and barriers can help maximize the uptake of digital health programs and enhance continued use.

Acknowledgments

This study was funded by the US Department of Health and Human Services, National Cancer Institute (R01CA218416), and Wake Forest University School of Medicine Comprehensive Cancer Center (P30CA012197). No generative artificial intelligence was used in any portion of the manuscript.

Data Availability

Data sharing is not applicable to this paper as no datasets other than transcripts were generated or analyzed during this study.

Authors' Contributions

MC and AR developed the interview guide and conducted the interviews, conducted complete analysis of the data, and were major contributors in writing the manuscript. KLF and EW contributed to the interview and were major contributors in writing the manuscript. MBD and AD contributed to the interview guide and to writing the manuscript. ACS contributed to writing the manuscript. DPM contributed to the interview guides and was a major contributor in writing the manuscript. All authors read and approved the final manuscript.

Conflicts of Interest

DPM and AD are coinventors of mPATH. DPM, AD, and Wake Forest University Health Sciences have an ownership interest in the mPATH app. Neither DPM nor AD participated in data collection or analysis. KLF and MD report grants from the National Cancer Institute (NCI) during the conduct of this study. ACS reports grants from the National Institutes of Health and the NCI during the conduct of this study and grants and personal fees from Shattuck Labs outside the submitted work. AD reports grants from the NCI during the conduct of this study. DPM reports grants from the NCI during the conduct of this study. All other authors declare no other conflicts of interest.

Abstract

Background: Patients with Parkinson disease (PD) along with subjective cognitive decline (PD-SCD) are considered an intermediate status between those with normal cognition (PD-NC) and those with mild cognitive impairment (PD-MCI). Wearable digital monitoring technologies and machine learning models offer significant potential for assessing cognitive impairment in patients with PD.

Objective: We aimed to evaluate the utility of wearable technology and machine learning for identifying ordinal cognitive stages (OCS) in PD based on timed up and go (TUG) tests (including single-task TUG [TUGst] and dual-task TUG [TUGdt]).

Methods: Patients with PD along with SCD, MCI, and NC were recruited in a movement disorder clinic. Patients performed TUGst and TUGdt gait trials wearing a motor function and motor symptom quantitative assessment system. In total, 209 kinematic parameters were synthesized for individual TUG to illustrate patients' motion profiles. We constructed dual-task cost parameters (DTC), describing the magnitude of the effect of the cognitive challenge on motion performance. Covariate-adjusted ordered logistic regression was used to compare parameter differences among 3 groups. Multiple machine learning models were used to classify the participants into 3 cognitive impairment levels, with features being selected based on *P* values from intergroup statistical tests. The total population was randomly divided into a training set and an independent validation set in a 7:3 ratio, and 10-fold cross-validation was used in the training set. Furthermore, this study used permutation importance and Shapley Additive Explanations (SHAP) analysis (including summary plots, bar plots, and waterfall plots) to explain the feature importance of the final model.

Results: The study included 65 age-matched patients (PD-NC: PD-SCD: PD-MCI= 14:21:30). Forty-five kinematic parameters were significantly different ($P<.05$) among the 3 groups, distributed across TUGst (n=25), TUGdt (n=12), and DTC (n=8) paradigms. Gait phase analysis revealed 35 parameters from walking phases, 9 from stand-to-sit transitions, and 1 from sit-to-stand transitions. Feature type distribution demonstrated predominance of variability features (n=20), followed by pace (n=12) and axial (n=8) characteristics. TUGdt paradigm analysis revealed pronounced movement differences between PD-MCI and both

XSL•FO
RenderX

PD-NC and PD-SCD groups, particularly in variability, amplitude, pace, and axial domains. Cross-paradigm analysis identified consistent significant differences in specific features. These findings provide objective kinematic biomarkers for early cognitive state identification in Parkinson disease, with TUGdt parameters demonstrating superior discriminative capacity.

Conclusions: This suggests patients with PD-SCD could have early kinetic signs of cognitive impairment, positioning them between PD-NC and PD-MCI, and our multiclass support vector machine classification model with kinematic parameters achieved a recall rate above 0.70 in both training and validation datasets. The feature importance analysis revealed that DTC_Trunk-Right Rotation Max, DTC_Trunk-Max Transverse Angular Velocity, and dTUG_Lumbar-Right Sway Max Std were the most critical features for distinguishing cognitive states, providing scientific evidence for cognitive function screening based on kinematic parameters.

Introduction

Parkinson disease (PD) with subjective cognitive decline (SCD) [1] is significantly associated with cognitive impairment, including attention and executive function abilities [2]. At the time of this writing, it is suggested that the cognition performance of patients with PD can be classified into three stages: (1) SCD as the prodromal phase (PD-SCD), (2) followed by MCI (PD-MCI), and (3) finally leading to dementia [3-6]. Longitudinal studies revealed that PD-SCD is more likely to develop into PD-MCI, and PD-SCD may have the potential to predict cognitive decline later [7]. Thus, it is essential to identify individuals with PD-SCD as early as possible.

Brain imaging showed functional and structural correlates between motor control and cognition [8]. Evidence implicates dopamine-dependent basal ganglia dysfunction in PD-related dual-task gait impairments. As the basal ganglia regulate automatic motor control, their degeneration may hinder concurrent motor-cognitive processing during walking [9]. In PD, basal ganglia dysfunction reduces movement automaticity, forcing increased cognitive control of actions. The functional magnetic resonance imaging [10] shows patients with PD overrecruit the premotor and prefrontal cortices during dual-task arm movements versus controls, a pattern also observed in single-task walking, suggesting pervasive compensatory cognitive engagement [11]. Notably, increased quantitative susceptibility mapping values in the cuneus significantly correlated with poorer Montreal Cognitive Assessment (MoCA) performance. The patients with PD-MCI showed elevated quantitative susceptibility mapping values in the cuneus, precuneus, caudate head, fusiform gyrus, and orbitofrontal cortex relative to cognitively normal PD controls [12-14]. Collectively, PD-related dopaminergic degeneration concurrently impairs motor and cognitive circuits, with particular dysfunction in the basal ganglia [15].

Timed Up and Go (TUG) tests (eg, single-task TUG [TUGst] tests and dual-task cognition-gait TUG [TUGdt] tests) have been commonly used to assess motor performance and illustrate the association between motor performance and cognition. The TUGdt test reflects motor-cognitive interactions by challenging the cognitive component of locomotion and thus can provide insight into the mechanisms underlying brain motor control and cognitive performance [16,17]. Gait modifications (ie, dual-task costs [DTCs]) are interpreted to reflect the magnitude of changes in motor performance when cortical attention is involved in gait processes [17].

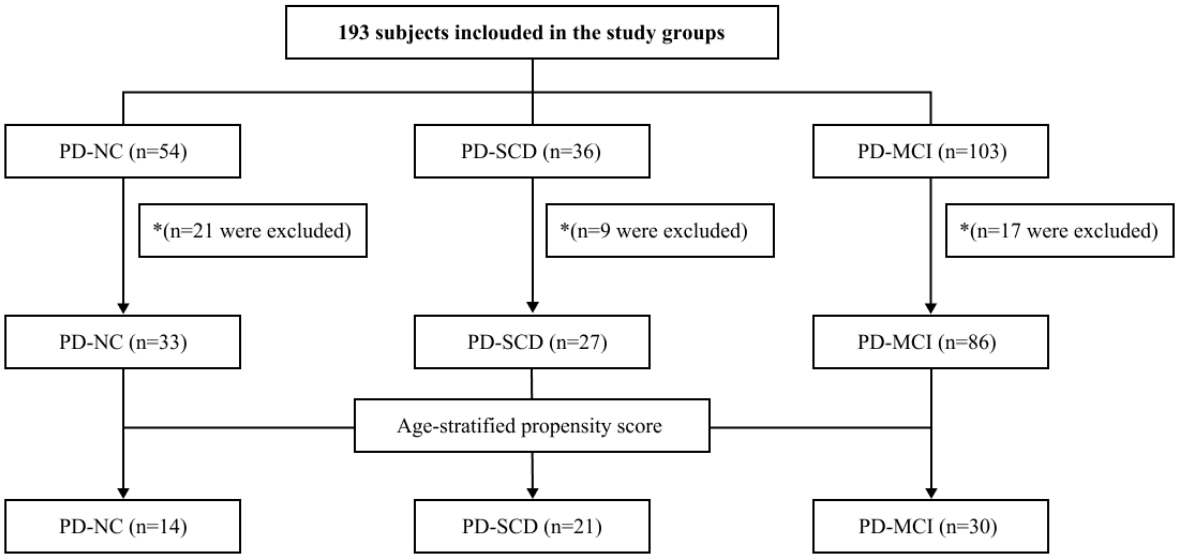
Wearable digital monitoring technologies combined with machine learning models potentially have considerable value for patients with PD and cognitive impairment [18,9]. Previous studies have demonstrated that PD-MCI exhibits greater postural instability and gait disturbances compared to those without MCI (PD-noMCI), particularly under dual-task conditions [19,20]. Russo et al [21,22], further corroborated the strong association between gait dysfunction and MCI in PD, reporting that patients with PD-MCI present with cognitive decline alongside more severe axial motor symptoms and increased postural flexion. Additionally, meta-analyses by other researchers have underscored the diagnostic value of integrating Kinect-based gait analysis—a critical behavioral marker—with machine learning for identifying cognitive impairment in PD [23,24].

The diagnostic criteria for PD-SCD are mainly based on subjective scales [25-27], and the variety of very diverse instruments used to identify SCD could potentially introduce bias. Thus, research on SCD has predominantly focused on areas such as assessment questionnaires, neuroimaging, and associations with emotion and/or objective cognitive functions [28,29]. There have been few studies combining wearable devices and machine learning methodologies for early screening. This gap is important because larger longitudinal studies have shown that patients with Parkinson disease—subjective cognitive decline have a higher likelihood of progressing to Parkinson disease—mild cognitive impairment within a 3-year follow-up period, highlighting the predictive value of PD-SCD for subsequent cognitive decline [7].

In this study, we hypothesized that patients with PD-SCD were intermediate in cognitive status between patients with PD with normal cognition (PD-NC) and PD-MCI. This study aimed to evaluate the utility of wearable technology and machine learning for identifying ordinal cognitive stages (OCS) in patients with PD based on TUG tests (eg, single-task TUG [TUGst] tests and dual-task cognition-gait TUG [TUGdt] tests), which have been commonly used to assess motor performance and demonstrate the association between motor performance and cognition [17].

XSL•FO
RenderX

To our knowledge, this study is pioneering in its inclusion of individuals with PD-SCD within a framework that uses wearable sensors and machine learning for screening.



Methods

Recruitment

The data collection process in this study used a rigorous screening and matching strategy (Figure 1). The initial research cohort comprised 193 participants who were preliminarily categorized into 3 groups based on cognitive functional status: PD with normal cognition (PD-NC; n=54), PD with subjective cognitive decline (PD-SCD; n=36), and PD with mild cognitive impairment (PD-MCI; n=103). During the first-stage screening process, some participants were excluded due to incomplete demographic records, partial scale completion, or missing gait measurement data. Specifically, 21 cases were excluded from the PD-NC group, 9 cases from the PD-SCD group, and 17 cases from the PD-MCI group. After preliminary screening, the sample sizes for each group were 33 cases for PD-NC, 27 cases for PD-SCD, and 86 cases for PD-MCI. To control for the influence of age as a significant confounding factor on research outcomes, we used age-stratified propensity score matching for all participants. This matching process ensured balanced age distribution across the 3 groups, effectively controlling for age differences' impact on cognitive function and gait performance. After age matching, the final sample size included in the analysis was 65 participants, consisting of 14 cases in the PD-NC group, 21 cases in the PD-SCD group, and 30 cases in the PD-MCI group. This matching strategy not only enhanced the internal validity of the study but also provided a more reliable data foundation for subsequent machine learning model analysis.

A consecutive inclusion of 65 age-matched patients from a movement disorder clinic was undertaken (PD-NC [n=14]; PD-SCD [n=21]; and PD-MCI [n=30]). Both physical and thorough interviews were done with them. Age, gender, education level, and duration of disease were recorded. All of the patients were diagnosed with idiopathic PD according to the International Parkinson and Movement Disorder Society (MDS) clinical diagnostic criteria. The inclusion criteria were as follows: (1) diagnosis of PD according to the criteria of the MDS, (2) stages 1-3 on the Hoehn-Yahr (H-Y) scale, (3) stable use of antiparkinsonian medication based on medical history, and (4) ability to walk independently for at least 5 minutes. Patients were excluded based on the following criteria: (1) those who diagnosed dementia, (2) a diagnose of secondary PD, (3) medical history indicates having history of brain disorders (eg, cerebral infarction, cerebral hemorrhage, or brain tumor), and (4) those with serious psychiatric diseases (eg, Hamilton Anxiety Scale [HAMA] ≥21 [30], Hamilton Depression Scale [HAMD] ≥17 [31], or obsessive-compulsive disorder). This study was approved by the Research Ethics Committee of the Second Affiliated Hospital of Nanchang University.

Figure 1. The data screening flowchart. PD-NC: Parkinson disease-normal cognition; PD-SCD: Parkinson disease-subjective cognitive decline; *The data are excluded because of the incomplete demographic records, partial scale completion, or the incomplete gait measurement. PD-MCI: Parkinson disease-mild cognitive impairment;.

Diagnostic Criteria for PD-NC, PD-SCD, and PD-MCI

The participants underwent a comprehensive neurocognitive assessment. Motor symptom severity was evaluated using the MDS Unified Parkinson Disease Rating Scale (MDS-UPDRS) and H-Y stage [32]. Cognitive function was assessed using the MoCA. The MoCA covers multiple cognitive domains, including memory, language, complex visuospatial processing, and executive function, and has a maximum score of 30. Emotional features were assessed with the HAMA and HAMD, which has been validated for use with patients with PD.

According to the guidelines for the diagnosis of dementia in PD published by the MDS, a cut-off score of <26 is recommended for PD-MCI; additionally, 1 point is added to the total score (if less than 30) for participants with ≤12 years of

XSL•FO
RenderX

education [33]. In this study, we define normal global cognition as MoCA ≥25/30 for participants with ≤12 years of education and 26/30 for participants with >12 years of education. Participants answered item 1.1 of MDS-UPDRS Part I, and based on the score, the participants were divided into 2 groups: a score of ≥1 indicated those with subjective cognitive complaints and a score of <1 indicated those without subjective cognitive complaints. Thus, we defined PD-SCD as individuals with item 1.1 of MDS-UPDRS Part I ≥1 as well as normal objective global cognition; PD-NC was identified as patients with PD with item 1.1 of MDS-UPDRS Part I <1 and normal objective global cognition [34,35].

Single-Task TUG (TUGst) and Dual-Task TUG (TUGdt) Gait Tests

Participants performed single-task TUG (TUGst) and dual-task TUG (TUGdt) gait trials wearing a Motor Function and Motor Symptom Quantitative Assessment System (MATRIX; GYENNO SCIENCE). The MATRIX consists of 10 inertial sensors (ie, 10 data recording channels) sampling at 100 Hz. Each inertial sensor consists of a (1) triaxial accelerometer with range=±16 g and sensitivity=16,384 LSB/g and a (2) triaxial gyroscope with range=±2000 dps and sensitivity=131 LSB/dps. The chest sensor was placed on the sternum of the chest, and the lumbar sensor was attached to the fifth lumbar vertebra. Two wrist sensors were bilaterally placed on the dorsal side of the wrist. Two thigh sensors were bilaterally placed 7 cm above the knee, while 2 shank sensors were bilaterally placed 7 cm below the knee. Two-foot sensors were bilaterally placed at the instep (dorsal side of the metatarsus) of each foot. All sensors were tightened to designated locations using straps. As a 3-axis accelerometer and a 3-axis gyro are combined in one sensor, each sensor of the MATRIX records 6 separate signals synchronously. Therefore, 60 signals (10 sensors×6 signals) were recorded in computers for feature extraction of a single TUG trial per participant. Please refer to previous research literature for the specific attached position and detailed metadata of sensors [36,37].

During the TUGst test, without the use of any mobility aids, participants stood up from a chair, walked 5 meters in a straight line, turned 180°, walked straight back to the chair, turned another 180°, and sat on the chair at their usual pace. During the TUGdt test, participants performed the usual-pace TUG test while subtracting 7 serially from 100 (ie, 93, 86, 79, and so on). To avoid learning effects and fatigue, participants performed both tests quietly and completed only one trial of each test.

Kinematic Parameters

To illustrate motion profiles of the arms, lumbar spine, trunk, feet, and shanks, 209 kinematic parameters were synthesized for individual TUG trials by gait event recognition based on signal data stored in computers [36,37]. Parameters were listed in Multimedia Appendix 1. This process involved several key aspects: data acquisition and preprocessing using MATRIX with 10 inertial sensors, each recording 6 independent signals (triaxial accelerometer and gyroscope), resulting in 60 raw signals per TUG trial; gait event recognition through algorithmic identification of key gait events, dividing the trial into walking phase, stand-to-sit transition, sit-to-stand transition, and turning phases; parameter extraction and classification based on gait event recognition, extracting 209 kinematic parameters from raw signals covering spatial and temporal characteristics such as velocity, range of motion, stride length, cadence, swing, and stance, as well as asymmetry features including velocity asymmetry and range of motion (RoM) asymmetry; and anatomical plane analysis considering sagittal, coronal, and transverse planes across multiple body segments including arms, lumbar spine, trunk, feet, and shanks. These parameters represent motion asymmetry for bilateral limbs, kinematic variability (SD of parameters), and task-related spatial and temporal characteristics, including velocity (degree per sec), range of motion (RoM, degree), peak velocity (degree per sec), and RoM (degree) of 3 anatomical planes, respectively (parameters the same as lumbar), stride velocity (m/s), cadence (step per min), gait cycle (sec), stride length (cm), step length (cm), swing (%), stance (%), peak angular velocity (degree per sec), RoM (degree), velocity asymmetry (%), RoM asymmetry (%), absolute deviation between limbs, walk duration (sec), and turning duration (sec). According to parameter definitions, 209 parameters were categorized into variability features, amplitude features, pace features, speed features, axial features, and asymmetry features of motion, ensuring comprehensive capture of motion characteristics across all body segments during TUG tasks and providing rich kinematic information for cognitive state classification. Please refer to previous research literature for specific algorithms [37].

Furthermore, DTC parameters, describing the magnitude of the effect of the cognitive challenge on motion performance, were calculated with equation

, in which i refers to each of the 209 parameters.

Data Analysis

Statistics

Quantitative variables following a normal distribution were represented with mean and SD (μ+σ), and statistical differences among multiple groups were tested with one-way ANOVA. Pairwise comparisons between group levels used a student *t* test. Nonnormal quantitative and qualitative or ordinal variables were summarized with median and IQR (lower quartile part or 25th percentile-upper quartile part or 75th percentile) and number of samples and population percentage n (%), respectively. The Kruskal-Wallis rank sum test was used to compare univariate differences on demographic, clinic characteristics, and kinematic parameters among 3 groups. A pairwise Wilcoxon rank sum test was used for 2×2 multiple comparisons between group levels. The ordered logistic regression with covariates (ie, education, age, length of the calf, weight, and BMI) adjusted was used to compare differences on kinematic parameters among multiple groups. Hypothesis testing for categorical variables was performed with the Pearson chi-square test or Fisher exact test. Statistical analyses were conducted using R (version 4.1.0; R Foundation for Statistical Computing) with R Studio (version 1.4.1717; RStudio, PBC).

XSL•FO
RenderX

Feature Selection, Modeling, and Interpretability

Kinematic parameters that statistically significantly different among 3 groups (with covariates adjusted in ordered logistic regression) were selected as candidate predictors, resulting in 45 kinematic features. Then, for candidate predictors, 2×2 multiple comparisons were applied to multiply compare the differences between PD-MCI and PD-SCD, PD-MCI and PD-NC, or PD-NC and PD-SCD, respectively. Parameters that significantly different among one of three comparisons were selected as predictors. To optimize model performance and prevent overfitting given the limited sample size (n=65), we selected the top 10 most discriminative features based on their statistical significance and clinical relevance, resulting in a final set of 10 kinematic features as predictors. This feature selection strategy was chosen to balance model complexity with available data, as including too many features relative to sample size can lead to overfitting and reduced generalization ability, while too few features may not capture sufficient discriminative information for accurate classification.

The total population was randomly divided into a training set and an independent validation set in a 7:3 ratio, and random forest, support vector machine (SVM), and K-nearest neighbors algorithms were used to classify the participants into 3 cognitive impairment levels (ie, PD-MCI, PD-SCD, and PD-NC). The training set was used to train and evaluate model performance, and the independent test set was used to test the final model. Ten-fold cross-validation was used to evaluate the classification performance of these models in the training set. Recall, precision, and accuracy were used to measure the accuracy and calculated as follows:

True positive = the number of cases correctly classified as PD-MCI, PD-SCD, or PD-NC;

False positive = the number of cases incorrectly classified as PD-MCI, PD-SCD, or PD-NC;

True negative = the number of cases correctly classified as PD-MCI, PD-SCD, or PD-NC;

False negative = number of cases incorrectly classified as PD-MCI, PD-SCD, or PD-NC;

(1.1)

(1.2)

(1.3)

Due to the small sample size (n=65) after age-matching, the model performance might be unstable with repeated data splits. Therefore, the additional validation using the bootstrap method to calculate CIs for recall, precision, and accuracy to evaluate the reliability of model performance.

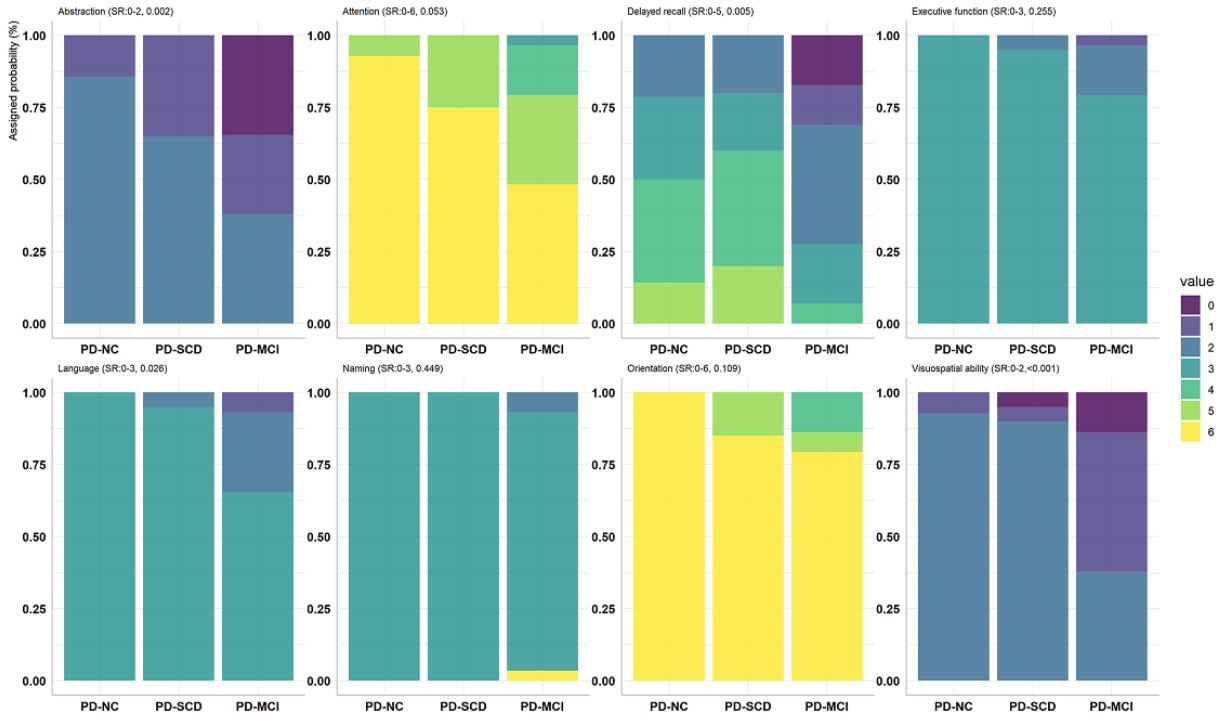
Furthermore, we used the permutation importance by randomly shuffling the values of a feature and observing the resulting degradation in model performance and mean absolute Shapley Additive Explanations (SHAP) value [38] (mean [|SHAP|]) to measure feature importance. SHAP deconstructs a prediction into a sum of contributions from each of the model's input variables, thus explaining how individual predictions are made by a machine learning model. And the waterfall plot based on SHAP was employed to visually display how the SHAP values (evidence) of each feature move the model output from our prior expectation under the background data distribution to the final model prediction given the evidence of all the features. The bottom of a waterfall plot starts as the expected value of the model output, and then each row shows how the positive (red) or negative (blue) contribution of each feature moves the value from the expected model output over the background dataset to the model output for this prediction. Mean (|SHAP|) is, on average, how much each variable impacts the predicted probability of participants being PD-NC, PD-MCI, and PD-SCD. The mean absolute SHAP value is a metric that quantifies the average absolute magnitude of SHAP values across all features in a model. Machine learning was conducted using Python (version 3.8.1627; Python Software Foundation) [39].

Ethical Considerations

This study was approved by the Research Ethics Committee of the Second Affiliated Hospital of Nanchang University, with all participants providing informed consent. Data were anonymized using ID numbers, and follow-up participants received travel compensation.

Results

Demographic and Clinic Characteristics in Groups of PD-NC, PD-SCD, and PD-MCI



There were no statistically significant differences among the PD-NC, PD-SCD, and PD-MCI groups in terms of demographic characteristics (including age, sex, height, thigh length, weight, education level, disease duration, and H-Y stage) or scores on MDS-UPDRS I, MDS-UPDRS II, MDS-UPDRS III, HAMA, and HAMD (P>.05).

The diagnostic criteria for PD-NC, PD-SCD, and PD-MCI were based on UPDRS1.1 scores and MoCA total scores, which showed statistically significant intergroup differences (P<.001; Multimedia Appendix 2). The MoCA scale and its subdomain scores exhibited different patterns of differences among the 3 groups (Figure 2). In terms of MoCA total scores, the PD-MCI group (23.00, 95% CI 22.00-25.00) was significantly lower than both the PD-NC group (28.00, 95% CI 27.00-29.00) and the PD-SCD group (27.00, 95% CI 27.00-28.00), while no significant difference was observed between PD-NC and PD-SCD groups. Among the MoCA subdomain scores, statistically significant differences were found among the 3 groups in abstraction (P=.002), delayed recall (P=.005), and visuospatial ability (P<.001), with the PD-MCI group showing significantly lower performance in these cognitive domains compared to PD-NC and PD-SCD groups. In attention, the differences among the 3 groups approached statistical significance (P=.05), with the PD-MCI group showing a trend toward decreased attention. However, no statistically significant differences were observed among the 3 groups in executive function (P=.25), language (P=.83), naming (P=.45), and orientation (P=.11; Figure 2). These findings align with the disease progression pattern of PD. As a chronic

XSL•FO
RenderX

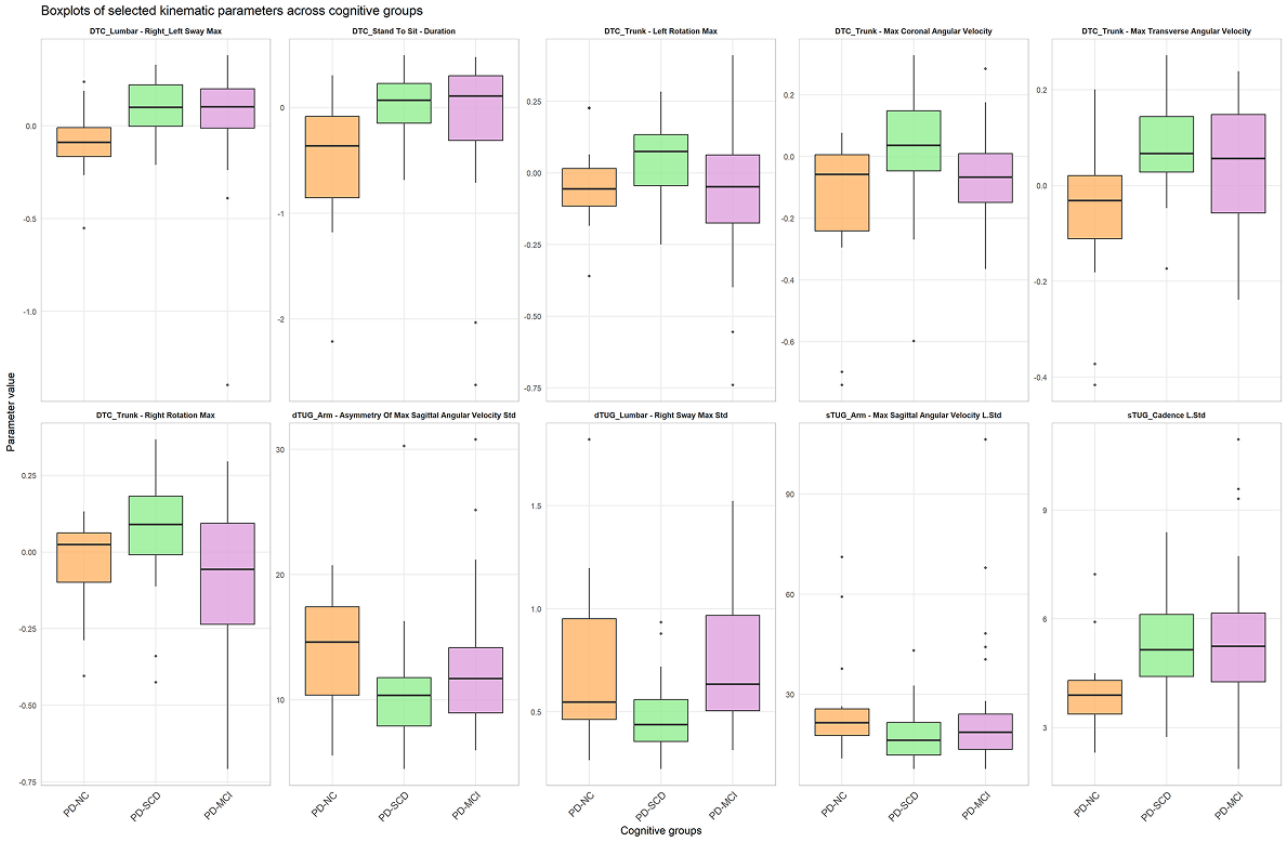
neurodegenerative condition, cognitive function may gradually deteriorate with disease progression, particularly in higher-order cognitive functions such as memory, visuospatial ability, and abstract thinking. The significant decline in delayed recall and visuospatial ability observed in patients with PD-MCI reflects the typical characteristics of PD-related cognitive impairment. In contrast, language, naming, and executive functions remain relatively preserved in the early stages, which is consistent with the domain-specific pattern of cognitive impairment in PD.

Figure 2. Distribution of Montreal Cognitive Assessment (MoCA) subdomain scores among Parkinson disease-normal cognition (PD-NC), Parkinson disease-subjective cognitive decline (PD-SCD), and Parkinson disease-mild cognitive impairment (PD-MCI). PD-MCI: Parkinson disease-mild cognitive impairment; PD-NC: Parkinson disease-normal cognition; PD-SCD: Parkinson disease-subjective cognitive decline.

Characteristics of Kinematic Parameters in Groups of PD-NC, PD-SCD, and PD-MCI

Screening procedures identified 45 kinematic parameters meeting the established criteria, distributed across TUGst (n=25), TUGdt (n=12), and DTC (n=8) paradigms. Gait phase analysis revealed 35 parameters from walking phases, 9 from stand-to-sit transitions, and 1 from sit-to-stand transitions. Feature type distribution demonstrated a predominance of variability features (n=20), followed by pace (n=12) and axial (n=8) characteristics. This distribution pattern reflects differential impacts of cognitive decline on gait control mechanisms, with movement precision (variability) and temporal coordination (pace) emerging as critical cognitive function indicators. TUGdt paradigm analysis revealed pronounced movement differences between PD-MCI and both PD-NC and PD-SCD groups, particularly in variability, amplitude, pace, and axial domains. Notable examples include “Shank-Max Sagittal Angular Velocity R Std” (21.12 vs 28.38 vs 21.38) and “Trunk-Left Rotation Max Std” (1.94 vs 1.99 vs 1.33) in variability measures. Amplitude analysis of “Shank-Symbolic Symmetry Index” demonstrated compensatory patterns (14.27 vs 9.75 vs 12.62), suggesting potential compensatory mechanisms during SCD stages. TUGst paradigm differences primarily manifested in pace characteristics, exemplified by “Double Support” (23.16 [4.76] vs 18.55 [3.04] vs 20.87 [3.75]) and “Stance _MAXLR” (62.17 [2.75] vs 60.06 [1.95] vs 61.17 [2.09]). DTC parameter analysis revealed a concentration of differences in variability features, including “Gait Speed R.Std” (–0.97 vs –0.30 vs –0.14) and “Shank-Max Sagittal Angular Velocity R.Std” (–1.67 vs –0.33 vs –0.30), demonstrating cognitive load effects on motor performance. Cross-paradigm analysis identified consistent significant differences in specific features, such as “Step Length_ABSLR” in DTC (–0.36 vs 0.16 vs 0.14), establishing step length asymmetry as a robust cognitive function biomarker. These findings provide objective kinematic biomarkers for early cognitive state identification in PD, with TUGdt parameters demonstrating superior discriminative capacity.

Multimedia Appendix 3 results demonstrate systematic kinematic feature differences across cognitive states, primarily in movement precision (variability) and temporal coordination (pace) domains. Enhanced differences in TUGdt paradigms align with theoretical frameworks predicting motor control degradation under increased cognitive load conditions. Compensatory pattern identification (eg, preserved performance in SCD stages) suggests early-stage compensatory mechanisms maintaining motor function. However, progressive cognitive decline appears to compromise these mechanisms, resulting in significant motor deterioration in MCI stages. These findings



XSL•FO
RenderX

establish objective kinematic biomarkers for early cognitive state identification and monitoring in PD, with TUGdt variability features demonstrating particular clinical translational potential.

Figure 3 presents boxplots illustrating the distribution of 10 selected kinematic parameters across the PD-NC, PD-SCD, and PD-MCI cognitive groups, visually demonstrating the differences among these groups for each parameter. The box in each boxplot represents the 25th percentile (Q1, bottom line of the box), the median (central line of the box), and the 75th percentile (Q3, top line of the box). The bottom and top of the error bars (whiskers) indicate the "Minimum" (Q1-1.5×IQR) and "Maximum" (Q3+1.5×IQR), where IQR is the interquartile range. Blue dots outside this range represent outliers.

As observed from the figure, for several DTC related parameters, such as "DTC_Lumbar-Right_Left Sway Max," "DTC_Stand To Sit-Duration," "DTC_Trunk-Max Transverse Angular Velocity," and "DTC_Trunk-Right Rotation Max," the median values for the PD-NC group are generally lower than those for the PD-SCD and PD-MCI groups, indicating lower motor costs under dual-task conditions in the normal cognition group. This aligns with the theory that impaired cognitive function leads to decreased motor control ability. For instance, "DTC_Stand To Sit-Duration" shows a median of approximately –0.05 for the PD-NC group, while the medians for the PD-SCD and PD-MCI groups are significantly higher than 0.20, suggesting that patients with cognitive impairment are more affected by cognitive challenges during the stand-to-sit transition. In dTUG (dual-task TUG) -related parameters, such as "dTUG_Arm-Asymmetry Of Max Sagittal Angular Velocity SD" and "dTUG_Lumbar-Right Sway Max SD," the median values for the PD-SCD group appear slightly lower than those for the PD-NC and PD-MCI groups. This might reflect a compensatory mechanism or different motor strategies used during the SCD stage. For sTUG (single-task TUG) related parameters, such as "sTUG_Cadence L SD," the median for the PD-NC group (approximately 3.5) is notably lower than that for both PD-SCD and PD-MCI groups (both approximately 5.5), indicating lower gait variability in cognitively normal patients under single-task conditions, whereas patients with cognitive impairment exhibit higher gait variability. These visual differences are consistent with the statistically significant results reported in Multimedia Appendix 3, further supporting the potential of these kinematic parameters as biomarkers for distinguishing different cognitive states.

Figure 3. Multiple-comparison results of represented kinematic parameters between pairs of groups. Multiple-comparison results of represented kinematic parameters between pairs of groups. DTC: dual-task cost; PD-MCI: Parkinson disease-mild cognitive impairment; PD-NC: Parkinson disease-normal cognition; PD-SCD: Parkinson disease-subjective cognitive decline.

Modeling and Interpretability

The best-performing model in the 3-class classification was the SVM model. Its classification accuracies on the training and test sets were 0.8 (0.69-0.86) and 0.6 (0.45-0.73), respectively, indicating a good performance on the training set but reduced performance on the test set (Multimedia Appendix 4). Regarding recognition capability per category on the training set, PD-MCI had a relatively higher recall (0.71), while the PD-NC and PD-SCD categories exhibited relatively higher precision, at 0.90 and 0.86, respectively. On the test set, PD-MCI maintained a relatively higher recall (0.78), while PD-NC and PD-SCD

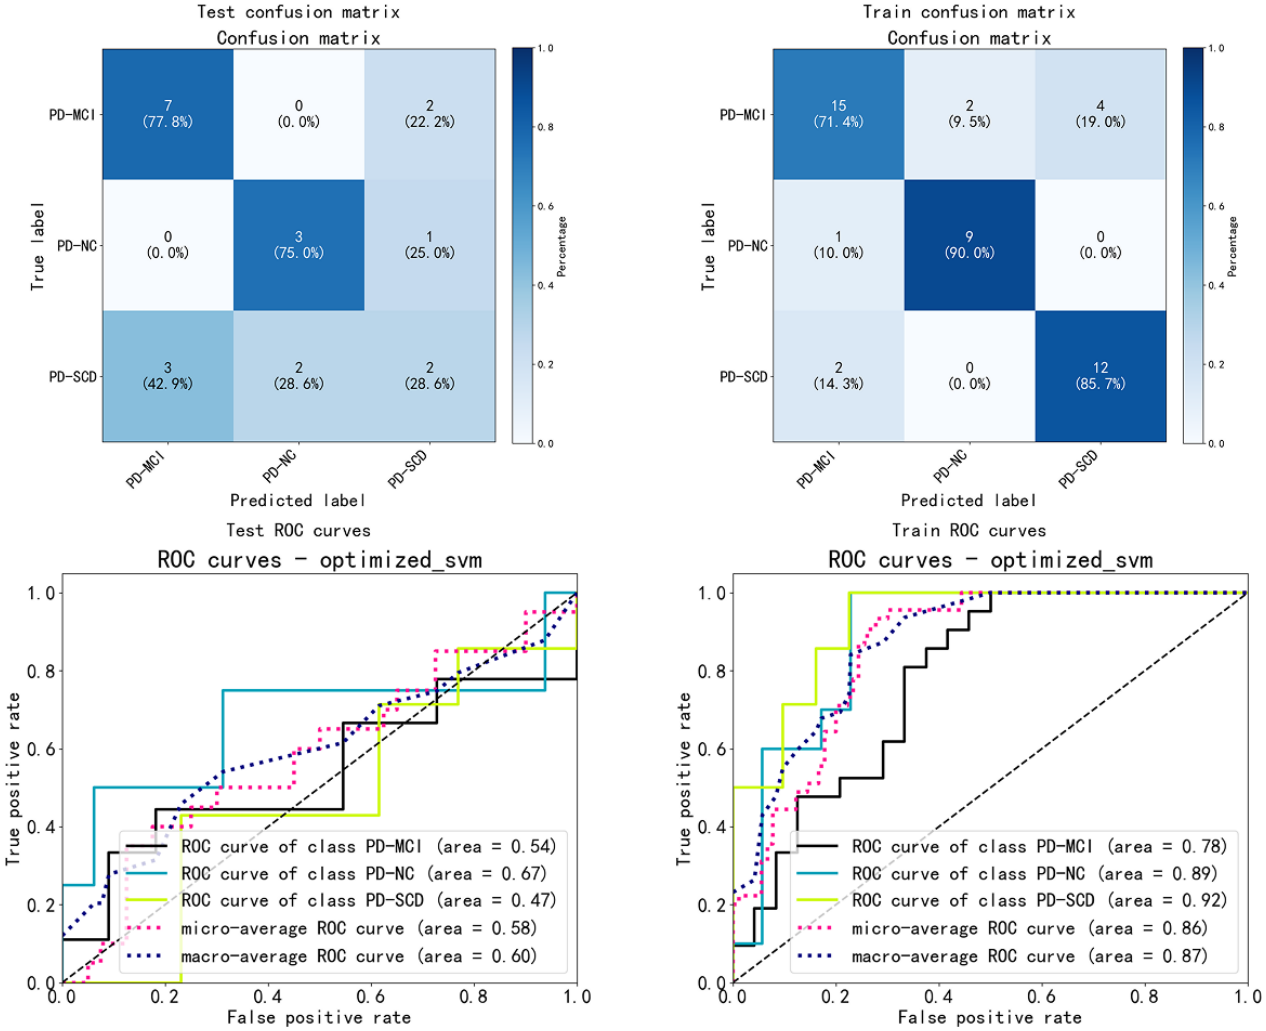
XSL•FO
RenderX

demonstrated relatively lower precision, at 0.75 and 0.29, respectively. Based on the receiver operating characteristic (ROC) curves (Figure 4), the macro-average ROC AUC on the training set was 0.87, compared to 0.60 on the test set.

Integrating participants' cognitive levels allows for a deeper explanation of the mechanistic differences in classifying MCI, SCD, and NC (Multimedia Appendix 5, Figure 5, and Multimedia Appendix 6). Regarding the distinction between MCI and NC, cognitive level analysis revealed significant differences between the 2 groups across multiple cognitive dimensions: the MoCA total score of the MCI group was significantly lower than that of the NC group (effect size, Cohen d=2.672, indicating a large effect); delayed recall ability was significantly lower in the MCI group than in the NC group (Cohen d=1.915); visuospatial ability was significantly lower in the MCI group than in the NC group (Cohen d=1.354). These significant differences in objective cognitive function provide a cognitive load basis for TUG task features to effectively distinguish MCI from NC. Due to limited cognitive resources, patients with MCI exhibit significant degradation in motor performance during dual-task TUG. This cognitive-motor interaction pattern can be effectively captured by TUG features.

Regarding the distinction between SCD and NC, cognitive level analysis revealed the fundamental cause of confusion. The SCD and NC groups showed no significant difference in MoCA total score (P=.14). Except for abstract ability, no significant differences were found in other cognitive subdomains, with most comparisons showing small-to-medium effect sizes.

This similarity in objective cognitive function explains why TUG features struggle to distinguish SCD from NC: although patients with SCD subjectively perceive cognitive changes, their objective cognitive resources are sufficient, leading to similar performance in dual-task TUG as NC, resulting in TUG features failing to effectively distinguish these 2 groups.



Concerning the distinction between MCI and SCD, cognitive level analysis showed significant differences in objective cognitive function between the 2 groups: the MoCA total score of the MCI group was significantly lower than that of the SCD group (Cohen d=2.301, large effect); delayed recall ability was significantly lower in the MCI group than in the SCD group (Cohen d=1.423); visuospatial ability was significantly lower in the MCI group than in the SCD group (Cohen d=1.528). However, despite significant cognitive differences between MCI and SCD, TUG features still faced difficulties distinguishing them, with 42.9% of SCD samples misclassified as MCI.

Feature importance analysis of cognitive levels further validated the cognitive level analysis results. The MoCA total score had the highest discriminative power ($F_{2,16}$=18.94; P<.001), followed by delayed recall ($F_{2,16}$=11.70; P<.001). This aligns highly with the significant decline in delayed recall observed in the MCI group in the cognitive level analysis (effect size, Cohen d=1.915; Figure 5). The decline in delayed recall ability may directly impact patient performance in dual-task TUG, as this task requires simultaneously processing motor and cognitive demands; the efficiency of cognitive resource allocation directly affects motor performance.

Furthermore, to gain a deeper understanding of the model's decision-making mechanism, we used 2 feature importance analysis methods (Figure 6). Permutation importance analysis evaluated the impact of features on model performance by randomly shuffling feature values, revealing that DTC_Trunk-Right Rotation Max (importance value=0.145) was the most critical feature, followed by DTC_Trunk-Max Transverse Angular Velocity (0.090) and dTUG_Lumbar-Right Sway Max Std (0.080). These findings emphasize the importance of trunk motor control under dual-task conditions for distinguishing cognitive states. SHAP analysis provided 3 different perspectives on feature importance assessment. The SHAP feature importance bar plot showed that sTUG_Cadence L Std (mean [SHAP]=0.23) had the highest average impact, followed by DTC_Trunk-related features. This discrepancy with permutation importance results reflects the different mechanisms of the 2 analysis methods; permutation importance focuses on the impact of feature absence on overall model performance, while SHAP analysis focuses on the direct impact of feature value changes on model output. The SHAP feature importance summary plot further revealed the complex relationship between feature values and their impact on model output. For most DTC features, higher feature values tended to produce larger positive SHAP values, pushing the model output toward higher values, indicating that increased trunk kinematic parameters under dual-task conditions are associated with cognitive decline. This pattern supports the cognitive-motor interaction theory, suggesting that when cognitive resources are limited, individuals exhibit greater motor variability under dual-task conditions. SHAP waterfall plots provided detailed explanations at the individual sample level, demonstrating how each feature drives predictions from baseline values to final outputs. For example, in correctly classified PD-MCI samples, DTC_Trunk-Max Transverse Angular Velocity and DTC_Trunk-Right Rotation Max contributed most strongly to predictions, while correctly classified PD-NC samples exhibited relatively stable dual-task motor features. These individual-level analyses revealed the model's decision-making mechanism in distinguishing different cognitive states, particularly the challenges faced when processing groups with similar cognitive states (such as PD-SCD and PD-NC; Multimedia Appendix 7).

Discussion

Principal Results

In this study, we included 65 patients with PD exhibiting various cognitive states (PD-NC: 14 cases, PD-SCD: 21 cases, and PD-MCI: 30 cases) and explored the method of using kinematic characteristics for the stratified cognitive stage classification of patients with PD by combining wearable sensors with machine learning. We first described the gait characteristics of PD-NC, PD-SCD, and PD-MCI, respectively; second, we explored the factors associated with gait kinematic parameters and cognitive status; next, we analyzed significantly different gait parameters among groups; and finally, we established a model that relies on various TUG task outcomes, which can distinguish individuals with PD-NC, PD-SCD, and PD-MCI. Our results demonstrated that kinematic features are associated with cognitive stages, patients with PD-SCD have underlying kinetic impairments similar to those with PD-MCI, and the diagnostic SVM model showed potential in differentiating cognitive impairments. The SVM model achieved classification accuracies of 0.8 (0.69-0.86) and 0.6 (0.45-0.73) on the training and test sets, respectively, with PD-MCI demonstrating the highest recall rates (0.71 on the training set, 0.78 on the test set) and macro-average ROC AUC values of 0.87 and 0.60 for the training and test sets.

Regarding the classification performance, the model demonstrated effective differentiation between MCI and NC groups due to significant differences in objective cognitive function (MoCA total score effect size, Cohen *d*=2.672), which provided a cognitive load basis for TUG task features to effectively distinguish these groups. However, the model faced significant challenges in distinguishing PD-SCD from both PD-NC and PD-MCI groups. Concerning the distinction between SCD and NC, cognitive level analysis revealed the fundamental cause of confusion. By definition, SCD refers to a subjective perception of cognitive decline, which is not necessarily aligned with the actual cognitive level. For instance, substantial cognitive impairment may occur without being perceived, whereas minor declines may be perceived as significant. Thus, it is difficult to determine which condition reflects a higher level of cognition. Consequently, NC and SCD may not exhibit clear differences in cognitive impairment; the 2 groups showed no significant difference in MoCA total score (*P*=.14). It is correspondingly challenging to distinguish between them based on motor performance. This suggests that SCD may represent a subtype with a higher risk of progressing to MCI, rather than a group that is necessarily closer to MCI in terms of cognitive function.

Regarding the distinction between SCD and MCI, cognitive level analysis showed significant differences in objective cognitive function between the 2 groups (MoCA total score effect size, Cohen *d*=2.301). However, despite significant cognitive differences between MCI and SCD, TUG features still faced difficulties distinguishing them, with 42.9% of SCD samples misclassified as MCI. This seemingly paradoxical result highlights an important mechanism of TUG task features: although MoCA assessment revealed significant cognitive differences between SCD and MCI, this difference primarily manifests in static cognitive tests. In the dynamic context of dual-task TUG, cognitive differences may be insufficient to produce noticeable variations in motor performance. Specifically, while patients with SCD had significantly higher MoCA scores than patients with MCI, their relative cognitive advantage during dual-task TUG might be counterbalanced by other factors, such as attentional allocation strategies, task priority adjustments, or motor control patterns. Furthermore, UPDRS score analysis revealed that the SCD group had the lowest UPDRS III (motor examination) score (20.143), indicating relatively better motor function in patients with SCD. This motor advantage might further compensate for the impact of cognitive differences on TUG performance. This underscores that performance in the TUG task, as a cognitive-motor dual-task paradigm, is not solely influenced by static cognitive function. Instead, it results from the combined effects of dynamic cognitive-motor interactions, attentional allocation, motor control, and other factors. When cognitive differences are counterbalanced by other factors in a dynamic task context, TUG feature-based classification models struggle to accurately distinguish different cognitive states.

Additionally, the limited sample size (n=65) after age-matching may have contributed to model performance instability, with the training set containing only 45 samples and the test set containing only 20 samples, including only 7 SCD samples in the test set, resulting in insufficient sample representativeness that hindered the model's ability to adequately validate SCD classification performance.

Comparison With Prior Work

Demographic Comparation With Other Studies

Consistent with other studies [8,20,40] patients with PD-MCI showed older age, a higher proportion of lower education, worse motor function assessed by MDS-UPDRS-III, and worse performance in global cognition and cognitive domains than the other 2 groups. Additionally, we observed a decrease across the 3 groups in various cognitive domains, including visuospatial ability, executive function, attention, language, abstract thinking, memory, and orientation. Specifically, the PD-NC group had the highest proportion of perfect scores, followed by patients with PD-SCD, with the PD-MCI group having the lowest proportion. These findings here were partially consistent with other studies, which reported that patients with PD-SCD exhibited poorer performance in attention, executive abilities, memory, and visuospatial functions compared to individuals with PD-NC [2,41-43]. Therefore, we believe that the findings of this study have strong generalizability.

Gait Performance Comparison Among Paradigms

In this study, we identified 45 distinct gait parameters that demonstrated significant variance across the 3 participant groups in the TUGst, TUGdt test, and DTC test. These parameters encompassed a range of dynamic attributes, including motion amplitude, pace, speed, and axial alignment, observed during the 5-meter walking, 180° turning, and sit-to-stand phases. Our findings are in line with prior cross-sectional research that has

XSL•FO
RenderX

established robust correlations between gait characteristics—such as pace, rhythm, and asymmetry—and cognitive function, as measured by the TUGst or TUGdt [22,44]. A study by Kim et al [45] revealed that individuals with PD who experience cognitive impairment exhibit a marked reduction in gait speed and stride length when contrasted with those without cognitive impairment. This underscored the adverse effect that cognitive impairment could have on the mobility of patients with PD. Our research observed a decline in step length, stride length, gait speed, and swing among all 3 participant groups (PD-NC, PD-SCD, and PD-MCI) during TUGdt as opposed to the TUGst. Also, kinematic characteristics observed during the TUGdt test exhibited a more pronounced association with the ordinal cognitive stages when compared to other assessments. Specifically, Shank-Max Sagittal Angular Velocity, Trunk-Sway Max SD, Shank-Swing Speed, Shank Forward-Backward Swing Max, gait speed, and straight-walking duration (first segment of the TUGdt test or DTC) were the top 6 features associated with cognitive performance. The result here was adjusted with covariates. This suggests that the introduction of cognitive tasks during the TUGst can disrupt the execution of motor tasks, consequently diminishing the participants' walking capabilities.

Gait Performance Comparison Across Participant Groups

In our analysis, we observed distinct patterns in gait performance across the different participant groups, highlighting the intricate relationship between cognitive function and motor control in PD. Here is a refined presentation of our findings:

1. Gait speed and swing speed decline: a pronounced decreasing trend in gait speed and swing speed was noted as cognitive function worsened across the 3 groups. This aligns with clinical observations where individuals with PD-MCI tend to exhibit poorer gait patterns [20]. Mechanistic insights suggest that the altered neural networks and neurotransmitter deficiencies in PD are linked to both gait disturbances and cognitive impairments [19,46]. The initiation of swinging motion is a complex interplay between passive trunk movement and the precise activation of muscles, regulated by the basal ganglia [47], indicating that cognitive decline may be associated with a slower swing speed.

2. Step and stride length variations: a significant difference in step length and stride length was found between PD-MCI and PD-NC groups, with PD-MCI showing shorter lengths, which is consistent with previous research [48,49]. Interestingly, the PD-SCD group showed longer step and stride lengths, though without statistical significance, possibly indicating early compensatory mechanisms. Neuroimaging studies have consistently demonstrated elevated activation levels in the prefrontal cortex during cognitive tasks in individuals with SCD when compared to those with normal cognition [50,51]. The prefrontal cortex is known for its involvement in attention and executive functions, both of which are closely linked to performance in the TUGdt test [52,53], the enhanced functional connectivity in this region may be an underlying neural mechanism for the decline in TUGdt performance [54]. Additional studies also demonstrated the presence of compensatory neural activity in the early stages of cognitive impairment, and the cognitive strategies can compensate for the decline in gait function [55,56]. Nevertheless, it is crucial to recognize this scarcity of research on the brain function of individuals with PD-SCD. To substantiate our hypothesis and findings, there is a clear need for more extensive, large-scale investigations into brain function within this cohort.

3. Poorest gait performance in patients with PD-MCI: patients with PD-MCI showed significantly poorer gait performance than the other 2 groups. Specifically, in the TUGdt test, both the PD-NC and PD-SCD exhibited shorter walking duration, longer step length and stride length, faster walking speed, swing speed, and angular velocity than the group of PD-MCI, suggesting that individuals with PD-MCI have poorer walking ability, and this was supported by previous studies [8,57,58].

Furthermore, when comparing the PD-MCI and PD-NC groups, we noticed significantly reduced angular velocity during turning and maximum sagittal plane angular velocity during walking in PD-MCI than in PD-NC in TUGdt (Multimedia Appendix 2). PD is characterized by a reduction in the range of motion and muscle strength at the hip, knee, and ankle joints [59,60]. Consequently, those with PD-MCI might struggle with activities like turning, which demand heightened coordination and cognitive capacity [61,62]. When comparing the PD-MCI and PD-SCD groups, we observed that the PD-MCI group had longer walking duration, support phase, stance, shorter step length, stride length, walking speed, arm swing speed, and arm swing amplitude in both TUGst and TUGdt. Our results support earlier research showing that severe cognitive impairments can lead to greater motor skill deficits in gait activities [63,64].

4. Subtle gait changes in PD-SCD: our study suggests that PD-SCD individuals show subtle changes in gait, which is supported by studies demonstrating individuals with poor walking ability during the TUG test have a significantly higher risk of developing MCI compared to those with normal walking ability [48,65].

The control of trunk posture is controlled by the frontal lobe [66,67]. Individuals with PD who have abnormal posture also experience noticeable clinical symptoms of impaired attention and executive ability [68], suggesting that there may be a shared brain activity in the frontal lobe between trunk posture abnormalities and attention and executive ability.

Modeling and Explanation

To automatically obtain patients' cognitive impairment level, 10 kinematic parameters were selected as predictors to construct a multiclass SVM classification model. The recall rate for PD-MCI is above 0.7, while the accuracy for the PD-SCD and PD-NC categories is relatively low. To our knowledge, this pioneering machine learning model, despite its moderate accuracy, represents the first attempt to delineate the cognitive impairment stages in patients with PD, particularly for the PD-SCD stage. Overall, motion speed–related features appeared to contribute most to distinguishing among PD-NC, PD-SCD, and PD-MCI groups. Differences across feature-importance analysis methods reflect the complexity of model decision-making. Permutation importance emphasizes the overall contribution of features, SHAP analysis focuses on the

XSL•FO
RenderX

direct impact of features on model output, and waterfall plots provide detailed explanations at the individual-sample level. These complementary analysis methods collectively revealed the important role of dual-task kinematic features in cognitive state assessment, particularly DTC features related to trunk motor control, providing scientific evidence for cognitive function screening–based on kinematic parameters.

Limitations

There are several limitations in our study. First, the MDS-UPDRS Part I 1.1 score ≥1 evaluating SCD was too simple compared with a comprehensive screening scale. However, SCD identified by MDS-UPDRS Part I 1.1 has been revealed to be associated with the development of PD-MCI, which validates the clinical significance of our measurement tool. Second, we used a short MoCA scale to assess global cognition rather than a comprehensive neuropsychological test focused on each cognitive domain. It is necessary to confirm our results with comprehensive neuropsychological tests. Next, the classification performance of the model needs to be further improved. Furthermore, a larger sample and follow-up multiple-center studies are essential to validate our cross-sectional results.

Conclusions

Our study examines kinematic features to distinguish between 65 patients with PD, including PD-NC, PD-SCD, and PD-MCI. Forty-five gait parameters differed significantly by group in the TUGst, TUGdt tests and DTC, with TUGdt parameters showing stronger cognitive association. Patients with PD-MCI had worse gait performance than patients with PD-NC and PD-SCD. The PD-SCD group showed reduced gait speed and swing speed but longer steps and strides, and our multiclass SVM classification model with kinematic parameters achieved a recall rate above 0.7 in both training and validation datasets. This suggests patients with PD-SCD could have early kinetic signs of cognitive impairment, positioning them between PD-NC and PD-MCI, and kinematic parameters could serve as predictors to distinguish the cognitive stage of patients with PD.

Abstract

Background: Early childhood caries (ECC) is a prevalent yet preventable disease that significantly impacts young children's health and quality of life. The World Health Organization's *Global Strategy and Action Plan on Oral Health 2023–2030* highlights the potential of mobile health programs to enhance engagement and support sustained oral health behavior change.

Objective: The aim of this study was to assess the effectiveness of the SmilesUp 12-week SMS text messaging–based education and support program to improve parents' management of their children's oral health behaviors compared to standard clinical care.

Methods: We conducted a multisite, assessor-blinded, parallel-design randomized controlled trial among parents of children aged 0 to 6 years who had an ECC diagnosis and attended 1 of 6 public dental clinics in metropolitan, regional, and rural New South Wales, Australia. Participants were randomly assigned to either an intervention group receiving the fully automated 12-week SmilesUp program (3 SMS text messages weekly) or a control group. Both groups continued to receive usual standard dental clinical treatment. The primary behavioral outcome was parent-reported twice-daily toothbrushing with fluoride toothpaste. Secondary outcomes included adherence to oral health–promoting bedtime routines and child consumption of sugar-sweetened foods and beverages. Oral health self-efficacy was measured using 6 behavioral theory–mapped items across oral hygiene, diet, and bedtime routines.

Results: A total of 154 participants were enrolled and randomized (n=78, 50.6% in the control group; n=76, 49.4% in the intervention group) across 6 sites, with 80.5% (124/154) completing the follow-up assessment. High program adherence was observed, with 96.1% (73/76) of intervention participants completing the program. At 12 weeks, a greater proportion of SmilesUp participants reported brushing their children's teeth twice daily (45/61, 73.8% vs 42/63, 66.7%; adjusted odds ratio [aOR] 2.45, 95% CI 0.95-6.74; *P*=.07), though this difference was not statistically significant. Significant improvements were observed in adherence to bedtime routines (54/61, 88.5% vs 45/63, 71.4%; aOR 3.25, 95% CI 1.15-10.18; *P*=.03) as well as oral health knowledge on toothbrushing (46/50, 92.0% vs 41/52, 78.8%; aOR 5.47, 95% CI 1.48-25.19; *P*=.02). No statistically significant differences were found in sugar-sweetened food (10/61, 16.4% vs 4/63, 6.3%; aOR 3.72, 95% CI 1.02-17.14; *P*=.06) or beverage (25/61, 41.0% vs. 27/63, 42.9%; aOR 1.08, 95% CI 0.49-2.30; *P*=.85) consumption.

Conclusions: These findings suggest that co-designed SMS text messaging–based programs show promise and may represent a feasible strategy for oral health behavior change. However, larger-scale and longer-term studies are needed to confirm sustained effectiveness using clinical outcomes. Future research should also explore ways mobile health can be scaled and cost-effectively embedded into comprehensive, interdisciplinary primary models of care.

mobile health; mHealth; dental caries; prevention; early childhood caries; co-design

Introduction

Early childhood caries (ECC) affects more than 600 million children worldwide and remains one of the most common yet preventable childhood diseases [1]. Untreated ECC can lead to significant pain, infection, and impaired quality of life, often resulting in costly dental procedures, including treatments requiring general anesthesia (GA) [2]. In New South Wales (NSW), Australia, 1 in 250 children requires a GA admission for planned dental treatment, with 8.4% (1979/23,559) readmitted within 2 years and a further 9% (1641/18,194) of their siblings requiring similar care [3]. Similar rates in the United Kingdom also indicate that dental caries is the leading cause of hospital admissions for children aged 5 to 9 years (2015-2018) [4]. Preventive behaviors to reduce the risk of ECC include twice-daily toothbrushing with fluoride toothpaste, limiting sugar intake, and avoiding milk or sugar-sweetened beverages at bedtime [5]. While primary care dental clinics play a key role in diagnosis and clinical treatment, parents and caregivers are central to forming and maintaining the preventive behaviors that underpin children's oral health [6]. The World Health Organization's (WHO) 2019 *Ending Childhood Dental Caries* report emphasizes that parental knowledge, motivation, and capability—conceptualized as oral health self-efficacy—are essential in establishing oral health–promoting behaviors [6]. Systematic reviews [5] informing this WHO report and the 2023 update to Australia's national oral health promotion messages [7] reinforce the preventive role that parents play. However, increasing parental knowledge alone is insufficient for sustained behavior change [8]. Traditional chairside advice and demonstration have limited effectiveness because behavior change requires repeated, practical, and accessible prompts that build parental oral health literacy and capability within the home environment [8,9].

Recognizing this gap, the WHO *Global Strategy and Action Plan on Oral Health 2023–2030* [10] advocates for the use of digital innovations, including mobile health (mHealth) [11]. mHealth interventions have shown to improve health behaviors for a broad range of cardiometabolic and chronic health conditions by increasing knowledge, capability, and motivation [12-14]. They are scalable, accessible, and effective across a range of noncommunicable diseases [12-14], yet their use in early childhood oral health remains emerging [15]. Existing programs for oral health largely target older adults and adolescents [16]. They narrowly focus on toothbrushing [17], are not of high quality [18,19], and are rarely grounded in behavioral theory [20,21].

To address these limitations, our research group undertook a comprehensive co-design process with parents to develop SmilesUp, a theory-informed mHealth intervention tailored to parental needs, preferences, and identified barriers and enablers [22]. The SmilesUp SMS text messaging program aims to enhance parental oral health self-efficacy by providing tailored information, including practical video demonstrations, and timely prompts delivered directly to parents within the home environment, where oral health habits are formed [22]. This randomized controlled trial (RCT) aimed to evaluate the impact of the SmilesUp SMS text messaging program on parental oral health behaviors, knowledge, oral health self-efficacy (capability, opportunity, and motivation), and overall engagement, addressing a critical gap in mHealth strategies to prevent ECC.

Methods

Study Design

This single-blinded parallel RCT (1:1 allocation ratio) was assessor blinded and carried out within NSW public dental clinics. The protocol has been previously published [23], and a concise summary of our methods is provided below. The trial adhered to the CONSORT-EHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and Online Telehealth; Checklist 1) reporting guidelines.

Participant Eligibility and Recruitment

Parents of children diagnosed with ECC who were either awaiting or undergoing dental treatment in the NSW public dental service in Australia were approached face-to-face for the study at 6 community dental health services, including 2 tertiary pediatric sites across metropolitan, rural, and regional areas. These areas collectively serve a population of approximately 4 million people and cover an area of 155,000 square kilometers. All clinics primarily offer a fee-free dental service for families unable to afford private care, with clinical and preventive care provided based on existing NSW public dental policies [24]. Prior to enrollment, all participants were given access to a participant information and consent form via eConsent through the REDCap platform (Multimedia Appendix 1). Parents of children who met all the following criteria were eligible to participate: (1) a clinical diagnosis of ECC, (2) age of 0 to 6 years inclusive, and (3) awaiting (or having attended) a public NSW dental service for dental caries treatment. Only 1 parent and 1 child per family were recruited. Parents were excluded if they (1) were already participating in an SMS text messaging–based study on lifestyle risk factors for health, (2) did not have proficient English-language skills to provide written informed consent, or (3) were unable to comply with study requirements. Parents of these children must also have basic computer and smartphone literacy and own an operational mobile phone capable of sending and receiving SMS text messages and accessing the internet.

Procedures

Following completion of eConsent (Multimedia Appendix 1) through the REDCap web link provided via their smartphones, general demographic data, including the parent's gender,

XSL•FO
RenderX

ethnicity, country of birth, age category (18-20, 20-25, 26-35, and 36-45 years), and level of education, were collected via self-report. Information on the child's age, number and order of siblings, Socio-Economic Indexes for Areas (SEIFA) rank [25,25] and whether the child had a planned dental procedure requiring GA was also collected from the parent. At the 12-week follow-up, data were collected through an online questionnaire available via the REDCap link that was provided as an SMS text message to the parent at the conclusion of the program. If the questionnaire was not completed, follow-up phone calls were made at the end of the 12 weeks.

Randomization and Blinding

Participants were randomly assigned to either the intervention or control group at a 1:1 allocation ratio stratified by recruitment site (community dental clinics vs tertiary pediatric settings) and modality of care (dental procedures requiring GA vs dental procedures not requiring GA). Randomization was generated and accessed only by the study statistician using the *randomizeR* library in R (version 4.3.2; R Foundation for Statistical Computing) and was based on permuted block sizes (2,4,6) [26]. Clinicians recruited parent participants who self-enrolled in the study, and participants were randomly assigned to the study groups via computer generation and notified via SMS text message. All researchers were blinded as the TextCare system automatically implemented the SMS text messaging program in the intervention arm. Due to the nature of the intervention, participants were not blinded, but dental care providers and those analyzing the data were.

Intervention

The SmilesUp intervention is a 12-week SMS text messaging program co-designed with parents and dental practitioners to target key ECC-related oral health behaviors, including twice-daily toothbrushing with fluoride toothpaste, bedtime routines, and consumption of sugar-sweetened foods and drinks [22]. The intervention aligns with WHO guidance to improve oral health through behavior change and is informed by the behavior change wheel (BCW) theory [27]. The BCW synthesizes 19 major behavior change theories to identify the capabilities, opportunities, and motivations required and the most appropriate intervention functions to support effective behavior change [27]. Messages aimed to improve oral health literacy and self-efficacy and provide brief reminders, reassurance, and links to smartphone-accessible video resources (Multimedia Appendix 2).

Participants directly received 36 semipersonalized messages (3 per week) to their mobile phones, delivered through the TextCare platform via an automated and preprogrammed schedule shaped by consumer engagement. Personalization included the children's names and parents' choice of morning or evening SMS text message delivery. The program was primarily one way but allowed for two-way communication, monitored asynchronously by a clinician researcher. Participants requiring clinical assistance received automated messages that contained the contact details for their nearest NSW public dental clinic or emergency services if the dental concern was urgent. Feedback on the program, including notifications on whether messages were received and read, was monitored asynchronously by a clinician researcher, with additional feedback collected at the 12-week follow-up.

The SmilesUp program was implemented alongside standard clinical dental care. The control group received standard care only, consisting of clinical assessment, treatment, and preventative advice provided by a dental practitioner. After completing the study period, parents in the control group were offered access to the SmilesUp intervention.

Outcomes

The primary outcome was achieving the target behavior of brushing the children's teeth twice a day with fluoride toothpaste. This item was analyzed dichotomously in response to an existing question used by NSW Health to evaluate other oral health programs: "How often do you brush your child's teeth with toothpaste?" [28]. The primary outcome was achieved if participants responded "Twice a day" or "More than twice a day"; all other responses were classified as not meeting the outcome. Secondary outcomes were oral health–promoting behaviors, including use of fluoride toothpaste, reduced sugar-sweetened beverage consumption, reduced sugar-sweetened food consumption, bedtime routines related to the frequency and timing of milk consumption at night, and water consumption. Outcomes were ascertained through parental self-report using a standardized NSW Health questionnaire [28]. All definitions for primary and secondary behavioral outcomes are described in an a priori statistical analysis plan, which can be found in Multimedia Appendix 1.

Additional oral health self-efficacy outcomes were assessed using an adapted questionnaire based on the capability, opportunity, and motivation–behavior (COM-B) framework [29]. These questions were optional to reduce survey fatigue at enrollment. Existing oral health self-efficacy tools primarily focus on oral hygiene and are not typically grounded in behavioral theory [21]. In contrast, the questionnaire used in this study was aligned with the COM-B framework, which also underpinned the co-design of the SmilesUp intervention [22]. This approach was selected because it could be applied to a broad range of oral health–promoting behaviors addressed by the intervention (oral hygiene, diet, and bedtime routines). Accordingly, the questionnaire applied the COM-B framework to each behavior and addressed (1) physical capability, (2) psychological capability (ie, knowledge capability), (3) physical opportunity, (4) social opportunity, (5) reflective motivation, and (6) automatic motivation (Multimedia Appendix 1). Acceptance of the program was also assessed via the number of participants who completed the SmilesUp SMS text messaging intervention [23].

Sample Size Calculation

A sample size of 150 participants provided 80% statistical power to detect a 25% increase in the target toothbrushing behavior in the intervention group from 53% to 78% compared to the control group at 12 weeks considering a 5% significance level and a 25% dropout rate. A cross-sectional study of a similar Australian population accessing public dental services found that 53% of children aged 3 to 8 years brushed their teeth twice a day with toothpaste [30].

XSL•FO
RenderX

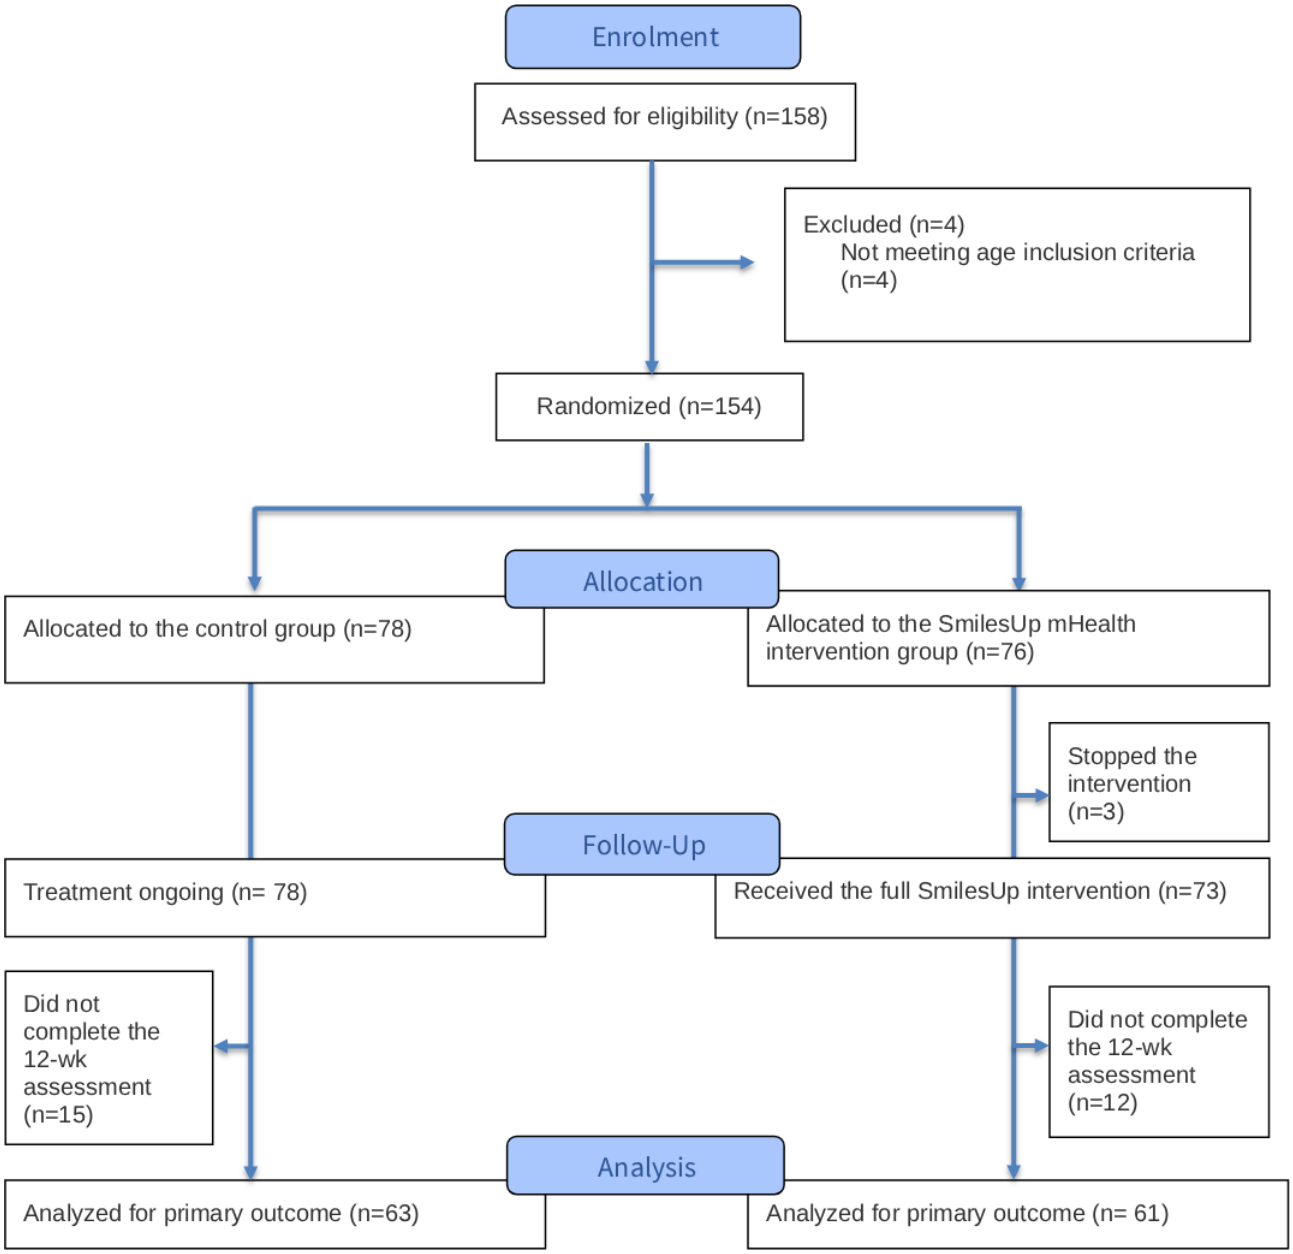
Statistical Analysis

Our statistical analysis followed an intention-to-treat principle and a prespecified statistical analysis plan (Multimedia Appendix 1). To assess the effectiveness of the intervention, a logistic regression model adjusting for whether parents performed toothbrushing for their children twice a day with toothpaste at baseline and the stratification variables was conducted, and adjusted odds ratios (aORs) with 95% CIs were reported. Similarly, all secondary behavioral outcomes were analyzed using the same logistic regression model. A statistical significance level of .05 was used. An interaction analysis of treatment and prespecified covariates (planned dental procedure requiring GA vs non-GA and tertiary vs nontertiary sites) was conducted to explore the heterogeneity of our results. No multiplicity adjustments were performed for secondary outcomes as they were exploratory by nature. If missingness was greater than 5%, missingness at random was assessed using 2-tailed *t* tests or chi-square tests for the relevant covariate. Additionally, a sensitivity analysis was conducted using multivariate imputation by chained equations with 50 imputations. No interim analyses were needed in alignment with stopping guidelines. All analyses were undertaken using R.

Ethical Considerations

This study was conducted in accordance with the principles of the Declaration of Helsinki. The protocol was reviewed and approved by the Western Sydney Local Health District Human Research Ethics Committee (2022/ETH01920). All participants took part voluntarily without compensation and provided written informed consent prior to enrollment, with the ability to opt out at any time. To ensure privacy and confidentiality, all collected data were deidentified. Additionally, the trial was prospectively registered with the Australian New Zealand Clinical Trials Registry (ACTRN12623000325606).

Results



Study Participants

Of the 154 participants who were recruited and randomized in this study between August 24, 2023, and May 10, 2024, a total of 76 (49.4%) in the intervention group and 78 (50.6%) in the control group (n=124, 80.5%) completed follow-up data collection of primary and secondary behavioral outcomes at the end of the 12-week intervention (Figure 1). Additional outcomes focused on oral health literacy and self-efficacy were collected from 66.2% (n=102) of the participants at 12 weeks. Recruitment was completed once the anticipated sample size was reached.

Most parent participants (144/154, 93.5%) were above 25 years of age, 74.0% (114/154) were female, 47.4% (73/154) had completed a university degree, 57.1% (88/154) were born overseas, 18.8% (29/154) used general health apps, and 5.2% (8/154) used oral health apps (Table 1). The mean age of the children was 4.2 (SD 1.7) years, 31.8% (49/154) had a planned dental procedure requiring GA, 83.1% (128/154) had a sibling, 21.4% (33/154) had 4 or more siblings, 33.8% (52/154) had a younger sibling in the family, and 37.7% (58/154) were from lower–socioeconomic status areas as determined via postcodes (Socio-Economic Indexes for Areas 1-3; Table 2).

Primary Outcomes

Of the 76 parents who were randomized to the intervention group, 73 (96.1%) completed the 12-week SmilesUp program. At 12 weeks, 73.8% (45/61) of participants who received the SmilesUp SMS text messaging program reported brushing their children's teeth twice a day compared to 66.7% (42/63) in the control group (aOR 2.45, 95% CI 0.95-6.74; *P*=.07; Table 3). The primary outcome was missing for 19.5% (30/154) and similar in both groups. Examination for bias indicated missingness to be at random (Multimedia Appendix 3). The sensitivity analysis using multiple imputation by chained equations analysis demonstrated that the study groups yielded similar results (aOR 1.93, 95% CI 0.75-4.96; *P*=.17) and was not statistically significant.

Our interaction analysis showed similar intervention effects among families who had or had not undergone a planned dental procedure requiring GA (*P*=.95) and whether families were recruited from tertiary or nontertiary settings (*P*=.12).

Table . Primary and secondary behavioral outcomes.

	Control, n (%)		Intervention, n (%)		aOR[a] (95% CI)	*P* value[b]
	Baseline (n=78)	12 wk (n=63)	Baseline (n=76)	12 wk (n=61)		
Primary outcome						
Met recommended toothbrushing requirements	49 (62.8)	42 (66.7)	43 (56.6)	45 (73.8)	2.45 (0.95-6.74)	.07
Secondary outcomes						
Met recommended fluoride toothpaste use	68 (87.2)	62 (98.4)	62 (81.6)	57 (93.4)	0.27 (0.01-2.18)	.27
Met oral health–promoting bedtime routines	58 (74.4)	45 (71.4)	60 (78.9)	54 (88.5)	3.25 (1.15-10.18)	.03
Met recommended sugar-sweetened beverage consumption	27 (34.6)	27 (42.9)	20 (26.3)	25 (41.0)	1.08 (0.49-2.39)	.85
Met recommended sugar-sweetened food consumption	8 (10.3)	4 (6.3)	7 (9.2)	10 (16.4)	3.72 (1.02-17.14)	.06
Met recommended water consumption	74 (94.9)	57 (90.5)	73 (96.1)	60 (98.4)	6.53 (0.90-139.76)	.11

[a]aOR: adjusted odds ratio.

[b]*P* value using logistic regression adjusting for the corresponding outcome at baseline and stratification variables (general anesthesia [GA] vs non-GA and tertiary vs nontertiary sites).

Secondary Outcomes

For secondary outcomes, intervention participants reported better oral health bedtime routines (54/61, 88.5% vs, 45/63, 71.4%; aOR 3.25, 95% CI 1.15-10.18; *P*=.03). Sugar-sweetened food consumption showed a consistent direction of effect, although it was not statistically significant (aOR 3.72, 95% CI 1.02-17.14; *P*=.06). There was no statistically significant difference between the groups for sugar-sweetened beverage consumption (aOR 1.08, 95% CI 0.49-2.39; *P*=.85), use of fluoride toothpaste (aOR 0.27, 95% CI 0.01-2.18; *P*=.27), or adequate water consumption (aOR 6.53, 95% CI 0.90-139.76; *P*=.11; Table 3).

Oral Health Self-Efficacy Outcomes

Additional outcomes of oral health self-efficacy were reported in a subset of participants in the intervention group (50/102, 49.0%) and the control group (52/102, 51.0%). They were overall suggestive of a pattern of improved self-efficacy, although few measures met statistical significance. A greater percentage of intervention participants reported improved knowledge on how to brush their children's teeth (aOR 5.47, 95% CI 1.48-25.19; *P*=.02) and how to maintain a healthy bedtime routine (aOR 5.76, 95% CI 1.38-32.16; *P*=.03). There was no difference in knowledge on providing healthy drink and snack options (aOR 2.7, 95% CI 0.60-14.97; *P*=.21) or automatic motivation regarding oral health–promoting bedtime routines (aOR 3.01, 95% CI 0.96-10.54; *P*=.07; Table 4).

Discussion

Principal Findings

The SmilesUp trial is the first SMS text messaging randomized controlled clinical trial specific for ECC home management, using the BCW framework [27] tested in an Australian public dental setting. Most participants completed the SmilesUp program, and while the primary outcome (twice-daily brushing) was not statistically significantly different, some secondary outcomes suggested improvements in oral health behaviors and oral health self-efficacy. Together, these findings suggest that the program may have potential benfit if implemented at scale; however, larger and longer confirmatory trials are needed to determine effectiveness over time.

In our sample, 18.8% (29/154) of parents reported using health apps, but only 5.2% (8/154) used oral health apps. This highlights both a gap and an opportunity to design high-quality mHealth oral health programs that respond to growing demand for digital preventive health care [31-33]. No interaction effects were observed among families whose children had a planned dental procedure requiring GA and those children who received care in community dental clinics without a GA. These findings indicate an opportunity to test the effect for families using community dental clinics with and without a GA in a future full-scale RCT and ensure that the study is adequately powered to enable subgroup analyses. Additionally, the intervention was highly acceptable, with a 96.1% (73/76) completion rate, indicating strong feasibility for a future confirmatory trial. Given the growing consumer preference for and acceptance of digital health support, particularly in the post–COVID-19 context [3,34], value-based health care systems should prioritize the integration of effective prevention-focused digital tools into routine health care delivery [31,34].

Comparison With Prior Studies

This trial extends existing evidence in the field by demonstrating that mHealth interventions showed a consistent direction of effect to influence behaviors alongside improved parental knowledge on ECC risk factors. Our findings on parental knowledge are consistent with those of the systematic review by Ajay et al [35] on mHealth interventions targeting ECC risk factors, which showed improvements in oral health knowledge only. Importantly, this study moves beyond knowledge outcomes by providing evidence that mHealth interventions have the potential to affect behavioral outcomes, including oral

XSL•FO
RenderX

health–promoting bedtime routines. Existing peer-reviewed literature demonstrates that changes in these behavioral outcomes are associated with favorable ECC clinical indicators, including the decayed, missing, filled teeth index; caries incidence; and the need for repeat invasive dental treatment [1,5,6].

Strengths

The strengths of this study include its randomized clinical trial design; its evaluation of a broad set of oral health–promoting behavioral outcomes; and its implementation across a diverse participant population in metropolitan, regional, and rural NSW. The findings demonstrate the feasibility of an SMS text messaging–based program irrespective of socioeconomic status, mobile phone type, and geographical location, as well as the low cost of implementation for health services [36]. Importantly, the intervention was co-designed with parents and pre-evaluated for acceptability and usefulness [22], which likely contributed to the high engagement and completion rates. Evaluating the intervention alongside standard clinical care demonstrated the added value of the intervention and highlights the importance of multilevel approaches to support parents in maintaining sustained preventative oral health–promoting behaviors [37].

Limitations

This study has limitations, including a follow-up rate of 80.5% (124/154), although this was balanced between the intervention and control groups [38]. The use of self-reported outcomes may have introduced social desirability bias compared to the use of clinical measures such as plaque scores; however, the randomized design ensured that this was balanced between the groups. The proportion of families reporting the primary outcome (twice-daily toothbrushing) at baseline was higher than anticipated (92/154, 59.7% compared to the anticipated 53%). Despite achieving close to the anticipated target of 78%, the study had limited ability to detect a statistically significant difference. This smaller-than-expected difference reduced the contrast between groups and, consequently, diminished the detectable effect size. Given the suggestions of benefit and low cost of the intervention, larger RCTs powered to detect smaller effect sizes would be justifiable. Recruitment within public dental clinics introduced selection bias; however, the inclusion of participants from diverse settings in metropolitan, regional, and rural areas may also support representativeness for the health system. The high level of missingness could have influenced the results; however, this was accounted for as participant characteristics were similar between groups (Multimedia Appendix 3). In fact, the high completion rate of participants previously not engaged in the target behavior of toothbrushing suggests that the intervention is particularly relevant for those most in need, highlighting potential benefits in health equity (Multimedia Appendix 3). The short follow-up period (12 weeks) limits conclusions regarding long-term behavioral maintenance and related clinical outcomes, highlighting the need for a full-scale RCT [38]. These future studies should explore whether mHealth initiatives such as SmilesUp can be effective in preventing longer-term clinical and service use related to ECC. Recruiting from a larger sample may also enhance the generalizability of these findings.

Future Directions

Clinically, the results of the SmilesUp trial indicate that digital interventions have the potential to improve oral health behaviors and parental self-efficacy, which may translate into reduced ECC outcomes. Compared to traditional chairside advice, mHealth offers a less resource intensive approach that directly supports families in their home settings. The limited effect on some behaviors, including sugar consumption, also highlights the need for multipronged and interdisciplinary collaborative mHealth approaches to address common risk factors [39,40]. From a policy perspective, future efforts should focus on integrating mHealth into value-based, interdisciplinary models of care that recognize preventative behavior change in home settings as a critical component of health care delivery, complementing clinical dental treatment to achieve long-term oral and general health [38].

A process evaluation is also required to inform implementation strategies for scale-up, including culturally appropriate adaptation of the programs and alignment with other interdisciplinary family-focused preventive mHealth programs delivered in primary care settings [41]. Interoperability with electronic oral health records could enhance uptake and data collection to allow health systems to prospectively and longitudinally measure the program's long-term effects, including clinical dental caries measures (decayed, missing, and filled teeth index), service use, and hospital admissions related to ECC [33,38]. Leveraging technologies including AI may further support tailored content delivery [42] and continuous improvement within learning health systems [43]. Future research should examine the impact of scaling mHealth programs that leverage AI on sustained oral health behavior change, long-term effectiveness, and cost-effectiveness.

Conclusions

The SmilesUp mHealth program signals benefits and the potential of mHealth interventions to enhance oral health behaviors and underscores the need for larger studies with longer follow-up to determine the sustainability of behavior change and its translation into clinical outcomes. Future research should also explore optimal strategies for embedding mHealth innovations within broader primary prevention and interdisciplinary primary care frameworks and assess long-term preventative effectiveness and cost-effectiveness when delivered at scale.

Abstract

Background: Delays in completing cancer screening diminish the preventive benefits of early detection, particularly among women receiving care in Federally Qualified Health Centers (FQHCs). Although many patients receive SMS reminders and complete screening, less is known about how quickly they complete testing or which patient-level and structural factors are associated with delays.

Objective: This study examined factors associated with time to cancer screening completion among women aged 50 years or older who received SMS reminders and completed screening across a large FQHC network in Texas. The study also compared time to completion across three cancer screening tests: human papillomavirus (HPV) or the Papanicolaou test (hereinafter “Pap test”), mammography, and the fecal immunochemical test (FIT) or Cologuard screening.

Methods: We conducted a secondary data analysis using electronic health record (EHR) data from a 56-clinic FQHC network in Texas. The initial cohort included 1803 women aged 50 years or older who (1) were overdue for HPV or Pap testing, mammography, or FIT or Cologuard screening, and (2) received at least three SMS reminders. Of those, 551 completed the screening and constituted the analytic cohort for this study. The outcome was the number of days from the initial SMS reminder to documented completion of the overdue screening test in the EHR. Kaplan-Meier methods were used to estimate time to completion by screening modality. A multivariable Cox proportional hazards model assessed associations of screening modality, sociodemographic, and clinical characteristics, and self-reported health-related social needs with the rate of screening completion.

Results: Overall, 40.8% (n=212) of patients overdue for HPV or Pap testing completed their screening, while 21.1% (n=138) of those overdue for mammography and 32.1% (n=201) of those overdue for FIT or Cologuard screening completed their respective screening. Median time to completion was 72.5 (95% CI 64 - 86) days for HPV or Pap screening and 52.0 days for both mammography (95% CI 43 - 64) and FIT or Cologuard screening (95% CI 52 - 53). In the adjusted model, screening completion was faster for FIT or Cologuard screening (hazard ratio [HR] 1.65, 95% CI 1.34 - 2.05) and mammography (HR 1.41, 95% CI 1.11 - 1.78) than for HPV or Pap screening. Patient-reported transportation limitation was associated with slower screening completion (HR 0.74, 95% CI 0.55 - 0.99).

Conclusions: These findings demonstrate meaningful variation in both the completion and timeliness of overdue cancer screening across screening modalities. Although HPV or Pap testing had the highest overall completion rate, time to completion was significantly shorter for mammography and FIT or Cologuard screening. The association between transportation limitations and delayed screening further underscores the influence of access-related barriers on timely preventive care. This suggests that efforts to improve cancer screening should extend beyond patient outreach to incorporate modality-specific strategies and interventions that address structural barriers to screening completion.

Introduction

Routine cancer screening is a significant contributor to the persistent decline in cancer mortality [1]; Federally Qualified Health Centers (FQHCs) provide preventive and primary care to almost 30 million individuals in the United States; yet, preventable cancer screening rates remain significantly lower among patients who receive care in FQHCs than among the general population [2-4]. Past studies comparing rates of cancer screenings have found persistent disparities in FQHC populations, regardless of cancer type including breast (FQHC: 45.4% vs general population: 78.2%), colorectal (FQHC: 40.2% vs general population: 72.3%), or cervical cancer (FQHC: 51.0% vs general population: 82.9%) [3,4]. FQHCs are required to report standardized quality measures, including breast, cervical, and colorectal cancer screening aligned with US Preventive Services Task Force (USPSTF) recommendations, and higher performance on these measures is associated with better preventive care delivery and progress toward national screening goals [5-7]. A growing body of evidence, including past research by our team, suggests that SMS text reminders for FQHC patients overdue for their cancer screenings may be an effective strategy toward reducing this disparity in preventive care [8-10].

Meta-analytic and clinical trial evidence support SMS reminders as a useful nudge that increases screening uptake for cervical, breast, and CRC screening, though absolute effects vary (often ~2 - 5 percentage points in mammography trials and larger in targeted fecal immunochemical test [FIT] programs) [6,7,10-18]. Studies also vary in the type of cancer, addition of phone calls or mailed notices, and message content [6,7,10-18]. Most previous studies have evaluated whether SMS-based interventions increase cancer screening completion. However, less attention has been paid to the timeliness of completion among patients who ultimately complete screening. One prior study in FQHC settings reported median intervals of 72 and 83 days from an abnormal FIT result to follow-up colonoscopy [19], suggesting that substantial delays may persist even among patients who ultimately complete the recommended follow-up. Patients receiving care at FQHCs often face socioeconomic and structural barriers [20] and longer times to screening completion, which may reduce opportunities for timely detection and follow-up and diminish the potential benefits of cancer screening.

Populations served by FQHCs are especially impacted by social determinants of health (SDOH), with common unmet social needs including transportation, food insecurity, and social support contributing to lower cancer screening rates. Individuals who lack reliable transportation are less likely to obtain guideline recommended cancer screenings, with one study reporting 41% lower odds of mammography adherence, independent of other SDOH [21,22]. However, it is unclear to what extent and which specific SDOH may facilitate or act as a barrier to SMS text reminder implementation in safety net populations. Previous studies have shown that time to screening completion varies across patient groups. For example, Vives et al [23] found that used FIT kits were returned sooner by women, older adults, individuals with higher deprivation scores, and those with prior screening experience. Similarly, a recent study found that younger rural adults took longer to return FIT kits, whereas women returned them sooner than men [24]. These findings demonstrate the value of examining time to completion in addition to overall screening completion.

Building on this prior body of evidence, this study examined factors associated with time to cancer screening completion among women aged 50 years or older who received SMS reminders and completed screening within a large FQHC network in Texas. The screening tests included human papillomavirus (HPV) or Papanicolaou testing (hereinafter “Pap testing”), mammography, the FIT, and Cologuard screening. Studies of this nature highlight how screening modality, socioeconomic factors, and health-related social needs may influence delays in completing recommended preventive care.

Methods

Data Source

Secondary electronic health record (EHR) data were obtained from a quality improvement (QI) intervention that examined the impact of SMS text message reminders on cancer screening test completion. The QI intervention was conducted at a large FQHC network in Texas. Because age ranges differ across the three cancer screening modalities, we restricted the analytic sample to women aged 50 years or older who had received at least three reminder SMS messages (three consecutive weeks) to complete any of the following overdue cancer screening tests: (1) HPV or Pap test, (2) mammography, or (3) FIT or Cologuard screening. For FIT and Cologuard screening, the FQHC provided home delivery of the test kits.

Intervention Design and Setting

The QI initiative used SMS messages to contact patients identified through the EHR as overdue for breast, cervical, or colorectal cancer screening. The present study examined the time from the first SMS reminder to EHR-documented completion of the overdue screening test and factors associated with the rate of completion. The rolling intervention was implemented from May 2023 through June 2024. The unit of analysis was the screening episode. Approximately 5% of patients were eligible for two screening modalities and could therefore contribute one observation to each relevant modality-specific analysis.

Participants and Eligibility

Patients were eligible for our analysis if they were (1) female and aged 50 years or older at the time of the first SMS reminder, (2) overdue for HPV or Pap testing, mammography, or FIT or Cologuard screening as of May 2023, (3) received at least three SMS reminders related to the overdue test, and (4) subsequently completed the corresponding screening test. Patients whose screening had been completed before the initial SMS reminder were excluded. Because this study focused on the timeliness of screening completion among patients who received the intervention messages and subsequently completed screening, we excluded patients in the control group, those who did not complete screening, and those who opted out.

XSL•FO
RenderX

The QI Intervention

During the intervention period, the FQHCs implemented an SMS text messaging reminder initiative for eligible female patients who were overdue for cancer screening. SMS messages were sent in English and Spanish and tailored to the cancer screening test for which the patient was overdue. The intervention messages were tailored to each patient's cancer test type: colorectal, breast, or cervical cancer screening. Patients received between 3 and 16 messages during the intervention period. The timing and frequency of messages varied across weeks and intervention pathways. Messages were generally sent between 9 AM and 11:30 AM Central Time, most often on Tuesdays through Fridays. Most messages were interactive, allowing patients to respond directly to the SMS messages or click embedded links to watch a short video, or to access additional information and scheduling resources. Some messages provided information about cancer screening tests, some included links to schedule cancer screening appointments, and some provided educational links about the benefits of screening and the risks of not completing screening.

Examples of the breast messages included, "Dense breasts have more fibrous tissue than fat. It is harder to spot cancer in dense breasts on a mammogram. If your mammogram shows dense breasts, you might be asked to get an ultrasound or MRI for a better view. Do it! Learn more: https://msg.care/8SSoY."

Another example was, "Hi %{patient_first_name}! %{provider_short_name} reminds you that you are due for a mammogram This is an important screening test for breast cancer. Call us at ###-###-#### to schedule."

Outcome and Follow-Up

The event was completion of the screening test for which the patient was overdue, as documented in the EHR. Time to completion was calculated as the number of days from the date of the first SMS reminder to the date of documented test completion. Patients without documented screening completion or who opted out were excluded from this analysis. The latest EHR observation date available in our dataset was July 2024, and the maximum observed time to completion was 249 days. Information on death, transfer of care, and screening completed outside the FQHC network was not consistently available and therefore could not be incorporated.

Covariates

Covariates were selected a priori based on their plausible relationships with access to, and completion of, preventive screening. EHR-derived variables included age at the first SMS reminder, insurance status, primary language, race and ethnicity, completion of an annual wellness visit during the preceding (12 mo per calendar year), BMI category, and documented histories of depression, hypertension, diabetes, and family history of cancer.

Age was categorized as 50 - 54, 55 - 59, 60 - 64, or 65 years or older. Insurance was categorized as uninsured, private insurance, Medicaid, or Medicare. Primary language was categorized as English, or Spanish or another language. Race and ethnicity were categorized as non-Hispanic White, non-Hispanic Black, Hispanic, or another race or multiple races and ethnicities. Overweight or obesity was defined as a BMI of ≥25 kg/m². Health-related social needs (HRSN) were obtained from patients' responses to the program's routine screening questionnaire and included social isolation, food insecurity, housing insecurity, and transportation limitations. Each measure was coded as positive or negative. The most recent response recorded before the first SMS reminder was used.

Missing Data

EHR-derived demographic and clinical covariates were complete in the source data. Missingness was present in the self-reported HRSN measures: 50% for food insecurity, 50% for housing insecurity, 44% for transportation limitations, and 43% for social isolation. No values were imputed. We compared demographic characteristics between observations included in and excluded from the complete-case analysis and found no substantial differences between the groups.

Statistical Analysis

We first summarized the characteristics of the study population using descriptive statistics. The time-to-event outcome, defined as the number of days from the start of the intervention to screening completion, was visualized using Kaplan-Meier curves. We plotted stratified curves for each cancer screening test type to visually compare completion trends. The proportional hazards assumption was assessed using Schoenfeld residuals, and no violations were detected (all P values were >.05). Subsequently, a Cox proportional hazards model was applied to quantify the associations between time to screening completion and the independent variables among patients who completed screening [25]. Hazard ratios (HRs) and their 95% CIs were derived by exponentiating the model coefficients. We also computed multicollinearity using variance inflation factors (VIFs) to ensure model stability. All analyses were performed using R (version 4.4.2) in RStudio (Posit, PBC), using the survival package. All tests were 2-sided with a significance level of P<.05.

Ethical Considerations

The University of Houston's Institutional Review Board reviewed and approved this secondary analysis of EHR data (STUDY00004081). The board approved waivers of informed consent because the study used existing clinical and QI data and involved no additional participant contact. The analytic dataset was deidentified before sharing with the research team for analysis and was stored on access-controlled institutional systems. Patients received no compensation for their inclusion in this secondary data analysis. This manuscript was prepared in accordance with STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) guidelines for cohort studies.

Results

Table S1 in Multimedia Appendix 1 shows screening completion rates overall and by screening type. The total sample of patients who received SMS reminders included 1803 individuals. In the HPV or Pap test group, 212 (40.38%) patients completed screening, while 313 (59.62%) did not complete screening. In

XSL•FO
RenderX

the mammography group, 138 (21.10%) patients completed screening, while 516 (78.90%) did not complete screening. In the FIT or Cologuard screening group, 201 (32.21%) patients completed screening, while 423 (67.79%) did not complete screening. Overall, 551 (30.56%) patients completed screening, and 1252 (69.44%) did not complete screening. Table 1 presents the descriptive statistics of the study sample. Among participants who completed a cancer screening test, 38.48% (n=212) were in the HPV or Pap test group, 25.05% (n=138) in the mammogram group, and 36.47% (n=201) in the FIT or Cologuard screening group. Regarding age group, 26.32% (n=145) of participants who completed a test were aged 50 - 54 years, 26.68% (n=147) were aged 55 - 59 years, 24.32% (n=134) were aged 60 - 64 years, and 22.68% (n=125) were aged 65 years or older. The proportion of participants whose primary language was English was 53.36% (n=294). In terms of insurance coverage, 52.63% (n=290) of patients were uninsured, 28.86% (n=159) had private insurance, 4.72% (n=26) had Medicaid, and 13.79% (n=76) had Medicare. Over half of the participants were Hispanic (n=302, 54.81%), 24.32% (n=134) were non-Hispanic White, 9.07% (n=50) were Black/African American, and 11.80% (n=65) were of other races (Asian, bi- or multiracial, and other racial categories). Regarding health-related variables, 25.41% (n=140) of participants had depressive disorder, 59.17% (n=326) had hypertension, 88.75% (n=489) had overweight or obesity, 34.48% (n=190) had diabetes, 7.80% (n=43) had a family history of cancer, and 21.78% (n=120) had a wellness visit in 2022. Additionally, 12.52% (n=69) of patients reported social isolation, 4.90% (n=27) reported having food insecurity, 13.79% (n=76) reported having housing insecurity, and 9.98% (n=55) had transportation limitations.

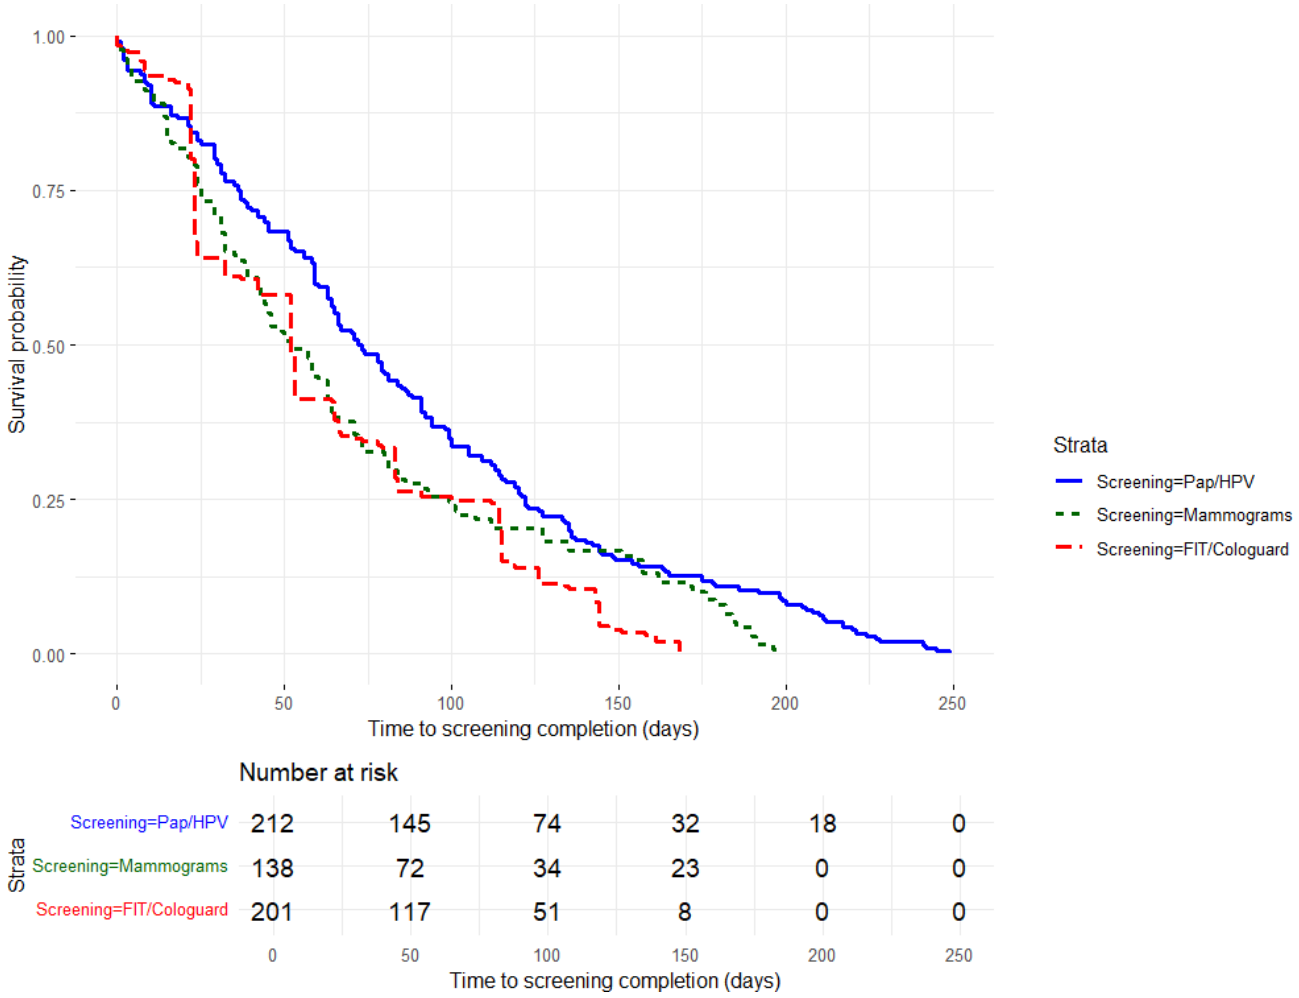
[a]HPV: human papillomavirus.

[b]Pap: Papanicolaou.

Table 2 shows the median survival times by type of cancer screening. The median survival times for the overall cohort, HPV or Pap testing, mammography, and FIT or Cologuard screening groups, were 59.0 (95% CI 53 - 65), 72.5 (95% CI 64 - 86), 52.0 (95% CI 43 - 64), and 52.0 (95% CI 52 - 53) days, respectively. Figure 1 shows Kaplan-Meier curves for time to cancer screening completion by type of cancer screening. Higher survival probabilities indicate a greater proportion of patients who had not yet completed screening at a given time point (ie, slower completion). The HPV or Pap testing cohort showed the highest survival probabilities, suggesting the slowest completion of follow-up. For the overall cohort, the completion period ranged from 0 to 248 days; for the FIT or Cologuard screening cohort, from 0 to 168 days; for the mammography cohort, from 0 to 248 days; and for the HPV or Pap testing cohort, from 0 to 248 days.

Table . Median survival times by cancer screening type.

Test	Events, n	Survival time (days), median (95% CI)
Overall	551	59.0 (53-65)
HPV[a] or Pap[b]	212	72.5 (64-86)
Mammography	138	52.0 (43-64)
FIT[c] or Cologuard screening	201	52.0 (52-53)



[a]HPV: human papillomavirus.

Figure 1. Survival probability by cancer screening type. FIT: fecal immunochemical test; HPV: human papillomavirus; Pap: Papanicolaou.

Finally, Table 3 presents the results of the Cox proportional hazards model. The model demonstrated no evidence of problematic multicollinearity (all VIFs<5). Compared to patients who were overdue for HPV or Pap screening, those in the FIT or Cologuard screening group (HR 1.65, 95% CI 1.34 - 2.05; *P*<.001) and the mammography group (HR 1.41, 95% CI 1.11 - 1.78; *P*<.001) had significantly shorter times to screening completion. Screening positive for transportation as a social need was associated with delayed screening completion (HR 0.74, 95% CI 0.55 - 0.99; *P*=.045).

Discussion

Principal Findings

In this study of women aged 50 years or older who completed cancer screening after receiving SMS reminders within a large FQHC network, we observed notable differences in the timeliness of screening completion across screening modalities. Compared to the HPV or Pap testing cohort, patients exhibited shorter times to screening completion for breast and colorectal cancer screening tests. Importantly, screening positive for transportation as a social need was associated with delayed screening completion, suggesting that transportation barriers may be an important factor related to timely preventive care. These findings suggest that social needs and screening modality may jointly contribute to suboptimal preventive cancer screening behaviors.

Although patients received similar intervention messages for breast, cervical, and colorectal cancer screening, the time required to complete screening differed across the three screening modalities. The finding of faster time to screening for FIT or Cologuard screening and mammography completion, compared to HPV or Pap testing, is noteworthy, and aligns with prior research elucidating variations in barriers to cancer screening across multiple sites [26,27]. Thus, our study findings may be reflective of these variations. The ability to complete FIT and Cologuard screening tests at home and return them by mail may reduce barriers such as scheduling conflicts, transportation challenges, and time constraints. The longer time to HPV or Pap testing completion may be attributable to delays in obtaining appointments with primary care providers or gynecologists, which may exceed wait times for mammography services. These differences and perceived burden may explain the shorter completion time we observed among patients assigned to the HPV or Pap testing intervention. Augmenting text message reminders with patient navigation to assist with identifying and addressing barriers to screening could reduce time to screening [28].

The observed association between transportation challenges and delayed screening completion has practical implications. Individuals may face transportation challenges due to transportation costs or difficulty navigating public transit [29,30]. This insight offers an actionable strategy for improving screening completion rates, especially among FQHC patients, and potentially reducing cancer outcomes disparities. For example, others have explored the use of mobile mammograms [31], in partnership with community stakeholders, to provide mammograms within the community and reduce transportation-related challenges. Additionally, strategies such as ride-share programs and insurance-covered transportation, which have been used to address transportation barriers to cancer treatment, may also offer an effective approach to addressing similar screening barriers [32-34]. For patients who ultimately complete screening, transportation assistance may reduce delays and facilitate more timely completion.

Limitations and Strengths

This study is not without limitations. First, due to the focus on one FQHC network in Texas and the inclusion of only women aged 50 years and older, the generalizability of the findings may be limited. Second, because patient-level information on death, transfer of care, loss to follow-up, and the end of observation was unavailable, censoring could not be reliably defined for patients without documented screening completion. This analysis was restricted to patients with valid documented completion dates. Accordingly, the findings represent associations among screening completers and should not be interpreted as factors associated with whether screening was completed or generalized to patients who did not complete screening or opted out. The study, however, focuses on patients in an FQHC population

XSL•FO
RenderX

who received SMS reminders and completed screening, allowing us to identify factors associated with faster or delayed completion among eventual completers. Third, there are other contextual factors, such as clinic-level workflows, provider recommendation patterns, and individual health beliefs, which may influence time to screening completion that are not captured in this study.

Additionally, our analysis treated each data point as independent. In reality, some individuals were likely eligible for more than one type of screening test, introducing potential correlation across observations. Still, because the study examined completion of each screening test separately, this limitation is unlikely to meaningfully affect the findings. Furthermore, HRSN variables relied on self-reported information, which may be subject to missingness or reporting bias. Patients with missing HRSN values were excluded from the analysis, which may have reduced the analytic sample size and introduced potential selection bias if those patients differed from those with complete HRSN data. Finally, due to data limitations, we were unable to control for other potential barriers to screening, such as scheduling conflicts, fear, anxiety, or preferred language other than English, which may have resulted in residual confounding.

Despite these limitations, this study has several strengths. First, our focus on patients served by FQHCs adds to the literature, given their lower screening uptake and longer time to screening completion than those of the general population. Second, our comparison of multiple screening modalities provides stakeholders with insights into differences in completion time and identifies which screening pathways may require more time or additional support for these three common cancers. Third, our inclusion of demographic, social needs, and health-related factors increases the robustness of the findings. Fourth, identifying transportation as a barrier highlights a clear and actionable target for interventions aimed at promoting timely completion of recommended cancer screening.

Conclusions

In closing, our findings show that the same SMS reminder intervention have varied effects across cancer screening modalities, suggesting that additional demands, such as structural barriers faced by underserved patients, influence timely cancer completion. Although all patients in this study ultimately completed screening, transportation challenges were associated with delayed completion, reinforcing the need for targeted transportation support in FQHC settings. These findings suggest that SMS reminders alone may be insufficient to address structural barriers. Efforts to reduce these barriers may promote faster screening completion, enhance the effectiveness of SMS-based interventions, and help reduce inequities in cancer prevention outcomes.

Abstract

Background: Smoking is a leading cause of mortality and morbidity worldwide. Efforts to reduce smoking prevalence have used SMS text message–based interventions, which typically send participants a series of short, informational, motivational, and practical messages over a set period. Evidence highlights the efficacy of using this approach to support smoking cessation, with such trials typically reporting the average treatment effects, in which causal inference is made regarding the average effect of a treatment on a heterogeneous sample. Nonetheless, using this approach to assessing treatment effects means we are unable to account for individual factors that impact the effectiveness of a treatment on outcomes, such as age, gender, and genetics.

Objective: This study aimed to estimate the individualized effects of an SMS text message–based smoking cessation intervention to ascertain which individuals benefited the most and least during an effectiveness trial.

Methods: Data from a randomized controlled trial including 1012 adults from the Swedish general population were used. The trial assessed the effects of an SMS text message–based intervention, NEXit (Nicotine Exit), that aimed to change behavior by increasing the importance of change, boosting knowledge on how to change, and instilling confidence for change. Outcomes assessed in the trial were prolonged abstinence and point prevalence of smoking cessation. Individualized treatment effects were modeled using baseline factors (demographics, psychosocial variables, and past behavior) to study who benefited the most and least from the intervention.

Results: For prolonged abstinence, there was evidence of heterogeneous effects, with those benefiting the most from NEXit being older adults, female participants, individuals with high confidence in their ability to quit, and those who believed that quitting was important. For point prevalence abstinence, older individuals and those reporting high confidence in the ability to quit, the importance of quitting, and knowledge for change benefited the most. For both outcomes, individuals who reported smoking for a longer duration and smoking more at baseline benefited less.

Conclusions: The results demonstrate how individuals respond differently to an SMS text message–based smoking cessation intervention. This provides an insight into who benefits the most and least from the intervention in terms of demographics, baseline characteristics, and behaviors. The study highlights which individuals need to be specifically targeted and/or have content developed to suit their individual needs to further reduce the prevalence of smoking.

Introduction

Smoking remains a leading cause of morbidity and mortality across the globe, with recent figures highlighting approximately 8 million deaths worldwide and 200 million disability-adjusted life years attributed to smoking [1,2]. In Sweden, the prevalence of smoking within the general population has consistently decreased over the last 2 decades, with the Public Health Agency of Sweden reporting that prevalence rates dropped to 6% for women and 5% for men in 2022 [3]. Despite this, smoking remains a leading cause of mortality and morbidity within Sweden [4] and is more prevalent in groups with lower

XSL•FO
RenderX

socioeconomic status [5]. To stem the associated morbidity and mortality and reduce health inequalities, effective interventions aimed at reducing the prevalence of smoking within the general population are needed.

Current efforts to reduce smoking prevalence have used SMS text message–based interventions, which typically comprised a series of short messages sent to participants over a designated time period (usually 2-3 mo) [6,7]. The aim of these interventions is to provide motivation to quit, support for quitting, and reinforcement of the decision to quit [7]. A series of meta-analyses have highlighted the effectiveness of SMS text message–based smoking cessation interventions, and all concluded positive effects were observed for both self-reported and biochemically verified abstinence [6-10].

In Sweden, a recent randomized controlled trial (RCT) estimated the effectiveness of receiving a SMS text message–based smoking cessation intervention against existing public support (ie, referral to the national Quitline and website, slutarokalinjen.se) [11]. The trial targeted the general population using the NEXit (Nicotine Exit) protocol [12]. Effect estimates were made at 3 and 6 months post randomization for both prolonged abstinence (ie, the Russell standard definition of not having smoked more than 5 cigarettes in the past 8 wk) and point prevalence of abstinence. At 3 months post randomization, the odds ratio (OR) of prolonged abstinence was 2.15 (95% compatibility interval [CoI] 1.51-3.06), and at 6 months, the OR of prolonged abstinence was 2.38 (95% CoI 1.62-3.57). For point prevalence of abstinence, the OR at 3 months was 1.70 (95% CoI 1.18-2.44), and at 6 months, it was 1.49 (95% CoI 1.03-2.14).

While the findings suggest the intervention is effective for smoking cessation, the results of the RCT were assessed at the group level, meaning we are unable to account for how individual differences impact outcomes. This is pertinent, as not everyone in the intervention group successfully quit smoking, meaning that some individuals benefited more from the intervention than others. Individual differences in terms of fixed (eg, age, ethnicity, gender) and modifiable (eg, socioeconomic status, psychological) health factors have been shown to impact abstinence rates [13-16], which can potentially account for why some individuals benefit more from treatment than others.

Currently, Sweden has a national target of becoming a “smoke-free” state (ie, <5% prevalence in the general population) [17]. To achieve this target, smoking cessation support such as the NEXit protocol needs to become specifically targeted to those who continue to smoke tobacco despite policy measures and interventions. The aim of this study is to ascertain who benefited the most and least in the recent NEXit trial [11] through a secondary analysis of the group-level data, which estimated the average treatment effect of NEXit in the Swedish general population. We aim to achieve this by assessing how baseline factors influence outcomes of the trial at the individual level.

Methods

Study Design

The current study investigated the individualized effects of the NEXit protocol using data from a 2-arm, parallel-group (1:1) RCT. The trial was registered in the ISRCTN registry on December 3, 2020 (ISRCTN13455271), and a protocol and an analysis plan were published prospectively [12].

Participants and Settings

A total of 1012 participants from the Swedish general public were recruited from 2 settings: (1) online advertisements, in which individuals clicked on a link that took them to an information page with instructions for signing up, and (2) primary health care units in southern Sweden, which used printed media (leaflets and posters) containing instructions for signing up. Individuals were required to be aged 18 years or older, have access to a mobile phone, and smoke at least one cigarette per week to participate in the trial. Regardless of medium, those interested in participating sent an SMS text message to a dedicated number and received a reply within 5 minutes with a link to the study information and the informed consent form. After providing consent, participants were asked to complete a baseline survey, which was used to assess eligibility. Immediately afterward, eligible participants were randomly assigned to 1 of 2 study groups.

Ethical Considerations

The trial received ethical approval from the Swedish Ethical Review Authority on June 16, 2020 (Dnr 2020 - 01427). Participants provided informed consent prior to the commencement of the main trial, which included consent for their deidentified data to be analyzed and published. Trial data are deidentified, and participants in the main trial did not receive compensation.

Interventions

Both the control and intervention groups were offered treatment as usual and were thus not prohibited from using publicly available smoking cessation support aids. Treatment as usual was referral to a national smoking cessation helpline and website; those recruited from primary care units also had the option of meeting with a nurse or smoking cessation counselor. Additionally, participants in the intervention group were given access to the NEXit SMS text messaging intervention. The intervention had 2 fairly similar versions: a general version and a version for those undergoing elective surgery (within 3 mo of signing up). The intervention consists of a 1- to 4-week motivational phase in which participants were encouraged to set a date on which to quit, followed by a 12-week program consisting of 157 cessation support messages. Messages were typically informational and encouraging, and they provided tips and techniques for creating a smoke-free environment and lifestyle. These included distraction techniques, tips to avoid weight gain, tips to cope with cravings, tips on how to avoid triggers, tips to self-regulate, and practical tips to help restructure the physical environment. The design of the messages was informed by intervention mapping [18] and the behavior change wheel [19], with various behavior change techniques being

XSL•FO
RenderX

utilized, including 1.2 problem solving, 1.4 action planning, 5.1 information about health consequences, 5.2 salience of consequences, 8.2 behavioral substitution, 8.4 habit reversal, 9.1 credible source, 10.9 self-reward, 12 restricting the physical environment, 12.3 avoidance to cues, and 12.4 distraction. Messages were sent daily to participants, and the elective surgery version contained additional messages regarding the impact of smoking on surgery and recovery. Participants could also text and request additional support if they had relapsed or were experiencing cravings.

Outcomes and Measures

The primary outcomes of the trial were assessed at 3 and 6 months post randomization:

1. Prolonged abstinence, using the Russell standard definition of not having smoked more than 5 cigarettes in the past 8 weeks at the 3-month follow-up and in the past 5 months at the 6-month follow-up
2. Point prevalence, defined as not smoking any cigarettes during the past 4 weeks at both follow-up intervals

Baseline factors assessed in this secondary analysis of individualized effects include factors that are associated with cessation, including demographics (age and gender) and smoking behaviors (number of years smoking, amount of cigarettes smoked per week, use of snus [akin to snuff tobacco], number of past quit attempts, and nicotine dependence score using the Fagerström scale, which uses 6 items to assess intensity of physical addiction, including quantity and frequency of smoking) [13,20-24]. The recruitment setting (online or primary care unit) and whether participants were undergoing elective surgery were also assessed. Psychosocial variables (importance of quitting, confidence in the ability to quit, and knowledge on how to quit) were assessed. These factors are reflective of the behavioral and control beliefs that drive behavior, as outlined in expectancy-value models of health [25,26]. Extant literature highlights that the demographic factors (age and gender) are associated with other baseline factors used in our modeling [13,20-22].

Randomization and Blinding

Randomization was completed using a computer-generated random sequence, stratified according to which version of the intervention was appropriate (general or surgery). Block randomization, using block sizes of 2 and 4, ensured equal numbers of participants were allocated to the groups. Participants received notification of group allocation via SMS text message. Research personnel were blinded to allocation, and all procedures of the study were automated, except follow-up calls to nonresponders. For a full description of all study procedures, see Bendtsen et al [12].

Statistical Model

The observed outcome (Y) was modeled as a function of group allocation (G) and baseline variables (X) to estimate the individualized treatment effect $\delta(xi)=P(Yi|G=1,X=xi)-P(Yi=|G=0,X=xi)$, following the approach by Hoogland et al [27]. Here, δxi represents the difference between the predicted probability of smoking cessation (Yi) for an individual (i) with baseline factors xi, if they had access to the intervention (G=1) versus if they did not (G=0). Individualized treatment effects were modeled for each participant as a function of baseline factors to study which individuals had the most and least benefit from the intervention.

Smoking cessation outcomes at 3 and 6 months post randomization were modeled using multilevel logistic regression with a time-by-group interaction term. Available data were used to estimate the model and predict outcomes for all randomized participants. The models included participant-level adaptive intercepts, covariates for baseline factors, and interactions between baseline factors and group allocation. Bayesian inference was used to estimate the parameters of the models [28]. To promote parsimonious models, priors that shrunk estimates toward the null for baseline factor interaction coefficients were used, specifically Cauchy priors centered at the null with a standard normal hyperprior for the scale parameter [28]. We used Student t test priors centered at 0, with 3 df and a scale of 2.5 for noninteraction coefficients and standard normal priors for adaptive and fixed intercepts. Individualized treatment effects were calculated from posterior predictive draws, resulting in posterior distributions over treatment effects for each individual. Medians of these posterior distributions were used as point estimates of δxi.

Linear regression was used to study associations between standardized estimated individualized effects and baseline factors. Student t test priors centered at 0 with 3 df and a scale of 2.5 for all coefficients in these models. Medians of posterior distributions of covariates were used as point estimates and created 95% CoI using the 2.5 and 97.5 percentiles of the posterior distributions. Estimation was done using CmdStan version 2.33.0 (Stan Project), which is a shell interface for Stan [29]. Plots were generated using the ggplot2 library in R.

Results

Participant Retention and Missing Data

Table 1 presents baseline factors for the 1012 participants recruited to the trial. At the 3-month follow-up interval, data were available for 66% of participants in the intervention group and 69% of participants in the control group. The corresponding proportions for the 6-month interval were 64% for both groups. These data were used to estimate the multilevel logistic regression models, which were subsequently used to estimate individualized treatment effects for all randomized participants. As reported in the primary findings of the trial [11], there was evidence that older participants were more likely to respond to follow-up at the 6-month interval, but no other associations were found between response and baseline factors. The CONSORT (Consolidated Standards of Reporting Trials) flowchart and checklist are presented in Figure 1 and Checklist 1.

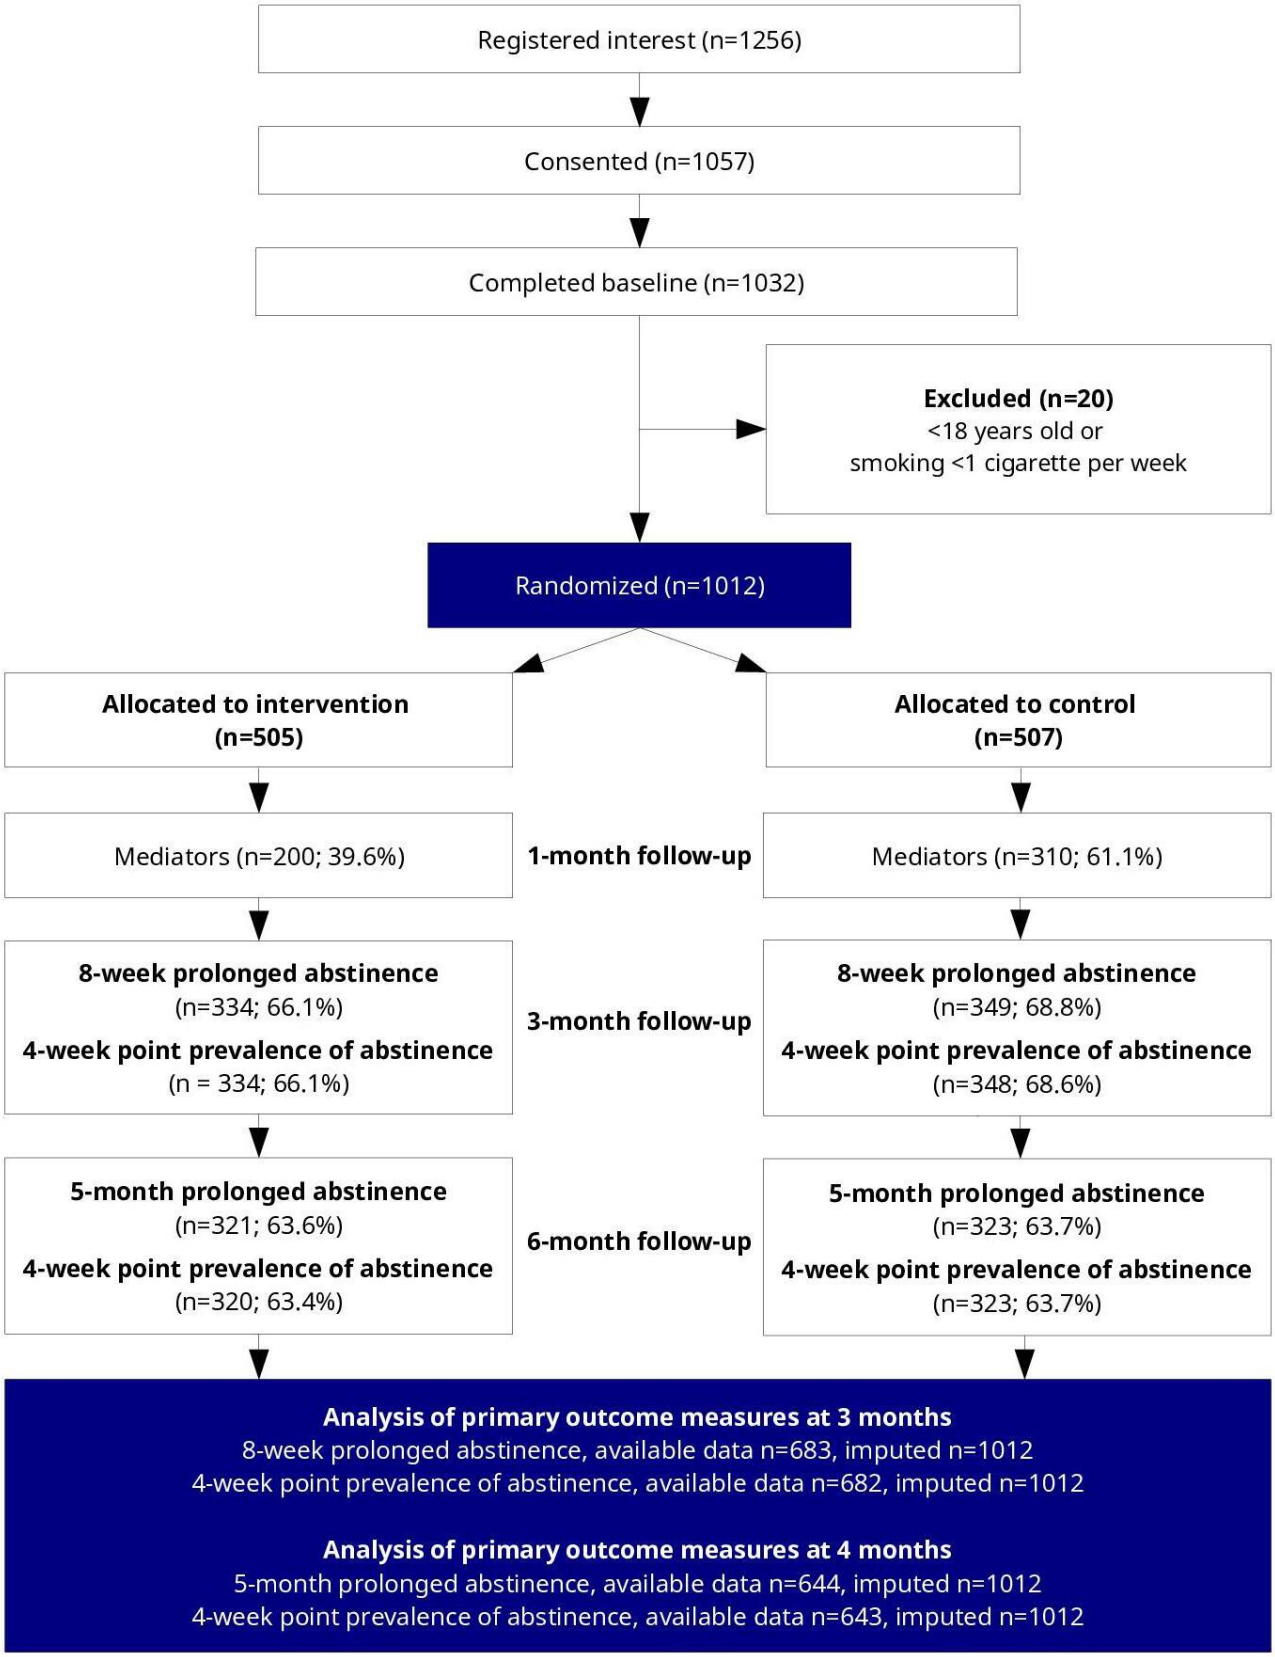
Elective surgery[e], n (%)	63 (6.2)	31 (6.1)	32 (6.3)

[a]The baseline questionnaire included a category “Other”; however, it was not chosen by any participant.

[b]Snus is a moist oral tobacco product, which is common in Sweden, sometimes translated as snuff.



[c]Participants were asked about the lifetime number of quit attempts.

[d]Three single-item measures were used to assess the importance, confidence, and know-how regarding smoking cessation. Responses ranged from 0 to 10, with 10 representing the highest agreement (ie, very important, very confident, very knowledgeable). The same items were used at follow-up as hypothesized mediators of effects.

[e]Participants self-reporting that they had planned elective surgery received additional intervention materials regarding smoking and surgery.

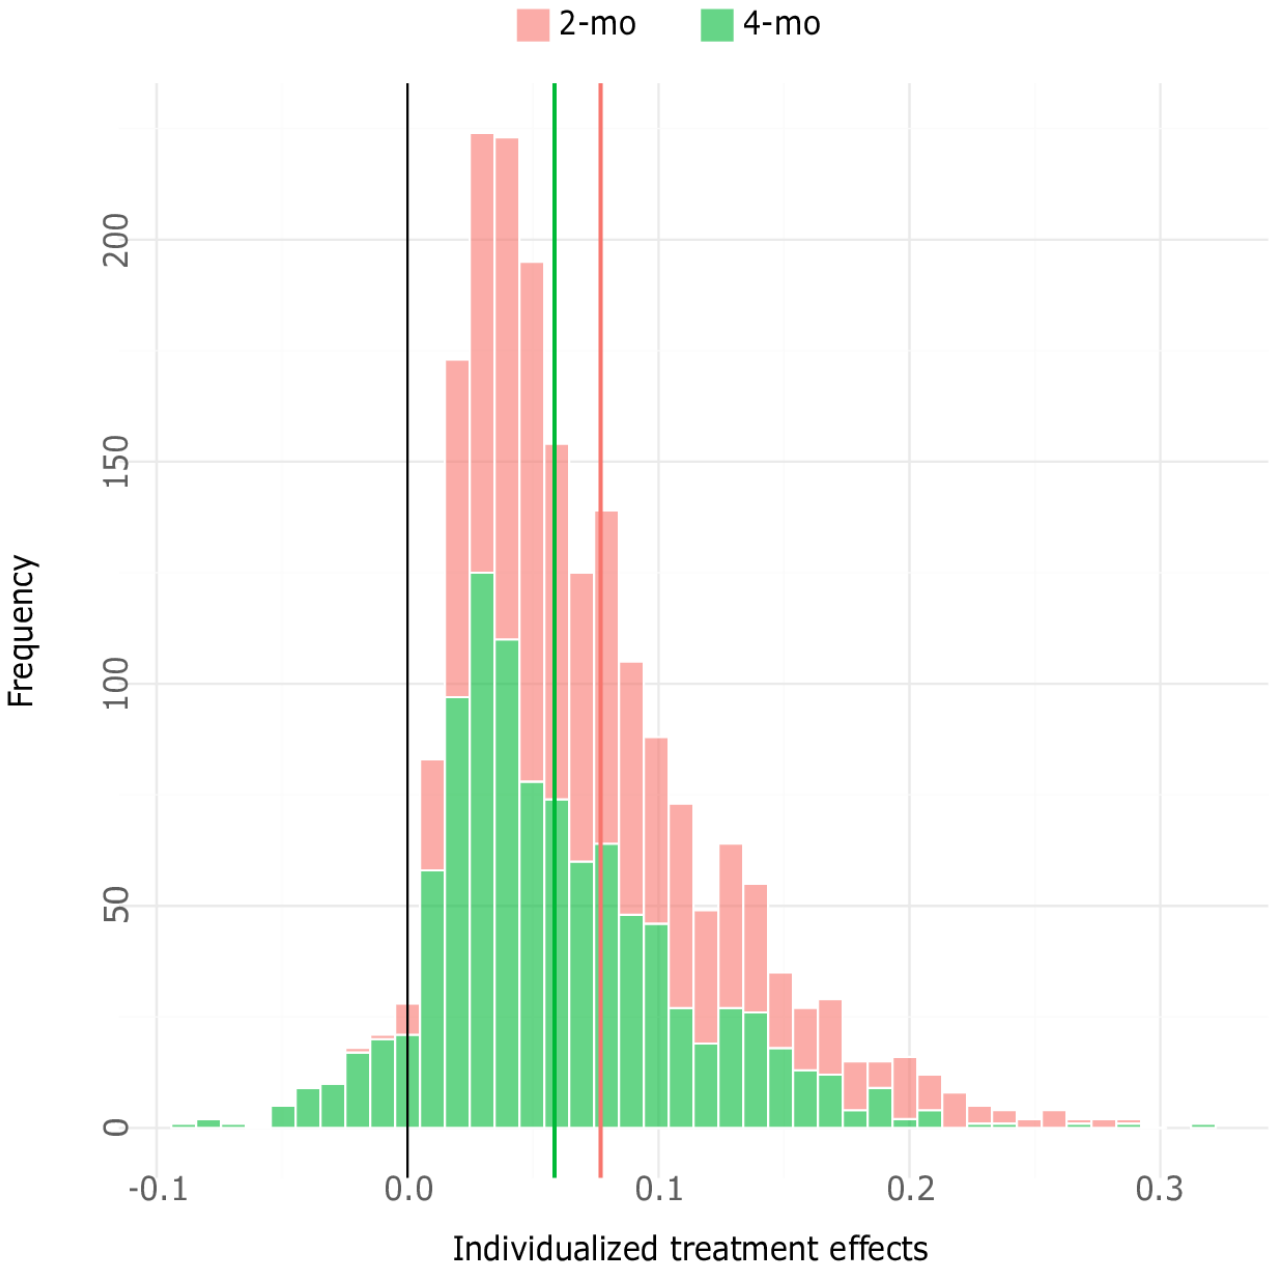
Baseline Factors and Individualized Treatment Effects

In Figure 2, the distribution of effects for 8-week or 5-month abstinence is presented for both the 3- and 6-month follow-up intervals, and Figure 3 provides the distribution of effects for point prevalence abstinence for both follow-ups. The figures show the effects of NEXit at the individual level, expressed as differences in probability (percentage points) of smoking cessation between having received the intervention and the control. From the figures, it is evident that most participants were predicted to benefit from the intervention; however, more

XSL•FO
RenderX



so in terms of prolonged abstinence at the 6-month follow-up interval. The mean individualized effect for point prevalence at the 3-month interval was 3.9 (SD 5.3) percentage points and 2.7 (SD 3.9) percentage points at the 6-month interval. For prolonged abstinence, the mean individualized effect was 7.5 (SD 8.5) percentage points at 3 months and 7.8 (SD 10.7) percentage points at 6 months. This indicates that the intervention was most effective in producing prolonged abstinence, but more importantly, that individualized effects were overdispersed and showed heterogeneity of effects in the population.

Figure 3. Distribution of effects for point prevalence abstinence.

Prolonged Abstinence

In Table 2, associations between baseline factors and standardized individualized treatment effects on prolonged abstinence are presented for both follow-up intervals. For both time points (3 and 6 mo), there was marked evidence for positive associations between individualized effects and gender, age, importance, and confidence. Meanwhile, there was marked evidence for negative associations between individualized effect and number of cigarettes smoked at baseline and years of smoking. Associations between individualized effects and recruitment setting, and past professional cessation support, were found for the 6-month follow-up period.

Interactions

To assess whether the heterogeneous main associations for age and gender were qualified by interactions, models with added interaction terms were estimated. The only interaction for which there was marked evidence was between gender and importance to quit smoking, which was associated with individualized effects of the intervention on prolonged abstinence. This suggests that the main association of gender for this outcome was accounted for by its interaction with importance. Please see Table 4 for estimates of the interaction and Figure 4 for plots illustrating these interactions.

Discussion

Age

The current study assessed the individualized treatment effects of the recent NEXit SMS text message–based intervention [11]. We found an association between age and individualized effects (ie, as age increases beyond the mean value), with older participants benefiting more than younger participants for both prolonged and point prevalence abstinence. This finding contrasts with evidence comparing effects across trials, which highlights that effective interventions for the adult population in general have similar effects for younger adults [30]. This disparity may be a result of the content of the intervention, which specifically focused on support to restructure the physical environment rather than support for the social environment. This is important, as younger adults have a high prevalence of social smoking [20], which may account for this effect. Future interventions for this subsample could include aspects targeting social factors. Nonetheless, evidence also highlights that younger adults are more likely to initiate cessation compared to older adults and smoke less heavily [13,20]; therefore, the results of the current analysis are encouraging, as they suggest that the subsample who are less likely to quit and who smoke more benefit the most from NEXit. The results also suggest that older adults in Sweden are willing to engage with digital health interventions. This finding contrasts with evidence that suggests a "digital divide" exists between older and younger adults in terms of acceptance and uptake of digital health interventions [31]. The current findings suggest that SMS text message–based interventions may be particularly apt for older adults.

Confidence and Know-How

Baseline confidence was associated with individualized effects for both prolonged and point prevalence abstinence, suggesting that those who had greater confidence in their ability to quit benefited more from NEXit. This finding supports extant literature that highlights higher rates of self-efficacy (ie, confidence) are associated with a greater likelihood of successful smoking cessation [32-34]. The results for know-how varied, with no association found for the first time point for both prolonged and point prevalence abstinence; however, an association was found at the second time point for both outcome measures, with those displaying a higher rating of know-how benefiting more. It may be the case that participants had been lacking knowledge on how to quit and maintain abstinence over a short period of time, while they may have had knowledge on how to sustain abstinence over a longer period. This suggests that NEXit may be beneficial to those who are unsure of how to initially stop smoking and maintain the initial phase of abstinence.

Gender

Associations between both importance and gender with individualized effects were found, with those who deemed it of greater importance to quit benefiting more, while effects were more pronounced for men compared to women. The finding for importance supports extant literature that has assessed motivation to quit (ie, the reasons smokers consider it important to quit), which suggests that higher motivation increases the likelihood of cessation and predicts abstinence [34-37]. Results compared across effectiveness trials highlight that women are less likely to remain abstinent than men [22], and the findings of the current study support this suggestion. Nonetheless, the association between effect and gender dissipated when adding the interaction term of gender and importance to the model, suggesting that, between men and women who deemed it of greater importance to quit, the effects of NEXit were greater for men. Future studies should consider exploring why importance may not be a driving force for change among women but is so for men. It should be noted that the sample included more women than men, reflecting greater treatment seeking among women. The parent trial was pragmatic in the sense that it was an effectiveness trial recruiting participants in a way that mimicked how a real-world implementation could work (ie, online advertisements). Therefore, our findings should most conservatively be generalized to those seeking help online, and not the general population, where the prevalence of smoking is more balanced.

On the other hand, for point prevalence, there were no marked associations between effects or interactions with respect to gender. This suggests that rates of relapse (or lack of) may have been similar between women and men, which is in contrast to evidence suggesting that women are more likely to relapse than

XSL•FO
RenderX

men [21]. The content for craving provided by NEXit may have been equally effective for the needs of both genders; evidence suggests that affective factors such as mood, anger, and perceived stress predict relapse in women, while the motivation to reduce craving is a unique relapse predictor in men [38]. The support for craving had specific content relating to stress management, reframing perspectives, and motivation.

The results highlight that confidence and importance (especially for men) are potential focal considerations for smoking cessation. Confidence and importance are integral parts of the decision to quit smoking, especially for individuals who are contemplating or preparing for a change and who may feel ambivalent about quitting [39]. It may be that those who reported the importance of quitting and their confidence as high were better psychologically prepared to change behavior. This suggests that future interventions should target improvements in both factors.

Smoking and Number of Quit Attempts

Associations between the number of cigarettes smoked and years of smoking with individualized effects were found for both prolonged and point prevalence abstinence, with those who smoked less and for a shorter duration benefiting the most. This suggests that NEXit is less beneficial for those who smoke more and have done so for a longer duration. Theories of addiction posit that when an addiction progresses, such as nicotine dependence, control over consumption shifts from goal-directed behavior to automatic or habitual motivation [40], hence those who smoke more and for longer *may* have been driven more by habit than goal-directed behavior. While the content of NEXit did include advice on how to avoid smoking cues, this may not have been enough for these heavier, longer-term smokers. Providing greater support for identifying what triggers habitual smoking and advice on how to plan for encountering triggers or cues may be beyond the scope of an SMS text message–based intervention. Potentially, this could be better achieved by smoking cessation counseling or through the usage of an interactive digital smoking cessation intervention, whereby end users are encouraged to record how they are triggered, along with creating their own plans to overcome their triggers, which can then be sent as reminders.

For prolonged abstinence, an association between quit attempts and individualized effect was found at 8 weeks, with those having fewer attempts at baseline benefiting more. The underlying action of NEXit may account for this finding, with the intervention theorized to be driven by instilling confidence in ability and raising the importance of quitting. Evidence highlights that self-efficacy (ie, confidence) and motivation (ie, importance) are key factors in smoking cessation for individuals who are less likely to make a quit attempt [37]. It may be that the mediating effects of confidence and importance on prolonged abstinence had a greater impact on this group than on those with greater recorded quit attempts at baseline. Nonetheless, at the 5-month follow-up, an individualized effect on prolonged abstinence was found for those reporting more quit attempts at baseline. This effect is potentially driven by these individuals building more confidence and gaining knowledge for quitting over the course of the trial.

Degree of Dependence

Finally, for the dependence score, only an association with individualized effect for point prevalence at 3 months was found, with those reporting less dependence benefiting more. No other associations with dependence were observed. Dependence as a factor in cessation and abstinence is well established; the likelihood of quitting is much greater at low levels of dependence, in comparison to high levels [41]. The disparity in our findings with the literature may be due to the methods used to assess dependency. We used a self-report measure, whereas many studies use biochemical measures of dependence [42]. While the Fagerström scale has been shown to predict abstinence across trials [24], self-report measures are more prone to biases in comparison to objective measures such as a saliva cotinine test. While future studies should consider both self-reports and biochemical measures, it may not be feasible for the digital modality. Furthermore, evidence highlights selection biases present in saliva testing [43], while recommendations suggest self-report measures are more appropriate for general population studies [43]. Nonetheless, our results for dependence could be interpreted to mean that, by and large, NEXit is equally effective regardless of dependence severity.

Limitations

The results provide insight into the individualized effects of the recent NEXit trial; however, they should be interpreted with some considerations. Typically in RCTs, the randomized component is tested, rather than a comparison across treatments, meaning individuals may adhere to or engage in an intervention at their own preference. Therefore, the results should be considered in terms of having access to the intervention rather than using it. Indeed, the aim of the trial was to estimate the effectiveness of providing a digital smoking cessation intervention; therefore, all intercurrent events were acceptable. We do note that since we did not collect data on the use of other interventions throughout the trial period, we cannot investigate if the NEXit intervention increased the utilization of other treatments.

Another limitation of this study is that a statistical model was used to predict and contrast outcomes. This means that the estimated effects are not based entirely on observed data but on predicted data. These predictions may have considerable uncertainty that is not readily quantifiable, as no individuals received both conditions; thus, no individual contrasts exist against which predictions can be compared. The result of this is that when comparing individualized effects against baseline factors, there is uncertainty that is not accounted for. More research is needed to develop methods to estimate the uncertainty of the statistical approach taken [27].

It should be noted that the relationships between baseline characteristics and individualized effects are associational and should not be interpreted as causal. Confounding and collider bias can substantially alter estimated associations. Further, the current study investigated several associations between baseline characteristics and individualized effects. The Bayesian inference paradigm informs which associations are stronger and weaker relative to one another and which associations have the

XSL•FO
RenderX

relatively strongest evidence, conditional on the data and prior knowledge. By using Student *t* test priors centered at 0, there was weak shrinkage induced in these estimations to protect against overestimation. Thus, the result of this study is all the associations presented and not only those that pass a prespecified threshold of significance (eg, null-hypothesis testing). In all, the findings presented in this study should be seen as exploratory, and future studies should look to confirm the associations as causal.

Conclusions

In conclusion, the results of this study highlight that individuals participating in the RCT of the NEXit intervention had heterogeneous outcomes, which were not discernible from the primary analysis of the RCT that compared the intervention and control groups [11]. The intervention was most effective among men, older individuals, those who smoked less at baseline and for a shorter duration, and those who had confidence in their ability and deemed it important to quit. The results have the potential to help refine smoking cessation interventions so that we can target those who persist in smoking despite current intervention efforts and policy measures.

Acknowledgments

Artificial intelligence chatbots were not used in any part of the manuscript writing.

Funding

This study was conducted under the auspices of a grant from The Swedish Cancer Society (Cancerfonden, 23 2888; principal investigator: MB). The parent trial was funded by Region Östergötland (Forsknings-ALF, Dnr: LIO-896081). The funder of the study had no role in study design, data collection, data analysis, data interpretation, or writing of the report.

Data Availability

The datasets generated or analyzed during this study are not publicly available due to the General Data Protection Regulation but are available upon reasonable request to marcus.bendtsen@liu.se.

Authors' Contributions

Data analysis: MB

Abstract

Background: China's diabetes epidemic faces critical gaps in glycemic control, with only 50.1% of treated patients achieving hemoglobin A_{1C} (HbA_{1c}) targets in 2021. Conventional interventions struggle with scalability in primary care, particularly for vulnerable populations.

Objective: This study aimed to evaluate the use of a WeChat-based health education tool (the WeWalk mini program, the Bayu Health public account, and a WeChat group) for improving glycemic control in community-dwelling patients with type 2 diabetes mellitus.

Methods: This multicenter randomized controlled trial enrolled 600 adults with type 2 diabetes from 3 communities in Chongqing, randomly allocating participants 1:1 to either a 12-week WeChat-based intervention (n=300, 50%) or a control group (n=300, 50%) in September 2020. The control group received 4 face-to-face traditional health education sessions, whereas the intervention group participated in a digital program: a 4-week course followed by an 8-week practical implementation. At baseline and 12 weeks after the intervention began, both groups were examined in terms of HbA_{1c} and fasting blood glucose (FBG) as the primary outcomes, as well as variables such as blood lipid profile, blood pressure, and physical fitness–related indexes as secondary outcomes. Longitudinal glycemic control was assessed through triplicate FBG measurements extracted from standardized electronic health records at the 2-year follow-up. Independent *t* tests or Mann-Whitney *U* tests were used to assess changes from baseline to follow-up between groups.

Results: A total of 92.7% (556/600) of the participants completed the 12-week follow-up visit. The WeChat-based intervention demonstrated superior glycemic control outcomes, with intervention participants achieving a 0.59% greater HbA_{1c} reduction than controls (−0.03% vs 0.56%; *P*<.001) and significant improvements in FBG levels (−0.69 vs 0.00 mmol/L; Δ=0.69; *P*=.001). Subgroup analysis revealed that WeChat-based health education was significantly effective in patients with diabetes with a disease duration of <10 years, educational level of junior high school or lower, and annual family income of <CN ¥50,000 (US $7172.10) . These benefits persisted throughout the 2-year follow-up, where the intervention group maintained lower FBG levels (6.87 vs 7.35 mmol/L; *P*=.001).

Conclusions: WeChat-based health education was beneficial for glycemic control in primary health care settings. However, the sustained efficacy and feasibility of this approach require further investigation.

KEYWORDS

WeChat; glycemic control; type 2 diabetes; randomized controlled trial; WeChat mini program; health education tool

Introduction

In recent years, the prevention and control of diabetes mellitus have become a global public health challenge, especially in China [1]. Effective management of type 2 diabetes mellitus (T2DM) relies critically on successful patient self-management [2], with structured diabetes self-management education (DSME) serving as a cornerstone of this process [3,4]. Despite this recognition, only 32.9% of patients with T2DM in China receive treatment, and among those treated, only 50.1% achieve adequate glycemic control [5]. This situation imposes substantial financial burdens on both patients and community health care systems [6,7].

Robust evidence from high-income countries, including Sweden [8], Spain [9], the United Kingdom [10], and New Zealand [11], has consistently demonstrated the efficacy of structured DSME programs in improving patient outcomes within primary care settings. These programs often emphasize lifestyle modifications, including balanced nutrition, regular physical activity, and weight management, as advocated by the World Health Organization [12]. Nevertheless, the traditional DSME model, which relies heavily on face-to-face and resource-intensive sessions, faces significant scalability challenges within the vast and heterogeneous primary health care environment [13]. Barriers to adopting these behaviors persist, including limited access to personalized health education and fragmented communication between patients and health care providers [14]. Therefore, building effective intervention systems for diabetes health education has become an important issue in primary health care in China.

The rapid proliferation of mobile health technologies has ushered in new opportunities for scalable diabetes management. Mobile apps have emerged as a cost-effective and efficient means of managing diabetes, primarily focusing on self-management and hospital appointments [15-17]. However, these apps often lack broad applicability for patients and family physicians in primary health care settings, neglecting the holistic needs of the community [18]. In contrast, ubiquitous social media platforms such as WeChat present a unique opportunity [19,20]. Their high penetration rate and familiar interface facilitate the delivery of structured educational content and enable continuous, interactive communication between patients and health care providers directly within the primary care context. Therefore, we designed an online free health education platform incorporating a WeChat mini program named WeWalk and a WeChat public account named Bayu Health.

This randomized controlled trial aimed to evaluate the effectiveness of WeChat-based interventions among patients with T2DM in Chinese community health centers. Our hypothesis was that mobile health education, which is based on the health belief model and social cognitive theory, would be more effective than conventional health education. We expected it to improve communication with community family physicians; foster peer-supportive social networks; promote healthy lifestyle changes; and ultimately, improve the effectiveness of diabetes self-management. By addressing these gaps and leveraging the potential of mobile health technology, this study contributes to the global effort in diabetes management.

Methods

Design

This study was designed as a 12-week, nonblinded randomized controlled trial to examine the efficacy of a WeChat-based intervention in patients with T2DM between September 2020 and December 2020. These participants were recruited from 3 community health service centers and followed up on at 12 weeks and 2 years after the intervention. Family physicians followed up on patients with diabetes via telephone to introduce the trial and determine potential participants' willingness to take part. These participants had established health records and had signed up for contracted family physician services at 3 community health service centers in Chongqing, China. Before the trial started, all the researchers involved were trained in uniform protocols, including trial procedures, questionnaires, and the use of the WeChat mini program and public account. A CONSORT (Consolidated Standards of Reporting Trials) checklist was completed to guide the trial's design, analysis, and findings (Checklist 1). Before conducting the formal research, we carried out a feasibility study, as shown in Multimedia Appendix 1.

Participants

On the basis of the inclusion and exclusion criteria, the family physician teams selected eligible participants for registration. The inclusion criteria for enrollment were as follows: (1) participants who were diagnosed with T2DM and met the 1999 World Health Organization diagnostic criteria; (2) receipt of the contracted family physician service within the validity period; (3) ability of the participants to undergo face-to-face interviews and voluntary participation in the trial; and (4) ownership of a smartphone and familiarity with the WeChat app, including chatting, subscribing to WeChat public accounts, and using WeChat mini programs. The exclusion criteria for this study were as follows: (1) participants with severe complications, such as ketoacidosis or hyperosmolar nonketotic diabetic coma; (2) participants with severe heart disease who would not tolerate moderate-intensity exercise; (3) participants who could not answer the questions clearly; and (4) participants who were taking part in other intervention studies.

A total of 900 eligible patients with T2DM were recruited by family physician teams from 3 communities, of whom 300 (33.3%) were excluded. Of these 300 excluded patients, 196 (65.3%) did not meet the inclusion criteria, 79 (26.3%) refused to participate, and 25 (8.3%) were excluded for other reasons. A total of 600 participants were randomized into the intervention group (n=300, 50%) or the control group (n=300, 50%). Moreover, 556 participants completed the 12-week follow-up

XSL•FO
RenderX

visit (intervention: n=278, 50%; control: n=278, 50%), and the retention rate was 92.7% (556/600).

Sample Size

The sample size was calculated based on a completely random design using the tests for 2 proportions. The trial was designed for analysis via 2-tailed tests, with type I and II error rates set at 0.05 and 0.2, respectively. A priori sample size calculations were conducted for the primary outcome of hemoglobin A_{1C} (HbA_{1c}) control rate (proportion of <7%). On the basis of national epidemiological data [1], the retention rate in the control group was estimated to be 35.2% in this study. We hypothesized that an 11% absolute risk reduction in the intervention group (24.2% event rate) derived from conservative adaptation of the Finnish Diabetes Prevention Study [21] would account for our digital intervention modality. With these parameters in the PASS software (version 15.0; NCSS, LLC), the total sample size required was 267 in each group. Considering a dropout rate of up to 10%, the final sample size was determined to be 300 patients in each group.

Allocation

After the willingness of patients to participate in the study was confirmed by the family physician teams, the baseline data of the participants were collected at the community health service centers. Randomization was performed by an independent statistician who generated the allocation sequence through computerized random number generation. The participants were assigned in a 1:1 ratio to the study groups, with allocation concealment ensured via opaque, sealed envelopes that were sequentially numbered.

Diabetes Health Education Team

Our multidisciplinary diabetes health education teams [22] were composed of the following: (1) a total of 18 family physicians from 6 family physician teams at 3 community health centers who were responsible for directly managing patients with diabetes and providing sustainable health education services; (2) an online health assistant who was responsible for functional maintenance and training on the health education platform; and (3) health education experts from the Military Health Education Center, including endocrinologists, rehabilitation therapists, ophthalmologists, dietitians, and coaches.

WeChat-Based Health Education Tool

The WeChat-based health education tool used in our study consisted of the WeWalk mini program, the Bayu Health public account, and the WeChat group. The WeWalk mini program, an interactive mobile health platform, integrates 5 core functional modules designed to promote diabetes self-management through physical activity monitoring and community engagement. This gamified intervention system uses behavioral economics principles and social cognitive theory to enhance users' health literacy and sustainable behavior change. Participants in the WeChat-based intervention group carried out daily health education activities to promote healthy behaviors. The WeChat public account Bayu Health was used to push diabetes self-management courses for the intervention group. The WeChat group was used mainly to organize and guide patients to participate in intervention activities. Multimedia Appendix 2 presents the functional modules of the WeWalk mini program and shows the QR codes of the WeWalk mini program and the Bayu Health public account.

Intervention Protocol

Control Group

The participants in the control group received standard health education, consisting of 4 sessions over a 12-week period provided by their family physician team. The contents of the education intervention focused on 5 key areas: diabetes knowledge, dietary control, exercise therapy, drug therapy, and self-monitoring of blood glucose. Education was provided during regular monthly follow-up visits or scheduled clinic appointments through in-person consultations.

Intervention Group

Participants in the intervention group received a 12-week theory-based diabetes self-management program delivered through an integrated WeChat platform. The intervention was structured in 2 sequential, theory-informed phases to facilitate knowledge acquisition and sustainable behavior change.

Stage 1: Structured Education (Weeks 1 - 4)

During the initial 4-week phase, the participants completed a structured self-management curriculum via the Bayu Health public account. Developed by the Military Health Education Center and aligned with China's national guidelines, the curriculum incorporated the health belief model to increase perceived susceptibility, severity, benefits, and self-efficacy. It consists of 30 evidence-based microlearning modules (videos and articles) covering lifestyle modification, glycemic control, medication adherence, and complication prevention. Health assistants reinforced engagement through daily performance summaries and the recognition of active participants in dedicated WeChat groups.

Stage 2: Guided Application (Weeks 5 - 12)

The subsequent 8-week phase focused on translating knowledge into practice via the WeWalk mini program. Grounded in principles of gamification and social cognitive theory, this stage included physician-supervised goal setting (Multimedia Appendix 3), photo-based tracking of physical activity and dietary patterns, and a gamified ranking system with virtual health points to incentivize consistent engagement. All user-generated health data were shared exclusively with the family physician teams via encrypted channels, enabling real-time clinical oversight while maintaining privacy.

Data Collection and Measurements

The participants underwent 2 follow-up assessments: after the intervention (12 weeks) and in the long term (2 years after the intervention). To assess the condition of the patients, the primary outcome measure of the study was the change in fasting blood glucose (FBG) and HbA_{1c} levels in the 2 groups at baseline and 12 weeks after the intervention began. The secondary outcomes included changes in weight, BMI, waist circumference, hip circumference, systolic blood pressure, diastolic blood pressure, and serum lipid profiles. Baseline assessments included

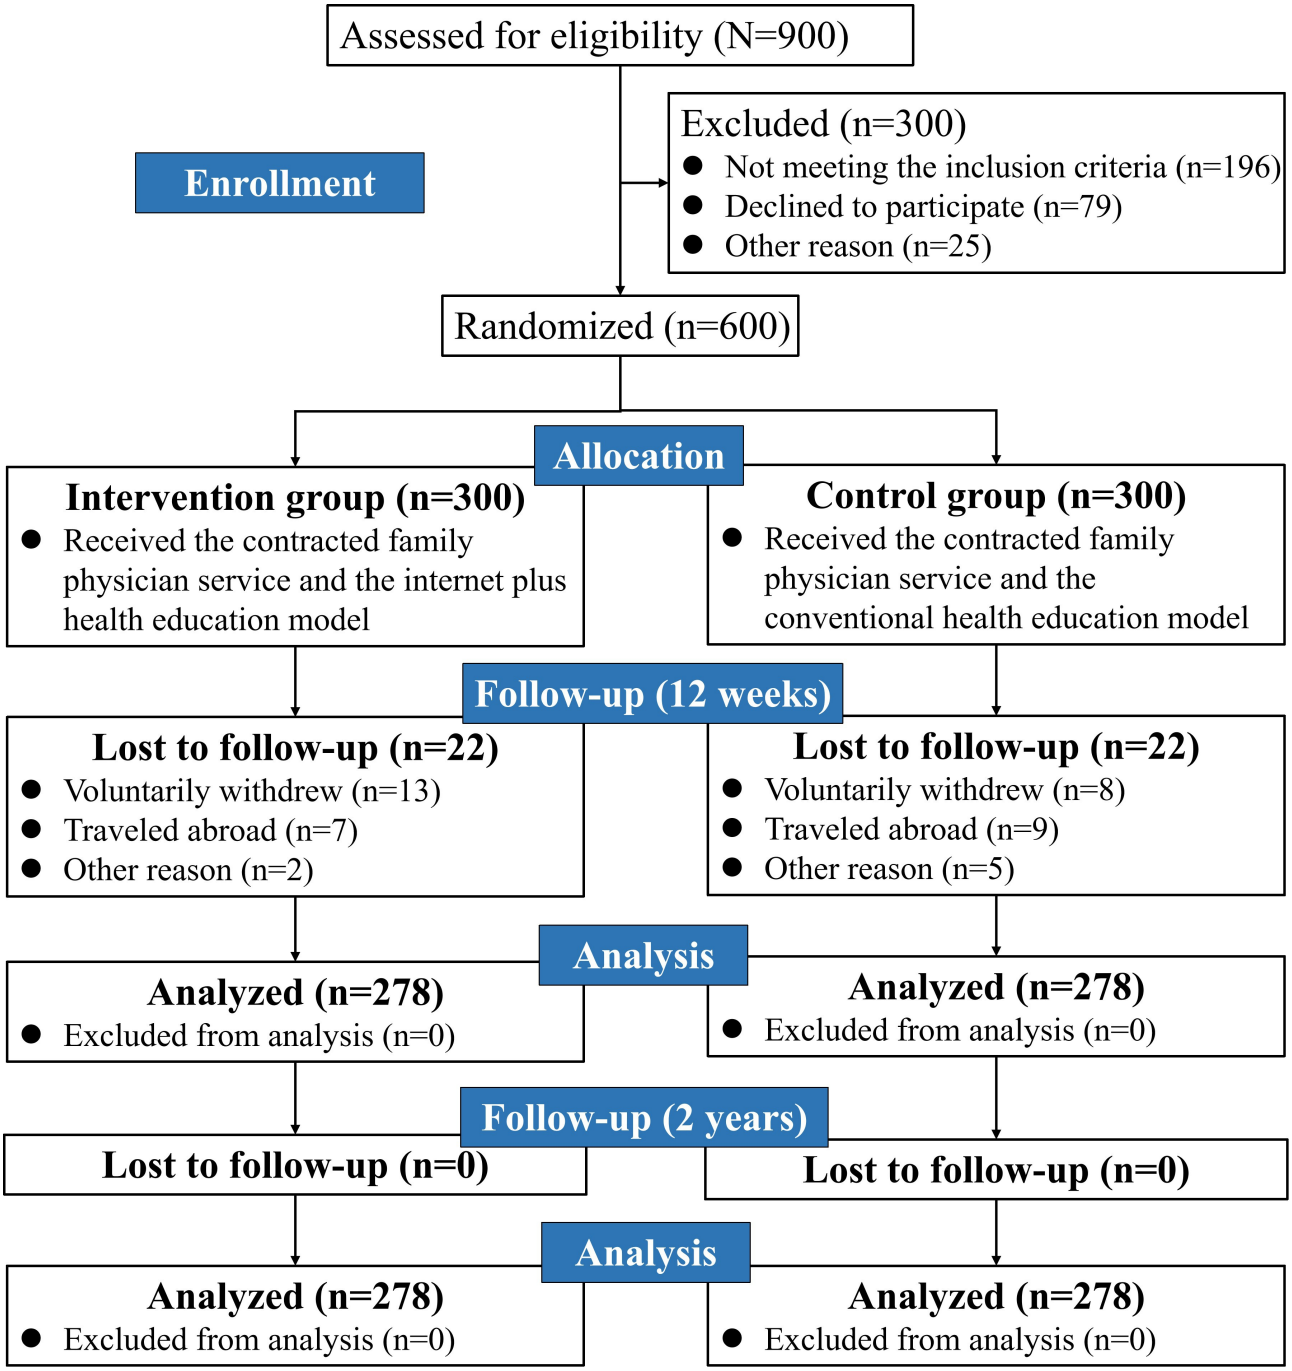
XSL•FO
RenderX

standardized questionnaires capturing demographics, medical and treatment history, comorbidities, and lifestyle factors, alongside fasting-state physical examinations conducted by certified personnel at community health service centers. Longitudinal glycemic control was assessed through triplicate FBG measurements extracted from standardized electronic health records at the 2-year follow-up.

Statistical Analysis

Data were double entered using EpiData (EpiData Association) and analyzed using SPSS (version 26; IBM Corp). Normally distributed variables expressed as means and SDs were compared using independent *t* tests; nonparametric variables reported as medians and IQRs were analyzed via Mann-Whitney *U* tests. Demographic (sex, educational level, and annual family income), clinical (hypoglycemic medication use and diabetic complications), and behavioral (smoking and alcohol use) variables were analyzed using the chi-square test at baseline. The chi-square test was used to test the differences in HbA_{1c} data before and after the intervention. Patients with diabetes were divided into 2 categories according to their HbA_{1c} levels: HbA_{1c}<7% (normal) and HbA_{1c}≥7% (abnormal) according to the guidelines for the prevention and treatment of T2DM in China (2017) [23]. P<.05 was considered statistically significant.

Ethical Considerations



This study was approved by the Army Medical University medical ethics committee (approval 2020-007-02) and registered at the Chinese Clinical Trial Registry (ChiCTR2300071926). Written informed consent was obtained from all participants before enrollment. All data were deidentified for analysis and stored securely to ensure confidentiality. Participants received no financial compensation but were provided with free medical checkups, medication guidance, and healthy lifestyle guidance.

Results

A total of 600 participants were randomized into the intervention or control group. Follow-up at 12 weeks was completed by 46.3% (n=278) of the participants per group (overall retention: n=556, 92.7%), with no further attrition at 2 years (Figure 1). The intervention and control groups were well balanced at baseline in terms of key demographic and clinical characteristics (Table 1).

[j]DBP: diastolic blood pressure.

Compared with conventional education, after the 12-week intervention, the WeChat-based program resulted in statistically and clinically significant improvements in several metabolic outcomes, as detailed in Table 2. Participants in the intervention group achieved significantly greater reductions in FBG and HbA_{1c} at follow-up (P<.001 in both cases). A favorable effect was also observed on triglyceride levels, which were significantly lower in the intervention group (P=.003). The waist circumference and waist-to-hip ratio (WHR) levels in the control group were significantly higher than those in the intervention group. However, no significant between-group differences were found for total cholesterol, low-density lipoprotein cholesterol, high-density lipoprotein cholesterol, or blood pressure (P>.05 in all cases).

The rate of normal HbA_{1c} levels was not significantly different between the 2 groups at baseline (*P*=.932), whereas it decreased significantly in the control group after the intervention (*P*=.001), as shown in Table 3. Subgroup analyses were performed according to different characteristics (sex, disease duration, educational level, and annual family income), and detailed data are shown in Table 3. Significant differences in the rate of normal HbA_{1c} levels were observed between the 2 groups after the intervention in the participants with disease duration (<10 years), educational level (junior high school or lower), and annual family income [<CN ¥50,000 (US $7172.10)].

[a]Between-group differences were assessed using the Mann-Whitney *U* test.

Discussion

Principal Findings

This study evaluated the short-term efficacy of a WeChat-based health education tool in primary care through a 12-week randomized trial with a 2-year follow-up on glycemic control. After 12 weeks, the intervention group had improved HbA_{1c} and FBG levels compared with those of the control group, especially in patients with diabetes with a disease duration of <10 years, an educational level of junior high school or lower, and a annual family income of <CN ¥50,000 (US $7172.10) . Significant between-group differences were found in waist circumference and triglycerides, but no significant changes were observed in BMI, hip circumference, WHR, total cholesterol, low-density lipoprotein cholesterol, high-density lipoprotein cholesterol, systolic blood pressure, or diastolic blood pressure. Two years after the intervention, FBG levels were significantly lower in the intervention group. However, the change in FBG from baseline was not significantly different between the groups.

Comparison With Prior Work

Our study adds to the growing body of international evidence confirming the efficacy of digital health interventions, including smartphone apps and telemedicine, in improving diabetes outcomes [24-26]. This global consensus is strongly supported by a series of studies in China that have demonstrated the effectiveness of telemedicine and app-based interventions for glycemic control [27-29]. Specifically, with respect to the WeChat platform, our results are consistent with and reinforce findings from regional studies in the Jiangsu [19], Jilin [30], and Henan [31] provinces. The convergence of evidence from these diverse settings solidifies the view that WeChat-based health education is a viable and effective strategy for improving blood glucose levels in patients with T2DM. The intervention likely works by first improving disease knowledge through structured education [20]; then increasing self-efficacy via interactive support [32]; and, finally, enhancing adherence to medication and healthy behaviors through regular reminders and self-monitoring [33].

We found that the reduction in the HbA_{1c} level in the intervention group was lower than that reported in other studies according to a systematic review of self-management among patients with type 2 diabetes via the WeChat app [34]. A similar eHealth intervention in Shanghai demonstrated a greater HbA_{1c} reduction (7.9% to 7.3%) than our study (7.39% to 7.35%) [28]. This difference may be attributed to regional disparities in health care infrastructure [35-37] and a critical design variation: their single-platform (WeChat public account) intervention likely offered a simpler user experience, whereas our multimodule design incorporating a mini program may have increased operational complexity for participants.

We found that WeChat-based health education improved the HbA_{1c} level in patients with diabetes with low income, low educational level, and short disease duration who contracted family physicians. Currently, health apps designed to enhance self-management of chronic illnesses require continuous patient involvement as a pivotal factor influencing clinical effectiveness [38-40]. A meta-analysis revealed that the dropout rate in clinical trials for smartphone apps was significantly higher among high-income countries than among lower-middle–income countries [41]. A national web-based survey in China revealed that educational level and family income were associated with

XSL•FO
RenderX

diabetes management app use in adult patients [42]. We speculated that patients with diabetes with shorter disease durations would have better acceptance of the WeChat-based health education tool, those with low educational levels would have higher expectations for our intervention, and our free program would be more attractive to low-income patients with diabetes.

Moreover, we found that the waist circumference and WHR in the intervention group were significantly lower than those in the control group. Indeed, sex was a confounding factor, with the waist circumference and WHR of female patients being out of balance in the 2 groups before the intervention. We observed that the BMI values increased in both groups after the intervention, presumably related to the end of the intervention in the winter. People are more likely to eat more food during the Spring Festival in China [43,44]. However, WeChat-based health education was effective in helping patients with diabetes control their body shape in the winter, which was similar to the findings of other studies [45].

The intervention was constructed based on the WeChat mini program and public account, which enhances communication between family physicians and patients [46]. The family physicians' online virtual clinics were set up on the WeWalk mini program to help patients easily contact their contracted family physicians. Compared with other diabetes management mobile apps, the WeWalk mini program is free to download and use and easy to operate, reducing the likelihood of users discontinuing use [42]. Furthermore, subgroup analysis revealed that WeChat-based health education was effective for glucose control based on evidence from 3 communities. The WeChat mini program provides remote supervision and ongoing support for patients and physicians, which makes it easy to achieve continuous efficacy in the long term [47]. We suggest integrating effective, low-cost digital solutions such as this WeChat mini program into national chronic disease management strategies. Further validation is needed to assess its efficacy in rural settings with different health care infrastructures.

Limitations

Our study has several limitations. First, due to the impact of COVID-19, formal follow-up was only conducted at 12 weeks, and only the short-term effects of WeChat-based health education were observed in our study. Regarding the long-term effects of WeChat-based health education, only FBG was evaluated in this study. However, this result still needs to be further evaluated through other indicators. Second, this study was based on 3 community health service centers but was not a cluster randomized controlled trial, which may lead to insufficient accuracy of the study results. Although the authorized supervisor prevented information contamination, they may have unintentionally disclosed intervention details while managing both groups. Third, no implementation fidelity data such as user engagement and use frequency of the intervention group were collected and analyzed. Finally, a future cost-effectiveness analysis and continuous real-world optimization are crucial next steps to definitively inform policy. We could explore incorporating artificial intelligence to provide more personalized, patient-specific educational content and support, thereby enhancing the scalability and integration of this WeChat-based intervention.

Conclusions

We conducted a randomized controlled trial in community-dwelling patients with T2DM to examine the efficacy of a WeChat-based health education intervention in Chongqing, China. By strategically integrating social media platforms with primary care services, this WeChat-based health education intervention achieved significant results in improving glycemic control in patients with T2DM. Future investigations should use longitudinal designs to evaluate the sustained efficacy and feasibility of implementing WeChat-based health education.

Acknowledgments

The authors thank all the participants in the study for their involvement and help. They gratefully acknowledge family physician teams from 3 community health service centers (Xinqiao, Chenjiaqiao, and Yubeilu) in Chongqing, China. They also sincerely thank Ms Shun-Rong Huang, Ms Wen-Mei Yang, and Ms Zhi Xiao from these family physician teams for their help in sample collection.

Funding

This research was financially supported by the Technical Innovation and Application Development Special Project in Chongqing, China (grant cstc2019jscx-msxmX0198).

Data Availability

The datasets generated or analyzed during this study are available from the corresponding author on reasonable request.

Authors' Contributions

CZ contributed to conceptualization, methodology, formal analysis, and writing—original draft. XD and XX contributed to software development and data curation. EYL, MJ, YW, JY, XW, LZ, HR, LL, FL, and TL were responsible for project implementation, participant recruitment, and data collection. XM contributed to the methodology and validation. JAC supervised the study, acquired funding, and reviewed the manuscript. All the authors approved the final version.

Abstract

Background: Medical nutrition therapy (MNT) serves as the foundational intervention in the clinical management of gestational diabetes mellitus (GDM) management. However, inadequate supportive care often hinders patients' ability to sustain dietary modifications and self-management behaviors, particularly for complex regimens. Flexible online interventions are thus gaining interest as adjuncts to clinical care, with the potential to improve the outcomes of GDM self-management.

Objective: This study sought to evaluate the benefits of WeChat-delivered medical nutrition therapy (WeMNT), a WeChat-delivered MNT intervention, for patients with GDM.

Methods: A parallel-group, single-blind randomized controlled trial (with outcome assessor blinding) was implemented at a university hospital's obstetric clinic. Eligible participants were those with a 24‐ to 28-week singleton pregnancy, a GDM diagnosis confirmed by the 75 g oral glucose tolerance test, no requirement for insulin therapy, and the ability to use a smartphone and WeChat, as well as to communicate in Chinese. Participants were randomized 1:1 to the intervention (n=47, 50%) or control group (n=47, 50%) using a random number table. The WeMNT intervention was designed per the behavior change wheel framework: (1) analyze capability-, opportunity-, and motivation-based barriers related to MNT adherence; (2) formulate targeted intervention functions; and (3) select evidence-based behavior change techniques. Three WeChat mini-programs served as the core delivery platform to implement the multifaceted intervention functions. The primary outcomes measured in this study included fasting blood glucose, 2-hour postprandial glucose (2hPG), hemoglobin A_{1c} (HbA_{1c}), and gestational weight gain (GWG). The secondary outcomes assessed included obstetric complications and neonatal parameters. Intention-to-treat analysis using adjusted generalized linear mixed models was conducted to evaluate the effects of the intervention.

Results: From March 2023 to October 2023, a total of 94 participants were enrolled in this study. Among the participants, 88 (93.62%) individuals (mean age 32.18, SD 5.04 years) successfully completed the study, 44 (46.81%) in the intervention group and 44 (46.81%) in the control group. Approximately 68.18% (30/44) of the participants in the intervention group demonstrated sustained adherence, as expected, adhered to the diet plan ≥60% of the days. Compared with the control group, the intervention group showed a significantly greater decrease in GWG over time (group×time interaction: β=−1.96, 95% CI −3.58 to −0.34; *P*=.02), with no significant effects on fasting blood glucose. Conversely, significant decreases in 2hPG (β=−0.12, 95% CI −0.19 to −0.04; *P*<.001) and HbA_{1c} (β=−0.49, 95% CI −0.74 to −0.23; *P*<.001) were noted in the intervention group. No unexpected maternal adverse events occurred, and no significant effects on other health outcomes were detected.

Conclusions: As a WeChat-delivered, behavior change wheel–informed intervention, WeMNT successfully reduced 2hPG, HbA_{1c}, and GWG in GDM management. Its integrated self-management model yields robust evidence, validating this patient-centered tool as a viable option for clinical adoption.

Introduction

Background

Gestational diabetes mellitus (GDM) refers to a prevalent pregnancy-associated metabolic disorder, defined by the onset or initial identification of glucose intolerance during gestation [1]. According to the International Diabetes Federation, the age-standardized prevalence of GDM in low- and middle-income countries increased from 6.8% in 2011 to 8.8% in 2021, representing a weighted relative increase of 29.4% (95% CI 22.1% - 37.2%) after adjusting for diagnostic criteria and study heterogeneity, in parallel with the growing epidemic of obesity [2,3]. Suboptimal glycemic regulation during GDM is associated with increased maternal risks, including preeclampsia, cesarean delivery, and postpartum hemorrhage. Beyond the perinatal period, women with a history of GDM face an increased likelihood of developing chronic conditions such as type 2 diabetes, metabolic syndrome, and cardiovascular disease in the long run [4]. Offspring exposed to maternal hyperglycemia face immediate risks of macrosomia, birth trauma, neonatal hypoglycemia, hyperbilirubinemia, and polycythemia. These infants also demonstrate increased susceptibility to obesity and diabetes later in life.

Medical nutrition therapy (MNT) is the primary approach for managing GDM and is frequently effective in achieving desired blood glucose levels [5]. The significant benefits of dietary interventions in GDM management also include improved maternal outcomes and reduced neonatal macrosomia risk compared with conventional care [6]. Specifically, low–glycemic index (GI) diets have been shown to attenuate glycemic excursions while mitigating the need for pharmacological interventions [6,7]. These outcomes are hypothesized to result from delayed carbohydrate absorption and enhanced satiety signaling associated with low-GI macronutrient profiles [7]. However, controversy persists regarding optimal carbohydrate modulation strategies. While certain trials advocate restrictive carbohydrate regimens (≤40% of total energy intake) for acute glycemic reduction, emerging data suggest that liberal intake of high-fiber complex carbohydrates (eg, whole grains and legumes) may offer superior long-term metabolic benefits [8]. This paradigm prioritizes glycemic stability and preserves maternal nutritional adequacy, potentially reducing the risk of ketogenesis compared with severe caloric restriction [9]. Regardless of whether a restrictive or more liberal carbohydrate regimen is adopted, individualized nutritional plans that consider mothers' specific characteristics (eg, health status, weight, ethnicity, and cultural preferences) are crucial for effective GDM management [10]. A joint care team comprising endocrinologists, obstetricians, certified dietitians, and diabetes education specialists is recommended to develop individualized treatment plans [5].

Enhanced dietary support significantly improved carbohydrate adherence in high-risk pregnancies [11]. Among obese women (BMI ≥30 kg/m^2), those receiving weekly 90-minute dietitian-led group counseling on carbohydrate-controlled diets (40% - 45% of total calories) demonstrated a 47% reduction in days with excessive carbohydrate intake (≥10% above target) compared with controls over 24 weeks (adjusted odds ratio 0.53, 95% CI 0.39 - 0.72; P<.001) [11]. A dietary plan is key to managing GDM, yet women often struggle to adopt and sustain new dietary habits and self-management behaviors [12]. Long-term adherence to complex dietary plans is challenging without continuous support [13]. Providing adequate self-management support empowers patients to control their diet and blood glucose levels. As they gain self-management skills, positive behavioral changes become evident [13]. Prescribed treatment plans instill a strong sense of responsibility in women with GDM, motivating them to strictly adhere to dietary and self-management guidelines [12]. Nevertheless, their clinical appointments with health care professionals are frequently too brief to provide the in-depth, comprehensive guidance necessary for effective GDM management [14,15]. Mobile health (mHealth) and digital interventions have become essential complementary tools for supporting women with GDM and health care professionals. Recent studies report an increasing reliance on digital platforms because of their flexibility and convenience, which help overcome limited clinical contact time and provide continuous, personalized support for self-management [16,17]. Both women and health care professionals expressed openness to using technology as an adjunct to standard care but emphasized the need for improvements in usability, such as enhanced content layout, user interface design, and data visualization [17]. Participants also highlighted the importance of features supporting diverse data recording, personalization, comprehensive information delivery, and effective communication with health care providers and peer networks [17]. Currently, various mHealth tools often do not fully address the needs of women with GDM [18]. Both patients and health care professionals have stressed the importance of improving usability, personalization, information adequacy, and communication functionalities [18]. These findings highlight the ongoing need to develop and optimize mHealth solutions to better support self-management among women with GDM.

Theoretical Framework

According to the literature, current behavior change interventions often have 2 major limitations: insufficient theoretical support and underuse of evidence-based frameworks [19]. To address these limitations, we adopted the behavior change wheel (BCW) as our core theoretical foundation [19]. With the embedded capability, opportunity, motivation behavior (COM-B) model, the BCW is distinguished in supporting researchers to analyze the origins of behavioral barriers and design theory-informed interventions [19]. Specifically, capability refers to an individual's psychological (eg, knowledge and cognitive skills) or physical (eg, motor ability) capacity to perform the target behavior; opportunity encompasses external enablers or constraints, including the physical environment (eg, access to resources) and social support (eg, family encouragement); and motivation integrates conscious decision-making (eg, goal setting) and subconscious drives (eg, emotional attitudes) that influence behavioral intent [19]. In the system, COM-B elements interact dynamically to shape behavior, enabling designers to first identify context-specific barriers to the target behavior and then map them to targeted

XSL•FO
RenderX

intervention functions most likely to drive meaningful change. This systematic mapping, in turn, facilitates the precise translation of intervention functions into fine-grained, measurable, and replicable behavior change techniques (BCTs)—a critical step in ensuring the scientific rigor and scalability of the intervention [19]. By grounding the intervention in the BCW, we establish a transparent, theory-driven link between identified behavioral barriers, intervention design choices, and measurable outcomes—addressing the field's need for more structured, evidence-based approaches to behavior change intervention development.

Goal of This Study

Building on the BCW framework, we developed WeChat-delivered medical nutrition therapy (WeMNT), a WeChat-delivered MNT program tailored for women with GDM. On the basis of clinical expertise and patient feedback, we hypothesized that WeMNT will improve the effectiveness of GDM management. This study aimed to evaluate the benefits of WeMNT, a WeChat-delivered MNT intervention program developed from clinical knowledge and the BCW framework, for women with GDM.

Methods

Study Design and Participants

This single-blind, parallel-group randomized controlled trial (RCT)—with blinding limited specifically to outcome assessors—was carried out at the obstetric clinic affiliated with a university hospital. The reporting of this study adhered to the CONSORT (Consolidated Standards of Reporting Trials) guidelines (Checklist 1). The inclusion criteria included singleton pregnancy at 24 to 28 weeks, GDM diagnosed by a 75 g oral glucose tolerance test (OGTT) [20], no insulin requirement, and the ability to use a smartphone with WeChat and to communicate in Chinese.

Sample Size Calculation

The study was powered based on the primary outcome of hemoglobin A_{1c} (HbA_{1c}). To determine the appropriate sample size, we first identified the effect size based on the relevant literature. A meta-analysis revealed that telemedicine interventions for women with GDM yielded an effect size of 0.63 (Cohen *d*, ie, a standardized mean difference between groups) for HbA_{1c} reduction; specifically, studies using WeChat as the intervention tool (6 RCTs in total) demonstrated a greater effect size of 0.84 for HbA_{1c} improvement [21]. Considering both clinical relevance and methodological conservatism, we determined a minimum effect size (Cohen *d*) of 0.65 for the sample size calculation.

G*Power 3.1 software [22] was used to perform the a priori sample size calculation using the following key parameters: effect size (*d*)=0.65, significance level (α)=.05 (2-tailed), and statistical power (1−β)=.80. The calculation results indicated a basic sample size of 78 participants. To address a potential 15% attrition rate, a common consideration in longitudinal clinical studies, the final sample size was adjusted to 94 participants, which ensured adequate statistical power for detecting the prespecified effect on the primary outcome (HbA_{1c}).

Recruitment and Randomization

Participants were enrolled during their standard antenatal care appointments. Clinic physicians and nursing staff assisted in recruitment by disseminating study information to potential participants who met the eligibility criteria and had recently completed the OGTT. Interested candidates underwent an initial eligibility assessment by the research team. A follow-up appointment was then scheduled at the clinic, typically within 1 week of the OGTT, to discuss the study in detail, obtain written informed consent, and initiate enrollment.

After providing informed consent, eligible participants were randomly assigned to either the intervention group (n=47, 50%) or the control group (n=47, 50%) in a 1:1 allocation ratio, with randomization sequences generated by a computer. To ensure allocation concealment, sequentially numbered, sealed, opaque envelopes were used. This process preserved the integrity of the randomization and minimized selection bias.

Intervention

To achieve the study's objective, we followed the 3-stage protocol specified in the BCW intervention design guide [19]. First, preliminary assessments and literature review were conducted, and the COM-B barriers impeding GDM patients' adherence to a personalized MNT plan were analyzed. The identified distinct COM-related barriers to MNT adherence include the following:

- Capability: deficits in nutritional knowledge and inability to formulate personalized MNT plans, accurately weigh food portions, or maintain dietary records
- Opportunity: lack of household weighing tools, work-related time constraints for learning and implementing MNT, and insufficient social support
- Motivation: inadequate awareness of MNT's clinical importance, concerns about disrupting daily routines, and anxieties regarding the potential impacts of MNT

Second, targeted intervention functions—including education, enablement, modeling, and environmental restructuring—were selected to address these COM-specific barriers. Finally, building on this foundation, evidence-based BCTs were further identified to operationalize the selected functions [23]. Specifically, a group of BCTs validated for type 2 diabetes self-management in the literature was adopted [24].

For delivery, WeChat mini-programs were prioritized as the core platform because of their high accessibility and user familiarity. Three WeChat mini-programs were designated as the core delivery platform to implement diverse intervention functions and facilitate participants' acquisition of relevant knowledge and practical skills. A schematic overview outlines the BCW-informed intervention development, COM categories, barriers, BCTs used, and WeMNT intervention operationalization, including BCT embedded in mini-program features (Table 1).

XSL•FO
RenderX

Table . Intervention development: capability, opportunity, and motivation (COM) categories, barriers, behavior change techniques (BCTs), and mini-programs.

COM categories and key barriers	Intervention functions	Policy categories	BCTs	WeChat platform	Intervention contents
Capability					
Deficits in nutritional knowledge	Education	Communication	• BCT4.1 Instruction on how to perform a behavior • BCT 4.2 Information about antecedents	• Mini-program "Diet Diary-Food Charts"	• Via the program, women learn GI[a] knowledge and practical nutritional skills (BCT4.1) and get nutritional choice antecedent info (BCT4.2).
Inability to accurately understand food portions and formulate personalized MNT[b] plans	Training	Service provision	• BCT4.1 Instruction on how to perform a behavior • BCT6.1 Demonstration of the behavior • BCT1.4 Action planning	• Mini-program "Diet Diary"	• Via the program, dietitians teach women to input clinical data, select food types and weights/portions, and make personal MNT plans (BCT4.1), demonstrate plan design and adjustment (BCT6.1), and cocreate daily meal schedules with reminders (BCT1.4).
Inability to maintain dietary records	Training	Service provision	• BCT2.3 Self-monitoring of behavior	• Mini-program "Diet Diary"	• Women use the program to log daily food portion weights and receive alerts on whether intake meets, falls below, or exceeds targets.
Opportunity					
Lack of household weighing tools	Environmental restructuring	Service provision	• BCT12.5 Adding objects to the environment		• The research team provided digital food scales to support accurate measurement.
Work-related time constraints for implementing MNT	Environmental restructuring	Service provision	• BCT7.1 Prompts/cues	• Mini-program "Diet Diary"	• Aligned with the MNT plan, the mini-program sends timed pop-up reminders (eg, "Check meal compliance 10 minutes premeal," "Log daily diet 5 minutes before bedtime").

XSL•FO
RenderX

COM categories and key barriers	Intervention functions	Policy categories	BCTs	WeChat platform	Intervention contents
Insufficient social support	Modeling	Service provision	• BCT12.2 Restructuring the social environment	• Group discussion	• A nurse moderated a WeChat group for peer support; women shared experiences/strategies weekly.
Motivation					
Inadequate awareness of MNT's clinical importance	Education	Service provision	• BCT4.3 Information about health consequences • BCT2.2 Feedback on behavior	• Mini-program "Diet Diary"; Video call	• Via the program, women self-learn MNT's medical value, disease-prognosis links, and noncompliance risks to fill cognitive gaps (BCT4.3). Persistent glucose issues triggered video consultations and potential multidisciplinary referrals (BCT2.2).
Worries about MNT disrupting daily routines	Modeling	Service provision	• BCT3.3 Social support	• Group discussion	• A nurse moderated a WeChat group for peer support; women shared experiences or strategies weekly.
Fears of MNT causing potential health impacts	Enablement	Service provision	• BCT2.4 Self-monitoring of the outcomes • BCT2.2 Feedback on behavior	• Mini-program "Pregnancy Sugar Weight Record" and "Fetal Weight Assessor" • Instant message or voice call	• Women input blood glucose, body weight, and fetal weight into the programs, which generate linked trend curves for all 3 and alert if values meet, fall below, or exceed targets. • Diabetes nurses weekly reviewed backend data, provided WeChat feedback, and adjusted meal plans with dietitians for off-target patients.

[a]GI: glycemic index.

[b]MNT: medical nutrition therapy.

Intervention Features

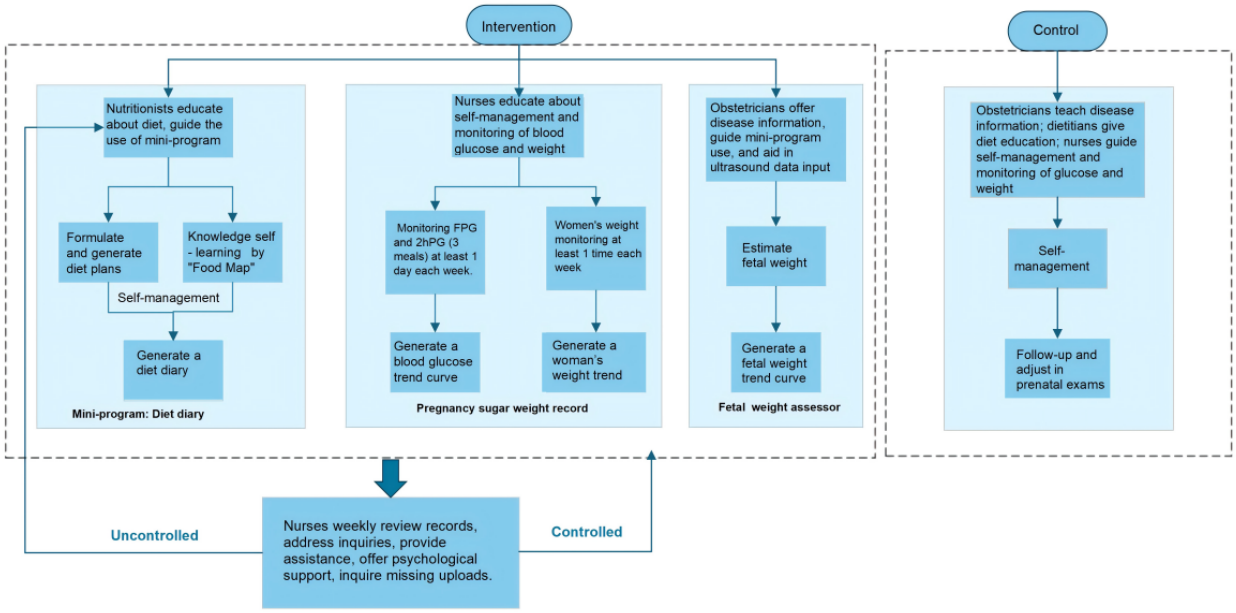
In this mHealth study, we used well-established, publicly available, nonprofit WeChat mini-programs as the intervention platform. First, the "Diet Diary" mini-program was developed by a certified dietitian, Zhongyi Gu, as a nonprofit public health tool aligned with the American Diabetes Association guidelines for GDM [5]. This mini-program integrates personalized meal planning, real-time dietary tracking, and weekly professional feedback to facilitate effective dietary management for users. Dietitians leveraged the mini-program to deliver step-by-step instructions on MNT plan formulation, demonstrating both the

XSL•FO
RenderX

plan design logic and mini-program operation through real-time interface walkthroughs to teach women how to use the platform independently. They then collaborated with women using the mini-program's action planning module to develop structured daily meal plans that specified food types and weights for each meal, with embedded reminders and real-time adjustment features tailored to individual clinical needs and daily routines. On the basis of the mini-program's "Food Charts" self-learning feature, women acquired knowledge about the GIs of 476 common foods, food selection, weighing, recording, and meal arrangement; access to antecedent information about nutritional choices; and learned about the health consequences of dietary behaviors linked to GI.

The second mini-program is the "Pregnancy Sugar Weight Record" mini-program. This mini-program offers 3 evidence-based modules: weight monitoring with personalized reference ranges based on prepregnancy BMI (pBMI), blood glucose monitoring with goals set with diabetes nurses, and an automated alert system for weight gain deviations. Weight measurements are standardized using calibrated digital scales and automatically synchronized with user profiles, with graphical trend visualization for weight gain deviations exceeding ±10% of target ranges.

The third mini-program is the "Fetal Weight Assessor" mini-program. This mini-program is designed for fetal growth monitoring, allowing participants to input key ultrasound parameters after routine prenatal examinations to estimate fetal weight. It also generates percentile curves to visualize growth trajectories relative to gestational age, aiding in comprehensive fetal growth assessment (Multimedia Appendix 1).



Intervention Process

Upon enrollment, each participant received an individualized MNT prescription developed by a study dietitian using the "Diet Diary" mini-program, which incorporated personal parameters (age, gestational age, and pBMI) and specified precise gram weights of food types for daily meals and snacks. Participants recorded all food and beverage intake (type and weight) daily via the same mini-program, with digital food scales provided to support accurate measurement, and used the "Food Charts" self-learning module to learn as needed about food selection, GI values, and portion control techniques. Concurrently, women logged blood glucose and body weight data weekly into the "Pregnancy Sugar Weight Record" mini-program for continuous health monitoring. Those unable to input data independently could use paper records, audio or video recordings, or photos, with nurses assisting with data entry. Obstetricians delivered disease information to the participants, instructed them on the operation of the "Fetal Weight Assessor" mini-program, and supported the accurate input of ultrasound examination data during scheduled antenatal visits. Following this step, the system calculated and estimated fetal weight using the collected ultrasound parameters. A dynamic fetal weight trend curve was generated to visualize the changes in fetal weight over time.

A multidisciplinary team (certified dietitians, nurses, and obstetricians) provided comprehensive support throughout the study. Diabetes nurses reviewed participants' dietary logs, blood glucose levels, and weight records weekly via the WeChat backend, delivering personalized feedback and evaluations through WeChat messages or voice calls—acknowledging adherence achievements, addressing inquiries, and offering constructive suggestions. For participants with persistently unmet glycemic targets, nurses collaborated with dietitians to analyze issues and adjust meal plans (eg, modifying carbohydrate distribution or introducing alternative foods). A real-time consultation channel ensured that dietary inquiries received responses within 12 hours, and the team routinely audited 20% of the records to maintain intervention adherence standards. A nurse-modified WeChat peer support group facilitated weekly discussions in which women exchanged experiences, practical strategies, and insights into glycemic management and MNT implementation, fostering mutual encouragement. For participants facing persistent glucose management challenges for more than 2 weeks, the care team arranged 15 to 30 minutes of individual video consultations to provide focused support; these sessions could also lead to referrals for further multidisciplinary evaluation if needed. Individualized WeChat communications (messages, voice recordings, and video calls) were additionally provided for participants with specific needs, offering one-on-one dietary consultation and guidance. Throughout the intervention, all communications maintained an empathetic, nonjudgmental tone, and participants retained the flexibility to adjust their involvement or pause monitoring as needed. Figure 1 shows the implementation process of the study.

XSL•FO
RenderX

Figure 1. Implementation process of the study. FPG: fasting blood glucose; 2hPG: 2-hour postprandial glucose.

Control Group: Standard Antenatal Care

Participants in the control group received routine GDM management in accordance with national guidelines. This included dietary guidance through printed educational materials, such as the Pagoda of Balanced Diet for Pregnant Women, which emphasized whole grains, lean proteins, and low-GI fruits. Biweekly 30-minute counseling sessions were conducted to address general dietary principles and portion sizes. Clinical monitoring involved regular weight, blood pressure, and capillary blood glucose measurements (fasting and postprandial) during scheduled antenatal visits, with participants recording self-monitored glucose values in paper logs. Additionally, exercise recommendations were provided to all study participants, including both the intervention and control groups, who were advised to engage in moderate-intensity walking for 30 minutes, 3 to 4 times weekly. Table 2 provides a detailed comparison of management approaches across modules between the WeMNT intervention and control groups.

Table . Comparison of management approaches across modules: WeChat-delivered medical nutrition therapy (WeMNT) versus standard care.

Component	Intervention group (WeMNT)	Control group
Dietary education, planning, and monitoring	Knowledge self-learning by "Food Charts" using the GI[a] database (476 foods), AI[b]-driven personalized meal plans, and real-time nutrient monitoring and analysis	Static PDF guidelines and general portion advice
Weight monitoring	Automated IOM[c] guideline alerts and trend visualization dashboards	Manual clinic measurements and verbal feedback
Glucose tracking	App-integrated data synchronization and weekly dietitian review	Paper-based logs and monthly physician review
Fetal surveillance	Ultrasound parameter input for fetal weight estimation and growth percentile curves	Standard ultrasound reports
Review, feedback, and support frequency	Daily self-monitoring+weekly professional feedback	Biweekly counseling+routine antenatal check-ups

[c]IOM: Institute of Medicine.

Data Collection

Data collection was performed by research nurses who were blinded to group allocation. Baseline data were collected during the OGTT, which was conducted between the 24th and 28th gestational weeks, and the intervention was initiated at the 28th gestational week. Two intermediate follow-up assessments were planned from intervention initiation to delivery, scheduled at the 32nd (1-mo follow-up) and 36th weeks (2-mo follow-up). The study end point was defined as delivery, including preterm delivery (consistent with clinical criteria, ie, delivery between the 28th and 37th gestational weeks) and term delivery (delivery

XSL•FO
RenderX

at or after the 38th gestational week). Participants with preterm delivery may miss the follow-up assessments scheduled thereafter and reach the study end point ahead of schedule (early closure) compared to term delivery (routine closure). Research nurses contacted participants by phone or WeChat to schedule data collection sessions, and all assessments were completed by participants in the obstetric clinic, with onsite researcher assistance available if needed. HbA_{1c} was measured twice, specifically at baseline and at the end point. To prevent contamination between groups, data collection procedures for the intervention and control groups were scheduled on separate dates at the study site.

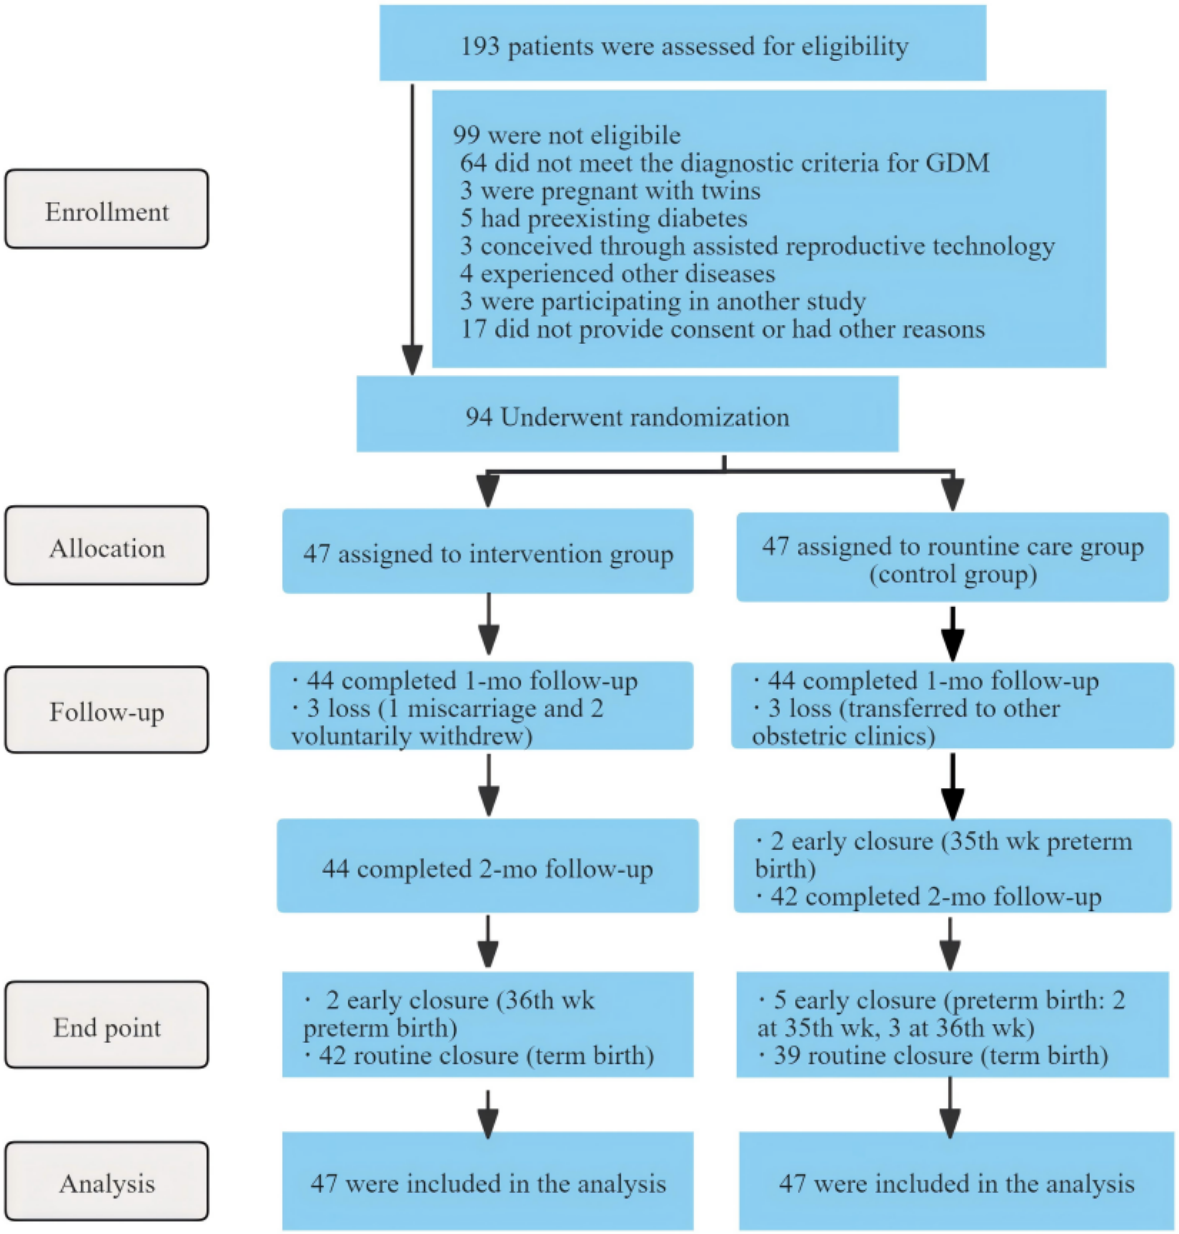
Ethical Considerations

This study was approved by the hospital institutional ethics committee (approval 2023-109-02) and abided by the principles of the Declaration of Helsinki. All patients who participated in the study participated voluntarily and obtained the informed consent from each patient in writing. Patients had the right to withdraw from the study at any time. All exported data must undergo anonymization by the data manager before statistical analysis can be conducted. Individuals cannot be identified in any results presentation. No financial compensation was provided to avoid coercion.

Outcome Measures

The primary outcome measures of this study included glycemic control status and weight changes during pregnancy. Glycemic control was assessed using fasting blood glucose (FPG) and 2hPG levels, both of which were measured on a Hitachi 7600 analyzer (Hitachi High-Technologies Corporation) using venous plasma samples. Additionally, HbA_{1c} was determined through high-performance liquid chromatography. Gestational weight gain (GWG) was defined as the weight accrued during pregnancy and was computed as the numerical difference between the measured weight values at each follow-up time point and the baseline. The secondary outcome measures included obstetric complications and neonatal outcomes, such as gestational hypertension, preterm birth (<37 wk), and neonatal birth weight. The amniotic fluid index (AFI) was included as a secondary outcome because of its reported association with GDM-related fetal oligohydramnios and polyhydramnios, which may increase the risks of preterm labor and cesarean delivery. AFI was measured by ultrasound using the 4-quadrant technique after the 36th week and prior to delivery, with oligohydramnios defined as an AFI<5 cm and polyhydramnios as an AFI>25 cm, respectively. All measurements were conducted in strict adherence to standardized clinical practices.

Statistical Analysis



Descriptive statistical analyses were performed, whereby continuous variables were summarized as means (SDs) and categorical variables were presented as frequencies and corresponding percentages. The primary efficacy analysis adhered to the intention-to-treat (ITT) principle, wherein all randomized participants (n=94) were analyzed according to their original group assignments—this included individuals who were excluded during the study or lost to follow-up. Among the 94 participants, 6 participants (6.38%) had transferred to other clinics, experienced miscarriage, or withdrew (missing data, Figure 2). Little's missing completely at random tests were performed on the postintervention outcome variables. The results were not statistically significant (P=.17 and P>.05), indicating that the missing data mechanism was completely at random.

Generalized linear mixed models (GLMMs) were used to assess the intervention's effects on primary outcomes (FPG, 2hPG, and GWG) across different time points: 4 (time: baseline, 1 mo, 2 mo, and end point)×2 (group: intervention vs control). General sociodemographic characteristics and blood glucose management–related data were incorporated as covariates in this model to control for potential confounding factors. Additionally, a distinct 2 (time: baseline and end point)×2 (group: intervention vs control) GLMM was established to examine longitudinal changes in HbA_{1c} levels and to compare between-group differences in HbA_{1c}. This analytical approach was selected because it can account for within-subject correlations and manage missing data under the missing-at-random assumption, enabling the use of all available data points without the need for multiple imputation. All GLMMs incorporated fixed effects for 3 key terms: the intervention group, time point, and the group×time interaction between group and time; a random intercept for each participant (1|ID) was also included to account for interindividual variability. To verify the robustness of the study findings, a per-protocol analysis was additionally performed, including only participants who completed the full intervention course and all scheduled follow-up assessments.

The secondary outcomes (maternal and fetal clinical measures) were analyzed using per-protocol methods. For the assessment of between-group disparities, we used independent-samples 2-tailed t tests to compare continuous variables (eg, AFI) and chi-square tests to analyze categorical variables such as the incidence of preeclampsia. All analyses were conducted using R software (R Foundation for Statistical Computing). The GLMMs were fitted using the lme4 package. A 2-sided P value <.05 was considered to indicate statistical significance.

Results

Overview

Between March 2023 and October 2023, a total of 94 participants were recruited for this study. Among them, 88 (93.62%) participants (mean age 32.18, SD 5.04 y) successfully completed the study: 44 (46.81%) participants in the intervention group and 44 (46.81%) in the control group. No adverse events or unintended effects were observed in either group throughout the study period. The participant flow and reasons for dropout are shown in Figure 2.

Participant Engagement

The backend records of the WeChat app showed that in the intervention group, 87.2% (41/47) of the participants used the "Diet Diary" mini-program for daily dietary logging, whereas 78.7% (37/47) used the "Pregnancy Sugar Weight Record" and "Fetal Weight Assessor" programs for weight tracking. For the remaining participants who encountered difficulties inputting the data themselves, nurses assisted in entering the information into the mini-programs. All the participants explored the "food charts" module, learning the GI values of 476 foods, food selection, and weighing. Initially, they engaged with these tools 2 to 3 times daily for 20 to 45 minutes, but usage decreased as they became more familiar with food attributes. They only revisited the information when needed. Among the 44 participants who completed the study, 54.5% (24/44) adhered to the diet plan ≥80% of the days, 13.6% (6/44) followed it for 60% to 79% of the days, 11.4% (5/44) followed it for 40% to 59% of the days, another 11.4% (5/44) for 20% to 39% of the

XSL•FO
RenderX

days, and 9.1% (4/44) for <20% of the days. In the control group, all 44 participants who completed the study reported independently studying the provided materials and following the dietary guidance for 60% to 80% of the days. No harms or unintended effects were found in each group.

Baseline Demographic Characteristics and Clinical Data

The sample had a mean age of 32.18 (SD 5.04; range 22 - 45) years (Table 3). The mean pBMI was 24.97 (SD 4) kg/m². For glycemic indicators, the mean FPG was 5.39 (SD 0.67) mmol/L, the mean 2hPG was 8.66 (SD 1.24) mmol/L, and the mean HbA_{1c} in the sample was 7.2% (SD 0.69).

Table . Baseline data across the intervention and control groups.

Characteristics	Total (N=94)	Intervention (n=47)	Control (n=47)
Age (y), mean (SD)	32.18 (5.04)	32.74 (4.91)	31.62 (5.15)

Changes in Primary Outcomes Over Time Between the mHealth and Control Groups

The GWG progressively increased over time in both groups, with the control group exhibiting greater increases (Figure 3). By the end point, the control group's mean weight had increased by 15.11 (SD 12.56) kg, whereas the intervention group's mean weight had increased by 13.31 (SD 12.21) kg (Table 4).

FPG levels fluctuated between the groups (Figure 3). In the control group, the FPG concentration increased by 0.17 (SD 0.61) mmol/L at 1 month and 0.32 (SD 0.70) mmol/L at 2 months but then slightly decreased by 0.15 (SD 0.62) mmol/L at the end point (Table 4). In contrast, the levels in the intervention group gradually decreased, with FPG levels decreasing by 0.15 (SD 0.70) mmol/L at 1 month, 0.06 (SD 0.78) mmol/L at 2 months, and 0.11 (SD 0.56) mmol/L at the end point.

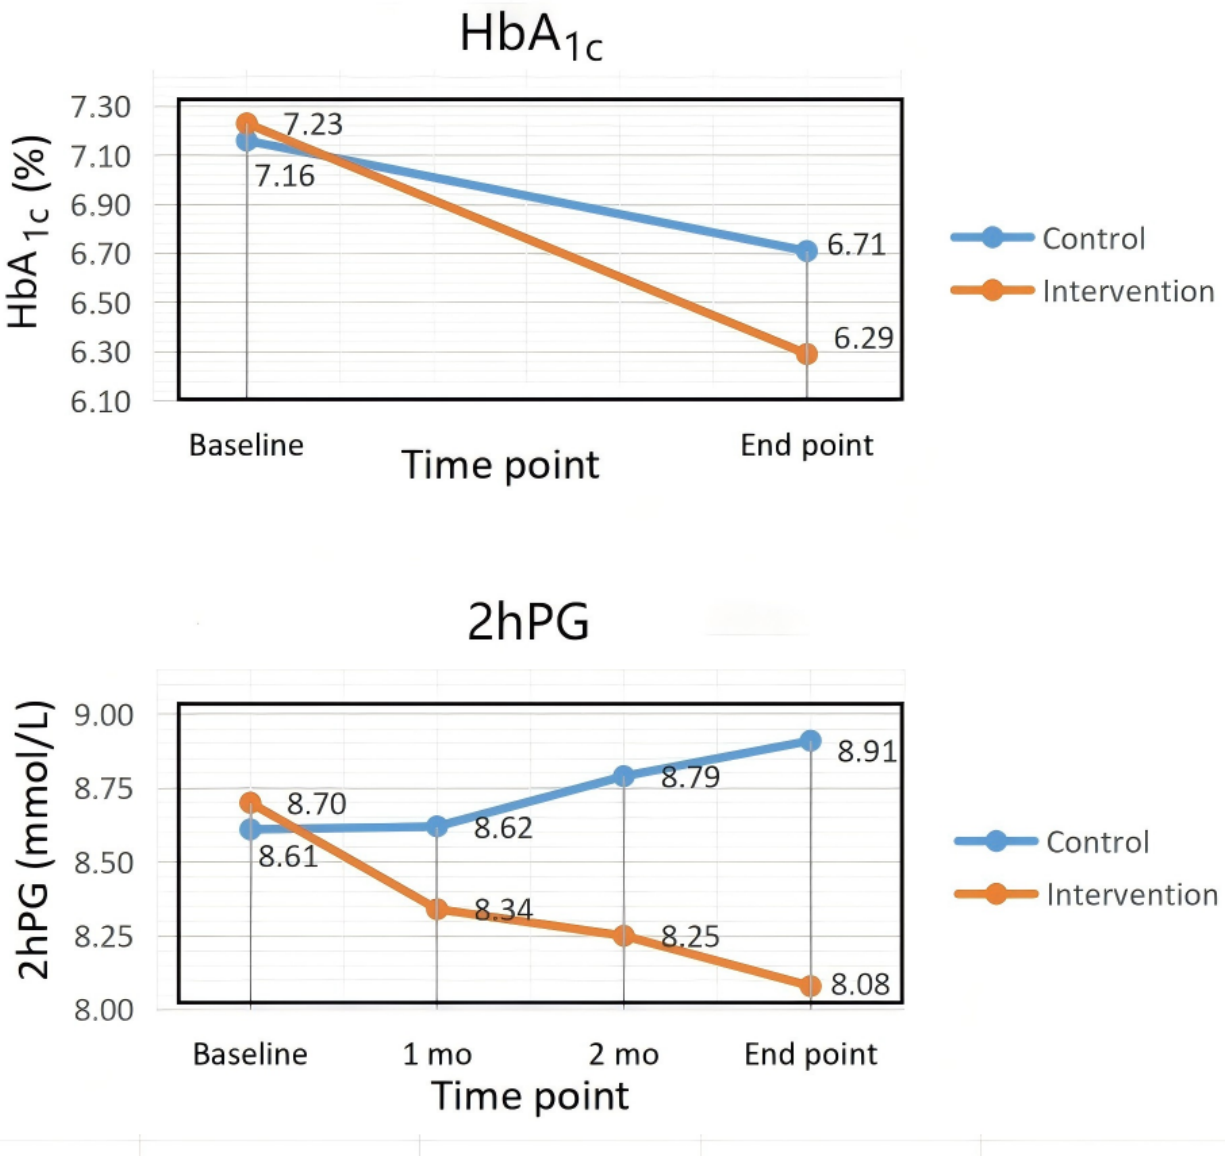
[a]GWG: gestational weight gain

[b]FPG: fasting blood glucose.

[c]2hPG: 2-hour postprandial glucose.

[d]HbA_{1c}: hemoglobin A_{1c}.

[e]HbA_{1c} was measured only at baseline and at the final end point of the study.



[f]N/A: not applicable.

Both groups showed a decreasing trend in HbA_{1c} levels (Figure 4), with the intervention group demonstrating substantially greater decreases. By the end point, the control group's mean HbA_{1c} had decreased to 6.71% (SD 0.62), representing a reduction of 0.43% (Table 4). The mean HbA_{1c} in the intervention group decreased to 6.29% (SD 0.75), indicating a more pronounced reduction of 0.92% from baseline.

Both groups showed an increase in 2hPG over time, but the intervention group demonstrated greater decreases (Figure 4). By the end point, the control group's mean 2hPG had risen to 8.91 (SD 1.23) mmol/L, representing an increase of 0.42 mmol/L (Table 4). In contrast, the mean 2hPG of the intervention group decreased to 8.08 (SD 1.51) mmol/L, indicating a reduction of 0.52 mmol/L from baseline.

Figure 4. Changes in hemoglobin A1c (HbA_{1c}) and 2-hour postprandial glucose (2hPG) between the intervention and control groups over time.

Effectiveness of the Intervention Through the ITT Analysis

Adjusted GLMMs with ITT analysis revealed a significant group×time interaction for GWG (Table 5); notably, the intervention group achieved a significantly greater reduction in GWG over time compared with the control group, as indicated by the negative coefficient of the group×time interaction (β=−1.96, 95% CI −3.58 to −0.34; *P*=.02). For FPG, no significant group×time interaction effect was observed. In contrast, both 2hPG and HbA_{1c} showed significant group×time interaction effects. Compared with the control group, the intervention group demonstrated substantially greater decreases in 2hPG (β=−0.12, 95% CI −0.19 to −0.04; *P*<.001) and HbA_{1c} (β=−0.49, 95% CI −0.74 to −0.23; *P*<.001) over time. The results of the per-protocol analyses (Multimedia Appendix 2) were consistent in terms of the direction and significance of the ITT analyses.

2hPG[c] (mmol/L)			
Time	0.04 (−0.02 to 0.09)	0.03	.22
Group	0.02 (−0.05 to 0.08)	0.03	.65
Group×time	−0.12 (−0.19 to −0.04)	0.04	<.001
HbA_{1c}[d] (%)			
Time	−0.44 (−0.62 to −0.26)	0.09	<.001
Group	0.07 (−0.21 to 0.35)	0.14	.64
Group×time	−0.49 (−0.74 to −0.23)	0.13	<.001

[a]GWG: gestational weight gain.

[b]FPG: fasting blood glucose.

[c]2hPG: 2-hour postprandial glucose.

[d]HbA_{1c}: hemoglobin A_{1c}.

Maternal and Fetal Outcomes

No unexpected maternal events were observed among the participants. Compared with that in the control group, the AFI in the intervention group was significantly different (Table 6). However, both values were within the normal range and were not expected to have adverse effects on the fetuses. The number of cases of preeclampsia, preterm infants, low-birth-weight infants (birth weight <2500 g), and macrosomia (birth weight >4000 g) were lower in the intervention group than those in the control group, yet the differences were not statistically significant (Table 6).

Table . Comparisons of the secondary outcomes between the intervention and control groups.

Group	AFI[a,b,c] (cm), mean (SD)	Preeclampsia[d,e], n (%)	Preterm birth[f,g], n (%)	Low birth weight[h,i], n (%)	Macrosomia[j,k], n (%)
Intervention (n=44)	12.01 (3.31)	1 (2.27)	2 (4.54)	1 (2.27)	4 (9.09)
Control (n=44)	13.49 (3.19)	3 (6.82)	5 (11.36)	3 (6.82)	7 (15.91)

Discussion

Principal Findings

Collectively, the WeMNT intervention demonstrated targeted efficacy in improving glycemic control among women with GDM, particularly in modulating GWG, 2hPG, and HbA_{1c} dynamics. While it failed to have a meaningful effect on FPG, the favorable changes in 2hPG and HbA_{1c} trajectories highlight the intervention's potential as a practical tool for GDM management. These findings underscore the importance of tailored dietary interventions to address specific glycemic outcomes during pregnancy, with further research needed to optimize the interventions for broader efficacy.

Prior studies on HbA_{1c} management have demonstrated that WeChat-delivered intervention tools—validated across 6 RCTs—yield a notable effect size of 0.84 (95% CI –0.22 to −1.46) [21]. Remarkably, in our MNT intervention cohort, HbA_{1c} levels substantially decreased. This promising outcome is most likely due to the mHealth technology we crafted. An mHealth intervention based on a behavioral model, whether used independently or in tandem with other approaches, confers a distinct advantage for effective blood glucose control [25]. Continuous self-tracking of blood glucose, a common intervention measure in GDM management, clarifies the links between glucose levels and nutrition, thereby supporting autonomous self-management without the need for direct health care assistance [26]. Using key BCTs in diabetes management, our project provides timely feedback and evaluations based on records and indicator data, acknowledging strengths and making improvement suggestions through WeChat instant messages and voice calls. It not only facilitates self-learning and monitoring of GDM and communication with health care professionals but also establishes WeChat peer groups to encourage experience sharing and mutual encouragement among patients. This feature effectively sustains participants' engagement and active involvement in managing their own care, a critical aspect of the intervention [27,28].

Evidence indicates that when HbA_{1c} levels are less than 7.3%, 2hPG may contribute up to 70% of total HbA_{1c} elevation [29]. In our GDM cohort, FPG had a mean of 5.38 (SD 0.69) mmol/L, with an average HbA_{1c} of 7.17% (SD 0.71%), suggesting that the increase in HbA_{1c} in this population is largely attributable to increased 2hPG levels. Given this relationship, dietary variations have a pronounced effect on 2hPG, rendering this parameter highly responsive to dietary interventions; HbA_{1c} consequently shares this sensitivity, as its elevation is closely linked to 2hPG fluctuations. In contrast, the intervention yielded no significant effects on FPG levels. These findings are consistent with the results of a meta-analysis focusing on dietary interventions for GDM, which reported a significant 2hPG reduction of 27.78 mg/dL (P<.001) and a transient FPG reduction of 24.07 mg/dL (P=.02) in intervention groups [6]; however, only the abovementioned results align with common observations in the field: FPG levels often do not significantly respond to dietary interventions in individuals with GDM [30].

Maternal weight gain throughout pregnancy constitutes a fundamental physiological process of gestation. Our regression model revealed a highly significant time main effect (β=15.10, 95% CI 13.96 - 16.25; P<.001), indicating that a substantial increase in maternal weight occurs as pregnancy progresses. Notably, mobile phones have emerged as a promising tool for GWG management in recent years. Prior studies have consistently demonstrated that smartphone apps exhibit remarkable efficacy in promoting healthy weight gain during pregnancy [31,32]. These technologies overcome the limitations of traditional face-to-face guidance by providing personalized dietary recommendations, supporting pregnant women in maintaining optimal weight trajectories during gestation. The findings of this study validated the effectiveness of mHealth interventions in controlling GWG. Our regression analysis revealed a significant group×time interaction effect (β=−1.96, 95% CI −3.58 to −0.34; P=.02), indicating a significantly gentler pattern of weight gain in the intervention group compared with the control group. While the effect size was small and its impact on final weight gain was limited, its value in controlling dynamic weight growth remained undiminished. These results align with the conclusions of previous studies, further confirming the potential of mHealth tools as an adjunct to routine antenatal care.

The unique advantages of our mHealth intervention lie in its targeted timing and strategy design, which address the unmet needs of pregnant women in the third trimester. Our intervention started at week 28 (the start of the third trimester), a time when physical constraints hinder exercise-based weight management [25]. Unlike exercise-reliant programs, it integrates core nutritional guidance (BCT 4.1/4.2), MNT plan design support (BCT 6.1), scheduled meal reminders (BCT 1.4), food portion logging, and real-time intake target alerts—helping participants use science-backed diets to curb excessive weight gain amid inevitable late-pregnancy physiological weight growth. A second key advantage is its focus on collaborative clinical and self-management efforts, which are critical for addressing inappropriate GWG and protecting maternal and child health. This dual-focused approach bridges the gap between clinical recommendations and real-world adherence.

Regarding other maternal and fetal outcomes, a comprehensive meta-analysis of 32 RCTs confirmed that mHealth strategies effectively improve glycemic control and reduce the risks of adverse maternal and fetal outcomes [19]. Specifically, the risk ratios were 0.49 for macrosomia (95% CI 0.30 - 0.80; P<.01), 0.48 for preeclampsia (95% CI 0.40 - 0.58; P<.01), and 0.27 for preterm birth (95% CI 0.20 - 0.35; P<.01). However, our study revealed no significant effects of the intervention on these outcomes or birth weight. Notably, our limited sample size may have restricted the detection of subtle effects, highlighting the need for further investigation of these endpoints in future research.

Limitations

This study has several limitations. First, it was impossible to implement blinding for the personnel involved in the WeMNT intervention. To address this issue, we crafted a protocol to guide the intervention, refined the guidance to align with it, and

XSL•FO
RenderX

equipped the team with the skills to execute it effectively. Second, this study, which was conducted in a single region with a homogeneous population, has limitations in terms of generalizability. To bridge the implementation gap, we documented each mHealth module's design and implementation, aligned with those of the BCW. This supports cross-setting validation and real-world generalization. Third, our study focused on short-term outcomes, and long-term effects on mothers and children remain undetermined. Future research should recruit larger, heterogeneous cohorts to evaluate the efficacy across diverse populations and extended timeframes. Finally, although we adjusted for key covariates in the sensitivity analyses, there may still be unmeasured confounders (eg, genetic predisposition and family medical history) that could influence the study outcomes. Future research should use multivariate regression or mixed effects models to achieve more effective control over these factors.

Conclusions

This study demonstrated that the WeMNT program effectively improved nutritional self-management and blood glucose control in patients, with significant reductions in 2hPG, HbA_{1c}, and GWGs, supporting its clinical adoption for GDM. However, long-term maternal-child outcomes remain unexplored and warrant larger, diverse cohort studies for extended evaluation.

Abstract

Background: The first 2000 days can profoundly influence long-term health. Healthy Beginnings for Hunter New England Kids (HB4HNEKids) is an SMS text messaging program delivered alongside routine Child and Family Health Nursing (CFHN) care, which provides families with evidence-based, age- and stage-related preventive health information across the first 2000 days.

Objective: This pilot study aimed to explore the feasibility, engagement, and acceptability of the HB4HNEKids program. It also aimed to explore the potential effectiveness of the program at 6 and/or 12 months post partum on outcomes including breastfeeding, child diet, child movement, and parental mental well-being.

Methods: During the pilot phase (October 2021 to July 2024), project records were used to assess the number of families enrolled, number of SMS text messages sent (feasibility), and the number of opt outs (engagement). Repeat cross-sectional surveys were conducted at 5 - 7 months post partum and again at 12 - 14 months post partum using validated survey instruments. Using convenience sampling methods, survey participants consisted of birthing parents who had received HB4HNEKids and a concurrent nonrandomized comparison group that did not receive the program. Surveys assessed parental self-reported engagement with the messages, program acceptability, breastfeeding status, child diet, child movement, and parental mental well-being. Mixed linear regression analyses were conducted to calculate mean differences and odds ratios.

Results: During the pilot phase, HB4HNEKids was delivered to 6243 families (73.4% of families contacted by CFHN). A total of 383 birthing parents completed the survey at 6 months (99/383, 26% receiving HB4HNEKids), and 283 completed the survey at 12 months (104/283, 37% receiving HB4HNEKids). Of the survey participants who received HB4HNEKids (n=200), between 76% and 83% reported that they always or very often read the SMS text messages, spending on average 5 - 7 minutes engaged with the content. At both survey time points, more than 90% of participants receiving HB4HNEKids agreed that the program was acceptable. Child daily intake of vegetables was significantly higher in the HB4HNEKids group (adjusted mean difference 0.23, 95% CI 0.07-0.40; *P*=.006) than in the comparison group at 12 months. Parents receiving HB4HNEKids also reported significantly better mental well-being scores (*P*=.005). While HB4HNEKids participants reported breastfeeding rates 5 percentage points greater than comparison participants at 6 and 12 months, this result was not statistically significant. There were no statistically significant differences between HB4HNEKids, and comparison participant responses related to child movement behaviors.

Conclusions: The HB4HNEKids SMS text messaging program is feasible to deliver at scale alongside routine CFHN care and is highly acceptable and engaging to parents. This pragmatic evaluation of the pilot, embedded into usual care, indicates potential

XSL•FO
RenderX

effectiveness of the program for improving child vegetable intakes and parental mental well-being. Further evaluation of this program using robust methodology is needed to determine the effectiveness of this innovative mHealth program across the first 2000 days.

Introduction

The first 2000 days of life represents a critical period between conception through to 5 years that significantly impacts on child's physical, emotional, social, and cognitive development, laying the foundations for a child's lifelong trajectories [1]. Breastfeeding practices, introduction to solid foods, development of movement behaviors, and optimal parental mental well-being can significantly influence child's health and developmental outcomes [2-4]. The mental well-being of parents can influence the quality of care given to infants and is associated with a variety of health and developmental outcomes [5-7]. While longer breastfeeding duration, child's consumption of fruits and vegetables, and increased physical activity are associated with enhanced cognitive development and reduced lifelong risk of chronic disease [2-4,8], current data suggest that these outcomes are below national and international targets [9-11].

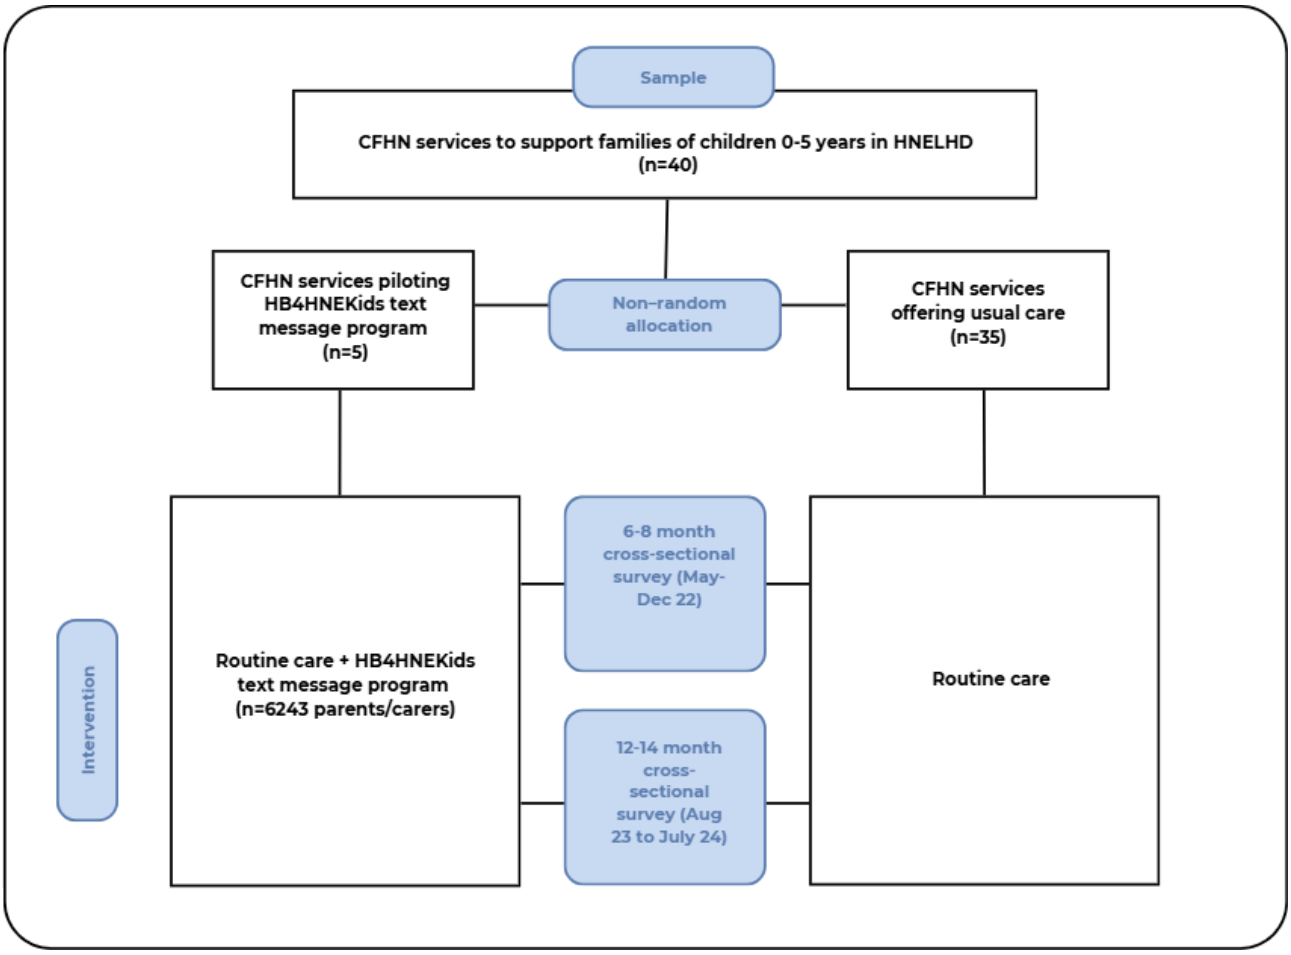
In alignment with key international, national, and state-level health policies, Child and Family Health Nursing (CFHN) services in New South Wales (NSW), Australia, provide care and support to families following the birth of infants, with the goal of enhancing child and family health, development, and well-being during the first 2000 days [12,13]. The services offered by CFHN are primarily delivered face-to-face and align to scheduled health and developmental checks, providing lactation education, emotional support, vaccinations, preventive health advice, and screening and secondary referral pathways. However, due to various health service barriers (eg, staff capacity and geographic location), care focuses on supporting families during the first few months of the child's life, with ongoing targeted services prioritized for those identified with additional needs. Furthermore, accessing face-to-face preventative health services can be challenging for parents, given caregiving responsibilities and work commitments [14,15]. Therefore, population-wide engagement with CFHN care significantly declines over the first 2000-day period, resulting in fragmented service utilization (NSW Ministry of Health, Health System Performance Report, internal data, 2025). This highlights the need for inclusive and accessible preventive health services to ensure that all families receive timely, trusted, and evidence-based support throughout the course of the first 2000 days.

Mobile health (mHealth) interventions represent a promising strategy to overcome some of the barriers to the traditional face-to-face support offered during the first 2000 days. Given that access to mobile phones and smartphones is relatively ubiquitous [16,17], mHealth interventions, including targeted SMS text messages delivered directly to parent or carer mobile phones, could improve the delivery of preventative care and health promotion during the first 2000 days [18]. This concept is supported by formative research conducted within the Hunter New England (HNE) region of NSW, Australia, which found that parents are highly accepting of receiving CFHN support via a variety of technology modalities (including websites, email, and SMS text messaging) on a variety of child– and family health–promoting topics (including healthy eating, introduction to solids, breastfeeding, sleep, and healthy growth) [19]. Systematic reviews also demonstrate that mHealth is effective in increasing multiple health behaviors including frequency of maternal contact with antenatal care, child immunization rates, and improving maternal and child health outcomes such as anxiety and depression, obesity prevention, and exclusive breastfeeding rates [20-25]. Additionally, a randomized controlled trial (RCT) conducted under robust research conditions demonstrates the efficacy of 1-way parent-targeted SMS text messaging interventions for improving infant feeding practices (ie, bottle use at bedtime) and reducing screen time [26]. This highlights the potential for 1-way SMS text message–based interventions during the postpartum period of the first 2000 days.

Despite the potential of mHealth interventions, few effective interventions have been embedded into health service delivery and implemented in real-world settings during the first 2000 days [27-29]. For mHealth interventions to effectively improve population health, they must be integrated into the settings, services, or health systems that reach the intended target population [29]. Given the limited translation of effective mHealth programs into usual health service delivery and building on the robust research evidence [18], there is a need to evaluate the feasibility, engagement, acceptability, and potential effectiveness of research innovations when embedded into routine care. The aim of this study was to pragmatically evaluate the feasibility, engagement, and acceptability of the pilot Healthy Beginnings for Hunter New England Kids (HB4HNEKids) program when embedded into routine CFHN service delivery. This pilot also explores the potential effectiveness of HB4HNEKids for improving child and parental health and well-being outcomes at 6 and/or 12 months post partum, including (1) breastfeeding, (2) child nutrition, (3) child movement, and (4) parental mental well-being.

Methods

Study Design



The feasibility, engagement, acceptability, and potential effectiveness of an SMS text messaging model of care delivered to families during the first 2000 days were evaluated as part of an observational study with a nonrandomized control arm. This study involved 2 cross-sectional surveys conducted with a

XSL•FO
RenderX

convenience sample of birthing parents located in the Hunter New England Local Health District (HNELHD) of NSW, Australia. As the 1-way SMS text messaging program (HB4HNEKids) was initially launched in October 2021 to parents attending 5 pilot CFHN services across 3 diverse local government areas (Armidale, Cessnock, and Newcastle/Lake Macquarie), the cross-sectional surveys include a subsample of participants who had received HB4HNEKids and a concurrent non–randomized comparison group of parents who did not receive HB4HNEKids. The first cross-sectional survey was undertaken between May and December 2022 and included birthing parents 5 - 7 months post partum. The second cross-sectional survey was conducted between August 2023 and July 2024 and included birthing parents 12 - 14 months post partum (Figure 1).

This repeat cross-sectional study is reported in accordance with the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) guidelines for cross-sectional studies (Checklist 1).

Figure 1. Flow of participants through the study. CFHN: Child and Family Health Nursing; HB4HNE: Healthy Beginnings for Hunter New England.

Ethical Considerations

Ethics approval for all maternal data was obtained from the Hunter New England Human Research Ethics Committee (16/11/16/4.07), Aboriginal Health and Medical Research Council (1236/16), and The University of Newcastle Human Research Ethics Committee (H-2017 - 0032). This research was conducted in compliance with informed consent guidelines, and study participant informed consent was sought prior to completion of surveys and implied upon the completion of a survey. Participant data were collected and securely stored using the REDCap (Research Electronic Data Capture), compliant with health service privacy and confidentiality policies. Data were anonymized, deidentified, and stored so that only authorized individuals could access the data. This research did not offer participants compensation for participating in the SMS text messaging program (HB4HNEKids) or the surveys.

Data Collection Procedures

Overview

Both the 6-month and 12-month surveys were developed using the REDCap (version 14.1.2; © 2025 Vanderbilt University) tool, hosted by HNELHD, which is a secure research electronic database commonly used in health service research [30,31]. Participants completed the survey either online or via computer-assisted telephone interview (CATI). Survey consent and responses were also stored in REDCap, providing a central survey database.

Eligibility for Participation in the Surveys

To evaluate the effectiveness of the pilot HB4HNEKids SMS text messaging program, a cross section of birthing parents who had accessed HNELHD maternity services was invited to participate in a survey at 2 time points. For the first survey, eligibility criteria for birthing parents were 26 - 37 weeks (ie,

XSL•FO
RenderX

approximately 6 months) post partum; those aged 18 years or older; had received antenatal care from any public antenatal service in HNE (providing antenatal care to approximately 70% of women across the district); had not had an unfortunate pregnancy-related outcome (ie, stillbirth); able to communicate in English; had previously provided consent to participate in a survey of antenatal care; and agreed to be contacted for future surveys. Eligibility for the second survey was the same as the first survey, except that birthing parents needed to be approximately 12 months post partum and have reached >34 weeks of gestation to be eligible to complete the survey.

Recruitment of Participants to Participate in the Survey

As per ethics approval, electronic medical records and previous antenatal survey data were used to identify the sample. Using this method, birthing parents who met eligibility criteria for survey participation were mailed printed information statements, providing an outline of the survey and a toll-free number to withdraw or decline participation.

Recruitment of Non-Aboriginal Participants to the Survey

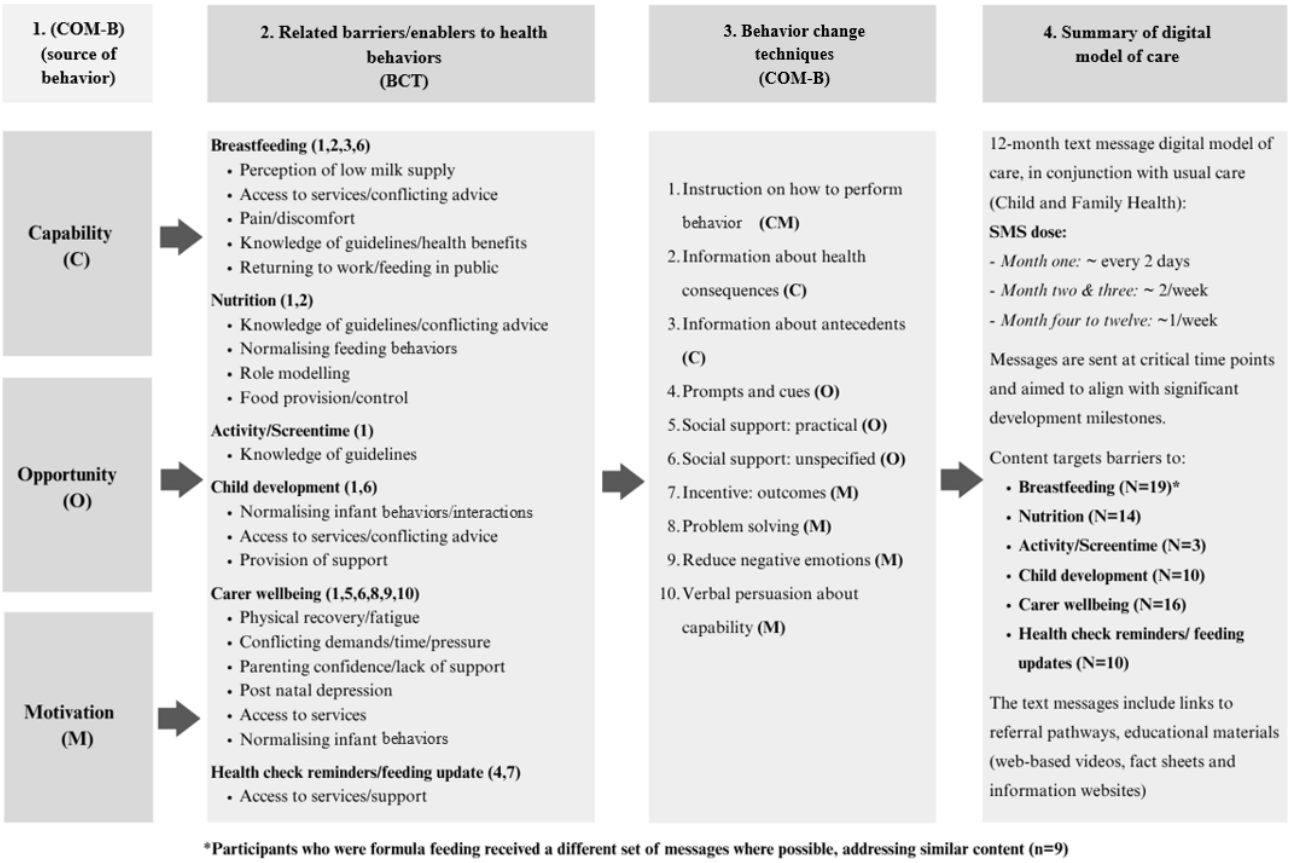
Participants were sent information statements if their child met the eligibility criteria for participation. One week after information statements were mailed, birthing parents were contacted by telephone and invited to participate in the survey via a CATI. Birthing parents received up to 10 phone call attempts over a 2-week period to invite survey participation. As per ethics approval, verbal consent to participate in the surveys was sought from the birthing parent at the time of the interview. Birthing parents who declined to participate during the CATI were offered the opportunity to complete the survey online and were sent an individual survey link to their mobile number or email address. Before accessing the online survey, participants were reminded in the survey's display screen that participation was voluntary and that it was possible to decline the survey at any point. Participant consent into the study and survey completion status (both via CATI and online) were saved into a central survey database, in REDCap, held by the research team.

Recruitment of Aboriginal Participants to the Survey

Following advice provided from local cultural consultation, birthing parents identifying as Aboriginal and/or Torres Strait Islander were sent an SMS text message 3 days after the mail out of the information statement. The SMS text message offered one of three options (1) to complete the survey via CATI, (2) to complete the survey online, or (3) decline participation. Participants could respond to the SMS text message to indicate their preferred method of contact. Those who opted to complete the survey online were sent an individual survey link to their mobile number which was active for 2 weeks. Those who opted to complete the survey via telephone or did not reply to the SMS text message within 5 days received a phone call from a female interviewer and were invited to participate in the study.

The Text Messaging Program—Healthy Beginnings for Hunter New England Kids

Overview



HB4HNEKids is an mHealth SMS text messaging program providing parents or carers with age- and stage-relevant preventative health information. The program is an adapted version of an RCT that demonstrated impact on reducing screen time and bottle use at bedtime at 12 months [26]. The HB4HNEKids program was adapted to strengthen a range of behavioral outcomes, supporting parents and children to develop preventive health behaviors during the first 2000 days. Implementation focused on overcoming health system and parent barriers to accessing health services and was therefore designed to be delivered alongside routine CFHN care. HB4HNEKids aims to offer timely, age- and stage-appropriate health promotion information directly to parents' and carers' mobile phones including preventive health information such as breastfeeding, infant feeding, movement behaviors, and parental well-being. The program also offers reminders for scheduled child health checks and immunizations, early developmental screening, and information on available support services.

Program Adaptation Process

HB4HNEKids was adapted from a prior RCT [26] to strengthen the effectiveness of SMS text message support offered across the first 2000 days and enhance alignment to usual CFHN care delivery. The HB4HNEKids program focuses on 6 key health behaviors, aligned with specific age and stage developmental milestones and key policy frameworks targeting the first 2000 days [13,32,33]. The process of adaptation involved (1) identifying priority health behaviors from policy frameworks, strategic plans, and expert consultation; (2) review of the literature to identify determinants of priority health behaviors; (3) use of behavioral theory (eg, Behavior Change Wheel [34] and Theoretical Domains Framework [35]) to develop SMS text messages embedding behavior change techniques to address the identified determinants; and (4) co-design of SMS text messages collaboratively with HNELHD health practitioners including CFHN, allied health professionals, public health practitioners, Aboriginal health workers, and representatives from multicultural health to ensure that wording and intent aligned with usual care (Figure 2).

XSL•FO
RenderX

Figure 2. Healthy Beginnings for Hunter New England Kids logic model.

All eligible families were offered HB4HNEKids either prior to or during the face-to-face routine 1 - to 4-week health check provided by CFHN services, as a digital program offered alongside usual care. The HB4HNEKids SMS text messages were short (often less than 160 characters) and included clickable links to evidenced-based "online" videos, fact sheets, websites, and relevant support services. Parents receiving the HB4HNEKids program were sent up to 44 SMS text messages in the first 6 months and a further 28 between 6 and 12 months to their nominated mobile number. Messages were sent 7 days a week, generally between the hours of 9 AM and 12 PM. While most messages were designed to be a 1-way SMS text message, the exception was the 2-way SMS text message sent to participants to confirm infant feeding status (on days 21, 97, and 150). Responses to feeding status were received in the messaging platform. Feeding status responses were stored in REDCap and monitored by a member of the research team each weekday. By collecting feeding status, the program content was tailored to better meet the individual needs of the participant (eg, families who were exclusively formula feeding did not receive content related to breastfeeding). Participants were sent a link on days 1, 51, and 296, which allowed participants to opt out and automatically unsubscribe from the program upon clicking. The opt out links remained valid or open allowing the participant to opt out of the program at any time.

Eligibility for Receipt of HB4HNEKids Program

All parents in HNELHD who had recently given birth are referred to CFHN services to receive ongoing care for their child until age 5 years. Parents due to receive a 1 - to 4-week health check from 1 of the 5 participating CFHN services located in the HNELHD between October 2021 and July 2024 were eligible for the HB4HNEKids SMS text message program alongside their usual CFHN care. Parents needed to have access to a mobile phone to be eligible to receive the program.

Recruitment of Women to the HB4HNEKids Program

As per the existing health service procedures, CFHN services received a referral from public and private maternity services in the HNELHD following the birth of a baby and discharge of the parent from hospital [36]. CFHN service staff then contacted birthing parents in their local catchment area to offer a 1 - to 4-week health check, which typically occurs within 3 business days of receipt of the CFHN referral. Staff from pilot CFHN services were encouraged to offer the HB4HNEKids program to all birthing parents within their catchment area. At the initial booking in contact, CFHN staff confirmed feeding status (breastfeeding, mixed feeding, and formula feeding), child's name, mobile number, and "clinician offer of service" (yes, client refused, and unable to contact after multiple attempts), and recorded this in a REDCap [31]. If CFHN service staff were unable to determine infant feeding status during the initial call (ie, due to language barriers), they would locate infant feeding status via the discharge summary provided by maternity services and enter this into REDCap.

Outcome Measures

Feasibility of Delivering HB4HNEKids via Routine CFH Care

During the relevant pilot time frame (October 2021 to July 2024), project record data (securely stored in REDCap) were

XSL•FO
RenderX

used to assess feasibility of the program as follows: (1) number of families enrolled in the HB4HNEKids program, (2) proportion of families enrolled in the HB4HNEKids program relative to the number of families contacted by CFHN services for the 1 - to 4-week appointment, (3) number of families who opted out of the HB4HNEKids program, and (4) number of messages sent as part of the HB4HNEKids program.

Engagement With HB4HNEKids Content

Within the 6-month and 12-month surveys, parents who had received HB4HNEKids were asked to report their engagement with the program SMS text message content. These items assessed how often participants read the SMS text messages and how often they clicked the website links within the SMS text messages, with response options including Always, Very often, Sometimes, Rarely, and Never. Participants were also asked to report average time spent (in minutes) engaged in the SMS text message content and links.

Acceptability of HB4HNEKids

To assess parent acceptability of the HB4HNEKids SMS text messaging program, measures of program acceptability were adapted from the psychometrically validated Acceptability of Intervention Measure by Weiner et al [37]. All survey items were assessed on a 5-point Likert scale (strongly disagree=1, disagree=2, neither agree nor disagree=3, agree=4, and strongly agree=5). Participants were coded as "agreeing" to statements, if they responded "strongly agree" or "agree" to any of the statements. Responses to Acceptability of Intervention Measure items were grouped according to (1) acceptability of the overall program, (2) acceptability of SMS text message timing, (3) acceptability of SMS text message content, and (4) acceptability of linked resources.

Potential Effectiveness

Breastfeeding Status, Introduction to Solids, and Breastfeeding Self-Efficacy at 6 and 12 Months

Infant feeding survey items were adapted from local, state, and national infant feeding surveys [38]. As per the Australian National Infant Feeding Survey, "current" breastfeeding status was reported if a parent reported "yes" to their "baby had received breastmilk since this time yesterday." Breastfeeding duration was assessed in accordance with the Centers for Disease Control and Prevention definitions of breastfeeding duration [39], as parents who had ceased breastfeeding were asked to report the age (in months) at which breastfeeding ceased. Participants were also asked to report age (in months) the infant was first introduced to soft, semisolid or solid food, using survey items from the Australian National Infant Feeding Survey [38].

The Breastfeeding Self-Efficacy Scale—Short Form tool was used to assess maternal breastfeeding self-efficacy [40], which has consistently been demonstrated as a valid and reliable measure of breastfeeding self-efficacy globally [41]. The Breastfeeding Self-Efficacy Scale—Short Form is a 14-item self-report instrument derived from the 33-item Breastfeeding Self-Efficacy Scale tool measuring breastfeeding confidence. All items are preceded by the phrase "I think I can always" and rated on a 5-point Likert scale, ranging from 1 (not at all confident) to 5 (always confident). As such, total score ranges from 14 to 70, with a higher score indicating greater levels of breastfeeding self-efficacy. The items were assessed within both the 6-month and 12-month surveys.

Child Nutrition at 12 Months

The Short Food Survey (SFS) developed by Hendrie et al [42] is a 38-item tool that captures parent-reported information on children's food group intakes and food choices and has been shown to produce a reliable estimate of compliance with dietary guidelines [42]. Four survey items from the SFS were used to assess child intake of fruit and vegetables at 12 months. Fruit intake was assessed by asking parents "How many serves of fruit does your child usually eat," including a prompt describing what a serve of fruit is (eg, 1 serve is equal to 2 small pieces of fruit, eg, apricots and plums; 1 medium apple, banana, or mandarin; or 1 cup of diced pieces, eg, diced peaches or diced fruit salad). To assess child intake of vegetables, responses to 3 survey items from the SFS were combined [42], including "How many servings of starchy vegetables (not including hot chips) does your child usually eat?" (prompt: starchy vegetables include potatoes and sweet potatoes; 1 serve is equal to ½ a cooked potato); "How many servings of salad vegetables does your child usually eat?" (prompt: salad vegetables include vegetables such as tomato, capsicum, cucumber, lettuce, and celery. A serve is equal to 1 cup of salad vegetables); and "How many servings of cooked vegetables does your child usually eat?" (prompt: a serve is equal to ½ cup of cooked vegetables).

The Children's Dietary Questionnaire [43] is a survey tool used to reliability assesses child intake patterns in either the previous week or 24 hours. We used survey items from the Children's Dietary Questionnaire to measure the mean weekly frequency of discretionary food consumption, captured by combining responses related to the frequency of child's intake of soft drinks (including cordial or sports drinks), takeaway foods (meals or snacks), chips (eg, baked potato gems/chips, hash browns, hot chops or French fries, wedges, or fried potatoes), savory snacks (eg, potato crisps, pretzels, or plain or flavored crackers), sweet snacks (eg, sweet biscuits, cakes, buns, muffins, and doughnuts), savory pastries, snack bars (eg, muesli bars or cereal bars), chocolate or lollies, and ice cream or ice-blocks. Items assessing child nutrition were included only within the 12-month survey.

Child Movement Behaviors at 12 Months

The Movement Behavior Questionnaire—Baby (MBQ-B) is a validated 6-item tool designed to be administered to parents of children younger than 18 months [44]. The MBQ-B assess frequency and duration of tummy time, time spent in active play or outdoor play, watching television, and using mobile digital devices. Items from the MBQ-B were used to assess child movement, restrained time, and screen time.

For active play, parents were asked "Thinking about the past week, on a typical day, how much time in total did you do some active play with your child? Active play could be crawling on the floor with your child, rolling around the floor with your child, playing at the park, dancing with your child, chasing your child." The response options ranged from 0 minutes per day to more than 2 hours per day. Given Australian 24-hour movement, guidelines recommend that toddlers (aged 1 - 2 years) should

XSL•FO
RenderX

achieve at least 3 hours of various physical activities each day, including energetic play, and parents reporting "more than 2 hours per day" of active play were coded as having children meeting physical activity guidelines [45]. To explore restrained time, parents were asked to report "On a typical day, how many times did you place your child in a baby carrier or sling, car seat or capsule, stroller or pram, highchair, bouncer, jolly jumper or play pen?," and "When thinking about each occasion that your child was in one of those devices, how long were they usually in it?." Given that the infant movement guidelines recommend not restraining an infant for more than 1 hour at a time [45], response options of "less than 15 minutes per day," "between 15 and 30 minutes per day," "between 30-35 minutes per day," and "between 45 to 60 minutes per day" were combined to indicate the proportion of parents compliant with this recommendation. Screen time behaviors were explored by asking participants 2 surveys items: "Thinking about the past week, on a typical day, how much time did your child spend watching television programs, videos/internet clips or movies on a television, computer or portable/mobile device such as iPad, tablet or smartphone?" (ie, passive screen time) and "Thinking about the past week, on a typical day, how much time did your child spend playing games, looking at photos, or video chatting (eg, FaceTime, Zoom, Skype) on a screen-based device such as a computer or laptop, video games console, iPad, tablet, or smartphone?" (ie, interactive screen time). Response options ranged between "0 minutes per day" and "more than 2 hours per day." Given Australian 24-hour movement guidelines recommend no screen time for children younger than 2 years [45], if a parent responded "0 minutes per day" to screen time items, they were coded as "not offering any screen time per day" indicating the proportion of children meeting screen time guidelines. These items were assessed only within the 12-month survey.

Parental Mental Well-Being at 12 Months

The Short Warwick Edinburgh Mental Wellbeing Scale (SWEMWBS) was used to capture parental mental well-being [46]. The SWEMWBS was funded by the Scottish Executive National Program for improving mental health and well-being, commissioned by NHS Health Scotland, developed by the University of Warwick and the University of Edinburgh, and is jointly owned by NHS Health Scotland, the University of Warwick, and the University of Edinburgh [47]. The SWEMWBS is a 7-item tool that has been positively worded to measure participant thoughts and feelings related to functioning over the past 2 weeks. The SWEMWBS is scored by summing the scores for each of the 7 items (scored 1 "none of the time" to 5 "all of the time") and then transformed into metric scores using the SWEMWBS conversion table [46]. Scores can range from 7 to 35, with higher scores indicating higher positive mental well-being, and has been shown to be a valid and reliable measure of mental well-being among caregivers [48]. The SWEMWBS was assessed within the 12-month survey only.

Participant Demographics and Pregnancy Characteristics

Within the survey, birthing parents were asked questions related to Aboriginal and/or Torres Strait Islander origin, country of birth, residential postcode, current employment status (full-time, part-time, casual, paid or unpaid maternity leave, unemployed, home duties, studies, retired, full-time carers, and unable to work due to health problems), timing of their return to work after birth (in months), and the child's date of birth. The survey items are based on those used in previous surveys with postpartum women [49]. Participant education status, first or subsequent pregnancy status, and maternal age data had been collected via previous surveys or medical record data. Participant residential postcode was used to determine geographical remoteness ("major cities" or "regional or remote") using the Accessibility/Remoteness Index of Australia [50]. Postcode was also used to determine socioeconomic areas ("most disadvantaged" or "least disadvantaged") using 2016 socioeconomic indexes for areas [51].

Data Analysis

Data were analyzed by an independent statistician using SAS statistical software (version 9.3, SAS Institute). Descriptive statistics were used to describe (1) characteristics of the samples, (2) feasibility outcomes, (3) program engagement outcomes, and (4) acceptability outcomes. Chi-square test or *t* test was used to compare the characteristics of participants between those who had received HB4HNEKids and those who had not (usual care control).

Sample size calculations were not conducted for this pilot feasibility study [52]. However, to explore the potential impact of the program on child breastfeeding, nutrition, and movement behaviors, as well as parental well-being outcomes (effectiveness), separate logistic regression analyses were conducted to examine differences between survey respondents who had received the HB4HNEKids program and those who had not (usual care control). Unadjusted and adjusted analyses were conducted at both time points. Analyses were adjusted for a range of key participant characteristics including parent age, Aboriginal and Torres Strait Islander status, highest level of education, socioeconomic status, and level of remoteness. Participants with missing data were excluded from analyses. Dichotomous outcomes were presented as odds ratios and 95% CIs, and continuous outcomes were presented as mean differences (MDs) and 95% CIs. A *P* value of <.05 was considered statistically significant.

Results

Feasibility of Delivering HB4HNEKids via Routine CFHN Care

During the 2.5-year pilot period (October 2021 to July 2024) of the HB4HNEKids program a total of 8501 families across the 5 CFHN services were eligible to receive the program. A total of 6243 families commenced the program (6243/8501, 73.4%), from which 430 families later withdrew, giving a 6.9% (430/6243) dropout rate. A total of 377,969 SMS text messages

XSL•FO
RenderX

were sent during the pilot period (average of 61 messages per family).

Characteristics of Cross-Sectional Survey Participants

Of the 780 birthing parents approached, a total of 383 (49% response rate) eligible participants completed the 6-month survey, whereby 26% (99) of survey participants had received the HB4HNEKids program. Of the 626 birthing parents approached, a total of 283 (45% response rate) participants completed the 12-month survey, from which 37% (104) survey participants had received the HB4HNEKids program. The 2 cross-sectional samples were similar in terms of birthing parent's age, education status, socioeconomic status, and remoteness of geographical location (Table 1). The 12-month sample included a higher proportion of participants identifying as Aboriginal and/or Torres Strait Islander (66/283, 23%), compared with the 6-month sample (43/383, 11%). By 12 months the proportion of participants on parental leave had significantly dropped, with 8% (22/283) of participants on parental leave, compared with 45% (173/383) at 6 months. Correspondingly, more participants engaged in employment at 12 months (188/283, 66% vs 114/383, 30%, respectively).

[c]Not available.

[d]Statistically significant (P<.05) difference for the demographic characteristic between survey participants who had received HB4HNEKids and those who had not (usual care control group).

Participants who had received HB4HNEKids at the 6-month survey had a higher proportion from “least disadvantaged” areas and higher proportion residing in major cities than usual care control participants. Similar differences between groups were found at 12 months. Additionally, HB4HNEKids participants had a lower proportion of participants identifying as Aboriginal and/or Torres Strait Islander and a higher proportion of participants who had completed tertiary education.

Engagement With HB4HNEKids Text Message Content at 6 and 12 Months

Of the survey participants receiving the HB4HNEKids program (n=200), 76% (73/96) and 83% (86/104) of participants from the 6-month and 12-month survey, respectively, reported that they always or very often read the HB4HNEKids SMS text messages. Participants from the 6-month survey reported spending an average of 7.43 minutes engaged in the SMS text message content of HB4HNEKids, while participants from the 12-month survey reported an average of 5.83 minutes engaged in the content. In addition, 43% (41/96) of participants from the 6-month survey and 31% (32/104) of participants from the 12-month survey reported that they always or very often clicked on the website links provided in the messages (Table 2).

Acceptability of HB4HNEKids

At 6 months and 12 months, most parents reported that the program was acceptable (Table 3), with more than 90% of parents agreeing or strongly agreeing with statements related to the overall acceptability of the program, timing of the messages, and message content. More than 80% of parents found the embedded website links acceptable.

Potential Effectiveness

Breastfeeding Status, Breastfeeding Duration, Introduction to Solids, and Breastfeeding Self-Efficacy

The proportion of parents currently breastfeeding was not significantly different based on whether the parent had participated in the HB4HNEKids program or not at both time points (6 months and 12 months). However, at both time points, HB4HNEKids participants reported a 5% higher point prevalence of breastfeeding than the comparison group participants (6 months: 66% vs 61%; 12 months: 46% vs 41%). There was no difference in breastfeeding duration for HB4HNEKids participants compared with comparison participants. Similarly, there were no statistically significant differences between HB4HNEKids and comparison participants at both time points for mean age of solids introduction and breastfeeding self-efficacy scores (Tables 4 and 5).

Child Nutrition at 12 Months

Child daily intake of vegetable serves was significantly higher in the HB4HNEKids group in both the unadjusted (MD 0.21, 95% CI 0.05-0.36; *P*=.009) and adjusted analyses (MD 0.23, 95% CI 0.07-0.40; *P*=.006) than in the comparison group. Child daily intake of fruit serves was significantly higher in the HB4HNEKids group than in the comparison group participants in the unadjusted analysis (MD 0.28, 95% CI 0.05-0.50; *P*=.02); however, this result did not remain statistically significant in the adjusted analyses (MD 0.20, 95% CI –0.04 to 0.45; *P*=.10). There was no difference in the frequency of child discretionary food intake per week between the groups (Table 6).

XSL•FO

[c]MD: mean difference.

[d]OR: odds ratio.

Child Movement at 12 Months

Table 6 includes unadjusted and adjusted analyses exploring the odds of participants meeting physical activity guidelines, restrained time guidelines, and screen time guidelines. There were no statistically significant differences between the proportion of HB4HNEKids participant and comparison participant responses related to meeting child movement guidelines (Table 6).

Parental Mental Well-Being at 12 Months

At 12 months, parents who had received the HB4HNEKids program reported a mean SWEMWBS score of 26.15, and comparison participants reported a mean SWEMWBS score of 24.2. Unadjusted and adjusted analyses indicate that parents who had received the HB4HNEKids program reported statistically significantly better mental well-being scores (unadjusted MD 1.93, 95% CI 0.94- 2.92, *P*<.001; adjusted MD 1.52, 95% CI 0.47-2.58, *P*=.005) than the comparison participants (Table 6).

Discussion

Principal Results

This study sought to evaluate the feasibility, engagement, and acceptability of the pilot HB4HNEKids program and explore its potential effectiveness on a range of child and parental health and well-being outcomes including breastfeeding, child nutrition, child movement, and parental mental well-being. Findings indicated that the program was feasible to deliver to families in HNELHD via CFHN services and is met with high acceptability and strong engagement from parents. Furthermore, the evaluation found that the program was likely effective in improving child vegetable intakes and parental mental well-being at 12-months. These findings provide support for further development and improvement of the program with formal testing as part of a larger RCT.

Comparison With Prior Work

This pragmatic evaluation demonstrates that the 1 - to 4-week CFHN service visit (attended by >80% of families in HNELHD) is a feasible way of enrolling new families into a mHealth program at scale. There remains scope to further optimize the reach of HB4HNEKids, given just 73.4% (6243/8501) of eligible families coming through the pilot CFHN services were enrolled into the program. However, the initial reach of the HB4HNEKids program appears relatively high in contrast with other digital health interventions (DHIs), with systematic reviews of DHIs reporting a median reach of just 21.8% - 33.6% [53]. Engagement is another critical factor in determining the success of DHIs, with systematic review evidence suggesting that engagement is associated with a variety of improved health behaviors including fruit and vegetable intake, weight status, smoking, and physical activity [54-56]. Our results indicate good participant engagement with the HB4HNEKids program, with most HB4HNEKids participants reporting that they "always" or "very often" read the SMS text messages, spending on average of 6 minutes interacting with each message. While a systematic review by Grady et al [57] found that SMS text messages are a key DHI design feature associated with engagement, the extensive co-design process undertaken in the design of the HB4HNEKids program may also be driving strong engagement rates [58]. This combined with low opt-out rates and high parent-reported acceptability, the HB4HNEKids

XSL•FO
RenderX

program holds significant promise for reaching and engaging parents in health promotion content during the first 2000 days.

Vegetable intake is a key indicator of a healthy diet providing an important source of essential vitamins and minerals [59]; however, only 18.5% of Australian children aged 2 - 3 years meet the recommended intake for vegetables, dropping to just 3.8% in children aged 4 - 8 years [60]. Although data collected from parents within the HNE region of NSW, Australia, indicate that children aged 12 months are not meeting the recommended serves of vegetables each day (2 - 3 serves), the evaluation indicates that children from families who were receiving HB4HNEKids were having 0.23 of a serve more vegetables per day than those from families in the usual care group [61] and represents an effect size consistent with other interventions that have demonstrated efficacy at increasing children's vegetable intake in home and community settings [62]. Although this effect size is modest in absolute terms, this increase aligns with the magnitude of change commonly observed in early life dietary interventions and reflects a behavioral shift that is difficult to achieve during the introduction-to-solids period [63,64]. Small increments in vegetable intake at this developmental stage may nonetheless carry clinical relevance, as early exposure contributes to flavor acceptance, supports the establishment of healthier dietary trajectories, and enhances intake of key micronutrients such as folate, vitamin A precursors, and potassium [59]. Evidence indicates that even limited increases in vegetable consumption can reduce the risk of micronutrient inadequacy [65] and are prospectively associated with healthier dietary patterns linked to lower noncommunicable disease risk in adulthood [66]. Therefore, future research to assess the sustainment of the program's effects over time is warranted to better quantify the child- and population-level benefit of the HB4HNEKids program.

Like other trials such as the original Health Beginnings RCT [26], our evaluation did not indicate a statistically significant difference in current breastfeeding rates between the HB4HNEKids and usual care participants. These findings are inconsistent with those of a recent systematic review of SMS text message–based interventions, with meta-analyses showing that they were effective at improving exclusive breastfeeding rates particularly when they engage families in the prenatal period [25]. However, given our pilot study was not powered for this outcome and still observed a 5-point prevalence difference in current breastfeeding rates (favoring HB4HNEKids participants) at 6 months and 12 months, this result is nonetheless highly encouraging. Even so, further development and optimization of the breastfeeding content offered within the program, or expanding the program to engage families earlier (ie, antenatally), could be of value.

In contrast with the original Healthy Beginnings RCT that found that families receiving SMS text message support (combined with accompanying printed resources) were significantly more likely to "never have screen time" than the control (adjusted odds ratio 1.28, 95% CI 1.08 - 1.52; $P<.05$) [26], our evaluation did not indicate any differences between HB4HNEKids and usual care participants screen time behaviors or any other movement behaviors at 12 months. While the SMS text message content of the HB4HNEKids program related to child screen time and movement behavior during the first 12 months mirrored that of the original Healthy Beginnings SMS text message content and focused on increasing parental knowledge of child movement and screen time guidelines (eg, 1 message on movement guidelines, 1 message on restrained time guidelines, and 1 message on screen time recommendations), the omission of the booklet content from HB4HNEKids could be driving this difference. However, given that formative research suggests that parents would prefer to be engaged in content focused on the benefits of certain movement and screen time behaviors, rather than the risks [67], there remains opportunity to strengthen parent-directed SMS text message content to better address known barriers and facilitators to child screen time and movement behaviors during the first 12 months.

The perinatal period demands significant emotional, psychological, social, and physical adaptation from parents and represents a period of change that can have implications on parental well-being and mental health outcomes. Parental mental health and well-being are of key importance during this early life stage, as it can influence parent-child relationships, the quality of care provided, and in turn the child's life trajectory [68-70]. Outside of the standardized mental health screening conducted by primary care services, there is limited support embedded within health services to generally support parental well-being [71,72]. Thus, the improved mental well-being scores at 12 months among those receiving the program compared with those who did not (MD 1.51, 95% CI 0.45-2.57; $P=.005$) are important.

Limitations

The results of this evaluation must be considered within the context of our study limitations. These include the use of our convenience sampling methods, which included only a small subsample of participants who had received the HB4HNEKids program, thus not providing data that are representative of the whole HNE region. Furthermore, given our response rates of approximately 45% - 49%, our findings may be subject to nonresponse bias. Given the cross-sectional nature of our evaluation, and that HB4HNEKids and comparison participants were not randomly allocated, we cannot be certain that the differences in child vegetable intakes and parental mental well-being outcomes are explicitly due to the SMS text messaging program [73]. Furthermore, most of the outcomes assessed within this evaluation were self-reported by participants and may be influenced by self-report, social desirability, or recall biases. However, where possible, validated survey tools were used. This pilot study was not powered to detect statistically significant differences between groups for many of the outcomes assessed, including proportion of currently breastfeeding and proportion of children meeting physical activity guidelines. The HB4HNEKids program is currently operating as a complimentary mHealth program alongside an existing routinely offered health service. The insight offered through this evaluation of a real-world health service intervention (while acknowledging the limitations stated) would be strengthened with the opportunity to evaluate the program using more robust methodologies and a larger sample size.

XSL•FO
RenderX

Conclusions

This evaluation of the pilot HB4HNEKids SMS text messaging program indicates that the program is feasible to deliver at scale, alongside routine CFHN care and is highly acceptable and engaging to parents. Our findings indicate possible efficacy of the program for improving child vegetable intake and parental mental well-being at 12 months. However, further evaluation of the program within larger representative samples using robust methodology is needed to determine the true impact of this innovative program.

Acknowledgments

The authors would like to acknowledge the Child and Family Health Services who contributed to enrolling participants into the program. This project was supported by HNELHD IT Services. Abstract

Background: Previous studies demonstrated the effectiveness of *SmartCoach*, a mobile phone–based life-skills training program for addiction prevention among adolescents. However, socially stratifying factors, such as educational level or migration background, were associated with lower program engagement and participation. To address these disparities, we optimized and tailored program elements, particularly for subgroups with low engagement, using qualitative interview data.

Objective: This study aimed to test whether the optimized program version was superior to the original one in terms of efficacy and program use. We hypothesized that optimization and advanced tailoring would result in increased program efficacy and engagement.

Methods: A 2-arm, parallel-group, double-blind, cluster-randomized controlled trial was conducted with assessments at baseline and follow-up after 6 months. Secondary and upper secondary school classes were randomized into two groups: (1) an intervention group receiving the optimized program version and (2) a control group receiving the original version. Participants in both groups received up to 4 weekly SMS text messages over 4 months to stimulate (1) self-management skills to cope with stress, (2) self-efficacy to resist social pressure, (3) observational learning, and (4) self-regulation. The optimized program version included additional reminders, extended time for challenges, simplified language, different days for weekly messages, and additional tailoring for participants with personal or parental backgrounds from non–German-speaking countries. This subgroup received shorter video clips and information on additional stressors, including acculturation and family conflicts. The primary outcomes of this trial were the quantity of alcohol use, the number of days per month that nicotine-containing products were smoked, and cannabis use days.

Results: A total of 1175 students from 67 Swiss secondary and upper secondary school classes were invited to participate in the study between September 2023 and September 2024. Of these 1175 students, 890 (75.7%; mean age 14.9, SD 1.3 y; women: n=511, 57.4%; men: n=379, 42.6%; nonbinary: n=0, 0.0%) participated in the study. Six-month follow-up assessments were completed by 552 (62.0%) of the 890 study participants. On average, program use did not differ between the study groups, with 12.6 (SD 12.8) of 38 possible activities completed in the intervention group and 12.5 (SD 12.7) activities in the control group (P=.18). The results concerning efficacy showed no significant differences between the study groups regarding the main outcomes of alcohol use quantity (P=.91), nicotine use days (P=.45), and cannabis use days (P=.67). Similarly, no significant group differences were observed for changes in perceived stress (P=.77) and social skills (P=.45).

Conclusions: The results did not show improved program use or efficacy in the optimized version of the program. Possible explanations include the relatively minor differences between the 2 program versions and the generally low prevalence rates of substance use in this age group, which limited the statistical power of the study.

Introduction

Background

Substance use remains a significant public health issue in Western Europe and Switzerland [1]. This is particularly concerning due to the developmental vulnerability of adolescents, who are at a critical stage of brain maturation, particularly in areas related to impulse control, decision-making, and emotional regulation, which makes them more susceptible to risk-taking behaviors, including experimentation with substances [2,3]. Social and environmental influences also play a significant role. Adolescents are highly influenced by peer norms and social acceptance, with peer pressure and group dynamics often encouraging substance use [4,5]. Numerous meta-analyses and systematic reviews have assessed the effectiveness of school-based programs in preventing alcohol, tobacco, and other substance use [6-8]. Despite varying methodological rigor and theoretical foundations, these reviews highlight that school-based prevention can be effective, particularly when programs are grounded in psychosocial theory, build drug resistance and general competence skills, and are delivered interactively by teachers or program providers. Such life-skills intervention programs to prevent substance use [9-11] primarily combine training in self-management skills (eg, adapting to stress, emotional self-regulation, and goal setting), social skills (eg, assertiveness and communication skills), and skills facilitating resistance to substance use (eg, opposing peer pressure to drink alcohol and identifying and resisting media influences). However, their implementation and dissemination in schools present serious challenges [12,13]. First, teachers and other professionals need the time, motivation, knowledge, and skills to deliver the program. Second, extensive resources, in terms of personnel, money, and time allocated to deliver substance use prevention, are required to prepare and administer such programs [14].

Digital interventions have great potential to overcome the aforementioned obstacles that hinder successful program implementation and larger-scale dissemination of life-skills training in schools. A hybrid life-skills training program, combining e-learning modules and in-person sessions, among US middle school students, led to significant reductions in substance use and increases in health knowledge, skills knowledge, and life skills compared to a control condition [12].

SmartCoach (Swiss Research Institute for Public Health and Addiction) presented the first automated mobile phone–based life-skills training program to prevent substance use among adolescents, whose long-term effectiveness has been tested in a controlled study [15]. It includes online feedback and individually tailored SMS text messages provided over several months. The content is based on social cognitive theory and addresses self-management skills, social skills, and substance use resistance skills. The results on its efficacy at the 18-month follow-up showed that compared to controls, those in the intervention group experienced significantly lower tobacco smoking and cannabis use prevalence, while no effects were observed for alcohol use, well-being, or social skills [16].

A major challenge in delivering life-skills training and other preventive interventions electronically is the lack of control over adolescents' engagement with the intervention. Several reviews on digital interventions to promote mental health [17,18] or to prevent substance use [19] in young people point to the relatively low levels of user engagement.

Poor program engagement typically jeopardizes program efficacy [20,21]. The *SmartCoach* efficacy study also showed several associations between engagement and intended outcomes, with adolescents who used the contests more frequently being more likely to be nonsmokers, and those who read the messages more attentively being less likely to drink in a problematic manner at the 6-month follow-up [22].

Several studies among adolescents and adults show associations between engagement in mobile health interventions and sociodemographic measures [22-24]. For example, in a SMS text messaging–based smoking cessation program in Switzerland, adolescents without an immigrant background showed higher program engagement [23]. In the *SmartCoach* program, students who attended a secondary school, as opposed to an upper secondary school, and those who reported a 2-sided immigration background (ie, both parents were not born in Switzerland), as opposed to those with no immigration background or a 1-sided immigration background, showed lower program engagement [22].

The challenge of low program use and engagement in mobile health (mHealth) interventions is increasingly discussed from scientific and practical perspectives; however, there is a lack of generalizable approaches that demonstrate how program engagement in existing mHealth programs can be systematically improved [25]. Promising approaches include advanced tailoring of intervention content [24,26] and involving adolescents in the design process to ensure the content is relevant and appealing to them [27,28].

These methods also provided the foundation for developing an optimized version of the *SmartCoach* program, which was tested in this study: first, subgroups with low program engagement were identified, and second, factors influencing user engagement and suggestions for program optimization were derived by using a participatory approach.

To identify subgroups with low program engagement, we evaluated several demographic and socioeconomic predictors of program participation and program engagement among 476 secondary and upper secondary school students in Switzerland in a previous study [29]. The results of that study concerning program engagement highlighted that a migration background, or more specifically, an origin from a non–German-speaking country, was the strongest single predictor of low program engagement [29].

Additionally, aiming to identify factors influencing user engagement and suggestions for the optimization of the *SmartCoach*, semistructured phone interviews were conducted among 171 program participants from the previous study [29]. The Capability, Opportunity, and Motivation model of behavior change [30] and the theoretical domains framework (TDF) [31] were used to assess behavioral influences [32].

XSL•FO
RenderX

Next to the general recommendations for advanced tailoring of the *SmartCoach* program content, specific recommendations for the subgroup of students originating from non–German-speaking countries were also derived from the previous qualitative study and implemented in this study (see the Methods section) [32].

Study objectives

The main objective of this study was to test program engagement and the efficacy of the *SmartCoach* version optimized in this way, compared to the original program version without advanced tailoring. We hypothesized that receiving the optimized intervention program, compared to the original version, would result in increased program efficacy, indicated by lower substance use at 6-month follow-up (primary outcomes), increased program engagement and social skills, as well as decreased levels of stress (secondary outcomes).

Methods

Study Design

This study aimed to test program engagement and the efficacy of the optimized program version with advanced tailoring compared to the original program version in a 2-arm parallel-group, double-blind, randomized controlled trial with assessments at baseline and at a 6-month follow-up.

Participants, Setting, and Procedure

In this study, secondary and upper secondary schools in the Swiss cantons of Aargau and Zurich were invited to participate by prevention experts from regional addiction prevention centers. Interested teachers were informed about the program's objectives and its implementation in their classes, and they allocated 45 to 90 minutes during regular school lessons for the program.

During this time, students were introduced to the topic through a brief workshop, informed about the program and the accompanying study, and invited to participate and sign up for the study. The workshop and information session were led by prevention experts or psychology master's students experienced in working with young people and delivering preventive interventions.

The 30‐ to 60-minute workshop aimed to spark students' interest in stress and provide basic information on its origins. Initially, students shared their understanding of stress in a group discussion. The concept of stress as an imbalance between demands and resources was then explained. Interactive exercises, such as repeatedly subtracting 7 from 996, were used to deliberately induce stress, allowing students to observe its effects on their bodies and thoughts. Finally, students described their stress levels in areas like family, friends, school, and the future using emojis.

Following this, students were introduced to the *SmartCoach* program and the related study through an introductory video [33]. Students were invited to participate in the study if they met the following criteria: (1) were at least 14 years old and (2) owned a mobile phone.

They were asked to complete an online baseline assessment and study registration using their smartphones. Students who consented to participate provided a self-defined username and mobile phone number and completed additional assessments on stress and social skills for tailoring the intervention content. They received individually tailored web-based feedback on their mobile phones. Students who did not give consent were thanked for their interest and asked to explain their reasons for not participating in a free-text field.

Those who decided to participate received personalized mobile phone–based life-skills training over the next 4 months. Follow-up assessments at month 6 in both study groups were conducted using a similar procedure: participants were invited to the online follow-up assessments via SMS text messaging, which included a link to the follow-up survey. After 3 reminders, nonresponders were additionally contacted via computer-assisted telephone interviews conducted by research assistants. Study participants were recruited between September 2023 and September 2024. The 6-month follow-up assessments were conducted between March 2024 and April 2025.

Ethical Considerations

The study was approved by the Ethics Committee of the Faculty of Arts and Sciences at the University of Zurich (approval 22.2.15; date of approval April 17, 2022). Digital informed consent was obtained from all study participants. Parental consent was required only for children under 15 years of age because the study was classified by the ethics committee as a research project with minimal risk [34]. Study participants completed the screening procedure and baseline assessment anonymously. No names were collected; instead, participants chose nicknames. Password protection and secure sockets layer encoding were used to ensure the privacy and security of data transfer. Study participants received an incentive of 10 Swiss Francs (1 Swiss Franc=US $1.23 as of June 23, 2026) for taking part in the follow-up survey.

Randomization and Allocation Concealment

To prevent spillover effects within school classes, we conducted a cluster-randomized controlled trial, using school classes as the randomization unit. Multiple classes per school were randomized. Given the diverse student populations across different secondary schools, we used stratified randomization with separate computer-generated randomization lists for each school. In addition, to ensure balanced sample sizes across study groups, we used block randomization with computer-generated randomly permuted blocks of 4 cases [35].

Prevention experts and master's students conducting the baseline assessment were blinded to the group allocation of school classes. Furthermore, the research assistants who performed the computer-assisted follow-up assessments for primary and secondary outcomes were also blinded to the group allocation. Additionally, students did not know whether they were allocated to the original or optimized programs.

RenderX

Intervention Program

Original Program Version

The intervention elements of the program were based on the social cognitive theory [36,37]. The key concepts of this theory, which were addressed within *SmartCoach*, were (1) outcome expectations, (2) self-efficacy, (3) observational learning, (4) facilitation, and (5) self-regulation. The *SmartCoach* program [33] provided tailored web-based feedback and SMS text messages to promote self-management skills, social skills, and substance use resistance skills over a period of 4 months. The intervention elements of the program were based on social cognitive theory [36,37] and the life-skills training [9]. Individually tailored web-based feedback was provided to program participants immediately after they completed the baseline assessment within their school classroom. This included textual and graphical feedback on general stress, levels of stress in various domains, individual applied and suggested coping strategies, and individual levels of social skills. Screenshots of the baseline assessment and the web-based feedback are shown in Figure 1.

Figure 1. Screenshots from the *SmartCoach* program (left: assessment of social skills; middle: feedback on level of stress; right: feedback on individual social skills).

Following the baseline assessment and feedback, program participants received between 2 and 4 individualized SMS text messages per week on their mobile phones for a period of 17 weeks. These messages were generated and sent by a fully automated (not artificial intelligence–based) system. For the first 7 weeks, the messages focused on self-management skills, for example, coping with stress, emotional self-regulation, and managing anger and frustration. In weeks 8 to 12, the messages focused on social skills, for example, making requests, refusing unreasonable requests, and meeting new people. In weeks 13 to 17, the SMS text messages focused on substance use resistance skills, for example, recognizing and resisting media influences, social norms of alcohol and tobacco use, and the associations between both self-management and social skills and substance use. The messages were tailored based on data from the baseline assessment and on SMS text messaging assessments that occurred over the course of the program.

During the 4-month coaching phase, participants received a total of 38 SMS text message prompts that invited interaction, such as replying to quizzes, retrieving media objects, and participating in challenges or contests. A friendly competition among participants was integrated into the program to stimulate engagement. Within the friendly competition, program participants could collect credits for each interaction (eg, answering monitoring SMS text messages, participating in quizzes, creating messages or pictures within contests, and accessing video links integrated into SMS text messages). The more credits participants collected, the higher their chances were of winning one of several attractive prizes, which were part of a prize draw (10 prizes with a total value of 500 Swiss Francs, eg, cinema tickets) after program completion. Participants were able to retrieve their number of credits compared to the number of credits of other program participants in their group (with a similar starting date) at any time from an individual profile page. Sample screenshots of the program from the coaching phase are shown in Figure 1.

Optimized Program Version

The optimized program version was developed as described in the "Background" section based on a quantitative study that identified students from non–German-speaking countries as a subgroup with particularly low program engagement [29], as well as on a qualitative examination of suggestions for program

XSL•FO
RenderX

optimization in this subgroup and also among other program participants [32]. The optimized program version included additional tailoring for participants with personal or parental backgrounds from non–German-speaking countries, who received shorter video clips. Furthermore, other stressors, including acculturation and family conflicts, were addressed, and the weekly SMS text messages were not always sent on Tuesdays but on different days of the week. A comprehensive overview of the program optimization version is displayed in Table 1.

Table . Program optimizations for all participants and additional optimizations for those with personal or parental backgrounds from non–German-speaking countries.

Suggestions from qualitative study [32]	Optimizations for all participants	Additional optimizations for participants with personal or parental backgrounds from non–German-speaking countries
Shorter videos	—[a]	Videos shortened to a maximum duration of 2 min.
Simplifying language	Complex or long sentences were revised and simplified to ensure clarity and accessibility.	—
General reminders	Participants who did not respond to certain prompts received additional reminder messages to encourage engagement.	—
Additional reminder message for upload within group challenges	Participants received a reminder message 1 h before the end of the group challenge submission deadline if no action was taken.	—
Reminder for voting in self-challenges	Participants received a reminder 1 h before the voting phase ended if they had not yet voted.	—
SMS on different days	Weekly interactive messages (eg, quizzes) were sent on 2 different days (Tuesdays and Fridays) rather than always on Tuesdays to better fit diverse routines.	—
Adapted timing for challenge participation	The time window for submitting entries to group challenges was adjusted to earlier in the afternoon (and prolonged from 2-4 h this way) to accommodate daily schedules.	—
Adapted timing for voting on challenges	The voting period was extended until 3 PM (an additional 3 h), allowing more flexibility for participants to engage.	—
Time for publication of group challenge results	Challenge results were sent out shortly after the extended voting period ended.	—
Regular updates on personal progress	Additional updates about collected points and status in the friendly competition were sent periodically.	—
Ensuring anonymity in group interactions	The program provided clearer and simplified explanations about anonymity to increase comfort and trust in participation.	—
More differentiated assessment of stress factors	The stress assessment was refined to distinguish between stress from family conflicts and stress from peer conflicts.	The explanation of family conflict stress included examples relating to cultural differences and intergenerational misunderstandings.
Addressing feelings of exclusion	—	New content was added to reflect on feelings of being an “outsider,” including migration-related themes like acculturation and identity development.
Addressing future-related stress	—	Specific questions and feedback regarding worries about the future were tailored to migration-related challenges (eg, education and residence status).

[a]Not applicable.

Assessments and Outcomes

Sociodemographic Data

Assessments of demographic and socioeconomic variables included the birth country of both parents and the students to determine a migration background. Since Swiss-German people are similar to Germans and Austrians in terms of language, culture, and socioeconomic background, a further variable was created based on the students' and their parents' country of birth, which describes their origin from a non–German-speaking country. Furthermore, we assessed gender, age, and perceived familial socioeconomic status from the perspective of the adolescent using a brief instrument [38,39] that was translated, adapted, and validated for German adolescents [40].

Program Use

Program use was operationalized in terms of the total number of interactions with the program that were logged by the system. During the 4-month coaching phase, participants received a total of 38 SMS text messages that prompted a total of 18 SMS text messaging–based reply activities (eg, replies to quiz questions or selection queries) and 20 media view activities (eg, views of video clips, images, or weblinks). These activities were logged through the *SmartCoach* system and were available for each program participant.

Outcomes

Baseline and follow-up assessments included the following:

- Alcohol use in the preceding 30 days was assessed by the consumption items of the Alcohol Use Disorders Identification Test (AUDIT-C) [41]. This test comprises three items assessing (1) frequency of alcohol consumption, (2) quantity of alcohol consumption, and (3) binge drinking, and it was also validated for use among adolescents [42]. Pictures were used to illustrate the quantity of a standard drink, which corresponds to 12 to 14 g of pure alcohol.
- Nicotine or tobacco use was assessed using the item: "Have you smoked a puff of nicotine-containing cigarettes, e-cigarettes, or vapes within the last 30 days?" If the participant responded "yes," we additionally assessed the number of nicotine or tobacco use days in the past 30 days.
- Cannabis use in the preceding 30 days was assessed using the item: "Have you smoked or used products containing cannabis within the last 30 days?" If the participant responded "yes," we additionally assessed the number of days they used cannabis.
- Perceived stress was assessed by a single item from the Swiss Juvenir study [43]: "How often have you had the feeling of being overstressed or overwhelmed in the last month?" with the answer options ranging from 1 "never" to 5 "all the time."
- Social skills were assessed using the brief version of the Interpersonal Competence Questionnaire-10 [44], which addresses the following domains: initiation of relationships, negative assertion, disclosure of personal information, emotional support, and conflict management.

The primary outcomes, according to the study registration, were alcohol use in the preceding 30 days, as measured by the AUDIT-C total score; the number of nicotine or tobacco use days in the past 30 days; and the number of cannabis use days in the preceding 30 days. Secondary outcomes included perceived stress, social skills, and program use captured via the total number of interactions with the program that were logged by the system.

Sample Size

The effect size calculations for this trial were based on a meta-analysis of the efficacy of SMS text messaging–based interventions for health promotion [26]. It tested a variety of participant, intervention, and methodological moderators and identified message tailoring, as well as personalization, as being significantly associated with greater intervention efficacy. The largest effect sizes were exhibited in those studies that used both message tailoring and targeting (Cohen d=0.44), followed by studies using message tailoring only (Cohen d=0.27), whereas the smallest effects were observed among studies that used only message targeting (Cohen d=0.07). Furthermore, the analysis also examined the impact of tailoring SMS text messages specifically based on demographic factors in message design. Interventions were significantly more efficacious when they used demographic factors (Cohen d=0.53) in tailoring than when they did not (Cohen d=0.22). Based on these findings, we expected an increased effectiveness of the optimized program version, which provides advanced tailoring based on several socially stratifying factors, by a small to medium magnitude. Assuming a Cohen d of 0.25, a sample size of 253 in each study group would be required to achieve 80% power for a t test (α=5%, 2-sided) to detect this difference based on a calculation using G*Power (Heinrich Heine University Düsseldorf). As secondary school students are nested within school classes, we additionally needed to consider a potential design effect for the calculation of the sample size for our study. Based on an average cluster size of 15 study participants [16] and an expected intracluster correlation coefficient of 0.05, a sample size of 430 per study group and a total of 860 study participants was required.

Data Analysis

To examine baseline differences between participants in the intervention and control groups, we performed chi-square tests for categorical variables, t-tests, and Mann-Whitney U tests for continuous variables. The same tests were applied to assess whether participants lost to follow-up differed from those who responded as a function of the study group.

We analyzed data according to the intention-to-treat principle (ITT). For the ITT analyses, we used multiple imputation procedures as described elsewhere [45]. Specifically, the imputation model included study group, demographic variables (gender, age, immigration background, and socioeconomic status), school-related factors (school type and class), baseline measures of all outcomes (stress, social skills, and substance use), and program engagement metrics. We generated 20 imputed datasets with 5 iterations each, and no systematic bias in convergence was observed. Binary variables were imputed using logistic regression, and both count and continuous variables were imputed using predictive mean matching.

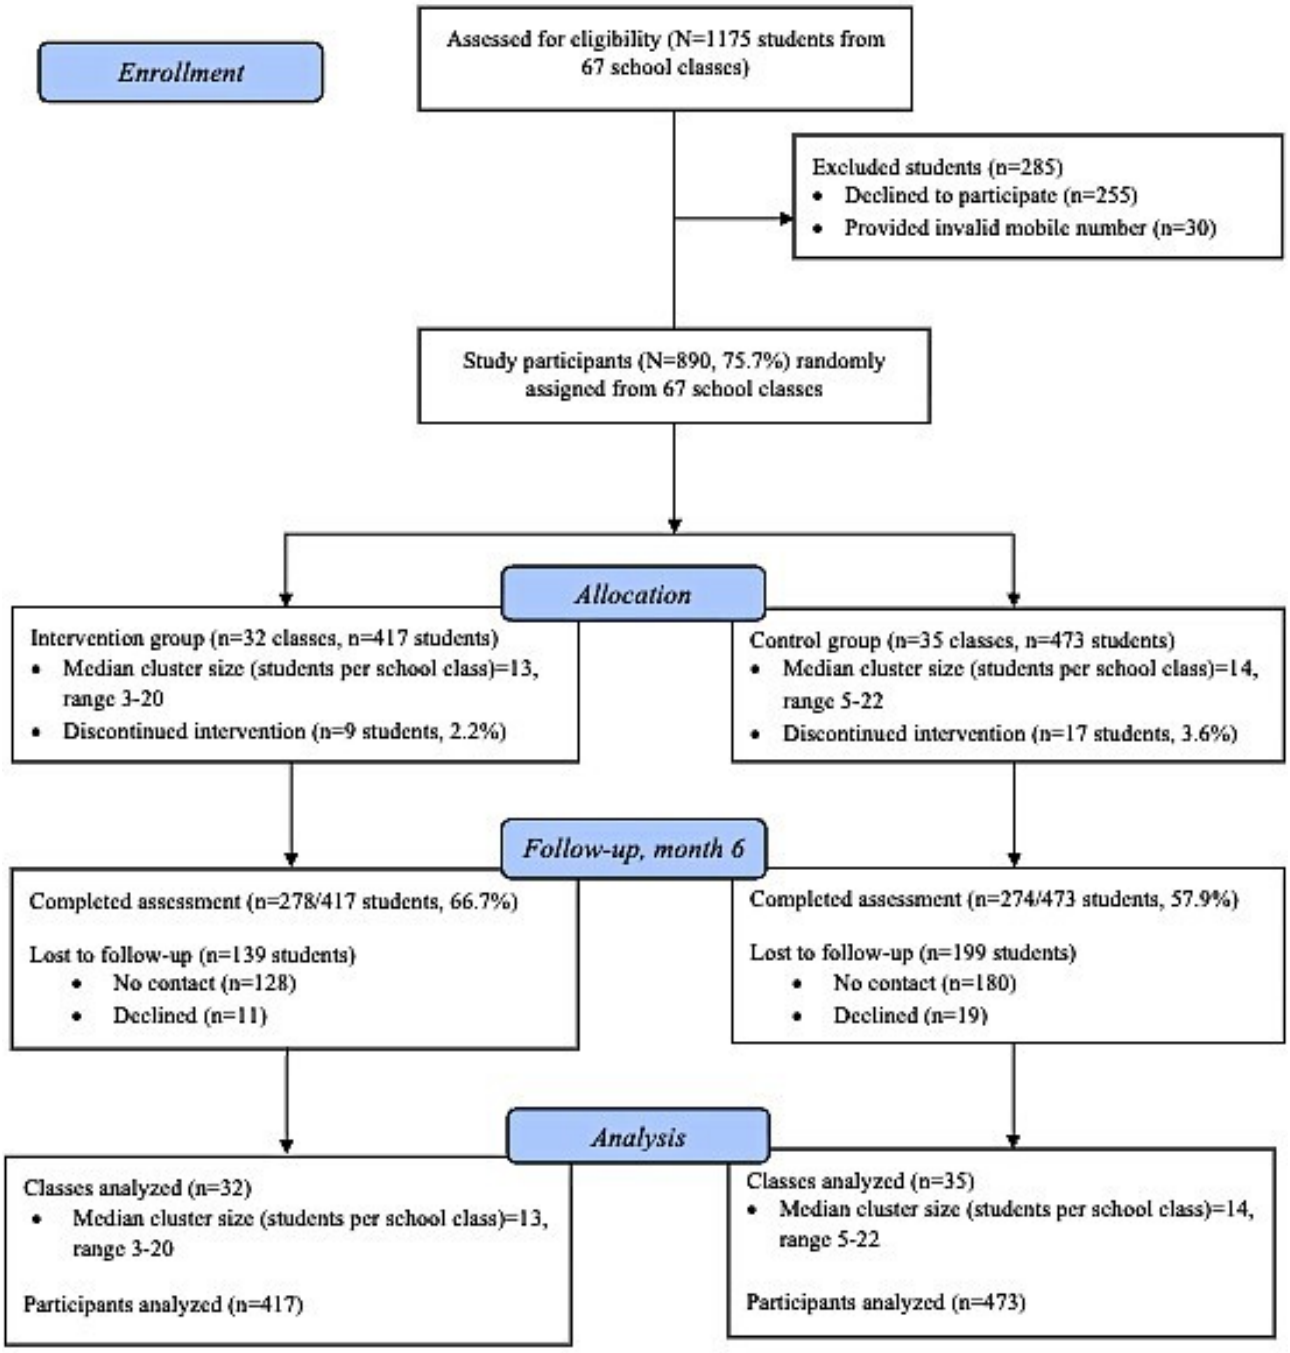
XSL•FO
RenderX

For all outcomes, we used generalized linear mixed models (GLMMs) with a random intercept for the school class. For count outcomes, we used Poisson GLMMs with a log link function and included the log of the baseline measure plus one as an offset term to model relative changes. For dichotomous outcomes, we used binomial GLMMs with a logit link. For continuous outcomes, we used linear mixed models with change scores (follow-up minus baseline) as the dependent variable. All models included the study group as the primary predictor, with age, gender, school type, juvenile stress, and baseline cannabis use as covariates. We included similar covariates in the program engagement models.

We did not adjust for multiple comparisons, as this was not prespecified in the sample size calculation or study protocol. To avoid post hoc bias, analyses followed the original protocol, using predefined significance thresholds without multiplicity correction.

To identify the moderators of the primary and secondary intervention outcomes, GLMMs with a random intercept for school class were used. Interaction terms between sociodemographic characteristics (gender, migration status, origin from a non–German-speaking country, socioeconomic status) measured at baseline and study group were included, one at a time, in the previously described models.

Results with a type I error rate of $P<.05$ on 2-sided tests were considered statistically significant. Analyses were performed using R version 3.6.1 with the lme4 package [45] for fitting mixed models.



Results

Study Participants

Figure 2 depicts participants' progression through the trial. At the online screening assessment, 1175 students were present in 67 classes. Of these 1175 students, 890 (75.7%) consented to participate in the study and provided a valid mobile phone number. Of the 255 students who declined to participate, 83 (32.5%) provided usable free-text information about their reasons for not taking part in the program and associated study. The most common reason given was a lack of desire or interest in participating in the program (n=47, 57%). A total of 22 (27%) students stated that they did not have their smartphone with them; another 5 (6%) indicated that they did not have a smartphone at all. Three (4%) students said they were unwell. Two (2%) students mentioned privacy concerns, 2 (2%) did not have parental consent, and 2 (2%) experienced technical difficulties with the internet or their smartphones.

XSL•FO
RenderX

Figure 2. Flowchart of study participants.

Thirty-two classes containing 417 students in total were randomly assigned to the intervention group, and 35 classes with 473 students in total were assigned to the control group. Six-month follow-up assessments were completed by 278 of 417 (66.7%) students in the intervention groups and 274 of 473 (57.9%) students in the control group.

Baseline characteristics for the study sample are shown in Table 2. The mean age was 14.9 (SD 1.3) years, and 511 (57.4%) of the 890 study participants were women.

Baseline differences between the intervention and control groups were identified for age, type of school, and perceived stress.

Concerning attrition bias, the analysis revealed that intervention group participants who were lost to follow-up were more likely to be men (χ^2_1=8.5; *P*=.003) and had a higher cannabis use prevalence at baseline (χ^2_1=6.0; *P*=.014). Furthermore, intervention group participants lost to follow-up were more likely to have lower levels of perceived stress ($F_{1,336}$=4.8; *P*=.03) than controls.

The intracluster correlation coefficients (ICCs) for the 3 primary outcomes were as follows: for AUDIT-C, ICC of 0.12 at baseline and 0.03 at follow-up and for nicotine or tobacco use days, ICC of 0.08 at baseline and 0.03 at follow-up. For cannabis use days, the random-intercept models did not converge at baseline and follow-up, indicating negligible between-cluster variance.

Program Use and Engagement

During the intervention program, which lasted for 4 months (17 wk), 9 (2.2%) of the 417 program participants in the intervention group and 17 (3.6%) of the 473 participants of the control group withdrew their participation (odds ratio 0.50, 95% CI 0.08 - 3.15; *P*=.46). Over the 4-month program, a total of 18 SMS text messaging–based reply activities (eg, replies to quiz questions or selection queries) and 20 media view activities (eg, views of video clips or images) were prompted. Considering

XSL•FO
RenderX

the total number of 38 possible activities, the mean number of activities carried out by participants was 12.6 (SD 12.8) in the intervention group and 12.5 (SD 12.7) in the control group (unstandardized regression coefficient from the linear mixed model b=−1.72, 95% CI −4.22 to 0.79; P=.18). Considering the number of SMS text messaging replies and media view activities separately, program engagement also did not differ significantly between the study groups: a mean number of 7.2 (SD 6.8) SMS text message reply activities were completed in the intervention group and 7.3 (SD 6.8) in the control group (b=−1.12, 95% CI −2.43 to 0.18; P=.10), while a mean of 5.4 (SD 6.6) media view activities were completed in the intervention group and 5.2 (SD 6.6) in the control group (b=0.18, 95% CI −0.92 to 1.28; P=.74).

Efficacy Based on 6-Month Follow-Up

The results of the complete-case (CC) and ITT analyses examining outcomes at the 6-month follow-up are presented in Tables 3 and 4. For count variables (Table 3), no significant group differences were observed for tobacco use days (ITT: rate ratio=0.75; P=.45) or cannabis use days (ITT: rate ratio=0.86; P=.67) in either the CC or ITT analyses.

Continuous outcomes (Table 4) including AUDIT-C score (ITT: P=0.91), perceived stress (ITT: P=0.77), and social skills (ITT: P=0.45) also did not differ significantly between groups in either CC or ITT analyses.

Table . Intervention effects for count outcomes.

[b]ICQ-10: Interpersonal Competence Questionnaire-10.

Moderator Analyses

No significant demographic or socioeconomic variables moderated the effect of the intervention on the primary or secondary outcomes.

Discussion

Principal Results

This study evaluated program engagement and the efficacy of an optimized mobile phone–based life-skills training program with advanced tailoring of intervention content, compared to the original program version among adolescents. The results revealed no significant differences between participants of the 2 program versions with respect to the considered indicators of program engagement and efficacy.

The proactive invitation to participate in the program and study in Swiss secondary school classes, combined with the offer of a low-threshold mobile phone–based intervention, enabled us to reach 3 out of 4 adolescents for participation in the *SmartCoach* program and the associated study. Given that the program lasted 17 weeks and that participants had to provide their mobile phone numbers, the high participation rate of 75.7% (890/1175) is remarkable though consistent with previous studies of the program in this target group [16,29].

Concerning program attrition, the overall results were positive, with only 2.2% (9/417) of the participants in the intervention group and 3.6% (17/473) of the control group withdrawing their participation. Relating to program use, the average number of completed activities was 13 out of 38 possible activities in both study groups, with no significant between-group differences either in this total number or in the more specific activities of SMS text message replies or media views. The moderator analyses also showed no differences in the program participation variables. Therefore, the initial hypothesis that the program optimizations or the advanced tailoring of program content would result in increased program use has to be rejected. Similarly, no statistically significant group differences were observed for the primary and secondary outcomes reflecting program efficacy.

Despite previous evidence supporting the effectiveness of *SmartCoach*, the optimized version did not demonstrate significant improvements over the original program. One critical factor that may have contributed to these nonsignificant results is the lack of statistical power, which might be related to the generally low substance use prevalence rates in this age group that may not have been sufficient to detect the relatively small differences between the optimized and original program versions. In relation to the overall program content and processes, only a small proportion of the content (maximum 8%, depending on the topic choice during the assessment) was changed. This is also due to the fact that, in the qualitative program evaluations relating to the Capability, Opportunity, and Motivation model of behavior change and theoretical domains framework, most young people were very satisfied with the original program and its content, and there were

XSL•FO
RenderX

relatively few requests for changes [32]. At the same time, it must be mentioned that this previous study did not reach the entire sample for the follow-up interviews, and some decisions to change program content were based on relatively small numbers. Furthermore, these specific adaptations might not have addressed the participants' real challenges regarding program engagement or may even have had a negative impact (eg, reminders might be perceived as annoying and evoke reactance; messages on a different day of the week might be helpful for some but could also be counterproductive for another subgroup). Future studies in which optimization suggestions are assessed should therefore collect them in two steps: first, optimization suggestions should be identified qualitatively, and in a second step, an independent sample should be used to check quantitatively whether these suggestions are desired by the majority or whether they are only the preferences of a minority. Another reason for the zero effects may be that the assumed effects of advanced tailoring were overly optimistic. One reason for this is that the 3 project packages (identification of subgroups with low program engagement, qualitative exploration and implementation of program optimizations, and this randomized controlled trial to test the effectiveness of the optimized program) were planned together in advance, including power calculations. Initially, we assumed that, in addition to the variable "parental background from non–German-speaking countries," other variables such as health literacy, socioeconomic status, and gender might influence program engagement. However, it turned out that they did not have a substantial effect in this initial study, and both the number of variables that could be used for improved tailoring and the necessary scope of program optimizations were rather small [29,32].

Limitations

Main limitations of this study are that (1) all primary outcome data rely on self-report, with the associated possibility that results may have been influenced by social desirability and potential recall bias. Measures used to avoid under- or overreporting of substance use included assurances of confidentiality and anonymous assessments conducted via online surveys without personal contact, which may have increased the reliability of self-reported data. (2) Cluster randomization according to school class did not result in a balancing of all baseline characteristics, and there was selective attrition according to gender, cannabis use prevalence, and perceived stress. Although we attempted to counteract this attrition bias as effectively as possible through multiple imputation, ITT analyses, and additional complete case analyses for sensitivity testing, a certain degree of bias and its effect on the results cannot be completely ruled out. (3) The results could not be generalized to secondary and upper secondary schools in Switzerland, as we recruited a convenience sample of school classes willing to participate in the study. However, the comparison of the substance use prevalence rates among a representative sample of 15-year-old students in Switzerland [1] and the baseline characteristics of the study sample does not reveal major deviations. The 30-day point prevalence rates for nicotine use were 20% in this study and 16% for cigarette consumption, with an additional 3% for e-cigarette use in the representative survey. For cannabis use, the 30-day point prevalence was 6% in this study and 9% in the national survey.

Conclusions and Outlook

This study is among the first to evaluate the impact of a mobile phone–based life-skills training program for adolescent substance use prevention, which integrates participatory tailoring based on user feedback within a randomized controlled trial setting. The results demonstrate that the program was feasible and acceptable, as indicated by a high participation rate and relatively low program attrition. However, the optimized version did not show improved engagement or efficacy compared to the original version.

Despite the lack of superiority of the optimized program version, the *SmartCoach* program offers a low-threshold and effective intervention program to prevent substance use among adolescents [16]. The SMS text messaging–based version is currently being revised as part of a European Union–funded project to create an instant messaging version using WhatsApp (Meta Platforms). This offers significant advantages over SMS, including the ability to send media such as pictures and video clips directly, as well as the option to send messages free of charge using an existing internet connection [46]. Furthermore, this instant messaging–based coaching program will integrate storytelling elements to provide meaning to the facts presented and allow participants to connect with the information both intellectually and emotionally [47]. For example, in the new program version, participants will accompany a Stone Age man or woman (Stoney) on a journey through a picture story to discover the origins of stress and learn how to cope with stressful situations. These situations will be based on those that participants provided information about during the baseline assessment. Compared to the revisions implemented in the context of this study, these more substantial program revisions could lead to better retention and engagement, ultimately improving the efficacy of the *SmartCoach* life-skills training program.

Acknowledgments

The authors thank Andreas Filler and his team from Pathmate Technologies for setting up the server and the intervention program. The authors declare the use of generative artificial intelligence (GAI) in the research and writing process. According to the GAIDeT taxonomy (2025), the following tasks were delegated to GAI tools under full human supervision: proofreading, editing, and summarizing the text. The GAI tool used was ChatGPT (OpenAI). Responsibility for the final manuscript lies entirely with the authors. GAI tools are not listed as authors and do not bear responsibility for the final outcomes.

Funding

Funding for this project was provided by the Swiss National Science Foundation (grant 10001C_204412/1). The funding institution had no role in the design or conduct of the study; the management, analysis, or interpretation of data; or the preparation, review, or approval of the manuscript.

Data Availability

The datasets generated and analyzed during this study will be made available on SWISSUbase [48].

Authors' Contributions

SH and MPS were responsible for funding acquisition and conceptualization of the study. SH, NK, and OS were involved in the development of the intervention program. SH, AW, OS, and NK were responsible for data collection, data curation, and validation. AW and NB were responsible for data analysis. All authors have read and agreed to the published version of the manuscript.

Conflicts of Interest

SH, NK, and OS were also involved in the development of the intervention program *SmartCoach* and its optimized program version.

Abstract

Background: Emerging data suggest that text message–based mobile health interventions may enhance physical activity levels in patients with cardiovascular disease enrolled in cardiac rehabilitation. The optimal characteristics of texts that lead to maximal patient engagement and drive meaningful behavioral change are not well understood.

Objective: This study aimed to understand how text- and participant-level characteristics impact physical activity levels after text delivery.

Methods: The VALENTINE (Virtual Application-Supported Environment to Increase Exercise) study was a randomized controlled trial designed to evaluate a mobile health intervention delivered to low- and moderate-risk adults enrolled in cardiac rehabilitation. Embedded within this study was a microrandomized trial focused on the effect of texts on physical activity levels among intervention participants. Participants in the intervention group received texts through a smartwatch (Apple Watch or Fitbit Versa) that were tailored to the time of day, day of the week (weekday vs weekend), weather, and time since enrollment in cardiac rehabilitation. Texts also differed in content type (walking vs antisedentary) and in the level of personalization (inclusion of the participant's name or not). Delivery was randomized at 4 user-selected time points daily, with participants having a 25% probability of receiving a text at any time point. The primary outcome was step count 60 minutes after a decision point. This analysis focuses on the text- and participant-level factors that moderated the intervention's effect on the primary outcome. Given potential measurement differences determined a priori, analyses were stratified by device type and phase of cardiac rehabilitation and adjusted for age, sex, and baseline activity status using a generalization of regression analysis.

Results: More than 70,552 randomizations occurred in 108 participants (mean age 59.5, SD 10.7 years; n=36, 33.3% female; n=19, 17.6% non-White; n=68, 63% Apple Watch users) over 6 months. Overall, no text characteristics (including personalization with the participant's name) or participant characteristics (including baseline physical activity) consistently impacted text

XSL•FO
RenderX

responsiveness for either device type. Although the findings were not consistently significant between device types and across phases of the trial, there was a trend toward increased responsiveness to texts that promoted walking (compared to antisedentary texts) and that were delivered to younger (aged <65 years) and male participants.

Conclusions: In this randomized clinical trial, we found that tailored texts improved physical activity levels among cardiac rehabilitation enrollees in the initiation phase, but this effect was not explained by text- or participant-level moderators. Additional work is needed to explore the impact of tailoring based on an extended set of personal and environmental factors to optimize the delivery and efficacy of text message–based interventions.

Introduction

Center-based cardiac rehabilitation (CR) is an evidence-based lifestyle program that improves functional capacity and quality of life and reduces morbidity and mortality in patients with cardiovascular disease (CVD) [1-5]. Despite these well-established benefits, participation in CR remains low, and physical activity levels often decline over time after program completion [3-5]. Emerging data suggest that mobile health (mHealth) interventions may be effective in extending the benefits of center-based CR beyond the supervised setting [6-10]. mHealth interventions encompass a range of technologies, including text messages, mobile phone apps, and transmission of physiological data (eg, heart rate, step count, and blood pressure) from sensors to mobile devices and web-based platforms [9]. Among these, texts are the most widely accessible. To drive meaningful and sustainable long-term behavioral change, optimizing key text features is crucial. Through strategic timing and frequency of delivery, personalized content, and engaging user interfaces, tailored text-based interventions can promote patient engagement and usability while preventing habituation to improve clinical outcomes [9,10].

The VALENTINE (Virtual Application-Supported Environment to Increase Exercise) study evaluated the impact of an mHealth intervention combining texts, a mobile app, and a smartwatch (Apple Watch or Fitbit Versa) on physical activity levels in enrollees undergoing CR over a 6-month period [11-13]. Nested within the VALENTINE study was a microrandomized trial designed to study the effect of texts on physical activity levels throughout the day. Microrandomized trials are a novel experimental design in which interventions such as texts are repeatedly randomized for delivery at different time points throughout the day. This powerful design enables assessment of the causal effects of individual intervention components on near-term outcomes, such as step count following text delivery, which are thought to influence longer-term behavioral or health outcomes, including sustained physical activity. The primary analysis of the VALENTINE study's microrandomized trial showed that the 60-minute step count increased early after text delivery for both Apple Watch and Fitbit users, with differential results by device type thereafter [12]. Understanding which text characteristics and contextual factors promoted this increase in physical activity, at least initially, is necessary to develop more effective text interventions.

Herein, we present a prespecified secondary analysis from the VALENTINE study's microrandomized trial, evaluating the impact of text tailoring on physical activity levels. The trial leveraged real-time data from participants' smartwatches about their current environment to tailor texts with the goal of promoting low-level physical activity. In this analysis, the primary objective was to evaluate the impact of both participant-level factors and text characteristics hypothesized to moderate intervention efficacy. We hypothesized that the step count in the 60 minutes following text delivery would differ significantly based on text characteristics, such as time of delivery, personalization with the participant's name, and level of activity prior to text delivery, as well as participant-level factors such as age, sex, and baseline activity status.

Methods

Overview

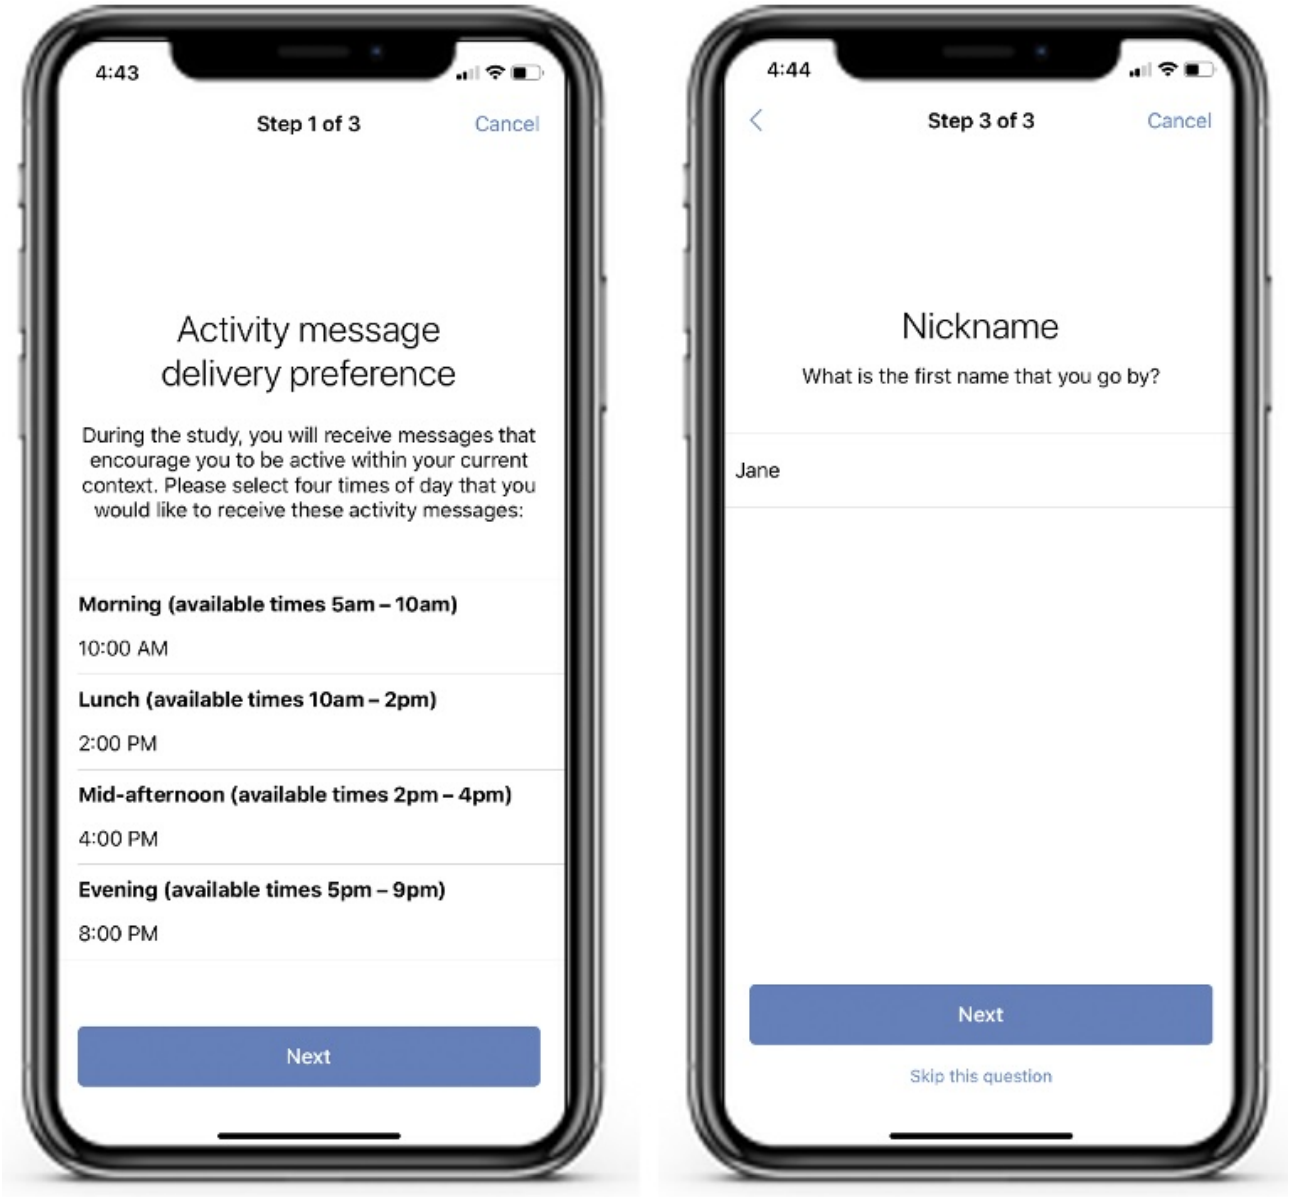
The VALENTINE study was a prospective, multicenter randomized clinical trial that remotely delivered an mHealth intervention to low- and moderate-risk patients enrolled in center-based CR (ClinicalTrials.gov NCT04587882). The primary objectives of the overall trial were (1) to evaluate the efficacy of a multicomponent mHealth intervention for augmenting and extending the benefits of center-based CR and (2) to evaluate the impact of text message delivery specifically on physical activity levels. The methodological details of the study have been previously described [11-13]. Briefly, adults aged ≤75 years who had completed 2 CR visits based on a qualifying diagnosis, owned a compatible smartphone, and spoke English were randomized to the intervention or control arm of the study. Patients who were unsafe to exercise without supervision due to a high-risk cardiovascular condition were excluded.

Ethical Considerations

This study was approved by the institutional review board of the University of Michigan (HUM00162365). Informed consent was obtained from all participants before randomization. Efforts were made to preserve patient privacy whenever possible, including instructions on removing the mobile app from their

XSL•FO
RenderX

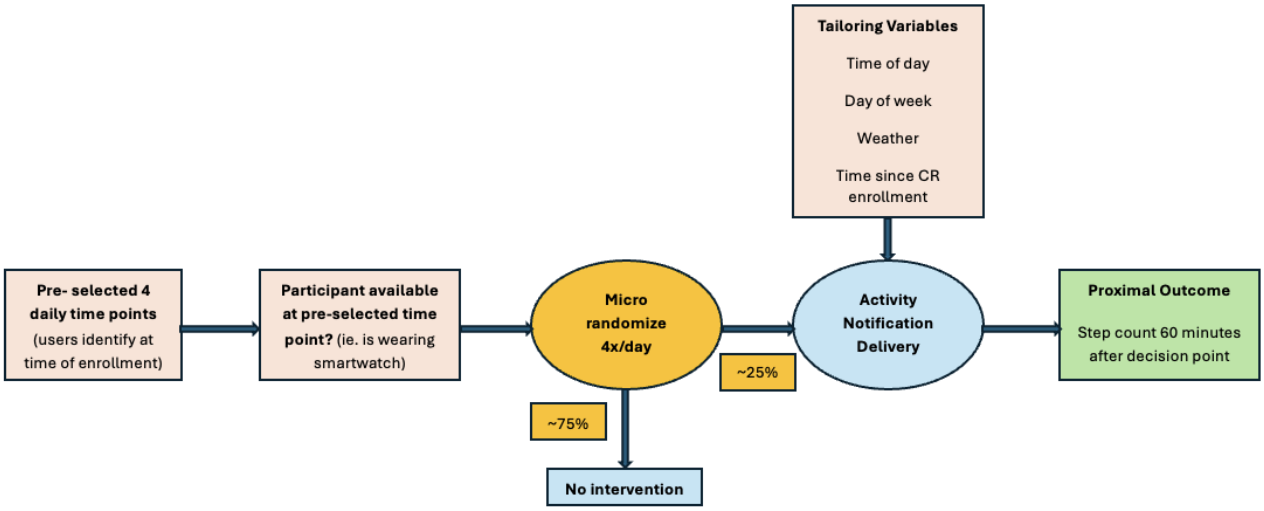
phones at the end of the study to prevent passive data collection. Other than wearable devices, no other compensation was provided for study participation.



Study Procedures

The VALENTINE study launched in October 2020 at an academic medical center and in July 2021 at a large community health care center in Michigan. Both the intervention and control groups underwent remote consent and enrollment visits and received a wearable device compatible with their smartphone (Apple Watch Series 4; Apple Inc or Fitbit Versa 2; Fitbit Inc) to track daily physical activity and receive texts. Additionally, participants in both groups participated in center-based CR concurrently.

Description of the Intervention



The VALENTINE study was designed to augment and extend the benefits of CR through an mHealth intervention. The intervention consisted of a mobile app that allowed activity tracking, goal setting, and microrandomized texts (Figure 1). The texts were delivered by SMS to participants' smartwatches and phones but could also be reviewed in the mobile study app. Texts were tailored to the time of day (morning, lunchtime, afternoon, or evening), day of the week (weekday vs weekend), weather (ie, indoor-based texts delivered if snow or rain was predicted), and time since enrollment in CR (corresponding to the initiation, 0-30 days; maintenance, 31-120 days; and completion, 121-182 days phases of CR). Participants were randomized to receive a text or no text at 4 user-selected time points (ie, decision points), with texts selected at random based on participants' environments (Figure 2). Participants had a 25% probability of receiving a text at each time point.

XSL•FO
RenderX

Figure 2. Microrandomized trial design diagram. CR: cardiac rehabilitation.

This secondary analysis focuses on the results of activity texts. Activity texts were designed to encourage low levels of physical activity in the hour after delivery and were written to be low intensity, short duration, and actionable in real time, as opposed to exercise, which is a planned behavior and often longer in duration and higher in intensity (Figure 3). There were a total of 284 possible activity texts that varied in recommended action (encouraging a short walk vs standing up and stretching) and framing (emphasizing the benefits of being active vs highlighting missed opportunities to meet goals). Approximately 50% of the activity texts were personalized with participants' preferred names, and approximately 30% included emojis or hyperlinks to the mobile app. The effectiveness of texts was assessed through proximal outcomes, which refer to the near-term effects of the intervention. The primary proximal outcome for activity texts was the step count 60 minutes following a decision point.

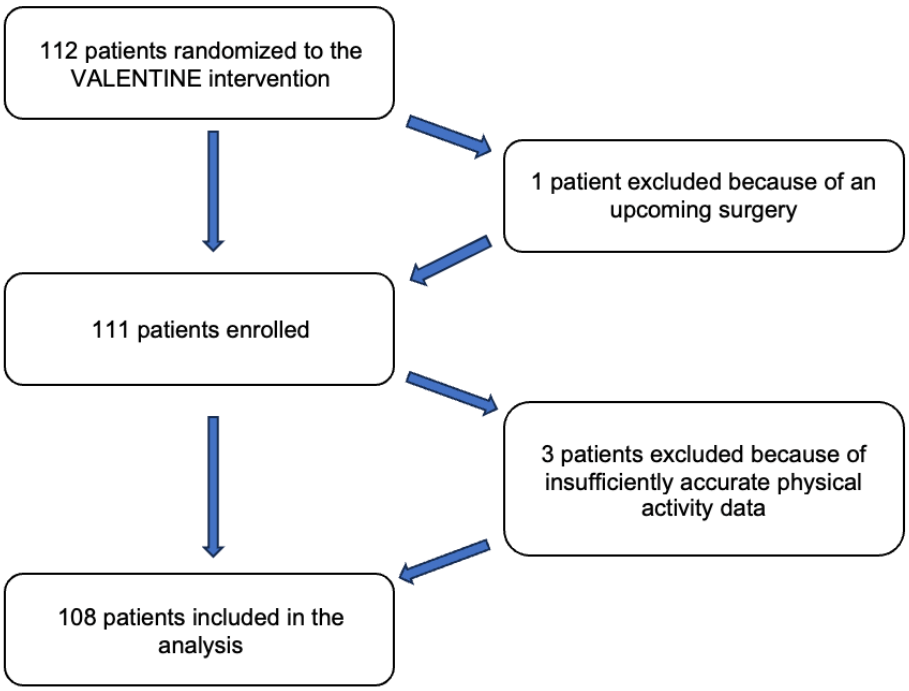
Figure 3. Example of activity text messages used in the VALENTINE (Virtual Application-Supported Environment to Increase Exercise) study.

Statistical Analysis

Baseline characteristics are described as mean (SD) for continuous variables and counts (percentage) for categorical variables. Student *t* tests (2-tailed) or chi-square tests were used for bivariate comparisons of continuous and categorical variables, respectively.

We decided a priori to analyze the data by device type (Apple Watch vs Fitbit) due to known differences in how each device measures physical activity [14]. The study was divided into initiation (days 1-30), maintenance (days 31-120), and completion (days 121-182) phases to account for participants' progression through CR. On the basis of the primary analysis results, which demonstrated an early effect of texts for both device types, this analysis focused on the overall and initiation phases of the study [12].

XSL•FO
RenderX



Our primary outcome for this analysis was the step count in the 60 minutes following a decision point. As the step count was positively skewed, 0.5 was added to all step counts before log transformation. All analyses were performed using a centered and weighted least squares method, a standard method to assess time-varying causal effects of a digital intervention in a microrandomized trial [15]. This method estimates parameters in models for treatment effects and allows the robust inclusion of covariates to reduce noise. Similar to the generalized estimating equations and multilevel models, this method accommodates the nested nature of the data and within-participant correlation across time and accounts for sequential randomization to estimate causal treatment effects. Additionally, regardless of sample size, this method yields consistent and asymptotically normal estimates of the marginal or moderated treatment effect of interest. We assessed causal effect moderation by the following covariates: age (<65 vs >65 years), baseline physical activity (>7000 vs <7000 steps in the first week of the study), sex, and step count 30 minutes before each decision point. Device-specific models evaluated the effect of delivering a text compared with no text at each decision point. At each decision point, participants were considered available to receive the intervention if they were wearing their smartwatches, which was operationalized by requiring at least 1 heart rate measurement on participants' smartwatches at least 30 minutes prior to a decision point. The interaction between treatment and a series of contextual factors (time of text delivery, weekend vs weekday, text content [antisedentary vs activity promoting], and personalization of the text using the participant's name), as well as participant characteristics (age category, sex, baseline activity status, presence of heart failure, and indication for CR referral), was explored. A *P* value <.05 was used to establish significance. All analyses were performed using SAS (version 14.2; SAS Institute Inc).

Results

Overview

From October 23, 2020, to March 25, 2022, 112 participants were randomized to the intervention arm of the study. Only 1 participant was excluded after randomization but before enrollment due to failure to meet the inclusion criteria (ie, upcoming surgery), and 3 had incomplete physical activity data for analysis (Figure 4). An additional 2 participants withdrew from the study after enrollment but allowed data collected up until their withdrawal date to be used. Of the 108 remaining participants, 36 (33.3%) were female, 89 (82.4%) were White, and 101 (93.5%) were non-Hispanic. Participants' mean age was 59.5 (SD 10.7) years, and their mean BMI was 30.4 (SD 6.5) kg/m^2; 68 (63%) participants owned an iPhone and were provided with an Apple Watch (Table 1). Throughout the study, these participants underwent 70,552 randomizations to receive or not receive a text over a median of 180.5 (IQR 172.5-182.0) days. Participants were available for 75.9% of decision points (77.3% Apple Watch vs 73.4% Fitbit), with availability defined as having at least 1 smartwatch heart rate measurement in the 30 minutes prior to randomization. On average, 0.91 (SD 0.86) texts per day were sent, although participants were only available to receive 0.80 texts per day.

Impact of Texts on Apple Watch Users

Baseline mean daily step count was 7536.0 (SD 3666.3) steps for Apple Watch users. During the initiation period of the study, delivering a text increased step count by a nonsignificant 10% (95% CI −1% to 20%; *P*=.05) in the 60 minutes after text delivery. Over the entire study period, walking texts increased step count more than antisedentary texts, although the difference was nonsignificant, with a relative risk ratio (RRR) of 1.08 (95% CI 1.00-1.17; *P*=.05; Table 2). In the study overall and in the initiation phase, text tailoring based on time of day, day of the week (weekend vs weekday), or personalization with participants' names did not significantly change the impact of texts on physical activity levels.

When analyzing the impact of texts based on participant characteristics, younger participants (RRR 1.27; 95% CI 1.07-1.51; *P*=.006; Table 2) and male participants (RRR 1.27; 95% CI 1.05-1.52; *P*=.01; Table 2) were more responsive to texts than older participants (age >65 years) and female participants during the initiation phase of the study. The indication for CR, the presence or absence of heart failure, and baseline physical activity levels did not significantly impact responsiveness to texts.

Impact of Texts on Fitbit Users

Baseline mean daily step count was 7011.2 (SD 3711.5) steps for Fitbit users. In the initiation phase of the study, texts increased step counts by 17% (95% CI 7%-28%; *P*<.001) in the 60 minutes after text delivery. In the initiation phase of the study, there was a trend, although not statistically significant, toward increased step count when texts were delivered at lunch compared to the afternoon (RRR 1.35; 95% CI 1.00-1.82; *P*=.05; Table 3). This trend, although not statistically significant, persisted for the overall study period (RRR 1.11; 95% CI 0.99-1.24; *P*=.07; Table 3). In the study overall and in the initiation phase, text tailoring based on day of the week or personalization with participants' names did not significantly impact step count.

When analyzing the impact of texts based on participant characteristics, male participants were more responsive to texts than female participants (RRR 1.10; 95% CI 1.02-1.18; *P*=.01; Table 3) in the overall study. The indication for CR significantly impacted participants' responsiveness to texts, with participants who underwent valve repair or replacement being more responsive to texts than those who underwent percutaneous coronary intervention (RRR 1.31; 95% CI 1.03-1.67; *P*=.03; Table 3) or coronary artery bypass grafting (RRR 1.48; 95% CI 1.17-1.87; *P*=.001; Table 3). Sex category, the presence or absence of heart failure, and baseline physical activity status did not significantly impact responsiveness to texts.

Discussion

Principal Findings

In the VALENTINE mHealth intervention designed to augment the benefits of CR through texts, we found that texts increased step counts in the 60 minutes following delivery by a statistically significant 17% for Fitbit users and a nonsignificant 10% for Apple Watch users in the initiation phase of the study. In this secondary analysis, the primary objective was to evaluate the intervention-level and participant-level moderators of text efficacy, examining the study period overall as well as the initiation phase, during which texts were most effective. We found that contextual factors related to texts, such as timing of delivery and content of texts, did not consistently affect step count in either Apple Watch or Fitbit users. Notably, although personalization of texts with participants' names was hypothesized to increase responsiveness based on prior studies [16-18], it did not result in increased step count compared to nonpersonalized texts for either device type in our study. Although participant-level factors, such as sex and age, occasionally had significant effects, these were not consistent across device types and phases of the trial. Notably, baseline physical activity was predicted to be a moderator of text responsiveness (participants with high baseline activity may not find texts as effective), but there was no statistically significant difference in text responsiveness between those with low and high baseline activity for either device type.

This study adds to a growing body of literature exploring the efficacy of text-based mHealth interventions and specifically ways to optimize delivery to elicit behavioral change. Prior studies have shown that texts can motivate patients with CVD to augment physical activity in the form of increased step count and time spent engaging in moderate-intensity exercise [16-23]. Meta-analyses, mostly in patient populations without CVD, have also shown that personalized and tailored texts that account

XSL•FO
RenderX

for user preferences, baseline characteristics, or real-time contextual data are more effective than generic texts in promoting engagement and responsiveness [18-21]. Although previous studies have analyzed different forms of text personalization and framing separately, no study has directly compared and evaluated multiple types of text tailoring within the same participant population, especially in patients with CVD [17-23]. Our study sought to address this gap by using a novel microrandomized trial design to randomize patients with CVD to different types of tailored texts and determine which factors were most effective for promoting physical activity.

Although the VALENTINE study did not identify text attributes that consistently increased activity levels, these results should not necessarily be interpreted as evidence that tailoring is ineffective but rather as a reflection of the complexity involved in tailoring texts. Despite focused efforts to tailor texts based on diverse factors hypothesized to be salient based on prior work [17,20,21,23], it is possible that the texts were not tailored to the most impactful factors, at least for this study population. For example, prior studies suggested that users desire personalized texts, which was enacted in the study by including participants' names in a subset of texts [16,17]. However, it is possible that participants seek personalization in other ways not included in this study, such as in the context of their specific health goals, recent activity trends, or work schedules [21-23]. Additionally, given participant heterogeneity, it is likely that there are inherent differences between participants that may make the same tailored text effective for some but not for others. More sophisticated strategies, such as the use of reinforcement learning algorithms, may be needed to account for these individual-level differences so that participants receive the types of texts to which they have responded historically [24].

Despite the results lacking statistical significance, the VALENTINE study did reveal some interesting associations that may warrant further exploration. For example, the content of texts appeared to be influential, with texts that promoted walking leading to a higher step count than texts that promoted antisedentary activities among Apple Watch users. The timing of texts may also matter, with Fitbit users responding more often to texts delivered at lunch, when participants may have had a work break to engage in physical activity. These are less explored but vital text attributes that are hypothesis-generating and should serve as early evidence for future work.

Our study also found that results varied between Apple Watch and Fitbit users, although the smaller participant sample size and lack of statistically significant results limit interpretation. Prior research has shown that key differences between the Apple Watch and the Fitbit, such as user interface, functionality, integration into daily life, and activity data collection methodology, influence user engagement and data accuracy [11-14]. Studies have also suggested differences in the characteristics of individuals who gravitate toward 1 device type over the other, with the Fitbit being marketed primarily as a health and fitness tool while the Apple Watch is a multipurpose device. However, very few studies have directly compared how the 2 devices could mediate behavioral change in mHealth interventions and what customizable factors matter for each device type. Future studies should explore how intrinsic features of wearable devices may cater to different individuals and contexts and thereby influence the efficacy of mHealth interventions.

Our study has several strengths. First, our study used a novel microrandomized design, a powerful experimental design for making causal inferences [25]. Through sequential randomized assignment, we were able to assess time-varying and contextual factors with the potential to moderate intervention efficacy, an inherent limitation of randomized controlled trials, which can only assess the impact of an intervention package in aggregate. Second, we explored multiple layers of tailoring, including text content and participant-level factors. Few studies have similarly analyzed multiple moderators of texts or tailored texts to factors such as content type (eg, walking vs antisedentary). Third, with the primary outcome being step count 60 minutes after a decision point, our study assessed the immediate and likely direct impact of texts rather than a more distant outcome that could be explained by confounding factors or other intervention components, as many mHealth interventions have multiple intervention components. Finally, our study included both Apple Watch and Fitbit users, capturing comparative data on wearable devices in the context of mHealth interventions and increasing participant inclusivity.

Our study also has limitations. First, the sample size for individual moderator subgroups was small, potentially limiting our ability to detect differences by text type or participant-level factors. Thus, this analysis should be viewed as hypothesis-generating but not confirmatory. However, we did collect a rich dataset consisting of 70,552 serial randomizations, which allowed powerful assessments of causal effects. Second, although the texts were tailored to many factors, other potentially impactful factors, such as real-time activity data or user preferences regarding text characteristics, were not incorporated. Future iterations will focus on adding this layer of personalization. Third, although baseline characteristics, such as demographics, baseline activity status, and indication for CR, were evaluated as moderators, other participant-level factors relevant to an mHealth trial were not assessed, such as digital literacy. However, given the highly accessible delivery format of texts, digital literacy is less likely to affect their impact. Fourth, although texts were delivered at a time when participants were thought to be available, text engagement data were not collected (ie, whether and when participants read the text on their smartwatch or opened it in the mobile app). Therefore, step count assessment following text delivery may not have always captured activity change after viewing a text or accounted for the fact that a participant was already active at the time of viewing the text. Nonetheless, the availability data still suggest meaningful exposure to the intervention in a timely manner. Fifth, the sample contained only low and moderate-risk patients with CVD who already owned smartphones, were enrolled in center-based CR, and had relatively high activity at baseline, suggesting a population with higher levels of digital literacy and intrinsic motivation. Given these already optimized characteristics at baseline, there may have been a ceiling effect in terms of how much more benefit participants gained from tailored texts. However, our sample is diverse in other clinically meaningful ways (more than one-third of participants were aged

XSL•FO
RenderX

≥65 years, and a subset of participants were from a community setting); therefore, our findings are still applicable to real-world CR populations. Finally, although we compared the relative impact of different tailoring variables, the study evaluated a package of tailored texts compared to no text and did not compare the impact of tailored texts to that of generic texts. Thus, we are unable to draw conclusions regarding the impact of tailoring more generally.

Conclusions

Overall, text message-based mHealth interventions are a promising approach for increasing physical activity levels among CR enrollees. In this secondary analysis of a microrandomized trial embedded within the VALENTINE study, we found that although tailored texts were associated with short-term increases in physical activity, no individual text-level or participant-level characteristic consistently moderated responsiveness across time periods and device types. These findings indicate that commonly used tailoring strategies, such as timing of text delivery, content type, or personalization with a participant's name, are insufficient on their own to optimize engagement and behavioral response in a heterogeneous patient population. Effective text tailoring likely requires a broader and more dynamic set of variables, including real-time behavioral data, evolving user preferences, and device-specific contexts. Future research should focus on developing learning algorithms that can learn and adapt to user preferences and adjust text delivery over time to more effectively augment and extend the benefits of center-based CR.

Abstract

Background: Walking is one of the most effective forms of physical activity; however, maintaining long-term engagement in digital step-counting interventions remains challenging.

Objective: This study aimed to evaluate the effects of personalized message interventions integrating the Information-Motivation-Behavioral Skills (IMB) model and regulatory focus theory (RFT) on walking behavior.

Methods: Participants were recruited offline through community advertisements containing a QR code that linked to an online sign-up form and were screened using an online baseline questionnaire by research staff, while all intervention delivery and outcome assessments were conducted via the WalkOn mobile app. A 12-week randomized controlled trial targeting 174 adults in Mapo-gu, Seoul, Korea, was conducted from April 1 to June 22, 2024. Of the 174 randomized participants, 141 (67 in the intervention group and 74 in the control group) engaged in the intervention. Both groups received incentives based on goal achievement and general health information, whereas the intervention group received weekly personalized messages provided by research staff according to midweek step-count performance. Primary outcomes included weekly goal achievement rates for the 25,000-step goal, step-count patterns, and consecutive 2-week goal achievement failure events. Analyses were conducted using generalized estimating equations (GEEs), linear mixed models (LMMs), and Cox proportional hazards models.

Results: Of the 174 participants randomized, 141 (81%) engaged in the intervention and were included in the analyses (67 intervention; 74 control), while 33 participants did not participate after randomization. The overall 12-week mean goal achievement rate was 87% in the intervention group and 87% in the control group, with no significant difference between the groups (odds ratio [OR] 1.12, 95% CI 0.29-4.37; *P*=.87). Weekly step-count patterns also showed no significant differences (group × time interaction: estimate=–417; SE 09; *P*=.31). However, the risk of consecutive 2-week goal achievement failure events was significantly lower in the intervention group (hazard ratio [HR] 0.67, 95% CI 0.52-0.86; *P*=.002). The intervention group showed an approximately 33% lower likelihood of consecutive 2-week goal achievement failure events than the control group.

Conclusions: Personalized message interventions did not show significant effects on overall step-count increase but were associated with a reduced risk of consecutive 2-week goal achievement failure events. These findings suggest that personalized messages may play an important role in improving behavior change sustainability and failure resilience. Incorporating personalized messaging strategies may enhance the effectiveness of digital health intervention design.

Introduction

Walking is one of the most accessible and effective forms of physical activity and is consistently associated with reduced risks of cardiovascular disease, cancer, type 2 diabetes, and dementia [1-3]. In particular, according to meta-analyses and large-scale cohort studies, walking briskly for 30 minutes daily, 5 days a week, has been shown to significantly reduce cardiovascular disease risk factors, improve blood pressure control, and contribute to healthy aging [1,2,4]. Additionally, walking for 30 minutes daily is associated with substantial health benefits, including improved mental health, enhanced mobility, and increased life expectancy [5]. Walking interventions have been emphasized in rehabilitation contexts and programs for older adults, and structured and sustained walking programs have shown particularly important benefits for mobility, balance, quality of life, and stroke recovery [6]. Recent studies have shown that even short walks of 5 to 11 minutes per day are associated with reduced mortality from cancer, cardiovascular disease, and all causes [7]. Walking is an ideal tool for population-level health promotion interventions due to its accessibility and scalability, as it requires no special equipment, can be performed in various environments, and can be adapted to an individual's fitness level [8].

Despite these clear health benefits, physical inactivity remains a serious public health problem worldwide, contributing to the burden of noncommunicable diseases and reduced quality of life [9]. As an innovative approach to address this issue, digital step-counting interventions using pedometers, smartphone apps, and wearable devices have emerged as promising strategies to encourage walking behavior and increase overall physical activity levels. These interventions have received significant attention owing to their accessibility, cost-effectiveness, and scalability across diverse populations.

The proliferation of digital health technologies has created unprecedented opportunities for individuals to monitor their physical activity on their own [10], and step counters provide real-time feedback on daily activity levels and enable users to track their progress toward the recommended physical activity guidelines. The appeal of such interventions lies in the simplicity and quantifiability of step counting, which can serve as a visible and motivating goal for individuals seeking to increase their physical activity.

There is growing evidence supporting the short-term effectiveness of digital step counting in promoting actual walking behavior. According to several systematic reviews and meta-analyses, such interventions significantly increased daily step counts, with an average increase of 1126 steps per day after 4 months of pedometer use, and sustained improvements were observed even up to 3 to 4 years later [11]. Similarly, interventions using smartphone apps have demonstrated an average daily increase of 1182 steps over 3 months [12]. These increases are often accompanied by meaningful improvements in health outcomes such as weight loss, reduced BMI, lower blood pressure, decreased triglyceride levels, and improved psychological well-being [12,13].

However, despite these initial positive results, there is growing evidence that digital step-counting interventions have significant limitations in maintaining long-term walking behavior changes. The novelty and enthusiasm surrounding these technologies tend to wane over time, leading to lower participation and adherence rates. Several longitudinal studies have reported that more than half of the participants discontinue device use within 6 months of a digital step-counting intervention [14]. The novelty effect begins to fade after approximately 3 months, with the effect size in long-term interventions decreasing by approximately 40% compared with short-term interventions [15]. These sustainability issues highlight the significant gap between the short- and long-term public health impacts, suggesting that maintaining high activity levels requires addressing complex psychological, social, and environmental factors beyond simple self-monitoring.

To overcome these limitations, digital walking interventions have evolved around step-counting technology using wearable devices and mobile apps, with various efforts to increase physical activity engagement [16]. Current digital walking interventions commonly integrate behavior change techniques (BCTs) such as self-monitoring, goal setting, social comparison, and gamification, which are increasingly enhanced through personalized feedback [17,18]. Among these approaches, personalized messaging has proven to be a particularly effective form of personalized feedback that supports behavior maintenance by providing tailored information and motivation based on individual behavioral data [19]. Research shows that personalized messages elicit higher levels of engagement and adherence than generic information approaches [20,21].

However, current digital walking interventions have several limitations that restrict their effectiveness. First, the accuracy of commercially available step counters can vary significantly in real-world settings, with limited representativeness and generalizability across diverse populations [22,23]. Second, user engagement and compliance tend to decrease over time, and the long-term maintenance of behavior change remains an ongoing challenge [11,24]. Third, existing personalized messaging research primarily focuses on general encouragement or simple performance feedback and lacks systematic research on differentiated theory-based messaging strategies according to individual real-time performance levels. Fourth, most studies rely on single behavior change theories, failing to comprehensively address individuals' complex motivations and change stages. These limitations emphasize the need for more sophisticated intervention approaches beyond simple feedback mechanisms.

Digital health interventions are increasingly integrating behavior change theories to improve their effectiveness [25,26]. While the effectiveness of an intervention depends on the appropriateness of the theoretical framework rather than the mere number of theories used, this study specifically integrates the Information-Motivation-Behavioral Skills (IMB) model and regulatory focus theory (RFT) to support the design of personalized walking interventions. Existing research is limited to adaptive approaches that comprehensively address information provision, motivation, and behavioral skill acquisition while dynamically adjusting prevention- or

XSL•FO
RenderX

promotion-focused messages according to individual weekly performance changes.

The IMB model proposes that three core components are necessary for behavior change [27]: (1) accurate information related to the behavior, (2) personal and social motivation to perform the behavior, and (3) behavioral skills to effectively perform the behavior [28,29]. This model provides a structured theoretical framework supporting users in understanding relevant information, developing intrinsic and extrinsic motivation, and acquiring the skills necessary for behavior change. Similarly, the RFT explains that individual motivational orientations are distinguished as prevention and promotion foci [30-32]. RFT proposes that individuals regulate goal pursuit through 2 distinct motivational orientations: promotion focus and prevention focus [33,34]. A promotion focus is concerned with aspirations, accomplishments, and advancement, motivating individuals to pursue gains and ideal outcomes. In contrast, a prevention focus centers on safety, responsibility, and the fulfillment of obligations, where the primary motivation is loss avoidance and the maintenance of a non-loss state. This theory can support habit formation by effectively encouraging the repetition and habituation of walking by connecting goal achievement with positive reinforcement and rewards.

However, the IMB model has limitations in that it does not consider differences in individual motivational orientations and regulatory focus types and fails to explain dynamic changes in motivational needs according to performance levels [35,36]. Conversely, RFT has limitations in that it does not provide specific behavior change mechanisms, focuses primarily on motivational orientation, and does not specify what types of information or skills should be provided according to the regulatory focus [33,37]. These limitations of each theory can be addressed through complementary integration.

The integration of the IMB model and RFT operates through integrative processes that mutually complement the limitations of each theory. This study proposes an integrative approach that differentiates the IMB's information component into loss or gain frames according to RFT's prevention and promotion foci, applies motivational strategies tailored to individual regulatory focus, and provides behavioral skills differentiated by regulatory focus (prevention focus: barrier removal; promotion focus: performance optimization). Conversely, the IMB model provides a foundation for integrating systematic information provision mechanisms, specific behavioral skill acquisition processes, and multilayered motivational systems to complement RFT's limitations.

Specifically, this study proposes a performance-based dynamic integration model that dynamically determines the regulatory focus based on participants' real-time step count performance and selectively applies IMB components accordingly. Low-performance groups (<12,500 steps) activate a prevention focus emphasizing information and behavioral skills, medium-performance groups (12,500-24,999 steps) apply a prevention focus and an IMB integrated approach, and high-performance groups (≥25,000 steps) activate a promotion focus emphasizing motivation.

Based on these theoretical and practical needs, this study aims to overcome existing research limitations and present new approaches. The originality of this study lies in the following aspects. First, we developed a personalized messaging system that is responsively adjusted weekly based on the participants' real-time step count performance. Second, we systematically implemented differentiated messaging strategies according to individual performance levels by applying a theoretical framework that integrates the IMB model and RFT. Third, we comprehensively evaluated the intervention effects from the perspective of behavior change maintenance, focusing on goal achievement sustainability and consecutive failure prevention beyond a simple step count increase. This approach overcomes the limitations of existing static and uniform personalized messaging and presents the possibility of dynamic, customized interventions tailored to individual change stages and performance levels.

Therefore, this study seeks to answer the following specific research questions: (1) Do personalized theory-based messages have significant effects on weekly step count goal (25,000 steps) achievement rates over 12 weeks? (2) Does the message intervention have significant effects on participants' step count patterns over 12 weeks? and (3) Do personalized messages reduce the risk of consecutive 2-week goal achievement failures? To answer these research questions, this study adopted a randomized controlled trial (RCT) design and conducted a 12-week digital walking intervention targeting 174 adults.

Methods

Study Design

This study was a 12-week RCT conducted from April 1 to June 22, 2024, to evaluate the effects of personalized health message interventions on walking behavior in Korean adults. A parallel-group design with a 1:1 allocation ratio was used. An active control group design was adopted to isolate the specific effects of personalized messaging by providing substantial nonpersonalized intervention components to the control group.

The trial was registered retrospectively with the Clinical Research Information Service (CRIS; KCT0010966). The registered study procedures corresponded to the protocol implemented in the trial. The study protocol, including primary outcomes and statistical analysis plans, was finalized prior to data analysis. No changes were made to the primary outcomes or analytical strategies after examination of the data. The registered protocol corresponds to the procedures implemented in the trial.

Sample Size

The sample size calculation was performed using G*Power. Assuming a small effect size (Cohen d=0.20), a significance level of α=0.05, and power of 80%, the required sample size for the primary comparison was 200 participants per group. However, the final number of participants randomized was 174, with 141 engaging in the study (67 in the intervention group and 74 in the control group). The impact of this reduced sample size on statistical power and precision is discussed in the Discussion section.

Study Participants

Overview

Residents of Mapo-gu, Seoul, were recruited through voluntary participation via community offline advertisements (eg, local posters and bulletin boards containing a QR code that linked to an online sign-up form) and were screened using an online baseline questionnaire by research staff. Eligibility criteria included being an adult aged 19 years or older, owning a smartphone capable of installing a mobile app, being able to walk independently, and having signed a consent form for study participation. Those with difficulty walking or an inability to use a smartphone app were excluded. A total of 174 participants were randomized (87 per group).

Participants received incentive points for achieving weekly walking goals during the intervention period. The incentive value progressively increased every 4 weeks (weeks 1-4: 1000 points [KRW 1000; KRW 1=US $0.00074 as of April 5, 2024]; weeks 5-8: 1500 points [KRW 1500]; weeks 9-12: 2000 points [KRW 2000]) to encourage sustained participation.

Randomization and Intervention

After baseline data collection, the participants were assigned to either the intervention or control group using a computer-generated randomization sequence created with the RAND function in Microsoft Excel. Following randomization, the intervention began, and participants were monitored throughout the 12-week intervention period. Both groups were presented with a weekly walking goal of 25,000 steps and used the WalkOn mobile app (Swallaby Co) for real-time step tracking.

The intervention was implemented using the WalkOn mobile app, a commercially available smartphone app that tracks users' daily step counts using built-in motion sensors and provides real-time feedback on walking activity. Step count data were automatically recorded and stored on the system server, allowing researchers to collect participants' walking data throughout the 12-week intervention period. Program participation was defined as having at least one recorded step count through the WalkOn mobile app after the intervention began. Participants who had no recorded step count data during the first week of the intervention were classified as nonparticipants and were considered not to have initiated the program. These participants had agreed to participate but had no recorded step-count data during the first week after randomization, indicating that the WalkOn step-tracking app had not been activated on their smartphones.

The weekly goal of 25,000 steps established in this study was set by converting the World Health Organization's (WHO) physical activity recommendations for adults—"at least 150 minutes of moderate-intensity physical activity per week"—into step counts [34]. According to previous research, 30 minutes of moderate walking corresponds to approximately 3000 steps when performed at a walking cadence of approximately 100 steps per minute [38,39]. Multiple controlled laboratory studies have confirmed that a cadence of 100 steps per minute corresponds to moderate physical activity intensity (3 metabolic equivalents [METs]) [40,41]. In addition, step-count–based physical activity classifications suggest that fewer than 5000 steps per day represents a sedentary lifestyle threshold [42]. Accordingly, accumulating approximately 25,000 steps per week represents a realistic and attainable behavioral target that encourages participants to move beyond sedentary activity levels while remaining feasible for community-based populations.

Based on these considerations, this study set the weekly step goal at 25,000 steps, equivalent to approximately 5 days of moderate walking per week. This threshold also allowed meaningful midweek performance classification (<50%, 50%-99%, and ≥100%) for the personalized messaging algorithm used in the intervention. Therefore, the selected goal was considered both practically achievable and consistent with the WHO physical activity recommendation standards.

The goal was intentionally based on approximately 5 days of activity rather than 7 days to reflect the WHO recommendation structure (30 minutes of moderate physical activity on at least 5 days per week). In addition, allowing 2 potential rest days per week reflects realistic physical activity patterns in community populations and improves the feasibility and sustainability of behavioral interventions.

Intervention Group (Personalized Message Group)

The intervention group received personalized health messages via KakaoTalk (Kakao Corp) every Friday based on walking performance from Monday to Wednesday of each week, in addition to basic intervention elements.

Participants' performance groups were determined based on the cumulative step counts recorded from Monday to Wednesday of each week, rather than projected weekly averages. These midweek step totals were compared with the predefined weekly goal of 25,000 steps to classify participants into three performance categories (<50%, 50%-99%, and ≥100%). Personalized messages were developed using RFT and the IMB model.

Participants were classified into three subgroups based on the cumulative step counts recorded from Monday to Wednesday of each week: (1) fewer than 12,500 steps received prevention-focused messages emphasizing information and behavioral skills; (2) 12,500 to 24,999 steps received prevention-focused messages, including all 3 IMB model components; and (3) 25,000 steps or more (≥100% of the weekly goal) received promotion-focused messages emphasizing motivation. Participants who accumulated ≥25,000 steps between Monday and Wednesday were considered to have already achieved the weekly goal ahead of schedule and therefore received promotion-focused reinforcement messages designed to sustain their walking behavior for the remainder of the week. Motivational elements were present across the intervention through goal setting and incentive systems; however, message content for the low-performance group primarily emphasized information and behavioral skills to address practical barriers to walking. The performance categories were predefined prior to study implementation and were directly linked to the weekly goal of 25,000 steps and the associated incentive system. Because incentives were provided upon achieving the 25,000-step weekly target, proportional

XSL•FO
RenderX

progress toward this predefined goal (<50%, 50%-99%, and ≥100%) was used to tailor intervention messages. Thus, the categorization reflected meaningful stages of goal attainment rather than arbitrary thresholds. The specific message strategies and theoretical components for each performance range are summarized in Table 1. Each message was personalized with the participants' names and specific performance feedback, including concrete walking suggestions reflecting the seasonal context and local characteristics.

Table 1. Theory-based personalized message components and examples by performance group.

Performance group	Step count range	Theoretical framework	Message focus and example[a]
High-performance group	≥25,000 steps per week	• RFT[b]: promotion focus • IMB[c]: motivation	• Focus: celebrating success and maintaining engagement • Example: "Great job! You've already achieved 25,000+ steps. You've earned 1,500 points. Congratulations!"
Medium-performance group	12,500 to 24,999 steps per week	• RFT: prevention focus • IMB: information, motivation, and behavioral skills	• Focus: emphasizing proximity to goal with specific behavioral suggestions • Example: "Mid-week check: You've reached more than half of your weekly goal (25,000 steps). How about evening walks to enjoy cricket sounds?"
Low-performance group	<12,500 steps per week	• RFT: prevention focus • IMB: information and behavioral skills	• Focus: providing specific behavioral strategies and preventing goal abandonment • Example: "Did you know that just a 5-minute walk after meals can help lower your blood sugar and boost your mood? Try a short stroll today!"

[a]Messages were delivered every Friday via KakaoTalk to intervention group participants (n=67) based on Monday to Wednesday step count assessment. Each message included personalized greetings using participants' names or nicknames.

[b]RFT: regulatory focus theory.

[c]IMB: Information-Motivation-Behavioral Skills.

Control Group (Active Control Group)

The control group was designed as an active control group that received all intervention elements except personalized messages. Specifically, they received the following components:

- Same incentive system: both groups received the same progressive incentive system for achieving weekly walking goals during the intervention period.
- General health information provision:
  participants received standardized, nonpersonalized health information weekly in card news format, including information on walking, smoking cessation, alcohol moderation, and community health resources.
- Social comparison feature:
  participants could experience social comparison and competitive motivation through real-time step count comparison features within the WalkOn app.
- Same goal setting:
  participants received the same weekly walking goal of 25,000 steps as the intervention group.

Through this active control group design, we aimed to isolate the effect of personalized messages and evaluate the added value of personalization beyond general health information provision or social comparison. All intervention components except personalized messaging were identical between the 2 groups.

Operational Definition of the Theoretical Framework

The IMB and RFT integrated framework developed in this study is a system that dynamically determines RFT's prevention and promotion focus according to participants' weekly step count performance and selectively combines and applies IMB model components (information, motivation, and behavioral skills) accordingly.

Performance-Based Regulatory Focus Determination

The participants were classified into 3 groups based on their midweek step count, with the personalization algorithm dynamically determining the regulatory frame to maximize motivational relevance. For the low-performance group (<12,500 steps per week; <50% achievement), messages used a prevention focus to emphasize "loss avoidance," highlighting potential negative health outcomes and the risk of failing the weekly commitment to prevent goal abandonment. The medium-performance group (12,500-24,999 steps per week; ≥50% achievement) received messages that maintained a prevention-oriented frame while emphasizing the possibility of achieving the weekly goal. Conversely, for the high-performance group (≥25,000 steps per week; 100% achievement), a promotion focus was applied to celebrate achievement and progress, focusing on positive gains and encouraging the pursuit of higher health aspirations. This dynamic application of RFT ensures that the motivational feedback remains tailored to the individual's real-time behavioral state.

IMB Component Application Strategy

The IMB model components were applied differently for each performance range. Low-performance ranges were centered on information and behavioral skills components, providing specific implementation methods and self-monitoring strategies. Medium performance ranges provided comprehensive support by integrating all information, motivation, and behavioral skills components. High-performance ranges were centered on

XSL•FO
RenderX

motivation components to induce achievement recognition and continued participation.

The information components emphasized the importance of goal achievement and current status feedback for prevention focus, achievement results, and rewards for promotion focus. Motivation components used supportive keywords like “cheer up” and “let’s do this together” for prevention focus, and recognition keywords like “excellent” and “congratulations” for promotion focus. Behavioral skills components provided specific practice strategies for prevention focus, and performance maintenance and expansion strategies for promotion focus.

Message Generation Algorithm

Personalized messages were automatically generated using the step-by-step algorithm.

Message Generation Procedure

In the first step, participants’ weekly step count data (Monday to Wednesday step count sum, with Thursday 12 AM as the cutoff) were collected to classify performance ranges. Midweek (Monday to Wednesday) step count assessment was intentionally implemented as an early trajectory monitoring strategy to facilitate timely feedback within the same weekly goal cycle. Because the intervention was fundamentally structured around the predefined weekly target of 25,000 steps, midweek performance evaluation allowed differentiated messaging to support goal attainment before the week concluded, rather than serving as a replacement for the weekly outcome measure. The second step determined the regulatory focus (prevention or promotion) according to the performance ranges and selected the IMB components to apply. The third step generated message content according to the selected components and added personalization elements.

Message Structure Template

All messages were structured identically: (1) greeting including the personal name, (2) specific step count feedback, (3) core message by performance range, (4) specific behavioral suggestions, and (5) encouragement and closing. Each message was limited to 150 to 200 characters to maintain conciseness while preserving a friendly and personal tone to strengthen relationships with the participants. Examples of the performance-level messages are provided in Multimedia Appendix 1.

Application of Personalization Elements

All messages included the participants’ real names, actual step counts, and goal achievement rates. They also suggested seasonally appropriate activities (spring: cherry blossom walks; summer: early morning walks) and specific locations reflecting local characteristics (Hangang Park and World Cup Park). Differential messages were provided according to change patterns compared with the previous weeks: encouragement for improvement, new strategy suggestions for stagnation, and supportive messages for decline.

Outcome Measurement

Baseline characteristics, including gender and age, were measured through preintervention surveys. Step count-related outcome variables were calculated using daily step count data automatically collected via the WalkOn app, which uses built-in smartphone accelerometers with weekly verification procedures to ensure data accuracy and integrity.

Although participants could withdraw from the WalkOn community at any time, the research team had securely exported and stored all step-count data for the 12-week intervention period in Microsoft Excel files before any withdrawals, ensuring that participant withdrawal did not affect the completeness or integrity of the final dataset.

Weekly Goal Achievement Rate

Weekly goal achievement rate was defined as the proportion of participants achieving ≥25,000 steps per week over 12 weeks, with individual achievement coded as binary (1=achievement; 0=nonachievement).

Twelve-Week Step Count Patterns

Step count patterns were analyzed using total weekly steps (Monday to Sunday) as a continuous variable to examine changes in step counts over the 12-week intervention period.

Consecutive 2-Week Goal Achievement Failure Events

Consecutive 2-week goal achievement failure was defined as the first occurrence of failing to achieve the weekly 25,000-step goal for 2 consecutive weeks. This definition was selected to distinguish temporary weekly fluctuations from sustained disruptions in walking adherence. Because weekly step performance may vary due to short-term contextual factors such as weather conditions, temporary illness, or schedule changes, a single week of goal failure may reflect natural variability rather than meaningful behavioral disengagement. In contrast, consecutive failure across 2 weeks can indicate an emerging lapse in behavioral persistence and therefore provides a more stable indicator of behavioral disruption within the weekly intervention cycle used in this study.

Statistical Analysis

Overview

Baseline characteristics were summarized using descriptive statistics. In accordance with CONSORT (Consolidated Standards of Reporting Trials) recommendations for RCTs, statistical significance testing between randomized groups was not performed. Baseline characteristics were compared between participants and nonparticipants after randomization to assess potential attrition bias.

Analysis of Weekly Goal Achievement

Generalized estimating equations (GEEs) were applied to evaluate changes in weekly goal achievement rates using logit link functions and exchangeable correlation structures to analyze the 12-week 25,000-step goal achievement status.

XSL•FO
RenderX

Analysis of Step Count Patterns

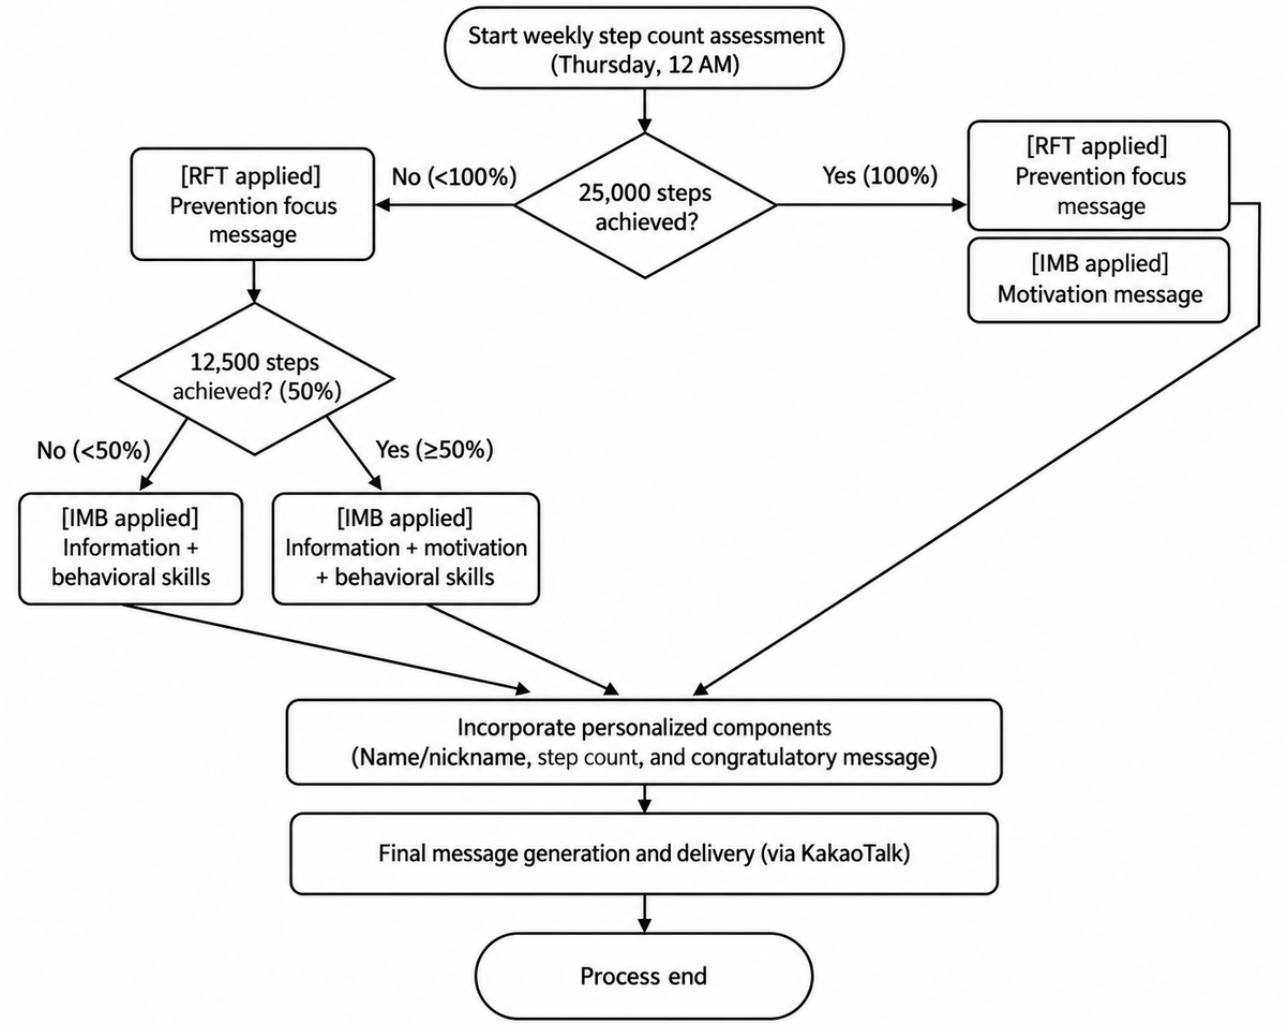
Linear mixed models (LMMs) were used to evaluate the 12-week step count patterns, including subject-specific random intercepts and random slopes, to account for within-individual correlations.

Analysis of Consecutive Goal Failure Events

Kaplan-Meier survival analysis and Cox proportional hazards models were applied to evaluate the intervention effects on consecutive 2-week goal achievement failure events.

All analyses included time, group, and time × group interactions as the main variables, with gender and age as adjustment variables. Primary analyses included a modified intention-to-treat analysis targeting 141 participants who actually participated in the intervention. Because 33 participants did not initiate the intervention and had no postbaseline outcome data, inclusion in repeated-measures analyses required at least 1 postbaseline observation. Therefore, the primary analyses followed a modified intention-to-treat approach including all participants who initiated the intervention (n=141). Sensitivity analyses using a full intention-to-treat framework including all randomized participants (n=174) with multiple imputation for missing data were additionally performed to assess robustness. Missing values were handled using multiple imputation methods. All analyses were performed using SPSS (version 28.0; IBM Corp), with statistical significance set at $P<.05$.

Ethical Considerations



This study was approved by the Institutional Review Board of Sahmyook University (SYU 2024-02-017). All participants provided written informed consent prior to enrollment and were informed of their right to withdraw at any time without penalty. Step count data were collected through the WalkOn mobile app and deidentified prior to analysis to ensure confidentiality. Participants in both groups received identical performance-based incentives (1000-2000 points [equivalent to KRW 1000-2000] per week depending on study phase).

Results

Personalized Messaging Algorithm

The personalized messaging algorithm used to generate and deliver messages according to participants' midweek step count performance is illustrated in Figure 1.

Participant Characteristics and Baseline Analysis

Of the 174 randomized participants, 141 (81%) engaged in the 12-week study, including 77% (67/87) in the intervention group and 85% (74/87) in the control group. A total of 33 participants did not participate after randomization (20/87, 23%) in the intervention group and 15% (13/87) in the control group. The participant flow is presented in Figure 2.

Figure 2. Flow of participants through the study. ITT: intention-to-treat.

Baseline characteristics of the randomized participants are presented in Table 2. In accordance with CONSORT recommendations, formal significance testing of baseline characteristics between randomized groups was not performed (CONSORT checklist is provided in Multimedia Appendix 2).

XSL•FO
RenderX

Table 2. Baseline characteristics of randomized participants and randomization verification. A total of 141 participants (67 in intervention; 74 in control) completed the 12-week intervention.

Variable	Total (n=174), n (%)	Intervention group (n=87), n (%)	Control group (n=87), n (%)
Gender			
Men	60 (34.5)	30 (35)	30 (35)
Women	114 (65.5)	57 (66)	57 (66)
Age group (years)			
20-29	17 (9.8)	10 (12)	7 (8)
30-39	26 (14.9)	11 (13)	15 (17)
40-49	58 (33.3)	24 (28)	34 (39)
50-59	54 (31)	31 (36)	23 (26)
≥60	19 (10.9)	11 (13)	8 (9)

Population Characteristics and Selection Bias Assessment

Among the 141 participants who engaged in the intervention, borderline differences in age group distribution were observed between groups (*P*=.06), whereas no significant differences were found in gender or baseline step counts.

To assess potential attrition-related selection bias, baseline characteristics were summarized using descriptive statistics for each study group (Tables S1 and S2 in Multimedia Appendix 3).

Intervention Effects on Weekly Goal Achievement Rates

Weekly goal achievement rates over the 12 weeks showed generally high levels in both groups; detailed week-by-week values are provided in Table S3 in Multimedia Appendix 4. The intervention group maintained relatively stable achievement rates during weeks 5 to 8, with the highest rate of 91% (61/67) observed in participants in weeks 4 to 6. The control group showed more variable patterns, with recovery in weeks 9 to 10 after midstudy declines.

GEE was applied to evaluate the effects of the personalized message interventions on weekly step count goal (25,000 steps) achievement rates over 12 weeks. Goal achievement status was set as a binary dependent variable (1=achievement; 0=nonachievement) using logit link functions and exchangeable correlation structures to account for internal correlations in repeated measurement data by subject. The model included time (week), group (intervention vs control), and time × group interaction as the main variables, analyzing 1692 observations (141 participants × 12 weeks).

GEE analysis results (Table 3) showed statistically significant changes in goal achievement rates over time (Wald χ^2_{11}=30.7; *P*=.001). Using week 1 as reference, most weeks did not differ significantly from week 1; however, the odds of goal achievement were significantly lower at week 12 (odds ratio [OR] 0.34, 95% CI 0.12-0.93; *P*=.04). Overall differences in goal achievement rates between intervention and control groups were not statistically significant (OR 1.12, 95% CI 0.29-4.37; *P*=.87). Additionally, time and group interaction effects were not significant (Wald χ^2_{11}=11.8; *P*=.38), confirming that personalized message interventions did not differentially influence goal achievement rate change patterns over time.

Step Count Patterns

LMM was applied to evaluate the effects of personalized message interventions on 12-week step count patterns. Step counts were set as continuous dependent variables, including subject-specific random intercepts and random slopes to account for within-individual correlations. The model included time (week), group (intervention vs control), and the time × group interaction as the main variables.

Weekly step counts over 12 weeks varied in both groups. The intervention group showed a lower overall mean weekly step count than the control group; detailed week-by-week values are presented in Table S4 in Multimedia Appendix 4. The intervention group showed a decreasing pattern from 57,217 steps in week 1 to 49,067 steps in week 12, whereas the control group showed a decreasing pattern from 60,940 steps in week 1 to 54,808 steps in week 12.

The intercept representing the estimated average weekly step count of the intervention group was 48,369 steps (SE 3524; *P*<.001, Table 4). Group effects representing between-group differences in average step counts were not significant (estimate 6184, SE 4856; *P*=.20), and step count changes over time (week) were also not significant (estimate 324, SE 642; *P*=.61). Moreover, the group × week interactions were not significant (estimate –417, SE 409; *P*=.31), confirming that personalized message interventions did not significantly influence step count patterns over 12 weeks.

Table 4. Linear mixed model results for weekly step count changes (N=1692 observations from 141 participants; model fit: −2 log likelihood=35,185.6; AIC[a]=35,345.6; BIC[b]=35,774.7).

Parameter	Estimate (SE)	95% CI	*P* value
Intercept	48,369 (3524)	41,437 to 55,299	<.001
Intervention group (vs control; reference: intervention)	6184 (4856)	–3369 to 15,736	.20
Week	324 (642)	–934 to 1582	.61
Group × week	–417 (409)	–1218 to 393	.31

Intervention Effects on Preventing Consecutive 2-Week Goal Achievement Failure Events

Kaplan-Meier survival analysis and Cox proportional hazards models were applied to evaluate the effects of personalized message interventions on reducing the risk of consecutive 2-week goal achievement failure events. Consecutive 2-week goal achievement failure was defined as the event of interest, and time to first occurrence was used as the survival time.

During the 12-week observation period, 37% (27/74) of participants in the control group and 34% (23/67) of participants in the intervention group experienced consecutive 2-week goal achievement failure events. The average time to first consecutive failure was 4.7 weeks in the control group and 4.9 weeks in the intervention group. Detailed event frequencies and survival statistics are presented in Tables S5 and S6 in Multimedia Appendix 5.

Kaplan-Meier survival analysis demonstrated a statistically significant difference in time to consecutive 2-week goal achievement failure between groups (log-rank χ^2_1=9.9; *P*=.002; Figure 3). By the end of the 12-week follow-up, more than half of the participants in both groups had not experienced consecutive failure events; therefore, the median survival time was not reached. The intervention group showed longer survival without consecutive failure compared with the control group, indicating improved resilience against repeated goal failure.

Figure 3. Kaplan-Meier survival curves for consecutive 2-week goal achievement failure.

The Cox proportional hazards model analysis results (Table 5) showed that the intervention group had a significantly reduced risk of consecutive 2-week goal achievement failure events compared with the control group (hazard ratio [HR] 0.68, 95% CI 0.53-0.87; *P*=.002). In models adjusted for gender and age group, the intervention group still had a significantly lower risk of consecutive 2-week goal achievement failure events than the control group (HR 0.67, 95% CI 0.52-0.86; *P*=.002), representing an approximately 32.9% risk reduction.

Table 5. Cox proportional hazards model results for consecutive 2-week goal achievement failure events.

Variable	Unadjusted model, HR[a] (95% CI)	Adjusted Model[b], HR (95% CI)	*P* value
Intervention group (vs control)	0.68 (0.53-0.87)	0.67 (0.52-0.86)	.002
Women (vs men)	—[c]	0.43 (0.33–0.55)	<.001
Age group (years; reference: 20-29)			
30-39	—	1.46 (0.76–2.83)	.26
40-49	—	1.48 (0.80–2.73)	.21
50-59	—	2.00 (1.09–3.67)	.03
≥60	—	1.62 (0.83–3.17)	.16

[a]HR: hazard ratio.

[b]Adjusted for gender and age group.

[c]Not applicable.

Among the adjustment variables, women had a significantly lower risk of consecutive 2-week goal achievement failure events than men (HR 0.43, 95% CI 0.33-0.55; *P*<.001), and by age group, participants aged 50-59 years had approximately twice the risk of consecutive 2-week goal achievement failure events compared with those aged 20-29 years (HR 2.00, 95% CI 1.09-3.67; *P*=.03).

Kaplan-Meier survival curves also showed that the intervention group maintained a higher survival probability for consecutive

XSL•FO
RenderX

2-week goal achievement failure events than the control group throughout the study period (Figure 2), consistent with the Cox proportional hazards model results.

Sensitivity Analyses

Sensitivity analyses including all randomized participants (n=174) yielded results consistent in direction with the primary analysis. The intervention group showed a lower risk of consecutive 2-week goal achievement failure (HR 0.67, 95% CI 0.29-1.58), although this was not statistically significant (*P*=.37).

Discussion

Interpretation of Main Results

This RCT found that personalized theory-based messages did not significantly improve overall weekly step goal achievement rates or step count patterns over 12 weeks but significantly reduced the risk of consecutive 2-week goal achievement failures (HR 0.67, 95% CI 0.52-0.86; *P*=.002). These findings suggest that personalized messaging may enhance behavioral resilience by preventing repeated goal failures, even if it does not substantially increase overall performance levels.

These results are particularly noteworthy in the context of the study design. The control group in this study was not a simple comparison group but received substantial active intervention. The control group participants received the same progressive incentive system as the intervention group (weeks 1-4: 1000 points [KRW 1000]; weeks 5-8: 1500 points [KRW 1500]; weeks 9-12: 2000 points [KRW 2000]) and continuously received general health information through weekly walking and health promotion card news. They also experienced social comparison and competitive motivation through real-time participant step count comparison features via the WalkOn app and received the same weekly 25,000-step goal as the intervention group.

The significant effect of personalized messages on consecutive failure prevention, even in this strong control group intervention environment, suggests the unique value of personalization. Particularly, despite both groups maintaining high goal achievement rates (intervention group: 87%, control group: 87%), the approximately 33% reduction in consecutive 2-week goal achievement failure events in the intervention group demonstrates that personalized messages play a special role in improving “failure resilience” [43,44].

Compared with existing research, the results of this study have a deeper meaning. While most digital walking intervention studies have reported only short-term step count increases using minimal intervention control groups [11,12], this study verified the pure effects of personalized messages through an active control group design. This represents an important contribution by clearly identifying the actual effects of personalized interventions while addressing the methodological limitations of existing research. Consecutive failure prevention effects suggest that personalized feedback positively influences behavioral sustainability [45-47], and confirming these results under rigorous control conditions demonstrates the unique contribution of this study.

Recent evidence has also demonstrated the effectiveness of personalized digital messaging for increasing physical activity [48]. For example, an RCT using a reinforcement learning–based adaptive messaging system reported that personalized messages tailored to participants’ behavioral data significantly increased daily step counts compared with nonpersonalized messaging approaches. These findings support the broader evidence that personalization strategies can enhance behavioral engagement and physical activity in digital health interventions.

However, unlike previous studies that primarily focused on increasing overall step counts, the present study evaluated whether personalized theory-based messages could prevent repeated weekly goal achievement failure. While our intervention did not significantly increase mean step counts compared with the control condition, it significantly reduced the risk of consecutive goal achievement failure. This suggests that personalized feedback may play a particularly important role in sustaining behavioral adherence and preventing disengagement rather than simply increasing activity volume.

The goal achievement rate increase pattern observed during the middle period (weeks 4-8) is particularly interesting. This suggests that personalized messages may have acted as protective factors when the novelty effects were diminishing [49]. The maximum 6 percentage point achievement rate difference at week 6 demonstrates that personalized messages are particularly effective during the “dropout risk period” of intervention participation [49,50]. This emphasizes the need for individualized motivational support, which cannot be sufficiently provided through general health information or social comparison alone [51].

Theoretical Contribution

This study contributes theoretically by systematically implementing differentiated messaging strategies according to individual performance levels by applying a theoretical framework that integrates the IMB model and RFT. While existing research primarily relied on single theories [52-54], this study attempted an adaptive approach that comprehensively addresses information, motivation, and behavioral skills while dynamically adjusting prevention- or promotion-focused messages according to individual performance changes.

The preventive effects on consecutive 2-week goal achievement failure events align with the theoretical predictions that RFT’s prevention focus supports behavioral sustainability through loss avoidance motivation [32]. Particularly, prevention-focused messages provided to participants with fewer than 12,500 steps may have effectively prevented goal abandonment. This demonstrates the importance of theory-based approaches that consider individual motivational orientations beyond simple performance feedback in personalized messages [53,55,56].

Practical Implications

The practical implications of this study are as follows. First, the finding that personalized messages are effective in preventing consecutive failures provides important insights for developing user retention strategies in the mobile health care industry. Considering the high dropout rates (over 40%) observed in existing wearable devices and smartphone applications,

XSL•FO
RenderX

according to a meta-research study [57], the responsive messaging system developed in this study can be used as a cost-effective solution for improving user engagement.

Second, the differential effects of gender and age group (women: HR 0.43, 95% CI 0.33-0.55; age group 50-59 years: HR 2.00, 95% CI 1.09-3.67) emphasize the importance of personalized approaches that consider demographic characteristics in personalized intervention design [58,59]. This study provides evidence for establishing differentiated strategies for target populations in national-level physical activity promotion policies [60].

Third, the weekly performance-based message reflection system developed in this study can be extended to other areas of health behavior change, such as chronic disease management, smoking cessation, and dietary improvement. Particularly, it can provide important evidence for the systematic application of behavior change theories and personalized algorithm designs in digital therapeutics development [61].

Study Limitations

This study has several limitations. First, although an a priori sample size calculation was conducted, the achieved sample size was smaller than the original recruitment target. As a result, statistical power to detect small between-group differences may have been limited, and nonsignificant findings for overall goal achievement and step count patterns should be interpreted cautiously. Therefore, this trial should not be interpreted as a fully powered confirmatory trial for detecting small between-group differences. Second, the relatively short 12-week follow-up period limited the ability to assess long-term maintenance of behavior change. Given the sharp decline in engagement after 6 months reported in previous studies [62], longer-term follow-up trials are warranted. Third, higher nonparticipation rates were observed in the intervention group (24.1% vs 14.9%). This difference may reflect the additional engagement burden associated with personalized messaging or the psychological pressure of continuous performance monitoring [63]. Although no significant baseline differences were observed between participants and nonparticipants, residual attrition-related bias due to postrandomization nonparticipation cannot be excluded. Fourth, participants were recruited from a single urban community in Mapo-gu, Seoul, which may limit generalizability to other regional or cultural contexts. Moreover, the trial included progressive monetary incentives and weekly researcher monitoring, conditions that may not be replicated in routine real-world implementation. Fifth, step counts were measured using built-in smartphone accelerometers, which may not capture all forms of physical activity and may vary in accuracy across devices. Participants were not blinded to group allocation, which may have introduced performance or expectation bias, a common limitation in eHealth trials. In addition, although primary outcomes were prespecified, the analysis of multiple outcomes raises the possibility of an inflated type I error.

Future Research Directions

Based on the results of this study, we propose the following follow-up research. First, long-term follow-up studies of 6 months or more should evaluate the sustained effects of personalized messages and their impact on habit formation. Second, research is needed to develop machine learning-based adaptive messaging systems that learn individual real-time response patterns and implement more sophisticated personalization. Third, generalizability should be verified through multisite RCTs targeting diverse populations (rural areas, older adults, and patients with chronic diseases). Fourth, research on optimizing message delivery methods (push notifications, chatbots, and voice messages) and message transmission frequency is required. Finally, research is necessary to comprehensively evaluate message acceptability, fatigue, privacy concerns, and so on through user experience research to increase implementation feasibility in actual clinical settings.

Conclusion

This study empirically evaluated the effects of personalized message interventions that integrate the IMB model and RFT on walking behavior maintenance. Although these interventions did not significantly affect the overall increase in step counts, they were confirmed to be effective in preventing consecutive goal achievement failures. Personalized tailored messages did not significantly affect the overall increase in step counts but had significant effects in preventing consecutive 2-week goal achievement failures. This demonstrates that personalized messages are important variables that enhance behavioral sustainability rather than simple performance improvement. This study provides important evidence for establishing user retention strategies in digital health care intervention design, showing that personalized feedback can contribute to improving user resilience and engagement sustainability. Performance-based personalized messaging strategies can be applied to various health behavior change areas for developing digital therapeutics or healthy lifestyle habits in the future. Future research should assess the long-term sustainability of personalized messaging and determine how these findings can support the refinement of adaptive digital health personalization systems.

Acknowledgments

We thank all participants and community collaborators who contributed to this study. The authors used ChatGPT (OpenAI) for translation and language editing during manuscript preparation. No AI tool was used for data analysis, data interpretation, or generation of scientific conclusions. All AI-assisted content was critically reviewed, revised, and approved by the authors, who take full responsibility for the integrity and accuracy of the manuscript.

Abstract

Background: Mobile health (mHealth) interventions show promise for supporting diabetic foot self-care; however, sustained engagement remains a challenge, particularly in low- and middle-income countries. While educational strategies are commonly used to address diabetic foot ulcers, they often fail to translate knowledge into long-term self-care. Understanding behavioral mechanisms underlying mHealth use, including the role of caregivers, is critical for improving implementation and effectiveness.

Objective: This study explored how behavioral interactions between people with diabetes and caregivers shape the use of an mHealth app for diabetic foot self-care.

Methods: This qualitative explanatory study was embedded within a parent study of an mHealth app for diabetic foot care that was conducted in primary care settings in Peru. It used the COM-B (capability, opportunity, motivation–behavior) model and the Theoretical Domains Framework (TDF) to identify mechanisms relevant for intervention design and scale-up. Semistructured interviews were conducted with people with diabetes and caregivers about their experiences related to accessing the app. Data were analyzed using deductive and inductive thematic analysis informed by the COM-B and TDF.

Results: In total, 14 people with diabetes (median age 54 y, 8 women and 6 men) and 10 caregivers (median age 28.5 y, all women) were interviewed. The app use depended on varying interactions between COM-B domains, while other behavioral determinants aligned with a single domain. Across domains, interactions between people with diabetes and caregivers also affected the app use. For example, caregivers often compensated for physical capability limitations through foot positioning or environmental adjustments. Environmental context and resources, including internet access, lighting, and device compatibility, affected the app use for all participants. Motivation for all participants was largely driven by beliefs about the app's preventive value, although reassurance from health professionals and altruism also emerged.

Conclusions: The app use often depended on collaboration between people with diabetes and caregivers as a dyad, rather than on independent users. This highlights the need to design digital interventions around caregiver demographics, competing responsibilities, and the additional responsibilities an app may introduce. Participants' preference for individual follow-up suggests

XSL•FO
RenderX

that nonphysician health personnel and other human support may help maintain continuity and reassurance alongside digital monitoring. Although the app was an early prototype intended for algorithmic training, participant experiences provided insight into real-world usability and contextual barriers for future app development.

Introduction

It is estimated that up to one-third of people with diabetes will develop a diabetic foot ulcer (DFU) in their lifetime [1]. DFU remains one of the most severe and preventable complications of diabetes, requiring continuous self-care behaviors such as routine foot inspection and early detection of preulcerative lesions [1,2]. Mobile health (mHealth) technologies have emerged as promising tools to support these behaviors by enabling remote monitoring, patient education, and self-management support [3]. Systematic reviews suggest that mobile app–assisted interventions can improve diabetes management outcomes and facilitate self-care behaviors; however, sustained engagement with these technologies remains inconsistent in real-world settings [4,5]. Many interventions report declining use over time, indicating that the availability of digital tools alone is insufficient to ensure long-term behavioral adoption [6-8].

Caregivers frequently play a critical role in supporting diabetes self-management, particularly in low- and middle-income countries, where family members often assist with daily health tasks, monitoring, and decision-making [9-11]. For individuals who are older or have mobility limitations, visual impairments, or lower digital literacy, caregiver involvement may become essential for technological support and the navigation of app interfaces. Despite this reality, most digital health interventions conceptualize technology use as an individual behavior, rarely examining caregivers as explicit behavioral actors influencing adoption and sustained use.

Previous studies on mHealth interventions for diabetic foot prevention have primarily focused on clinical outcomes, technological performance, or usability assessments [12,13]. While these studies provide important evidence on feasibility and acceptability, they often overlook the behavioral mechanisms that determine whether individuals incorporate digital tools into everyday routines. Moreover, the factors that influence the behavior of caregivers of people with diabetes have not been explored in this context. As a result, there remains a limited understanding of how sustained engagement with mHealth technologies for diabetic foot self-monitoring is influenced by personal, physical, and social environments [7].

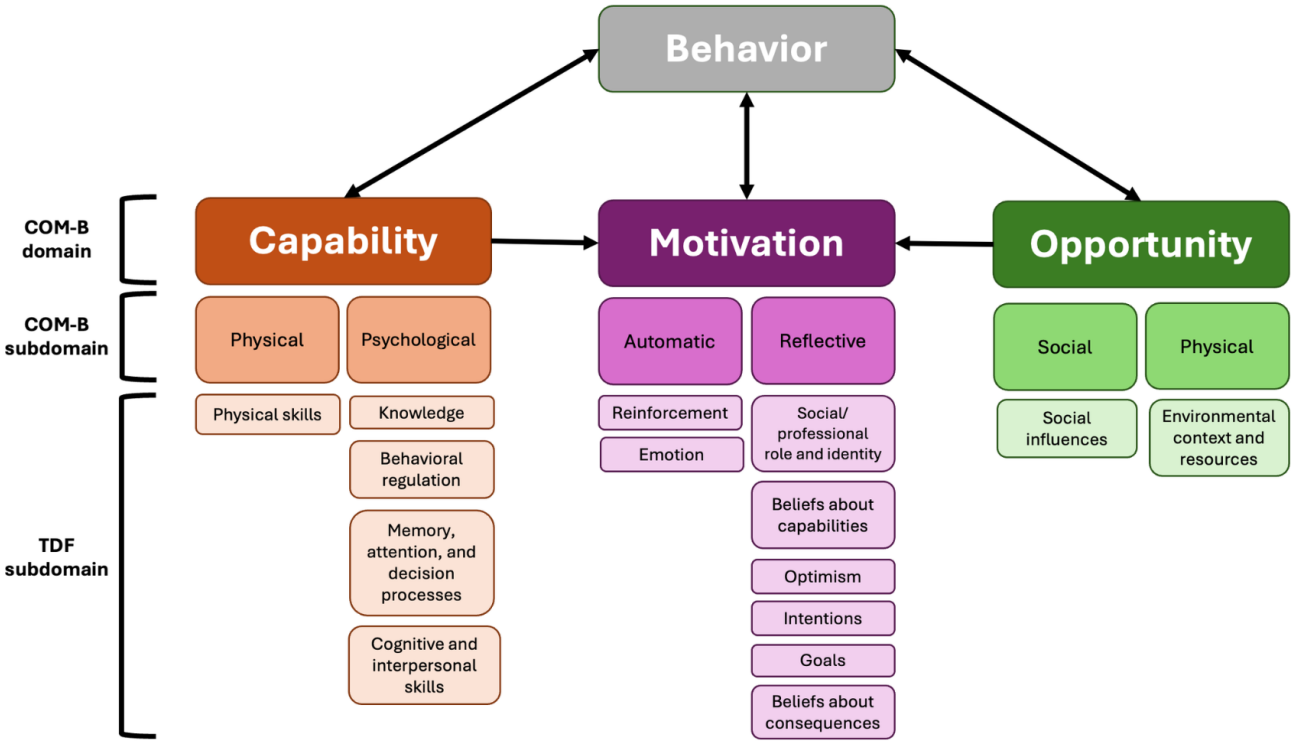
To better understand and improve sustained engagement with these types of interventions, behavioral theory can provide a structured framework for examining determinants of technology use. The COM-B (capability, opportunity, motivation–behavior) model conceptualizes behavior as the result of interactions between individuals' capabilities, opportunities, and motivations [14]. The Theoretical Domains Framework (TDF) complements COM-B by providing additional granularity to explore underlying mechanisms, such as knowledge, skills, social influences, reinforcement, and emotional responses, which influence behavioral performance [15]. Together, these frameworks enable a systematic analysis of how behavioral determinants interact within real-world contexts to shape the engagement of people with diabetes and caregivers with digital health interventions.

Methods

Study Context

The Foot Selfie study was established as an innovative approach to address the burden of DFU in Peru, emphasizing prevention and early identification of foot ulcers. In phase 1 of the project, an initial version of a mobile app (Android package kit [APK]) was designed with a single functionality of capturing and uploading foot images for training an AI algorithm to detect healthy skin and 6 preulcerative lesions. These lesions included fissures, erythemas, calluses, hemorrhagic calluses, discoloration, and ulcers. The first cohort of participants for image collection included 1000 adults with type 1 or type 2 diabetes mellitus in hospital settings. After initial image collection in hospital settings, a subsample of up to 200 individuals was invited, according to specific selection criteria, to use the app at home for follow-up image capture. In total, 12,164 images were collected from phase 1. During phase 2 of the parent study, individuals who participated in at-home follow-up were selected to participate in this study according to the selection criteria detailed below. At this stage, the app was designed to be fully self-directed and did not provide diagnostic feedback. Participants were informed that submitted images were not a substitute for clinical care. However, if the research team identified a concerning lesion or potential complication during study procedures, participants were contacted and advised to seek appropriate clinical evaluation. Weekly follow-up from field personnel (nurses) emerged somewhat organically and typically occurred when participants stopped using the app.

Study Design



This study used a qualitative descriptive design and was explicitly informed by the COM-B model to examine determinants of app use behavior [14]. To deepen interpretation, domains from the TDF were used to provide additional context within the COM-B domains [16] (Figure 1). The target behavior for all participants was defined as the use of the app to capture

XSL•FO
RenderX

photographs of the foot for early detection of preulcerative lesions.

People with type 2 diabetes and caregivers who had participated in at-home use of the early prototype for a 1-month period and had consented to be recontacted were invited to participate in semistructured interviews. Data were collected between August 2024 and February 2025. The COREQ (Consolidated Criteria for Reporting Qualitative Research) was used to ensure detailed reporting [17].

Figure 1. Overview of the COM-B (capability, opportunity, motivation–behavior) model and Theoretical Domains Framework (TDF). This figure demonstrates the 3 COM-B domains, their subdomains, and the associated TDF domains that inform behavior. Adapted from Atkins et al [16]. This framework was applied independently to each participant—people with diabetes and caregivers—and compared afterward.

Study Setting

Qualitative data collection was conducted in Lima, Peru, a region selected for its epidemiological relevance to the burden of diabetes. Lima, the country's capital, concentrates approximately one-third of the national population and reported the highest number of diabetes cases in 2025 [18].

The people with diabetes in the study were receiving care for this condition at endocrinology and diabetic foot service units at 5 high-complexity (category III-1, according to the Peruvian Ministry of Health classification) hospitals: Hospital María Auxiliadora, Hospital Dos de Mayo, Hospital Cayetano Heredia, Hospital Arzobispo Loayza, and Hospital de Emergencias Villa El Salvador.

The multidisciplinary research team was composed of researchers with backgrounds in public health, social sciences, and medicine, with significant collective experience in diabetes research. Interview supervision and data collection were led by an anthropologist with extensive expertise in qualitative research and behavioral design.

All interviewers had prior training in qualitative interviewing, and they did not have an established personal relationship with participants at the time the interviews were conducted.

The analysis was supported by team members trained in public health, biology, and project management and was led by a researcher with a background in epidemiology and global health. Discussions were held throughout the study to consider how researchers' backgrounds could influence data collection and interpretation.

Study Participants and Sampling

For interview selection, a purposive sampling strategy with predefined user profiles was used to ensure variation in experiences with app use. Four profiles were defined: (1) people with diabetes who were frequent users, (2) people with diabetes who were infrequent users, (3) caregivers who were frequent users, and (4) caregivers who were infrequent users. Frequent users were defined as individuals who used the app 6 or more times during the month-long study period, whereas infrequent users were those who used the app fewer than 6 times that month.

Eligible participants were approached via 2 strategies. First, potential participants who had already finished using the app at home were contacted by telephone and invited to an interview. Second, potential participants who were invited to start using the app at home were also invited to participate in this study. For this option, researchers visited health care facilities and invited individuals in waiting rooms to participate. When approached, potential participants received information on the study objectives, conditions of participation, and voluntary nature of participation.

XSL•FO
RenderX

Study participants included people with diabetes and caregivers who had participated in the at-home use of the app to capture foot images. The demonstration of app interface and standard image capture is provided in Multimedia Appendix 1. The caregivers interviewed were not the caregivers of the people with diabetes interviewed in this qualitative sample, but instead they were the caregivers of other patients enrolled in the same parent study.

Data Collection

In-depth individual interviews were conducted using a semistructured guide based on the COM-B subdomains. The interview guide in both the original Spanish and its English translation is provided in Multimedia Appendix 2. The guide explored initial experiences with the app, foot-monitoring habits, frequency and conditions of use, technological barriers, digital accessibility (device type, connectivity, and storage), social support, perceptions of diabetic foot risk, and suggestions for improving the tool's design.

Questions were adapted according to participants' profiles (people with diabetes or caregivers) while maintaining conceptual consistency across interviews. When feasible, participants were asked to describe or demonstrate how they accessed the app and captured foot photographs to identify practical usability challenges.

Most interviews were conducted in participants' homes, and one interview was conducted remotely via videoconference based on participants' preferences and availability. All interviews were conducted in private settings without the presence of third parties.

Interviews lasted approximately 45 to 60 minutes. All interviews were audio-recorded with prior authorization and transcribed verbatim. Repeat interviews were not conducted, and transcripts were not returned to participants. Data collection continued until meaning saturation was reached, which is defined as the point at which additional interviews no longer generated new insights or perspectives relevant to the analytic categories, indicating sufficient depth and coverage of the study objectives [19].

Data Analysis

All interviews were anonymized using alphanumeric codes and analyzed in 2 sequential stages.

In the first stage, a deductive thematic analysis guided by the COM-B model and the TDF was conducted. The COM-B model provided the overarching behavioral structure, while the TDF offered an additional contextual layer for classifying determinants within each domain. Separate analytical matrices were constructed for people with diabetes and caregivers. Two researchers independently coded excerpts and classified them into COM-B domains and corresponding TDF subdomains, followed by consensus meetings to resolve discrepancies.

In the second stage, an inductive analysis was conducted within each domain to identify emergent cross-cutting themes among and between participant types. These themes were then compared between people with diabetes and caregivers to examine patterns shared between and distinct to the 2 groups. To do so, a second synthesis matrix was used to reorganize coded excerpts into themes while maintaining explicit links to the COM-B and TDF domains. Regular analytic meetings with the senior qualitative researcher and the broader research team were held to refine interpretations and strengthen analytic rigor. A sample matrix with domain and coding labels can be found in Multimedia Appendix 3.

Data management and analysis were manually conducted using structured Microsoft Excel matrices due to the team's familiarity with this software. No specialized qualitative software was used. All quotes presented in this paper were originally collected in Spanish and have been translated into English for reporting purposes.

Ethical Considerations

This study has received ethical approval from the following committees: the Institutional Ethics Committee of the Universidad Peruana Cayetano Heredia (reference number 210819), Lima, Peru, and the London School of Hygiene & Tropical Medicine Research Ethics Committee (reference number 30662), United Kingdom, as required for studies involving London School of Hygiene & Tropical Medicine–affiliated investigators and those funded by the UK Medical Research Council.

All participants provided written informed consent before enrollment. For qualitative interviews, additional consent was obtained for audio-recording. Participation was voluntary, and individuals could withdraw at any time without affecting their access to care.

To protect participants' privacy and confidentiality, identifying information was removed from the study dataset, and each participant was assigned a unique study code. Study data were maintained in a secure spreadsheet accessible only to the research team. Participants who attended interviews in person received 20 Peruvian soles (US $5.89) to help cover transportation costs.

Results

General Findings

A total of 24 interviews were conducted: 14 with people with type 2 diabetes and 10 with caregivers. All caregivers interviewed were identified as female, were predominantly younger than 30 years, and were almost all informal family caregivers, except for one nonfamily caregiver (Table 1). In contrast, most people with diabetes were older than 50 years and had attained only up to a secondary education.

XSL•FO
RenderX

Table . Sociodemographic characteristics of interview participants, by role (caregiver vs patient).

Participant characteristic	Caregiver (N=10)	People with diabetes (N=14)
Gender		
Male	0	6
Female	10	8
Age group (y)		
≤30	6	0
31 - 39	1	0
40 - 49	2	2
50 - 59	1	6
60 - 69	0	5
70 - 79	0	1
Highest education level attained[a]		
Primary	1	1
Secondary	5	11
Higher education[b]	4	2
History of ulceration	—[c]	6
History of amputation	—	4
History of deformity	—	7

[a]Primary and secondary education categories include participants who both completed and did not complete that level.

[b]Higher education in Peru includes postsecondary education at universities or nonuniversity higher education institutions (eg, technical or professional institutes), regardless of degree completion status.

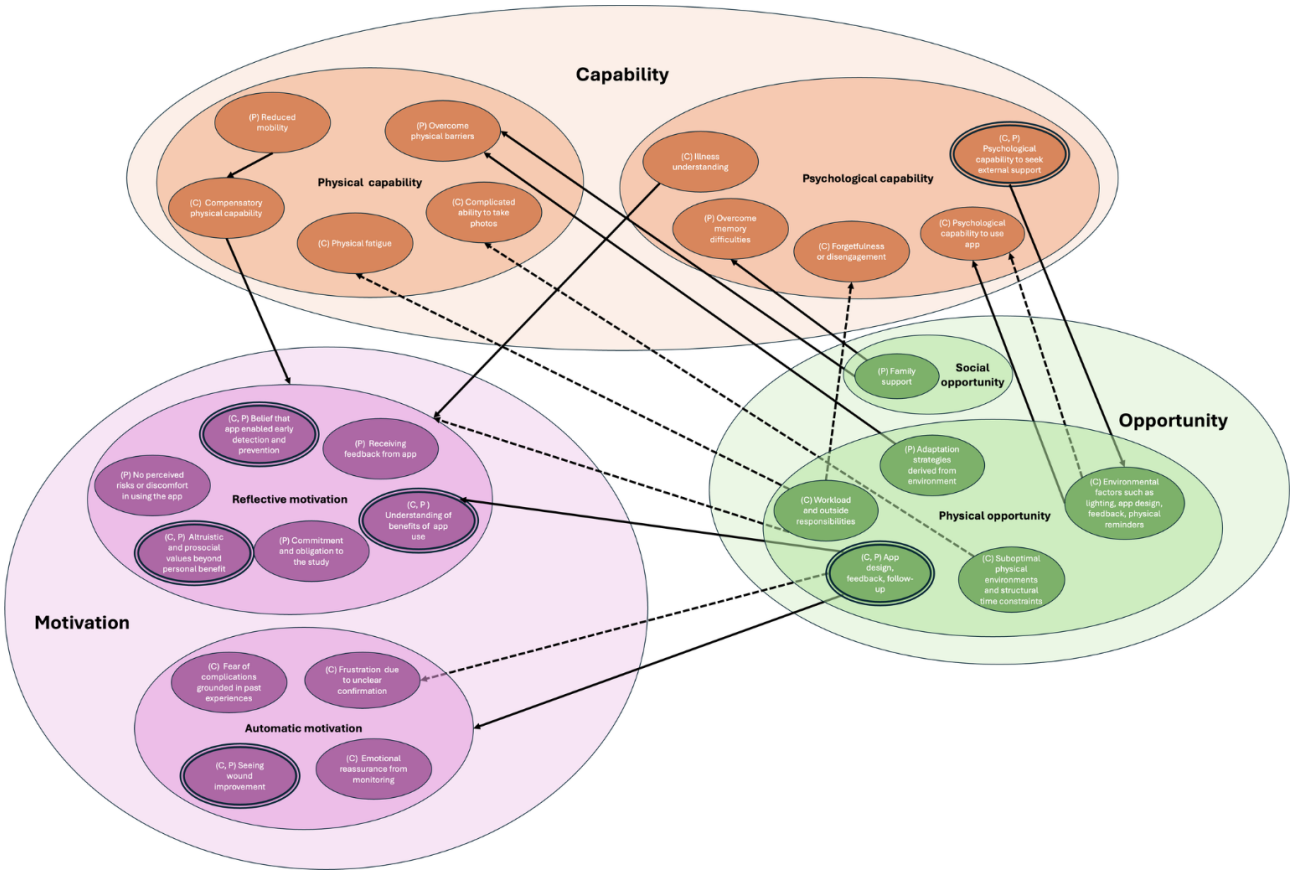
[c]Not applicable.

Across transcripts, 239 excerpts were coded for people with diabetes and 332 for caregivers, using COM-B and TDF domains. These coded excerpts were inductively collapsed into general facilitators and barriers mapped to capability, opportunity, and motivation (Tables 2 and 3). Overall, although some themes predominantly aligned with a single COM-B domain, our analysis revealed substantial overlap across domains, with capability, opportunity, and motivation interacting dynamically to shape the app use. The following sections detail these cross-domain interactions, which are also visually summarized in Figure 2.

XSL•FO
RenderX

Table . Summary of facilitators and barriers across COM-B (capability, opportunity, motivation–behavior) domains identified among people with diabetes.

COM-B domain	General themes
Physical capability	
Facilitators	• Independent ability to position and photograph the foot
Barriers	• Limited mobility or difficulty reaching/visualizing the foot • Physical fatigue or late-night exhaustion • Need for assistance to complete positioning
Psychological capability	
Facilitators	• Development of routines and reminder strategies • Use of adaptive strategies (pillows, selfie sticks, and lamp positioning)
Barriers	• Limited digital literacy • Forgetfulness or inconsistent routine • Initial confusion regarding installation and workflow
Physical opportunity	
Facilitators	• Access to smartphones, internet connectivity, and adequate lighting • Organized home spaces and established routines • Ability to complete monitoring without traveling to hospital
Barriers	• Unstable internet connectivity and device incompatibility • App crashes, slow loading, and unclear submission confirmation • Inadequate lighting or physical setup
Social opportunity	
Facilitators	• Assistance from family members or household contacts • External reminders from relatives • Follow-up communication from health professionals
Barriers	• Dependence on others for technical or physical assistance • Inconsistent follow-up from field personnel during and after study completion
Automatic motivation	
Facilitators	• Emotional reassurance from perceived monitoring • Satisfaction from observing wound improvement • Routine formation through repeated use
Barriers	• No barrier identified
Reflective motivation	
Facilitators	• Belief in early detection and prevention benefits • Perceived convenience compared to hospital visits • Commitment to research participation and helping others
Barrier	• Doubt about whether photos were reviewed or useful • Participation primarily driven by obligation rather than perceived personal value



XSL•FO
RenderX

Table . Summary of facilitators and barriers across COM-B (capability, opportunity, motivation–behavior) domains identified among caregivers.

COM-B domain	General themes
Physical capability	
Facilitators	• Physical ability to position, lift, and assist people with diabetes enabled photo-taking despite mobility limitations of the person with diabetes • Physical capability is strengthened through repetition and routine performance
Barriers	• Physical fatigue from caregiving load, work, or illness reduced consistency of app use • Patient mobility limitations required assistance for task completion
Psychological capability	
Facilitators	• Knowledge of diabetic foot risk increased preparedness and engagement • Caregivers demonstrated higher digital literacy than patients • Caregivers exercised behavioral regulation and sought out answers themselves
Barriers	• Memory, lapses, attention, and cognitive overload • Initial confusion regarding installation of the app and workflow
Physical opportunity	
Facilitators	• Access to smartphones, internet connectivity, and adequate lighting • Organized home spaces and established routines • Remote monitoring reduced need for hospital travel
Barriers	• Unstable internet connectivity and device incompatibility • App crashes, slow loading, and unclear submission of pictures (lack of confirmation) • Time constraints due to work and caregiving responsibilities • Inadequate lighting or physical setup
Social opportunity	
Facilitators	• Family collaboration and task-sharing among relatives • Follow-up and accountability from field personnel • Patient reminders and mutual reinforcement within the household
Barriers	• Limited or inconsistent family support • Discontinuation of follow-up from field personnel
Automatic motivation	
Facilitators	• Emotional reassurance from perceived monitoring • Satisfaction from observing wound improvement • Fear of complications (eg, amputation) prompting vigilance • Routine formation through repeated use
Barriers	• Frustration and stress from technical failures
Reflective motivation	
Facilitators	• Belief in early detection and prevention benefits • Perceived convenience compared to hospital visits • Commitment to research participation and helping others
Barrier	• Doubt about whether photos were reviewed or useful

XSL•FO
RenderX

Figure 2. Cross-domain interactions that influence the sustained use of the app among people with diabetes and caregivers. This conceptual model illustrates how capability (purple), opportunity (green), and motivation (orange) domains interact to shape engagement with the intervention. Nodes labeled (P) reflect patient-specific influences, (C) reflect caregiver-specific influences, and double-lined (C and P) reflect shared determinants. Solid arrows indicate positive influences, whereas dashed arrows represent negative relationships.

Capability

The biggest difference observed between caregivers and people with diabetes was their capabilities. When people with diabetes had reduced mobility, caregivers' physical capabilities acted as a compensatory facilitator, enabling task completion through lifting, positioning, or adapting the environment (TDF domain: physical skills). A person's lack of physical capability served as a motivating factor for caregivers to use the app.

> *Only I could handle the app, position my mom […] I adjust her, and then I just take the photo.* [Caregiver, female, 23 years old]

Still, even when caregivers had additional skills required to use the app, physical fatigue from the caregiving load, work, or illness served as a barrier, reducing consistency and delaying task completion. In this way, people with diabetes and caregivers alike experienced physical capability barriers, but for different reasons.

> *I would get home at 10 at night… I was already sleepy, tired, and then it would be tomorrow already, and I wouldn't take it anymore.* [Caregiver, female, 50 years old]

> *Well, what happens is that since it's the feet, it's like I'm a bit overweight, but that depends on me, not on the application.* [Patient, female, 50 years old]

Interestingly, some people with diabetes used adaptation strategies to overcome these limitations, such as using a pillow or a selfie stick or taking a photo during the day to take advantage of the lighting (TDF domain: behavioral regulation).

> *On the second day it was difficult for me because I had to take the photos by myself and for [the app] to take the photo […] I had to put pillows, then I used the little stick to take photos.* [Patient, female, 41 years old]

Many people with diabetes were psychologically capable of using the app and acquired this ability through practice and other strategies, such as setting reminders and developing routines for taking pictures (TDF domain: behavioral regulation). Caregivers also experienced initial confusion with the app, which was resolved through practice, demonstration, repetition, or troubleshooting (TDF domain: memory, attention, and decision processes).

> *The first few days, yes, two or three days I would get confused [with the app] […] But afterward it became easier. Afterward you get the…the trick. The trick, as they say, right? And then normally, you send [the photo].* [Patient, male, 51 years old]

> *At first it was a little difficult, but after that…I got the hang of it.* [Caregiver, female, 25 years old]

Additionally, caregivers seemed to better understand the seriousness of diabetic foot complications (eg, infection and

XSL•FO
RenderX

amputation) and the purpose of the app as preventive monitoring, which made them more motivated and cognitively prepared to engage (TDF domain: knowledge). This understanding reframed the task from "taking photos" to preventing future harm, which supported sustained attention and follow-through.

> *I am aware that a person with diabetes… can become infected and progress to the point that they can amputate it.* [Caregiver, female, 25 years old]

Opportunity

Both caregivers and people with diabetes who had the opportunity to perform foot monitoring depended on having access to the internet, smartphones, lighting, usable home spaces, and physical reminders. For caregivers, these environmental conditions enabled the behavior and interacted with capability: poor lighting or device limitations increased physical strain and cognitive effort, while adequate setups reduced both (TDF domain: environmental context and resources). People with diabetes who had these adequate environmental conditions were able to perform the behavior consistently, while those who did not were unable to complete the task without adaptation (TDF domain: environmental context and resources).

> *We always looked for the room with good lighting.* [Caregiver, female, 21 years old]

> *Well, in my case, I have internet at home […] I never had any problems.* [Patient, female, 50 years old]

> *The first day, two days, yes, it took us a while because sometimes with the light my foot would come out crooked, then little by little I learned the position […] and at night I would turn on my lamp so that it would focus on me […] sometimes the light would reflect and I would say, no, the light is positioned wrong, I remember.* [Patient, male, 65 years old]

In terms of app performance, people with diabetes reported that although the app was often easy to use due to its intuitive interface, structural barriers—including device incompatibility, inability to verify whether photos had been successfully sent, and the need to repeatedly reenter the app workflow—created disruptions in their opportunity to complete the task consistently. For caregivers, clear visual design and feedback enabled opportunity and motivation by making photo-taking more feasible. Conversely, slow loading, crashes, unclear confirmation, and device incompatibility disrupted opportunity, decreased motivation, and simultaneously increased cognitive uncertainty and frustration.

> *I had to buy another cellphone, because the one I had wouldn't go in anymore […] No, it wouldn't allow it.* [Patient, male, 51 years old]

> *It would freeze […] I had to take the photo again.* [Caregiver, female, 27 years old]

Caregivers frequently faced structural time constraints due to work, caregiving for others, unstable schedules, and an overall lack of routine. These factors limited physical opportunities to perform the task, even when motivation and capability were present. These constraints also produced fatigue, forgetfulness, or disengagement.

> *[…] I just don't have enough time to stay and check. Even though it doesn't take long, honestly, I don't have a set schedule — sometimes I work in the morning, sometimes in the afternoon, sometimes at night.* [Caregiver, female, 23 years old]

Social support was a dominant structural enabler of participation for people with diabetes and caregivers, but the underlying mechanisms differed. Many people with diabetes depended on children, siblings, or even building staff to take photos, enter login credentials, or troubleshoot (TDF domain: social influences). For several people with diabetes, independent use was not feasible without assistance due to physical positioning challenges, digital literacy limitations, or difficulty visualizing their own feet.

> *Sometimes my husband [took the photographs]. I told him, move here or he would take about 10 photos and then I would choose.* [Patient, female, 41 years old]

> *It became difficult for me so I looked for the security guard to help me take the photo, nothing more. I did the programming and he would just take the photo.* [Patient, male, 65 years old]

In contrast, caregivers' reliance on social support did not stem from a lack of capability. Caregivers were generally able to perform the task independently; however, sustaining participation required coordination within the household. Family collaboration functioned as task-sharing rather than substitution, with relatives rotating through roles such as taking photos, providing reminders, or assisting when the primary caregiver was unavailable. Follow-up by health staff similarly reinforced continuity by serving as an external structure of accountability.

> *And if I couldn't, like I'm telling you, if I couldn't be there one or two days, my son was here with him all day. And he stayed like that. He would watch how I [took the photos], and he had already memorized it too.* [Caregiver, female, 42 years old]

> *The same doctor, the nurse, kept communicating that there was progress, and afterward she told me: 'Okay, that's fine, up to here,' and we didn't send any more photos.* [Caregiver, female, 23 years old]

Motivation

By far, the most common motivator mentioned among caregivers and people with diabetes was a belief about the consequences of app use, whether that was a belief in the potential for prevention of DFU or a belief in the convenience of taking care of your feet at home rather than in a hospital (TDF domain: beliefs about consequences). Caregivers were motivated when they believed that the app enabled early detection and prevention, reframing the behavior as proactive rather than reactive. Motivation to use the app for people with diabetes arose from personal benefits and the detection of health problems that were not initially perceived.

XSL•FO
RenderX

> *If a lesion were to suddenly appear and you let me know, we can act sooner. That way we prevent it.* [Caregiver, female, 32 years old]

> *…Because in the long run the benefit will be for us, the diagnoses will be for us, not for the person who received the photos, but for ourselves, so that's why I did it.* [Patient, female, 53 years old]

> *No, no, because I dedicate 10 minutes and that's it, I can dedicate more hours to TikTok, to Facebook, and this is something useful, and you learn. If they send me, put this on, you can eat this, I don't know, more information about my disease, great, I read it, because I read.* [Patient, female, 50 years old]

Among people with diabetes, some participated in photo-taking out of commitment to the research study, which ties into the "reflective motivation" TDF domain of social/professional role or identity. In these cases, the use of the app exclusively arises out of an obligation and a belief in the value of their commitment (TDF domain: intentions). However, some still recognized the app's usefulness, which helped reinforce more consistent use through curiosity, self-care, and control over their health.

> *More than anything because I had made a commitment to the young lady (research team member), I had committed to helping. So with the study, more than anything it was for that reason, because I am a person that if I commit to something it is because I am going to try to do it, to fulfill it.* [Patient, female, 53 years old]

An unexpected motivator that emerged for both caregivers and people with diabetes was a desire to help others or altruism. Some caregivers framed their use of the app not as a means to benefit their own family members, but as a way to contribute to research, support other people with diabetes, and improve care for the broader community (TDF domain: social/professional role and identity). This altruistic framing sustained engagement even when direct personal benefits were limited or uncertain. People with diabetes expressed a desire to help other people with diabetes and share experiences even when they felt exhausted or faced difficulties in daily life.

> *Why? Because you're going to help someone else. Well, that's what moved me, that it is to help other people to see. I think that's why it motivates you to do it, that it's help for others, right? To tell you about your experience […] I liked it because it is to help other people.* [Patient, female, 41 years old]

> *I'm not doing it only for my mom… but because I see that it's an app that is going to help other people.* [Caregiver, female, 25 years old]

For people with diabetes, automatic motivation interpreted as reinforcement functioned as a key facilitator. Receiving feedback on submitted photos or observing visible wound improvement generated satisfaction, reassurance, and increased confidence in their ability to manage their condition (TDF domain: reinforcement). These positive emotional responses and sense of relief reinforced routine use and strengthened habit formation over time. Similarly, caregivers described reinforcement through visible clinical progress or confirmation from health care staff. Observing improvement in the foot or receiving acknowledgment that images had been reviewed produced pride and relief, reinforcing continued monitoring behavior.

> *Now [the application] was useful because they have seen that I am well and they have monitored me and I like being well.* [Patient, female, 50 years old]

> *Sometimes it felt good […] even with the wound. Whenever it improves, you feel happy: 'Look at how the photo looks!' Comparing the first photo with the last is always nice because it's the change—you can see the improvement.* [Caregiver, female, 23 years old]

Emotion-driven vigilance was also prominent, particularly among caregivers (TDF domain: emotion). Fear of complications, especially amputation, served as a powerful emotional driver that heightened attention and sustained adherence to monitoring. This fear was often grounded in prior experiences with severe diabetic complications within the family or community.

> *That's what scares me—that it could get to that point… that they might have to amputate the foot.* [Caregiver, female, 21 years old]

In one particular instance involving a caregiver, frustration and uncertainty about the app undermined automatic motivation. Technical failures, unclear confirmation of image receipt, and ambiguity about whether photos were being reviewed generated stress, disengagement, and overall demotivation. Ultimately, these negative emotional responses led to the permanent abandonment of the prototype app by this caregiver.

> *That stressed me out… and that made me quit [the app].* [Caregiver, female, 21 years old]

Discussion

Principal Findings

In this study, we explored behavioral influences on the use of an mHealth app for diabetic foot care in Peru. After our analysis with the COM-B model and TDF, we found that the sustained use of the app for the detection of DFUs and preulcerative lesions was not always determined by a single behavioral domain but rather by interactions among capability, opportunity, and motivation among people with diabetes and caregivers. These interactions were strongly influenced by conditions across the social, technological, and health care systems in Peru, highlighting the importance of incorporating stakeholder experiences and behaviors from the earliest stages of implementation, including the algorithmic development of an mHealth intervention.

When discussing individual domains, physical capability barriers were particularly evident among people with diabetes who had mobility limitations, while caregivers frequently compensated by positioning the foot to take pictures or by making environmental adjustments, such as modifying light and room settings. Opportunity was strongly shaped by structural and

XSL•FO
RenderX

technological conditions, including device compatibility, internet access, and home environments, which in turn conditioned how these behaviors could be carried out. Meanwhile, motivation was largely driven by beliefs about the preventive value of the intervention, emotional responses to first-hand experiences with DFU, and reassurance that health professionals were monitoring submitted images. Other motivational influences included altruistic reasons for sustaining engagement with the app, whereas uncertainty about whether images were being received could undermine motivation. Together, these results highlight that engagement with our digital self-care intervention stems from various behavioral interactions rather than only isolated determinants.

A key contribution of this study is the identification of people with diabetes and their caregivers as a behavioral unit or dyad in the use of digital health technologies. While many mHealth interventions conceptualize self-monitoring as an empowering, individual activity [20-22], our findings show that the routine use often depended on collaboration within the household. In several multigenerational households, family members, mostly children or grandchildren, rotated responsibilities when the primary caregiver was unavailable. Previous research on remote monitoring technologies for diabetes similarly suggests that caregiver involvement can facilitate adherence and improve clinical outcomes, particularly among older adults and individuals with lower digital literacy [23].

In our sample, this dynamic was also reflected in the demographic profile of participants. People with diabetes were substantially older than caregivers (median age of 54 y vs 28.5 y) and had generally attained lower levels of formal education. These differences may have contributed to variations in both familiarity with smartphone interfaces and illness-related knowledge, as reported in other studies [24,25]. Although smartphone ownership is widespread in Peru [26-28], several people with diabetes described challenges related to positioning the foot for photographs, reading small text, or navigating app steps. Despite these physical struggles, people with diabetes whom we interviewed still demonstrated adequate psychological capability to understand the purpose of the intervention and even used adaptation strategies to continue using the app. In these cases, caregivers did not replace the decision-making capacity of people with diabetes but instead bridged physical and informational gaps associated with performing the task. By supporting the practical and cognitive demands associated with technology use, caregivers enabled participation among people with diabetes who might otherwise be excluded from technological interventions [29,30].

Building on the concept of a dyadic relationship between people with diabetes and caregivers, the involvement of caregivers also introduces additional complexity. While digital technologies are often promoted as tools that reduce caregiver burden, evidence suggests that they may simultaneously introduce new responsibilities and stressors [31]. Studies examining the impact of assistive technologies on informal caregivers have found that while these tools can improve communication, monitoring, and perceived safety, they may also generate frustration when technical difficulties arise or when the technology requires additional time and attention to operate [31].

Importantly, the caregiving role itself is highly gendered, which may intersect with the age-related differences in digital literacy that we observed. In our sample, all caregivers interviewed were women, a pattern that reflects broader trends documented in the literature, where informal caregiving responsibilities disproportionately fall on female family members, particularly in Latin American contexts [31-33]. Although we used a purposive sampling strategy to capture a diverse range of app-use profiles (eg, frequent and infrequent users) as well as variation in gender, our caregiver sample did not include male caregivers. As a result, our findings may not fully capture the behaviors and interactions between people with diabetes and male caregivers. This gendered pattern is important because research examining the use of technology among informal female caregivers has shown that, while digital tools may support caregiving tasks, they can also add to existing responsibilities and contribute to declines in caregivers' physical and mental well-being over time [32]. This is especially relevant in settings where caregiving responsibilities are often balanced alongside employment, household duties, or educational commitments.

Similar patterns emerged in our investigation. Caregivers frequently described time constraints, competing responsibilities, and fatigue that limited their ability to perform monitoring tasks consistently. However, most participants did not describe the app itself as a direct burden. Instead, the challenges they described were primarily related to the broader demands of caregiving and daily life, such as work or school obligations. Only one caregiver explicitly reported disengaging from the app due to frustration with technical difficulties, which were also reported by Holthe et al [34] as a source of stress for caregivers working with assistive technology. These instances suggest that even relatively simple digital monitoring interventions can introduce new routines and obligations that must be considered during intervention design.

Another important finding relates to participants' strong preference for follow-up and reassurance from health care professionals. Both caregivers and people with diabetes described feeling more motivated to use the app when they believed that a clinician was reviewing their images or monitoring their progress. Previous studies of digital interventions have similarly shown that remote monitoring had a reassuring effect on people with diabetes and allowed them to share the responsibility of their health care decisions with others [21,29]. Interestingly, although these studies involved clinicians directly reviewing patients' results, our mHealth app did not include clinicians' review of submitted images for diagnosis. Instead, follow-up only occurred if any lesions were found or if participants had discontinued the app use. During interviews, participants often interpreted this follow-up communication and the submission of photos as physicians reviewing their images, even though this was not outlined in the participant information and consent forms. This finding in particular has been considered for future iterations of the app within the Foot Selfie study. Future versions of the app are set to provide clearer feedback confirming whether images were successfully submitted and clarifying that diagnostic feedback is AI-generated rather than determined by a physician.

XSL•FO
RenderX

This demonstrated preference for follow-up may be related to the broader preference for clinician-guided care and paternalism described in Peru and other contexts outside of Western medicine [35-37]. Although paternalism is often defined as physicians making decisions for people with diabetes without regard for patient autonomy, in this cultural context, the desire for authority may instead reflect how people with diabetes interpret care and attention from health care professionals, as seen in other qualitative studies [38]. In other words, follow-up appeared to signal concern and commitment from clinicians, which in turn increased the perceived value of the app among participants. This interpretation is consistent with a preliminary study from our research group, in which both the intervention and control arms of a DFU prevention trial remained more engaged than expected, suggesting that regular contact and follow-up may itself influence self-care behaviors [39]. Brandt et al [40] reinforced this finding and found that participants were not as motivated or adherent with a mobile self-help intervention in Peru when they were left without the support of a nurse. Taken together, these findings suggest that sustained engagement in our study may have been driven in part by participants' perception that a health professional was monitoring their submissions, rather than by the digital intervention alone.

Participants' desire for continuity of care in this study raises questions about the sustainability of implementing such an intervention if its primary goal is to address gaps in access to care and promote preventive self-management. The feasibility of having health care professionals regularly reviewing submissions is limited, particularly in a health care system such as Peru's that is already resource-constrained and where people with diabetes often experience long wait times to access specialist care [37]. In this context, AI-assisted identification of preulcerative lesions may provide a form of timely preliminary review, helping prioritize clinicians' attention for participants who need further evaluation. As a whole, future implementation of the app may be more effective if it incorporates other actors, including caregivers, nonphysician health personnel, and AI-assisted triage, to support continuity without relying solely on regular clinician review.

Limitations

Although the use of the COM-B model combined with the TDF provided a structured approach to understanding behavioral determinants of app use, the interpretation of qualitative interview data remains inherently subjective. The analytic framework may also have shaped how themes were identified and interpreted. To enhance analytic rigor, regular meetings were held within the research team to review coding decisions and discuss interpretations. Because the analysis relied on predefined theoretical domains, it is possible that certain factors influencing behavior were interpreted primarily through the lens of COM-B and TDF, despite regular team-based reviews of coding decisions.

During interviews, participants may have exhibited social desirability bias by portraying the app more favorably, even though the interviewers were not previously known to them. Despite sampling participants who were not frequent users of the app, it is still possible that individuals with negative experiences might not have fully disclosed them due to this bias. To mitigate this, we conducted semistructured interviews, and interviewers were trained to build trust, maintain confidentiality, and remain neutral. Additionally, the caregivers we interviewed were not the caregivers of the people with diabetes included in our sample, limiting our ability to directly assess concordance or discordance in beliefs within patient-caregiver dyads.

Implications

Importantly, the app used during the study was an early prototype developed for algorithmic training. While participants reported several technical challenges that at times affected engagement, these experiences provided critical insight into real-world usability and contextual barriers. Incorporating user feedback from this early stage allowed for refinement of the app through subsequent cocreation workshops with stakeholders and engineers, resulting in an improved version better aligned with the needs of people with diabetes in Peru.

Our findings also imply that app design should prioritize usability across diverse technological contexts, including compatibility with older devices and clear feedback confirming successful data submission. Alongside this, interventions should explicitly consider caregivers as key actors in digital self-monitoring programs, particularly for older adults or individuals with limited mobility. Training materials, reminders, and communication features may therefore need to address both people with diabetes and caregivers. Prior research examining dyadic relationships in chronic heart failure care similarly highlights how interactions between people with heart failure and caregivers can influence disease management behaviors, suggesting that approaches engaging both members of the caregiving dyad may strengthen the effectiveness of self-management interventions [25]. Furthermore, since the use of mHealth tools can, at times, be a burden for caregivers, informal task-sharing among other household members should be considered for implementation. Finally, the strong desire for professional follow-up suggests that future versions of the intervention may benefit from hybrid models combining self-monitoring with targeted human support. The AI-assisted identification of concerning findings could help guide review by nurses or other nonphysician health professionals, with escalation when needed, preserving the preventive focus of the intervention while supporting realistic continuity of care.

Conclusions

As mHealth interventions for diabetic foot self-care continue to expand, our study demonstrates how examining behavioral interactions between people with diabetes and caregivers can inform the development of person-centered mobile interventions. We found that sustained engagement with the app for diabetic foot self-care emerges from dynamic interactions between capability, opportunity, and motivation rather than any single behavioral determinant for participants. In this study, the app frequently depended on collaboration between people with diabetes and various household caregivers or family members, who together functioned as a behavioral unit that jointly enabled participation in digital monitoring. This central finding

XSL•FO
RenderX

underscores the importance of designing digital health interventions that account for household caregiving dynamics, technological constraints, and user perceptions of clinical support. As these insights are incorporated into future versions of the app, considering behavioral and contextual factors may improve the implementation and long-term adoption of mHealth tools aimed at preventing diabetic foot complications in Peru and other low- and middle-income settings, as well as within health care organizations.

Acknowledgments

The authors thank all study participants and their caregivers for their time, commitment, and collaboration throughout the study. They also acknowledge the field team for their essential role in participant training, image collection, and follow-up activities. The authors also thank Pedro Távara and Ana Bautista for their valuable contribution as interviewers in Piura and Lima, respectively. They are especially grateful to the health care professionals from the endocrinology services and the administrative staff of the 5 participating public hospitals in Lima, including Hospital Nacional Cayetano Heredia, Hospital María Auxiliadora, Hospital Nacional Dos de Mayo, Hospital Nacional Arzobispo Loayza, and Hospital de Emergencias Villa El Salvador, for their support, collaboration, and facilitation of study activities. Finally, the authors would like to thank Lucas Taipe for his assistance in developing an app prototype with German Comina for this study. The authors acknowledge that ChatGPT (Open AI) was used to help translate anonymized interview quotes and the interview guide from Spanish to English. Native, Spanish-speaking authors reviewed and edited the final version of each quote included in this manuscript for correctness and accuracy.

Funding

This study was supported by the Medical Research Council of the United Kingdom (grant number MR/X004163/1). The funder had no role in the conceptualization and design of this study and did not have any role in the collection of data or the decision to publish. SMR was supported by the US Fulbright Open Research Award Program in Peru.

Data Availability

The research team is committed to broad and open dissemination of findings. All peer-reviewed journal articles resulting from this study will be published in an open-access format and made freely available at the time of publication. Deidentified anonymized datasets and study materials will be available upon reasonable request to the corresponding author, in line with institutional policies and data-sharing agreements.

Authors' Contributions

ML-P and JJ Miranda conceived the Foot Selfie study. JJ Miranda, ML-P, JHZ-T, PP, J Siddique, J Seiglie, HL, SJ, LD, DB, DGA, and GC secured study funding. LC-C led day-to-day study planning and implementation activities. JHZ-T and JJ Mantilla conceived this substudy and led the overall study design. SMR, GA-H, and SGC worked on transcript analysis and thematic coding of the data. SMR, JHZ-T, GA-H, JJ Mantilla, and LC-C drafted the manuscript. SMR, JHZ-T, GA-H, JJ Miranda, LC-C, SGC, JJ Mantilla, PP, J Siddique, J Seiglie, HL, SJ, LD, DB, DGA, GC, and ML-P contributed to the refinement of the study, reviewed, and approved the final manuscript.

Conflicts of Interest

The authors declare no financial conflicts of interest. JJ Miranda, ML-P, JHZ-T, PP, J Siddique, J Seiglie, HL, SJ, LD, DB, DGA, and GC are co-investigators on the parent grant that supported the broader project from which this study emerged. GC, JJ Mantilla, SGC, and LC-C also held roles related to the development of the app and/or the qualitative analysis reported in this manuscript. These roles are disclosed for transparency.

Abstract

Background: Over-the-counter (OTC) medicines are frequently used during pregnancy. As these medicines are often used without medical supervision, accessible and reliable safety information is essential. However, finding reliable and understandable information on the safety of these medicines during pregnancy is often experienced as difficult. Hence, there is a need for a new easily accessible electronic health (eHealth) tool that empowers women to actively seek information to support safer self-medication practices during pregnancy and breastfeeding.

Objective: This study aimed to describe the development and dissemination process of a Dutch mobile app providing reliable safety information on OTC medicines during pregnancy and breastfeeding using a development and formative evaluation approach.

Methods: The app was developed over a 2-year project comprising 5 phases, including preparation, development, preimplementation, implementation, and evaluation. Mixed-method strategies, including questionnaires, focus groups, and user feedback rounds, were applied to involve the target population in the development process. Medicine safety information in the app was based on the latest scientific evidence. First-year app-usage outcomes included app downloads, usage patterns, and information-seeking behavior.

Results: Input from 253 potential users formed the foundation for the development of the MediMama app (Netherlands Pharmacovigilance Centre Lareb), with users expressing a need for clear, reliable, and easily accessible information on medication safety during pregnancy and breastfeeding. The app was launched on Mother's Day 2024 and provides safety information on over 250 OTC medicines, including supplements and herbal remedies, across 27 medicine categories. Promotion occurred through multiple online and offline channels. During its first year, the MediMama app was downloaded 22,415 times, with an average of 370 unique daily users, indicating substantial user engagement. Information on paracetamol (acetaminophen) and nasal sprays was most frequently accessed, reflecting the need for information on commonly used OTC medicines among the target population.

Conclusions: One year after its launch, the MediMama app is considered a promising tool in maternity care, meeting the target population's need for accessible OTC medicine safety information. The app aims to support informed decision-making, contributing to safer medication use during pregnancy and breastfeeding. Further research is required to evaluate the effectiveness of the implementation strategy, as well as the app's impact on maternal medication use behaviors and health outcomes.

Introduction

Medication use during pregnancy and breastfeeding is common, with an estimated 80% - 90% of women reporting the use of at least one (prescribed) medicine during pregnancy [1,2]. Nonprescription or over-the-counter (OTC) medicines are frequently used to manage pregnancy-related or seasonal symptoms such as heartburn, pain, or cold symptoms [3,4]. Although readily available in supermarkets and drugstores, OTC medicines are not without risk. Inappropriate use of some OTC medicines may increase the risk of congenital anomalies, adverse perinatal outcomes, and long-term health consequences for the offspring [3,5]. For instance, use of nonsteroidal anti-inflammatory drugs such as ibuprofen or naproxen in the second half of pregnancy has been associated with higher risks

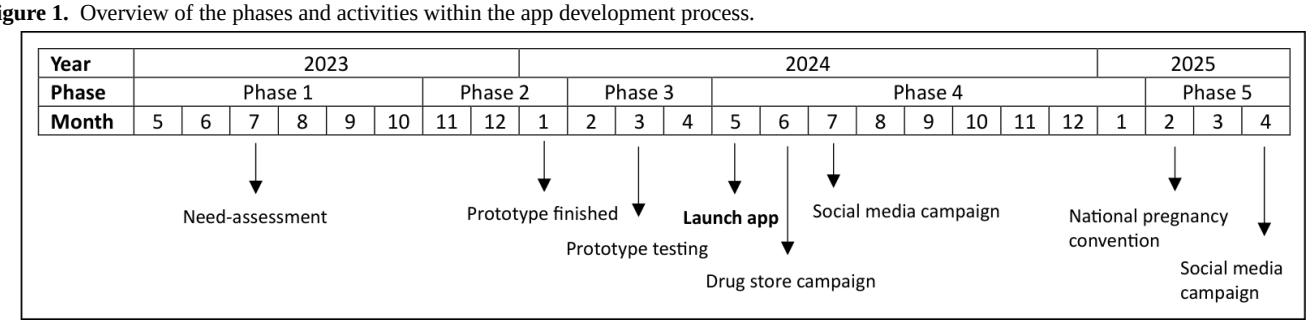
of constriction of the ductus arteriosus, oligohydramnios, and fetal renal dysfunction [6-8]. Similarly, the use of certain antihistamines during breastfeeding may reduce milk supply or cause sedation and irritability in infants, especially at high doses or with prolonged use [9,10]. While some women may be unaware of these potential risks, others tend to overestimate teratogenic risks and may be reluctant to use necessary medications to manage health conditions (eg, fever or pain during pregnancy), which in some cases could result in greater harm than the medications themselves [11,12].

Empowering women to make informed medication choices is therefore essential. Compared with prescription medicines, OTC medicines are widely available, less stringently regulated, and frequently used without professional guidance [3]. This shifts the responsibility for safety assessment to the individual user. Uninformed decisions about taking OTC medicines (including herbs, homeopathic remedies, and supplements) may lead to the usage of unsafe medicines without the user even being aware. While teratogenic risk information is available online, it has been suggested to be unclear, hard to find, or challenging to interpret for the lay audience. Hence, new interventions tailored to the target population are needed. Electronic health (eHealth) apps are described as the next generation in prenatal care and have been demonstrated to improve antenatal care quality, medication adherence, and pregnancy outcomes [13-16]. Research suggests that up to 95% of pregnant women search online for health information [17,18]. Mobile apps have become one of the primary sources of information and tend to rapidly replace traditional methods of obtaining information from health professionals and written resources [13,19-21]. Consequently, there are more apps available with pregnancy-related information compared to any other medical topic at the time of this writing [22].

While online information is easily accessible for women of reproductive age, it also entails risks, particularly regarding the reliability and accuracy of online sources [23,24]. Conflicting information from multiple online sources is common and can result in women seeking additional unreliable sources, experiencing increased anxiety or even avoiding necessary medication [18,25,26]. For example, previous research suggests that the main reasons women are hesitant to take medication during lactation include fear of harming the infant, lack of clear and consistent information, and conflicting advice (eg, between health care providers and the often outdated and overly restrictive information provided in the product label) [27-31]. This can lead women to discontinue breastfeeding or avoid necessary medication, even though most medications are compatible with breastfeeding [32,33]. Therefore, it is important to develop a single tool that is integrated across all stages of maternity care, providing reliable, clear, and comprehensible safety information.



Although several apps providing medication safety information for pregnancy or breastfeeding have been developed, awareness and use of these tools remain suboptimal, as they are often not easily accessible or widely known to users [34-36]. In addition, since brands of OTC medicines, use patterns, and regulatory recommendations on safety during pregnancy and lactation differ between countries, each country bears responsibility for providing, maintaining, and effectively disseminating locally relevant recommendations on medication safety [37,38]. In response to these challenges, this study aims to describe the development and dissemination process of a free and easily accessible Dutch mobile app on the safety of OTC medicines during pregnancy and breastfeeding.

Methods

Overview

The app is developed by the Dutch Teratology Information Service (TIS), part of Pharmacovigilance Centre Lareb. The Dutch TIS is the national knowledge center for medication safety during pregnancy and breastfeeding [39]. TIS provides evidence-based information on over 1100 (primarily prescription) drugs through a knowledge bank on its public website, which receives approximately 1.5 million visits annually [40]. Next to the knowledge bank, there was a desire for easier and faster access to information on OTC medications, for example, when standing in the drugstore. Inspired by a widely used Dutch app on the safety of food during pregnancy (the ZwangerHap app; The Netherlands Nutrition Centre) [41], a grant proposal for the development of a new app on the safety of OTC medication was submitted to and approved by the Netherlands Organization for Health Research and Development (ZonMw; grant number: 10140162210007). The 2-year development and implementation project started on May 1, 2023. This study followed a development and formative evaluation approach in which data were collected through questionnaires and focus groups to iteratively refine the new mobile app. This study followed 5 consecutive phases, including preparation, development, preimplementation, implementation, and evaluation (Figure 1). The month numbers displayed in Figure 1 represent the month of the year.
