Abstract

Background: Telemedicine has emerged as a critical strategy to address health care access gaps in hard-to-reach areas, particularly in resource-constrained settings. While telemedicine services have expanded across India, evidence on post-implementation experiences, specifically regarding the integration of portable diagnostic tools, and the assisting role of frontline health care workers, remains limited. Understanding these sociotechnical dynamics is essential for optimizing digital health interventions in remote areas.

Objective: This study aimed to explore perceptions, experiences, and implementation processes of an assisted telemedicine model where frontline health care workers facilitate real-time, doorstep patient-assisted-to-doctor consultations using portable diagnostics and a customized portal among health care workers and patients in hard-to-reach villages of Rajasthan, India.

Methods: A qualitative descriptive study was conducted in 5 remote villages of Balotra district, Rajasthan, between December 2025 and January 2026, following a 10-month telemedicine intervention. In-depth, semistructured interviews were conducted with 28 participants, including medical officers (n=3, 10.71%), nurses, and accredited social health activists or auxiliary nurse midwives (n=10, 35.71%), and patients (n=15, 53.57%). Cadre-specific semistructured interview guides were developed using the Consolidated Framework for Implementation Research and Technology Acceptance Model. Interviews were analyzed using a reflexive thematic analysis approach, incorporating both inductive and deductive coding approaches in NVivo 15 (Lumivero). Triangulation across participant groups and analytic perspectives was used to enhance credibility and trustworthiness.

Results: The analysis revealed that the assisted telemedicine model fundamentally reconfigured treatment-seeking behavior by providing doorstep care, significantly reducing travel burdens, and out-of-pocket expenditures. Frontline health care workers acted as crucial sociotechnical mediators, bridging the digital divide and fostering patient trust, particularly among women and older adults. Health care providers reported increased clinical confidence and workflow efficiency, supported by real-time vital monitoring and cross-verification via digital chatbots. However, implementation was challenged by intermittent network connectivity, diagnostic limitations for conditions requiring physical palpation, and occasional stock-outs of essential medicines. Despite these barriers, the gradual acceptance of the system was heavily facilitated by the continuous engagement and cultural mediation of local health workers.

Conclusions: Telemedicine was perceived as a feasible and acceptable model for extending primary health care services in hard-to-reach areas, provided it is embedded within an assisted model supported by trained frontline workers and responsive technical systems. The findings emphasize the need to shift health care policy toward mediated-digital models, formally recognizing community health workers as digital health navigators. Future scale-up must prioritize strengthening rural digital infrastructure and ensuring a reliable supply chain for essential medicines to sustain long-term engagement and health equity.

Introduction

Telemedicine has emerged as a critical tool for bridging health care access gaps, particularly in hard-to-reach areas with limited medical resources. Over the past two decades, it has evolved from experimental pilot projects into a core component of modern health delivery, extending specialist and primary care to remote populations [1]. This technology uses information and communication technologies to deliver health care services remotely, thereby enhancing accessibility and improving patient outcomes in remote areas [2]. It significantly reduces patient transportation costs and improves the efficiency of medical services in areas with scarce medical resources [3]. Nevertheless, the adoption of telemedicine worldwide remains uneven, with infrastructural, organizational, and regulatory barriers consistently limiting its scale-up in resource-constrained settings [4]. Telemedicine can lower overall health care costs by streamlining service delivery and minimizing the need for physical consultations. Moreover, it can empower individuals in these regions, who often face greater challenges in accessing health care, by improving inclusivity and participation in health care services [5,6].

The integration of telemedicine is especially pertinent in lower-middle-income countries such as India, where vast populations and significant geographical distances between urban centers and rural towns create substantial barriers to accessing specialized health care services. In addition, especially in regions such as Rajasthan, where geographical barriers and a sparse distribution of health care facilities often hinder timely access to essential medical care, telemedicine can promote equitable health care by extending specialist consultations and ongoing care to remote populations. Moreover, telemedicine implementation in Health and Wellness Centers facilitates consultation, screening, and remote monitoring, enabling individuals to connect with health care providers and receive medical advice. This is particularly beneficial for patients with chronic conditions, enabling continuous monitoring and timely interventions without extensive travel [7,8].

To contextualize this implementation, India's national telemedicine initiatives, such as the eSanjeevani platform (developed by the Centre for Development of Advanced Computing, Ministry of Health and Family Welfare, Government of India), have largely focused on facility-based models (eg, doctor-to-doctor consultations at Health and Wellness Centres or subcenters) to bridge the urban-rural health care divide [9]. While these facility-based models address specialist shortages, they still require patients to travel to a local health facility, which remains a barrier in geographically isolated terrains. The intervention evaluated in this study represents a distinct piloting and evidence generation stage of an adapted mobile health model [8]. Specifically, it introduces an assisted telemedicine model that extends care beyond the subcenter level directly to the patient's doorstep. In this workflow, frontline health care workers (accredited social health activists [ASHAs], auxiliary nurse midwives [ANMs], and nurses) conduct home visits or respond to patient calls, capture real-time vital parameters using portable digital diagnostic tools, and upload the data to a customized telemedicine portal. The health worker then facilitates a live video consultation between the patient and a remote medical officer, who generates an e-prescription that the health worker downloads and delivers to the patient. The added value of this specific intervention lies in its mobility and real-time diagnostic capability, effectively overcoming the geographical barriers inherent in standard facility-based models by bringing the digital health hub directly to the patient's home [10,11]. This implementation-focused perspective is consistent with iCHECK-DH (Guidelines and Checklist for the Reporting on Digital Health Implementations; Checklist 1), which emphasizes documenting the contextual factors, implementation processes, and adaptations that shape digital health delivery in real-world settings [12].

This study aimed to address the gap by presenting in-depth qualitative findings from Balotra district of Rajasthan, which marks its geographical remoteness and limited health infrastructure on the post-implementation delivery of telemedicine. The insights on perception of acceptability, operational challenges, and actionable recommendations have been drawn from interviews with ASHAs, ANMs, nursing officers (NOs), medical officers (MOs), and patients who used the telemedicine facilities.

Methods

Study Design

A qualitative descriptive study design was used to understand the experiences and perceptions of frontline health care workers and patients involved in the implementation and delivery of telemedicine services in hard-to-reach areas of Balotra district of Rajasthan. The study used in-depth interviews (IDIs) to document lived experiences, perceived benefits, implementation challenges, acceptability, and recommendations for improvement among those who used telemedicine services during the intervention group's implementation phase. This manuscript is reported in accordance with the COREQ (Consolidated Criteria for Reporting Qualitative Research) checklist (Checklist 2). Additionally, the reporting of the digital health implementation context, intervention characteristics, and structural barriers was guided by the iCHECK-DH mentioned in Checklist 1 [12].

Study Setting

The study was conducted in 5 randomly chosen hard-to-reach areas of the Balotra district of Rajasthan between December 2025 and January 2026, where health care is severely constrained due to a lack of proper health care accessibility, geographical isolation, limited access to specialist care, a health care worker shortage, and minimal existing health care infrastructure. These areas were facilitated with telemedicine services, in which teleconsultations were operational from 8 AM to 5 PM for 5 working days, supported by trained frontline health care workers.

Study Context

As part of the telemedicine intervention (parent project), a team of frontline health care workers, ASHAs or ANMs, and nurses were trained to operate digital diagnostic devices and a customized telemedicine portal and were deployed with medical kits and smartphones to facilitate teleconsultations with doctors.

XSL•FO
RenderX

Five teams were assigned to the 5 randomly selected villages, and their contact information was shared across the community through an initial door-to-door survey. During operational hours, frontline workers visited patients at their doorsteps or patients visited them, measured vital parameters such as blood pressure (BP), oxygen saturation (SpO_2), and heart rate, conducted electrocardiography (ECG) if required, and provided real-time video consultations with the MOs sitting remotely. The MOs used patients' data and interactions with patients to provide medical advice, e-prescriptions, and referrals, as needed. The telemedicine portal was developed on the MERN stack (MongoDB, Express, React, and Node.js) with WebRTC integration to allow secure transmission and storage of patient data, live e-prescription generation, and follow-up management.

Study Participants

The study included 28 participants from multiple stakeholder groups who were directly involved in or had experience with telemedicine services during the intervention period, enabling a comprehensive understanding of telemedicine implementation and delivery in hard-to-reach areas. Purposive sampling was used to recruit both frontline health care workers and patients to ensure representation of diverse experiences and perspectives. Frontline health care workers (n=13) were purposively recruited through their respective primary health centers and project headquarters and comprised 5 (38.5%) ASHAs or ANMs, 5 (38.5%) nurses, and 3 (23.1%) MOs. Patients were purposively selected from the telemedicine intervention registry (n=4401) with assistance from local ASHA workers, who identified individuals with varied demographic characteristics, frequencies of telemedicine use, health conditions, and levels of engagement with the system. Fifteen patients, representing both genders and different age groups, were selected, with 3 participants recruited from each of the 5 intervention villages. This purposive selection ensured variation in participants' experiences, symptoms, and patterns of telemedicine use, thereby providing diverse perspectives on the implementation and use of telemedicine services.

Data Collection

Qualitative data were collected through face-to-face IDIs conducted post-implementation of the intervention project for 10 months within the intervention group villages. RS Chowhan, RKH, and project staff, holding ME, PhD, and MHA, respectively, conducted the IDIs. All received training in qualitative research methods, including thematic analysis and conducting IDIs, at Indian Council of Medical Research (ICMR)-National Institute for Implementation Research on Non-Communicable Diseases (NIIRNCD), Jodhpur. Separate semistructured interview guides were developed for ASHAs, ANMs, or nurses, MOs, and patients based on the Consolidated Framework for Implementation Research (CFIR) and technology acceptance model (TAM) frameworks after a literature review and through multiple rounds of discussion with the research team and domain experts to ensure questionnaire alignment with study objectives and to reflect differences in roles, experiences, and interaction with the telemedicine system.

Trained qualitative researchers with no prior relationship with participants conducted interviews in the local language (Hindi or Marwari). Each interview lasted approximately 30 to 35 minutes and was audio recorded with written consent in a quiet, private space, ensuring participants' comfort, anonymity, and confidentiality. Semistructured interview guides for patients, MOs, and nurses were used to facilitate data collection (Multimedia Appendix 1).

Data Analysis

The study was grounded in a critical realist epistemological perspective, acknowledging the objective realities of the rural health care infrastructure while recognizing that participants' experiences and perceptions of the telemedicine system are socially constructed and context dependent. The audio recordings were transcribed into English by bilingual researchers and verified by the principal investigator for consistency, accuracy, and data integrity, without distorting participant intent throughout the translation process. Transcribed files and audio recordings were securely stored in password-protected folders. Data saturation was achieved when no new themes were obtained. The thematic analysis incorporated both deductive (literature-driven themes) and inductive (field-driven themes) coding approaches as described by Braun and Clarke using NVivo 15 software (Lumivero) [13]. This study used an integrated theoretical approach combining the CFIR and the TAM. CFIR guided the deductive analysis of multilevel implementation determinants, while TAM served as an interpretive framework to explore individual perceptions of telemedicine, including ease of use, usefulness, and intention to use.

Thematic saturation was assessed concurrently during data collection and analysis by the qualitative research team (RS Chowhan and RK). Saturation was assessed independently for each of the 3 stakeholder groups (MOs, frontline health care workers, and patients) to ensure diverse perspectives were adequately captured. Regarding the MOs (n=3, 10.71%), the intervention specifically deployed exactly 3 (10.71%) MOs to cover the 5 remote villages. Therefore, n=3 represents a complete census of the MO cadre involved in this specific pilot, not a sample. Their interviews were extensive (30 - 40 min), and thematic saturation for their specific operational context was achieved within this bounded group. For frontline health care workers (n=10) and patients (n=15), recruitment continued until no new themes or codes emerged from successive interviews.

Triangulation was applied during data analysis to enhance credibility. Data source triangulation was achieved by comparing perspectives across MOs, frontline health care workers, and patients involved in the telemedicine intervention. Investigator triangulation was ensured through the involvement of multiple trained researchers in data collection and coding, with iterative discussions to reach consensus. Theoretical triangulation was further applied by integrating CFIR to examine implementation contexts and processes, alongside TAM to interpret individual perceptions of telemedicine use. Rigor and trustworthiness criteria, as described by Lincoln and Guba [14], were applied to enhance credibility, dependability, confirmability, and contextual transferability through data saturation, systematic

XSL•FO
RenderX

coding, the use of verbatim quotations, and detailed descriptions of the study setting and participants.

In alignment with the COREQ checklist, the research team maintained reflexive journals during data collection and analysis to document personal assumptions and biases regarding digital health interventions. Field notes were taken during and immediately after each interview to capture nonverbal cues, environmental context, and initial analytical memos. There were no refusals or dropouts among the eligible participants approached for the study (0% nonparticipation rate). Owing to the low literacy levels among some patient participants and logistical constraints in remote field settings, transcripts were not returned to participants for formal member checking; however, preliminary findings were shared and discussed with local community health leaders to ensure contextual accuracy.

A detailed codebook outlining codes, categories, and thematic hierarchies for patients, MOs, and ASHAs or ANMs and nurses is provided in Multimedia Appendix 2.

Ethical Considerations

This study is part of the telemedicine intervention project titled "Acceptance of Digital Medical Tools and Telemedicine in Hard-to-Reach Areas as Augmentation of Conventional Physical Clinics and Face-to-Face Consultation," funded under grant IIRP-2023 - 0000151. Ethical approval was obtained from the Institutional Ethics Committee of ICMR-NIIRNCD, Jodhpur, India (approval IEC-NIIRNCD/2023/DEC/FR/013; approved on December 22, 2023). The study was prospectively registered with the Clinical Trials Registry-India (CTRI/2024/10/076070). The study was conducted in accordance with the Declaration of Helsinki. Written informed consent was obtained from all participants prior to data collection. Participants were assured confidentiality and anonymity, and all identifying information was removed from transcripts before analysis. Participants did not receive financial compensation for their participation in the study; however, standard refreshments were offered during the interview sessions as a gesture of appreciation for their time.

Results

Overview

A total of 28 participants were included in the study, comprising 3 (10.7%) MOs, 10 (35.7%) nurses and ASHAs or ANMs, and 15 (53.6%) patients (3 from each of 5 villages). Data were collected through cadre-specific semistructured interviews, which were audio recorded and transcribed verbatim. Recruitment and data collection continued until thematic saturation was achieved within each participant group. Findings are presented cadre wise according to 3 participant categories. Participant characteristics and thematic tables are mentioned in Multimedia Appendix 3, and the COREQ checklist is presented in Checklist 2. An overview of key themes emerging from each cadre's interviews is illustrated in Figures 1-3. The conceptual framework has been added to showcase the perspectives integrated across stakeholders in Figure 4. The final participant composition and characteristics are presented in Table 1.

MOs' Insights

Theme 1: Roles and Responsibilities—From Individual Readiness to Routine Telemedicine Practice

MOs described telemedicine adoption as a progressive process shaped by prior clinical experience, digital exposure, and evolving professional responsibilities. Their accounts reflected the CFIR domain of Individuals—Capability, as MOs drew on previous clinical training and project experience to operationalize remote care within their routine practice. One MO described his professional pathway and current responsibility within the telemedicine model:

> *I have been working as a medical officer in the Telemedicine Project. Before this, I did my internship at my medical college, and after that, I joined here as a Medical Officer. My responsibility is to provide teleconsultation & I have 2 years of experience in the same project.* [MO02]

Prior familiarity with digital health platforms also influenced the ease with which MOs transitioned to virtual consultations. In terms of the TAM construct of perceived ease of use, previous exposure to existing telemedicine systems reduced the learning burden associated with the new portal. One MO explained:

> *I have used portals like e-Sanjeevani portals before this telemedicine project, so It has been comfortable enough for me to upload data, make video calls.* [MO03]

At the same time, the introduction of new portable diagnostic devices required adaptation. This again reflected TAM's perceived ease of use, as MOs compared earlier clinical tools with the simplified but unfamiliar portable equipment used in the project. One MO stated:

> *Before the project, pulse oximeter, manual BP apparatus, and ECG machine of nine leads were part of my workflow, while in this project portable Spandan ECG machine with three leads has been a new experience for me.* [MO03]

Together, these accounts suggest that MOs' readiness for telemedicine was not uniform but was shaped by cumulative clinical experience, prior digital exposure, and gradual adaptation to new diagnostic and consultation workflows.

Theme 2: Training and System Onboarding—Building Confidence Through Structured Support

Structured training and ongoing system-level support were central to MOs' confidence in delivering telemedicine. This aligned with the CFIR Inner Setting domain, particularly Access to Knowledge and Information, because formal induction training provided the knowledge required to use the portal, conduct video consultations, and generate e-prescriptions. One MO described the initial training process:

> *Two weeks of induction training were provided on how to use the telemedicine portal, how to connect with nurses and patients through video calls, and how to generate e-prescriptions.* [MO01]

In addition to formal training, MOs emphasized the importance of real-time collaboration with nursing and field staff. This reflected the CFIR construct of Available Resources within the Inner Setting because the presence of trained support staff during consultations made remote clinical workflows more manageable. One MO explained:

> *The nursing staff also assisted in positioning the patient and sharing vital signs during the video call. This coordination made teleconsultation easier.* [MO03]

MOs also reported that continuous technical and clinical support reduced early hesitation and enabled them to use the system more efficiently over time. This again highlighted the CFIR Inner Setting—Available Resources domain, as accessible support mechanisms helped convert initial uncertainty into routine use. One MO stated:

> *Initially, we were not very confident about video consultations, but because technical and clinical support was always available, our hesitation reduced. Over time, it became more efficient and comfortable to use.* [MO02]

These findings indicate that MOs' adoption of telemedicine was supported not only by individual capability but also by structured onboarding, team-based assistance, and responsive technical support.

XSL•FO
RenderX

Theme 3: System Use and Workflow Integration—Platform Design and Adaptive Communication

Once MOs became familiar with the telemedicine system, platform design and adaptive communication strategies played an important role in integrating teleconsultations into routine clinical workflows. The centralized design of the portal was appreciated because it brought multiple consultation-related functions into a single interface. This reflected the CFIR construct of Innovation—Innovation Design, as a well-organized system reduced clinical friction and supported efficient decision-making. One MO explained:

> *The telemedicine portal was well-designed and user-friendly. All patient details, vitals, doctor notes, video consultations, and e-prescriptions were available on a single screen, which reduced errors and saved time.* [MO02]

However, network instability sometimes disrupted communication during consultations. MOs described using alternative communication mechanisms, such as the chatbot, when symptoms could not be clearly conveyed through video. This reflected the CFIR domain of Implementation Process—Tailoring Strategies because clinicians and field teams adapted the consultation process according to local connectivity constraints. One MO stated:

> *There were network issues at patients' side, because of which at times the symptoms were not clearly stated and understood, and then with the help of a chatbot, it was communicated.* [MO03]

Technical difficulties such as server downtime and login problems were also reported, although MOs noted that these issues were generally resolved quickly. This again highlighted the importance of the CFIR Inner Setting—Information Technology Infrastructure, as the reliability of technical support influenced whether workflow disruptions became minor interruptions or major barriers to care. One MO explained:

> *We faced server downtime, login issues due to poor network connectivity, and occasional portal crashes. However, these technical problems were resolved promptly.* [MO01]

These accounts suggest that workflow continuity depended not only on the usability of the digital platform but also on the availability of fallback mechanisms and responsive technical support when connectivity or system problems occurred.

Theme 4: Clinical Decision-Making and Diagnostic Confidence—Remote Evidence and Clinical Boundaries

MOs reported that digital recording of vital signs and photographic verification strengthened their confidence in remotely obtained clinical information. This aligned with the CFIR construct of Innovation—Innovation Evidence Base because the ability to review entered vitals and cross-check photographic evidence enhanced trust in the quality of remote clinical data. One MO described the verification process:

> *The field staff would send the data by typing in the vital signs and uploading photos of the digital devices on the chatbot, allowing us to cross-verify the data. If there was any issue with the readings or if the patient's symptoms differed from those recorded, we would ask to recheck.* [MO02]

At the same time, MOs recognized that telemedicine had clinical boundaries. Although remote consultations were sufficient for many routine conditions, certain clinical situations still required physical examination. This reflected the CFIR domain of Individuals—Capability, as MOs exercised professional judgment about when teleconsultation was appropriate and when in-person care was necessary. One MO stated:

> *I was confident to treat patients as per the telemedicine guidelines, but certain cases of dermatological conditions, emergencies, and ANC visits needed in-person examination.* [MO01]

Thus, telemedicine was perceived as a valuable model for routine primary care delivery, but MOs maintained clear clinical boundaries and referred patients to face-to-face examination when physical assessment was essential.

Theme 5: Communication and Trust—Frontline Mediation and Continuity of Care

MOs described patient acceptance as developing through continued communication, follow-up, and positive experiences with the service. This reflected the CFIR Inner Setting—Communication domain because sustained interaction between patients, frontline workers, and remote clinicians helped build trust in the telemedicine model. One MO reported:

> *Patients reported high satisfaction with teleconsultation services and maintained regular contact with ASHA and ANM. Many continued follow-ups for chronic conditions and sought timely advice for acute illnesses.* [MO01]

Communication during teleconsultations was also shaped by local language use and cultural expectations. This aligned with the CFIR Outer Setting—Local Attitudes domain because rural patients' comfort with video-based care was influenced by language, gender norms, and familiarity with digital interaction. One MO explained:

> *People from rural areas use local language, and a few patients, especially women, were shy or hesitant to speak on video.* [MO03]

Continued information exchange between MOs and field workers supported follow-up and allowed clinicians to monitor patient progress. This reflected the CFIR construct of Innovation—Innovation Recipient Impact, as the telemedicine model influenced not only individual consultations but also ongoing care relationships. One MO stated:

> *We took follow-ups when patients revisited for check-ups. Sometimes, field workers also updated us about the patient's progress.* [MO02]

These findings indicate that acceptance of telemedicine was supported not simply by the availability of remote consultation but by sustained interpersonal mediation and continuity between remote clinicians and community-based health workers.

XSL•FO
RenderX

Theme 6: Collaboration and Coordination—Team Learning and Feedback-Driven Improvement

MOs emphasized that telemedicine delivery depended on coordination among clinical, nursing, technical, and community teams. This reflected the CFIR Inner Setting—Learning Centeredness domain because collective preparation and shared understanding were important before the service was deployed in the field. One MO described this process:

> *Before the field deployment of telemedicine services, we met, trained and explained he project details to all the ASHA, ANM, nursing staff, and peers.* [MO02]

Feedback from clinical staff also contributed to iterative improvements in the telemedicine workflow. This aligned with the CFIR domain of Implementation Process—Reflecting and Evaluating because monthly review and practical feedback led to modifications that simplified the consultation process. One MO explained:

> *Earlier, workflow required multiple systems for teleconsultations, but monthly feedback led to integration of video calls, chatbot, and e-prescription generation on a single screen.* [MO02]

These accounts show that implementation was not a one-time deployment but an evolving process in which team coordination, training, and continuous feedback shaped the usability and effectiveness of the telemedicine system.

Theme 7: Sustainability, Integration, and Reflective Evaluation—Adaptation, Adoption, and Long-Term Value

MOs described several practical adaptations that helped sustain telemedicine delivery when digital infrastructure was unstable. This reflected the CFIR domain of Implementation Process—Adapting because clinicians and field teams developed workarounds to maintain service continuity. One MO stated:

> *Network connectivity sometimes led to video call disruptions and portal lag, so we shifted to alternative modes such as video call through a hotspot Wi-Fi.* [MO03]

MOs also viewed telemedicine as a valuable long-term addition to primary health care delivery. This aligned with the CFIR Inner Setting—Mission Alignment domain because telemedicine was seen as complementary to existing services and consistent with broader goals of improving access in remote areas. One MO explained:

> *Telemedicine is a valuable long-term support tool with improvements in features such as chatbots and video calls to benefit patients in real-time.* [MO01]

The commitment of MOs extended beyond routine working hours in some situations, reflecting both individual motivation and the adoptability of the model. This aligned with the CFIR construct of Implementation Outcome—Adoptability, as clinicians were willing to use personal devices when necessary to ensure continuity of care. One MO stated:

> *Consultations were not done on weekends, but if needed, we used phones for consultations from our homes.* [MO03]

MOs also acted as internal champions for telemedicine by discussing complex cases with colleagues and sharing positive experiences with peers. This again supported the CFIR domain of Implementation Outcome—Adoptability because professional endorsement and peer communication can strengthen broader acceptance of digital health innovations. One MO explained:

> *We discussed critical cases and shared experiences to consult with our fellow specialists. I have shared the usefulness of telemedicine among rural populations with my peers.* [MO01]

Finally, MOs reflected on the long-term benefits of telemedicine for patients, particularly older patients, while also identifying the need for privacy-sensitive physical spaces. This reflected the CFIR domain of Implementation Outcome—Reflecting and Evaluating because participants evaluated both the benefits of the service and the improvements required for equitable and sustainable implementation. One MO stated:

> *Telemedicine enabled access to medical reports, e-prescriptions, and teleconsultations from home, reducing hospital visits, particularly for elderly patients. Additionally, the provision of a separate examination room for female patients or patients with sensitive conditions should be made.* [MO01]

These reflections suggest that while MOs broadly endorsed the telemedicine model, they recognized that its long-term sustainability and equity depend on technological refinement, reliable infrastructure, peer support, and attention to culturally appropriate physical spaces at the point of care.

Nurses' Insights

Theme 1: Background and Digital Experience

Nurses and ASHA or ANM workers described their roles as extending beyond basic facilitation of teleconsultations to include patient assessment, vital sign measurement, digital data entry, coordination with remote doctors, patient education, and follow-up. This reflected the CFIR domain of Individuals—Capability, as frontline workers took on an expanded clinical and digital role within the assisted telemedicine model. One nurse described this end-to-end role:

> *I accompanied ASHA and ANM workers to villages, shared contact details, responded to calls by visiting households, assessed patients' conditions, conducted teleconsultations, and shared e-prescriptions.* [N04]

Similarly, an ASHA worker described simultaneously assessing patients, recording BP, SpO_2, and ECG, communicating findings to doctors, explaining prescriptions, and creating community awareness (ASHA01). These accounts indicate that the assisted telemedicine model fundamentally expanded the scope of frontline practice, positioning these workers as the primary clinical and digital interface between patients and remote doctors.

XSL•FO
RenderX

Prior clinical and technical exposure appeared to facilitate adaptation to the digital workflow. In terms of the TAM construct of perceived ease of use, existing familiarity with clinical monitoring equipment eased the transition to portable diagnostic tools, while structured hands-on training provided the skills required to perform the expanded role. A nurse noted previous experience with ventilators, patient monitoring systems, and 12-lead ECG, suggesting that existing familiarity with clinical monitoring equipment eased the transition to portable diagnostic tools (NO10). Structured onboarding further reinforced this readiness; one nurse described 10 days of practical training covering vital sign measurement on dummy patients, ECG operation, portal use, video consultations, chatbot functions, e-prescriptions, and monitoring doctor availability (NO04).

Together, these findings suggest that frontline workers' initial readiness for telemedicine was shaped by prior clinical experience, digital familiarity, and the expanded professional responsibilities they assumed within the telemedicine workflow.

Theme 2: Onboarding and Training

Structured hands-on training provided the skills required to perform the expanded frontline role. This aligned with the CFIR Inner Setting—Access to Knowledge and Information domain because formal training equipped workers with the practical knowledge needed to operate devices, use the portal, and coordinate teleconsultations. One nurse described the training process:

> *We received 10 days of training on taking BP, SpO_2 , and ECG on a dummy patient, uploading data to the portal, conducting video calls with doctors, and logging into the nurse profile. We also learned to use the chatbot to enter patient details, upload medical reports, connect with doctors, receive e-prescriptions, and monitor doctors' availability status.* [N04]

Continued access to technical assistance further supported implementation. This reflected the CFIR Inner Setting—Available Resources domain, as responsive technical support helped frontline workers resolve operational problems quickly. One ASHA worker reported:

> *We contacted the IT team of our department for any issues and usually received solutions the same day.* [ASHA03]

Together, these findings suggest that frontline workers' capacity to deliver telemedicine was built through a combination of prior clinical experience, structured practical training, and responsive post-deployment support.

Theme 3: Usability and Technical Functionality

Frontline workers generally found routine devices and the telemedicine portal manageable after training, although the portable ECG initially required additional familiarization. This aligned with the TAM construct of perceived ease of use, as workers' confidence improved through training and repeated use. An ASHA worker explained:

> *ECG was newer and more difficult at first, but after training, I understood it better.* [ASHA04]

The portal and app were also considered accessible, with bilingual instructions in Hindi and English and clearly structured data entry fields facilitating use among workers with varying levels of digital familiarity. An ASHA worker stated:

> *The portal and app were easy to understand with instructions in both Hindi and English and clear columns for details, so there was no problem using it.* [ASHA03]

Connectivity remained an important operational constraint, particularly during video consultations. This reflected the CFIR Inner Setting—Information Technology Infrastructure domain because network limitations directly affected the reliability of real-time consultations. Workers reported using the chatbot and other communication channels when network availability was inadequate. As an ANM explained:

> *Sometimes there was no network, then we used the chatbot or other alternatives for consultation.* [ANM01]

Similarly, when the portal was unavailable, workers shifted consultations to alternative video calling apps and simultaneously reported technical failures to the IT team while maintaining direct communication with doctors. This reflected the CFIR domain of Implementation Process—Adapting, as frontline workers developed practical workarounds to maintain service continuity. One nurse stated:

> *If the portal did not work, then we made the patient talk to the doctor through video call on another app.* [N03]

Another nurse explained:

> *We conveyed technical failure to the IT team and talked to the doctors directly on the video call.* [N04]

Taken together, these accounts suggest that continuity of telemedicine depended not only on system usability but also on frontline workers' ability to adapt workflows dynamically and access timely technical support when digital infrastructure failed.

Theme 4: Communication Practices and Patient Support

Nurses and community health workers played an important intermediary role in introducing telemedicine, addressing hesitation, and making remote consultations understandable to patients. This aligned with the CFIR Outer Setting—Local Conditions domain because frontline workers used existing community relationships to improve access and encourage use of the service. ASHA workers shared their phone numbers during awareness meetings and health camps so that patients could contact them directly when unwell. One ASHA worker reported:

> *We shared our phone numbers during awareness meetings and camps, and patient called us directly whenever they fell sick so that we could visit them for teleconsultations.* [ASHA02]

Local examples of patients who had benefited from telemedicine were used to build confidence among hesitant community members. This reflected the CFIR domain of Implementation Process—Engaging because trust was generated through local

XSL•FO
RenderX

evidence and repeated interpersonal communication. One ASHA worker stated:

> *We used examples of treated patients of the village itself to build trust.* [ASHA01]

Continued counseling and motivation were also considered essential for patients accustomed to conventional face-to-face care. Another ASHA worker noted:

> *With proper counselling and motivation, it is easier to make them believe and trust the telemedicine services.* [ASHA02]

During consultations, frontline workers mediated linguistic and health literacy barriers by translating doctors' instructions and explaining digital prescriptions. This reflected the CFIR domain of Implementation Process—Doing because frontline workers actively facilitated the consultation process and ensured that medical advice was understood. A nurse stated:

> *During teleconsultation, if the patient did not understand the doctors' instructions, then I explained the advice in their local language.* [N02]

Another nurse described explaining prescription abbreviations and translating e-prescription instructions into the local language:

> *We clarified instructions like BD (twice daily) or SOS (only when needed), and explained the e-prescription in local language to patients.* [N03]

Gender and privacy concerns also influenced acceptance. This aligned with the CFIR construct of Innovation—Innovation Recipient Impact because patients' acceptance of telemedicine was shaped by reassurance, confidentiality, and observed benefits. An ANM reported that some female patients initially hesitated about video consultations but became more accepting after reassurance about data confidentiality, discussion of other patients' recovery, and explanation of the benefits of telemedicine:

> *Female patients hesitated and doubted video calls, but after assurance of data confidentiality, citing fellow patients' recovery and explaining the benefits of telemedicine, they trusted and accepted the services.* [ANM01]

The frontline role also extended beyond the initial teleconsultation to monitoring treatment adherence and assessing patient improvement. This reflected the TAM construct of perceived usefulness because follow-up reinforced the practical value of telemedicine for patients. A nurse described:

> *During teleconsultation, if the patient is provided with a 7-day course, then we do a follow-up within 5 days to see whether they have taken the medicines on time, or any health improvement is noted or arrange another consultation.* [N01]

Patients also returned with positive feedback and reported recovery, reinforcing frontline workers' confidence in the service and validating the model's clinical utility at the community level. An ASHA worker stated:

> *Patients came back with positive feedback and reported recovery.* [ASHA03]

These findings indicate that frontline workers functioned as clinical, linguistic, and cultural intermediaries, connecting the digital system with patients' social, linguistic, and practical needs.

Theme 5: Feedback and System Improvement

Although frontline workers perceived clear benefits from telemedicine, they identified several conditions required for sustained implementation. This reflected the CFIR domain of Implementation Process—Assessing Context because participants highlighted gaps in medicines, physical infrastructure, connectivity, and devices that needed to be addressed to strengthen service delivery. One nurse summarized the importance of integrating medicines into the model:

> *If the medicines were made available to us, we could support the patient in a better way.* [N02]

An ASHA worker advocated for dedicated consultation spaces, noting:

> *A proper place for teleconsultation should be set up with a medical facility where the patient can easily reach and be examined.* [ASHA04]

An ANM further emphasized the need for technology adapted to rural connectivity constraints, stating:

> *Low-internet-compatible devices and tablets are needed for smoother data entry and better video calls, along with simple video/user guides for troubleshooting.* [ANM01]

Ongoing feedback from frontline workers additionally contributed to system improvement. This aligned with the CFIR domain of Implementation Process—Reflecting and Evaluating because technical and operational problems were reported, reviewed, and resolved during implementation. Participants described technical and operational problems being reported to the project team and resolved within a few days. One nurse stated:

> *The issue reported to the team and that get solved next time or in 2-3 days.* [N02]

Online training was also provided when additional support was required. One nurse explained:

> *We were provided online training whenever needed to do things correctly in the field.* [N05]

Coordination between frontline workers and remote doctors also provided an important safety mechanism during technical disruptions. This reflected the CFIR domain of Individuals—Capability, as clinicians and frontline workers used alternative communication methods to maintain care when the primary system failed. One nurse stated:

> *When the portal was down, doctors supported us through alternate video calls, guiding patients with diagnosis and treatment so continuity of care was never disrupted.* [N03]

XSL•FO
RenderX

Thus, continuity was supported by a combination of structured follow-up practices, interprofessional communication, responsive technical support, and iterative learning rather than by the digital platform alone.

Theme 6: Reflections and Future Engagement

Despite the constraints identified, frontline workers expressed strong support for continuation because telemedicine reduced travel, waiting time, and costs, particularly for older and geographically remote patients. This reflected the CFIR construct of Innovation—Relative Advantage and the TAM construct of perceived usefulness because frontline workers judged telemedicine to be beneficial compared with conventional care-seeking pathways. An ANM stated:

> *Earlier we had to travel far and wait in queues; now telemedicine gives us treatment at home, saving time and money.* [ANM01]

An ASHA worker similarly advocated for the service's continuation, noting:

> *Telemedicine should continue as it saves time and money and helps elderly and remote patients get treatment at home.* [ASHA03]

At the same time, participants recognized that further improvements were necessary for long-term sustainability. This reflected the CFIR domain of Implementation Process—Reflecting and Evaluating because frontline workers evaluated both the benefits of the service and the system-level improvements required for continued delivery. One nurse summarized:

> *Telemedicine gave timely care and relief at home, but better connectivity, medicines, and extended hours are needed.* [N05]

These reflections suggest that while frontline workers strongly endorsed the telemedicine model, its long-term sustainability depends on addressing systemic gaps in physical infrastructure, medicine supply, digital connectivity, and service availability.

Patients' Insights

Theme 1: Telemedicine Addressed Important Barriers to Conventional Health Care Access

Patients described telemedicine primarily in relation to the practical difficulties they previously experienced when seeking conventional health care. This reflected the CFIR domain of the Outer Setting—Local Conditions, as participants reported long travel distances, transportation costs, accompanying family members, waiting times, and disruption of daily activities. One participant explained the logistical burden:

> *With no nearby hospital, we had to travel 40 km or use private care, leading to an accompanying person, high costs and loss of time.* [PT08]

Awareness of telemedicine was largely generated through ASHA workers, project staff, and community members, which aligned with the CFIR construct of Individuals—Motivation, as interpersonal networks drove the initial desire to try the service. As one participant described:

> *I came to know about telemedicine through the villagers and the project staff, about the direct consultation with doctors on video call.* [PT03]

Furthermore, positive experiences shared within villages encouraged its use, reflecting the TAM construct of social influence. Another participant noted:

> *People in my village encouraged me to use telemedicine because of its benefits, but I haven't seen it used like this in nearby villages.* [PT02]

These accounts indicate that initial engagement was driven not by institutional marketing but by organic, community-level diffusion through trusted personal networks. Additionally, patients' baseline digital readiness was limited; reflecting the CFIR domain of Individuals—Capability, 1 patient recalled having seen a BP machine at the anganwadi but never at home (PT07), highlighting the absolute necessity of the assisted telemedicine model.

Theme 2: Local Health Workers Enabled Patients to Navigate the Digital Care Pathway

Patients did not generally experience telemedicine as a fully self-directed digital service. Instead, local health workers provided the practical bridge between patients and remote doctors. This reflected the CFIR domain of Implementation Process—Engaging, as frontline workers registered patients, recorded symptoms and vital signs, facilitated video consultations, and explained prescriptions. One participant described the structured workflow:

> *Team visits homes daily to register patients, record symptoms, connect with doctors online, and note e-prescriptions.* [PT15]

Another stated:

> *The telemedicine staff and ASHA assisted us in teleconsultation with the doctor, explaining symptoms and e-prescription.* [PT09]

This active facilitation compensated for the patients' limited direct experience with digital devices. Patients' confidence also developed through repeated exposure and communication in familiar language, which addressed the CFIR Outer Setting—Local Attitudes regarding cultural and linguistic comfort. One participant explained that the consultation language was easy to understand and that continued support could enable educated family members to assist with future use:

> *The consultation language was easy to understand. With better systems and continued support, my educated family members can use it, and I can encourage them.* [PT11]

Thus, patients' engagement with telemedicine appeared to depend substantially on human mediation and the Innovation Design of the assisted delivery model rather than digital access alone.

Theme 3: Trust, Communication, and Privacy Shaped Acceptance of Remote Consultations

Patients described trust as developing through familiarity with local health workers, clear communication, and positive

XSL•FO
RenderX

experiences with treatment. This aligned with the CFIR construct of Innovation—Innovation Evidence Base, as observable clinical effectiveness validated the remote care model. One participant stated:

> *The team members have earned our trust and act as our trusted link to the doctors, especially because the treatment works.* [PT07]

Privacy and confidentiality were also important for patients' comfort during remote consultations. This reflected the CFIR Inner Setting—Recipient Centeredness, as respectful interactions and data protection ensured patient dignity in a close-knit community setting. One participant reported:

> *My privacy was respected, and my health information was kept confidential.* [PT01]

These accounts suggest that acceptance of telemedicine was influenced not only by access to a remote doctor but also by the quality of interpersonal mediation surrounding the consultation, including reassurance, understandable communication, and confidence that personal health information would remain private.

Theme 4: Convenience and Perceived Benefits Reinforced Continued Use

Patients consistently emphasized the practical value of receiving care closer to home. This strongly reflected the TAM construct of perceived usefulness, as telemedicine was perceived to reduce travel, time, financial expenditure, and disruption to daily activities. One participant reported:

> *My health improved, and worries reduced as I do not have to go to the doctor physically and can get treatment at the doorstep.* [PT10]

Another emphasized the comparative benefits:

> *Telemedicine helps in avoiding long travelling distances, saves money, time and effort with sufficient care.* [PT08]

These perceived advantages contributed to a strong TAM behavioral intention to continue using the service and to recommend it to others. One participant stated:

> *We will definitely use these services because they come to our doorstep at lower cost and save our time and money.* [PT12]

Furthermore, acceptance extended beyond individual users through organic peer support, reflecting actual system use and community-level diffusion. One patient reported actively supporting hesitant peers:

> *I have helped women and elderly patients who were hesitant to speak on video calls by explaining and supporting them.* [PT01]

This suggests that satisfied patients assumed informal advocacy roles that reinforced community-level adoption.

Theme 5: Technical and Service Limitations Remained Important Constraints

Despite generally positive experiences, patients identified limitations that restricted the completeness and reliability of telemedicine. Network instability sometimes resulted in interrupted audio and blurred video during consultations, highlighting constraints within the CFIR Inner Setting—Information Technology Infrastructure. One participant noted:

> *Sometimes we faced network issues like unstable connectivity, voice breaks, and video blurring during video consultations.* [PT09]

Participants also reported that medicines and certain diagnostic tests were not always available through the telemedicine service, requiring visits to government hospitals. This reflected gaps in local resource availability and the Outer Setting. One participant stated:

> *They do not provide medicines or perform tests for dengue, malaria, blood infection and allergies, for which we have to visit nearby government hospitals, which is a disadvantage.* [PT12]

Patients therefore suggested that the service would be more useful if medicines, injections, and basic investigations were available locally with trained staff:

> *The service would improve if medicines, injections, and basic tests were available locally with trained staff.* [PT08]

Importantly, patients also provided a balanced assessment of the service's operational reliability, reflecting the CFIR Inner Setting—Work Infrastructure. One participant reported:

> *We never faced any major planning or scheduling problems; only occasional delays happened when the network was poor, or doctors were busy.* [PT05]

Patients further recognized the workload pressures on frontline workers and advocated for enhanced institutional support, noting:

> *With proper training, enough staff, and support like medicines and tools, the health workers can manage the work smoothly and help everyone better.* [PT09]

They also valued the responsiveness of the project team to feedback, an essential component of the CFIR Implementation Process—Reflecting and Evaluating, although quicker responses and follow-up were suggested as areas for improvement:

> *The team listens to suggestions and responds well, but a quicker response and follow-up would help.* [PT15]

Theme 6: Patients Viewed Telemedicine as a Useful Addition to Community Health Care

Overall, patients' accounts reflected a positive assessment of telemedicine particularly because it brought medical consultation closer to their homes and reduced the logistical burden of conventional health care seeking. Engaging in the CFIR Implementation Process—Reflecting and Evaluating, one participant summarized this experience:

> *Telemedicine has been very helpful for us as it gives good treatment in the village, saves time and money,*

XSL•FO
RenderX

> *avoids long travel, and makes us feel confident that care is available when we need it.* [PT11]

At the same time, patients' reflections indicate that continued engagement depended on maintaining the human support surrounding the technology and addressing practical limitations, such as connectivity, medicine availability, diagnostic services, staffing, and follow-up. Participants also expressed willingness to remain involved in future discussions and service improvement, reflecting the CFIR Implementation Outcome—Implementability and a sense of shared ownership. One participant stated:

> *I am ready to talk again, and to help if needed in the future.* [PT02]

This willingness to contribute suggests that patients had transitioned from passive recipients to active stakeholders in the telemedicine model.

Discussion

Principal Findings

A primary innovation of this study lies in the empirical validation of the assisted telemedicine model in hard-to-reach terrains. Unlike traditional direct-to-consumer telehealth models that assume a baseline of digital literacy, this study highlights a novel sociotechnical mediation framework where frontline workers (ASHAs, ANMs, and NOs) act as digital health navigators. By combining human cultural mediation with portable, specialized diagnostic tools (such as the Spandan ECG by Sunfox Technologies Pvt. Ltd.), this model overcomes the critical barriers of the digital divide and the lack of physical examination, offering a highly scalable blueprint for universal health coverage in resource-constrained settings. This study provides a comprehensive evaluation of telemedicine implementation within rural, hard-to-reach districts, specifically identifying the sociotechnical factors that facilitate digital adoption among underserved populations. By assessing the efficacy of an assisted model, using frontline health care workers and portable diagnostic tools for real-time vital screening, the findings suggest a potential shift in treatment-seeking behavior compared to traditional face-to-face consultations. This analysis offers valuable insights for optimizing digital health interventions.

Sociotechnical Intermediation and Assisted Adoption Model

The persistent shortage of skilled health care providers in rural India remains a primary obstacle to achieving universal health coverage, with approximately 74% of medical practitioners serving only 28% of the population [15,16]. While the National Rural Health Mission has introduced financial incentives and contractual appointments, a significant gap remains in reaching isolated terrains. A distinguishing feature of this study is the identification of the assisted telemedicine model, where frontline workers act as essential technical and cultural mediators. Unlike previous models that rely on direct patient-to-provider interfaces, our findings reveal an increase in acceptance driven by ASHAs, ANMs, and nurses who bridge the digital divide for patients unfamiliar with screens. This is particularly crucial for women and older patients in hard-to-reach areas who may hesitate to consult male specialists or navigate complex portals [17]. By providing a human connection, the study demonstrates that acceptance is not merely a product of software functionality but of a structured human touch in a system that builds trust and overcomes cultural barriers [18,19].

Clinical Efficacy of Digital Medical Tools and Decision-Making in Remote Care

A key contribution of this study is the evaluation of specialized digital tools, including the portable Spandan ECG (Sunfox Technologies Pvt. Ltd.) for real-time first-level cardiac screening, along with the measurement of vital parameters, such as BP, SpO_2, and heart rate. While telemedicine is often criticized for a lack of physical examination [20], our study reveals a robust workflow where field staff record vitals (BP, SpO_2, and heart rate) and upload photographic evidence of digital devices via chatbots for clinician cross-verification. This protocol significantly enhances diagnostic confidence and data accuracy, a finding that moves beyond generic teleconsultation literature.

Despite these advancements, diagnostic limitations remain in dermatology and emergency care where physical palpation is irreplaceable. However, our findings align with those of large-scale health care systems, showing that sustained digital interaction can improve glycemic control and continuity of care for chronic conditions [21,22]. The efficacy of this model is therefore contingent on the robustness of rural digital infrastructure, such as BharatNet, and the hands-on training of health care workers to manage these sophisticated tools [23,24]. In such environments, the burden of managing chronic conditions shifts to these intermediaries, necessitating robust educational interventions to prevent implementation fatigue and ensure the quality of remote clinical evidence [25,26].

Reconfiguring Treatment-Seeking Behavior and Health Equity

Our study provides empirical evidence of a fundamental shift in treatment-seeking behavior among rural populations. Traditionally, patients in remote Rajasthan or Maharashtra faced prohibitive logistical and financial barriers, often traveling up to 850 km for specialist care. By bringing health care to the "doorstep," this study shows that telemedicine reduces attrition in traditional testing cascades and allows patients to reinvest the time saved into essential economic activities such as farming [27].

This study emphasizes that while telemedicine enhances equity and reduces financial hardship, its success is conditional. Trust building is a critical determinant; repeated technical failures or doctor unavailability can lead to a rapid loss of faith in the system. When functioning reliably, telemedicine acts as a peer-support and counseling platform, fostering treatment adherence. Ultimately, this research suggests that while digital health can bridge the health care divide, it requires addressing underlying gaps in connectivity, staffing, and trust to ensure long-term sustainability and systemic integration [28,29].

XSL•FO
RenderX

Policy Implications for Scalable Digital Health Systems

The findings of this study underscore the need to shift health care policy from "provider-centric" to "mediated-digital" models. For telemedicine to be effectively integrated into the existing public health framework, policy interventions must prioritize formalizing the ASHA and ANM roles as "digital health navigators." Furthermore, to sustain the positive shift in treatment-seeking behavior, future initiatives should focus on strengthening the rural digital infrastructure (BharatNet) and providing standardized, hands-on training for portable diagnostic tools.

Strengths and Limitations

This study's multistakeholder design provides a 360-degree view of the telemedicine ecosystem by integrating the perspectives of MOs, frontline health care workers (nurses and ASHAs or ANMs), and patients themselves. This approach enabled a holistic understanding of how the telemedicine model operates across different levels of the health care hierarchy. Furthermore, the use of the CFIR and TAM frameworks provided a robust theoretical foundation for moving beyond anecdotal evidence, enabling a structured analysis of how capability, motivation, and system design influence digital adoption in resource-limited settings. The inclusion of specific evaluations of portable diagnostic tools, such as the Spandan ECG (Sunfox Technologies Pvt. Ltd.), adds a layer of clinical relevance often missing from broader qualitative digital health studies.

While the study captures in-depth, real-world experiences of patients and frontline health care workers who were actively involved in telemedicine services, the findings are context specific to this implementation setting. The extended implementation period and inclusion of multiple stakeholder groups strengthen the relevance of the findings. Additionally, patients who opted to visit primary health Centerscenters despite the availability of telemedicine services were not included in this study.

Conclusions

This study provides rich qualitative insights into the post-implementation delivery and use of telemedicine in remote areas of Rajasthan. Telemedicine was perceived as acceptable, useful, and supportive of continuity of care by both patients and frontline health care workers when embedded within existing primary health care systems. The shift in treatment-seeking behavior observed offers valuable evidence to support the further integration of digital health into the National Rural Health Mission.

Telemedicine should be viewed not as a secondary substitute for in-person care, but as a robust, complementary system that, when supported by trained mediators and reliable infrastructure, can significantly advance the goal of universal health coverage for India's most vulnerable populations.

Abstract

Background: Poor medication adherence is a critical impediment to effective chronic obstructive pulmonary disease (COPD) management and remains challenging to track in routine care. Digital therapeutic interventions may improve chronic disease management through remote monitoring and patient education. However, most existing digital interventions focus on individual components of disease management, and evidence from longer-term pragmatic randomized controlled trials evaluating integrated digital therapeutics in routine clinical practice remains limited.

Objective: This study aimed to evaluate the effectiveness of a multicomponent digital therapeutic program combining electronic inhaler monitoring (EIM) with behavioral support in improving medication adherence and symptom-related outcomes among patients with COPD prescribed pressurized metered-dose inhalers, and to assess patient engagement and implementation in routine clinical practice.

Methods: In this prospective, open-label, unblinded, randomized controlled trial, patients with COPD prescribed pressurized metered-dose inhalers were enrolled and randomized in a 2:1 ratio to either the intervention group or the control group. All participants received an EIM device to objectively record inhaler use throughout the 24-week study period. Patients in the intervention group also received personalized medication reminders from the EIM, adherence feedback, educational content, and clinician-supported follow-up through an integrated digital management platform based on EIM-derived data, whereas the control group received usual care. The primary outcome was medication adherence over 24 weeks. Secondary outcomes included exacerbations, COPD symptoms, quality of life, and lung function.

Results: A total of 158 participants were randomized, including 106 in the intervention group and 52 in the control group. The median monitoring coverage was 161.5 (IQR 86.3 - 168.0) days during the follow-up period. The self-reported adherence measured using the Test of Adherence to Inhalers showed no significant between-group differences at any follow-up time point. However, the electronically monitored adherence was significantly higher in the intervention group than in the control group (59.5% vs 33.1%, *P*=.009). Adherence declined over time in both groups, decreasing from 85.3% during weeks 0 to 4 to 43.0% during weeks 12 to 24 in the intervention group and from 76.8% to 11.9% in the control group over the same intervals, resulting in a progressively larger between-group difference over follow-up. No significant differences were observed in exacerbations, health-related quality of life, symptom burden, lung function, or mental health outcomes. In an exploratory analysis, a significantly greater proportion of participants in the intervention group achieved the minimal clinically important difference in the COPD Assessment Test score than in the control group (odds ratio 2.21, 95% CI 1.11 - 4.41; *P*=.02).

Conclusions: The multicomponent digital therapeutic program significantly improved objective medication adherence in patients with COPD over 24 weeks. While most clinical outcomes did not differ significantly between groups, the higher proportion of participants achieving a clinically meaningful improvement in the COPD Assessment Test score warrants further investigation.

KEYWORDS

digital therapeutics; chronic obstructive pulmonary disease; COPD; adherence; electronic inhaler monitoring

Introduction

Chronic obstructive pulmonary disease (COPD) is a leading cause of morbidity and mortality worldwide and imposes a substantial burden on health care systems [1-3]. Inhaled pharmacotherapy remains the cornerstone of COPD management. However, suboptimal adherence to inhaled therapy remains highly prevalent and is a major barrier to effective disease control, contributing to an increased risk of exacerbations and a higher symptom burden [4,5]. Adherence is influenced by multiple interrelated factors at the patient, inhaler, and health care provider levels, including age, cognitive and physical abilities, health literacy, behavioral determinants, inhaler complexity and usability, and health care professionals' competency and capacity to provide appropriate inhaler education. The multidimensional nature of these factors highlights the complexity of addressing medication nonadherence in routine COPD care [6,7]. Monitoring adherence to inhaled therapy is also challenging in routine clinical practice. Traditional approaches such as patient self-report and pharmacy refill records are prone to substantial inaccuracies and may overestimate adherence due to recall bias or demonstration of idealized inhaler technique, failing to capture real-world medication use [8].

Recent advances in digital health have introduced digital therapeutic interventions designed to improve chronic disease management through behavioral support, remote monitoring, and patient education. In respiratory diseases, digital therapeutic programs typically include digital inhaler platforms and mobile health apps [9,10]. Digital inhaler monitoring devices attached to inhalers, which can objectively record medication use, provide automated reminders, and enable personalized adherence feedback, have been shown to improve adherence, enhance disease control, and reduce health care burden in chronic airway diseases in previous trials. However, most existing studies have focused on asthma and have evaluated individual components, such as adherence reminders, inhaler monitoring, or telehealth consultations. In COPD, few interventions have combined objective inhaler medication monitoring with patient self-management tools and remote clinician monitoring within a single platform [11-17]. Evidence from randomized trials evaluating integrated digital therapeutic programs in COPD remains limited, particularly in real-world clinical settings.

To address this gap, we developed a multicomponent digital therapeutic program integrating an electronic inhaler monitoring (EIM) device with a mobile management app and conducted the DIGI-COPD (Effectiveness of a Multi-Component Digital Therapeutic Program on Inhaled Medication Adherence in COPD) trial to evaluate whether this intervention could improve inhaled medication adherence and clinical outcomes in patients with COPD.

Methods

Study Design

This prospective, open-label, unblinded pilot randomized trial was conducted at the respiratory outpatient clinic of China-Japan Friendship Hospital, Beijing, China. Patients were recruited through physician recommendation during outpatient visits or self-referral in response to advertisements posted in the outpatient area. All potential participants underwent eligibility screening by the research team, which included review of medical records and spirometry results obtained within the previous 6 months, and were invited to an introductory meeting to review the study details and ask questions. Those who met the eligibility criteria and agreed to participate provided written informed consent, and baseline information was then collected.

At baseline, demographic and clinical characteristics, medical and smoking history, and exacerbation history of the participants were collected. All participants completed the modified Medical Research Council (mMRC), COPD Assessment Test (CAT), St George's Respiratory Questionnaire for Chronic Obstructive Pulmonary Disease (SGRQ-C), Patient Health Questionnaire-9 (PHQ-9), Generalized Anxiety Disorder-7 (GAD-7), and Test of Adherence to Inhalers (TAI) questionnaires [18]. Trained assessors evaluated participants' inhaler technique using the metered-dose inhaler score [19] and performed physical examination (height, weight, waist and hip circumference, blood pressure, resting pulse rate, and oxygen saturation). Follow-up assessments were conducted at weeks 4, 12, and 24. This study was reported in accordance with the CONSORT (Consolidated Standards of Reporting Trials) guidelines (Checklist 1).

Participants and Randomization

Patients were eligible if they (1) fully understood and were willing to sign the written informed consent, (2) were local residents diagnosed with COPD by a physician, (3) were aged 40 years or older, (4) were prescribed a metered-dose inhaler as long-term treatment, and (5) were able to use a smartphone app after training. COPD diagnosis was confirmed during screening by reviewing medical records and spirometry results obtained within the previous 6 months, including a documented postbronchodilator FEV_1/FVC (forced expiratory volume in 1 second/forced vital capacity) <0.70.

Participants were randomized in a 2:1 ratio (intervention:control) stratified into 2 strata according to baseline CAT score (<10 vs ≥10) using a computer-generated randomization sequence. Neither researchers nor participants were blinded to group assignment.

Sample Size

The initial sample size was estimated based on a previous questionnaire conducted by our research group, in which 258 of 737 (35.01%) patients with COPD were classified as having good adherence. Assuming a 15% absolute increase in the

XSL•FO
RenderX

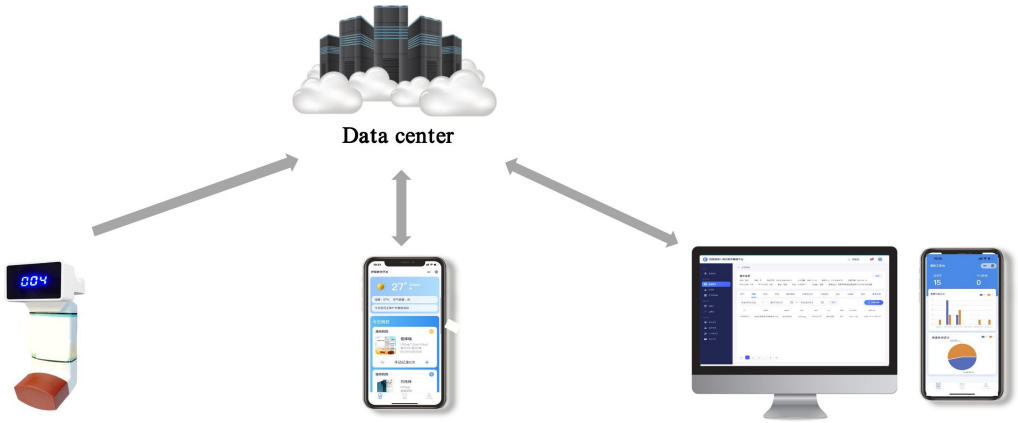
proportion of patients with good adherence in the intervention group at week 24, with an α of 0.05 and 90% power, the estimated sample size was 400 participants in the intervention group and 200 in the control group, allowing for approximately 20% loss to follow-up. However, as this was a pilot study, recruitment was conducted within a predefined study period and was constrained by available funding and research personnel.

Intervention

The multicomponent digital therapeutic program comprised an EIM and a remote management platform for both patients and clinicians, supporting both patient self-management and clinician oversight (Figure 1A).

The same EIM was compatible with any pressurized metered-dose inhaler (pMDI) device regardless of whether the prescribed regimen was dual bronchodilation therapy, consisting of a long-acting beta-agonist and a long-acting muscarinic antagonist, or triple therapy, consisting of a long-acting beta-agonist, a long-acting muscarinic antagonist, and inhaled corticosteroids, as it was externally attached to the pMDI. It passively recorded each inhalation event with a time stamp and transmitted the data via a cellular network to the patient's mobile phone. The adherence data were then synchronized with the patient app and, with patient consent, transmitted to a cloud-based data center. A built-in buzzer delivered audible reminders at scheduled dosing times for the intervention group. The device emitted a daily "heartbeat" signal to confirm proper functioning (Figure 1B). The safety of the device has been tested by the China Mobile Electronic Component Testing Center.

The management app enabled patients to visualize adherence data through graphs and tables, generate monthly adherence reports, complete a daily COPD Exacerbation Recognition Tool (CERT) diary [20], and record vital signs. Additional features included accessing step counts and weather information, setting medication reminders, self-reporting of CAT and mMRC scores, and viewing educational content. Clinicians could remotely monitor patient data via mobile or desktop devices, identify high-risk individuals, and initiate timely, individualized communication (Figure 1C).



Participants in the intervention group received an EIM with a reminder paired with a mobile management app, which delivered personalized reminders and adherence feedback based on EIM data. They were instructed to complete a daily CERT diary and record vital signs in the app, which displayed trends and generated monthly reports on adherence, physiological parameters, and symptoms. Participants in the control group received an EIM without reminders, solely for recording inhaler use. They also had the app installed solely to relay EIM data, without access to adherence feedback or educational content, or clinician access for review. Both groups continued to receive usual care from their physicians at each scheduled follow-up visit.

Outcome Measures

The primary outcomes were the proportion of participants with good adherence (TAI score ≥46) and the average daily adherence (calculated as the ratio of actual inhalations over prescribed inhalations) recorded by EIM during the study period. The TAI questionnaire assessed self-reported adherence during the preceding week and was administered at baseline and each scheduled follow-up visit. Adherence was continuously recorded by the EIM and summarized as the average daily adherence over the corresponding follow-up intervals (weeks 0 - 4, 4 - 12, and 12 - 24). The secondary outcomes included CAT score, mMRC score, PHQ-9 score, GAD-7 score, lung function, and the number of exacerbations between groups.

Statistical Analysis

All 158 randomized participants were included in the intention-to-treat analysis for primary and secondary outcomes. Continuous data were presented as mean with SD or median with IQR and analyzed using 2-tailed Student *t* tests or Mann-Whitney *U* tests as appropriate, and categorical data were presented as numbers with percentages and analyzed using the chi-square test or Fisher exact test. Two-sided tests were used throughout, and a value of $P<.05$ was considered statistically significant. Statistical analyses were conducted using IBM SPSS (version 29.0.1.0) for data management and descriptive statistics, R (version 4.4.2; R Foundation for Statistical Computing) for linear mixed-effects modeling and advanced analyses, and GraphPad Prism (version 10.4.1) for data visualization.

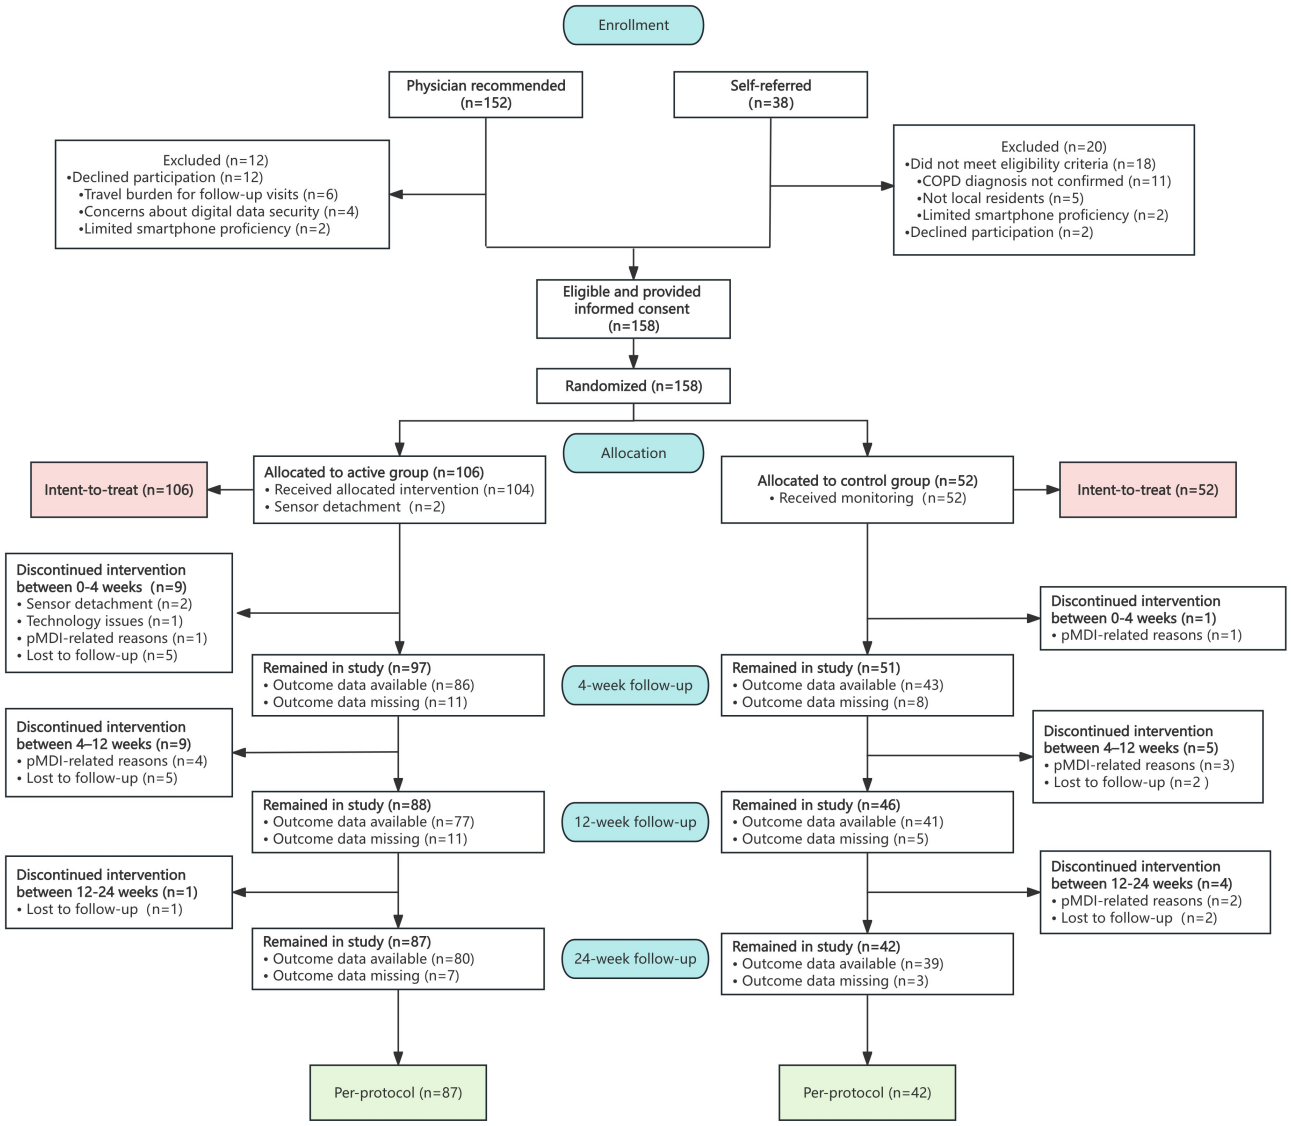
The primary outcome was analyzed using a linear mixed-effects model, with follow-up adherence measurements as the dependent variable, and group, time, and their interaction as fixed effects. A random intercept was included to account for within-participant correlation, and an unstructured covariance matrix was used for repeated measures over unequally spaced visits. Secondary outcomes were analyzed as follows: acute exacerbations using negative binomial regression; lung function and SGRQ scores using linear mixed models (after the Levene test indicated heterogeneity of variance, $P=.046$); and PHQ-9, GAD-7, mMRC, and CAT scores using linear mixed models. All models were adjusted for corresponding baseline values.

Subgroup analyses for mMRC and CAT scores examined potential effect modification by including group, time, subgroup, and their 3-way interaction terms in linear mixed models, with a significance threshold of $P<.10$ for interaction terms and not adjusted for multiple comparisons because it was considered exploratory. For other secondary outcomes, potential effect modification was examined using linear regression models that included group, subgroup, and their interaction term.

Ethical Considerations

The study was approved by the China-Japan Friendship Hospital Ethics Committee (approval number 2022-KY-129) and was conducted in accordance with the Declaration of Helsinki (1975, as revised in 2008) and applicable Chinese regulations. Written informed consent was obtained from all participants before enrollment. Participant data were deidentified prior to analysis and stored on secure password-protected servers accessible only to authorized study personnel. Participants did not receive any financial compensation for participation. As appreciation for their time and contribution, participants were offered 1 complimentary lung function test at the 24-week follow-up and permanent access to the EIM device and integrated digital management platform after study completion, regardless of study group.

Results



Participant Characteristics

Participant recruitment was conducted between March 6, 2023, and January 31, 2024, and follow-up was completed on July 17, 2024. In the context of the COVID-19 pandemic during the recruitment period, a total of 158 eligible participants provided written informed consent by the end of the predefined study period, with 106 assigned to the intervention group and 52 to the control group. Participants continued their physician-prescribed inhaled therapy throughout the study. A total of 19 participants in the intervention group and 10 in the control group withdrew during the study, of whom 11 discontinued due to pMDI cessation (Figure 2). Among the remaining participants, 2 in the intervention group (1 switched from dual bronchodilation to triple therapy and 1 switched from triple therapy to dual bronchodilation) and 1 in the control group (switched from dual bronchodilation to triple therapy) had their inhaled regimens switched by their physicians during the study, without changing the pMDI device. No other changes in inhaled therapy were documented.

Baseline characteristics were similar between groups. A total of 129 (81.6%) participants were male, and the mean age was 64 (SD 8.30) years. The mean number of acute exacerbations in the previous year (including mild, moderate, and severe) was 0.95 (SD 1.34), and 72.2% (n=114) of participants were classified as having good adherence based on the self-reported TAI questionnaire (Table 1).

Adherence (Primary Outcome)

Except for 2 participants in the intervention group with sensor detachment, 156 participants had at least one valid daily adherence record. The median number of valid monitoring days was 161.5 (IQR 86.3 - 168.0). TAI scores were collected at 3 follow-up visits, with response rates of 82.9% (n=131; 88 intervention vs 43 control), 75.3% (n=119; 77 vs 42), and 79.1% (n=125; 85 vs 40). No statistically significant differences were observed between groups in the proportion of participants classified as having good TAI adherence at any visits (Table 2). Linear mixed-effects modeling indicated that neither the main effect of group (*P*=.64), time within group (*P*=.051), nor the group × time interaction (*P*=.66) reached statistical significance.

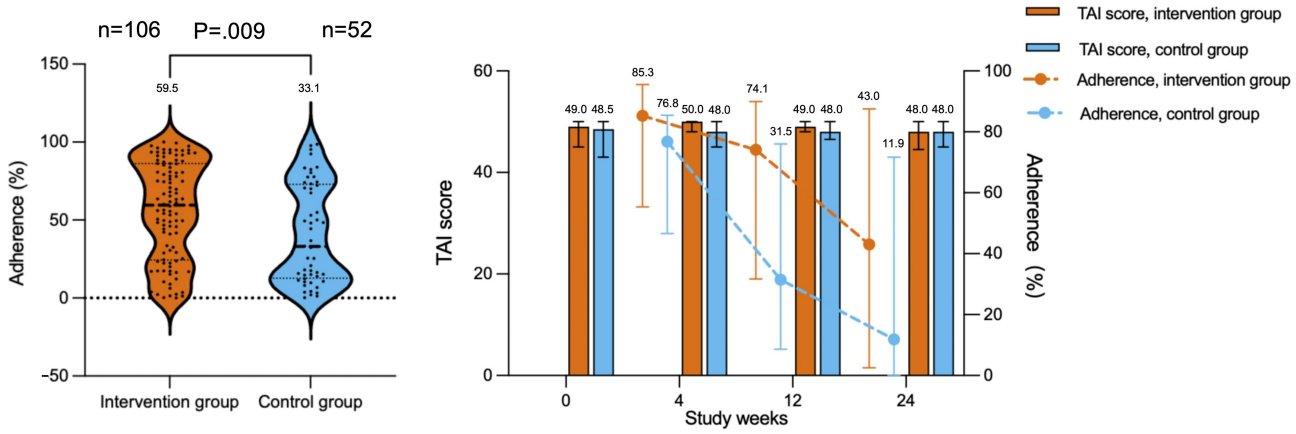
	Intervention group (n=106)	Control group (n=52)	*P* value	Intervention group (n=106)	Control group (n=52)	*P* value	Intervention group (n=106)	Control group (n=52)	*P* value
TAI[a] score ≥46, n (%)	92 (86.8)	41 (78.8)	.20	88 (83.0)	42 (80.0)	.73	77 (72.6)	38 (73.1)	.95
Electronic adherence[b] (%), median (IQR)	85.27 (55.36 - 95.54)	76.79 (46.65 - 85.49)	.04[c]	74.11 (31.70 - 89.96)	31.47 (8.59 - 76.00)	.004[c]	43.01 (2.53 - 87.57)	11.90 (0.00 - 71.73)	.03[c]



[a]TAI: Test of Adherence to Inhalers. TAI was assessed at weeks 4, 12, and 24, with each assessment reflecting self-reported adherence during the preceding 1 week.

[b]Electronic adherence was continuously recorded by the electronic inhaler monitoring and averaged over the corresponding intervals (weeks 0 - 4, 4 - 12, and 12 - 24).

[c]Statistically significant values (*P*<.05).

Over the 24-week study period, the electronically measured medication adherence was significantly higher in the intervention group than the control group (59.52% vs 33.11%; *P*=.009; Figure 3A). The between-group difference increased over time: 85.27% vs 76.79% during weeks 0 to 4 (*P*=.04), 74.11% vs 31.47% during weeks 4 to 12 (*P*=.004), and 43.01% vs 11.90% during weeks 12 to 24 (*P*=.03; Table 2 and Figure 3B). The proportion of days with 100% of prescribed inhalations taken was also higher in the intervention group than in the control group (31.5% vs 16.7%; *P*=.007). Linear mixed-effects modeling revealed a significant main effect of group (*P*=.004) and time within groups (*P*<.001), whereas the group × time interaction did not reach statistical significance (*P*=.24).

Figure 3. Adherence (median and IQR) over 24 weeks. (A) Violin plot of electronically measured adherence averaged over 24 weeks. (B) Test of Adherence to Inhalers (TAI) score at baseline, weeks 4, 12, and 24 and electronically measured adherence averaged over weeks 0 to 4, 4 to 12, and 12 to 24.

COPD Assessments (Secondary Outcomes)

No statistically significant between-group differences were observed for SGRQ-C scores, PHQ-9 score, GAD-7 score, mMRC grade, CAT score, or lung function at week 24 (Table 3).

No significant between-group differences were detected for continuous CAT and mMRC scores either; however, longitudinal analyses showed significant changes over time in both groups (main effect of time, both *P*<.001). Compared with baseline, the mean change in CAT score was −7.09 (95% CI −10.55 to −3.62) at week 4,−8.60 (95% CI −12.03 to −5.17) at week 12, and −8.72 (95% CI −12.18 to −5.25) at week 24 (all *P*<.001). The mean change in mMRC grade was −0.59 (95% CI −0.97 to −0.22), −0.87 (95% CI −1.25 to −0.50), and −0.93 (95% CI −1.32 to −0.54) at weeks 4, 12, and 24 (Figure 4). Exploratory generalized estimating equation analysis showed that the intervention group had higher odds of achieving the minimal clinically important difference in CAT scores over follow-up (odds ratio 2.21, 95% CI 1.11 - 4.41; *P*=.02), with a significant group × time interaction (*P*<.001). However, no individual follow-up time point remained statistically significant after Bonferroni correction for multiple comparisons (Figure 5).

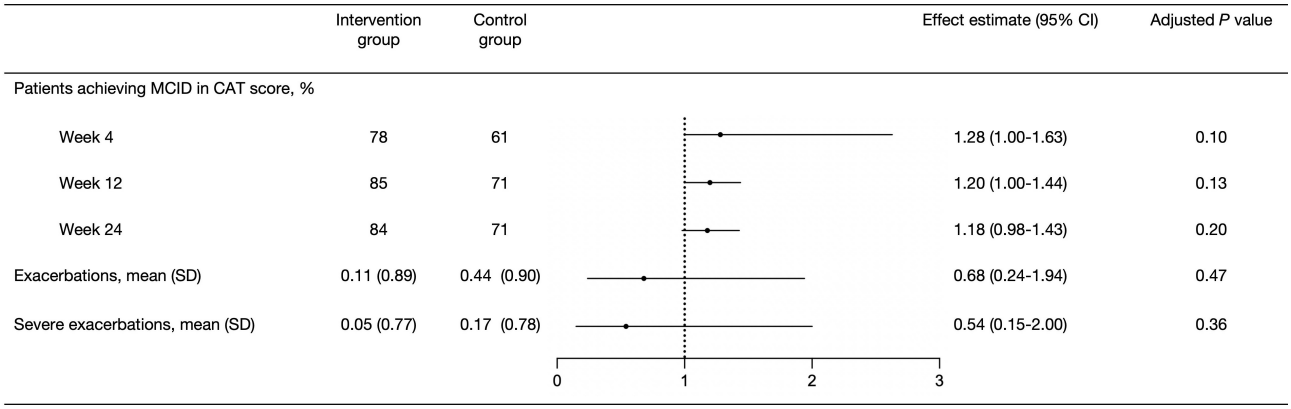

Figure 4. (A) COPD Assessment Test (CAT) and modified Medical Research Council (mMRC) scores over 24 weeks. Mean scores at weeks 4, 12, and 24. (B) Mean reduction from baseline at weeks 4, 12, and 24. COPD: chronic obstructive pulmonary disease; MCID: minimal clinically important difference.

During the 24-week follow-up, the mean number of moderate-to-severe exacerbations was 0.11 (SD 0.89) in the intervention group and 0.44 (SD 0.90) in the control group, with 8 (7.5%) and 10 (19.2%) participants, respectively, experiencing at least one event. After adjustment for baseline exacerbation history, negative binomial regression showed no statistically significant between-group differences in moderate-to-severe exacerbations (incidence rate ratio 0.68, 95% CI 0.24 - 1.94; *P*=.47) or severe exacerbations (incidence rate ratio 0.54, 95% CI 0.15 - 2.00; *P*=.36; Figure 5). Baseline exacerbation history was a strong predictor of subsequent events, with each additional exacerbation at baseline associated with a 3.69-fold higher risk of exacerbation at 24 weeks (risk ratio 3.69, 95% CI 2.37 - 5.75; *P*<.001).

RenderX

Figure 5. Effect of the intervention on COPD Assessment Test (CAT) and exacerbations. COPD: chronic obstructive pulmonary disease; MCID: minimal clinically important difference.

Post Hoc Analyses (Exploratory Outcomes)

To further explore potential factors associated with adherence and clinical outcomes, we conducted post hoc exploratory correlation analyses, subgroup analyses, and multivariable regression.

Exploratory Pearson correlation analysis of the main outcome and baseline information showed that the average adherence of the intervention group was positively correlated with age (Pearson correlation coefficient, r=0.31; P=.03) and the presence of an acute exacerbation in the past year (r=0.225, P=.02), whereas no significant correlation was observed in the control group (r=0.049; P=.28).

Exploratory subgroup analyses for secondary outcomes were conducted according to age (<60 vs≥60 y), sex, GOLD (Global Initiative for Chronic Obstructive Lung Disease) stage, baseline TAI score (<46 vs ≥ 46), baseline mMRC grade (<2 vs≥2), history of exacerbations (0 vs ≥1), and electronic adherence (<80% vs ≥80%). For acute exacerbations at week 24, potential effect modification was observed by mMRC grade (P=.02), GOLD stage (P=.03), and adherence (P=.045). Patients with mMRC ≥2, GOLD stage 3, or adherence ≥80% showed greater reductions with the intervention (mean differences −0.68, 95% CI −1.10 to −0.26; P=.002; −1.75, 95% CI −2.72 to −0.78; P<.001; and −0.79, 95% CI −1.32 to −0.26; P=.004) compared with the respective comparator subgroups. No significant differential response pattern was observed for the other subgroups.

To identify characteristics associated with high adherence (adherence ≥80%), we performed univariate logistic regression analyses using baseline variables. Eleven variables were associated with high adherence (P<.20 or area under the curve [AUC]>0.6). Among these, GOLD group (AUC=0.631; P=.03) and BMI (AUC=0.614; P=.03) exhibited the highest predictive ability. A multivariable logistic model incorporating these 2 variables yielded a mean cross-validated AUC of 0.611 (SD 0.046) after 5-fold cross-validation, with a sensitivity of 31.7% and a specificity of 83.3%.

Engagement and Satisfaction

The EIM demonstrated satisfactory performance in tracking medication adherence, but the completion rates of actively reported measures via the patient mobile app were notably low. During the 168-day follow-up period, the average completion rate for the daily CERT diary was only 7.0% (SD 23.7%), accompanied by a 2.3% (SD 16.5%) completion rate for body temperature logs and 5.3% (SD 23.2%) for oxygen saturation recordings. This finding may be attributed to the predominantly older adult study population, who generally exhibit lower proficiency and frequency in smartphone use. These results underscore the need for future digital therapeutic tools to incorporate more automated and user-friendly symptom monitoring modalities that minimize reliance on active patient input. Despite the low engagement with active app features, the end-of-study user satisfaction survey revealed favorable attitudes toward the digital therapeutic software. Among the 158 participants, 101 (63.9%) reported being “very satisfied” with the device, and 98 (62.0%) rated it as very convenient to use.

Adverse Events

No adverse events were reported during the study.

Discussion

This randomized controlled study provides evidence supporting the feasibility and preliminary effectiveness of a digital therapeutic intervention in Chinese patients with COPD. Participants receiving the digital therapeutic intervention integrating EIM with a digital management platform demonstrated significantly higher objectively measured inhaler adherence compared with electronic monitoring alone over the 24-week study period. However, improvements in clinical outcomes, including exacerbations, health-related quality of life, symptoms, and lung function, did not reach statistical significance. These findings suggest that digital therapeutics may be effective in improving medication-taking behavior, whereas larger and longer studies are needed to determine their impact on clinical outcomes.

Our results are consistent with previous studies in populations with asthma, in which electronic monitoring revealed adherence gaps not captured by patient self-report, emphasizing the value of objective, technology-enabled assessment in chronic airway disease management [21-24]. Despite the older age profile of patients with COPD relative to typical asthma cohorts, our results suggest that older adult patients can effectively engage with digital inhaler technologies. However, we observed a gradual decline in adherence over time despite digital support,

XSL•FO
RenderX

suggesting that maintaining long-term behavioral change remains challenging. This finding highlights the value of regular, in-person clinical follow-up alongside digital tools to maintain long-term adherence [25]. Thus, we conducted exploratory telephone follow-ups in December 2025 to provide preliminary information regarding the longer-term implementation of the intervention. A total of 128 patients participated in this follow-up, of whom 91 continued to use inhaled medications, and 87 reported daily adherence in the past week. Future studies with predefined long-term follow-up protocols are needed to determine whether digital therapeutics can produce sustained behavioral and clinical benefits.

Notably, electronically measured adherence and self-reported adherence showed marked divergence. This discrepancy may be partly attributable to differences in the assessment windows: TAI assessed self-reported adherence during the preceding 1 week at prespecified follow-up visits, whereas EIM continuously captured inhaler use and summarized adherence over longer follow-up intervals. However, the magnitude of the observed difference suggests that the assessment window alone does not fully account for the divergence. Self-reported adherence is susceptible to recall bias and social desirability bias, as patients may overestimate their medication use during clinic visits. In addition, TAI includes items assessing medication-taking behavior as well as behavioral and perceptual factors related to nonadherence, whereas EIM primarily captures only the occurrence and timing of inhaler use. These findings highlight the complementary value of both objective monitoring and subjective self-report in assessing adherence and evaluating adherence-promoting strategies.

After adjusting for baseline values, the intervention group showed numerically better outcomes in exacerbation frequency, symptom scores, and lung function, though none reached statistical significance. These findings likely reflect the study being powered for adherence rather than clinical outcomes, moderate baseline disease severity, low exacerbation rates, and a relatively short 24-week follow-up. Additionally, CAT and mMRC scores improved over time in both groups. Given that both groups received regular follow-up and study participation itself may increase disease awareness and self-management behaviors, these improvements may partly reflect nonspecific effects, including increased attention or Hawthorne effects, rather than the isolated effect of the digital therapeutic intervention. Future studies incorporating attention-matched control conditions, factorial intervention designs, and longer follow-up are needed to better determine the independent contribution of specific digital therapeutic components. Although no statistically significant differences were observed in mental health measures, slightly higher PHQ-9 and GAD-7 scores in the intervention group suggest a need to monitor psychological burden associated with digital interventions. Previous literature indicates that higher eHealth literacy can improve quality of life, sleep quality, and resilience but may also be associated with increased anxiety and depression, highlighting the need for careful monitoring of potential adverse effects on mental health [26].

Subgroup analysis suggested that the effect of the digital therapeutic on acute exacerbations may be more pronounced in patients with greater symptom burden, more severe disease, and higher adherence. The observed reduction in acute exacerbations among patients with higher adherence suggests that improved medication adherence may represent one potential pathway through which digital therapeutics could influence clinical outcomes [27]. However, these findings should be interpreted cautiously, given the exploratory nature of the analyses, and require confirmation in future adequately powered studies. Multivariable regression analysis showed that the baseline GOLD grade and BMI modestly predicted high adherence. This indicates that, in clinical practice, adherence cannot be reliably predicted based solely on basic physiological or disease severity indicators. Dynamic factors during the intervention, such as patient engagement, social or family support, digital literacy, or behavioral patterns, may be stronger determinants of adherence than static baseline characteristics. Therefore, future research should integrate multidimensional assessments to better capture the complexity of medication adherence behavior and to elucidate the mechanisms underlying responses to digital therapeutics, including how specific functional designs influence patient behavioral change and how factors such as patients' behavioral patterns, cognitive characteristics, and technology acceptance modulate intervention outcomes. By integrating behavioral science theories with digital technologies to develop more targeted intervention modules, we may further enhance the clinical efficacy of digital therapeutics and facilitate their evolution from a "one-size-fits-all" approach toward precision and personalized health management [28,29].

This study has several limitations. First, this was a single-center study recruiting through physician recommendation and patient self-referral. This may have introduced selection bias as individuals who agreed to participate were predominantly urban and educated and may have been more motivated and receptive to digital health technologies. In addition, the open-label design resulted in unequal levels of participant interaction between groups, and improvements in subjective outcomes may have been partly influenced by increased attention, behavioral reinforcement, or Hawthorne effects. These factors may limit the generalizability of the findings and may also have attenuated between-group differences in secondary clinical outcomes, as participants may have represented a more engaged subgroup of the population with COPD. Second, the EIM used is compatible only with pMDI devices and provides temporal reminders without guidance on inhalation technique. Third, the reliance on smartphone use among mostly older adult participants may exacerbate health inequities in underserved populations. Fourth, low completion rates of actively reported symptom diaries limited early detection of exacerbations. In addition, because the CERT diary was available only to the intervention group, the 2 groups differed with respect to the availability of systematic symptom data between scheduled visits. This differential access reflects the intended design of the digital therapeutic program; however, the very low completion rates in the intervention group suggest that the actual impact of this differential monitoring on clinical management may have been limited. Nonetheless, we cannot exclude the possibility that even sporadic symptom reports contributed to clinical awareness and earlier intervention in some cases. Fifth, the 6-month follow-up may be insufficient to capture long-term behavioral

XSL•FO
RenderX

or clinical outcomes. Finally, health care resource use and cost-effectiveness data were not collected, precluding economic evaluation.

In summary, this study demonstrates that a digital therapeutic program can significantly improve inhaler adherence among Chinese patients with COPD, even in older adults, while the translation into short-term clinical benefit remains uncertain. These findings support the feasibility of digital therapeutics and highlight the need for longer-term studies incorporating automated, user-friendly monitoring and targeted behavioral strategies to maximize clinical impact. Future research should focus on identifying patient subgroups most likely to benefit and integrating behavioral science with digital health design to optimize personalized COPD management [7,28,29].

Abstract

Background: Achilles tendon rupture significantly affects patient mobility and quality of life. Postoperative rehabilitation is critical to regain ankle function, strength, and return to activity. Home-based digital rehabilitation has emerged as an accessible alternative to traditional clinic-based physiotherapy; however, high-quality evidence comparing these approaches after Achilles tendon repair remains scarce.

Objective: This randomized controlled trial aimed to evaluate whether a home-based digital exercise program (DEP) is noninferior to clinic-based face-to-face physiotherapy for restoring ankle range of motion (ROM), strength, patient-reported outcomes, and cost-effectiveness following open Achilles tendon repair.

Methods: Between August 2020 and June 2023, 200 adult patients (mean age 36.5, SD 5.0 years; n=135, 67.5% male) undergoing open Achilles tendon repair at 2 trauma centers were randomly assigned (1:1) to either a 12-week home-based DEP group (n=100) or traditional 12-week clinic-based physiotherapy (CP group, n=100) in Shanghai. The digital program was delivered through an online app, providing instructional videos, real-time telecommunication, daily exercise tasks, and monitoring of adherence. The clinic-based group received weekly physiotherapist-supervised sessions. The primary outcome was ankle ROM at 12 weeks postoperatively. Secondary outcomes included plantarflexion strength at 0° and 12°, heel-rise index and height, Achilles Tendon Total Rupture Score (ATRS), Victorian Institute of Sport Assessment–Achilles scores, adherence, patient satisfaction, cost-effectiveness, and adverse events assessed at 6, 12, and 24 weeks. Mixed-effects models were applied for intention-to-treat analyses, and sensitivity analyses were performed in the per-protocol population.

Results: At 12 weeks postoperatively, the DEP group was noninferior to the CP group for ankle ROM: mean difference (DEP–CP=−0.08°) with a 1-sided 95% CI lower bound of −2.16°, exceeding the noninferiority margin of −5° (P<.001). Secondary clinical outcomes at 12 weeks showed no material between-group differences, and after Holm-Bonferroni adjustment for multiplicity across secondary endpoints, no comparison reached statistical significance. Standardized effects at 12 weeks were trivial to small (|Cohen d|≤0.16). Patients rated DEP higher for convenience and ease of access in unadjusted analyses, but these did not remain significant after multiplicity correction (adjusted P=.08). DEP significantly reduced total rehabilitation costs vs CP (CNY 59,260.77 vs 68,432.80), with economic analyses favoring DEP. Adverse events were comparable between groups (DEP: 18, 18% patients and CP: 22, 22% patients; P>.05). The exchange rate used in this study was 1 US $=6.90 Chinese Yuan.

Conclusions: The home-based DEP following Achilles tendon repair provided comparable clinical outcomes to traditional physiotherapy while significantly improving cost-effectiveness. These findings support the broader adoption of tele-supervised digital rehabilitation as a safe and effective alternative.

KEYWORDS

achilles tendon rupture; digital exercise program; home-based rehabilitation; physiotherapy; cost-effectiveness

Introduction

Achilles tendon rupture is one of the most common tendon injuries of the lower extremity, typically affecting physically active adults in midlife during sports activities [1]. This injury carries a substantial burden, as it often causes sudden pain, loss of function, and prolonged disability, with a profound impact on patients' mobility and quality of life [2]. Management of acute ruptures can be surgical (open or minimally invasive repair) or nonsurgical; however, in either case, a structured rehabilitation program is critical to optimize outcomes. Early functional rehabilitation has been shown to reduce complications and improve recovery speed compared with prolonged immobilization [1,3]. Evidence from meta-analyses indicates that rehabilitative strategies emphasizing early weight-bearing and ankle mobilization after Achilles repair lead to higher patient satisfaction and faster return to sport without increasing the risk of adverse events [3]. As a result, current best practice encourages supervised, progressive rehabilitation to restore ankle range of motion (ROM), muscle strength, and functional performance after tendon healing.

Despite advances in surgical techniques, patients often experience significant deficits for months or even years after Achilles tendon injury. Studies have found that even at 1 - 2 years post surgery, many individuals exhibit persistent deficits in calf muscle strength and endurance and incomplete recovery of ankle biomechanics [2,4]. These long-term impairments underscore the importance of effective rehabilitation programs to maximize functional outcomes. Standard postoperative rehabilitation for Achilles repair usually involves in-person physiotherapy sessions focusing on incremental tendon loading, gait retraining, and exercises to improve plantarflexion strength and ankle ROM. Outcomes are typically tracked using objective measures, such as ankle ROM goniometry, isometric and isokinetic plantarflexion strength testing, and single-leg heel-rise tests, as well as patient-reported outcome scores. Common validated instruments include the Achilles Tendon Total Rupture Score (ATRS) and the Victorian Institute of Sport Assessment–Achilles (VISA-A) questionnaire, which assess symptoms and functional abilities in daily activities and sports. These metrics frequently reveal that without comprehensive rehabilitation, patients may experience persistent functional deficits and lower satisfaction [2,4]. Thus, there is a strong rationale for interventions that enhance rehabilitation adherence and effectiveness after Achilles tendon repair.

In recent years, digital health and telemedicine have opened new avenues for delivering rehabilitation outside of the traditional clinic setting. Mobile health technologies, such as smartphone apps, online platforms, and videoconferencing tools, allow patients to perform prescribed exercises at home under remote guidance. Telerehabilitation programs have grown particularly prominent, accelerated by the COVID-19 pandemic, which necessitated alternatives to face-to-face therapy. Such programs typically provide instructional exercise videos, progress tracking, and sometimes real-time feedback or virtual coaching. These home-based digital exercise solutions aim to increase accessibility and patient engagement in rehabilitation, especially for those facing barriers to frequent clinic visits. Early studies in other orthopedic populations have demonstrated the potential of telerehabilitation: after knee and hip replacements, home-based telerehabilitation has yielded recovery outcomes comparable to conventional in-person physiotherapy [5]. In a 2017 systematic review of postorthopedic surgery rehabilitation, strong evidence supported telerehabilitation as an effective alternative in total joint arthroplasty, with similar improvements in function and pain as standard care [5]. Telehealth approaches can also confer practical advantages, including convenience, reduced travel time, and greater cost-effectiveness. A recent meta-analysis reported that telerehabilitation can provide equivalent or improved health outcomes while lowering overall costs and enhancing patient satisfaction and adherence to exercise programs [6]. These findings suggest that well-designed digital rehab interventions can meet the therapeutic needs of patients without the logistical constraints of clinic-based therapy.

However, despite the growing adoption of digital rehabilitation, there remains a lack of high-quality evidence specifically for Achilles tendon rupture rehabilitation. Rehabilitation after Achilles repair poses unique challenges, balancing tendon protection with early mobilization, and it is unclear whether a purely home-based app-guided regimen can match the effectiveness of hands-on physiotherapist supervision. No large randomized controlled trials have definitively compared remote digital rehabilitation to traditional in-person rehabilitation after Achilles tendon repair. Some related research in chronic Achilles conditions is promising [7], but the postoperative scenario has distinct demands and outcome measures. Given the importance of restoring ankle ROM, plantarflexion strength, and functional performance after Achilles tendon surgery, it is crucial to determine whether at-home digital programs can deliver these results on par with standard care. This study was designed to address this gap by evaluating a 12-week home-based digital exercise program (DEP) in comparison with a conventional 12-week physiotherapist-supervised rehabilitation program. By using a noninferiority randomized controlled trial, the aim is to rigorously test whether the digital home program is not worse than clinic-based rehabilitation in improving ankle mobility and functional outcomes, while also examining differences in cost-effectiveness.

Methods

Study Design and Setting

We conducted a 2-center, parallel-group randomized controlled trial with a noninferiority design to compare a 12-week home-based DEP with a clinic-based physiotherapy program for patients after open repair of Achilles tendon rupture. The trial took place at Shanghai Sixth People's Hospital and Shanghai Xinhua Hospital, 2 tertiary academic centers, from August 2020 to June 2023. Eligible patients were randomized in a 1:1 ratio to the digital or conventional rehabilitation arm.

XSL•FO
RenderX

We adhered to CONSORT (Consolidated Standards of Reporting Trials) [8] guidelines for trial reporting.

Participants

Participants were recruited on the day following their emergency admission to the 2 participating hospitals. One of the coordinators screened the eligibility of participants and explained all potential harms and benefits to eligible participants before written informed consent was obtained. The inclusion and exclusion criteria are provided in Textbox 1.

Textbox 1. Inclusion and exclusion criteria.

Inclusion criteria:

- Adults (18-65 years) who were scheduled to undergo open surgical repair for an acute, complete Achilles tendon rupture.
- Surgery was planned within 2 weeks after injury.
- Participants had to commit to the rehabilitation program, follow-up visits, and be willing to provide written informed consent.
- Access to a smartphone and basic proficiency with the app.

Exclusion criteria:

- Participants with a history of prior Achilles tendon rupture, chronic corticosteroid use, or uncontrolled diabetes (due to potential impaired healing), or any significant comorbidity affecting the lower limb (eg, neuropathy or severe arthritis).
- Coexisting inflammatory arthritis, neurological conditions, or other lower-limb musculoskeletal disorders.
- Uncontrolled comorbidities (eg, diabetes and heart disease) that could interfere with recovery.
- Participants unable to participate in exercise (due to other injuries or contraindications) or unable to use the smartphone app or attend follow-ups.

Intervention

All participants received standard postoperative care in the initial phase: a posterior splint or boot with the ankle in plantar flexion for 2 weeks, followed by protected weight-bearing as tolerated in a walking boot up to 6 weeks. At approximately 2 - 3 weeks postsurgery (after suture removal and when acute pain subsided), participants began the assigned intervention program.

Home-Based DEP Group

Participants randomized to the experimental group received a 12-week exercise program delivered via the “Joymotion” (Shanghai Medmotion Medical Management Co, Ltd) smartphone app. This app provides daily interactive exercise modules with video demonstrations and audio instructions for each exercise. Participants were assigned step-by-step daily rehabilitation tasks, which they performed at home while following a Physiotherapeutic Achilles-Specific Exercise program (details in Multimedia Appendix 1). The app included features for logging completed exercises and tracking progress over time. Participants could receive feedback and motivational prompts through the app, and the system flagged any missed sessions. A licensed physiotherapist remotely monitored each participant’s adherence and performance through the app’s dashboard and supervised the progression of exercises weekly, adjusting the difficulty or adding new exercises as appropriate. The therapist and participant communicated via in-app messaging or phone or video calls if issues arose, ensuring expert oversight despite the home setting. Physiotherapists maintained a high level of supervision intensity for the DEP group. They responded to participant queries within approximately 2 hours and provided feedback after each exercise session, with additional weekly summary feedback to guide the participant’s progression. We monitored intervention fidelity using the app’s dashboard metrics, including the average response time to participant messages and the frequency of feedback provided, to ensure the digital program was delivered consistently as designed. This interactive telerehabilitation approach was designed to mirror the content of standard physiotherapy in a convenient home format.

Clinic-Based Physiotherapist Rehabilitation (CP Group)

Patients in the control group underwent a conventional rehabilitation regimen of supervised physical therapy at participating hospitals and 2 other assigned physical therapy clinics in Shanghai. This consisted of weekly in-clinic physiotherapy sessions (Physiotherapeutic Achilles-Specific Exercise program) for 12 weeks postoperative. In each session, a physiotherapist guided the patient through a standardized Achilles tendon rehab protocol, including joint mobilization, stretching, strengthening of the gastrocsoleus, balance and proprioception exercises, and functional training. The program was progressive: early sessions emphasized a gentle ROM and isometric strength exercises, advancing to resistance exercises, tendon loading drills, and functional activities in later weeks, in line with typical Achilles rehab guidelines. Between these weekly appointments, control patients were instructed in a home exercise program to perform on their own at least 5 days per week. However, unlike the digital group, they did not receive daily interactive guidance or monitoring between visits.

We recorded any deviations from the protocol or cointerventions. Compliance was encouraged in both groups, and adherence data were collected via app logs for the digital group and attendance records for the clinic group. Both groups were managed by experienced physiotherapists. We monitored adverse events throughout the program in both groups.

Outcomes

The primary outcome was the ankle ROM of the affected side at 12 weeks postoperatively. We defined this as the active ROM in dorsiflexion (movement from the neutral ankle position to maximum dorsiflexion) measured in degrees with a goniometer. For consistency, measurements were taken with the patient supine and knee extended (to standardize gastrocnemius tension). We also recorded plantar flexion ROM, but dorsiflexion limitation was of primary interest given its functional importance after Achilles repair. At the 12-week endpoint, a blinded assessor measured the ankle ROM of both the injured and contralateral limbs; the primary analysis focused on the between-group difference in injured-side ROM.

Secondary outcomes included functional, strength, patient-reported, and economic measures, assessed at baseline (at the beginning of the intervention) and at 6-, 12-, and 24-week post surgery:

1. Plantarflexion muscle strength: isometric plantarflexion strength of the affected calf was measured at 2 ankle positions, 0° (neutral ankle) and 12° of dorsiflexion, using a dynamometer. Strength was recorded in Newton-meters (Nm) as the peak torque the patient could generate in a 3-second maximal voluntary contraction [9]. These 2 positions were chosen to assess strength across the ankle's range (neutral vs a dorsiflexed, more elongated tendon position). Any strength deficit compared to the contralateral side was calculated as a percentage.
2. Heel-rise index and height: we evaluated calf muscle endurance and power using the single-leg heel-rise test. Patients performed single-leg heel raises to exhaustion on both the injured and uninjured sides. The heel-rise index was calculated as the ratio of the affected limb's performance relative to the healthy side [10]. Performance was quantified as the total work or height × repetition product achieved; specifically, we counted the number of consecutive heel raises and measured the maximum heel-rise height (in cm) achieved by the affected limb and then compared it to the contralateral limb. A heel-rise index of 100% indicates full recovery (equal performance to the uninjured side), whereas lower percentages indicate residual deficits [10]. We also reported heel-rise height (the maximum height of a single heel rise on the injured side) as a separate outcome, since it reflects calf muscle function and tendon elasticity.
3. The ATRS: a validated patient-reported outcome for Achilles tendon rupture recovery. The ATRS consists of 10 items assessing symptoms and activity limitations [11]. Each item is scored 0 - 10, and total scores range from 0 to 100, with 100 indicating no symptoms or functional limitations (best outcome) and 0 indicating maximal impairment. ATRS is reliable, valid, and responsive for patients with Achilles rupture and is a common primary outcome in Achilles rehabilitation studies [11].
4. The VISA-A questionnaire: originally developed for Achilles tendinopathy, we included this 8-item instrument to gauge Achilles tendon pain and function as another patient-reported metric. VISA-A scores also range from 0 to 100 (100=asymptomatic, full function). It covers pain during activity, function in daily living, and the ability to participate in sports [12]. While VISA-A is not specific to acute rupture, we hypothesized that it would capture complementary information on tendon function and any tendinopathy-like symptoms during recovery.
5. Cost-effectiveness: it was assessed by calculating the incremental cost-effectiveness ratio (ICER) between the DEP and clinic-based physiotherapy (CP) groups. Costs included intervention-related costs, health care resource usage, and productivity losses due to absenteeism and presenteeism. Data were collected from hospital records and patient-reported logs. Cost-effectiveness analysis was conducted based on the outcomes at 12 weeks of follow-up (at the end of the intervention).

All outcomes were measured by assessors blinded to group allocation (described below in the "Randomization, Allocation, and Blinding" subheading). The primary endpoint for efficacy was at 12 weeks postoperative (end of the program), with longer-term outcomes at 24 weeks used to observe maintained effects or any late differences.

Sample Size Calculation

This trial was powered to evaluate the noninferiority of the digital rehabilitation program compared to standard physiotherapy in terms of 12-week ankle ROM. No definitive minimal clinically important difference for ankle dorsiflexion ROM after Achilles repair has been established in the literature [13]. Based on clinical judgment and prior data on variability, we set a noninferiority margin (Δ) of 5 degrees of ankle ROM. A difference of 5° was deemed the largest loss of ROM that would be considered clinically unimportant to patients. Notably, postoperative studies have found that by 6 months after Achilles repair, side-to-side dorsiflexion differences are on average near 0° (with a SD of 3°). Thus, a 5° deficit is larger than normal variability yet small enough to be functionally negligible. This choice is also consistent with the principle that the noninferiority margin should be smaller than the expected minimal clinically important difference for the outcome. Using a 1-sided type I error of .05 (α) and power (1–β) of .80, we calculated the required sample size per group for 2 independent means in a noninferiority design and estimated approximately 50 patients per group to be needed to detect noninferiority [8,14,15]. To account for potential dropouts or loss to follow-up (we anticipated 40% attrition by 24 weeks), we aimed to recruit 85 patients in each group.

Randomization, Allocation, and Blinding

Participants were randomized in a 1:1 ratio to either the digital rehab group or the clinic-based rehab group. An independent researcher (not involved in recruitment or assessment) generated the random allocation sequence using a computer program. We used variable block sizes of 4 and 6 to ensure concealment and balanced group sizes. The allocations were sealed in opaque, sequentially numbered envelopes. After a participant was enrolled and completed all baseline assessments, the next envelope in sequence was opened to reveal the assignment. This ensured allocation concealment until the point of assignment. Randomization was not stratified (since all participants had

XSL•FO
RenderX

similar baseline characteristics) and thus was purely random within blocks.

Due to the nature of the interventions, it was not possible to blind the participants or treating physiotherapists to group assignments. Participants obviously knew whether they were using an app at home or attending in-person therapy sessions. However, we implemented measures to blind outcome assessments and analyses to reduce bias. All outcome evaluations at 6, 12, and 24 weeks were performed by a research assistant blinded to the patient's group at the outpatient department of 2 participating hospitals. This assessor was not involved in delivering the rehabilitation to either group. Participants were instructed not to reveal details of their rehabilitation program or discuss their therapy during assessment visits. The assessor recorded the outcomes without knowledge of which intervention was received. Furthermore, the trial statistician was kept blinded to group labels when analyzing primary outcomes; groups were coded anonymously until after the primary analysis was complete. By maintaining assessor and analyst blinding, we aimed to minimize measurement and analytical bias. Participants themselves were aware of their treatment, so participant blinding was not possible, but they were informed of the importance of unbiased assessment.

Statistical Analysis

The primary outcome was the between-group difference in ankle ROM at 12 weeks. We prespecified a noninferiority margin $\Delta=-5°$ and tested $H: \mu^{DEP-CP} \leq -5°$ vs $H_1: \mu^{DEP-CP} > -5°$ using a 1-sided test at $\alpha=.05$. Mixed-effects models with fixed effects for group, time point at 6, 12, and 24 weeks, and group × time, and a random intercept for participants were used. Analyses followed a prespecified intention-to-treat (ITT) framework as primary and a per-protocol (PP) framework as sensitivity. ITT used linear mixed-effects models that incorporated all available observations under a missing-at-random assumption and retained participants in their randomized groups regardless of adherence. PP used a complete-case approach that included only participants who completed all scheduled follow-ups. Missingness occurred only at the visit level because a missed follow-up meant all variables for that visit were absent. There was no item-level missingness within attended visits.

For secondary outcomes at Week 12, we present 2-sided 95 % CIs and *P* values from the same mixed-effects model, and Holm-Bonferroni control for multiplicity across the Week 12 clinical outcomes (familywise $\alpha=.05$); 6 and 24 weeks are presented descriptively. For the effect size, Cohen *d* at Week 12 was used as the standardized mean difference using the pooled SD from the ITT group. Patient satisfaction and acceptability items were treated as a separate hypothesis family; their *P* values were adjusted for multiplicity using the Holm-Bonferroni procedure (familywise $\alpha=.05$). PP analyses served as sensitivity checks.

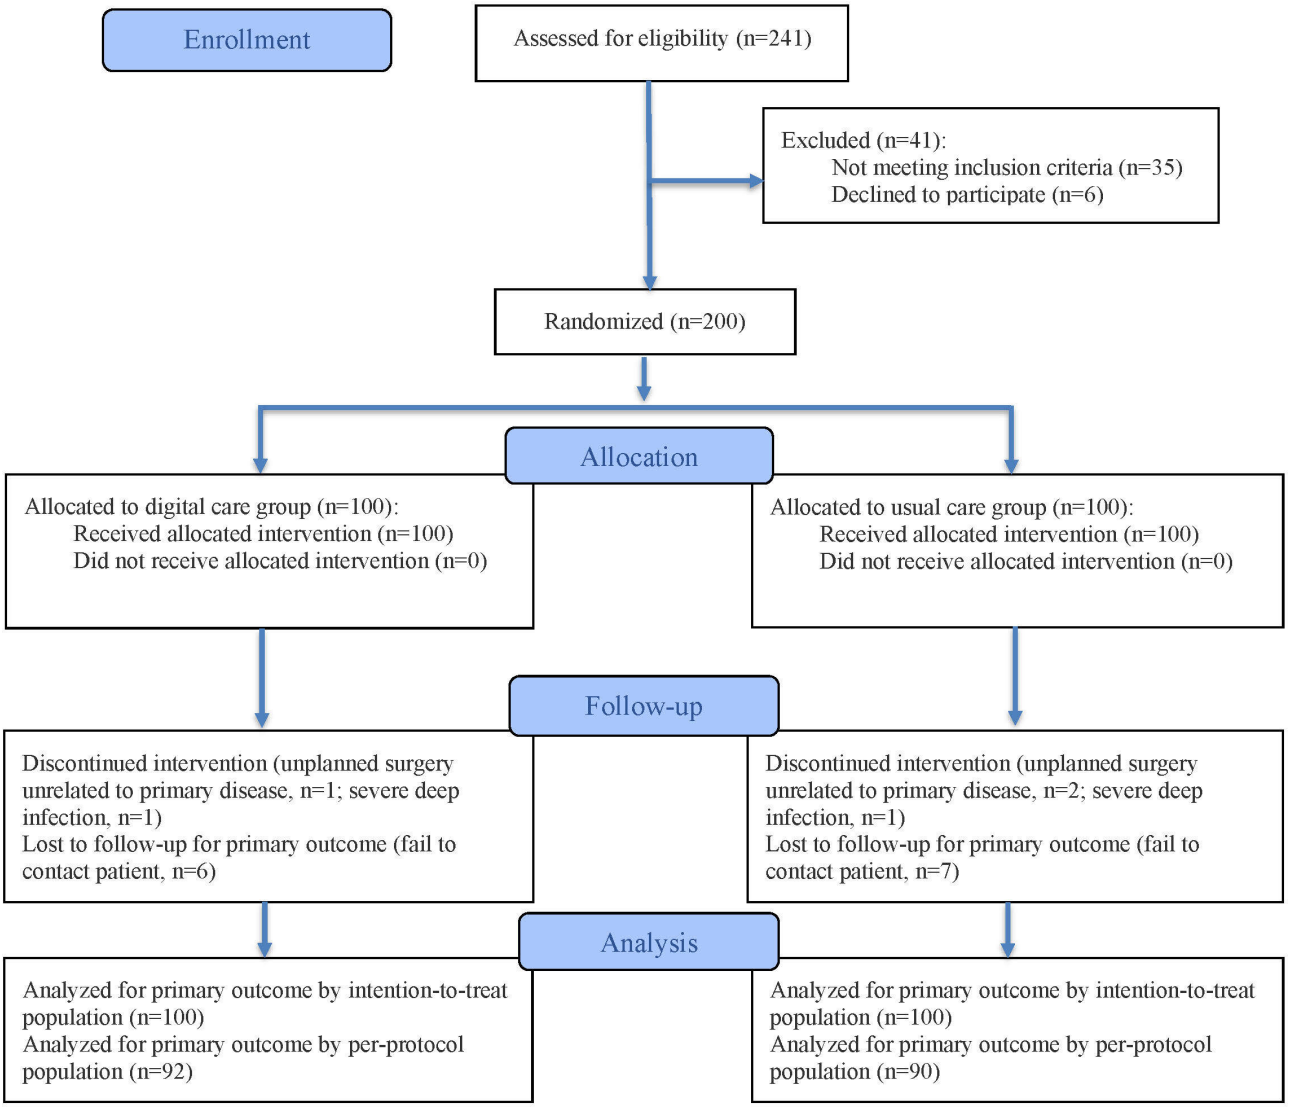
For cost-effectiveness analysis, total costs for each participant were calculated, and the difference in mean cost between groups was evaluated. In a cost-effectiveness plane, we will compare cost vs effectiveness for the 2 strategies. If the digital program were cheaper and with no worse outcome, it would be a dominant strategy. Otherwise, an ICER (cost per unit of benefit) will be computed. Nonparametric bootstrap methods (10,000 resamples) will be used to estimate uncertainty in the ICER and to construct cost-effectiveness acceptability curves.

We aimed to minimize missing data by thorough follow-up, but any remaining missing outcome data were handled under the ITT framework. The mixed-effects models can accommodate missing values under a missing-at-random assumption by using all available data for each participant. Baseline variables and other outcomes would be used in a chained equations imputation model to predict missing values, and analyses would be repeated on imputed datasets to ensure results are robust.

Data analysis was conducted using SPSS (version 28.0; IBM Corp) and R (version 4.2.2; the R Core Team). The trial results will be reported according to the CONSORT guidelines [8], including the noninferiority margin and CIs for primary outcomes.

Ethical Considerations

Ethical approval was obtained from the Institutional Review Board of Shanghai Sixth People's Hospital (IRB no 2020-KY-089[K]), and this approval was also acknowledged by Shanghai Xinhua Hospital. All procedures were conducted in accordance with the Declaration of Helsinki. Written informed consent was obtained from all participants before enrollment, and participants were informed of their right to withdraw from the study at any time. All personal data were anonymized (deidentified) to ensure participant privacy and confidentiality. No financial or other compensation was provided to participants for their participation in this study.



Results

Participants

We evaluated 241 patients with acute Achilles tendon injury, and 200 were randomized. The flowchart of our study is specified in Figure 1 (92 participants in the DEP group and 90 participants in the CP group completed the entire follow-up investigation). The baseline characteristics were comparable between the DEP and CP groups. Most participants were male, with 71 out of 100 (71%) in the DEP group and 64 out of 100 (64%) in the CP group (*P*=.21), with a mean age of approximately 37 and 36 years, respectively (*P*=.08). Average BMI was similar between groups (DEP: 25.0 kg/m^2; CP: 25.0 kg/m^2; *P*=.25). Education levels and insurance types were evenly distributed between the groups (*P*=.55 and *P*=.66, respectively). Smoking status did not significantly differ between groups; 17 out of 100 (17%) in the DEP group and 21 out of 100 (21%) in the CP group were smokers (*P*=.47). Injury distribution (right vs left side) was also balanced (*P*=.57). Time from rupture to surgery averaged around 3.5 days in both groups (DEP: mean 3.55, SD 0.63; CP: mean 3.59, SD 0.58; *P*=.60; Table 1).

Primary and Secondary Outcomes

The primary and secondary outcomes changes (Table 2) and mixed-effects model estimates across time (Table 3) are presented. The primary analysis supported noninferiority of DEP for ankle ROM at 12 weeks. The estimated mean difference was −0.081°(DEP – CP); the 1-sided 95% CI lower bound was −2.16°, which is above the noninferiority margin of −5° (*P*<.001). In the PP population, results were consistent (difference −0.218°; 1-sided 95% CI lower bound −2.38°; *P*<.001; Table 4).

Table . Primary outcome (ankle range of motion [ROM]) noninferiority analysis at 12 weeks. Difference is digital exercise program (DEP) – clinic-based physiotherapy (CP); noninferiority margin (Δ)=−5°.

Population	Mean difference (°)	One-sided 95% CI lower bound (°)	Noninferiority *P* value
Intention-to-treat population	−0.081	−2.16	<.001
Per-protocol population	−0.218	−2.38	<.001

At Week 12, unadjusted model estimates showed no significant between-group differences for plantarflexion strength (0° and 12°), heel-rise index, heel-rise height, ATRS, or VISA-A. After Holm-Bonferroni correction across these 6 secondary clinical endpoints, none was significant (all adjusted *P*≥.99).

To contextualize magnitudes, Week 12 Cohen *d* values indicated trivial to small effects: ankle ROM d=−0.16; plantarflexion strength 0° d=−0.02; plantarflexion strength 12° d=−0.03; heel-rise index d=+0.04 ; heel-rise height d=−0.01; ATRS d=+0.13; VISA-A d=−0.06 (positive d favors DEP; Table 2). We summarized participant-level and visit-level missingness by group and time point in Table S1 in Multimedia Appendices 1 and 2.

Cost-Effectiveness Analysis

The average total cost per participant was significantly lower in the DEP group compared to the CP group during the 24-week postoperative period (CNY 59,260.77 vs CNY 68,432.80;

XSL•FO
RenderX

difference=−9172.03; *P*<.001). The exchange rate used in this study was 1 US $=6.90 Chinese Yuan. Major cost savings for the DEP group arose from rehabilitation costs (difference=−3932.65; *P*<.001), primary care expenses (difference=−1820.62; *P*<.001), secondary care costs (difference=−2245.19; *P*<.001), medication (difference=−1073.66; *P*<.001), and transportation (difference=−960.10; *P*<.001). Incremental cost-effectiveness analysis showed negative ICER values for primary and secondary outcomes, indicating cost savings without clinically relevant differences between groups. Specifically, the ICER for ankle ROM was CNY 113,234.94 per additional unit improvement, highlighting significant cost savings without sacrificing clinical effectiveness. Similar patterns were observed for secondary outcomes, including ATRS (ICER=−31,737.13) and VISA-A (ICER=−98,623.98), reinforcing the economic advantage of the digital rehabilitation program (Tables 5 and 6).

Table . Average total cost per patient in the digital exercise program (DEP) group and clinic-based physiotherapy (CP) group during the 24 weeks after the postoperative period.

Cost category (CNY[a])	DEP[b] group (n=100), mean (SD)	CP[c] group (n=100), mean (SD)	*P* value

Patients' Adherence

In the DEP group, participants completed a mean of 28.5 (SD 2.6) of 30 educational modules and attended 5.7 (SD 1.1) of 6 scheduled video consultations (metrics specific to the digital program; not applicable to the CP group). At 24 weeks, patient ratings were high in both groups. Although mean scores favored DEP for convenience (mean 4.6, SD 0.5 vs mean 4.4, SD 0.7) and ease of use and access (mean 4.4, SD 0.7 vs mean 4.2, SD 0.5), these differences were not significant after Holm-Bonferroni adjustment within the satisfaction or acceptability family (both adjusted P=.08). Helpfulness (mean 4.7, SD 0.4 vs mean 4.7, SD 0.5; adjusted P≥.99) and communication with the physiotherapist (mean 4.8, SD 0.4 vs mean 4.7, SD 0.4; adjusted P=.16) were similarly high and comparable between groups (Table 7).

Table . Patients' adherence to treatment (intention-to-treat population).

Outcome measure	DEP[a] group (n=100), mean (SD)	CP[b] group (n=100), mean (SD)	Adjusted P value

[a]DEP: digital exercise program.

[b]CP: clinic-based physiotherapy.

[c]N/A: not applicable.

Adverse Events

The incidence of adverse events was similar between the DEP and CP groups: 18 out of 100 (18%) patients in the DEP group vs 22 out of 100 (22%) patients in the CP group experienced an adverse event. Most adverse events were related to therapy, primarily ankle pain (DEP: 8 and CP: 10) and swelling (DEP: 6 and CP: 5). Muscle strain occurred equally (2 per group). Serious adverse events were rare, occurring in 3 out of 100 (3%) patients in each group, including deep infections (DEP: 1 and CP: 1) and unrelated surgeries (DEP: 1 and CP: 2). One patient in the DEP group withdrew because of relocation. No substantial differences in safety profiles emerged, suggesting comparable tolerability and safety of both rehabilitation programs (Table 8).

[a]DEP: digital exercise program.

[b]CP: clinic-based physiotherapy.

[c]Four patients sustained gastrocnemius muscle strain during exercise with minor consequent symptoms.

[d]Three patients developed superficial infection and eventually healed with conservative treatment.

[e]Patients with serious adverse events were automatically withdrawn from the study.

Discussion

Principal Findings

This randomized controlled trial demonstrated that the home-based DEP was noninferior to traditional clinic-based physiotherapy for patients following open Achilles tendon repair. At the primary endpoint, ankle ROM showed no significant differences between groups, affirming the effectiveness of the digital rehabilitation approach. Similarly, no meaningful differences emerged across secondary outcomes, including plantarflexion strength, heel-rise tests, and patient-reported outcomes, at all time points assessed (6, 12, and 24 weeks). Importantly, the DEP strategy achieved these clinical results at significantly lower costs, with average savings of approximately CNY 9172 per patient compared to the conventional approach. Incremental cost-effectiveness analyses further indicated that DEP delivered equivalent or improved cost-effectiveness across all measured outcomes. Additionally, adherence to rehabilitation was notably high in the digital group, where participants reported greater convenience and ease of use compared to face-to-face rehabilitation. Adverse events and serious adverse events were infrequent and evenly distributed between the 2 groups, suggesting comparable safety profiles. Collectively, these findings suggest that a structured digital home rehabilitation program can effectively substitute clinic-based physiotherapy after Achilles tendon repair, offering a safe, cost-effective, and patient-friendly alternative.

Our noninferiority analysis using a 1-sided 95% CI lower bound confirmed that DEP is not inferior to CP for restoring ankle ROM at 12 weeks. Importantly, standardized effect sizes were uniformly small ($|d| \leq 0.16$), emphasizing that between-group differences were not only statistically nonsignificant after multiplicity control but also clinically negligible in magnitude. Furthermore, multiple-adjusted analyses of secondary endpoints showed no clinically relevant advantages for CP over DEP. While unadjusted patient-reported convenience and access ratings favored DEP, these did not meet family-wise significance after correction and should be interpreted as exploratory.

XSL•FO
RenderX

A high-quality randomized controlled trial on acute Achilles tendon rupture rehabilitation found that a home-based digital rehabilitation program produced clinical outcomes equivalent to conventional in-clinic physiotherapy. Patients in the digital rehab group achieved similar ankle ROM, calf muscle strength, and patient-reported outcome measures as those attending standard physiotherapy, indicating noninferiority of the telehealth approach. This finding is consistent with prior evidence in related conditions, for example, a noninferiority trial in chronic Achilles tendinopathy reported no worse pain or functional outcomes with telehealth-only or hybrid care compared to all in-person treatment [7]. Such results suggest that when rehab protocols are well-designed and supervised remotely, patients can attain comparable functional recovery to traditional face-to-face therapy.

Our trial's results align with broader Achilles rupture rehabilitation evidence, emphasizing that rehabilitation protocols, rather than the setting, drive outcomes. Past research shows that early functional rehabilitation is critical for optimal recovery after Achilles repair. For example, whether managed operatively or nonoperatively, patients who undergo an accelerated rehab program (early weight-bearing and mobilization) attain excellent strength, ROM, and return-to-activity outcomes [16]. Willits et al [16] demonstrated that nonoperative treatment with an aggressive rehab protocol yielded strength and functional scores equivalent to surgical repair, highlighting rehab's importance in tendon healing. In practice, many components of Achilles rehab (joint mobilizations, progressive loading exercises, and balance training) can be instructed and progressed remotely. A recent small study even found that an unsupervised, home-based exercise program after Achilles repair achieved high VISA-A scores and no increase in complications compared to traditional supervised therapy [17]. These findings reinforce that, as long as evidence-based rehabilitation principles are followed, including protection in early healing and progressive loading to restore tendon capacity, outcomes after Achilles rupture can be excellent with either clinic or home-based guidance. The digital model simply provides a different delivery mechanism for the same key interventions, and the trial confirms it can do so without compromising efficacy.

Growing evidence in other musculoskeletal conditions bolsters the trial's implications. In total joint arthroplasty, multiple studies have shown telerehabilitation to be comparable to standard outpatient rehabilitation for restoring function. A comprehensive meta-analysis of 11 randomized controlled trials in posttotal knee replacement patients found no significant differences in pain reduction or functional improvement between telehealth and in-person rehabilitation, with telerehabilitation yielding similar gains in walking ability, strength, and ROM [18]. Notably, remote programs often come with lower health care usage and cost. Tsang et al [18] reported that telerehabilitation after knee replacement significantly reduced hospital visits and was more cost-effective than usual care. Likewise, technology-assisted rehabilitation after hip or knee arthroplasty has been shown to improve pain and mobility outcomes on par with or better than usual care, partly by enabling more frequent exercise and immediate feedback through apps or video coaching [19]. Beyond postsurgical care, tele-physiotherapy has proven effective in chronic orthopedic conditions. For instance, in knee and hip osteoarthritis and tendinopathies, real-time video- or phone-based rehabilitation produces pain relief and functional gains equivalent to face-to-face therapy [7,19]. Systematic reviews consistently conclude that telerehabilitation is a safe and effective modality for musculoskeletal rehabilitation, with outcomes in pain, strength, and quality of life similar to traditional care across diverse conditions [7,19].

Importantly, some studies suggested that telehealth models can confer additional advantages, such as greater exercise adherence and empowerment. Patients often become more actively involved in self-management when guided remotely, which can enhance long-term exercise habits. However, clinicians implementing telerehabilitation should ensure proper patient selection and education. Key success factors include an initial in-person assessment when needed, clear exercise instructions (via videos or mobile apps), and regular follow-up to maintain accountability. When these conditions are met, the literature strongly supports that digital rehabilitation matches conventional physiotherapy in outcomes for Achilles tendon repair and beyond, offering a convenient alternative without loss of efficacy [18,19].

Interactive telerehabilitation may improve exercise adherence. In a randomized trial after total knee arthroplasty, patients using a guided telehealth platform had significantly higher adherence to prescribed exercises than the usual-care group [20]. The engaging digital interface and at-home convenience can motivate patients to complete rehabilitation exercises regularly.

Overall, patient satisfaction with telerehabilitation is high when implemented properly. During the COVID-19 pandemic, both patients and physiotherapists reported positive experiences with telehealth musculoskeletal care [21]. Patients often appreciate the flexibility and reduced travel burden, and many find remote coaching effective for guidance and feedback. That said, some individuals may miss hands-on contact; addressing patient education and ensuring a user-friendly technology experience are important for maintaining satisfaction.

Clinical Implication of the Study

Our cost-effectiveness analysis confirmed that the DEP intervention was a dominant strategy, providing equivalent effectiveness at a significantly lower cost compared to the clinic-based physiotherapy program. This study has significant clinical implications, indicating that home-based digital rehabilitation can effectively substitute traditional in-clinic physiotherapy following Achilles tendon repair. Clinicians can confidently implement structured telerehabilitation programs, which provide comparable clinical outcomes with additional benefits such as cost savings, convenience, and high patient adherence. Particularly, patients with geographic, logistical, or time constraints may benefit substantially from remotely supervised rehabilitation. Health care systems could leverage digital rehabilitation solutions to enhance resource allocation efficiency and reduce health care costs without compromising clinical quality. Moreover, physiotherapists can expand their service delivery through digital platforms, improving patient

XSL•FO
RenderX

engagement, continuity of care, and accessibility to expert guidance. However, careful patient selection and initial training remain essential to optimize telehealth outcomes, underscoring the necessity for ongoing professional education in digital rehabilitation practices.

Strength and Limitation

This study's strengths include its rigorous randomized controlled trial design, adequate sample size based on a clear noninferiority margin, and comprehensive assessment of both clinical and economic outcomes. Adherence and satisfaction were meticulously monitored, enhancing practical insights into patient acceptability of digital rehabilitation. However, limitations must be acknowledged. First, blinding participants and therapists was inherently impossible, potentially introducing performance bias. Second, follow-up was relatively short; thus, longer-term outcomes remain uncertain. Third, generalizability may be restricted, as the study design focused predominantly on younger, technology-proficient patients. Fourth, the use of the VISA-A score, a scale originally validated for chronic tendinopathy, has inherent limitations in acute rupture patients [13,22]. Some VISA-A items (eg, 30-minute walking endurance) are not feasible in early postoperative rehabilitation, making the score insensitive to early improvements [13,22]. Moreover, VISA-A changes do not necessarily reflect structural tendon healing, and the instrument is generally less responsive to recovery progress in acute ruptures compared to the ATRS [11]. We included the VISA-A as a complementary patient-reported measure of tendon-related symptoms, but we interpret its findings alongside objective outcomes (ankle ROM and calf strength) for a more comprehensive assessment [11]. Given our cohort's relatively young mean age and requirement for smartphone use, older adults and those with limited digital literacy were underrepresented. These groups often face barriers to telerehabilitation (eg, limited internet access and difficulty using smartphone interfaces), so the generalizability of DEP to these populations is uncertain. Finally, despite rigorous adherence monitoring, actual exercise intensity and fidelity to prescribed techniques in home settings were not objectively quantified, possibly influencing rehabilitation outcomes.

Conclusion

Home-based digital exercise after Achilles tendon repair was clinically noninferior to traditional clinic-based physiotherapy, providing similar functional outcomes, safety, greater patient convenience, adherence, and significant cost savings. These findings support broader adoption of structured telerehabilitation programs, offering effective, accessible, and patient-centered postoperative care. Further research should evaluate long-term outcomes and applicability across diverse patient populations.

Acknowledgments

We sincerely thank all the patients who participated in this study. The authors also confirm that no generative artificial intelligence (AI) tools (such as ChatGPT) were used in the writing of this manuscript.

Abstract

Background: Remote patient monitoring (RPM) is recommended for hypertension control. However, less is known about short-term responses of hypertension to RPM and which program components are most important for hypertension control.

Objective: This study aimed to evaluate the association between frequency of blood pressure monitoring, nurse monitoring, and their combination and hypertension control within 3 months.

Methods: This retrospective cohort study was conducted among a convenience sample of 1464 patients with hypertension enrolled in the Brook Remote Care RPM program who sought care at any of the 68 participating primary care clinics in New York or Massachusetts, United States, between 2021 and 2023. Patients with at least 3 blood pressure measures for 70% of the weeks they were in the program were defined as having adequate readings. Brook nurses monitored patients from certain clinics, whereas clinic nurses monitored other patients. Hypertension control was defined as a weekly average blood pressure of less than 140/90 mm Hg. Generalized linear models with a binomial specification and log link were used to estimate the prevalence ratio (PR) and 95% CI of the mutually adjusted associations between adequate blood pressure readings and Brook nurse monitoring, as well as their combination with hypertension control, at 4, 8, and 12 weeks, adjusted for patient age and sex.

Results: At weeks 4, 8, and 12, patients with adequate readings had 10% (PR=1.10, 95% CI 1.02-1.20), 12% (PR=1.12, 95% CI 1.04-1.20), and 15% (PR=1.15, 95% CI 1.07-1.24) higher prevalence of hypertension control than patients with lower frequencies of readings, respectively. Brook nurse monitoring was associated with 16% (PR=1.16, 95% CI 1.07-1.27), 6% (PR=1.06, 95% CI 0.99-1.15), and 8% (PR=1.08, 95% CI 1.00-1.16) higher prevalence of hypertension control at weeks 4, 8, and 12, respectively, compared to clinical staff monitoring. The combination of adequate readings plus Brook nurse monitoring was associated with 26% (PR=1.26, 95% CI 1.11-1.44), 17% (PR=1.17, 95% CI 1.05-1.31), and 27% (PR=1.27, 95% CI 1.12-1.43) higher prevalence of hypertension control at weeks 4, 8, and 12, respectively, compared to an inadequate number of blood pressure readings and not receiving Brook nurse monitoring.

Conclusions: This is the first study to compare outcomes for RPM patients using clinical nurse monitoring and independent staff monitoring. This study represents a contribution to the literature on clinical outcomes for RPM patients with a focus on short-term, rather than longer-term, hypertension control, evaluation of nurse monitoring conducted by Brook Health compared to clinical staff, and the joint association of monitoring frequency and Brook nurse monitoring on hypertension control. Our study findings suggest that both frequency of monitoring and specialized nurse monitoring improve hypertension control within 3 months of program enrollment. The combination of higher monitoring frequency and Brook nurse monitoring may serve as a cost-effective approach to hypertension control in high-risk populations that overcomes the limitations of clinical care staff.

remote patient monitoring; RPM; hypertension control; nurse monitoring; hypertension; engagement

Introduction

In the United States, the prevalence of hypertension in the adult population is 48%, and only 22% achieve hypertension control with a blood pressure of less than 140/90 mm Hg [1]. Patients with hypertension incur approximately US $2000 higher medical expenditures than their counterparts without hypertension, accounting for a total health care cost of US $130 billion [2]. While hypertension may contribute to premature mortality, patients can be treated, and progression can be prevented to achieve hypertension control.

The World Health Organization's guidelines on the treatment of hypertension in adults recommend telemonitoring and community- or home-based self-care to improve blood pressure

XSL•FO
RenderX

control as part of an integrated system, although the certainty of the evidence supporting these recommendations has been rated as low [3]. Patients with chronic conditions, including hypertension, have reported improved knowledge of their health status, more timely care, and better self-management of their conditions using remote monitoring [4]. A meta-analysis of 18 randomized controlled trials found that remote patient monitoring (RPM) lowered systolic blood pressure by 4.2 mm Hg and diastolic blood pressure by 2.4 mm Hg and increased the proportion of patients with hypertension control by 11% at 1 year of follow-up [5].

Beyond home monitoring, clinical guidelines recommend lifestyle changes and medication adherence for hypertension management and prevention [6]. Both lifestyle and pharmacological interventions have been shown to be cost-effective approaches for the reduction of blood pressure [7,8]. Thus, interest in the potential clinical benefits of joint programs that offer remote monitoring and lifestyle management for hypertension control has grown. In remote settings, nurses generally coordinate care for RPM and provide essential services for patients, including medication titration and lifestyle modification consultations [9-11].

Studies have shown that RPM programs coupled with care coordination are more effective for blood pressure reduction and hypertension control than RPM alone [12-14]. Previous studies have compared differences in average blood pressure and hypertension control between RPM and usual care groups at 3, 6, and 12 months [15,16]. However, results from a non–physician-led, entirely remote hypertension management program suggest that hypertension control is achievable at 7 weeks on average [17]. Moreover, an information and communications technology–based integrated care model showed clinically meaningful reductions in systolic blood pressure at 4 weeks [18].

A recent systematic review found that nurse-led telehealth interventions reduced blood pressure, more specifically, systolic blood pressure, based on randomized controlled trials and quasi-experimental studies [19]. Among the studies that were included in this review, few assessed the effectiveness of RPM and care coordination independently for hypertension control. Choi et al [13] found that patients who conducted remote blood pressure monitoring and received weekly virtual consultations had significantly lower systolic and diastolic blood pressure after 8 weeks than patients conducting blood pressure monitoring alone. Brennan et al [20] showed that privately insured African American individuals with hypertension who received a high-intensity, multimodal disease management program with nurse support had lower systolic blood pressure on average, had higher odds of achieving optimal blood pressure, and were more likely to record blood pressure at least once a week compared to a control group with a light-support educational program after 12 months. Hebert et al [21] compared a blood pressure monitoring intervention alone and nurse management in concert with blood pressure monitoring to usual care and found that the nurse management with blood pressure monitoring group had significantly lower systolic blood pressure at 9 months than the usual care group. No differences in systolic or diastolic blood pressure or hypertension control were observed for the blood pressure monitoring alone group at 9 or 18 months. While these studies demonstrate the effectiveness of nurse-led hypertension telehealth interventions, the specific components that affect these changes remain unclear. Moreover, all studies included in the aforementioned review by Kappes et al [19] assessed outcomes at 2 to 18 months. Therefore, there remains a gap in knowledge on the short-term independent and joint impacts of blood pressure monitoring and nurse monitoring among a diverse population of patients with hypertension.

Importantly, existing studies have explored whether nurse-led programs are effective for hypertension. There is a paucity of evidence on whether independent RPM companies with full-time nursing staff dedicated to monitoring patients offer more benefits than monitoring provided by clinical nursing staff. Given the costs of remote care [22], more research is needed to assess the short-term responses of hypertension to components of RPM and care coordination and whether RPM companies offer cost-effective programming. Therefore, the objective of this study was to examine the associations between both frequency of blood pressure readings and nurse monitoring and hypertension control at 4, 8, and 12 weeks for a population of patients with hypertension enrolled in an ongoing RPM program with nurse monitoring. We hypothesized that patients who recorded their blood pressure more frequently and who received monitoring from Brook nurses were more likely to achieve hypertension control within 3 months of program enrollment.

Methods

Study Design and Settings

The data used for this retrospective cohort study were drawn from a convenience sample of patients with hypertension enrolled in Brook Health's RPM program between December 2020 and December 2023. Brook Health is a commercial digital health company that offers continuous telemonitoring programs that include a mobile app with educational content and tracking tools, telemonitoring devices, health coaching, and remote nurse monitoring and care coordination to individuals with various chronic medical conditions (eg, diabetes, hypertension, obesity, chronic obstructive pulmonary disease, and congestive heart failure) who sought care at any of the 68 (36 as of December 2023) participating primary care clinics in New York or Massachusetts, United States.

Patient eligibility for Brook RPM referral is clinic specific; however, only patients with low or no copays were enrolled in the Brook RPM program. If interested and eligible, patients were then provided with remote monitoring instruments based on their diagnoses (ie, a blood pressure cuff, scale, pulse oximeter, and/or glucose monitor) and were provided with a health coach and nurse monitor. Duration of patient monitoring, coaching, and nursing is jointly determined by health care providers and patients, but patients are in the program for 12 to 15 months on average. The independent variables in this analysis included Brook nurse monitoring compared to clinical staff monitoring and frequency of blood pressure monitoring. The dependent variable was hypertension control within 12 weeks of program initiation.

Ethical Considerations

Approval for this secondary analysis of existing data without additional consent was provided by the University at Buffalo Institutional Review Board (00007012). Waiver of informed consent for primary and secondary data analysis was granted by the University at Buffalo Institutional Review Board as the study presents no more than minimal risk to patients. A deidentified, limited dataset was used for this study, and data access was limited to the research team to protect participant information. No compensation was provided to study participants as we used deidentified, secondary data. No identification of individual participants is possible in any images included in the manuscript or supplementary materials.

Variables

Patients enrolled in the Brook RPM hypertension program were provided with remote cellular blood pressure cuffs (BodyTrace and Tellihealth). Patients with obesity diagnoses were also provided with remote scales (BodyTrace and Withings) to monitor weight (in kilograms) and physical activity trackers (Fitbit) to monitor physical activity (in seconds). Weight was converted to pounds, and physical activity was converted to minutes.

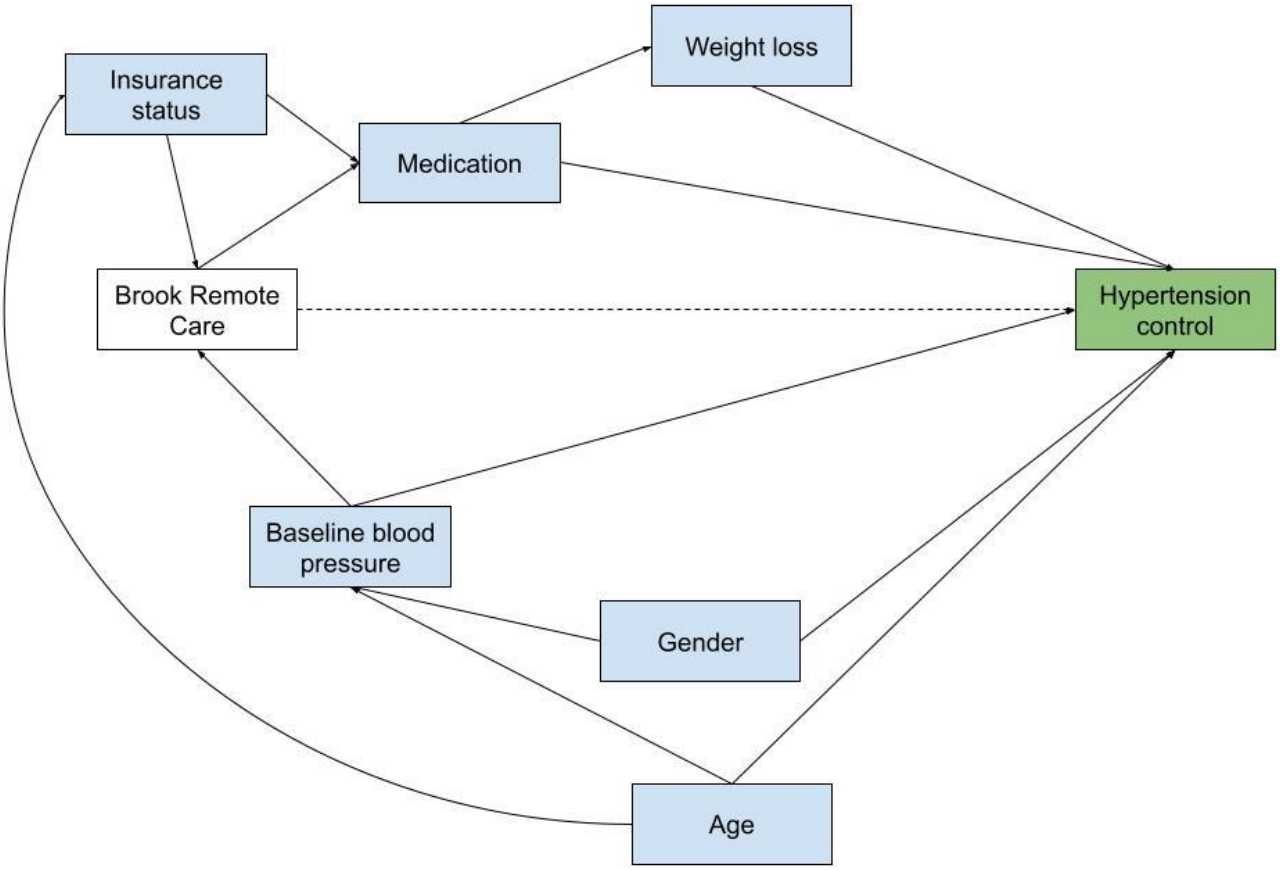
Brook RPM Program Components

Brook conducted nurse monitoring for most participating clinics during the study years, whereas the remainder of the clinics conducted monitoring using their own nursing staff. Brook RPM nurse monitors and health coaches provided personalized recommendations to patients based on patient need and diagnosis. Generally, nurse monitors encouraged patients to record at least one blood pressure reading per day, although other patients were advised to record blood pressure more frequently depending on hypertension severity and presence of other comorbidities. Patients were instructed to record their blood pressure 1 to 2 hours after taking medication, before activity, or after 15 to 30 minutes of postactivity rest.

Each patient on the monitoring service received a phone call from a nurse once a month. These monthly calls were used to check patients' status, as well as to reinforce medication compliance and adherence to device use. The monthly phone call interaction was also used to reinforce signs and symptoms for which they should call their physician or 911 to ensure that urgent and emergent care were obtained when necessary. Patients also received calls as needed based on routine readings for symptom checks and validations for any readings that were outside of the designated parameters; these calls offered opportunities for early intervention.

Patient systolic and diastolic blood pressure measured using remote blood pressure cuffs was directly transmitted to the Brook data server. The first date with a blood pressure recording was considered a patient's activation date. We calculated baseline values of systolic and diastolic blood pressure using the average of all blood pressures recorded in the first week following the activation date. To determine whether patients adhered to blood pressure monitoring protocols, we first counted the total number of weeks with at least 3 blood pressure measurements as Brook Health patients recorded blood pressure 3 days a week on average. We calculated the proportion of weeks with at least 3 blood pressure measurements with the total number of weeks in the program as the denominator for each patient. Finally, we defined patients with at least 70% of their weeks in the program with at least 3 blood pressure measurements as patients with adequate blood pressure readings. On average, Brook Health patients submitted blood pressure readings 3 days a week for more than half of the weeks they were enrolled in the program; therefore, we selected 70% of weeks in the program to capture the patients with highest monitoring activity.

Blood Pressure Outcomes



The primary outcome for this study was hypertension control, which we defined as an average weekly systolic blood pressure of less than 140 mm Hg and diastolic blood pressure of less than 90 mm Hg in weeks 4, 8, and 12 of the Brook RPM program.

Covariates

Potential confounders in this study were identified a priori using directed acyclic graphs (Figure 1). Patient age, sex, and health insurance type were collected from patient electronic health records. Diagnoses of patient comorbidities that informed patient care and follow-up were reported as binary indicators. Baseline weight (in pounds) and physical activity (in minutes) included the first measures for each patient.

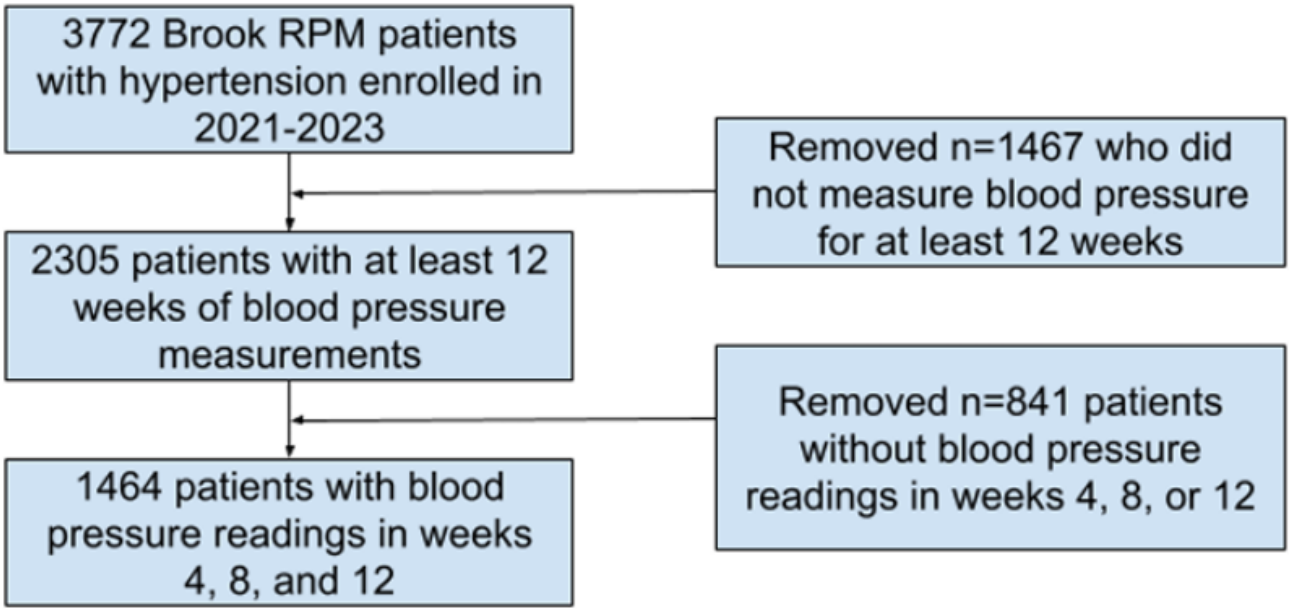
XSL•FO
RenderX

Figure 1. Directed acyclic graph of the association between Brook Remote Care and hypertension control.

Statistical Analysis

Patient demographic and health characteristics were presented using counts and percentages for binary variables and medians and IQRs for continuous variables. We applied chi-square tests to assess the bivariate associations between blood pressure control at 4, 8, and 12 weeks and both adequate blood pressure readings and Brook nurse monitoring. To estimate the association between both adequate blood pressure readings and Brook nurse monitoring and hypertension control, we used generalized linear models with a log link and binomial family (*epitools* package) [23] mutually adjusted for Brook nurse monitoring and adequate blood pressure readings, respectively; age; and sex. All analyses were conducted using R (version 4.3.1; R Foundation for Statistical Computing) [24]. This study was conducted in accordance with the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) reporting guidelines (Checklist 1).

Sensitivity Analysis



To control for the potential influence of other comorbidities on these associations, we conducted an analysis among a subset of patients diagnosed with hypertension only at 4, 8, and 12 weeks using adjusted generalized linear models with a log link and binomial family.

Results

Our study sample included 38.8% (1464/3772) of the patients enrolled in the Brook RPM program for hypertension (Figure 2). The median age of the patients was 71 (IQR 64-78) years (Table 1). In total, 52.9% (775/1464) of the patients were female, and 67.7% (991/1464) were enrolled in the Brook RPM program in 2023. At baseline, median systolic and diastolic blood pressure were 136.8 (IQR 126.6-149.0) mm Hg and 80.8 (IQR 73.0-88.4) mm Hg, respectively. At baseline, 12.2% (179/1464) of the patients were diagnosed with diabetes, 25.1% (368/1464) were diagnosed with obesity, 1.6% (23/1464) were diagnosed with chronic obstructive pulmonary disease, and 13.6% (199/1464) were diagnosed with congestive heart failure. Patient characteristics were similar when comparing the group of patients who recorded adequate blood pressure readings and received Brook nurse monitoring to those with neither (Multimedia Appendix 1).

[a]Missing 774 observations.

[b]Missing 1188 observations.

[c]COPD: chronic obstructive pulmonary disease.

In unadjusted bivariate analyses, Brook RPM patients who measured their blood pressure at least 3 times a week for at least 70% of the weeks they were enrolled in the program (ie, “adequate” readings) had higher proportions of hypertension control at 4 weeks (557/858, 64.9% vs 358/606, 59.1%; *P*=.03), 8 weeks (613/858, 71.4% vs 388/606, 64.0%; *P*=.003), and 12 weeks (622/858, 72.5% vs 379/606, 62.5%; *P*<.001) than patients who did not submit adequate readings (Table 2). A higher proportion of patients receiving Brook nurse monitoring achieved hypertension control at week 4 (616/936, 65.8% vs

XSL•FO
RenderX

299/528, 56.6%; *P*<.001), week 8 (653/936, 69.8% vs 348/528, 65.9%; *P*=.14), and week 12 (659/936, 70.4% vs 342/528, 64.8%; *P*=.03) than patients receiving nurse monitoring from nursing staff at their primary care clinics. Among the group of patients who recorded adequate blood pressure readings and received Brook nurse monitoring, 68.8% (379/551), 73.5% (405/551), and 74.2% (409/551) achieved hypertension control at 4, 8, and 12 weeks, respectively (Multimedia Appendix 2).

In multivariable analyses, patients with adequate blood pressure readings had higher prevalence of hypertension control at week 4 (prevalence ratio [PR]=1.10, 95% CI 1.02-1.20), week 8 (PR=1.12, 95% CI 1.04-1.20), and week 12 (PR=1.15, 95% CI 1.07-1.24) than those who did not have adequate readings (Table 3). In models mutually adjusted for adequate readings, patients who received Brook nurse monitoring had higher prevalence of hypertension control at week 4 (PR=1.16, 95% CI 1.07-1.27), week 8 (PR=1.06, 95% CI 0.99-1.15), and week 12 (PR=1.08, 95% CI 1.00-1.16) than patients monitored by staff at primary care clinics. Patients who recorded adequate blood pressure readings and received Brook nurse monitoring (772/1464, 52.7%) had higher prevalence of hypertension control at week 4 (PR=1.26, 95% CI 1.11-1.46), week 8 (PR=1.17, 95% CI 1.05-1.31), and week 12 (PR=1.27, 95% CI 1.12-1.43) than patients who recorded blood pressure less frequently and who received remote monitoring from clinical staff. These associations among adequate readings, nurse monitoring, and blood pressure control were generally similar, though slightly higher in magnitude, in the sensitivity analyses (Multimedia Appendix 3).

Discussion

Principal Findings

This longitudinal retrospective cohort study among a convenience sample of patients at any of the 68 participating primary care clinics across New York and Massachusetts, United States, enrolled in the Brook RPM program for hypertension examined the associations between 2 Brook RPM program components—Brook nurse monitoring relative to clinical nurse monitoring and frequency of blood pressure readings—and hypertension control at 4, 8, and 12 weeks. Patients who

XSL•FO
RenderX

recorded blood pressure more than 70% of their time in the program had higher prevalence of hypertension control than those who did not. Brook nurse monitoring was associated with greater prevalence of hypertension control than clinical nursing staff monitoring. The group of patients with high frequency of blood pressure readings and who received Brook nurse monitoring had the highest prevalence of hypertension control compared to all other groups.

Evaluation of the frequency of blood pressure readings recorded by patients is important to guide clinical recommendations for RPM. Frazier et al [25] observed that mean arterial pressure reductions were greatest for patients with higher frequencies of measurements per month over the course of a 6-month RPM program. Despite the Centers for Medicare and Medicaid Services stipulation that Current Procedural Terminology codes for initial equipment setup and monthly data collection are billed only for patients who record at least 16 measurements per month [26], there is no evidence documenting the clinical relevance of these suggested monitoring frequencies. Therefore, more studies evaluating the clinical implications of monitoring intensity are needed.

Team-based care has been recommended as a cost-effective approach for patients' hypertension control and management [27]. Our study observed that, compared to nurse monitoring provided by clinical staff, Brook nurse monitoring was consistently associated with higher hypertension control among patients, highlighting that the quality of nurse interactions may be more impactful for hypertension control than simply having a nurse monitor present. A pragmatic observational cohort study among Medicare patients with uncontrolled hypertension who sought care at primary care clinics in Chicago, Illinois (age range 65-85 years), and the general hypertension population found that RPM plus care coordination provided by nurses showed clinically meaningful improvements in hypertension control at 3 and 6 months compared to usual care and RPM alone [12]. Additionally, a cluster randomized trial of the HyperLink RPM program that provided pharmacist-led care coordination to patients attending primary care in Minnesota showed that the telemonitoring intervention had 25% to 30% higher absolute hypertension control at 6 and 12 months than usual care [28]. An experimental longitudinal study among African American individuals with uncontrolled hypertension found that a 12-month nurse-managed telemonitoring program that provided RPM and nurse calls to patients led to statistically and clinically significant reductions in systolic blood pressure compared to usual care, with the greatest reductions observed in the first 3 months of the program [9]. Moreover, in a mediation analysis, secure messaging with a pharmacist accounted for 96% of the effects of an RPM program on hypertension control after 12 months [29].

A unique contribution of our Brook RPM study is the short-term hypertension control response examined at 4, 8, and 12 weeks in relation to program components. Most studies have evaluated digital health interventions in relation to hypertension control and blood pressure outcomes at longer periods, such as 6 and 12 months of program participation [19,30]. However, there is evidence that RPM shows promise for improving blood pressure outcomes at earlier time points [17,18,31]. Naqvi et al [31] observed an 18.4 mm Hg reduction in systolic blood pressure among those using RPM after 3 months compared to controls. A non–physician-led hypertension management program that included a Bluetooth-enabled home blood pressure device was shown to lead to hypertension control for 91% of patients after approximately 7 weeks of consistent measurement [17]. A study among 20 patients with difficult-to-control hypertension enrolled in an information and communications technology–based program that included telemonitoring and weekly access to nurses showed that systolic blood pressure measured at home decreased by 15 mm Hg on average after 4 weeks [18]. In concert with these study findings, our study showed improved blood pressure control among patients who recorded blood pressure more frequently and who received Brook nurse monitoring at 4, 8, and 12 weeks.

Limitations

Our study findings have limited generalizability as Brook RPM patients are older, reside in western New York or eastern Massachusetts, and are generally enrolled in Medicare health insurance plans that cover RPM costs with low to no patient cost sharing. Patients who received Brook nurse monitoring were identified based on primary care clinics, as Brook nurses conduct monitoring for patients at certain clinics. This definition masks the variability in individual patient experiences as monitoring protocols are tailored to patient needs. Moreover, the level of monitoring provided by clinical staff and the differences between staff within the same clinic as well as between clinics are unclear as clinical monitoring protocols are not made available to Brook Health. Additionally, most Brook patients were encouraged to monitor their blood pressure at least once a day. However, we used a more data-driven estimate of monitoring intensity to define adequate blood pressure readings in this study (ie, 70% of weeks in the program with at least 3 days of blood pressure readings) as most patients did not consistently record their blood pressure every day for all weeks in the program. The use of a complete-case analysis may introduce bias into our study, and we encourage cautious interpretation of study findings. Additionally, uncontrolled confounding may bias our study findings as we lacked information on important demographic and clinical characteristics that likely confound these associations, and health insurance information was incomplete and not accounted for in our analysis due to a high degree of missingness. For instance, baseline blood pressure used to determine eligibility for the Brook Health program was not available for this study as it was based on clinical medical records, and patient medication adherence was only available through nurse notes, which were not complete. Therefore, our study may be subject to residual confounding that may bias our results. However, it is more likely that these variables do not act as true confounders but rather serve as mediators between the program's nurse monitoring component and hypertension control.

Conclusions

This is the first study to compare short-term hypertension control outcomes for RPM patients using clinical nurse monitoring and independent RPM staff monitoring. Our study findings suggest that both frequency of monitoring and specialized nurse

XSL•FO
RenderX

monitoring improve hypertension control within 3 months of program enrollment. The combination of higher monitoring frequency and Brook nurse monitoring may represent a cost-effective approach to improving hypertension control in high-risk populations by addressing limitations in clinical care staffing. Professional RPM companies with full-time staff may augment the benefits of RPM provided by clinical care providers who have other responsibilities. Future studies should further evaluate the impact of individual and collective program components on health outcomes and assess these potential impacts at various time points of program participation.

Abstract

Background: The comorbidity of dementia and type 2 diabetes mellitus exacerbates the burden on family caregivers (FCGs). Mobile health (mHealth) technology offers a promising alternative to overcome the spatiotemporal limitations of traditional interventions, but evidence for its efficacy in supporting dementia–type 2 diabetes mellitus caregivers remains scarce.

Objective: This study aimed to evaluate the effectiveness of an mHealth supportive care program for FCGs of individuals with dementia and diabetes, focusing on caregiver burden, social support, and dementia care knowledge.

Methods: A 2-arm, parallel-group randomized controlled trial was conducted. Between September 2022 and January 2023, FCGs were recruited from 5 urban and 10 rural communities under a community health center in Xiamen, China. Eligible caregivers were legally related to the patient, providing care for more than 8 hours per day for at least 1 month, conscious adults with basic literacy, owning and able to use a smartphone, and willing to provide informed consent. Their care recipients met diagnostic criteria for both dementia and type 2 diabetes, aged more than 60 years. Participants were randomly allocated (1:1) to intervention (n=30) or wait-list control (n=30). The intervention group received a 12-week mHealth supportive care program via the "Xiamen i-Health" platform, comprising 6 core modules (updated biweekly) and on-demand teleconsultation, in addition to conventional offline health education. The control group received conventional monthly 1-hour home-visit health education only. The primary outcome was caregiver burden measured by the Caregiver Burden Inventory (CBI). Secondary outcomes included social support (Social Support Rating Scale; SSRS) and dementia care knowledge (Dementia Care Knowledge Scale; DCKS). Assessments were performed at baseline (T0) and 3-month postintervention (T1). Only data collectors and statistical analysts were blinded.

Results: Of 108 potential participants, 60 were randomly assigned. Per-protocol analysis included 55 participants (intervention group n=28 and control n=27). Postintervention, the intervention group showed a significantly greater reduction in CBI scores compared to the control group (between-group difference, Z=−3.534, P<.001, r=0.477). The intervention group also demonstrated significantly greater improvements in SSRS (Z=2.494, P=.01) and DCKS scores (Z=−4.233, P<.001, r=0.570). Subgroup analyses revealed that the reduction in caregiver burden was more pronounced among male, younger (60 y), physical labor, and lower-income caregivers. No intervention-related adverse events were reported.

Conclusions: This theoretically grounded mHealth supportive care program effectively reduced burden and improved outcomes for FCGs managing dementia-diabetes comorbidity. The integrated online-offline delivery model shows particular promise for male, younger, manual labor, and lower-income caregivers, suggesting mHealth's potential to address health equity. These findings provide a feasible model for scalable caregiver support in resource-limited primary care settings. Future research should involve multicenter trials with longer follow-up and cost-effectiveness analyses.

Introduction

Dementia care remains a significant public health challenge for health systems worldwide. By 2019, the economic cost of dementia had escalated to $1.3 trillion globally [1], posing a substantial financial strain. In China, the older population (age ≥60 y) living with dementia has reached 15.07 million, with incidence rates increasing markedly with age [2]. While pharmacological treatments delay disease progression to some extent, the absence of definitive curative measures leads to patients progressively losing their self-care, work, and social abilities [3]. This dramatically increases the demand for dementia care, requiring round-the-clock care for advanced disease [4]. Notably, in China, approximately 70% of patients with dementia rely on family caregivers (FCGs), who bear a disproportionately heavy burden and face numerous challenges. The caregiving challenge becomes markedly more complex when dementia coexists with type 2 diabetes mellitus (T2DM). Epidemiological studies demonstrate that T2DM elevates Alzheimer disease risk by 1.5 to 2 times [5], driven by shared pathophysiology including insulin resistance and oxidative stress that accelerate cognitive decline [6]. The progression from mild cognitive impairment to dementia occurs in 6% to 25% of patients with T2DM, markedly higher than the 0.2% to 3.9% observed in age-matched controls [5]. This comorbidity leads to compounded cognitive deterioration [7] and severely impairs self-care management [8] and long-term quality of life [9]. Patients often struggle with medication adherence, frequently forgetting or duplicating doses, which results in dangerous glycemic fluctuations that may further exacerbate cognitive dysfunction [10]. China's metabolic disease epidemic further amplifies this issue, with over 140.9 million diabetes cases [11], 95% being T2DM [12]. The clinical complexity of dementia-T2DM comorbidity generates substantially greater caregiver burdens, as FCGs must concurrently manage dementia-related behavioral symptoms and diabetes-specific care requirements, including meticulous medication supervision, dietary control, and hypoglycemia prevention. These patients exhibit highly variable symptomatology [13,14] and extremely high care dependency [15], yet existing research predominantly focuses on patient self-management rather than critical external determinants like social support, caregiving contexts, or health care resource availability [16-18].

As a vital extension of the health care system, FCGs play an indispensable role in caring for patients with dementia and diabetes [19,20]. Enhancing FCG care skills and addressing their care needs are pivotal to mitigating public health pressures and improving patient quality of life. In developing countries, the paucity of primary health care resources shifts a greater proportion of caregiving responsibilities to FCGs, thereby augmenting their burden. While FCGs, as unpaid caregivers [21], may derive emotional fulfillment and personal growth from caregiving [22], they face numerous challenges, including psychological, emotional, physical, and financial burdens [23], which often lead to social isolation and reduced quality of life and physical health [24-27]. In China, strong family ties and a profound sense of responsibility socially obligate family members to undertake caregiving duties, placing an emotional burden on them when caring for frail relatives [28]. Studies indicate that caregivers are more likely to choose institutionalization when experiencing high emotional stress and burden [29], and those under greater stress face a 63% higher mortality rate compared to others [30]. Consequently, caregivers are frequently referred to as "hidden patients" [31].

Furthermore, as FCGs are often instructed to prioritize managing patients' symptoms [32], their needs are frequently overlooked and unacknowledged by health and social care professionals [33]. Patients with dementia and diabetes require intricate and meticulous care due to cognitive decline and metabolic abnormalities, increasing caregiving challenges and placing higher demands on FCGs. According to a survey by the Alzheimer's Disease Society of China, the primary challenges faced by the FCGs of patients with dementia include inadequate caregiving skills, limited care resources, and restricted treatment services. The level of care often exceeds the FCGs' capabilities, potentially increasing their burden and worsening mental health issues [34]. Developing effective strategies to support caregiving is imperative. Targeted interventions to train and support FCGs can enhance their competence [35], reducing caregiver stress and burden.

Social support and caregiving knowledge are critical for dementia-combined diabetes caregivers. Studies have shown that educational interventions can significantly reduce caregiver anxiety and burden and improve patient quality of life [36,37], while unmet information needs can lead to reduced caregiving outcomes [38]. Werner et al [39] noted that caregivers need timely, personalized, and accessible information support. Effective interventions (eg, providing education and practical information) can improve knowledge, reduce stress, and enhance caregiving [40-42]. In addition, caregiver needs span emotional social support, knowledge and skills training, and self-management [43], but existing resources often lack credibility or have mismatched learning styles [44]. Digital support tools (eg, teleconsultation) can provide flexible and professional guidance that can improve caregiver mental health [45] and reduce caregiver stress and burden [46-48], and multicomponent interventions are particularly effective [49,50].

The World Health Organization emphasizes the importance of supporting families caring for older adults in its guidelines for community-based integrated care [51]. Advancements in mobile health (mHealth) technology, which overcome time and space constraints and expand the intervention scope, have led to its widespread application in chronic disease management and home care [52,53]. Internet-based supportive interventions have been implemented in countries such as the United Kingdom [54], Germany [55], and India [56], offering convenient and effective support to alleviate the physical and mental burdens of caregiving. However, few studies in China have examined such interventions, and most lack theoretical framework support and standardization. The following key gaps remain in existing caregiver support research. First, the majority of current studies only address caregivers of individuals with dementia only [57,58] or diabetes only [59,60], while interventions for dementia-T2DM co-morbidities caregivers remain scarce. Second, less than 30% of digital intervention studies have articulated their theoretical underpinnings, limiting

XSL•FO
RenderX

reproducibility [61,62]. Third, systematic reviews have found incomplete reporting of the implementation process of home and community-based interventions in existing studies (only 28% of studies reported on implementation outcomes) [63], which limits the generalized use of interventions. Fourth, there are fewer relevant studies in China, and most lack theoretical framework support and standardized protocols.

Roy's Adaptation Model and Fitch's Theory of Supportive Care are widely used theoretical frameworks for constructing care programs. Roy's Adaptation Model explains how individuals cope with environmental changes through adaptation, focusing on their adaptation level, stimulating factors, and adaptive mechanisms. While this model provides valuable insights into individual coping dynamics, its emphasis on adaptive processes rather than structured care delivery makes it less suitable for guiding standardized intervention design. In contrast, Fitch's Theory of Supportive Care addresses and optimizes patients' physiological, psychological, social, and environmental care needs, emphasizing the importance of personalized care planning, which is more appropriate for this study. Since its inception, this theory has been extensively applied in research addressing supportive care needs for patients and FCGs both domestically and internationally [64-68], yielding notable outcomes. Traditional intervention programs often rely on in-person or telephone formats, focusing mainly on health education while neglecting supportive care needs. Additionally, limited human resources in primary health care services constrain traditional offline interventions, creating significant implementation challenges. While some research platforms have explored online interventions, these often lack transparency in service fees and operate on a small scale, limiting their generalization and promotion. In this context, mHealth supportive care programs offer unique advantages by overcoming the resource and implementation challenges of traditional interventions and providing a novel pathway to meet supportive care needs with promising development prospects.

Building upon Fitch's Theory of Supportive Care [69] and evidence from cross-sectional surveys, we developed an integrated online-offline mHealth supportive care program targeting FCGs of individuals with comorbid dementia and diabetes in urban-rural grassroots communities. This study aims to clarify the intervention effects of the mHealth supportive care program, with the primary outcome being caregiver burden measured by the Caregiver Burden Inventory (CBI), and secondary outcomes including social support assessed by the Social Support Rating Scale (SSRS) and dementia care knowledge measured by the Dementia Care Knowledge Scale (DCKS). Additionally, subgroup analyses were conducted to evaluate potential heterogeneity of intervention effects across different demographic characteristics such as gender, age, careers, and monthly family income. We hypothesize that, at 3-month follow-up, (a) FCGs receiving the mHealth intervention will demonstrate a significantly greater reduction in CBI scores compared with routine-care controls, and (b) the intervention group will show significantly larger improvements in SSRS and DCKS scores; furthermore, (c) intervention effects may differ across demographic subgroups. Findings from this study will provide evidence for scalable supportive care strategies to address caregiving disparities in resource-limited settings.

Methods

Study Design and Objectives

This 2-arm, parallel-group randomized controlled trial evaluated the efficacy of an mHealth supportive care program for FCGs of individuals with comorbid dementia and diabetes. The trial was designed and reported in accordance with the CONSORT (Consolidated Standards of Reporting Trials) 2025 statement [70] (see Checklist 1) and its extension for reporting trials of electronic and mobile health applications (CONSORT-EHEALTH [Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and Online Telehealth]) [71] (see Checklist 2).

Sample Size

Simple Size Calculation

The sample size was calculated based on a 1:1 ratio between the intervention and control groups, using the sample size calculation method for comparing the means of two samples. The calculation formula is as follows:n1=n2=2[(μα+μβ)δ/σ]+142μα 2

Based on a literature review, the caregiver burden was selected as the primary outcome measure for this study. n_1 and n_2 represent the required sample sizes for the two groups, respectively. Due to the lack of prior data from identical designs, the sample size calculation was based on the SD (σ=6.85) and clinically important difference (δ=6.87) reported in a quasi-experimental study [72], which tested a dementia caregiver intervention under comparable conditions. Power analysis (α=.05, β=.1, 2-tailed) indicated 22 participants per group. During the recruitment process, participants showed great enthusiasm in signing up, with the number of applicants exceeding the actual required number by 16. In consideration of ethical principles and the fact that a larger sample size would enhance reliability, we ultimately enrolled 30 per group (total N=60) to further strengthen robustness. Given the exploratory nature of this study, the sample size was estimated based on prior effect sizes, but statistical power may still be limited.

Participants

Participate Enrollment

This study was conducted at a community health center in Xiamen, Fujian Province, from September 2022 to January 2023. Participants were recruited from 5 urban neighborhood committees and 10 rural villages under the jurisdiction of the selected health center to ensure urban-rural diversity. Due to COVID-19 pandemic restrictions and limited research resources, a single community health center was chosen as the study site.

Inclusion Criteria

The inclusion criteria for care recipients are as follows:

- meeting the diagnostic criteria for dementia
- meeting the diagnostic criteria for type 2 diabetes
- aged ≥60 years and permanent resident in the study area

XSL•FO
RenderX

The inclusion criteria for caregivers are as follows:

- legally related to the patient (spouse, child, or sibling), excluding paid caregivers
- providing care ≥8 hours per day, ≥5 days per week for ≥1 month [51]
- conscious adult with basic literacy and comprehension skills
- owning a smartphone with internet access and proficiency in its use
- willing to provide informed consent and participate voluntarily

Providing care ≥8 hours/day, ≥5 days/week for ≥1 month [51]

Exclusion Criteria

Patients or caregivers meeting any of the following conditions were excluded:

- having severe physical illness, major diseases, or terminal conditions
- having substance or alcohol dependence
- currently participating in similar intervention studies

Withdrawal Criteria

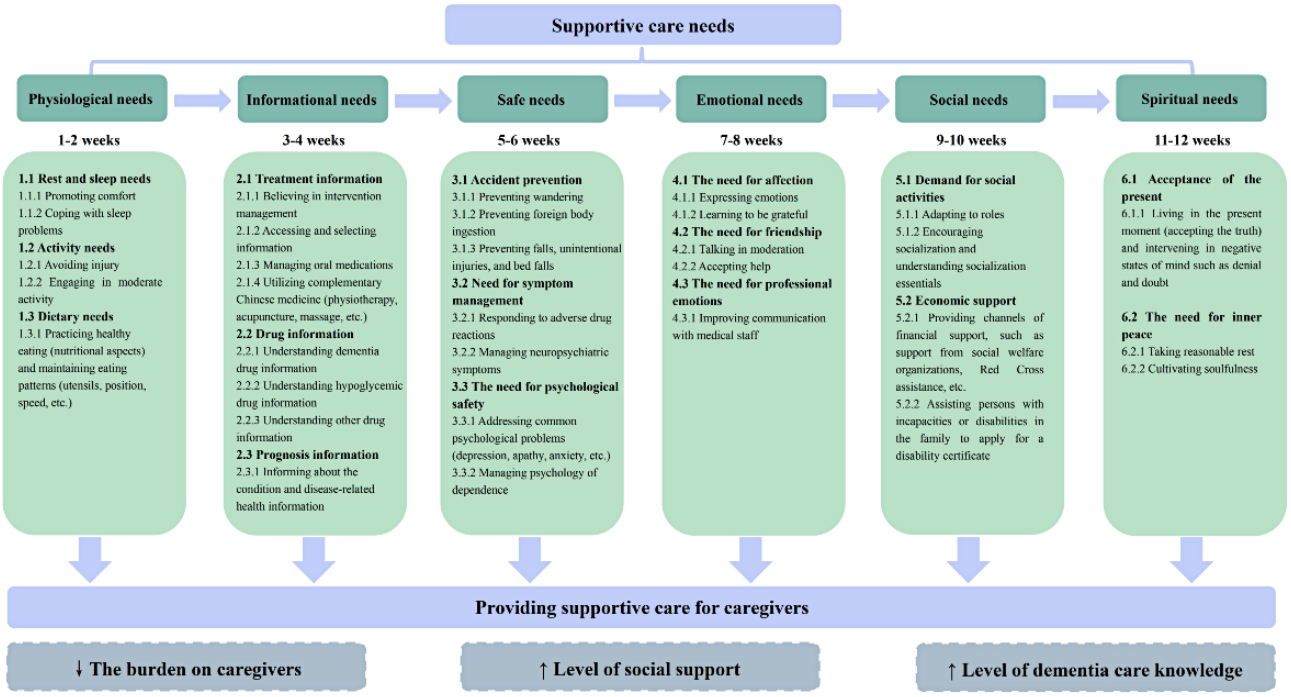
Participation would be terminated in the following conditions:

- if the care recipient was hospitalized for severe illness or passed away
- if the participant voluntarily withdrew from the study for any reason

Randomization, Allocation Concealment, and Blinding

Random allocation was set at a 1:1 ratio. Participants who were ultimately enrolled in the study were numbered in the order of enrollment. A digital custodian, who did not directly participate in this study, used a computer to generate a random number sequence from 1 to 60. The custodian placed each random number in sequentially numbered, opaque envelopes, which were then sealed and stored to reduce selection and information bias. Researchers inquired about the group assignment of participants by calling the digital custodian. The custodian opened the envelopes in numerical order and informed the researchers of the group assignments. Participants with random numbers 1 - 30 were assigned to the intervention group, and those with 31 - 60 were assigned to the control group. Since this study was based on an mHealth-supported care intervention, blinding the intervention implementers and participants was challenging. Therefore, blinding was only implemented for data collectors and statistical analysts.

Interventions



All routine care for patients in both groups was independently performed by FCGs. The control group received offline basic health services and health education, whereas the intervention group received an mHealth supportive care program in addition to the services provided to the control group. The intervention was developed and reported following the TIDieR (Template for Intervention Description and Replication) checklist (see Checklist 3).

Following standard community geriatric chronic disease management protocols, control group participants received monthly home visits (1 hour per session for 12 wk) where implementers delivered targeted health education and addressed caregiver-initiated queries regarding dementia-diabetes comorbidity management. The educational program comprised the following: (a) Diabetes management training: systematic instruction on essential care components, including nutritional regulation, sleep optimization, and exercise regimens; pharmacological guidance included drug categorization, therapeutic mechanisms, dosage administration, and compliance enhancement techniques; training on glycemic monitoring protocols focused on accurate fasting and 2-hour postprandial blood glucose assessment; instruction included early detection of hypoglycemic episodes, ophthalmologic complication signs, crisis management, and dermatological protection measures. (b) Dementia management training: Comprehensive instruction on basic caregiving competencies, including nutritional support, sleep cycle regulation, and physical activity facilitation; educational content encompassed dementia etiology, prognostic trajectories, stage-dependent symptom management, and prevention protocols for elopement, falls, and scald injuries.

The mHealth supportive care intervention was developed based on Fitch's theoretical model [69], which systematically addresses caregivers' multidimensional needs. The intervention's theoretical structure is illustrated in Figure 1; the 6 core intervention modules directly operationalize Fitch's domains. This intervention program was further informed by baseline epidemiological surveys quantifying caregiving burdens, needs analyses of FCGs, and evidence synthesis through a systematic literature review and Delphi expert consensus. Implementation utilized a robust, municipally administered public health mobile infrastructure to guarantee program fidelity and continuity. The intervention group accessed supplementary weekly mHealth interventions through the "Xiamen i-Health" portal (12 structured sessions across 12 weeks with fortnightly module updates), complemented by asynchronous consultation capabilities. Preintervention preparations and specific steps for implementation are documented in Multimedia Appendix 1. The implementation team comprised professionals with decade-long gerontological nursing practice and 6-year specialized intervention management tenure. Rigorous centralized training was conducted to maintain intervention fidelity, mitigate operational variability, and standardize delivery protocols.

Figure 1. The mHealth supportive care program based on Fitch's supportive care model for caregivers of patients with dementia and type 2 diabetes: design and intervention components.

Data Collection and Outcome Measures

Self-Designed Questionnaire

The self-designed questionnaire, developed based on the research objectives and a review of relevant literature [64,72-74], gathered demographic and clinical information, including age, gender, careers, educational levels, monthly family income, living with patient, relationship with patients, as well as current medical history and family history. The questionnaire was evaluated and refined by an expert panel of 5 clinical nursing specialists, all with more than a decade of experience.

Primary Outcome

The CBI was used to evaluate the burden experienced by the FCGs of individuals with dementia and diabetes. Zhang [75] adapted this scale from the Chinese version of the CBI developed by Taiwanese scholar Chen et al. [73], with modifications to suit the linguistic characteristics of mainland China. Each item is scored using a Likert 5-point scale ranging from strongly agree (4 points) to strongly disagree (0 points). The total score of the scale ranges from 0 to 96, with higher scores indicating a heavier caregiver burden. Scores ≥24 suggest the need for therapeutic intervention, whereas scores ≥36 indicate a risk of severe burden. The overall Cronbach α coefficient for this scale [75] is 0.77, with an average content validity index (CVI) of 0.95 per item, indicating good reliability and validity. It has been widely used in similar studies [76,77].

Secondary Outcomes

The SSRS is a 10-item rating scale that evaluates the psychological support an individual receives in social life and their utilization of such support. The Chinese scholar Shuiyuan [78] developed this scale based on the sociocultural context and familial structure characteristic of Chinese society, ensuring its relevance and validity for use in Chinese populations. The objective support score is the sum of items 2, 4, and 6; the subjective support score is the sum of items 1, 3, 4, and 5; and utilization of support score is the sum of items 8, 9, and 10. Generally, scores below 20 indicate low social support, 20 - 30 indicate moderate social support, and 30 - 40 indicate satisfactory social support. The test-retest reliability of this scale [78] is 0.92, with item consistency ranging from 0.89 to 0.94 and a Cronbach α coefficient of 0.89. The scale demonstrates good reliability and validity, accurately reflecting an individual's level of social support. It has been widely used in similar studies [79,80].

The DCKS was used to assess the FCGs' extent of knowledge about dementia caring [81]. This questionnaire, based on Maslow's hierarchy of needs, covers personal hygiene, diet, excretion, sleep, disease and rehabilitation, medication, environmental and travel safety, social relationships and family ties, self-esteem, and self-actualization. A Likert scale was used, with 1 point for a correct answer and 0 points for an incorrect answer or "don't know." The DCKS scores range from 0 to 22, with higher scores reflecting a higher level of dementia care knowledge. The Cronbach α coefficient for the overall scale [81] is 0.626, with CVI ranging from 0.86 to 1 and an average CVI index of 0.95. It has been widely used in similar studies [82].

Adverse Events Monitoring

As this trial evaluated a low-risk supportive care intervention, no systematic, active surveillance for specific adverse events was prespecified. However, any unintended effects or concerns raised by participants during home visits or via the mHealth platform were documented. Furthermore, all instances of participant withdrawal were tracked and reviewed for any potential link to the intervention.

XSL•FO
RenderX

Statistical Analysis

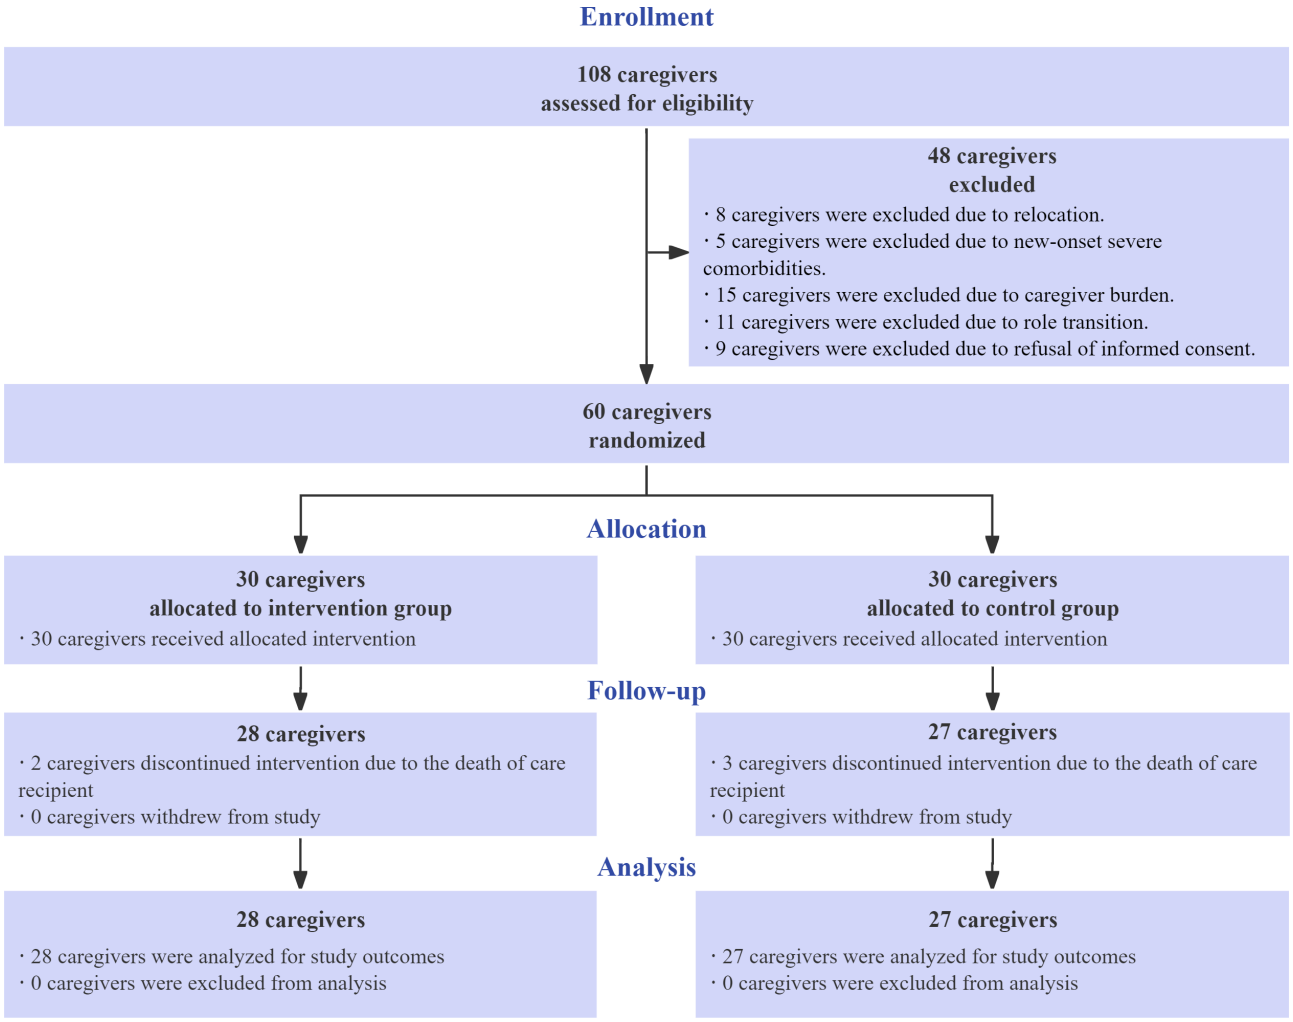
Data analysis was conducted using IBM SPSS Statistics for Windows version 25.0. Quantitative data with a normal distribution were presented as mean (SD), whereas nonnormally distributed data were presented as median with IQR. Categorical data were presented as frequency and percentage. For comparisons between 2 independent samples, the independent-sample *t* test was used for normally distributed data, whereas the Mann-Whitney *U* test was used for nonnormally distributed data. Comparisons pre- and post-intervention were conducted using a paired *t* test for normally distributed differences or Wilcoxon signed-rank test for nondistributed differences. The χ^2 test or Fisher exact test was used for comparisons of categorical data between groups, and rank-sum tests were used for comparisons of ordinal data. Effect sizes were calculated as Cohen *d* (continuous) or rank correlation r (nonparametric), with 95% CIs reported where applicable. Given the 2-time-point design of this pilot RCT and the completeness of the per-protocol dataset, repeated measures ANOVA was selected as the primary framework for testing group × time interactions and the critical 3-way (group × time × subgroup) interactions in preplanned subgroup analyses. Where significant interactions were detected ($P<.05$), simple effects analyses were performed. The dataset for the final per-protocol analysis was complete, with no missing data at the item level for any outcome measures among participants who completed the follow-up.

Ethical Considerations

This study was approved by the Ethics Committee of Fujian Provincial Hospital (approval K2021-05-024). Due to delays in the institutional ethics approval process during the COVID-19 pandemic, this trial was retrospectively registered. The trial is registered at ClinicalTrials.gov (NCT06785857; Date: Jan 21, 2025). No changes were made to the trial methods or outcomes after the trial commenced.

Prior to enrollment, all participating caregivers provided written informed consent after being fully informed of the study objectives, procedures, and their right to withdraw at any time without penalty. To ensure confidentiality, all collected data were deidentified and stored securely, with access limited to authorized researchers only. Although no monetary compensation was offered, small gifts (soap, tissue, shopping bags) valued at approximately 20 RMB (equivalent to approximately US $2.97 based on the average exchange rate during the intervention period in 2022) were provided as tokens of appreciation during home visits. We further confirm that no identifiable images, audio, video, or text of participants are included in this manuscript or its supplementary materials. No deviations from the prespecified trial protocol occurred after the commencement of the study.

No patients or members of the public were involved in the design, conduct, reporting, or dissemination of this research.



Results

Participants

A total of 108 potential participants were assessed for eligibility in this study. Out of the 60 who were eligible, 48 were excluded due to scheduling conflicts and a lack of interest. Consequently, 60 individuals agreed to participate and were randomly assigned to either the intervention group (n=30) or the control group (n=30) after providing informed consent. Herein, due to the death of care recipients during intervention, the number of remaining participants was 28 in the intervention group and 27 in the control group. Ultimately, a total of 55 out of 60 (91.67%) participants completed the follow-up assessments (Figure 2).

Figure 2. Consolidated Standards of Reporting Trials (CONSORT) flow diagram of participant enrollment, allocation, follow-up, and analysis in a 2-arm, parallel-group, pilot randomized controlled trial evaluating an mHealth supportive care program for family caregivers of individuals with dementia and type 2 diabetes in Xiamen, China (September 2022 to January 2023).

Demographic and Baseline Characteristics

Table 1 presents the sociodemographic characteristics of the caregivers. No significant differences were observed in the characteristics between the intervention and control groups (P>.05), indicating that no significant differences between the groups at baseline. Over half (27/55, 49.09%) of the FCGs were aged ≥60. Most caregivers were married (47/55, 85.45%), and 72.73% (40/55) had completed education at the junior high school and above level. Notably, 90.91% (50/55) of caregivers lived with the patients, and 76.36% (42/55) were the patients' children.

Comparison of Outcome Measures Pre-intervention

The primary outcome measure in this study was caregiver burden, assessed using the CBI. Secondary outcome measures included caregiver social support level and knowledge level, which were evaluated using the SSRS and DCKS, respectively. Preintervention, no significant differences were detected between the intervention and control groups in CBI (z=−0.675, P=.50), SSRS (t_{53}=−0.949, P=.35), and DCKS (t_{53}=−1.256, P=.22), indicating that the groups were not statistically different (Table 2).

Subgroup Analysis of Intervention Effects by Caregiver Characteristics

The 3-way interaction analyses indicated that changes in SSRS and DCKS scores were not significantly moderated by the examined demographic variables (all 3-way interactions *P*>.05; see Multimedia Appendix 2). For CBI score changes, 3-way interaction tests revealed significant time×group×gender ($F_{1,51}$=6.712, *P*=.01), time×group×age ($F_{1,51}$=7.784, *P*=.007), time×group×careers ($F_{1,51}$=8.327, *P*=.006), time×group×educational level ($F_{1,51}$=8.325, *P*=.006), and time×group×monthly family income ($F_{1,51}$=3.793, *P*=.03); therefore, subgroup analyses were conducted by sex, age, careers, educational level, and monthly family income.

As shown in Table 5, the gender subgroup analysis indicated that male participants in the control group had significantly higher CBI scores postintervention compared to those in the intervention group (t_{23}=5.289, *P*=.01), whereas no significant differences were observed between the groups for females (t_{28}=0.427, *P*=.59). In the age subgroup analysis, caregivers under 60 years in the control group exhibited higher CBI scores (t_{25}=4.088, *P*=.02), with no differences found among those aged 60 years and older (t_{26}=0.363, *P*=.64). The careers subgroup analysis revealed that participants engaged in physical labor had higher scores in the control group (t_{38}=4.249, *P*=.02), while no differences were noted for those in mental labor (t_{13}=0.208, *P*=.72). Regarding the educational level subgroup analysis, caregivers with primary education or below in the control group showed significantly higher CBI scores post-intervention (t_{13}=4.494, *P*=.04), whereas no significant differences were observed among those with junior high school education and above (t_{38}=1.273, *P*=.16). In the monthly family income subgroup, caregivers with incomes between 1000 and 3000 RMB (approximately US $149-446) showed a marginally significant trend toward higher scores in the control group (t_9=6.422, *P*=.06), and no statistical differences were observed in the higher income groups.

Adverse Events

No serious adverse events or intervention-related harms were reported among caregivers in either group during the trial. All participant withdrawals (2 in the intervention group and 3 in the control group) were attributable to the death of their care recipients. No predefined adverse outcomes or deaths occurred among the caregiver participants.

Discussion

Principal Results

This study evaluated an mHealth supportive care program based on Fitch's theoretical framework for community-recruited caregivers of people with dementia and diabetes. Screening, recruitment, and participation outcomes indicated that although the number of participants was limited, the vast majority were willing to participate and complete the program. Over the 12-week intervention period, under the supervision and guidance of community health workers, the program exerted positive effects on FCGs of individuals with dementia and diabetes. Specifically, the intervention group demonstrated a statistically significant and substantial reduction in caregiver burden, along with considerable improvements in dementia care knowledge and perceived social support. These robust findings align with existing literature [83,84], supporting the efficacy of structured digital health interventions in alleviating caregiver burden while enhancing caregiving knowledge and perceived support.

Comparison With Prior Work

The observed intervention effects can be attributed to the program's systematic approach to meeting the multidimensional needs of FCGs. The significant reduction in caregiver burden is consistent with the Stress Process Model [85], which suggests that interventions enhancing caregivers' coping resources can alleviate their burden. The platform facilitated health care professionals' delivery of accurate, comprehensible information to FCGs, potentially increasing caregivers' confidence in dementia management, which has a positive effect on reducing caregiver burden [86]. Furthermore, the emotional, social, and spiritual needs module also encouraged caregivers to seek help from family, friends, and health care professionals, activating social support networks and thereby alleviating stress. This buffering effect aligns with the social support model [87], emphasizing the role of social networks in reducing caregiving stress. It is noteworthy that, despite a clinically meaningful reduction (approximately 15%), postintervention burden scores remained above the high-threshold level (36). This underscores the persistent, severe strain inherent in dementia caregiving [88] and highlights that while mHealth support can provide significant relief, it may need to be part of longer-term, adaptive, or multicomponent strategies to address profound, chronic burden fully.

The significant improvement in social support scores within the intervention group indicates the program's efficacy in enhancing caregivers' perception and utilization of social support, aligning with the findings of Tremont et al [89], which underscores the importance of strengthening social support for caregivers. The mechanism of action for this change is consistent with the social support buffer model [87]. On the one hand, the design of the social demand module not only facilitates communication between FCGs and health care workers to reduce social isolation [90] but also provides practical advice for FCGs to cope with stressors and improve their social support capacity. On the other hand, the online platform provided FCGs facing stigmatization, social isolation, or resource deprivation with key alternative pathways for emotional recognition and practical advice, as evidenced in other stigmatized health domains [91-94]. This dual-support model proved effective in alleviating negative emotions such as loneliness and helplessness [95,96], thereby improving caregivers' quality of life [97,98].

Acquiring relevant knowledge is a prerequisite and foundation for improving skill levels [99]. The median dementia care knowledge score in the intervention group increased significantly from 11 to 19, with a significant between-group difference also observed. This was reflected in caregivers' enhanced ability to recognize early complications more accurately, perform more standardized medication management (eg, avoiding incorrect and missed doses), and use nonpharmacological intervention techniques to address common behavioral symptoms. This design aligns with the "goal-oriented" principle of adult learning by providing learners with a clear modular knowledge structure. This improvement (approximately 73%) far exceeded the 20% to 30% knowledge gain achieved by home care workers through online training reported in the studies by Yeh et al [100,101], demonstrating the effectiveness of the mHealth supportive care program designed based on the supportive care framework in this study. This improvement can be attributed to the combination of online learning modules, hands-on demonstration videos, and offline follow-up coaching, which together reinforced caregivers' competence and confidence in managing dementia care [102,103].

The differential intervention effects on caregiver burden across demographic subgroups are a critical finding. Greater burden reduction among male, younger (<60 y), manual labor, caregivers with primary education or below, and lower-income caregivers suggests that the mHealth program's value is particularly pronounced for those who may face barriers to traditional support. This aligns with literature noting higher technology acceptance among males [104,105] and the greater reliance on accessible, free resources among economically disadvantaged groups [106-109], and the finding that individuals with lower educational attainment, who often have limited access to diverse health information sources [110,111], may rely more on structured digital tools that lower the barrier to information acquisition [112]. Conversely, the attenuated effects observed among female caregivers may stem from a misalignment between the intervention's primarily informational and instrumental support and their often more pronounced needs for emotional coping strategies and skills to manage role conflict and intra-family dynamics [113-115]. The text-based, asynchronous nature of the mHealth platform might have been less effective in addressing these immediate emotional and relational stressors. For older caregivers (≥60 y), lower digital literacy and potential discomfort with mobile technology [116,117] could have hindered full engagement with the digital

XSL•FO
RenderX

modules, thereby diluting the intervention's potential impact [118]. Among knowledge workers and caregivers with higher educational attainment (junior high school and above), their preexisting proficiency in information-seeking and likely higher access to alternative educational resources may have diminished the marginal benefit provided by our structured program. Similarly, higher-income caregivers likely have established access to private care services or consultations [119], making a supplementary public mHealth program less critical for burden alleviation. Importantly, the consistent improvements in social support and knowledge across all subgroups confirm that the program's core educational and connective functions delivered universal value, irrespective of these moderating factors for burden reduction.

Limitations

This study has several limitations that warrant consideration. First, although the study achieved statistical power, the geographical restriction to a single urban-rural cluster in Xiamen (5 neighborhood committees and 10 villages) may limit the generalizability of the findings. Additionally, the relatively small sample size could further constrain the population representativeness. Second, this study did not evaluate the cost-effectiveness of the mHealth supportive care program, which is critical for real-world implementation. Third, the COVID-19 pandemic disrupted in-person follow-ups, necessitating alternative methods (eg, phone interviews) that may introduce bias. Then, the DCKS used in this study demonstrated a Cronbach α of 0.626, which, while acceptable for a pilot study, suggests that future large-scale studies should consider using more established scales or further refining this instrument. The scale's reliability may be influenced by item quantity, cultural adaptation factors, and participant heterogeneity. Finally, although the 12-week intervention duration is consistent with comparable studies [120-124], the intervention period was insufficient to assess long-term effects on patient quality of life or program sustainability.

Conclusions

This study examined the efficacy of a supportive care framework-based mHealth intervention for FCGs of individuals with dementia and diabetes. Its primary innovation lies in its theory-driven design that addresses the complex, multidimensional needs of this comorbid caregiving population, distinguishing it from interventions targeting single conditions. The program significantly improved caregiver burden, social support, and dementia care knowledge, contributing novel evidence to a sparsely researched area. Importantly, subgroup analyses revealed differential effectiveness across demographic groups, suggesting that mHealth interventions can be tailored to enhance equity in access to support resources. In practical terms, by offering convenient, low-cost services, integrating health care resources, and enhancing personalized education, the program demonstrates the substantial potential of mHealth technology to improve caregiving outcomes. Furthermore, integrating structured mHealth support with existing community health resources presents a viable and scalable strategy to alleviate caregiver burden in resource-constrained settings. This approach not only helps FCGs cope with practical challenges but also provides a new perspective for promoting health equity at the grassroots level. Future research and implementation should incorporate adaptive or tailored features to meet diverse caregiver needs and advance health equity. Subsequent research should prioritize multicenter trials with longer follow-up, formal cost-effectiveness analyses, and the development of strategies to personalize digital supportive care.

Acknowledgments

We thank all the caregivers of people with dementia combined with diabetes and community health workers who participated in this study.

YY and HL are co-corresponding authors (emails: yuanjiao1994@126.com and leehong99@126.com, respectively), with HL as the senior corresponding author.

Conflicts of Interest

None declared.

Editorial Notice

This randomized study was only retrospectively registered because of substantial delays in the institutional ethics review process during the COVID-19 pandemic, which prevented completion of registration prior to participant enrollment. The study commenced promptly upon receiving expedited ethics approval to address the urgent support needs of caregivers in locked-down communities. The editor granted an exception from ICMJE rules mandating prospective registration of randomized trials because the risk of bias appears low and because the primary purpose was to examine the intervention's effect on the caregivers (as providers) rather than on the patients. The majority of outcomes—social support and dementia care knowledge—directly assess the providers' own psychosocial state and skill acquisition and are not patient-level health outcomes. However, readers are advised to carefully assess the validity of any potential explicit or implicit claims related to primary outcomes or effectiveness, as retrospective registration does not prevent authors from changing their outcome measures retrospectively.

Effectiveness of a Telecare-Based Intervention Program in Supporting Informal Caregivers of Community-Dwelling Older Adults in Reducing Stress Levels: Randomized Controlled Trial

Abstract

Background: Informal caregivers are essential in supporting community-dwelling older adults, especially as global populations age. However, caregiving responsibilities often result in high stress, depressive symptoms, and diminished quality of life. Traditional support services are fragmented, and many programs overlook caregivers' emotional and informational needs. Telecare—the remote delivery of health and social care via digital technologies—offers a promising approach to provide accessible, personalized, and timely support.

Objective: This study evaluated the effectiveness of a telecare-based intervention program, developed by a health-social partnership team, in improving psychological well-being and caregiving outcomes among informal caregivers of community-dwelling older adults. We hypothesized that caregivers in the intervention group would show greater improvements in stress, self-efficacy, depression, quality of life, and caregiving burden compared to those receiving usual care.

Methods: A single-blind randomized controlled trial was conducted from January to December 2023, with 75 informal caregivers providing care to older adults (aged ≥60 y) for at least 4 hours per week. Participants were randomized to an intervention group (n=38, 51%) or a control group (n=37, 49%). The 3-month intervention included (1) biweekly online nurse case management supported by a multidisciplinary health-social team, (2) personalized WhatsApp videos on caregiving skills, and (3) a password-protected caregiver website offering resources and peer discussion. The control group attended 6 in-person educational sessions at a community center. Outcomes such as stress, self-efficacy, depression, quality of life, and caregiving burden were measured at baseline and postintervention.

Results: Participants had a mean age of 65.5 (SD 9.617) years, and 81.3% (61/74) were female. Baseline characteristics were similar between groups. Compared to controls, the intervention group showed significantly higher self-efficacy (t=1.98; P=.04) and lower depression (t=−2.24; P=.03) at follow-up. Within-group improvements in the intervention group were also observed for stress, depression, self-efficacy, mental quality of life, and caregiving burden. No significant between-group differences were found for stress, quality of life, or caregiving burden. No significant within-group improvements were observed in the control group.

Conclusions: This study provides novel evidence that a digitally delivered, nurse-led telecare program—integrating health and social services—can improve psychological outcomes among informal caregivers. These findings have practical implications for health systems seeking scalable, low-barrier solutions to support caregivers. Telecare models may be a valuable complement to traditional services, enhancing caregiver resilience and promoting aging in place while alleviating long-term strain on institutional care systems.

Introduction

Background

With declining fertility and increasing life expectancy, global populations are aging rapidly. In Hong Kong, the proportion of older adults is projected to rise from 17.9% in 2018 to 31.9% by 2038, placing increasing pressure on health care and welfare systems [1,2]. Most older adults prefer aging in place over institutional care, even when frail, making informal caregivers central to community-based elderly care [3].

These caregivers assist with daily tasks, medical appointments, and decision-making, often acting as crucial advocates for their loved ones [4,5]. While their contributions help reduce health care use and improve outcomes for older adults, caregiving is physically and emotionally demanding. Many caregivers face limited access to support, inadequate training, and social isolation, leading to feelings of guilt, fatigue, and mental distress. Studies show that more than 60% of caregivers experience high caregiving burden, 55% report depressive symptoms, and 40% face poor family functioning [6-8].

Despite their vital role, informal caregivers often receive far less support than care recipients. In Hong Kong, the lack of an integrated health and social care system contributes to fragmented services, making it difficult for caregivers to seek timely and coordinated assistance [9]. A local study in 2022 found that many caregivers expressed a strong need for a centralized platform offering information, caregiving resources, and service referrals [10,11].

Advances in digital health offer promising solutions. Telecare, which leverages information and communication technologies, enables remote monitoring and timely support from health care professionals [12,13]. It is especially useful for working caregivers, offering both practical information and emotional support without the constraints of time and location [3,14].

Several systematic reviews have demonstrated that telehealth or telecare interventions—often delivered via phone or videoconferencing—can moderately reduce caregiver stress, burden, and depressive symptoms, particularly among those caring for individuals with chronic conditions or dementia [14,15]. However, most studies have focused on specific clinical populations and lacked integration with broader community-based health and social services [14]. Few programs have incorporated real-time digital case management, asynchronous tailored messaging, and interactive web-based peer support in a comprehensive model. Furthermore, although some telecare interventions have been tested among older adults with multimorbidity and young populations [16], there remains a significant gap in research targeting informal caregivers of community-dwelling older adults with diverse needs. Addressing these gaps, this study evaluates the effectiveness of a multicomponent telecare program, co-developed by a health-social partnership team, in improving caregivers' psychological well-being and caregiving outcomes. We hypothesized that participants in the intervention group would demonstrate greater reductions in stress and depression and greater improvements in self-efficacy, quality of life, and caregiving burden compared to those receiving usual care.

Conceptual Framework

The design of this program was informed by Lazarus and Folkman's [17] transactional theory of stress and coping and the COPE (Creativity, Optimism, Planning, and Expert Information) model. In line with the transactional theory, the intervention aimed to reduce caregiver stress by enhancing their appraisal and coping capacity. Caregivers were supported to adopt problem-focused strategies (eg, goal setting and seeking solutions) and emotion-focused strategies (eg, stress management and emotional support) to manage caregiving challenges [18].

The COPE model provided a practical framework for empowering caregivers through the intervention components. For instance, creativity was encouraged through guided problem-solving discussions; optimism was fostered by reframing challenges and sharing success stories; planning was embedded in structured goal-setting and action plans; and expert information was delivered via health-social professionals and curated digital content [19]. Together, these models guided the development of a multicomponent program that aimed to enhance caregivers' psychological well-being and self-efficacy in managing care responsibilities.

Methods

Overview

The details can be found in the published protocol [20]. The reporting of the trial adhered to the CONSORT (CONsolidated Standards Of Reporting Trials) 2025 checklist (Checklist 1).

Study Design and Setting

This is a single-blinded, 2-armed randomized controlled trial. The study was conducted in collaboration with one of the largest nongovernmental organizations in the world, which has more than 1.7 million older members.

Participants, Recruitment Strategy, and Randomization

The criteria for the inclusion of participants were as follows: (1) being aged ≥18 years; (2) having no cognitive impairment; (3) being able to understand and communicate in Cantonese; (4) providing care for older adults aged ≥60 years for a minimum of 4 hours per week over a period of at least 3 months; (5) being a current smartphone user; (6) having knowledge of how to access the internet; (7) committing to attend biweekly online meetings with the program providers, lasting 15 to 30 minutes, over a period of 3 months; and (8) being willing to receive individual-specific video messages covering caregiving skills via WhatsApp (Meta Platforms Inc.). Exclusion criteria included (1) being an alcoholic or using psychiatric drugs, (2) being illiterate (inability to read and write), (3) having a diagnosis of

XSL•FO
RenderX

chronic mental problems, and (4) having previously participated in health or social programs offered by other organizations.

Participants were recruited between January 2023 and September 2024. The intervention was delivered from January 2023 to December 2024. In community centers, a trained research assistant assessed and recruited eligible participants by sharing details of the study with them and inviting them to join. Verbal consent was obtained from those who agreed to join the program. Following the collection of baseline data, the research assistant contacted the principal investigator of the research team to proceed with randomization. The principal investigator used a software program called "Research Randomizer" to generate numbers, which were placed in sealed envelopes. Each envelope corresponded to either the intervention group ("1") or the control group ("2"). The envelopes were opened sequentially upon receiving a call from the research assistant. In this study, the research assistant was blinded to group assignments, whereas the principal investigator and health care providers were not blinded.

Intervention Group

Overview

The participants in the telecare-based intervention group received a 3-month program consisting of three intervention components: (1) online nurse case management supported by a health-social partnership team, (2) individual-specific video messages covering caregiving skills via WhatsApp, and (3) an online information center and discussion forum accessed via a password-protected, newly developed caregiver website.

Online Nurse Case Management Supported by a Health-Social Partnership Team

Online case management was facilitated by a registered nurse who played a leading role, along with a team of health care professionals from various disciplines, including physiotherapists, Chinese medicine practitioners, and social workers. The registered nurse conducted individual Zoom meetings with each participant in the intervention group every 2 weeks, for a total of 6 Zoom meetings per participant throughout the intervention period. During the initial meeting, the nurse encouraged caregivers to share their current situation and explored any needs or difficulties they were facing, using the Omaha system. The Omaha system comprises the Problem Classification Scheme, the Problem Rating Scale for Outcomes, and the Intervention Scheme [20,21]. This structured approach assisted the nurse in identifying the health needs of the caregivers, setting intervention goals, and evaluating the effectiveness of the intervention. Subsequently, personalized care plans were developed for each participant. The nurse provided recommendations and consulted other health care professionals from relevant disciplines as needed. Follow-up meetings involved ongoing communication with caregivers to discuss any updated situations and provide tailored physical, social, and emotional support based on their specific needs. The nurses offered additional resources and made referrals to the health-social partnership team whenever necessary. This approach leveraged technology to facilitate the provision of coordinated care tailored to the unique needs of each individual. It involved coordinating the efforts of health care professionals to ensure that the clients' requirements were effectively met.

Individual-Specific Video Messages Covering Caregiving Skills Via WhatsApp

With the widespread popularity of WhatsApp, the registered nurse used this platform to offer additional support to the caregivers. The nurse sent individualized messages or videos weekly to the participants through WhatsApp, focusing on their needs as identified from Zoom meetings. The information that was shared encompassed caregiving knowledge and skills, self-care recommendations, health information, and tips for managing emotions. Using this convenient communication tool, the nurse ensured the timely delivery of information while also providing an opportunity for participants to engage in asynchronous communication with the nurse. In the event that participants had any questions or concerns, they could easily respond to the nurse's messages through WhatsApp, allowing the nurse to provide prompt responses and support.

Online Information Center and Discussion Forum Via a Password-Protected, Newly Developed Caregiver Website

A new website was created specifically for informal caregivers, consisting of two components: an information center and a discussion forum. At the beginning of the intervention period, each participant was randomly assigned a preset username and password to log into the website. The usernames were kept anonymous to encourage participants to take part without hesitation, and the passwords were securely protected.

The research assistant played a role in maintaining the website by posting 2 to 3 pieces of useful information in the information center on a weekly basis for caregivers to read. Caregivers were able to comment on these posts and raise questions related to caregiving. Members of the health-social partnership team promptly replied to these questions, providing valuable insights and guidance.

Regarding the discussion forum, participants had the freedom to initiate any caregiving-related questions or discuss the challenges they were facing at any time. The members of the health-social team were available to respond to these questions, and participants were also encouraged to interact with each other, sharing their perspectives and providing suggestions. To foster engagement, the research assistant occasionally initiated new discussion topics, encouraging participants to share their own experiences.

The website served as more than just a source of knowledge and information for caregivers; it also provided them with a platform to express their feelings, receive encouragement, and connect with other caregivers who shared similar experiences.

Control Group

In addition to the telecare-based intervention group, the control group also received the usual services from community centers. The participants in the control group attended 6 face-to-face educational talks during the intervention period, which took place at the community center. These talks were conducted by members of the health-social partnership team, including a

XSL•FO
RenderX

registered nurse, a Chinese medicine practitioner, a physiotherapist, and a mental health nurse.

Each talk covered 1 or 2 specific topics and lasted approximately 2 hours. The health care professionals provided informal caregivers with knowledge and live demonstrations related to self-care and elderly care. The topics addressed during the talks included the management of chronic diseases, acupressure techniques, eye and oral care for older adults, pain management strategies, lifting and transfer techniques, fall prevention measures, swallowing issues, and the management of insomnia. During the questions and answers session of each talk, participants had the opportunity to ask questions and seek clarification on the topics that had been discussed. Upon completion of the follow-up data collection, participants in the control group were offered access to the online caregiver platform and its educational resources to ensure equitable support and knowledge dissemination.

Data Collection

The data were collected at two time points: at baseline (T1) and at the follow-up after the interventions (T2). Data collection for the study involved the use of Qualtrics, a survey platform, where participants were provided with a link to complete the questionnaires themselves. However, for participants who encountered difficulties in filling out the questionnaires online, alternative methods were used. In such cases, data collection took place face-to-face with the assistance of the research assistant and staff from the nongovernmental organizations. They provided support and guidance to the participants, ensuring that the questionnaires were completed accurately and comprehensively. This approach allowed for flexibility in data collection, accommodating participants who may have experienced challenges with completing the online survey.

Outcome Measures

Primary Outcome

The 14-Item Chinese Version of the Perceived Stress Scale

The primary outcome of the study was the stress level of the caregivers. The 14-item Chinese version of the Perceived Stress Scale was used to evaluate the participants' perception of stress and the degree to which they perceived their lives to be uncontrollable [22]. All items are rated on a 5-point Likert scale, ranging from 0 (never) to 4 (very often), and 7 of them (4, 5, 6, 7, 9, 10, and 13) are reverse-scored, with higher scores representing lesser perceived stress. The overall Cronbach α of the Chinese version of the Perceived Stress Scale was 0.906, indicating good reliability [23].

Secondary Outcomes

The secondary outcomes included self-efficacy, depression, quality of life, and caregiving burden of the caregivers.

Self-Efficacy—The Chinese Version of the General Self-Efficacy Scale

The self-efficacy of the individuals was assessed using the Chinese version of the General Self-Efficacy Scale. It is a scale that is widely used to assess an individual's belief in his or her own capacity to cope with stressful situations or difficulties [24,25]. It contains 10 items, and scores for each item range from 1 (not at all true) to 4 (exactly true). The higher the total score, the greater the individual's self-efficacy. The reliability of the Chinese version of the General Self-Efficacy Scale is good, with a Cronbach α of >0.91, indicating internal consistency [26]. The scale has been shown to have good criterion validity and good psychometric properties [27].

Depression—The Chinese Version of the Center for Epidemiologic Studies Depression Scale

The Chinese version of the Center for Epidemiologic Studies Depression Scale is a widely used self-reported questionnaire consisting of 20 items that assess depression symptomatology. It is designed to measure the frequency and severity of depressive symptoms experienced by individuals. The scale has been widely used in research and clinical settings to assess symptoms of depression in Chinese-speaking populations [28-30]. The Chinese version of the Center for Epidemiologic Studies Depression Scale has been validated, with a Cronbach α and intraclass correlation coefficient of the total scale and subscales ranging from 0.82 to 0.88 and from 0.73 to 0.81, respectively [31].

Quality of Life—The Chinese Short Form-12 Health Survey Version 2

The Chinese Short Form-12 Health Survey version 2 is a measure used to assess health-related quality of life. It evaluates 8 domains, namely physical functioning, role physical, bodily pain, general health, vitality, social functioning, role emotional, and mental health [32]. It consists of 12 items divided into a physical component summary score and a mental component summary score [33]. Higher scores indicate that an individual has a better health-related quality of life. The reliability of the Chinese Short Form-12 Health Survey version 2 was good, with a Cronbach α of 0.81 [34].

Caregiving Burden—The Short Form of the Zarit Burden Interview

The Chinese version of the Zarit Burden Interview is a 22-item scale widely used to assess the level of caregiving burden of informal caregivers [35]. The response to each item is rated on a 5-point scale, ranging from 0 (never) to 4 (always). The total score ranges from 0 to 88, with higher scores indicating a greater caregiving burden. The Chinese version of the short form of the Zarit Burden Interview demonstrates very good internal consistency, with a Cronbach α of 0.875 [36,37].

Background Demographic Data

The background demographic data were collected at baseline (T1). They included age, gender, marital status, educational level, employment, economic status, caregiving experience, time of providing care to the older adult per week, relationship with the care recipient, and experience using a smartphone.

Sample Size

A 2-tailed alpha of .05, a power of 80% (a beta error probability of .2), and an effect size of 0.403 were used to determine the size of the sample. This effect size was based on a recent telephone-based mobile health program that assessed the same

XSL•FO
RenderX

primary outcome measure as in this study, namely perceived stress level [38]. On the basis of these considerations, a sample size of 34 individuals per group was necessary.

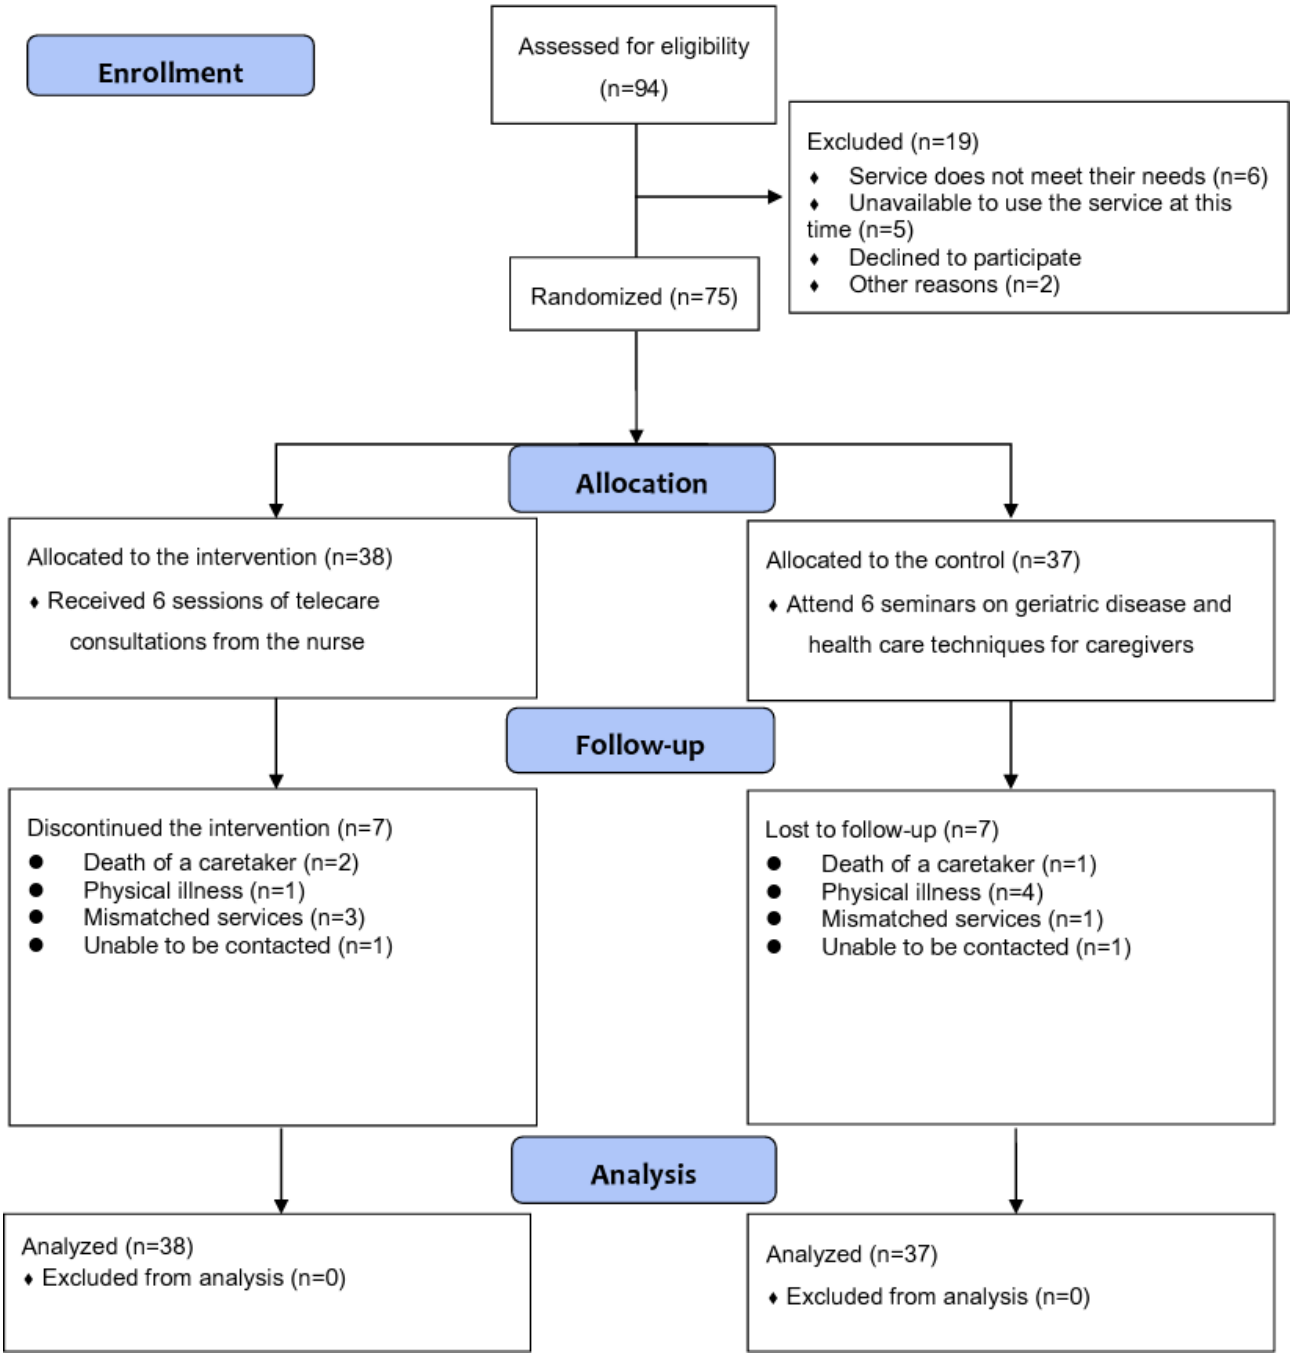
Considering an attrition rate of 10% to 15% reported in a previous program [38], a dropout rate of 15% was assumed for this study. Taking into account this dropout rate, the total sample size required was 80 participants, with 40 participants allocated to each group.

Statistical Analysis

The statistical analysis was conducted using the Statistical Package for the Social Sciences (version 29.0). To compare the demographic data of the intervention and control groups at baseline, the Mann-Whitney *U* test, *t* tests, and chi-square tests were used. Normality was tested using frequency distribution histograms, and all data were found to conform to a normal distribution. Therefore, independent *t* tests (two-tailed) were used to analyze the mean differences in primary and secondary outcomes between the two groups, and paired *t* tests (two-tailed) were used to compare within-group changes before and after the intervention. A primary intention-to-treat analysis was performed. Missing outcome data for participants lost to follow-up were addressed using multiple imputation based on the assumption of missing completely at random. A significant result was determined when the *P* value (level of significance) was .04 for a 2-tailed test, indicating a statistically significant difference.

Ethical Considerations

This study was approved by the Human Subjects Ethics Sub-Committee of the Hong Kong Polytechnic University (reference number HSEARS20210907001). All participants were provided with detailed information about the study's purpose, procedures, risks, and benefits. Written informed consent was obtained from all participants before data collection, and they were informed of their right to withdraw at any time without consequences. All collected data were anonymized, and identifying information was removed before analysis to ensure confidentiality. Secure storage procedures were implemented to safeguard digital and paper records. No personal identifiers were used in reporting results. Participants received a supermarket coupon valued at HK $50 (approximately US $6.50) as a token of appreciation for their time and effort.



Results

Baseline Characteristics

A total of 94 participants were assessed for eligibility. Of these, 75 (79.8%) individuals (n=38, 51%, in the intervention group; and n=37, 49%, in the control group) were eventually recruited and randomized for the study. Seven participants from both groups dropped out for various reasons, such as the death of a caretaker, physical illness, mismatched services, or they were unable to be contacted (Figure 1). Among the 75 participants, 14 (18.7%) were male and 61 (81.3%) were female, with a mean age of 65.5 years. Approximately 62.7% (47/75) were retired, and 52.0% (39/75) were caregivers for their parents. A significant proportion (44/75, 58.6%) had been taking care of older adults for 5 years or longer. All participants were experienced in using smartphones. There were no statistically significant differences in participant characteristics or outcome measures between the groups at baseline. Table 1 presents the demographic characteristics of the participants at baseline.

>18	5 (6.7)	4 (10.5)	1 (2.7)	.

Perceived Stress Level

There were no statistically significant differences in the means between the 2 groups at T2. However, a statistically significant within-group difference was found in the intervention group, where the perceived stress level of the participants was lower at postintervention than preintervention (t=−2.21; P=.04). No within-group difference was observed in the control group.

Self-Efficacy

The intervention group had statistically significant higher self-efficacy scores (t=1.98; P=.04) when compared to the control group. There was also a within-group effect on self-efficacy level in the intervention group (t=−2.28; P=.03).

Depression

The participants in the intervention group had statistically lower depression scores than those in the control group (t=−2.24; P=.03). The intervention group showed a significant within-group effect (t=2.98; P=.009), whereas no significant within-group effect was observed in the control group.

Quality of Life

There were no statistically significant within-group effects in either the intervention group or the control group from T1 to

XSL•FO
RenderX

T2 in the physical components of quality of life. A statistically significant within-group difference was observed in the intervention group from T1 to T2 in the mental components of quality of life. There was no between-group difference at T2 in either the physical or mental components of quality of life.

Caregiving Burden

Similar to perceived stress levels, there was no statistically significant between-group difference at T2 for caregiving burden. However, a statistically significant within-group difference was found in the intervention group from T1 to T2 (t=2.89; P=.009), where participants had a lower caregiving burden postintervention than preintervention.

Comparisons within and between groups in the pretest and posttest mean scores for all primary and secondary outcomes can be found in Table 2.

Discussion

Principal Findings

As populations increasingly age, the role of informal caregivers remains critical in promoting aging in place and ensuring continuity of care. This randomized controlled trial evaluated the effectiveness of a theory-informed, telecare-based intervention in improving caregiver outcomes. The findings demonstrate that caregivers who received the intervention reported significantly higher self-efficacy and lower levels of depression compared to those receiving usual care. Additionally, significant within-group improvements were observed in stress levels, mental quality of life, and caregiving burden in the intervention group, although not reflected in between-group comparisons.

The findings of this randomized controlled trial provide evidence that a telecare-based intervention, grounded in psychological and behavioral theories, can significantly improve depression and self-efficacy among informal caregivers of older adults. These findings align with prior studies demonstrating that accessible, technology-enabled interventions can offer caregivers both emotional support and practical guidance, leading to enhanced psychological resilience and self-management skills [39,40]. Notably, the individualized approach in this intervention—through nurse-led case management and tailored video content—may have allowed caregivers to address their unique caregiving challenges, which supports findings from prior personalized eHealth models [41].

While between-group differences were not observed for perceived stress and caregiving burden, significant within-group improvements in these domains suggest that the intervention had a positive psychosocial effect. This reinforces the importance of early and sustained caregiver support, particularly in settings where community resources are fragmented. Given the rising demand for informal care and global efforts to enable aging in place, these results contribute to a growing body of literature supporting the integration of digital care into community-based services.

The observed reduction in depression among participants may also be attributed to the intervention's multidimensional support system. Caregivers had multiple channels for engagement, including structured video consultations, asynchronous communication via WhatsApp, and peer interaction on a dedicated web platform. This combination not only improved knowledge and problem-solving capabilities but may also have addressed the social isolation frequently reported by caregivers [42]. The inclusion of personalized content likely enhanced relevance and motivation, 2 factors known to influence behavior change in caregiver populations [43].

The lack of significant improvement in the physical components of quality of life may be attributed to the short duration of the intervention, as changes in physical functioning often require longer follow-up or more intensive caregiver support services. Additionally, variations in care recipients' health status and caregiving intensity could have influenced these outcomes. Future studies should consider stratifying analyses by caregiving complexity and incorporating longer-term follow-up, cost-effectiveness analysis, and implementation evaluation to better understand differential effects and inform wider adoption.

Limitations

Several limitations should be noted. First, this trial was prospectively powered for the primary outcome and not powered for subgroup analyses or for detecting smaller effects on secondary outcomes; these estimates should therefore be interpreted with caution. Second, the intervention could not be blinded to participants or providers, potentially introducing response bias. Third, some participants encountered technical difficulties with WhatsApp and the online forum, suggesting that digital literacy and access may affect scalability. Fourth, the duration and content of nurse case management sessions were not formally tracked, limiting fidelity assessment. Fifth, only short-term effects were measured; long-term follow-up is needed to assess sustained impact.

Additionally, we did not collect data on care recipients' functional status, digital literacy, or the caregivers' relationship to the care recipient and caregiving network size. These contextual factors may influence intervention effectiveness and should be considered in future research to enable subgroup analyses and more tailored support.

Conclusions

This study demonstrates that integrating health-social partnership teams with telecare services can significantly improve caregivers' psychological outcomes. Such community-based interventions offer accessible, tailored support to informal caregivers, helping to reduce emotional burden and promote mental well-being—both of which are essential to sustaining long-term caregiving capacity and ensuring quality of care.

Acknowledgments

The authors would like to thank the Salvation Army for their collaboration and express our gratitude to the telecommunications company for their technical support.

Ho Ching Lau was originally the sixth author in the byline but has been removed from the authorship list due to uncontactability during the production process as they were unable to approve revisions or the final, accepted version of the manuscript. Additionally, the Salvation Army and Ho Ching Lau's immediate supervisor at the Salvation Army approve the removal on the ground of uncontactability and confirm Ho Ching Lau was unable to approve the final version of the manuscript or provide a licence to publish agreement. All remaining authors approve of this change and the assessment of the Salvation Army.

Abstract

Background: Interhospital transfer delays remain a major barrier to timely reperfusion therapy and are associated with worse functional outcomes in acute ischemic stroke (AIS), particularly in rural regions.

Objective: This study evaluated whether videoconferencing teleconsultation, compared with the standard referral process, was associated with improved transfer efficiency, treatment delivery, and functional outcomes for patients with AIS requiring interhospital transfer in a hub-and-spoke model.

Methods: We conducted a retrospective cohort study of patients with AIS identified as potential candidates for endovascular thrombectomy (EVT) who were transferred from a primary stroke center (PSC) to a comprehensive stroke center (CSC) between January 2022 and December 2024. Patients were managed using either videoconferencing teleconsultation or the standard referral process, defined as telephone-based consultation between emergency physicians at the PSC and CSC, in which clinical evaluation and thrombolysis decisions were made primarily by the PSC emergency physicians. Group allocation was determined via institutional workflow. The primary outcome was door-in-door-out time, with additional analyses on its components. Secondary outcomes included intravenous thrombolysis rate at the PSC, EVT rates at the CSC, door-to-puncture time, reperfusion rates, and 90-day functional outcomes assessed via modified Rankin Scale shift analysis. Safety outcomes included all-cause mortality within 90 days and symptomatic intracranial hemorrhage after intravenous thrombolysis and/or EVT.

Results: A total of 83 patients were included, with 41 (49.4%) in the teleconsultation group and 42 (50.6%) in the standard referral process group (mean age 73.3, SD 12.9 years), and baseline characteristics were comparable. Teleconsultation was associated with a significant reduction in door-in-door-out time (mean 95.2, SD 22.9 vs 132.3, SD 41.5 minutes; $P<.001$) by shortening computed tomography angiography–to-ambulance notification time (mean 44.6, SD 17.4 vs 79.5, SD 37.6 minutes; $P<.001$). The teleconsultation group had higher intravenous thrombolysis rates at the PSC (26/41, 63.4% in the teleconsultation group vs 17/42, 40.5% in the standard referral process group; $P=.04$), higher EVT rates (14/41, 34.1% in the teleconsultation group vs 6/42, 14.3% in the standard referral process group; $P=.03$), and shorter door-to-puncture time (mean 83.0, SD 35.5 vs 118.5, SD 25.9 minutes; $P=.04$) at the CSC. Patients who received teleconsultation demonstrated a greater shift toward better functional outcomes at the 90th day (27/41, 65.9%; odds ratio 4.55, 95% CI 1.96-11.11; $P<.001$) than patients who did not (13/42, 31.0%; odds ratio 1.35, 95% CI 0.63-2.94; $P=.07$). Safety outcomes were comparable between groups.

Conclusions: Videoconferencing teleconsultation was associated with improved transfer efficiency and higher use of reperfusion therapies and was potentially associated with better functional outcomes. This model may represent a feasible strategy for optimizing stroke care pathways in rural settings. Future studies are warranted to assess its applicability in broader stroke populations beyond conventional EVT eligibility criteria across multicenter networks.

KEYWORDS

acute ischemic stroke; rural; teleconsultation; videoconferencing; transfer efficiency

Introduction

Acute ischemic stroke (AIS) treatment is highly time sensitive as delays in reperfusion therapies such as intravenous thrombolysis and endovascular thrombectomy (EVT) significantly reduce their efficacy [1]. The hub-and-spoke model, widely used in AIS management, connects primary stroke centers (PSCs) with comprehensive stroke centers (CSCs) to provide timely access to advanced care [2]. However, this model often encounters delays, particularly at the PSC level. Current guidelines recommend door-in-door-out (DIDO) times within 120 minutes, but many institutions struggle to meet this target [3,4]. These delays significantly impact EVT initiation and worsen clinical outcomes [5].

In rural regions lacking stroke neurologists, telestroke networks have emerged as a promising solution by facilitating remote neurologic expertise [3]. However, despite prior studies demonstrating improved thrombolysis rates with teleconsultation [6,7], its effects on components of DIDO time and long-term functional outcomes remain less understood. Moreover, existing research has largely focused on telephone-based consultation, with limited integration of videoconferencing-enabled real-time assessment, including clinical evaluation, supervision of thrombolysis administration, imaging interpretation, and treatment planning, which may further optimize stroke-related decision-making and enhance interhospital coordination [8,9].

We hypothesized that videoconferencing teleconsultation would shorten DIDO time, optimize stroke-related decision-making, and improve long-term functional outcomes in patients with AIS transferred from a PSC to a CSC.

Methods

Study Design and Participants

This retrospective cohort study (December 2024) included patients with AIS identified as potential EVT candidates transferred from a PSC in a rural region of central Taiwan (Puli Branch of Taichung Veterans General Hospital) to a CSC (Taichung Veterans General Hospital). Patients were categorized into teleconsultation and standard referral process groups based on whether real-time videoconferencing for neurologic consultation was used. Demographic characteristics and ancillary tests were assessed upon CSC arrival; the National Institutes of Health Stroke Scale (NIHSS) and modified Rankin Scale (mRS) at presentation to the PSC were scored by emergency physicians in the standard referral process group or by neurologists in the teleconsultation group at the PSC.

The primary outcome was DIDO time, defined as the duration from the patient's arrival at the PSC to their departure. To identify specific areas of improvement, DIDO time was subdivided into 3 components, as described in a previously validated study [10]: door to computed tomography angiography (CTA; time from arrival to completion of CTA), CTA to notification (time from completion of CTA to notifying the CSC), and notification to departure (time from notification to ambulance departure). Secondary outcomes included intravenous thrombolysis (tissue-type plasminogen activator [tPA], the only thrombolytic agent in our stroke network) rates at the PSC; EVT rates at the CSC; EVT-related factors at the CSC, including door-to-puncture time, reperfusion rate (defined by a modified treatment in cerebral infarction score of >2b), and rate of tPA administration prior to EVT; and 90-day functional outcomes assessed via the mRS. The safety outcomes included all-cause mortality within 90 days and symptomatic intracranial hemorrhage (sICH) after tPA and/or EVT, defined via follow-up brain computed tomography performed 22 to 36 hours after tPA and/or EVT, which was validated by a previous study [11].

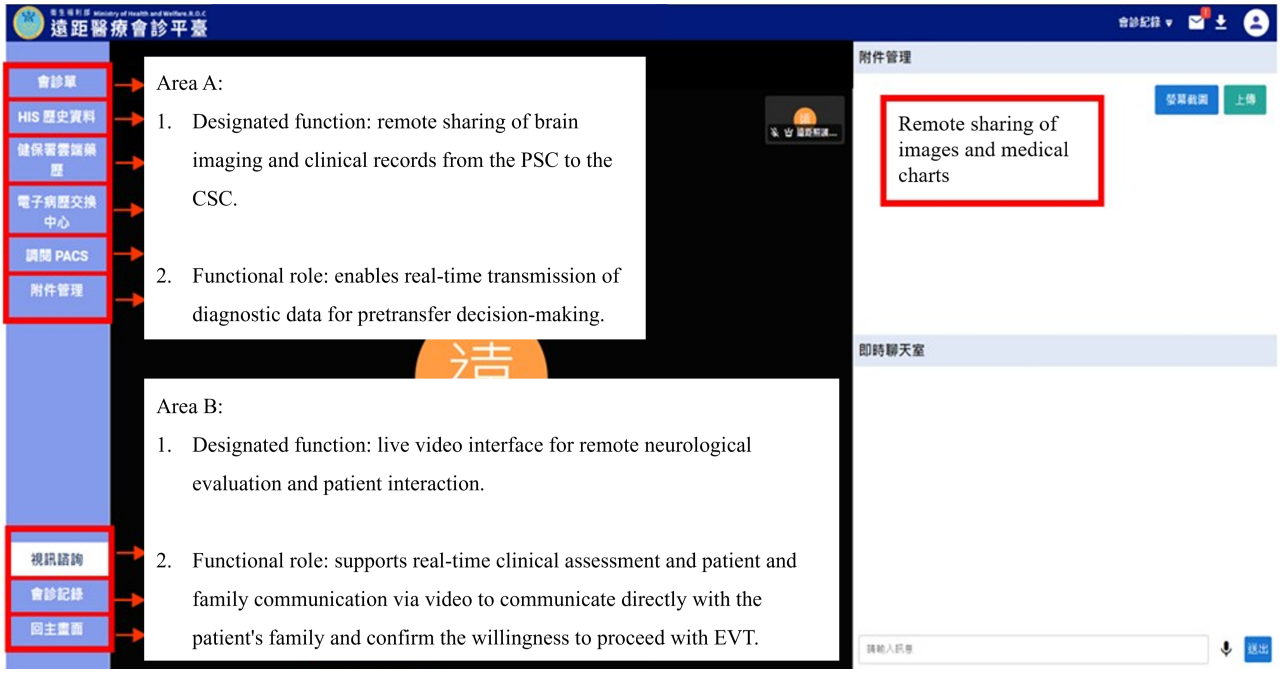
Ethical Considerations

This retrospective cohort study was approved by the Institutional Review Board of Taichung Veterans General Hospital (CE25005B), which granted a waiver of informed consent due to the retrospective nature of the study and the use of existing clinical data as the study posed no more than minimal risk to participants. A deidentified dataset was used for all analyses, and access to the data was restricted to the research team to protect participant privacy and confidentiality. No compensation was provided to study participants. No identifiable participant information or images are included in this manuscript or the supplementary materials.

Study Inclusion and Exclusion Criteria

The inclusion criteria for this study were as follows: (1) patients clinically diagnosed with cerebral infarction by emergency physicians at the PSC at the time of patient arrival and (2) patients identified as potential candidates for EVT by neurologists in the teleconsultation group or by emergency physicians at the PSC in the standard referral process group.

The exclusion criteria were (1) patients diagnosed with hemorrhagic infarction or other stroke mimics based on brain CTA at the PSC; (2) patients exceeding the EVT time window, defined as 6 hours from onset for anterior circulation symptoms or 24 hours from onset for posterior circulation symptoms, as assessed by emergency physicians in the standard referral process group or neurologists in the teleconsultation group based on international guidelines in place at the time [12] and the reimbursement framework of the Taiwan National Health Insurance system; (3) follow-up period of less than 90 days; (4) patients with missing data; and (5) patients not transferred to the CSC via ambulance.



The Process of Teleconsultation and Standard Referral Process

In the teleconsultation group, the videoconferencing process was initiated upon patient arrival at the PSC. Using a 5G-enabled online consultation system, the neurologist at the CSC accessed

XSL•FO
RenderX

shared medical images and charts remotely before or during the brain CTA process. The structural layout and key functional components of the 5G-enabled teleconsultation interface are shown in Figure 1. Following completion of the brain CTA, the neurologist used videoconferencing to directly interact with the patient and their family. This process involved the following six steps: (1) confirming the diagnosis of AIS, (2) assessing the patient and calculating the NIHSS score, (3) verifying the indications and contraindications for intravenous thrombolysis, (4) supervising tPA administration if indicated, (5) communicating directly with the patient's family to explain the indications and risks of EVT, and (6) precoordinating with the neurointerventionalist at the CSC to prepare the operating room after obtaining consent.

Figure 1. The 5G-enabled teleconsultation interface. CSC: comprehensive stroke center; EVT: endovascular thrombectomy; PSC: primary stroke center.

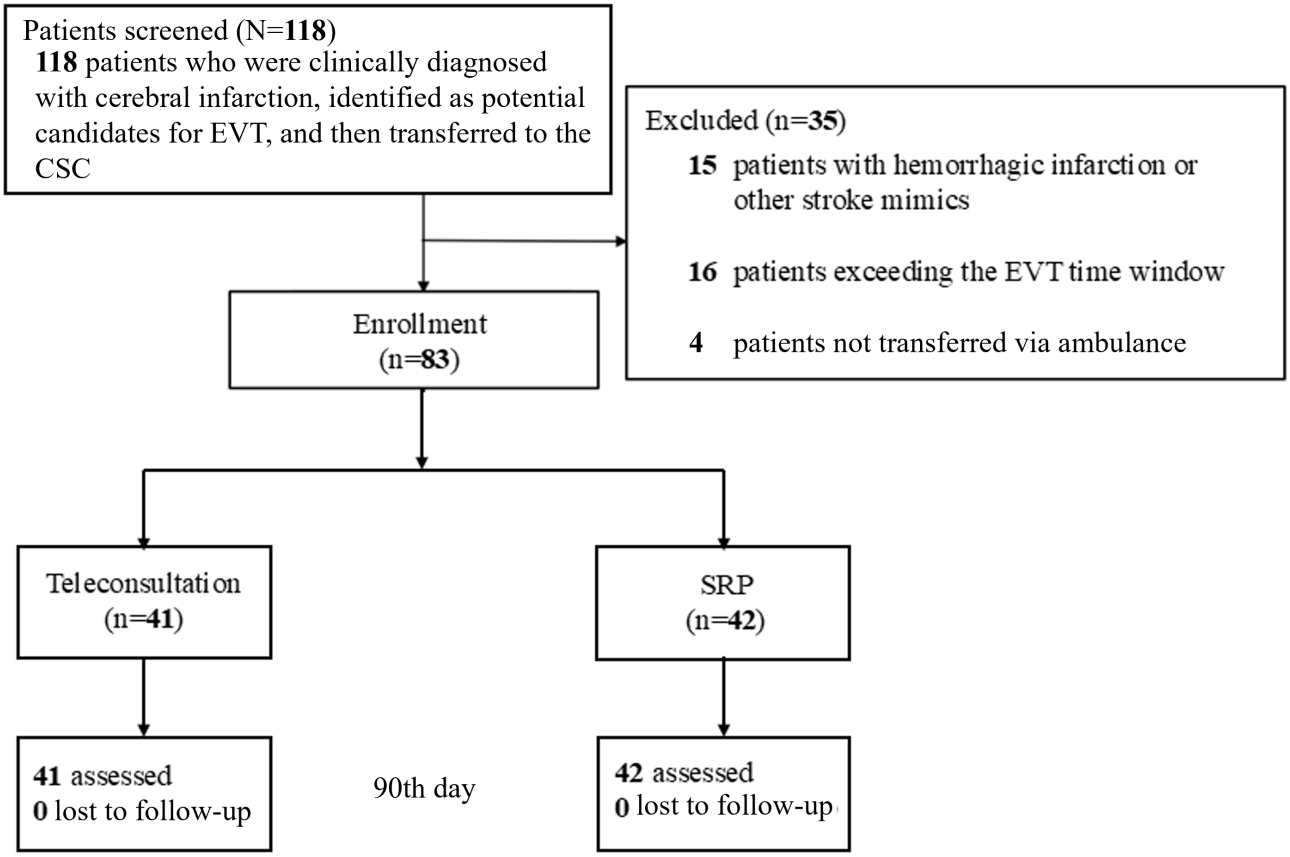
In contrast, the standard referral process involved direct telephone communication between emergency physicians at the PSC and CSC. In this process, the PSC emergency physician independently decided on the administration of tPA, managed the thrombolysis procedure, and determined whether the patient was a potential EVT candidate.

Patients were allocated according to institutional workflow, with the standard referral process used during regular working hours and teleconsultation used during off-hours, including weekday nights and weekends.

Statistical Analyses

Descriptive statistics were reported as means and SDs or medians and IQRs. Group differences were analyzed using the independent 2-tailed *t* test for normally distributed continuous variables, the Mann-Whitney *U* test for nonnormally distributed continuous variables, and the chi-square test for categorical variables. A *P* value of less than .05 was considered statistically significant.

We used independent *t* tests for the primary efficacy outcome, DIDO time and its components. The secondary outcomes, except for the functional outcomes, were analyzed using independent *t* tests or Mann-Whitney *U* tests for continuous variables and chi-square tests for categorical variables. Safety outcomes were compared using the chi-square test. To evaluate functional outcomes, we compared the shift in mRS from presentation to the PSC to the 90th day between groups using proportional odds logistic regression to calculate the odds ratio (OR) for mRS improvement, indicating the likelihood of shifting toward better functional outcomes. The distribution of mRS scores at presentation to the PSC and on the 90th day for each group was visualized using stacked bar charts.



Results

Participants and Baseline Characteristics

A total of 83 patients were enrolled, with 41 (49.4%) in the teleconsultation group and 42 (50.6%) in the standard referral process group (Figure 2). The mean age was 73.3 years, and the baseline characteristics were comparable between the 2 groups. There were no significant differences in gender, comorbidities, smoking, mRS at presentation to the PSC, or NIHSS scores (Table 1).

Primary Outcome

The DIDO time was significantly shorter in the teleconsultation group than in the standard referral process group (mean 95.2, SD 22.9 vs 132.3, SD 41.5 minutes; *P*<.001). Among the DIDO components, the CTA-to-notification time was significantly reduced in the teleconsultation group (mean 44.6, SD 17.4 vs 79.5, SD 37.6 minutes; *P*<.001). Other components, including door-to-CTA time and notification-to-departure time, showed no significant differences except for a borderline significance in the notification-to-departure time (mean 29.2, SD 3.3 vs 30.9, SD 3.9 minutes; *P*=.05; Table 2).

Table . Primary outcome: the door-in-door-out (DIDO) time and the DIDO components between groups.

	Teleconsultation (n=41), mean (SD)	SRP[a] (n=42), mean (SD)	*P* value
DIDO time (min)	95.2 (22.9)	132.3 (41.5)	<.001[b]

Secondary Outcomes

For stroke-related decision-making, the rates of tPA at the PSC (26/41, 63.4% vs 17/42, 40.5%; *P*=.04) and EVT at the CSC (14/41, 34.2% vs 6/42, 14.3%; *P*=.03) were higher in the teleconsultation group than in the standard referral process group. Among EVT-related factors in the CSC, the door-to-puncture time was shorter in the teleconsultation group (mean 83.0, SD 35.5 vs 118.5, SD 25.9 minutes; *P*=.04). The rate of tPA administration prior to EVT revealed no significant differences (9/14, 64.3% vs 4/6, 66.7%; *P*=.92). The reperfusion rate was higher in the teleconsultation group (13/14, 92.9% vs 3/6, 50%; *P*=.03; Table 3).

Table . Secondary outcomes and safety outcomes.

	Teleconsultation (n=41)	SRP[a] (n=42)	*P* value
Stroke-related decision-making, n/N (%)			
Intravenous thrombolysis at the PSC[b]	26/41 (63.4)	17/42 (40.5)	.04[c]
EVT[d] at the CSC[e]	14/41 (34.1)	6/42 (14.3)	.03[c]
EVT-related factors			
Door-to-puncture time (min), mean (SD)	83.0 (35.5)	118.5 (25.9)	.04[f]
Intravenous thrombolysis before EVT, n/N (%)	9/14 (64.3)	4/6 (66.7)	.92[c]
Reperfusion rate (mTICI[g] score of >2b), n/N (%)	13/14 (92.9)	3/6 (50)	.03[c]
Safety outcomes, n/N (%)			
All-cause mortality	5/41 (12.2)	7/42 (16.7)	.56[c]
sICH[h] after intravenous thrombolysis and/or EVT	3/31 (9.7)	2/19 (10.5)	.92[c]

[a]SRP: standard referral process.

[b]PSC: primary stroke center.

[c]*P* value analyzed using the Mann-Whitney *U* test.

[d]EVT: endovascular thrombectomy.

[e]CSC: comprehensive stroke center.

[g]mTICI: modified treatment in cerebral infarction.

[h]sICH: symptomatic intracranial hemorrhage.

Among functional outcomes, at the 90th day, the teleconsultation group demonstrated a greater shift toward better mRS scores (27/41, 65.9% of the participants; OR 4.55, 95% CI 1.96-11.11; *P*<.001) compared to the standard referral process group (13/42, 31.0% of the participants; OR 1.35, 95% CI 0.63-2.94; *P*=.07; Figure 3).

XSL•FO
RenderX

Figure 3. The modified Rankin Scale (mRS) score at presentation to the primary stroke center and the functional outcomes at the 90th day. OR: odds ratio; SRP: standard referral process.

Safety Outcomes

There was no significant difference in all-cause mortality within 90 days between groups (5/41, 12.2% vs 7/42, 16.7%; *P*=.56) or in the incidence of sICH after tPA and/or EVT (3/31, 9.7% vs 2/19, 10.5%; *P*=.92; Table 3).

Discussion

Principal Findings

Our study suggests that videoconferencing teleconsultation is associated with improved interhospital transfer efficiency and functional outcomes for patients with AIS within a hub-and-spoke model. The DIDO time, a critical metric for transfer efficiency, was significantly reduced in the teleconsultation group, driven primarily by a shorter CTA-to-notification time. During the study period, EVT eligibility was determined based on national health insurance reimbursement policies in Taiwan, which adopted extended time windows for anterior circulation stroke only after November 2023. To maintain consistency in inclusion criteria, patients beyond the previous time window were excluded.

Prior research, including a retrospective cohort study in a Dutch ambulance region, identified CTA-to-notification time as the largest contributor to total DIDO time, often exceeding 40% [10]. This delay is primarily attributed to the sequential nature of imaging interpretation, decision-making, and notifying the receiving center. Traditionally, these steps occur in isolation, resulting in cumulative delays before a final transfer decision is made. In our study, the significant reduction in CTA-to-notification time observed in the teleconsultation group may be related to the integration of real-time teleconsultation and 5G-enabled patient assessment, both of which likely contributed to a more streamlined workflow.

First, real-time teleconsultation allowed CSC neurologists to engage in the diagnostic process earlier, either while CTA was being performed or during the interval awaiting the formal CTA report. This parallel approach eliminated the traditional stepwise delays, allowing neurologists to simultaneously interpret imaging results, assess stroke severity, and discuss treatment plans with PSC emergency physicians. The ability to directly support PSC physicians in evaluating tPA eligibility and communicating with patients and their families may have facilitated faster decision-making and contributed to the higher tPA administration rate. This aligns with prior studies demonstrating that teleconsultation improves thrombolysis rates, particularly in facilities lacking on-site neurologists [13,14]. Second, the 5G-enabled patient assessment likely played a role in improving workflow efficiency by integrating real-time video and clinical data sharing. Unlike conventional workflows in which imaging review and patient assessment occur in separate sequential steps, this system enabled CSC neurologists to

XSL•FO
RenderX

conduct simultaneous neurological evaluations and imaging interpretation, ensuring that NIHSS scoring and stroke severity assessments were completed without unnecessary delays [15]. By minimizing gaps between imaging interpretation and transfer notification, decision-making efficiency was likely enhanced [16]. Third, neurologists provided supervision of thrombolysis administration, ensuring protocol adherence and reducing procedural uncertainties, which may have contributed to optimizing treatment delivery and alleviating the workload of PSC physicians [17]. The combined effect of these improvements underscores the potential of videoconferencing teleconsultation in enhancing acute stroke management in resource-limited settings where on-site stroke expertise is unavailable.

Beyond facilitating initial treatment decisions at the PSC, teleconsultation was also associated with higher EVT rates and improved procedural efficiency at the CSC. Traditional telephone-based handovers are often fragmented, leading to delays in aligning treatment plans and preparing intervention teams [18]. In contrast, the video-based teleconsultation model enabled synchronized discussions between PSC and CSC teams, ensuring immediate procedural planning and early mobilization of neurointerventionalists [19]. This streamlined coordination likely contributed to the higher EVT rates, consistent with prior studies showing that pretransfer consultation increases EVT use. Furthermore, the reduction in door-to-puncture time suggests that early procedural activation played a crucial role in optimizing workflow efficiency. Teleconsultation enabled neurologists to assess imaging remotely before patient arrival, confirm EVT candidacy in advance, and initiate angiography suite preparations, leading to a more time-efficient transition. These findings align with evidence suggesting that early procedural planning and pretransfer activation of interventional teams are key determinants in reducing door-to-puncture time [19-21]. The improvement in reperfusion rates likely reflects the combined impact of increased EVT use and shorter procedural delays, which is highly time dependent [1,22].

Although teleconsultation has been well established to improve stroke-related decision-making, its effect on long-term functional outcomes remains controversial [8,23]. Prior studies have shown that hospitals with telestroke capacity achieve higher rates of reperfusion treatment and lower 30-day mortality than hospitals without telestroke capacity in rural settings [23]. As our PSC was located in a rural region, our findings reinforced the role of telestroke networks in expanding access to acute stroke therapies in rural stroke care. However, prior studies have not consistently demonstrated a direct association between telestroke network implementation and long-term functional improvement [5,8,24-27]. Notably, a previous study reported that telestroke network implementation did not significantly alter hospital transfer decisions, suggesting its primary role in improving treatment efficiency rather than hospital selection [28]. However, our current PSC-to-CSC model ensured that all eligible patients were transferred to the same CSC, eliminating confounding effects from variable hospital destinations. This allowed for a more precise evaluation of functional outcomes without interhospital transfer variability.

Our study provides additional evidence suggesting that videoconferencing teleconsultation may be associated with improved functional outcomes. Compared with prior studies that primarily focused on PSC-level decision-making, our study evaluated an integrated workflow spanning both a PSC and a CSC. By incorporating real-time video-based patient assessment, this model enables simultaneous clinical evaluation, imaging interpretation, and treatment planning. In addition to improving transfer efficiency, the observed association between workflow optimization and functional outcomes suggests a potential downstream clinical benefit of teleconsultation beyond conventional process measures. These findings are consistent with those of the TEMPiS (Telemedical Project for Integrative Stroke Care) trial [25], which demonstrated that telestroke networks were associated with a lower proportion of poor outcomes, reinforcing the benefits of telemedicine in acute stroke management. However, while prior research has primarily emphasized reducing severe disability and mortality, our study further explored functional outcome improvements. Taken together, our findings suggest that the potential benefit of teleconsultation may extend beyond isolated improvements in treatment rates to encompass system-wide optimization of stroke care pathways. Future research should investigate whether similar benefits can be observed in more diverse stroke networks.

Notably, while this study used a single hub–and–single spoke design, the streamlined and well-defined teleconsultation workflow described herein suggests that the model is highly feasible and potentially scalable. We have provided a detailed account of the process, encompassing early identification at the PSC, interhospital communication, and pretransfer decision-making. Given that implementation requires only a stable internet connection, standard videoconferencing tools, and a dedicated stroke team on call, this approach could be adapted in other underserved regions aiming to strengthen acute stroke care delivery through telemedicine.

Safety outcomes, including rates of sICH and all-cause mortality, were comparable between groups, supporting the safety of integrating teleconsultation into stroke care. In addition, the comparable rates of tPA administration prior to EVT suggest that the process does not compromise standard protocols but, instead, enhances patient selection and coordination for advanced therapies, which is in line with prior studies demonstrating that remote supervision of intravenous tPA via telemedicine is both feasible and safe [29].

Importantly, beyond clinical outcome measures, our study highlights the role of videoconferencing teleconsultation as a system-level digital health intervention that enables real-time, synchronized decision-making across geographically separated care settings. Unlike conventional telestroke models that primarily support decision-making at the PSC, our approach integrates pretransfer evaluation, interhospital communication, and procedural preparation at the CSC into a continuous workflow. This end-to-end coordination represents a key advancement in telemedicine-enabled stroke care, shifting from isolated decision support toward comprehensive workflow integration. Such a model may be particularly relevant for rural

XSL•FO
RenderX

and resource-limited regions, where timely access to specialized stroke care remains a major challenge.

The strengths of this study include a detailed analysis of DIDO time, allowing for precise identification of workflow inefficiencies. The integration of real-time videoconferencing facilitated real-time patient assessment, ensuring direct NIHSS scoring and verification of tPA eligibility. Furthermore, the PSC in our study serves as the primary stroke referral center for multiple rural townships in central Taiwan, including Puli, Guoxing, Ren'ai, Yuchi, and Zhongliao, with a total service population of approximately 150,000. Our findings may offer applicable insights for enhancing rural stroke care.

However, several limitations should be considered. First, the relatively small sample size limits the statistical power of this study and may affect the precision of effect estimates, particularly for secondary and safety outcomes. As a result, this study may be underpowered to detect modest differences between groups, and the observed associations, especially regarding functional outcomes, should be interpreted with caution. Second, the single hub–and–single spoke design, chosen to minimize variability in transfer times by ensuring that all patients were transported via ambulance, may further limit the generalizability of our findings to more complex, multicenter stroke networks. Third, the retrospective design might introduce potential selection bias as treatment decisions were based on real-world clinical practice rather than on randomized allocation. Fourth, the inclusion criteria were aligned with the reimbursement policy of the Taiwan National Health Insurance system, which covers EVT within 6 hours for anterior circulation stroke and within 24 hours for posterior circulation stroke. This policy-driven framework may have resulted in the inclusion of patients who were transferred but ultimately did not undergo EVT. In addition, group allocation was determined by institutional workflow, which may introduce selection bias. Notably, workflow efficiency remained improved in the teleconsultation group despite being implemented during off-hours.

Conclusions

Videoconferencing teleconsultation was associated with improved interhospital transfer efficiency, facilitated timely reperfusion therapy, and may be associated with better functional outcomes in patients with AIS within a hub-and-spoke model while maintaining patient safety. Future research should evaluate this model's scalability in multicenter networks and its impact on broader stroke populations beyond standard EVT eligibility criteria.

Acknowledgments

The authors appreciate all the participants in this study and the superintendents of Taichung Veterans General Hospital, Professor Shih-Ann Chen and Professor Yun-Ching Fu, for establishing the Telehealth Center, whose advanced insights contributed to this manuscript. The authors also sincerely thank Professor I-Hui Lee, the mentor of the first author (CSW), for her valuable guidance in study design.

Funding

This research did not receive any specific grants from public, commercial, or not-for-profit funding agencies.

Abstract

Background: Deep brain stimulation (DBS) is widely performed in patients with advanced Parkinson disease (PD). Recent advances in technology have facilitated remote programming of DBS devices, reflecting an emerging trend in neuromodulation approaches, and offering a potential framework for patient-centered care. These online sessions for patients with PD who underwent de novo implantation of DBS devices have been reported to be safe and effective, similar to in-clinic sessions. Currently, evidence for patients with chronically implanted DBS devices remains limited.

Objective: This study aimed to evaluate the safety, feasibility, and preliminary efficacy of online sessions for patients with PD who had chronically implanted DBS devices, and to determine whether this approach could reduce patient burden without compromising clinical management.

Methods: A prospective, single-arm, longitudinal, nonrandomized, self-controlled cohort study was conducted at 2 centers in Japan. Eighteen patients with PD who had chronically implanted DBS devices were enrolled. Two in-clinic sessions were substituted with online sessions. The Movement Disorder Society Unified Parkinson's Disease Rating Scale Part III scores were assessed at baseline, after in-clinic sessions, and online sessions. The Multidimensional Evaluation Scale for Patient Impression Change—Japanese version, Patient's Global Impression of Change, and Clinical Global Impression of Change were each administered after both in-clinic and online sessions. The Telehealth Usability Questionnaire and the Online Usability Questionnaire for Programming were evaluated once after online sessions.

Results: The Movement Disorder Society Unified Parkinson's Disease Rating Scale Part III scores did not differ significantly across the 3 assessments. The Multidimensional Evaluation Scale for Patient Impression Change—Japanese version scores revealed that no items but item 3, "overall sleep," significantly worsened after online sessions. The Patient's Global Impression of Change and Clinical Global Impression of Change scores were comparable between in-clinic and online sessions. The Telehealth Usability Questionnaire scores indicated that online sessions were generally favorable, although the "Reliability" was rated comparatively lower. The mean total time and cost saved per visit were 280 minutes and 7974 yen (US $1≈155 JPY), respectively. One patient experienced a fall and lumbar compression fracture during the online visit period and dropped out of the study because of hospitalization.

Conclusions: Online sessions may be a feasible option for a subset of patients with PD carrying chronically implanted DBS devices. Although online sessions cannot fully replace in-person assessments, they may serve as a practical alternative when adequate caregiver support, sufficient digital literacy, and a reliable connection are ensured. Clinicians should note that sleep-related symptoms may worsen in some patients. While time and cost savings are not direct indicators of care quality, these benefits still provide meaningful support for patients and caregivers. Overall, online sessions may complement routine follow-up in stable patients undergoing chronic DBS therapy.

KEYWORDS

Parkinson disease; telemedicine; deep brain stimulation; remote consultation; motor disorders; global burden of disease; caregiver burden

Introduction

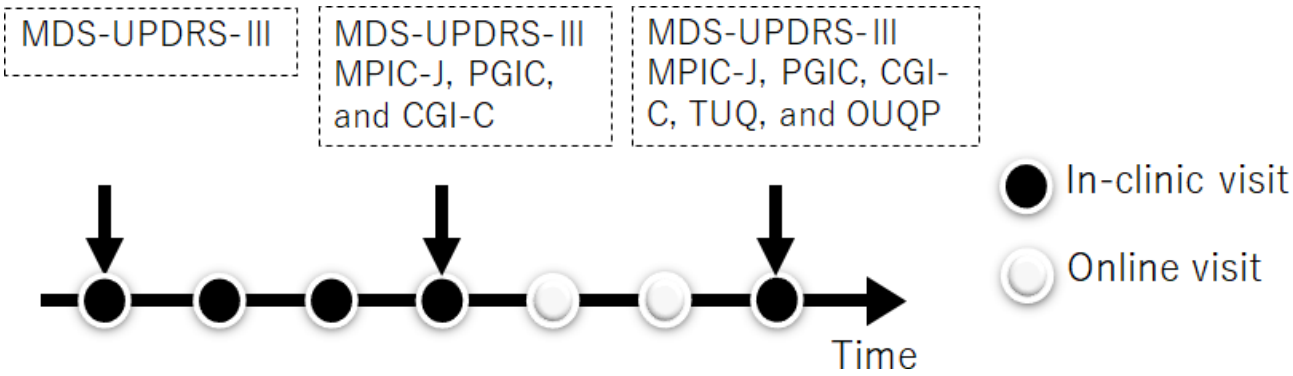
Online Sessions as an Emerging Modality in Parkinson Disease Care

Parkinson disease (PD) is a multisystem neurodegenerative disorder characterized by motor and nonmotor symptoms [1]. Due to its progressive nature, the burden on patients and their caregivers increases over time. Recent studies have demonstrated the effectiveness of online sessions including remotely supervised exercise and telerehabilitation for patients with PD [2-6]. The advancement and prevalence of remote technologies, in part owing to the COVID-19 pandemic, have promoted remote programming and surveillance in patients who have undergone deep brain stimulation (DBS) [7-18]. Several studies have shown that online sessions are highly effective, particularly in reducing the cost and time burden for patients with PD who underwent DBS, as well as their caregivers [8-11,15-18].

Current Evidence on Online Sessions for DBS

In patients with de novo DBS, 2 randomized studies and several observational studies have shown that remote programming is safe, effective, and comparable with in-clinic adjustments, with high satisfaction rates [7,11,12,15,16,18]. These findings suggest that online sessions can support early postoperative management and reduce the need for frequent hospital visits. In contrast, evidence in patients who had chronically implanted DBS devices is more limited. Retrospective and cross-sectional studies indicate that remote programming may reduce travel distance, time, and financial burden, and that patient satisfaction is generally favorable [8,10,13,14,17]. However, these studies are heterogeneous, mostly observational, and lack prospective evaluation.

Rationale and Objective for This Study



The clinical needs of patients who had undergone chronic DBS differ from those of de novo cases, as long-term follow-up typically involves clinical review, medication management, and device checks rather than frequent parameter adjustments. Thus, despite accumulating evidence, prospective, population-specific data on the safety and feasibility of online sessions in chronic DBS care remain insufficient. To date, no prospective study has evaluated online sessions in patients with PD who underwent chronic implantation of DBS devices, and detailed data are still lacking. Given these gaps, we aimed to explore whether online sessions could be implemented safely and feasibly in patients with chronic DBS devices, while assessing their preliminary efficacy in maintaining clinical stability and reducing patient burden—particularly travel-related demands—without compromising routine clinical management.

Methods

Study Design

A prospective, single-arm, longitudinal, multicenter, nonblinded, nonrandomized, and self-controlled cohort trial was conducted at Tokushima University Hospital and Kurashiki Heisei Hospital in Japan between 2023 and 2024. All participants had been treated with in-clinic sessions, followed by 2 consecutive online sessions (Figure 1).

Figure 1. Schematic figure explaining the planning of the experiment. CGI-C: Clinical Global Impression of Change; MDS-UPDRS-III: Movement Disorder Society Unified Parkinson's Disease Rating Scale Part III; MPIC-J: Multidimensional Evaluation Scale for Patient Impression Change—Japanese Version; OUQP: Online Usability Questionnaire for Programming; PGIC: Patient's Global Impression of Change; TUQ: Telehealth Usability Questionnaire.

Ethical Considerations

This study was approved by the Ethics Committee of Tokushima University (approval number 4409, date of approval August 28, 2023) and the Ethics Committee of Kurashiki Heisei Hospital (approval number R05-008, date of approval July 4, 2023) in accordance with the Declaration of Helsinki. The participants received detailed study information and signed informed consent forms before enrollment. To protect participant privacy, all data were deidentified, stored on secure institutional servers, and accessible only to authorized study personnel. No audio or video recordings were collected during online sessions, and all telehealth communications were conducted through encrypted,

XSL•FO
RenderX

institution-approved platforms. Participants did not receive financial compensation for study participation.

Participants

All participants met the following inclusion criteria: (1) adult patients (aged 18 years and older) diagnosed with PD, (2) those who had received bilateral subthalamic nucleus (STN) DBS using the Infinity DBS system with the NeuroSphere Virtual Clinic remote care (Abbott), (3) those who had a follow-up period of at least 3 years postsurgery, (4) those who had never experienced online sessions, and (5) those who are able to operate the online system with or without caregivers and consented to be included in this study. For the sample size calculation, we estimated that 15 participants would provide 80% power (with a 5% probability of type I error) and a large effect size using G*Power 3.1. Therefore, we set the target sample size to at least 17 participants and estimated a dropout rate of 10%.

Assessments

Primary Outcomes

Clinical Motor Assessments

The Movement Disorder Society Unified Parkinson's Disease Rating Scale Part III (MDS-UPDRS-III) scores were recorded before and after each of the 2 in-clinic sessions and 2 online sessions, using identical in-person, face-to-face assessment protocols conducted by the same evaluators with active DBS stimulation and on medications (Figure 1).

Safety Assessments

Safety was evaluated throughout the study period by monitoring adverse events. Participants were reported any new or worsening medical conditions during both in-clinic and online sessions. All adverse events, including falls, injuries, or any clinical deterioration, were recorded by the investigators, regardless of their perceived relationship to the online sessions.

Secondary Outcomes

Patient-Reported Assessments

Three self-reported numerical rating scales, including the Multidimensional Evaluation Scale for Patient Impression Change—Japanese version (MPIC-J) [19,20], Patient's Global Impression of Change (PGIC) [21], and Clinical Global Impression of Change (CGI-C) [22,23], were obtained before and after the 2 online sessions (Figure 1). Two self-reported numerical rating scales, the Telehealth Usability Questionnaire (TUQ) [24] and Online Usability Questionnaire for Programming (OUQP), were evaluated after the 2 online sessions (Figure 1).

The MPIC assesses 8 domains (overall status, pain, sleep, mood, physical functioning, coping with pain, managing pain flare-ups, and medication effectiveness) with 7 ratings: 1 = very much improved, 2 = much improved, 3 = minimally improved, 4 = no change, 5 = minimally worse, 6 = much worse, and 7 = very much worse [19]. PGIC was rated on the 7-point scale: 1 = no change (or condition has got worse); 2 = almost the same, hardly any change at all; 3 = a little better but no noticeable change; 4 = somewhat better, but the change has not made any real difference; 5 = moderately better, and a slight but noticeable change; 6 = better, and a definite improvement that has made a real and worthwhile difference; and 7 = a great deal better, and a considerable improvement that has made all the difference [25]. The CGI-C was also rated on the 7-point scale: 1 = very much improved, 2 = much improved, 3 = minimally improved, 4 = no change from baseline (the initiation of treatment), 5 = minimally worse, 6 = much worse, and 7 = very much worse since the initiation of treatment [22,23]. The TUQ has 6 subdomains, with each consisting of 3 - 4 questionnaires with 5 answers: "Strongly disagree," "Disagree," "Neutral," "Agree," and "Strongly Agree." Subdomains are "Usefulness," "Ease of use and learnability," "Interface quality," "Interaction quality," "Reliability," and "Satisfaction and future use" [24]. The OUQP was developed by modifying the assessment items originally proposed by Deer et al [9], a 6-item questionnaire with cost and time savings. Patient satisfaction was assessed using 3 criteria: answering yes/no or neither. Patients were additionally invited to comment on any challenges or difficulties they experienced during the online sessions.

Clinician-Reported Assessments

Clinician satisfaction with the online sessions was assessed using 5 criteria in the OUQP. Clinicians also provided qualitative feedback regarding any operational or clinical difficulties encountered during remote programming.

Cost and Time Burden Evaluation

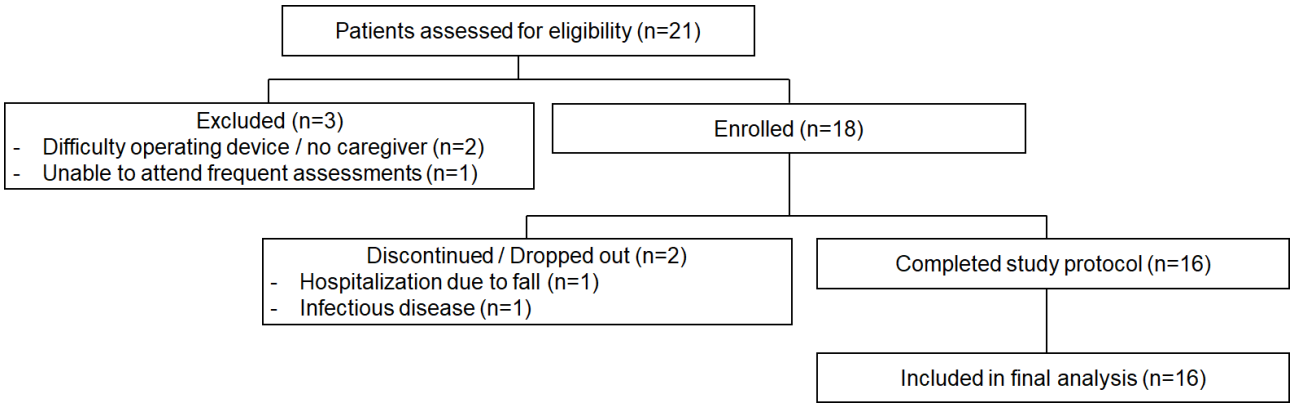
Patients were also asked to report the cost and time burdens associated with their in-clinic sessions. The OUQP included items assessing perceived time and cost savings during online sessions. Patient satisfaction with online sessions was assessed using 3 yes/no/neither questions, and patients were asked to describe any difficulties encountered. The Japanese version of PGIC, CGI-C, TUQ, and OUQP is provided in Multimedia Appendix 1.

Statistics

All measured data are presented as mean (SD). The 2-tailed *t* test (matched pairs) was used to analyze the 2 groups when the normality of distribution was verified by the Shapiro-Wilk test. If normality was not confirmed, the Wilcoxon rank-sum test was used. Significance and effect size were determined using Hedges *g* when normality was observed, or Cliff δ when it was not. The Friedman test was applied to compare repeated measures of MDS-UPDRS-III across the 3 assessment points and to evaluate seasonal variation in exposure days across 4 seasons (spring, summer, autumn, and winter).

For any MPIC-J items that showed statistically significant pre-post differences, additional exploratory analyses were conducted to evaluate the clinical relevance of the observed changes. Specifically, the minimally important change (MIC) was estimated using the MPIC-J 7-point global change scale as an anchor; receiver operating characteristic (ROC) analysis was performed to identify the optimal cutoff discriminating subjective worsening, and distribution-based estimates (0.5 SD) were also calculated. Correlation analyses were performed to explore associations between changes in clinical outcomes and candidate explanatory variables. Point-biserial correlation

XSL•FO
RenderX



coefficients (*r*) were used for sex, which was treated as a dichotomous variable. For all other continuous or ordinal variables, Spearman rank correlation coefficients (ρ) were calculated. All statistical analyses were performed using R (version 4.2.1; R Core Team) [26], and the significance level was set at $P<.05$.

Results

Overview of Participants

Between August 2023 and April 2024, 21 patients were screened for eligibility from 2 hospitals. Three patients were excluded from the study for the following reasons: 2 patients had difficulty operating the equipment and no familial support, and 1 patient found it challenging to attend frequent assessment appointments. Eighteen patients were enrolled, of whom 2 discontinued participation because of hospitalization and infectious disease. The dropout rate was 11% (2/18). All data points were complete, and no missing values were identified throughout the dataset (Figure 2).

Figure 2. Participant flow diagram. A total of 21 patients were screened; 3 were excluded due to difficulty operating the device or inability to attend frequent assessments. Eighteen patients were enrolled, of whom 2 were discontinued because of hospitalization or infectious disease. Sixteen patients completed all assessments and were included in the final analysis.

The demographic profile was as follows: 50% (8/16) were female, average age was 67.1 (SD 8.4) years (95% CI 62.6 - 71.5), average Hoehn-Yahr Scale score was 3.7 (SD 1.0; 95% CI 3.1 - 4.2), average duration of illness was 15.8 (SD 4.4) years (95% CI 13.4 - 18.1), average duration after bilateral STN-DBS was 6.6 (SD 1.9) years (95% CI 5.5 - 7.6), and the average distance from the resident to the clinic was 42.8 (SD 49.7) kilometers (95% CI 16.3 - 69.3; Table 1). There was no difference in the duration between each assessment visit of in-clinic and online sessions (mean 138.4, SD 64.5 days, 95% CI 104.1 - 172.8 vs mean 152.6, SD 57.2 days, 95% CI 122.2 - 209.8; $P=.53$; Hedges $g=0.220$). Friedman tests revealed no significant seasonal variation in exposure days across the 4 seasons for in-clinic sessions (mean 56.8, SD 33.2 days, 95% CI 39.0 - 74.6; $\chi^2_3=6.73$; $P=.081$; Kendall $W=0.140$) or online sessions (mean 54.7, SD 36.2 days, 95% CI 35.8 - 73.6; $\chi^2_3=6.83$; $P=.078$; Kendall $W=0.143$). No adjustments were made to antiparkinsonian medications or to any sleep-affecting drugs throughout all study periods.

[c]M: male.

Primary Outcome

Motor Assessments

All 16 patients completed all the assessments. Motor symptoms were assessed by using MDS-UPDRS-III. The average total scores were 24.9 (SD 21.1; 95% CI 13.7 - 36.2), 28.6 (SD 22.5; 95% CI 16.6 - 40.6), and 28.8 (SD 22.0; 95% CI 17.1 - 40.6) at baseline, after in-clinic session, and after online session. Friedman test revealed no differences between the groups (P=.27, Friedman χ^2_2=2.63). Comparison of the rate of change (%) in total MDS-UPDRS-III scores between in-clinic and online sessions revealed n significant difference (mean −19.3%, SD 33.4% vs mean −3.2%, SD 35.3%; P=.31; Hedges g=0.474). These findings indicate no statistically or clinically meaningful worsening of motor symptoms in online sessions compared with in-clinic sessions.

Safety

One patient experienced a fall and lumbar compression fracture during the online visits period. and dropped out from the study because of hospitalization. No other adverse events were observed.

Secondary Outcomes

Patient-Reported Assessments

In comparison of MPIC-J scores of in-clinic and online sessions, no items but MPIC-J item 3 (overall sleep) showed significant difference (mean 3.31, SD 0.85 vs mean 4.19, SD 0.88; P=.013, Cliff δ=−0.49) (Table 2). To further examine the clinical relevance of this change, exploratory analyses were performed for MPIC-J item 3. The mean change of 0.88 points exceeded the distribution-based threshold of 0.5 SD (=0.43), indicating a moderate magnitude of change. Using the MPIC-J 7-point global change scale as an anchor, participants who reported “minimally worse” sleep (MPIC-J score=5; n=4) showed a mean increase of 2.0 points in MPIC-J item 3, representing a reference value for the MIC in the worsening direction. ROC analysis, in which MPIC-J scores were dichotomized into “worsened” (5-7) and “not worsened” (1-4), identified a 1-point increase in MPIC-J item 3 as the optimal cutoff for discriminating subjective worsening (sensitivity 1.00 and specificity 0.73). Taken together, although the observed mean change exceeded the distribution-based threshold, it did not reach the ROC-derived cutoff (1 point) or the anchor-based MIC estimate

XSL•FO
RenderX

(2 points), suggesting that the magnitude of sleep deterioration may be limited in its clinical significance.

Correlation analyses were conducted to evaluate whether the change in MPIC-J item 3 was associated with baseline characteristics, exposure-related factors such as the duration of in-person and online sessions, or changes in other clinical measures (Tables S1-S3 in Multimedia Appendix 2). No baseline characteristics showed significant correlations with the change in MPIC-J item 3. The duration of in-person sessions was not associated with ΔMPIC-J item 3 (ρ=0.0077, *P*=.98). In contrast, the duration of online sessions showed a strong positive correlation with ΔMPIC-J item 3 (ρ=0.71, *P*=.0021), and this association remained significant after Bonferroni correction. Regarding exposure-related and change-based variables, ΔMDS-UPDRS-III during the in-person period showed a positive correlation with ΔMPIC-J item 3 (ρ=0.52, *P*=.038), and ΔMPIC-J item 7 (coping with pain) was also correlated with ΔMPIC-J item 3 (ρ=0.54, *P*=.031). ΔMPIC-J item 2 (pain) showed a similar trend (ρ=0.44, *P*=.086). This implies that patients with greater clinical instability were more likely to experience sleep deterioration when they spent a longer proportion of the follow-up period in online sessions. However, none of these correlations remained significant after Bonferroni correction, indicating that these associations should be interpreted as exploratory and may reflect covarying deterioration across multiple domains rather than robust predictors of sleep worsening.

There was no difference between in-clinic and online sessions for both PGIC and CGI-C (mean 1.88, SD 1.05, 95% CI 1.31 - 2.44 vs mean 1.81, SD 0.95, 95% CI 1.31 - 2.32, *P*=.73, Cliff δ=0.01 for PGIC-1; mean 5.19, SD 0.81, 95% CI 4.76 - 5.62 vs mean 5.06, SD 1.25, 95% CI 4.40 - 5.73, *P*≥.99, Cliff δ=−0.10 for PGIC-2; and mean 3.81, SD 0.73, 95% CI 3.43 - 4.20 vs mean 3.63, SD 0.70, 95% CI 3.25 - 4.00, *P*=.53, Cliff δ=0.15 for CGI-C).

Table . MPIC-J[a] scores on in-clinic and online sessions.

Items	In-clinic		Online		*P* value	Cliff δ
	Mean (SD)	95% CI	Mean (SD)	95% CI		
Overall status	3.94 (0.97)	3.42 - 4.45	4.31 (0.98)	3.79 - 4.85	.27	−0.22
Overall pain	3.94 (0.66)	3.59 - 4.29	4.25 (1.03)	3.70 - 4.80	.13	−0.13

[b]*P*<.05.

Usability

The TUQ revealed that more than 70% of the patients responded with “Neutral,” “Agree,” or “Strongly agree” to all items except item 15, “I think the visits provided over the telehealth system are the same as in-person visits.” For this item, 25% (4/16) of patients selected “Disagree,” and 6.25% (1/16) of patients selected “Strongly disagree” (Table 3). There were 6 subdomains in the TUQ: “usefulness” (items 1 - 3), “ease of use and learnability” (items 4 - 6), “interface quality” (items 7 - 10), “interaction quality” (items 11 - 14), “reliability” (items 15 - 17), and “satisfaction and future use” (items 18 - 21). In favor of online sessions, selecting “Strongly agree” or “Agree” was 70.8% (34/48) in “usefulness” domain, 85.4% (41/48) in “ease of use and learnability” domain, 53.1% (34/64) in “interface quality” domain, 62.5% (40/64) in “interaction quality” domain, 37.5% (18/48) in “reliability” domain, and 62.5% (40/64) in “satisfaction and future use” domain (Tables 3 and 4). Overall, patients found the online sessions useful, feasible, and satisfactory, although some concerns about reliability were noted.

Table . Subdomains in Telehealth Usability Questionnaire.

Subdomains	In favor of in-clinic sessions	Neutral	In favor of online sessions
Usefulness, %	10.4	18.8	70.8
Ease of Use and Learnability, %	6.3	8.3	85.4
Interface Quality, %	14.1	32.8	53.1
Interaction Quality, %	7.8	29.7	62.5
Reliability, %	14.6	47.9	37.5
Satisfaction and Future Use, %	9.4	28.1	62.5

The OUQP revealed that 2 clinicians experienced no difficulty in using online devices and felt a reduced necessity for in-clinic sessions in 62.5% (10/16) of the patients; however, sometimes it was not easy to provide rapid treatment resolution (5/16, 31.3%; Table 5). The reasons were, in part, the inability of clinicians to touch patients directly (eg, inability to check the rigidity of extremities) and the anxiety of the patients for not consulting in person. Approximately 70% of patients with PD were satisfied with online sessions; however, the preference for online sessions was 37.5% (6/16), which was the same percentage as the preference for an in-clinic session.

Table . Online Usability Questionnaire for Programming.

Items	Yes	No	Neither
For physician, %			
Ability to establish an audiovisual connection	100.0	0.0	0.0
Achieving the clinical goals of a programming session	100.0	0.0	0.0
Ability to complete a session	100.0	0.0	0.0
Reduction in the need for an in-person follow-up after a remote session	62.5	18.8	18.8
Providing rapid treatment resolution	68.8	0.0	31.3
For patient, %			
Satisfied with a remote session	68.8	12.5	18.8
Preference for a remote session	37.5	37.5	25.0
Providing rapid treatment resolution	56.2	37.5	6.3

Reduction in Time and Cost Burdens

The mean time and cost per patient visit were 148.4 (SD 81.1 minutes; 95% CI 105.2 - 191.6) and 4365.0 (SD 7472.9 Japanese yen [US $1≈155 JPY]; 95% CI 383.0 - 8,347.0), respectively. Seventy-five percent of patients with PD required caregivers for their visit, irrespective of in-clinic or online sessions. The average number of caregivers attending the patients was 0.88 (SD 0.60; 95% CI 0.56 - 1.19) per visit (Table 1). The average total time and cost saved per visit for patients and caregivers were calculated as 280.0 (SD 181.5 minutes; 95% CI 183.3 - 376.7) and 7974.4 (SD 14,235.9 JPY [US $1≈155 JPY]; 95% CI 388.6 - 15,560.1), respectively (Table 1).

Discussion

Main Findings in Patients Under Chronic DBS

Our study demonstrated the feasibility of online sessions using the NeuroSphere Virtual Clinic remote care system compared with the conventional in-clinic sessions. Motor symptoms did not change in either group, as assessed using the MDS-UPDRS-III. Motor stability in patients under chronic DBS is expected over short intervals, regardless of visit modality; therefore, the absence of deterioration might not be interpreted as evidence of clinical effectiveness. This study provides a prospective evaluation of the effect of online sessions on patients who have already been implanted with and under chronic DBS. To our knowledge, this is the first study to investigate the effects of online sessions using DBS devices in Japanese patients. While the prospective design improves data quality compared with retrospective reports, the single-arm nature of this study precludes definitive causal inferences.

The only adverse event occurred between the last in-clinic visit and the first online session, making it unlikely that the event was related to the online sessions. Overall, online sessions appeared to be feasible and clinically acceptable from a safety perspective for patients with PD who have chronically implanted DBS devices. Although the fall was not clearly attributable to online sessions, the inability to directly assess rigidity, balance, and gait remains an inherent limitation of remote care. As expected, there was a substantial reduction in both cost and time burden for patients and caregivers [8,9,11,15-18].

Patient-Reported Outcomes and Usability

In this study, approximately half of the patients thought that online sessions were equivalent to in-clinic sessions, as reflected in TUQ item 15 and the OUQP. Around 70% of patients reported satisfaction with the online sessions (TUQ item 21 and OUQP; Tables 3 and 5). Given that TUQ subdomain "Usefulness" refers to "the positive effects on clinical outcomes" or "reduction in clinical cost" [24], our results indicated that 70.8% (34/48) of the patients felt that online sessions had positive effects on clinical outcomes. Previous retrospective studies assessing patients with chronic DBS implantation indicated that 62% of patients preferred online visits [17]. A cross-sectional survey of teleprogramming after each online session for patients with chronic pain equipped with the NeuroSphere Virtual Clinic remote care showed that 93.8% (15/16) of the patients prefer the online session [9]. Similarly, a cross-sectional survey of teleprogramming following online sessions in patients with PD who had undergone de novo DBS implantation found that 100% of patients were satisfied with the online sessions and expressed a willingness to participate in future [11]. PD is progressive, and the burden of in-clinic visits for both patients and caregivers increases as symptoms worsen. In this context, online systems may help reduce that burden without negatively affecting patients' core motor symptoms, although this requires confirmation in controlled studies.

XSL•FO
RenderX

Sleep Deterioration and Its Clinical Interpretation

One unexpected finding was a potential signal of deterioration in sleep status in patients who received online sessions, which has not been previously reported (Table 2), although the observed change in sleep status consistently fell below the established MIC thresholds, indicating limited clinical relevance. Exploratory correlations suggested that patients with preexisting clinical instability—such as motor worsening or fluctuations in pain-related domains—were more likely to show sleep deterioration.

Interestingly, the duration of online sessions showed a strong association with ΔMPIC-J item 3. Because the online period varied among patients, this association is unlikely to reflect intentional differences in exposure to online sessions. Instead, it may imply that patients with greater instability were more susceptible to sleep deterioration when they spent a longer proportion of the follow-up period in online sessions. These exploratory correlations could imply a potential interaction between patient instability and the extent of online follow-up; however, these findings should be interpreted with caution. Taken together, these findings suggest a need for further investigation into whether sleep deterioration during online-based DBS management may not be solely attributable to the online modality itself but rather an emergence in clinically unstable patients who may instead benefit from shorter online follow-up and earlier return to in-person assessment.

Comparison With Previous Studies and Added Value of This Study

According to a randomized controlled trial, online programming sessions for de novo implanted DBS systems resulted in approximately 38% shorter treatment duration compared with in-clinic optimization and increased patient access to therapy adjustments by nearly 1.9 times [18]. Given the strong therapeutic impact of the initial stimulation, there is concern that the added value of online sessions may be overlooked or inadequately assessed. In addition, Chen et al [15] reported the possibility that physicians may adjust medications less frequently during remote programming than during in-hospital programming for de novo DBS-implanted patients with PD. This raises the possibility of bias due to differences in dopamine levels. In our study, we targeted patients with PD with an average duration of 6.6 (SD 1.9, range 4.5 - 10, median 5.5) years, representing the longest follow-up period reported in the literature. In contrast to the evidence in patients who have undergone de novo DBS, studies involving chronically implanted DBS systems have been retrospective or cross-sectional (Table 6). These reports suggest that remote programming can substantially reduce travel time and financial burden and is generally well accepted by patients [10,17] but lacked prospective evaluation of safety, usability, or clinical stability in long-term DBS management. Our study partially addresses this gap by providing preliminary prospective evaluation in patients who had chronically implanted DBS devices, offering a baseline for future comparative trials. It also offers the first population-specific data from Japan, using a device platform not previously examined in this context. By focusing on long-term DBS users, we examined the specific population for whom online sessions are presently feasible in real-world Japanese clinical settings. The inclusion of detailed usability measures (TUQ and OUQP) and the observation of a potential signal in sleep-related symptoms further add domain-specific insights not highlighted in earlier reports. Together, these findings suggest the feasibility and acceptable short-term safety profile of integrating online sessions into DBS care. Although time and cost savings are not direct care quality measures, our descriptive estimates—based on a typical frequency of 6 clinic visits per year—suggested that patients and caregivers might save approximately 28 hours and 47,844 JPY (US $1≈155 JPY).

Table . Summary of key studies on teleprogramming in deep brain stimulation for Parkinson disease.

Study (year)	Population type	Study design	Values, n[a]	Main outcomes	Key findings
PD[b] with chronic DBS[c]					
Present study (2026)	PD with chronic STN-DBS[d] (mean 6.6 years postoperatively)	Prospective, single-arm, multicenter, and self-controlled cohort	16	MDS-UPDRS-III[e], MPIC-J[f], PGIC[g], CGI-C[h], TUQ[i], OUQP[j], and time/cost savings	No motor worsening. Modest sleep deterioration. Saved 280 minutes and 7974 JPY[k] (US $1≈155 JPY) per visit. 70% satisfaction.
Ma et al (2021) [10]	PD with STN-DBS (mean 27.0 months postoperatively)	Retrospective, single-center database review	90	Motor symptoms (UPDRS-III) and time/cost savings	Saved >12 hours (for 90% of patients) and >2000 CNY[l] (US $1≈155 JPY) (for 76.7%) per visit. Feasible for long-term management.
Wan et al (2024) [17]	Patients with chronic DBS	Single-center cross-sectional survey	132	Patient burden, attitudes, and satisfaction	Teleprogramming reduces burden; 62% of chronic patients preferred online visits.
Pintér et al (2022) [14]	Movement disorders (PD, dystonia, and ET) with DBS (mean 5.8 years postoperatively)	Retrospective, single-center registry-based modeling	319	Modeled travel distance, time, cost, and caregiver burden	Saved 415.2 kilometers and 342.1 minutes per visit. Estimated to save 17 days of caregiver leave over 10 years.
Zhang et al (2021) [13]	Movement disorders (PD and dystonia) with DBS (median 6.7 months postoperatively)	Retrospective, national multicenter observational study	196	Frequency of requests, safety, and satisfaction	89% of 909 sessions were satisfactory. Essential for care during pandemic without serious adverse events.
Zhang et al (2020) [8]	Movement disorders (PD, dystonia, and ET[m]) with DBS (median 6.7 months)	Retrospective, single-center observational study	589	Implementation of Bluetooth technology	Safe and efficient parameter adjustments. Average travel distance saved: 1141 kilometers.
PD with de novo DBS					
Gharabaghi et al (2025) [18]	PD with de novo STN-DBS implantation	Prospective, multicenter, randomized controlled trial	38	Time to symptom improvement (PGI-C), QoL[n], and safety	Remote group achieved clinical benefit 15.1 days faster than in-clinic group. Safe postoperative optimization.
Wan et al (2024) [16]	PD with de novo STN-DBS	Retrospective, single-center controlled study	18	ΔUPDRS-III, ΔPDQ-8[o], and ΔLEDD[p] (1-year follow-up)	No significant difference in motor improvement or LEDD reduction between in-clinic and online groups.
Chen et al (2022) [15]	PD with de novo STN-DBS	Retrospective, single-center controlled study	58	ΔMDS-UPDRS-III, LEDD reduction, and sessions	Improvement in motor scores was similar across remote, hospital, and combined groups.
Xu et al (2021) [12]	PD with de novo DBS	Retrospective, single-center observational study	28	Motor symptoms (UPDRS-III) and satisfaction	UPDRS-III scores significantly improved. 93.75% were satisfied with the procedure convenience.
Li et al (2017) [7]	PD with de novo bilateral STN-DBS	Prospective, single-center, randomized controlled trial	31	Safety and efficacy of remote programming	Remote adjustment was found effective compared with sham stimulation. Early safety verification.

[p]LEDD: levodopa equivalent daily dose.

Barriers to Implementation and Practical Implications for Chronic DBS Care

Two patients were excluded from this study because of insufficient caregiver support and lack of digital literacy. Caregiver support is essential for patients with PD at these stages. Patients with PD may experience difficulty using small screens on tablet computers or smartphones due to motor impairments and cognitive dysfunction. These limitations may partly explain the relatively low agreement rates in the "Reliability" and "Interface quality" subdomains of the TUQ. These subdomains assess, "how easily the user can recover from an error and how the system provides guidance to the user in the event of an error" and "how pleasant the telemedicine technology or computer system was to use for the consumer," respectively (Tables 3 and 4) [24]. It remains difficult for clinicians to establish online consultation systems in hospitals because of limited medical resources. Administrative challenges include difficulties obtaining official prescriptions and a lack of medical insurance coverage [17]. The OUQP showed that it was sometimes difficult to provide rapid treatment resolution (31.3%; Table 5). This was, in part, due to the inability to touch the patients directly (eg, the inability to check the rigidity of the extremities). These challenges should be addressed to improve feasibility. Despite these concerns, it is surprising to see many patients satisfied with online sessions and inclined to use in the future as shown in the TUQ subdomain "Satisfaction and future use" (Table 4).

Limitations

This study has some limitations. First, this was a single-arm longitudinal study without a comparator group, which limits causal inference and the ability to contextualize the observed changes. Long-term patients with PD equipped with DBS devices with no experience of online sessions are rare, making recruitment challenging; therefore, a single-arm design was the most feasible approach for this population. Second, the small sample size may have reduced the statistical power. Although it was determined a priori using conservative assumptions, the study may still have been underpowered to detect smaller effects. Third, the observation period for the online sessions was short and longer online sessions may yield different effects. Fourth, the study population was necessarily selective, as patients without caregiver support or with low digital literacy were unable to participate. This introduces a potential selection bias and limits the generalizability of our findings to more vulnerable groups. At the same time, patients who can realistically engage in remote DBS care in routine clinical practice are typically those with caregiver support and sufficient digital literacy; therefore, the present cohort also reflects the subset of patients who had undergone chronic DBS for whom online sessions are currently feasible. Finally, the findings apply specifically to patients with bilateral STN-DBS using the Infinity/NeuroSphere remote care system within a Japanese health care setting with adequate infrastructure, which further limits the applicability of our findings to other devices, stimulation targets, or health care systems. The absence of randomization, blinding, or parallel controls also raises the possibility of observer, performance, detection, and expectation bias. Thus, we must evaluate our results carefully because of these limitations.

Conclusions

Sharma et al [27] described ideal candidates for online sessions as those who have a supportive caregiver, do not have cognitive or psychiatric impairment, or have impediments to in-person visits. Given that establishing a relationship with the DBS care team is essential for patients who had undergone de novo DBS

XSL•FO
RenderX

[27] and that the postoperative levodopa equivalent daily dose reduction rate may be lower in patients managed online [15], online sessions might be most suitable for patients with chronically implanted DBS devices. The absence of statistically or clinically meaningful worsening in all aspects—with only a modest and clinically limited change in sleep status—in patients with PD and chronic DBS implantations supports the feasibility of incorporating online sessions, or a hybrid of in-clinic and online sessions, into DBS care. Such approaches could be considered as a potential means to alleviate the burden on patients and caregivers. Future studies incorporating validated sleep-specific instruments, such as the Pittsburgh Sleep Quality Index, objective measures including actigraphy, and longer follow-up periods, will be essential to determine whether the sleep changes identified here represent transient fluctuations or clinically relevant deterioration. Despite some limitations, the online sessions showed potential feasibility and an acceptable safety profile in this preliminary evaluation, suggesting their potential role in reducing the time and cost burden for patients.

Abstract

Background: As Canada's population ages, accessible tools for chronic health monitoring are increasingly needed. Traditional and contact-based devices pose barriers for underserved populations due to cost, maintenance, and usability. Contactless sensing technologies offer a promising alternative, but equitable development requires inclusive engagement and diverse data collection.

Objective: This study aimed, first, to gather perspectives from culturally and health-diverse older adults on innovative contactless vital sign monitoring technology and, second, to build on a diverse dataset for developing and testing the contactless sensing software VitalSeer by the National Research Council of Canada.

Methods: A mixed methods study was conducted with older adults from diverse backgrounds across 3 sites. Participants were asked to respond to a questionnaire that had closed- and open-ended questions regarding their perspectives on contactless sensing technology. Video and reference vital sign data were collected from each participant using a portable system designed specifically for gathering controlled data.

Results: We collected data from 48 participants (mean age 70, SD 8 years), of whom 98% (n=47) expressed a positive perception of the usefulness of a contactless sensing system. We also identified four themes from the qualitative analysis of the open-ended questions: (1) perceived value—system potential and clinical relevance; (2) ease of use—noninvasiveness and comfort; (3) trust and transparency—data security and clarity of design; and (4) inclusion and improvement—accessibility, functionality, and feature expansion. Finally, the collected data, 288 minutes of concurrent video and reference vital sign data, will be used to test and enhance contactless sensing software for diverse older adult populations.

Conclusions: This work advances the goal of inclusive medical device research and development. It highlights the potential for contactless sensing to be adopted to support independent living for older, diverse adults. Research is ongoing to adapt the technology for widespread adoption.

KEYWORDS

contactless monitoring; vital signs; digital intervention; remote monitoring; older adults; telemedicine

Introduction

Background

As Canada's population ages, the demand for health care services, particularly those aimed at monitoring and managing chronic health conditions, is growing [1]. Traditional monitoring solutions require in-person checkups, which can be physically exhausting and disruptive [2,3]. Current contact-based solutions, such as using a pulse oximeter, might be undesirable or less suitable for some populations. Limiting factors include the cost of purchase, the need to manage an extra device, and the need to properly maintain and use it regularly. Older adults, particularly those living independently in underserved populations, may not have access to adequate tools for monitoring their health, putting them at greater risk [4].

Research has found that well-structured community engagement efforts, developed through meaningful consultation and active participation, can lead to positive changes in health behaviors, better access to health care services, enhanced health literacy, and improved health outcomes [5]. Integrating diverse perspectives in health technology development is crucial to address disparities in health outcomes, barriers to service access, and representation gaps [6]. Historically, marginalized and underserved populations have been excluded from health technology development, leading to poor uptake and even

XSL•FO
RenderX

technological bias within important health assistive devices [7,8]. Additional barriers, such as cost, maintenance, and unclear added value, further deter widespread use among these demographics [9].

VitalSeer [10,11] is a software technology under development by the National Research Council of Canada for contactless, noninvasive vital signs assessment. It uses camera-based remote photoplethysmography (rPPG) to measure heart rate, respiratory rate, and oxygen saturation (SpO_2) [12]. This technology could enable an easy-to-use monitoring solution that uses ubiquitous cameras, for example, mobile phone cameras, webcams, or home surveillance cameras. Sensing based on rPPG relies on the analysis of the light reflected by superficial tissues through the skin, so it can be affected by several extrinsic and intrinsic factors, such as the quality of the camera, skin type and tone, and environmental lighting conditions. Therefore, representative data acquired from a diverse population are critical to ensuring applicability.

The purpose of this study was to engage diverse populations for the development of contactless sensing technology [10] and to gather pertinent perceptions for technology improvement and eventual deployment. The contributions of this work include (1) a report on the perceptions of contactless sensing technologies from diverse populations in real-world community settings and (2) the acquisition of diverse high-quality data for VitalSeer development and testing.

Objective

The primary objective of this study was to gather perceptions about technology adoption from older adults with diverse health and cultural backgrounds. In parallel, a secondary objective was to collect high-quality diverse data to support the development of the technology.

Methods

Study Design

We conducted a mixed methods study using a concurrent triangulation design, in which closed-ended questions and open-ended questions were administered to the same convenience sample of older adults living in British Columbia, Canada. Quantitative and qualitative data were collected concurrently during the same study sessions, analyzed independently, and then integrated during the interpretation phase. Quantitative findings were used to identify patterns and trends, while qualitative responses were used to contextualize and explain those themes, with convergence across both datasets used to strengthen our conclusions.

Ethical Considerations

Ethical approval for the study was obtained from the University of British Columbia Ethics Board (H23-02571) and the National Research Council of Canada (NRC 2020 - 134).

All participants provided informed consent before participating in the study. Initial consent discussions were conducted via telephone calls and in person to explain the study objectives and address participants' questions.

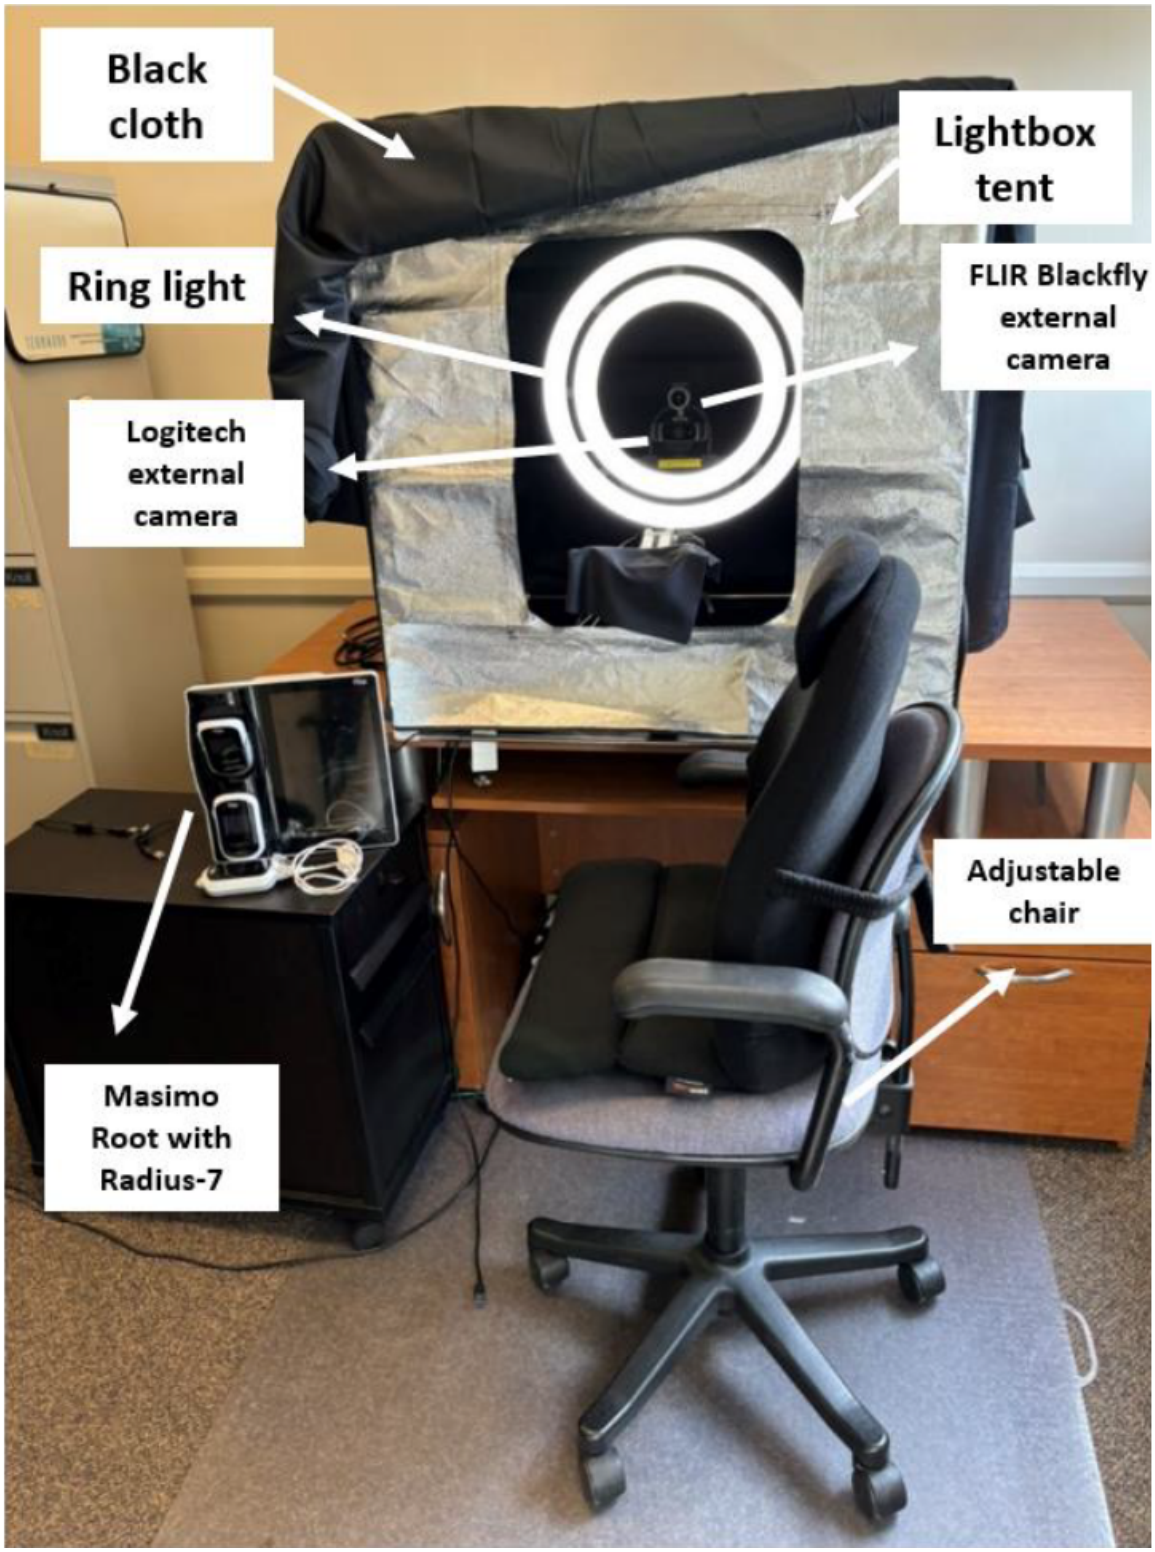
All study data were deidentified before analysis by replacing identifiable information, such as names, with participant IDs. Study data were stored securely, and only study team members could access them.

Participants received a CAD $10 (CAD $1=US $0.71 as of June 17, 2026) e-gift card as a token of appreciation for their time and participation.

Sampling and Recruitment

Participant recruitment was facilitated through REACH BC, an online research platform for the Canadian province of British Columbia. Additionally, the research team conducted extensive outreach to multicultural older adult home and community centers in the Lower Mainland region of Vancouver, British Columbia. Out of 49 centers approached, 2 (4.1%) were selected for facilitating on-site participant recruitment and study conduct: Unique Get Together Society and South Granville Seniors Centre. The centers were chosen based on their representation of a diverse range of ethnic groups, including Black, Latino, White, and Chinese communities. Furthermore, interest and capacity to participate, proximity to the research lab, and the availability of suitable space were also factors considered for selection.

Eligibility criteria prioritized older adults aged 60 years and older, who could attend a 1-hour in-person session at participating community centers. Participants younger than 60 years were allowed to participate for broader inclusion across cultural and ethnic backgrounds (people of color and Indigenous communities). Participants were required to remain still for approximately 2 minutes at a time. Proficiency in English was required unless a multilingual member of the research team was available to assist with instructions. Furthermore, participants needed to be in generally good health and capable of sitting still. The study emphasized the inclusion of individuals from diverse backgrounds, with varying skin tones and health conditions, to ensure a representative sample. Individual sessions were conducted at either a laboratory or one of 2 community centers.



Data Collection

Recordings

A deployable system, henceforth referred to as a "lightbox," was designed specifically for controlled data collection in this study. The lightbox featured an LED ring-light enclosure for uniform illumination, a chin rest to help participants remain still and minimize motion during video acquisitions, a metal support structure to mount 2 cameras (a consumer-grade Logitech webcam and a research-grade FLIR Blackfly), both directed at the participant's face, and a black cloth to cover the participant and block external light from entering. The lightbox was specifically designed to help collect data under optimal and reproducible conditions, ensuring minimal influence by external variables, such as fluctuations in ambient light and participant movement. Adjacent to the lightbox was a Lenovo T470s laptop (Windows 10) running the VitalSeer software. The cameras were connected via USB, and the laptop was connected to Ethernet for optimal bandwidth, as depicted in Figure 1.

XSL•FO
RenderX

Figure 1. Hardware configuration of the data collection system at the research team's laboratory.

Reference physiological parameters were measured from Food and Drug Administration–cleared and Health Canada–approved Masimo medical contact-based patient monitoring devices. These devices included a reference pulse oximeter, which provides noninvasive measurements of heart rate, respiratory rate, and SpO_2, and the Masimo Root monitor equipped with the Radius-7 continuous monitoring system (Masimo Corp). The Masimo Root system uses advanced signal extraction technology to deliver highly accurate vital sign measurements even in challenging clinical environments, such as low perfusion or motion artifacts.

Participants underwent three 2-minute recordings. Simultaneous readings from the Masimo Root system served as the gold standard for comparison, as these data were later used for validation.

XSL•FO
RenderX

Questionnaire

The questionnaire assessed user perceptions, acceptance, and usability of the remote health monitoring system using Likert-scale and open-ended questions. It evaluated perceived usefulness for self-monitoring and remote health care, willingness to share data, comfort with prolonged use, and concerns about wearables. Open-ended questions gathered feedback on user experience, system improvements, and overall satisfaction. This approach provided insights into user needs and barriers, informing system refinements for real-world application.

The questionnaire was administered at the end of the session after the VitalSeer recordings were completed. The survey contained a mix of quantitative and qualitative elements, including 6 rating scale questions and 4 open-ended questions to allow participants to provide more detailed feedback (Table 1). Skin tone scale data were also collected during study sessions using the Fitzpatrick skin type classification system [13]. Participants self-identified their skin type using the Fitzpatrick scale (I-VI), and a research team member (TY, NJ, or ST) also independently categorized each participant based on visible facial skin characteristics. In cases of discrepancy, the team revisited the classification and assigned the closest matching Fitzpatrick skin type.

Table . Participants' postsession questionnaire.

Question text	Type
I feel that the system that collects my vital signs would be useful to me in self-monitoring my health by frequently tracking of my vital signs at home	Likert scale (5-point)
I feel that the system that collects vital signs would be helpful for healthcare providers to monitor their patients remotely (*e.g.*, for patients living in rural/remote areas)	Likert scale (5-point)
In the future, I would be willing to send my health-related data and share my results from the system to my healthcare provider online	Likert scale (5-point)
In the future, I would be willing to use the system for a longer duration (*e.g.*, one week) to track my health-related data, after my visit to emergency department or hospital	Likert scale (5-point)
In the future, I think the system will be helpful to me for managing the health-related concerns related to wearable sensors that touch skin and are used between multiple users	Likert scale (5-point)
In the future, I think the system at home will be helpful for me to self-manage my health and live more independently	Likert scale (5-point)
After testing the system, what do you think about it? (What did/did not like about it)?	Open-ended
Do you have any suggestions for improving the system?	Open-ended
Do you have any suggestions for us to help improve your experience?	Open-ended
On a scale of 1-10, how was your overall test experience with the system today? Would you like to elaborate?	Open-ended

Data Processing and Analysis

Quantitative data were analyzed descriptively using SPSS Statistics for Mac (Version 29.0; IBM Corp). Frequencies and percentages were calculated for Likert-scale responses, and demographic variables were summarized using descriptive statistics (frequencies and proportions).

Qualitative feedback from the open-ended questions was analyzed using NVivo 12 (Lumivero) following reflexive thematic analysis. The analysis involved familiarization with the data through repeated reading of responses, inductive code generation, theme development, theme review and refinement, and final theme definition and naming. Codes were generated inductively from participant responses rather than a predefined coding framework, allowing themes to emerge directly from the data. Two coders (TY and NJ) independently reviewed and coded the responses, comparing findings throughout to enhance consistency and credibility. In cases of disagreement, coders collaboratively reviewed the relevant data and reassessed their interpretations. Where consensus could not be reached, KH reviewed the codes within the context of the research questions and made the final decision.

Ensuring Rigor and Trustworthiness

We ensured the rigor and trustworthiness of our research through triangulation, combining closed-ended responses and open-ended responses to capture and explore deeper perspectives. Peer debriefing by 2 independent coders (TY and NJ) validated themes, ensuring consistency and accuracy.

We also documented each research step to maintain transparency and reduce bias, enhancing credibility. The team's positionality also strengthened the process: KH, with more than 25 years of experience in mixed methodologies, provided theoretical expertise; TY, who is experienced in qualitative methods and has an MBBS, contributed clinical insights and methodological knowledge; and NJ, a researcher with an engineering background, added relevant academic and practical experience.

XSL•FO
RenderX

Results

Participants

We conducted a focused community recruitment phase over 34 days (March 2-April 4, 2024), following several months of engagement with community stakeholders. A total of 48 participants were recruited, with 26 sessions held at community centers. Most participants were aged between 66 and 70 years. The mean age of participants was 70 (SD 8) years. Detailed demographic information, including age, sex, data collection location, and Fitzpatrick skin tone [13] (as observed by the study team), is presented in Table 2 and Figure 2. The study also included 5 participants aged 60 or younger, comprising 4 Black individuals and 1 Indigenous participant.

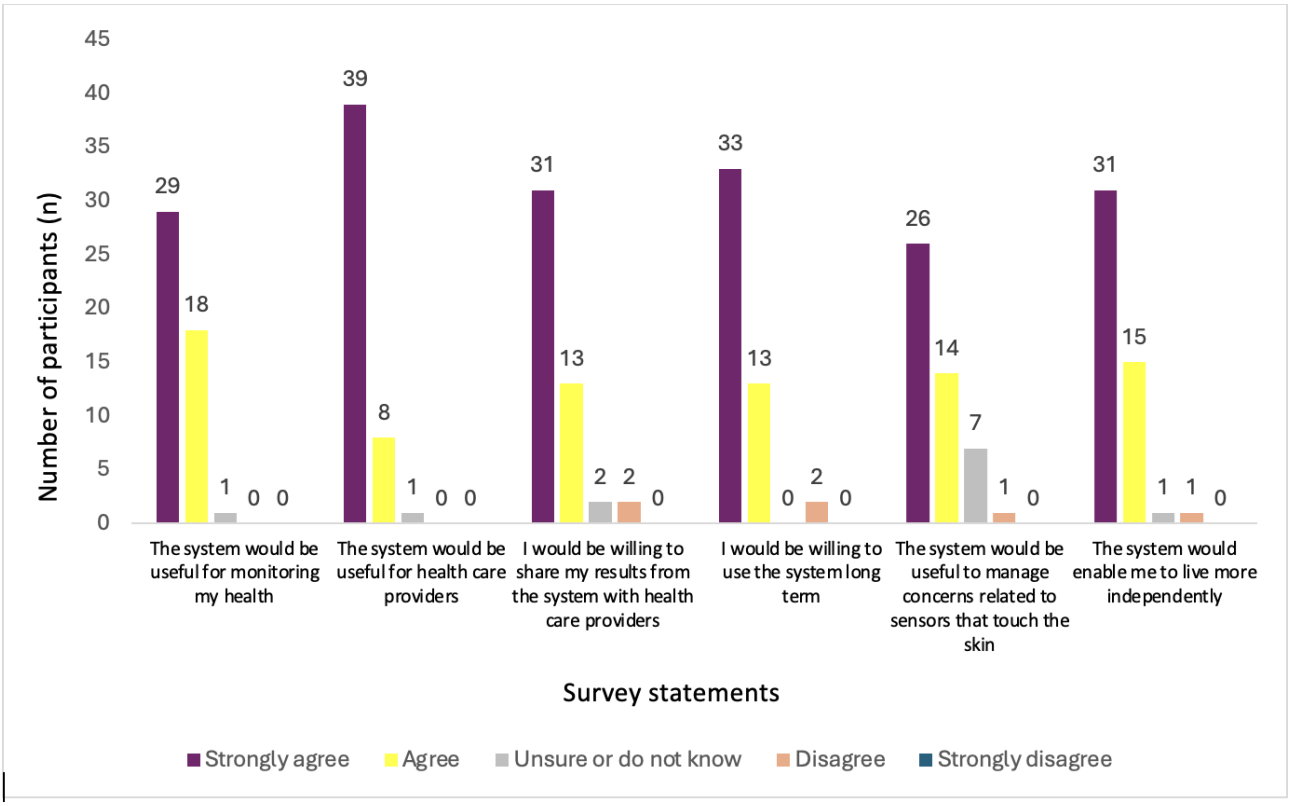


Table . Participant demographics (N=48).

Demographics	Participants, n (%)
Age group (y)	
<55	1 (2.1)
56 - 60	4 (8.3)
61 - 65	8 (16.7)
66 - 70	14 (29.2)
71 - 75	5 (10.4)
76 - 80	8 (16.7)
≥81	8 (16.7)
Sex	
Female	29 (60.4)
Male	19 (39.6)
Location	
UBC[a] Digital Emergency Medicine Laboratory	22 (45.8)
Unique Get Together Society	13 (27.1)
South Granville Senior Center	13 (27.1)
Fitzpatrick skin tone scale, type I	3 (6.25)

[a]UBC: The University of British Columbia.

XSL•FO
RenderX

Figure 2. Responses to Likert-scale questionnaire items regarding perceptions of the contactless monitoring system.

Recordings

Each of the 48 participants contributed 3 rounds of recordings, resulting in 144 distinct recordings. Each of these recordings consisted of paired video data (from 2 cameras) over 2 minutes, yielding 288 minutes of high-quality, controlled video data for each of the 2 cameras. In addition, reference vital sign data were collected from Food and Drug Administration–cleared and Health Canada–approved Masimo medical contact-based patient monitoring devices that correspond to the videos.

Questionnaire

Likert-Scale Questions

Figure 2 shows that most (47/48, 98%) participants agreed that contactless monitoring would be useful for independently monitoring their vital signs. Participants largely agreed on several other points, including the willingness to share results with health care providers, long-term use, and benefits for independent living.

However, 8% (4/48) of participants disagreed or were unsure about sharing their results with health care providers, 4% (2/48) disagreed with using the system long term, and 2% (1/48) felt that the system would not help manage concerns related to contact monitoring or support independent living.

Open-Ended Questions

Overview

We asked participants open-ended questions to elicit further perceptions of the technology. We identified four overarching themes that reflect participants' perceptions of the system: (1) perceived value—system potential and clinical relevance; (2) ease of use—noninvasiveness and comfort; (3) trust and transparency—data security and clarity of design; and (4) inclusion and improvement—accessibility, functionality, and feature expansion.

Each theme is broken down into subthemes, with participant quotes used to illustrate key points.

Theme 1: Perceived Value—System Potential and Clinical Relevance

Value for Remote Monitoring in Chronic Conditions

Participants emphasized the potential of VitalSeer to support at-home health monitoring, especially for individuals with chronic or respiratory conditions. Many saw it as a valuable tool that could allow early detection of symptoms and continuous monitoring without the need for frequent clinic visits. They believed this would be particularly useful for patients with long-term conditions who often require close surveillance:

> *This system has a lot of potential, especially for people with breathing problems or conditions like COPD. It could help doctors catch issues early.* [Participant 12]

> *This could be a very useful tool for patients to use and for doctors to gain data on their patients. It is very promising even in this test configuration.* [Participant 31]

Anticipated Benefits for Patients and Clinicians

In addition to monitoring individual health, participants highlighted the broader benefit of the system in supporting clinical decision-making. They felt that providing real-time access to vital signs could enhance health care providers' ability

XSL•FO
RenderX

to respond quickly to changes in a patient's health, enabling more efficient and personalized care. This was viewed as a win-win for both patients and clinicians:

> *If this works as intended, it'll reduce my visits to the clinic and still help my doctor stay updated on my health.* [Participant 3]

> *The idea that doctors can see what's going on in real-time from home—that's huge.* [Participant 19]

Brief Positive Feedback Without Detailed Commentary

While the majority offered detailed responses, a small proportion (12.5%) simply described the system as "fine," "good," or "satisfactory" without elaboration. This may reflect satisfaction without specific points of critique, or it may indicate a neutral experience with no strong positive or negative reactions. Although not descriptive, this feedback suggests the system was at least acceptable in its current form:

> *Good.* [Participant 38]

> *Fine. It worked okay.* [Participant 40]

Theme 2: Ease of Use—Noninvasiveness and Comfort

Simple and Fast to Use

A key feature appreciated by participants was the system's simplicity. Many emphasized how quick and effortless it felt to use, with a minimal learning curve. This ease of use was seen as crucial for ensuring long-term engagement, especially for users with limited time or low interest in technology. The process was described as unobtrusive and easy to fit into everyday life:

> *It was easy and fast; I didn't feel like it took much time out of my day.* [Participant 5]

> *Convenient and easy to navigate.* [Participant 13]

Low Technical Barriers

Even participants with limited prior experience using digital health tools commented on how straightforward the system was. They appreciated not having to deal with complicated instructions or setup steps. This accessibility was framed as especially important for broad adoption, including among older adults or individuals less familiar with technology:

> *Not complicated.* [Participant 37]

> *Effortless.* [Participant 29]

Noninvasive Experience

Participants highlighted that the system's noncontact approach was one of its most appealing features. Unlike wearables or devices that require physical contact or attachment, for many, this hands-off approach appeared to be convenient for daily use:

> *The fact that it's non-invasive makes it less stressful to use daily.* [Participant 43]

> *I like that it doesn't require me to wear anything or have anything attached to my body.* [Participant 30]

Theme 3: Trust and Transparency—Data Security and Clarity of Design

Concerns About Data Privacy and Protection

Several participants raised concerns about the safety of personal health data collected by the system. Given the sensitivity of the information involved, they wanted clear assurances that their data would be securely transmitted and stored. Participants highlighted this as a critical factor in determining their willingness to use the system regularly:

> *The big concern would be data security during transmission.* [Participant 26]

> *If I'm going to be using this regularly, I need to know that my data is safe.* [Participant 11]

Lack of Transparency About Data Use

Participants also expressed a desire for more transparency about how the data collected would be used. Specifically, they wanted to understand what types of data were being recorded, who would have access to them, and how they would inform their care. This was seen as important for building trust and encouraging users to engage with the system fully:

> *I want to know exactly what data is being collected and how it will help in the long run.* [Participant 30]

> *More explanation would help. It's not very clear right now how this ties into my overall care.* [Participant 41]

Perception of an Unfinished Design

Some participants described the system as still in development and wanted clearer communication about its future direction. These participants noted a lack of polish in the current interface and requested updates on what improvements could be expected. They felt that greater transparency in the development process would improve their confidence in the system:

> *The design feels a bit unfinished. If we could get more information about where it's heading, it would help us trust it more.* [Participant 21]

> *It looks like it's still in progress. I'd like to see more polish before using it daily.* [Participant 8]

Theme 4: Inclusion and Improvement—Accessibility, Functionality, and Feature Expansion

Barriers for Older Adults and Low-Tech Users

Participants raised concerns about the system's accessibility for older adults or users unfamiliar with technology. They emphasized that many older adults might lack smartphones, tablets, or reliable internet access. These barriers could prevent widespread adoption unless targeted solutions, such as simplified interfaces or alternative access methods, were implemented:

> *This is not going to be feasible for adults who do not have access to a computer or cellphone. How are you going to solve that problem?* [Participant 9]

> *It's a great idea, but I'm worried about how people with little tech knowledge will manage.* [Participant 24]

XSL•FO
RenderX

Need for Training and Visual Support

To support wider usability, participants recommended features such as color-coded feedback and audio instructions. These additions were viewed as particularly important for older adults, many of whom may struggle to interpret numerical health data. Suggestions included multilingual audio guidance and visuals that clearly indicate whether a measurement is within a healthy range:

> *Color coding for vital signs (numbers) so seniors will understand if the numbers are good.* [Participant 17]
>
> *Voice guidance in the app use—especially in multiple languages—would really help.* [Participant 23]

Desire for Expanded Monitoring Features

Several participants suggested that the system include other vital signs, such as blood pressure, SpO_2, and temperature. These metrics were viewed as essential for people managing chronic illnesses—particularly in communities where conditions like hypertension are common:

> *Blood pressure in the Black community is important… hypertension is a typical problem, so consider that one in VitalSeer.* [Participant 38]
>
> *What would be useful would be a warning for low O_2 saturation.* [Participant 46]

Suggestions for Practical Design Considerations

Participants also made comments about day-to-day use cases—such as whether the system would function properly if someone was wearing glasses or makeup. Others noted that low internet connectivity in rural or remote areas might prevent some users from accessing the system altogether:

> *At this time, it is OK to remove the glasses, but later, you need to consider not removing them.* [Participant 2]
>
> *This needs to work for rural users with slow or no internet.* [Participant 36]

Discussion

Principal Findings

This study demonstrates the feasibility of contactless sensing research and development in real-world community settings beyond the laboratory, engaging older adults from diverse backgrounds. The study participants included an older adult population comprising Black, Latino, White, Indigenous, and Chinese communities. Contactless sensing technology was well received, making it a promising solution for monitoring vital signs among older adults. Feedback from the participants provided insights into technology adoption.

Comparison With Previous Work

Our findings also show interest in technological solutions to support independent living for older adults. Noninvasive features helped increase acceptance by overcoming a major barrier to technology adoption in older adults compared with previous studies [14-17]. Although several studies have explored the use of contactless health monitoring systems [18], few have advanced to real-world testing. Most research on rPPG has largely been limited to laboratory settings [19-21]. Our study implemented a field-based approach and revealed important insights into the practical challenges and adoption of the technology when used by diverse older adults. While participants raised comments related to ease of use and data privacy, security, and monitoring, these findings were consistent with findings from previous studies [16,22]. It will be important to identify, implement, and communicate measures that can help build trust in these technologies.

The data collection in this research also contributes to the development and robustness of the VitalSeer software through the inclusion of participants with varying skin tones, a known variable that affects the accuracy of rPPG-based systems [18,23]. The inclusion of diverse participants also reflects a commitment to equity, diversity, and inclusion in health care technology development. By ensuring representation across different skin tones, genders, and health conditions, this work promotes solutions that are accessible, effective, and beneficial to all.

Novelty of This Clinical Study

One of the most important contributions of this study is its focus on diverse and underserved populations, addressing a significant issue in both health care and research: the underrepresentation of marginalized groups. By including a wide range of participants from various backgrounds, this study supports equitable health care solutions. Remote monitoring technologies have the potential to bridge gaps in health care access by providing individuals in underserved communities with tools to manage their health autonomously, particularly those who face barriers to frequent in-person medical visits. To our knowledge, this study is the first to elicit open-ended feedback from diverse participants to understand the perceived benefits and limitations of contactless sensing technology.

The use of contactless sensing technology in this study also shows that it can be implemented outside laboratory and traditional clinical environments, suggesting it can be made accessible to individuals who may not regularly interact with the health care system.

Limitations

Camera-based vital sign monitoring is susceptible to poor lighting conditions [23,24]. In this study, we used the lightbox to control the environment and ensure high-quality data collection. The effect of lighting on rPPG quality is an area of continued research; the methods used for signal acquisition and analysis are expected to evolve and improve with time.

We cannot discount the possibility that the presence and use of the lightbox may have altered some participants' perceptions of contactless sensing technology. If future researchers evaluate perceptions of a technological concept, it may be advisable to administer questionnaires before exposing participants to development or testing measures (in this study, the presence of the lightbox) that could influence their responses.

Implications for Practice

The findings from this study have several implications for both health care practice and policy. First, the deployment of the

XSL•FO
RenderX

contactless sensing technology in this study in community settings suggests that it could eventually be scaled up for broader use in home health monitoring programs, particularly for older populations. Such systems have the potential to ease the strain on health care facilities by empowering older adults to independently monitor and manage their health from home. This reduces the need for frequent hospital visits or long-term care stays, which is particularly beneficial in Canada, where rising emergency department wait times have been documented [18,23].

From a policy perspective, the results suggest that with the right design and implementation strategies, contactless monitoring systems can help close some of the gaps in health care access that disproportionately affect underserved populations. Future policy initiatives should focus on integrating these technologies into public health strategies, particularly in remote areas.

Future Directions

Moving forward, several avenues for future research emerge from this study. First, insights and video data from this study will assist in the ongoing development of the VitalSeer software, including its current extension to the mobile environment. Future research could also focus on expanding participant pools to target, for example, individuals with severe health conditions. Participants with mobility impairments might provide valuable insights into how these technologies can be more effectively integrated. Finally, studies should explore the long-term impact of using contactless sensing technologies in home settings, particularly how their use influences health outcomes, quality of life, and health care use over time.

Conclusions

In conclusion, contactless sensing represents a promising advancement in health monitoring. The development and testing we conducted in real-world settings, with a diverse sample population, highlight its potential to be successfully adopted to improve health outcomes and support aging in place for older adults. Further research and development are ongoing to ensure applicability under varying lighting conditions and the inclusion of additional features. These refinements will help facilitate its widespread adoption in Canada for both home and hospital use.

Acknowledgments

The authors thank the participants for their time and for sharing their insights. The authors also thank the Unique Get Together Society and the South Granville Seniors Centre for referring participants to the study and providing space to carry out the study. Generative artificial intelligence tools were not used to generate or edit any portion of the scientific content, analysis, results, or interpretation in this manuscript. All content, study design, data analysis, interpretation, and conclusions were fully developed and verified by the authors.

Abstract

Background: Telerehabilitation programs use information and communications technologies to facilitate exercise training, self-management education, and health behavior modifications for nonhospitalized patients. In recent years, 2 systematic reviews have examined the effectiveness of telerehabilitation in the recovery of patients with hip fractures but have yielded inconsistent results. This is a significant gap because tools to assess clinical domains such as pain, range of motion, and deformity are crucial for patient outcomes. Moreover, the long-term effects of telerehabilitation on postoperative functional recovery in patients with hip fractures have not been investigated.

Objective: To address the abovementioned research gap, this systematic review aimed to evaluate the short- and long-term effects of telerehabilitation on postoperative functional recovery in patients with hip fractures.

Methods: We searched the PubMed, Cochrane Library, Embase, and Web of Science databases from inception to March 31, 2025. Randomized controlled trials investigating the effect of postoperative telerehabilitation in patients with hip fractures were included in this systematic review. Outcomes of interest included hip function measured using the Harris Hip Score; functional mobility measured using the Short Physical Performance Battery and the timed up and go test; and ability to perform basic activities of daily living measured using the Functional Independence Measure, Barthel index, or modified Barthel index. Meta-analyses were performed using the RevMan software (version 5.3).

Results: A thorough literature search conducted in April 2025 yielded a total of 8 studies involving 740 patients for inclusion in this systematic review. Meta-analysis showed that telerehabilitation was effective for improving the Harris Hip Score at the intervention end point (2 included studies involving 156 participants; mean difference [MD] 7.42, 95% CI 5.61-9.23; P<.001; I^2=3%), the Short Physical Performance Battery score at the end point (4 included studies involving 430 participants; MD 1.34, 95% CI 1.14-1.55; P<.001; I^2=33%) and at follow-up (2 included studies involving 292 participants; MD 1.17, 95% CI 1.00-1.34; P<.001; I^2=0%), the timed up and go score at the end point (4 included studies involving 156 participants; MD –8.45, 95% CI −11.28 to −5.62; P<.001; I^2=0%) and at follow-up (2 included studies involving 63 participants; MD −7.66, 95% CI −13.78 to −1.53; P=.01; I^2=0%), and ability to perform basic activities of daily living at the end point (5 included studies involving 354 participants; standardized MD 1.65, 95% CI 0.78-2.51; P<.001; I^2=91%) and at follow-up (standardized MD 0.43, 95% CI 0.05-0.81; P=.03; I^2=48%).

Conclusions: Our review found that postoperative telerehabilitation may benefit short- and long-term functional recovery in patients with hip fractures compared to conventional rehabilitation. However, the evidence was weak due to the limited number and insufficient quality of the included studies and the heterogeneity across the studies.

RenderX

Introduction

Hip fractures are a major global public health challenge, with an annual incidence of over 10 million cases [1]. They are most prevalent among adults aged 65 years and older, a population in which fractures are correlated with high mortality rates and a substantial burden on patients and their families [2]. The standard management for hip fractures involves surgical intervention followed by rehabilitation to restore walking ability [3,4]. Despite this, most older patients fail to recover their prefracture level of function, and this persistent impairment may lead to an increased risk of falls [5]. Therefore, long-term postoperative management for older adults with hip fractures is essential to enhance their functional recovery and overall quality of life.

Since the COVID-19 pandemic, telerehabilitation has gained popularity, with physical therapists increasingly willing to incorporate it into their routine practices, prompting health care facilities to adopt innovative methods for engaging with patients. As a branch of telemedicine, telerehabilitation is defined as the use of remote health care methodologies, specifically information and communications technologies, to deliver therapeutic rehabilitation services outside of medical institutions [6]. Telerehabilitation programs use information and communications technologies such as telephones and videoconferencing to facilitate exercise training, self-management, and lifestyle modifications for nonhospitalized patients [7,8].

In recent years, several systematic reviews have been published regarding the effectiveness of telerehabilitation programs for patients with specific chronic diseases, including cardiac, respiratory, and neurological disorders [9,10]. Of note, 2 previous systematic reviews have examined the effectiveness of postoperative telerehabilitation in the recovery of patients with hip fractures, yielding inconsistent results. One review found that, compared to conventional intervention, telerehabilitation was not effective in improving postoperative mobility (as measured using the timed up and go [TUG] test and gait speed) or in alleviating pain but facilitated the ability to perform basic activities of daily living (BADLs) with a clinically irrelevant improvement [11]. Another recently published systematic review found that, compared to traditional rehabilitation, digital health interventions significantly improved postoperative mobility and the ability to perform BADLs, as indicated by the improvement in the TUG performance, the Short Physical Performance Battery (SPPB) score, and the Functional Independence Measure (FIM) score [12]. However, specific measurement tools for hip function, such as the Harris Hip Score (HHS), have not been examined in any systematic review. This is a significant research gap because these tools assess crucial clinical domains, including pain, range of motion, and deformity, that are key outcomes for patients with hip fractures. Moreover, the long-term effects of telerehabilitation on postoperative functional recovery in patients with hip fractures have not been investigated.

Therefore, this systematic review aimed to evaluate the short- and long-term effects of telerehabilitation on postoperative functional recovery in patients with hip fractures. The outcomes of interest included hip function as measured using the HHS [13]; functional mobility as measured using the TUG test [14,15] and SPPB [16-18]; and ability to perform BADLs as measured using the Barthel index (BI), modified BI (MBI), or FIM. We hypothesized that telerehabilitation would be effective for improving postoperative short- and long-term functional recovery in patients with hip fractures compared to conventional rehabilitation.

Methods

This systematic review and meta-analysis adhered to the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 guidelines [19], with a registration in PROSPERO (CRD42024498569).

Literature Search

Two researchers (CC and PPQ) independently searched the PubMed, Embase, Web of Science, and CENTRAL databases from inception to March 31, 2025. The search was limited to English-language literature. Randomized controlled trials investigating the effectiveness of postoperative telerehabilitation treatment for patients with hip fractures were included (Multimedia Appendix 1).

Additional articles were identified by reviewing the reference lists of relevant reviews. The following keywords and the corresponding MeSH (Medical Subject Headings) terms were used: (telerehabilitation OR telerehabilitations OR tele-rehabilitation OR tele-rehabilitations OR remote rehabilitation OR remote rehabilitations OR rehabilitation, remote OR rehabilitations, remote OR virtual rehabilitation OR virtual rehabilitations OR rehabilitation, virtual OR rehabilitations, virtual) AND (hip fractures OR fractures, hip OR intertrochanteric fracture OR intertrochanteric fractures OR trochanteric fractures OR fractures, trochanteric OR femur trochlear fracture OR femur trochlear fractures OR trochlear fracture, femur OR trochlear fractures, femur OR fractures, femur trochlear OR femoral trochlear fracture OR femoral trochlear fractures OR fracture, femoral trochlear OR fractures, femoral trochlear OR trochlear fracture, femoral OR trochlear fractures, femoral OR subtrochanteric fracture OR subtrochanteric fractures).

Eligibility Criteria

The inclusion criteria were as follows: (1) studies involving participants diagnosed with a hip fracture who were in a stable condition (no further fractures were observed or reported) after surgical intervention; (2) studies involving telerehabilitation as the primary intervention following surgery, including the use of SMS text messaging, telephones, smartphones, and internet-based and software-based methods; (3) studies that reported at least one outcome of interest, including the HHS, TUG test, SPPB score, BI, MBI, and FIM; and (4) randomized controlled trials.

The exclusion criteria were (1) only study protocol or conference abstract available and (2) unavailability of the full text.

XSL•FO
RenderX

Study Selection

The search results were imported into EndNote X9 (Clarivate Analytics) for duplicate removal. To ensure the accuracy of this process, 2 authors (CC and PPQ) manually verified the deleted duplicates. The titles and abstracts of the remaining records were then screened independently by these authors (CC and PPQ). Full texts were retrieved for further review if deemed eligible by either author. Any disagreements between the reviewers were resolved through discussion with a third author (CL).

Data Extraction

Two authors (CC and PPQ) independently extracted data from the included studies. The extracted data encompassed the following: basic study information (the first author, publication year, and country), participant baseline characteristics (sample size, age, and gender), details of the telerehabilitation and control interventions, and outcome measures (including follow-up period and measurement tools).

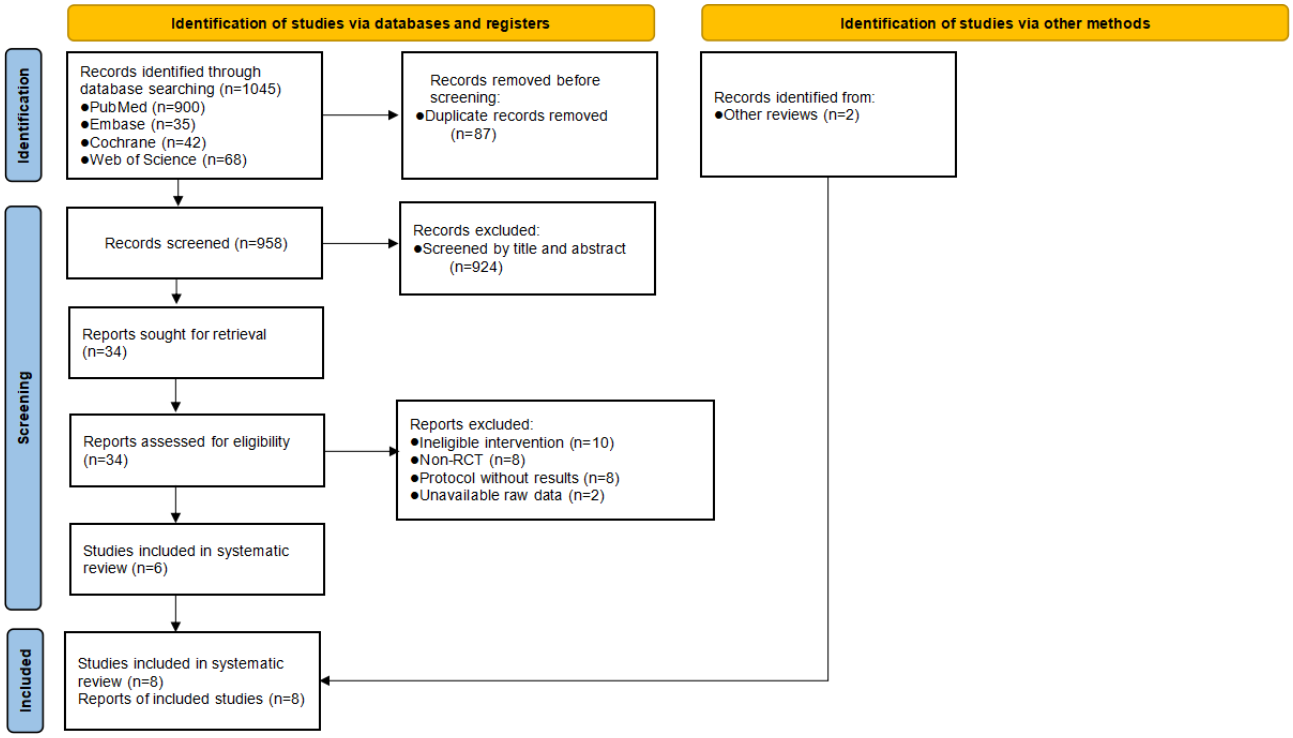
Quality Evaluation

Two authors (CC and PPQ) independently evaluated the quality of the included studies using version 2 of the Cochrane risk-of-bias tool for randomized trials [20]. The risk-of-bias assessment consisted of the following domains: (1) randomization process, (2) deviations from intended interventions, (3) missing outcome data, (4) measurement of the outcome, and (5) selection of the reported results. The overall risk of bias was classified as low risk of bias, some concerns, and high risk of bias.

Data Analysis

The Cochrane Collaboration's Review Manager software (version 5.3) was used for all statistical analyses. The overall estimate of the treatment effect was calculated using the means and SDs of outcome scores for continuous data in the telerehabilitation intervention and control groups. Short- and long-term effects were analyzed by comparing the differences in outcome scores between the 2 groups at the intervention end point and at the last follow-up time point, respectively. For studies using the same measurement tool, we calculated a pooled estimate of the mean differences (MDs) with 95% CIs. In cases in which different measurement tools were used, we used standardized MDs (SMDs).

To investigate potential clinical and methodological heterogeneity across the included studies, the following factors were summarized and compared: (1) patient characteristics (age and baseline scores of the outcomes of interest), (2) characteristics of telerehabilitation (duration, frequency, and delivery mode), (3) type of control intervention, (4) follow-up period for the outcomes of interest, and (5) risk of bias. Where low clinical and methodological heterogeneity was found across the studies in a given meta-analysis, a fixed-effects model was used; otherwise, a random-effects model was applied. Statistical heterogeneity was quantified using the I^2 statistic. I^2 values greater than 50% were considered to indicate substantial heterogeneity [21]. When substantial statistical heterogeneity was present and a sufficient number of studies were available, subgroup analyses were performed based on the abovementioned factors contributing to clinical or methodological heterogeneity. Furthermore, a sensitivity analysis was planned to assess the impact on the pooled results provided that a sufficient number of studies were available. This was performed by excluding studies with a high risk of bias or those that differed substantially from others in the factors considered for subgroup analyses.



Results

Study Identification

The initial database search yielded a total of 1045 records, of which 6 (0.6%) met the eligibility criteria and were included. A further 2 studies were identified by checking the reference lists of relevant reviews [11], resulting in a total of 8 studies for the systematic review and meta-analysis. The study selection process is illustrated in the PRISMA flow diagram (Figure 1).

XSL•FO
RenderX

Figure 1. Flow diagram for the systematic search. RCT: randomized controlled trial.

Study Characteristics

The 8 included studies comprised 740 patients, including 569 female and 161 male individuals. The sample sizes varied from 31 to 232 in the individual studies.

The treatment strategies for postoperative telerehabilitation for patients with hip fractures included strengthening, balance, coordination, stretching exercises, BADL training, introduction of walking aids, and safety education. Most included studies provided telerehabilitation through mobile apps or software [5,22-28] supervised by professionals remotely, one study used a DVD supervised via telephone calls [27], and one study used a telephone call as the primary strategy [28]. The control interventions comprised home-based exercise through written materials [5,25,26], in-person rehabilitation [23,24], follow-up assessment through telephone [22] and health nutrition education [27], and no intervention [28]. The duration of telerehabilitation varied from 35 minutes to 6 months. The follow-up periods varied from 3 weeks to 9 months [23,25-28]. Table 1 presents the main characteristics of the included studies [5,22-28].

Risk of Bias in the Included Studies

Four studies [23,24,26,28] had a low risk of bias, 3 [22,25,27] had some concerns, and 1 [5] had a high risk of bias. Overall, the randomization process was the most problematic domain as 3 studies poorly described the method used [5,22,25]. The results of the methodological quality assessment are provided in Figure 2 [5,22-28].

XSL•FO
RenderX

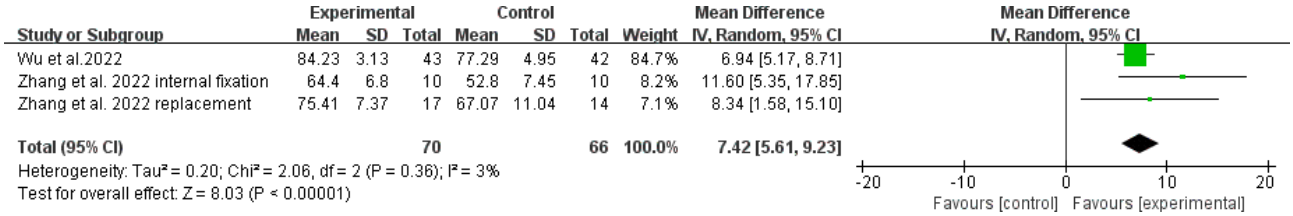

Figure 2. A detailed breakdown of the methodological quality assessment for the included studies. Overall, 4 studies exhibited a low risk of bias, 3 raised some concerns, and 1 exhibited a high risk of bias [5,22-28].

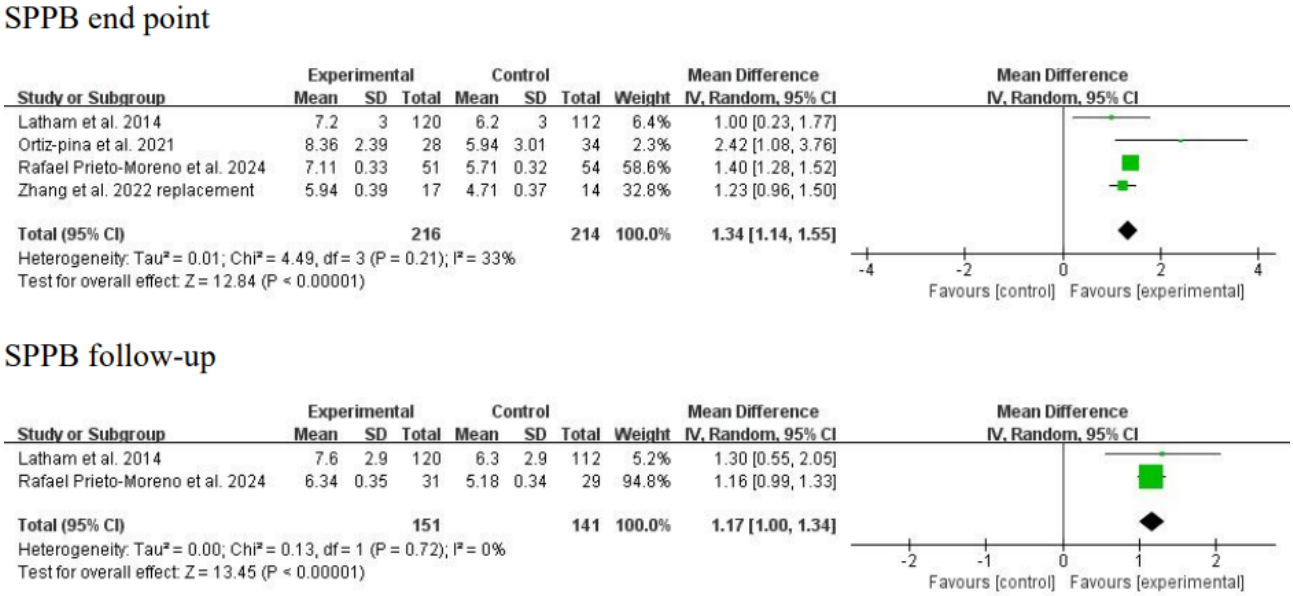
Effectiveness of Postoperative Telerehabilitation on Functional Recovery at the Intervention End Point and Follow-Up

HHS was measured in 2 studies involving a total of 156 participants at the intervention end point [5,22]. Low clinical heterogeneity was observed in patient characteristics (mean age range 72-77 years; comparable baseline mean HHS between 34.9 and 43.6). However, substantial clinical heterogeneity was found regarding the duration of telerehabilitation (6 months [5] vs 3 months [22]). A random-effects meta-analysis yielded a statistically significant, positive result (MD 7.42, 95% CI 5.61-9.23; *P*<.001; Figure 3 [5,22]) with low statistical heterogeneity (I^2=3%; *P*=.36; Figure 3 [5,22]).

Figure 3. Forest plot of Harris Hip Score (HHS) results at the intervention end point. The analysis yielded a positive result with a mean difference of 7.42 (95% CI 5.61-9.23; *P*<.001; I^2=3%) [5,22]. IV: inverse variance.



SPPB was measured in 4 studies (n=430 participants) at the intervention end point [22-24,27]. Considerable clinical heterogeneity was observed in baseline SPPB scores (mean scores 4.71-5.9 [22,27] vs 2.69-3.21 [23,24]). Furthermore, both the duration of telerehabilitation (3 months [22-24] vs 6 months [27]) and the type of control intervention (telephone assessment [22,27] vs in-person rehabilitation [23,24]) varied across studies. A random-effects meta-analysis showed a significant positive result at the intervention end point (MD 1.34, 95% CI 1.14-1.55; *P*<.001; Figure 4 [22-24,27]) with low to moderate statistical heterogeneity (I^2=33%; *P*=.21; Figure 4 [22-24,27]). SPPB was

XSL•FO
RenderX

measured in 2 studies (n=292 participants) at follow-up [23,27]. In addition to the aforementioned clinical heterogeneity, great methodological heterogeneity was noted in the follow-up period (3 months [27] vs 9 months after the intervention [23]). The random-effects analysis remained significant at follow-up (MD 1.17, 95% CI 1.00-1.34; *P*<.001; Figure 4 [22-24,27]) with low statistical heterogeneity (I^2=0%; *P*=.72; Figure 4 [22-24,27]).

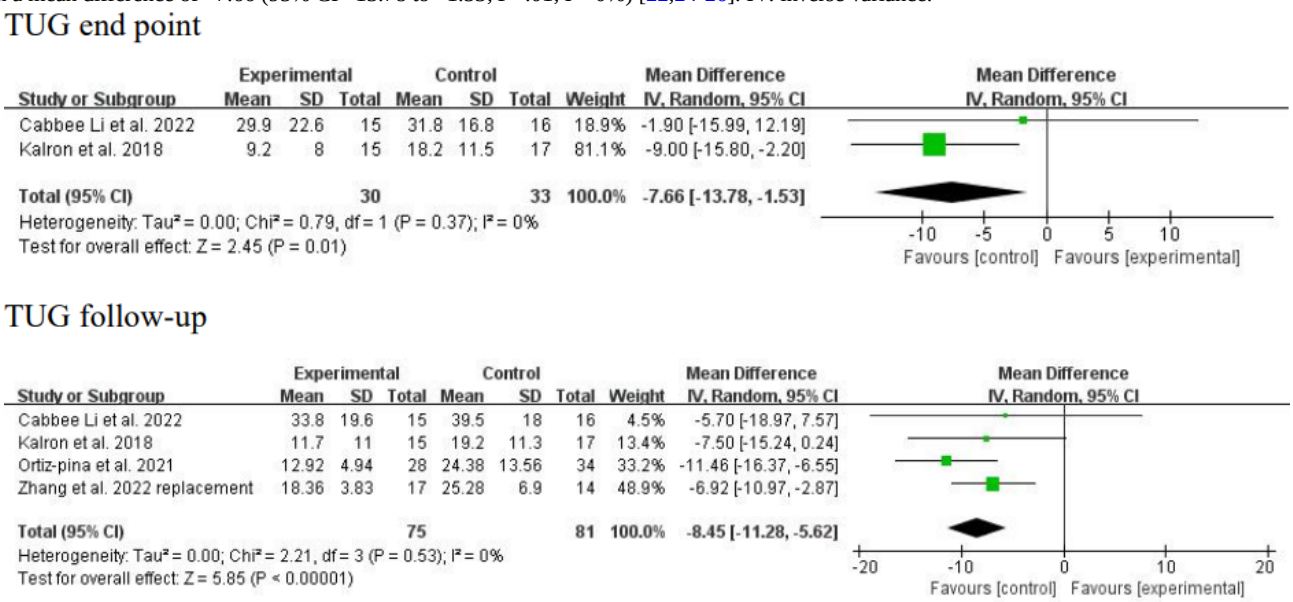


Figure 4. Forest plot of Short Physical Performance Battery (SPPB) results at the intervention end point and follow-up. The analysis yielded a positive result at the intervention end point with a mean difference of 1.34 (95% CI 1.14-1.55; *P*<.001; I^2=33%). The analysis yielded a positive result at follow-up with a mean difference of 1.17 (95% CI 1.00-1.34; *P*<.001; I^2=0%) [22-24,27]. IV: inverse variance.

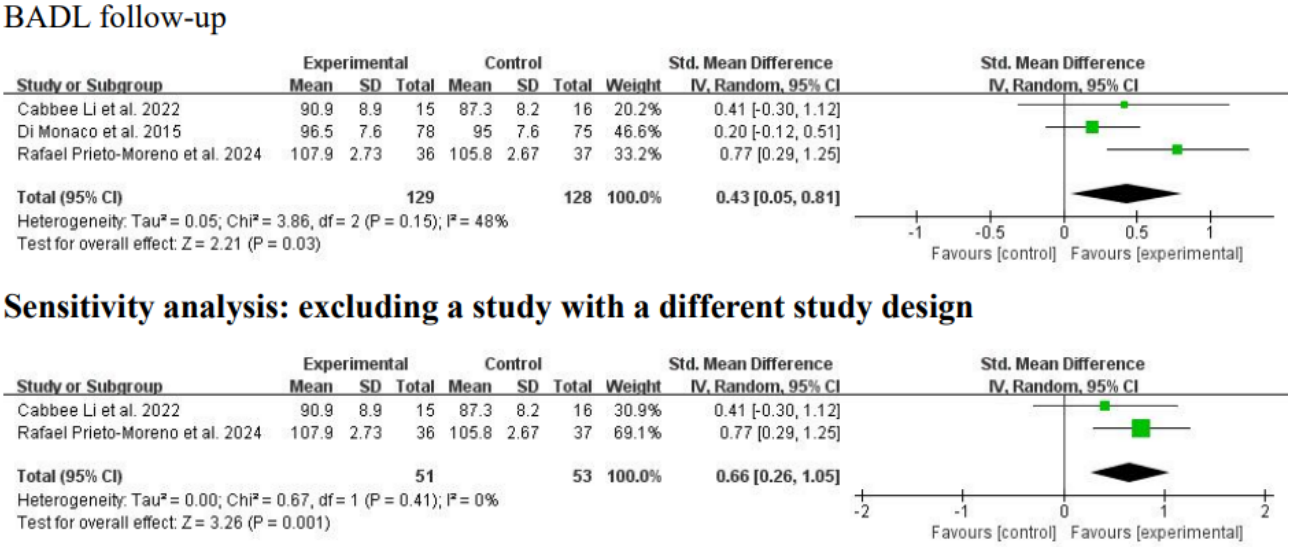
The TUG test was measured in 4 studies (n=156 participants) at the intervention end point [22,24-26]. Considerable clinical heterogeneity was found regarding the patient characteristics (mean age 65.7-67.3 years [26] vs 75.17-82.1 years [22,24,25]; mean baseline TUG score 21.4-25.6 [26] vs 39.7-45.2 [25] vs 66.53-99.72 [24]; data unavailable for the study by Zhang et al [22]). The duration of telerehabilitation (3-6 weeks [25,26] vs 3 months [22,24]) and type of control intervention (written materials [25,26] vs telephone assessment [22] vs in-person rehabilitation [24]) also varied. A random-effects meta-analysis demonstrated a significant positive result at the intervention end point (MD –8.45, 95% CI −11.28 to −5.62; *P*<.001; Figure 5) with low statistical heterogeneity (I^2=0%; *P*=.53; Figure 5 [22,24-26]). The TUG test was measured in 2 studies (n=63 participants) at follow-up [25,26]. Low methodological heterogeneity was observed in the follow-up period (3-4 weeks after the intervention [25,26]) and risk of bias (low to moderate risk of bias [25,26]). However, due to the considerable clinical heterogeneity noted above (in patient age and baseline function), a random-effects model was applied. This analysis yielded a significant positive result at follow-up (MD −7.66, 95% CI −13.78 to −1.53; *P*=.001; I^2=0%; *P*=.37; Figure 5 [22,24-26]).

XSL•FO
RenderX

Figure 5. Forest plot of timed up and go (TUG) test results at the intervention end point and follow-up. The analysis yielded a positive result at the intervention end point with a mean difference of –8.45 (95% CI –11.28 to –5.62; *P*<.001; I^2=0%). The analysis yielded a positive result at follow-up with a mean difference of –7.66 (95% CI –13.78 to –1.53; *P*=.01; I^2=0%) [22,24-26]. IV: inverse variance.



Because various BADL measurement tools were used across the included studies, SMDs were used as the effect size measure. Zhang et al [22] reported BADL outcomes separately for the hip replacement and internal fixation groups. BADLs were measured in 5 studies (n=354 participants) at the intervention end point [5,22-25]. Considerable clinical heterogeneity was observed regarding patient characteristics (baseline dependence level: maximal dependence [5,22] vs mild to moderate dependence [23-25]), duration of telerehabilitation (3 weeks [25] vs 3 months [22-24] vs 6 months [5]), and type of control intervention (written materials [25] vs telephone assessment [5,22] vs in-person rehabilitation [23,24]). In addition, substantial methodological heterogeneity was observed in the risk of bias (high [5] vs some concerns [22,25] vs low [23,24]). A random-effects meta-analysis yielded a significant positive result with high heterogeneity (SMD 1.65, 95% CI 0.78-2.51; *P*<.001; I^2=91%; *P*<.001; Figure 6 [5,22-25]). Subgroup analyses were conducted based on baseline dependence level, duration of telerehabilitation, and type of control intervention. For studies involving patients with a high baseline dependence level [5,22], the analysis showed a positive result with high heterogeneity (SMD 1.87, 95% CI 0.59-3.16; *P*=.004; I^2=89%; *P*<.001; Figure 6 [5,22-25]). For studies with a lower baseline dependence level [23-25], the result was also positive with high heterogeneity (SMD 1.42, 95% CI 0.04-2.81; *P*=.04; I^2=94%; *P*<.001; Figure 6 [5,22-25]). Subgroup analysis by duration of telerehabilitation was not possible due to an insufficient number of studies. For studies with telephone-based assessment as a control intervention [5,22], the result was positive with high heterogeneity (SMD 1.87, 95% CI 0.59-3.16; *P*=.004; I^2=89%; *P*<.001; Figure 6 [5,22-25]). For studies with in-person rehabilitation as the control [23,24], the result was similarly positive with high heterogeneity (SMD 1.90, 95% CI 0.16-3.63; *P*=.03; I^2=95%; *P*<.001; Figure 6 [5,22-25]). A sensitivity analysis was conducted by (1) excluding 2 studies with intervention durations shorter [25] or longer [5] than 3 months and (2) excluding 1 study with a high risk of bias [5]. Pooling the 3 remaining studies with a 3-month intervention duration [22-24] using a random-effects model yielded a positive result with low statistical heterogeneity (SMD 1.13, 95% CI 0.76-1.50; *P*<.001; I^2=0%; *P*=.82; Figure 6 [5,22-25]). Pooling the 4 studies with low to moderate risk of bias [22-25] yielded a positive result with high heterogeneity (SMD 1.36, 95% CI 0.52-2.21; *P*=.002; I^2=88%; *P*<.001). BADLs were measured in 3 studies (n=257 participants) at follow-up [23,25,28]. Considerable clinical heterogeneity was observed regarding baseline dependence level (mild to moderate dependence [23,25] vs minimal dependence [28]), duration of telerehabilitation (2.5-3 weeks [25,28] vs 12 weeks [23]), delivery mode of telerehabilitation (telephone based [28] vs software based [23,25]), and type of control intervention (no intervention [28] vs in-person rehabilitation [23] vs written materials [25]). Moreover, substantial methodological heterogeneity was found in the follow-up period (3 weeks [25] vs 5.5 months [28] vs 9 months [23] after the intervention). A random-effects model yielded a positive result with moderate heterogeneity at follow-up (SMD 0.43, 95% CI 0.05-0.81; *P*=.03; I^2=48%; *P*=.15; Figure 7 [23,25,28]). A sensitivity analysis excluded 1 study [28] that differed substantially from the others in design (baseline dependence level, type of telerehabilitation, and type of control intervention). A random-effects model for the remaining 2 studies [23,25] yielded a positive result with low heterogeneity (SMD 0.66, 95% CI 0.26-1.05; *P*=.001; I^2=0%; *P*=.41; Figure 7 [23,25,28]).

Figure 7. Forest plot of basic activity of daily living (BADL) results at follow-up. The analysis yielded a positive result at follow-up with a standardized mean difference of 0.43 (95% CI 0.05-0.81; P=.03; I^2=48%). A sensitivity analysis was conducted by excluding a study with a different study design from the others [23,25,28]. IV: inverse variance.

Discussion

Principal Findings

Our review found that postoperative telerehabilitation was effective in improving short- and long-term hip function, functional mobility, and ability to perform BADLs in patients with hip fractures compared to conventional rehabilitation. However, current evidence was weak due to the limited number and insufficient quality of the included studies and the heterogeneity across studies.

Our findings align with previous evidence that telerehabilitation is beneficial to short-term recovery of functional mobility and ability to perform BADLs at posttreatment compared to usual care [12]. Moreover, our review found that hip function was also improved after telerehabilitation. In addition, our findings revealed the effect of telerehabilitation on long-term recovery (3 weeks to 9 months after the intervention) in functional mobility and the ability to perform BADLs. The effectiveness in improving BADLs showed substantial heterogeneity across the included studies in the postintervention analysis. Although subgroup analyses were conducted based on the type of control intervention and the baseline dependence level, they failed to reduce the heterogeneity. A potential source of heterogeneity may be the duration of telerehabilitation as the statistical heterogeneity decreased dramatically when 2 studies with telerehabilitation shorter (3 weeks) [25] and longer (6 months) [5] than 3 months were excluded. Another potential source of heterogeneity may be differences in adherence to the telerehabilitation programs. Although only 2 of the 5 studies in the BADL analysis reported adherence rates for telerehabilitation, the substantial difference (87% [25] vs 15% [24]) suggests considerable variability in compliance across studies.

This systematic review revealed that telerehabilitation strategies, including exercises for strengthening the lower extremities, balance, coordination, stretching, and BADL training, introduction of walking aids, and safety education are commonly used for patients with hip fractures. According to clinical practice guidelines, postoperative progressive resistance exercises and balance training are strongly recommended, and BADL training and complication prevention are suggested for older patients with hip fractures [29]. However, it is essential to standardize these training programs to mitigate the risk of adverse events [30,31].

Regarding the delivery mode of telerehabilitation, most studies used software- or mobile app–based telerehabilitation with remote supervision by professionals, and only 2 studies conducted before 2015 used DVD-based or telephone-based telerehabilitation. Recently, the application of virtual reality has become an increasingly common approach in telerehabilitation, with superior long-term benefits for patients with total knee replacements compared with traditional rehabilitation [32]. Although all these remote rehabilitation approaches could facilitate adherence to postoperative management, reduce costs, and decrease the burden on therapists and caregivers, the efficacy of different delivery strategies could vary. Future studies are needed to compare the cost-effectiveness ratio between different delivery modes of telerehabilitation.

Our findings may have several clinical implications. First, substantial clinically important improvements in functional mobility, as measured using the SPPS [33] and TUG test [34,35], were observed following telerehabilitation compared to usual care at the postintervention and follow-up time points. However, the overall improvement in HHS (7.35 points) fell below the minimal clinically important improvement threshold (15.9-18 points) [36]. For BADLs, a large short-term effect size (SMD 1.65) was found, but this decreased to a small to moderate effect at the long-term follow-up (SMD 0.43). Furthermore, no included studies demonstrated a clinically relevant improvement for BADLs (21 points on the FIM [37] and 9.8 points on the BI [38]). These findings indicate that telerehabilitation may be more beneficial for functional mobility than for hip function or BADLs. Second, we noted that most included studies were conducted in countries with established research environments

XSL•FO
RenderX

(Israel, Spain, Portugal, and the United States), with China being the only included country with an emerging research landscape. Therefore, the generalizability of telerehabilitation requires further investigation, specifically in terms of its feasibility and effectiveness in low- and middle-income countries. Third, the included studies exhibited variable follow-up periods (3 weeks to 9 months), which impedes the investigation of long-term effects. Future studies could adopt a more standardized follow-up schedule (eg, every 3 months after the intervention). Fourth, adherence to telerehabilitation was poorly reported in the included studies, leaving its influence on the effect size unclear. As a key proposed benefit of telerehabilitation is the facilitation of prolonged rehabilitation training—and studies have demonstrated higher compliance in telerehabilitation groups, potentially leading to greater improvement [22,26]—detailed adherence data are crucial for interpreting effectiveness. Future studies should report adherence and compliance rates in detail and develop effective supervision approaches to ensure the efficacy of telerehabilitation.

Limitations

This study has several limitations. First, it only included literature published in English, which may have omitted relevant evidence from articles published in other languages, potentially introducing language bias and limiting the generalizability of the findings. Second, the small number of included studies and the substantial heterogeneity observed influenced the strength of the evidence. Third, no statistical analysis for publication bias was conducted due to the small number of included studies.

Conclusions

Telerehabilitation is effective for short- and long-term functional recovery in postoperative patients with hip fractures compared to conventional rehabilitation. However, the evidence is weak due to the limited number of included studies and the high heterogeneity across studies. Future high-quality studies with larger sample sizes are needed to investigate the effectiveness of telerehabilitation. These studies should report the intervention strategies, delivery modes, and adherence rates of interventions in detail; incorporate comprehensive outcome measures for hip function (eg, HHS), functional mobility (eg, SPPS and TUG test), and ability to perform BADLs (eg, BI, MBI, and FIM); and apply a relatively standard follow-up period to investigate the long-term effect of telerehabilitation.

Abstract

Background: Telehealth can improve access to care for people living with multiple sclerosis (MS), but information on its acceptance is limited in Switzerland.

Objective: This study aimed to determine the proportion of people living with MS willing to accept telehealth as a new default and the factors associated with their acceptance.

Methods: We conducted a cross-sectional analysis using survey data from the Swiss Multiple Sclerosis Registry. We defined "telehealth as a default" as a health care model where remote consultations (telephone and/or video calls) are the primary mode of interaction between patients and their physicians, with in-person visits based on clinical necessity. Multivariable logistic regression was performed to evaluate the association between telehealth acceptance and sociodemographic and health-related factors. Telehealth acceptance was described in relation to 3 survey variables that mirrored key constructs from the Non-Adoption, Abandonment, Scale-Up, Spread, and Sustainability (NASSS) framework. The variables were digital communication preferences, internet use for health provider searches, and experience with telemedicine.

Results: Among 427 respondents, 15.5% (66/427) reported a willingness to accept telehealth as their default. In this group, only 21.2% (14/66) had experience using telemedicine. A descriptive analysis of our 3 NASSS-derived key constructs showed that among the 78.5% (335/427) respondents who generally agreed to digital access to health data, only 17.0% (57/335) accepted telehealth as a default. Notably, 30.7% (129/427) of participants stated a wish for support for using devices or the internet. Among those 129 individuals, 17.1% (22/129) were willing to accept telehealth as a default. Of the 89 people with prior telehealth experience, 15.7% (14/89) were willing to accept telehealth. In multivariable analysis, digital communication with health care providers (adjusted odds ratio [aOR] 14.56, 95% CI 6.18 - 39.04; *P*<.001*)*, current internet use for health care provider search (aOR 7.78, 95% CI 1.34 - 45.32; *P*=.021), and a secondary progressive MS diagnosis (aOR 0.22, 95% CI 0.05 - 0.72; *P*=.021) were independently associated with accepting telehealth as a default.

Conclusions: Our findings suggest a low acceptance of telehealth as a default among people living with MS in Switzerland. While our 3 postulated NASSS-derived key constructs were not associated with telehealth acceptance, we noted additional behavioral factors, including previous digital communication with health care providers and using the internet to search for health care provider information, which were associated with telehealth acceptance. Moreover, advanced disease states like secondary progressive MS were negatively associated with telehealth acceptance. Thus, telehealth as a default will be most acceptable in

XSL•FO
RenderX

people living with MS who already use the internet for their health, and those with less severe disease. Future research should explore provider perspectives and evaluate long-term strategies for the acceptance of telehealth in MS care.

KEYWORDS

acceptance; chronic disease management; digital health; multiple sclerosis; patient preferences; telehealth as a default; telemedicine

Introduction

Telehealth, the use of information and communication technology to provide remote health care, is a relatively novel approach in chronic disease management [1]. If widely adopted, it has the potential to improve access, continuity, and quality of care while reducing costs for populations with chronic diseases [2,3]. Evidence of patient benefits through its application in chronic disease care is promising. When used among people with cardiovascular disease (CVD), half of them had improved CVD risk scores [4]. When used among people living with diabetes, the quality of care was comparable to standard care while improving access and reducing the cost of care [5]. Among people living with cancer, it improved the quality of life and psychological well-being [6]. The COVID-19 pandemic also accelerated the use of telehealth in patient care, demonstrating its feasibility and acceptability for both patients and clinicians in chronic disease care, including multiple sclerosis (MS) [7,8].

In MS care, telehealth has been used for follow-up consultations, cognitive assessments, rehabilitation, and the management of symptoms that may limit mobility or access to specialist care. Altman et al [9] reported that both people living with MS and health care providers had a high level of satisfaction with telehealth. A review reported that people living with MS and their health care providers generally viewed telehealth as an acceptable and effective alternative to traditional in-person visits [10]. Also, telehealth has been reported to improve self-management [11,12], anxiety and depression [13-15], and activities of daily living in people living with MS [16]. Finally, no adverse events were reported with telerehabilitation for people living with MS [17].

The successful implementation of telehealth in MS and other chronic diseases is influenced by a range of enablers and barriers. Enablers include the perceived value proposition of the technology, such as improved access, convenience, and patient outcomes, alongside supportive organizational structures and positive attitudes among both patients and clinicians [18-20]. Conversely, barriers often arise from the severity of the disease, organizational complexity, technological challenges, digital literacy gaps, and concerns regarding data security or the adequacy of remote clinical assessments [16,21-23].

To systematically assess enabling and inhibiting factors, several frameworks have been proposed [24-26]. A widely used framework is the Non-Adoption, Abandonment, Scale-Up, Spread, and Sustainability (NASSS) framework [27]. The NASSS framework provides a comprehensive approach to understanding the adoption and sustained use of technologies in health care and has been used for a wide range of technologies and disease areas [27], including the use of telehealth in chronic care for conditions like CVDs, cancers, and neurological disorders [26]. The framework evaluates the complexity of technology acceptance within 7 constructs included in NASSS, which aim to identify and address factors influencing technology acceptance, anticipate barriers to implementation, and design interventions that are more likely to achieve scale-up and sustainability.

In MS care, few studies examine under what conditions people living with MS would accept telehealth as a default. In our study, we define “telehealth as a default” as a health care delivery model where remote consultations are the primary mode of interaction between patients and their physicians, with in-person visits occurring based on clinical necessity [28]. Previous studies report high patient and provider satisfaction [29], variable confidence in using telehealth in MS care [19], barriers limiting telehealth adoption [23]; but fail to report what conditions would enable or inhibit telehealth as a default among people living with MS.

Overall, many preconditions for successful telehealth implementation in Switzerland should be in place, including the presumed (and partially demonstrated) advantages of telehealth, the generally positive health-seeking attitude of people living with MS in Switzerland [30,31], and the push from global and national authorities for digital infrastructure to reduce diagnostic and therapeutic delays [1,32,33]. However, it remains unclear to what extent the Swiss population of people living with MS is capable and willing to engage in telehealth as a default mode for routine consultations. Therefore, our research seeks to assess the proportion of people living with MS in Switzerland potentially willing to accept telehealth as a default and the factors influencing their acceptance. Our findings are contextualized using the NASSS framework [34] and will provide information on how to target people living with MS with telehealth and consequently improve the quality of care for people living with MS.

Methods

Study Design and Setting

This study was a nested cross-sectional analysis within the Swiss Multiple Sclerosis Registry (SMSR), an ongoing observational cohort initiated in 2016. The SMSR recruits adults with MS residing or receiving treatment in Switzerland. Participation is voluntary and requires written informed consent, alongside confirmation of MS or clinically isolated syndrome (CIS) diagnosis. Upon enrollment, participants complete a baseline questionnaire and are invited to provide self-reported data via follow-up questionnaires approximately twice a year, available both online and in paper format.

XSL•FO
RenderX

Ethical Considerations

Ethical approval for the SMSR was granted by the ethics committee of the Canton of Zurich (PB–2016–00894; BASEC-NR 2019–01027). Further details on the SMSR have been previously published [35,36]. All participants had previously provided informed consent to be contacted and the use of their data for research purposes, including secondary analyses. Participation in this survey was voluntary, and individuals could decline without consequences. All data provided to the study team were fully anonymized. To protect participants' privacy and confidentiality, only anonymized data were used for this analysis, and results are reported in aggregate such that no individual participant can be identified. Participants received no compensation for completing the survey.

For this analysis, we used data from an anonymous, complementary online survey conducted between April 2023 and June 2023. This survey is a follow-up investigation of an earlier study on patterns of digital device use and digital literacy that was launched in October 2020 [37]. The 2023 survey used for this analysis was conducted online, in German, and offered independently of routine SMSR follow-ups (n=1720 eligible; 431 respondents; Multimedia Appendix 1). The rationale for offering the follow-up survey to a limited subsample had several reasons. First, we aimed to inform ongoing debates on telehealth and electronic health records promptly and therefore decided to offer the survey only in one language and online, also to facilitate data analysis. Second, our decision to offer the survey online and anonymously was also designed to attract inactive participants (ie, those who had not completed surveys in the past 2 years but remained in the cohort). Including these participants was intended to mitigate nonresponse bias and to capture perspectives from people living with MS who may be less engaged with research or digital tools. Third, the well-described SMSR source population and the existence of results from the 2020 study, which was offered to the full SMSR study population in all languages and participation modes (online and paper-pencil), enabled us to examine the generalizability and projections of key findings based on the limited, second survey (Multimedia Appendix 1).

Using the NASSS Framework for Hypothesis Development and Interpretation of Findings

The NASSS framework provides a structured approach to understanding the facilitators and barriers to technology uptake [34]. In our study, we used the NASSS framework to generate hypotheses, given the available data, for which factors may determine the acceptance of telehealth as a default by people living with MS in Switzerland. It comprises 7 domains: *the condition*—the nature of the health condition; *the technology*—the technology itself (eg, usability and reliability); *the value proposition*—the value of the technology to health care stakeholders; *the adopters*—the individuals expected to adopt the technology (patients, clinicians, and carers); *the organization*—the health care organizational context; *the wider system*—the wider system including policy and regulatory factors; and *embedding over time*—how the technology and its use may evolve through processes of embedding and adaptation. To describe the complexity of technology acceptance in the aforementioned domains, the NASSS framework defines a "simple technology" as one that has few components and its successful implementation is predictable, a "complicated technology" as one that has multiple components and its success is largely predictable, and a "complex technology" as one that has numerous interacting components with limited chances of succeeding and hence, less likely to be adopted [27]. Systematic reviews applying the NASSS framework have identified that barriers are most frequently encountered within the domains of organization and adopter system, while enablers are linked to clear value propositions and alignment with patient needs [26,34,38].

Main Outcomes

The primary study outcome was the proportion of participants who accepted telehealth as a default method for consultations. The acceptance of telehealth as a default was assessed using the following question: "Agreement to Digital Default (Would you find it beneficial for your medical care if medical consultations were through telemedicine?)," collected as a Likert scale from 0 (completely disagree) to 4 (completely agree). For further analysis, a binary variable was created where "Yes" included Likert levels (3,4) and "No" included levels (0,1,2). When describing the prevalence of acceptance in the population, we refer to the observed proportion as "low acceptance" descriptively; we did not define formal quantitative thresholds for low versus high acceptance.

Main Explanatory Variables of Interest

We hypothesized 3 main drivers of telehealth acceptance that are included in our data: (1) knowledge of and prior experience with telehealth, (2) general openness toward digital health tools and electronic health records, and (3) needs and wishes for digital support.

Knowledge of and experience with telehealth was assessed using the following question: "Do you have knowledge of telemedicine offerings, and have you already gathered experiences with telemedicine?" Answer options were "neither knowledge of nor experience with telemedicine," "knowledge of but no experience with telemedicine," or "knowledge of and experience with telemedicine."

Openness for use of other digital health tools was assessed through items on willingness to accept other digital health services (eg, file sharing, health data use, and provider communication) and experience with telemedicine. Each variable was collected as a Likert scale ranging from 0 (completely disagree with digital default) to 4 (completely agree with specific digital default).

Digital support needs were assessed with two items: (1) "Do you require support in using digital devices (eg, smartphones, laptops)?" and (2) "Do you need assistance with internet-related tasks (eg, security, navigation, program management)?" Each was rated on a Likert scale from 0 (no support needed) to 2 (extensive support needed). Participants reporting moderate (1) or extensive support (2) needs for both items were classified as requiring digital support.

XSL•FO
RenderX

Other Explanatory Variables

Covariates included age (categorized as 18‐30, 31‐40, 41‐50, 51‐60, 61‐70, >70 y), sex (male or female), MS type (CIS or relapsing-remitting MS, primary progressive MS [PPMS], secondary progressive MS [SPMS]), and frequency of internet use for health-related purposes (eg, appointment scheduling and provider communication). Prior or current telemedicine use was included as a binary variable. Additional covariates included concerns related to internet use (eg, data security and information reliability). Internet use frequency was categorized as never, less than monthly, monthly, weekly, daily, or several times daily. A composite "use score" (range 0‐5) was calculated by summing the number of online activities performed at least monthly.

Statistical Analysis

We first described the study population using MS type, sociodemographic characteristics, and experience with telemedicine. We then compared key variables based on previous telehealth experience (Multimedia Appendix 2) and openness to default telehealth consultations (see Table 1). In this study, a complete case analysis was undertaken. We excluded persons where key variables were missing from the analysis, leading to the exclusion of 4 participants.

[a]MS: multiple sclerosis.

[b]CIS: clinically isolated syndrome.

[c]RRMS: relapsing-remitting multiple sclerosis.

[d]PPMS: primary progressive multiple sclerosis.

[e]SPMS: secondary progressive multiple sclerosis.

Univariable logistic regression models were used to identify factors associated with willingness to accept default telehealth consultations (Multimedia Appendix 3). All prespecified variables relating to the use of digital tools and attitudes toward digitalization were included in the full multivariable logistic regression model, which also included predefined adjustments for potential confounders (age, sex, MS type, and telemedicine experience). A 2-sided *P* value <.05 was considered statistically significant. All analyses were conducted using R (version 4.4.2; R Foundation for Statistical Computing).

Reporting Framework

This paper was written following the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) guidelines (Checklist 1) for cross-sectional studies [39].

Results

Sociodemographic Data

Of 431 survey respondents, 4 had missing information regarding age. Therefore, a total of 427 participants with complete data were included in the analysis. The study sample consisted of 30.2% (129/427) men and 69.8% (298/427) women, with 41% (175/427) of participants aged between 18 and 50 years. Of the respondents, 66.7% (285/427) reported having relapsing-remitting MS or CIS, while 11.9% (51/427) had PPMS and 21.3% (91/427) SPMS. A total of 20.9% (89/427) reported previous experience with telemedicine consultations (Table 2).

[c]RRMS: relapsing-remitting multiple sclerosis.

[d]PPMS: primary progressive multiple sclerosis.

[e]SPMS: secondary progressive multiple sclerosis.

Acceptance of Telehealth as a Default Method of Consultation

A total of 66 out of 427 (15.5%) participants were open to a default telehealth consultation (Table 1). Among this group, 21.2% (14/66) had previous telemedicine experience. Although 78.5% (335/427) agreed to default digital access to health data, only 17.3 (58/335) agreed to default to telehealth. Of the 30.2% (129/427) participants needing hardware and software support, 81.4% (105/129) did not agree to telehealth as a default. Older age groups greater than or equal to 60 years 90.1% (73/81,) and those concerned with data security 86.7% (235/271,) and information validity 87.3%(220/252,) rarely accepted telehealth as a default.

Factors Associated With Acceptance of Telehealth as a Default

Multivariable Regression

In the multivariable regression model (Table 3), default communication with health care providers (adjusted odds ratio [aOR] 14.56, 95% CI 6.18 - 39.04; *P*<.001), internet use for health care provider search (aOR 7.78, 95% CI 1.34 - 45.32; *P*=.021) and a SPMS diagnosis (aOR 0.22, 95% CI 0.05 - 0.72; *P*=.021) were independently associated with an agreement to default telehealth consultation. Other factors, such as concerns about invalid information, data security, and telemedicine experience, did not show significant associations when adjusted for other predictors. The multivariable model showed low multicollinearity (variance inflation factor <1.5), suggesting that the predictors are not highly correlated with each other and that the regression coefficients can be reliably interpreted.

XSL•FO

Discussion

Summary of Findings

This cross-sectional study determined the proportion of people living with MS who are willing to accept telehealth as a default and the factors influencing their acceptance. We found that only 66 out of 427 (15.5%) participants were willing to accept telehealth as a default, which was positively associated with a general openness for digital communication with health care providers or using the internet for health care provider searches. We also found a negative association of telehealth acceptance with having SPMS.

The Proportion of People Living With MS Who Accepted Telehealth as a Default

In our study, less than one-fifth of people living with MS accepted telehealth as a default. However, this finding contrasts with other studies reporting over 70% acceptance of telehealth among people living with MS compared to in-person visits [23,29,40]. These earlier studies examined acceptance and satisfaction with telehealth during the COVID-19 pandemic, a period in which the extensive use of telemedicine ensured continuity of care, which probably contributed to increased acceptance. Hence, the difference in rates of acceptance might be explained by the forced global shift to digital services to curb the pandemic. Also, these earlier investigations did not specifically assess accepting telehealth as a default. Our low acceptance rate could also be due to the complexity of MS and factors like comorbidities and the older age of our study sample [41]. MS severity is often linked with more physical impairments, comorbidities, and aging [42]. In our study, persons with PPMS and SPMS, as well as persons aged over 60 years, were overrepresented compared with the projected population of people living with MS in Switzerland (Multimedia Appendix 1). These sample differences may explain the low percentage of telehealth acceptance as a default. Indeed, studies have repeatedly shown that people aged above 60 years are least accepting telehealth as a default; that corroborates with research on technology acceptance in older populations [23,27,43-45]. Nevertheless, some research highlights that older adults may still be receptive to telehealth when it addresses access barriers, reduces the burden of travel, or is perceived as enhancing continuity of care [46,47]; hence, addressing these preconditions may increase acceptance of telehealth.

The contrast between the high acceptance of default digital access to health data (78.5%) and the low acceptance of telehealth as default MS care (17.1%) suggests that people living with MS may favor asynchronous over synchronous digital modalities. Asynchronous tools such as secure messaging, patient portals, and digital care paths enable patients to access information, contact their care team, and receive tailored feedback without the need for real-time interaction and have been shown to support chronic disease management and self-management, including in MS [48-50]. Our findings most likely suggest the use of asynchronous telehealth as a complementary, but not necessarily default, component of chronic MS care.

Factors Associated With Accepting Telehealth as a Default

In our multivariable regression analysis, neither of the 3 prepostulated NASSS constructs as possible drivers of telehealth acceptance (hypotheses 1 - 3) showed independent associations. For example, although prior telemedicine experience has been linked to greater acceptance in other settings, it was not significantly associated with acceptance in our cohort. Only 20% of participants reported any prior telemedicine experience—consistent with the generally low acceptance of telehealth among people living with MS in Switzerland [32]—which likely limited its influence in our analysis.

However, we found that a general acceptance toward digital communication with health care providers, as well as regular internet use to search for health care providers, was positively associated with a willingness to accept telehealth as a default.

XSL•FO
RenderX

A general acceptance of digital communication may indeed ease a transition toward telehealth, accelerated by the COVID-19 pandemic, when tools for digital communication through voice and video became more widely adopted, also among older populations [8,10,29,51]. The positive association of prior experience with online searches of health care providers is more challenging to interpret but may signal a general interest in using the internet as a tool for personal health management [7,11]. In the first digital survey, frequent online searches for health care providers distinguished a subgroup of people living with MS with greater health awareness who regularly used digital tools for managing their condition [37]. In general, individuals familiar with digital tools may perceive a lower cognitive and practical barrier in using telehealth [52]. This observation could also be true for those who use the web to search for care providers. Most likely explaining the positive association between telehealth and prior use of the internet for health care provider search found in our study, because the user's perceived effort with technology will be relatively low [45].

Individuals with SPMS were less likely to endorse telehealth as a default. This may reflect the greater physical and cognitive burden associated with SPMS—which can limit mobility, manual dexterity, and cognitive processing—and thereby reduce patients' ability or willingness to use the internet-based devices for medical consultations [23,41].

In Switzerland, telehealth expanded during the COVID-19 pandemic [8]. Remote consultations (mainly telephone and video) are reimbursed via existing tariff positions, and some basic insurance products use telemedicine "gatekeeper" models that require initial contact with a telemedicine provider. Despite this structural role, data on outpatient MS telehealth use remain limited, and our findings suggest that people living with MS do not yet view telehealth as an acceptable default for specialist care.

Contextualizing Our Findings Using the NASSS Framework

We further applied the NASSS framework to our findings to contextualize the results and to understand the complexity of implementing telehealth as a default in MS care [27]. Our review of the results identified four NASSS domains that are reflected by our study as follows:

1. Condition (MS complexity): MS is a heterogeneous disease with varying degrees of physical and cognitive impairment. Our finding of a negative association between SPMS and telehealth acceptance suggests that those with more severe or chronic forms of MS are less likely to accept telehealth by default, which is consistent with the literature [23,26,41].
2. Technology (telehealth use): the acceptance of telehealth as a default depends on prior digital literacy and technology exposure. In our cohort, only 20% had prior telemedicine experience, and over half expressed concerns about data security. These are moderating factors in digital health acceptance [44]. While global health bodies and the Swiss federal government promote digital health, acceptance may likely depend on how people living with MS engage with technology [1,32].
3. Value proposition (perceived benefits of telehealth)*:* over 70% of participants supported digital access to health data, but 80% declined telehealth as a default. Therefore, while most survey respondents are generally open toward provider-facing digital health tools in MS care, they seem more reluctant to actively engage with digital health technologies themselves. This finding could highlight a need to better communicate the potential benefits of telehealth to people living with MS [24,45]. While people with chronic diseases may accept certain aspects of digital health care [23], efforts are needed to better inform people living with MS on the value of telehealth to their health care.
4. Adopter system (integration into existing health care services)*:* one-third of participants who declined telehealth by default expressed the wish for support to use computer hardware or software. The presence of structured support systems is a critical factor in technology acceptance [7,44]. Addressing digital literacy gaps, easing the onboarding of persons with MS onto telehealth, and providing ongoing technical support and assistance could enhance the feasibility of telehealth as a default option for people living with MS [7,18].

While our analysis focused on 4 NASSS domains, we did not capture factors related to the organizational context, wider system, or long-term adaptation (Multimedia Appendix 4). This limits our understanding of how systemic factors—such as provider readiness, policy frameworks, and reimbursement models—may influence the acceptance of telehealth by default. These omissions are important, as they likely shape how people living with MS perceive and engage with telehealth beyond individual factors. Future research should prioritize collecting data on these broader domains to enable a more comprehensive use of the NASSS framework.

Strengths and Limitations

Our study has several limitations. First, given our recruitment methods and mode of survey delivery, our study population is not intended to be representative of the Swiss population of persons with MS at large (details provided in Iaquinto et al)[53]. Overall, our study sample seems to be older and more frequently of a PPMS or SPMS type. Therefore, we may have underestimated the general acceptability of telehealth (even after bias mitigation through reweighting our estimates based on our earlier, more inclusive digital health survey). However, the deviations of our (reweighted) samples from the Swiss population of persons with MS are unlikely to materially alter our main conclusion that the general openness to accept telehealth is presently quite low. Second, because the survey was administered online and focused on eHealth, it is possible that more digitally interested people living with MS were more likely to participate, which could in principle bias acceptance estimates upward, although the very low observed acceptance makes substantial overestimation unlikely.

Furthermore, since our study is a secondary data analysis, omitting some NASSS-relevant items, we were unable to assess certain NASSS domains, such as organizational factors, the wider health care system, and long-term sustainability. Also,

XSL•FO
RenderX

within the value proposition and adopter system domains, we were unable to consider the perspectives of health care providers and institutions. However, by assessing the perspective of people living with MS, our study offers important insights into the real-world acceptance of technology by the population of interest. Lastly, this study was conducted post-COVID-19 era, when the pressure to use telehealth is relatively low, and there is an increasing need for things to return to how they were before the pandemic, a possible reason for the low uptake.

However, our study has the following strengths. To our knowledge, this is the first study to specifically assess the acceptance of telehealth as a default in MS care. We also identified subgroups requiring targeted support to improve telehealth acceptance. Taken together, our study has identified some additional aspects that might pave the way toward an individualized telehealth setting suited for people with chronic diseases.

Implications and Recommendations

The low acceptance of telehealth as a default highlights the need for measures that address the barriers affecting acceptance. These measures may include targeted communication campaigns or having technical staff available to assist people living with MS with technical questions during onboarding. Our findings suggest that individuals who already engage with digital health tools for health management-related tasks, such as provider searches, are more receptive to telehealth. This suggests that furthering positive experiences with digital communication and provider interactions may also enhance the acceptance of telehealth. Furthermore, given that approximately one-third of participants required support with digital devices, implementing technical support and training programs could improve uptake. Policymakers and health care providers should prioritize these measures to ensure equitable digital health care access for people living with MS.

Clinically, our data argue against telehealth as a universal default model for MS care. Since participants with more severe disease were less likely to accept telehealth as the default modality. A more nuanced approach could involve triaging people living with MS according to disease severity, stability, and complexity: telehealth could be preferentially offered to those with stable, less severe disease for routine follow-up and counseling, whereas individuals with higher disability, new or complex symptoms, or substantial care coordination needs would continue to receive in-person visits by default. Such a stratified approach may optimize resource use while respecting individual preferences and clinical safety.

Conclusions

The acceptance and scaling of telehealth as a default is complex. Our study highlights the need for targeted implementation and testing of telehealth among a diverse cohort of people living with MS. These findings hint at potential considerations for the acceptance of telehealth as a default among people living with chronic diseases. Acceptance may be potentially improved if support is provided, and the value of these technologies is discussed with target patient groups. Such information should be accompanied by trust-building measures in data security and privacy, as well as offers for improving digital literacy for those in need. We conclude that acceptance of telehealth as a default needs to be targeted to the group of people living with chronic diseases most likely to benefit from it, and future research should explore provider perspectives and evaluate long-term strategies for integrating telehealth in MS care and chronic disease care.

Acknowledgments

Abstract

Background: The global integration of telehealth into the management of Parkinson disease (PD) addresses critical gaps in health care access, especially for patients with limited mobility in underserved regions. Despite accelerated adoption during the COVID-19 pandemic, evidence regarding telehealth's multidimensional efficacy remains inconsistent. Previous meta-analyses reported conflicting outcomes for quality of life (QOL), motor symptoms, and neuropsychiatric comorbidities.

Objective: This study aimed to quantitatively synthesize the effects of telehealth interventions across six core PD domains: (1) QOL, (2) depression, (3) anxiety, (4) motor symptoms, (5) activities of daily living (ADL), and (6) cognition.

Methods: PubMed, Embase, Cochrane Library, Scopus, and Web of Science were systematically searched until June 21, 2024. In adherence to PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines, English-language randomized controlled trials evaluating telehealth interventions for PD were included. Study quality was assessed using the Cochrane Risk of Bias tool. A dual analytical approach using random-effects models was applied to address heterogeneity. Studies reporting a single effect size were analyzed using the Hartung-Knapp-Sidik-Jonkman correction. Studies with multiple dependent effect sizes were analyzed using a 3-level random-effects meta-analysis with t-distribution inference, accounting for sampling, within-study, and between-study variance. Effect sizes were expressed as standardized mean differences (SMD) with 95% CIs. Heterogeneity was quantified using the τ^2; prediction intervals were not calculated due to the limited number of studies. Prespecified subgroup analyses examined intervention types (digital vs traditional telehealth) and follow-up durations. Sensitivity analyses and assessments for small-study effects (multilevel Egger tests, funnel plots) were conducted.

Results: A total of 15 randomized controlled trials (765 participants) demonstrated significant telehealth benefits: QOL significantly improved on the Medical Outcomes Study 36-Item Short Form Health Survey and Brunnsviken Brief Quality of Life Scale (SMD 0.39, 95% CI 0.06-0.72; *P*=.03), with marginal improvement on the Parkinson Disease Questionnaire-8 (SMD –0.42, 95% CI –0.88 to 0.03; *P*=.07). Telephone-based interventions outperformed digital approaches (*P*=.002). Depression symptoms were significantly reduced (SMD –0.64, 95% CI –0.93 to 0.34; *P*<.001), particularly with traditional telehealth (*P*<.001).

XSL•FO
RenderX

Anxiety also decreased significantly (SMD –0.64, 95% CI –0.92 to 0.35; *P*=.003) with negligible heterogeneity (I^2=0%). Motor symptoms improved (SMD –0.46, 95% CI –0.69 to 0.24; *P*=.001), and ADL showed substantial impairment reduction (SMD –0.79, 95% CI –1.04 to –0.54; *P*=.002). Cognition was significantly enhanced (SMD 1.12, 95% CI 0.03 to 2.20; *P*=.045) though with moderate heterogeneity (I^2=52.3%) and significant publication bias (*P*<.001). Follow-up duration did not significantly moderate effects.

Conclusions: Telehealth interventions significantly enhance multiple PD domains, with traditional (telephone/tablet-based) approaches demonstrating particular advantages for QOL and depression. Digital interventions showed more limited efficacy. These findings support telehealth as a multifaceted management tool for PD, although cognition outcomes require further investigation.

KEYWORDS

depression; meta-analysis; motor symptoms; Parkinson disease; quality of life; systematic review; telehealth intervention

Introduction

Parkinson disease (PD), currently the second-most common neurodegenerative disorder after Alzheimer disease, affects approximately 1% of individuals aged 55 years or older, typically manifesting around the age of 60 years [1]. The incidence of PD increases with advancing age, particularly among individuals older than 60 years [1]. Currently, PD affects nearly 6 million people globally [2]. By 2030, China is expected to have approximately 4.94 million patients with PD, representing nearly half of global cases [3]. This demographic shift could significantly strain national economies and health care systems [3].

Patients with PD experience a range of motor and nonmotor symptoms. Motor symptoms include tremors, rigidity, bradykinesia, postural instability, and gait freezing [4]. Nonmotor symptoms encompass cognitive decline, pain, fatigue, psychiatric conditions such as depression and anxiety, and sleep disturbances [5,6]. These symptoms substantially reduce patients' quality of life (QOL) and increase psychological stress and physical demands on caregivers [7]. Traditionally, management and evaluation for patients with PD require visits to outpatient clinics or hospitals for advanced diagnostics and assessments [8]. However, many patients encounter significant barriers to accessing such facilities, including limited mobility, fear of falling, depressive symptoms, fatigue, and time constraints. These barriers can worsen their symptoms, delay treatment, lead to potentially life-threatening complications, and increase overall disease burden [9]. Consequently, a growing number of researchers advocate telehealth as a means to improve PD diagnosis, treatment, and rehabilitation. Telehealth aims to overcome challenges associated with in-person consultations and geographical disparities in health care resources, thereby reducing delays in treatment, decreasing morbidity and mortality, and improving QOL among patients with PD [10].

Telehealth uses digital information and communication technologies to connect patients with health care providers and deliver medical services [11]. These technologies include internet-connected desktop computers, tablets, smartphones, and wearable devices [12,13]. The COVID-19 pandemic significantly accelerated the adoption of telehealth among patients with PD, improving health care accessibility. Research supports the practicality of telehealth and underscores its perceived effectiveness by patients with PD and neurologists [10,14-16]. Neurologists can independently conduct comprehensive assessments using the Movement Disorders Society-Unified Parkinson's Disease Rating Scale Part III (MDS-UPDRS-III), enabling more accurate evaluations in patients' usual settings rather than clinical environments. This method provides a more accurate reflection of the patients' actual condition [10,17-19]. Advantages of telehealth, such as time and cost efficiency, have resulted in high patient satisfaction [14-16,20-22]. Additionally, telehealth facilitates virtual monitoring for rehabilitation, psychotherapy, and advanced PD treatments [23-25]. It promotes interdisciplinary collaboration and provides education and training opportunities for physicians and health care workers in developing regions, overcoming geographic, travel, and financial barriers [10].

Numerous studies have confirmed the practicality and effectiveness of telehealth in managing patients with PD; yet, findings regarding QOL, anxiety, depression, motor function, activities of daily living (ADL), and cognitive function have been variable [8,26,27]. A meta-analysis by Chen et al [26] in 2020 demonstrated that telehealth interventions effectively reduced motor symptoms compared with traditional care. However, these interventions showed no substantial improvements in QOL, depression, cognitive functions, or balance abilities, contrasting with more recent findings [28-31]. A systematic review by Leon-Salas et al [8] published in 2023 indicated limited and inconclusive data regarding telehealth services for patients with PD. Following the COVID-19 pandemic, an influx of new studies necessitates an updated synthesis and analysis to clarify the effects of telehealth interventions on patients with PD. Additionally, a 2024 systematic review by Federico et al [27] reported telerehabilitation outcomes comparable to in-person therapy for patients with PD. However, the review focused solely on telerehabilitation for various neurological disorders without extensively evaluating broader telehealth effects in patients with PD.

XSL•FO
RenderX

Thus, the objective of this research was to systematically compile and analyze the most recent data on telehealth intervention effects in patients with PD.

Methods

Overview

This systematic review and meta-analysis was conducted in strict accordance with PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines (Multimedia Appendix 1) [32]. To ensure transparency and reproducibility, the study protocol was registered with PROSPERO (registration number CRD42024520169).

Inclusion and Exclusion Criteria

The selection criteria followed the PICOS framework: (1) Population: individuals officially diagnosed with PD; (2) Interventions: telehealth or telemedicine interventions delivered via telephone, internet, or other digital communication technologies [11]; (3) Comparison/Control: studies with an experimental group compared to control groups using standard care, routine care, conventional care, or waitlist control; (4) Outcomes: assessment of intervention effects on overall health or specific behavioral and psychological symptoms associated with Parkinsonism; (5) Study type: only randomized controlled trials (RCTs).

The exclusion criteria were as follows: (1) studies published in non-English languages, (2) incomplete studies, such as research protocols or ongoing studies, (3) studies where interventions were exclusively telehealth-based without a comparison group, or where no telehealth intervention was applied, (4) studies lacking sufficient details on relevant outcome measures, and (5) studies without adequate statistical data for analysis. No publication date limitations were applied.

Search Strategy

Two researchers (MS and FT) systematically searched 5 English-language databases (PubMed, Embase, Cochrane Library, Scopus, and Web of Science) from database inception until June 21, 2024. The comprehensive search strategy combined subject headings and keywords related to three main topics: (1) PD, (2) telehealth, and (3) RCTs. There were no limits on publication status or dates. The detailed search methods are provided in Multimedia Appendix 2. Additionally, references of included studies were manually reviewed.

Study Selection and Data Extraction

The reference management tool EndNote X9 (Clarivate Analytics) was used for data management. After removing duplicates, 2 reviewers (MS and FT) independently screened titles and abstracts based on predefined inclusion and exclusion criteria. Potentially relevant articles underwent full-text assessment to determine eligibility. Any discrepancies were resolved through discussion, and when consensus was unattainable, a third reviewer (Luomin) was consulted for a final decision.

Data extraction used a specifically designed form. Extracted information included authors' names, publication dates, country, study design, sample size, demographic and clinical characteristics (average age, gender distribution, and disease attributes), type and duration of interventions and control groups, outcome measures, and key study findings.

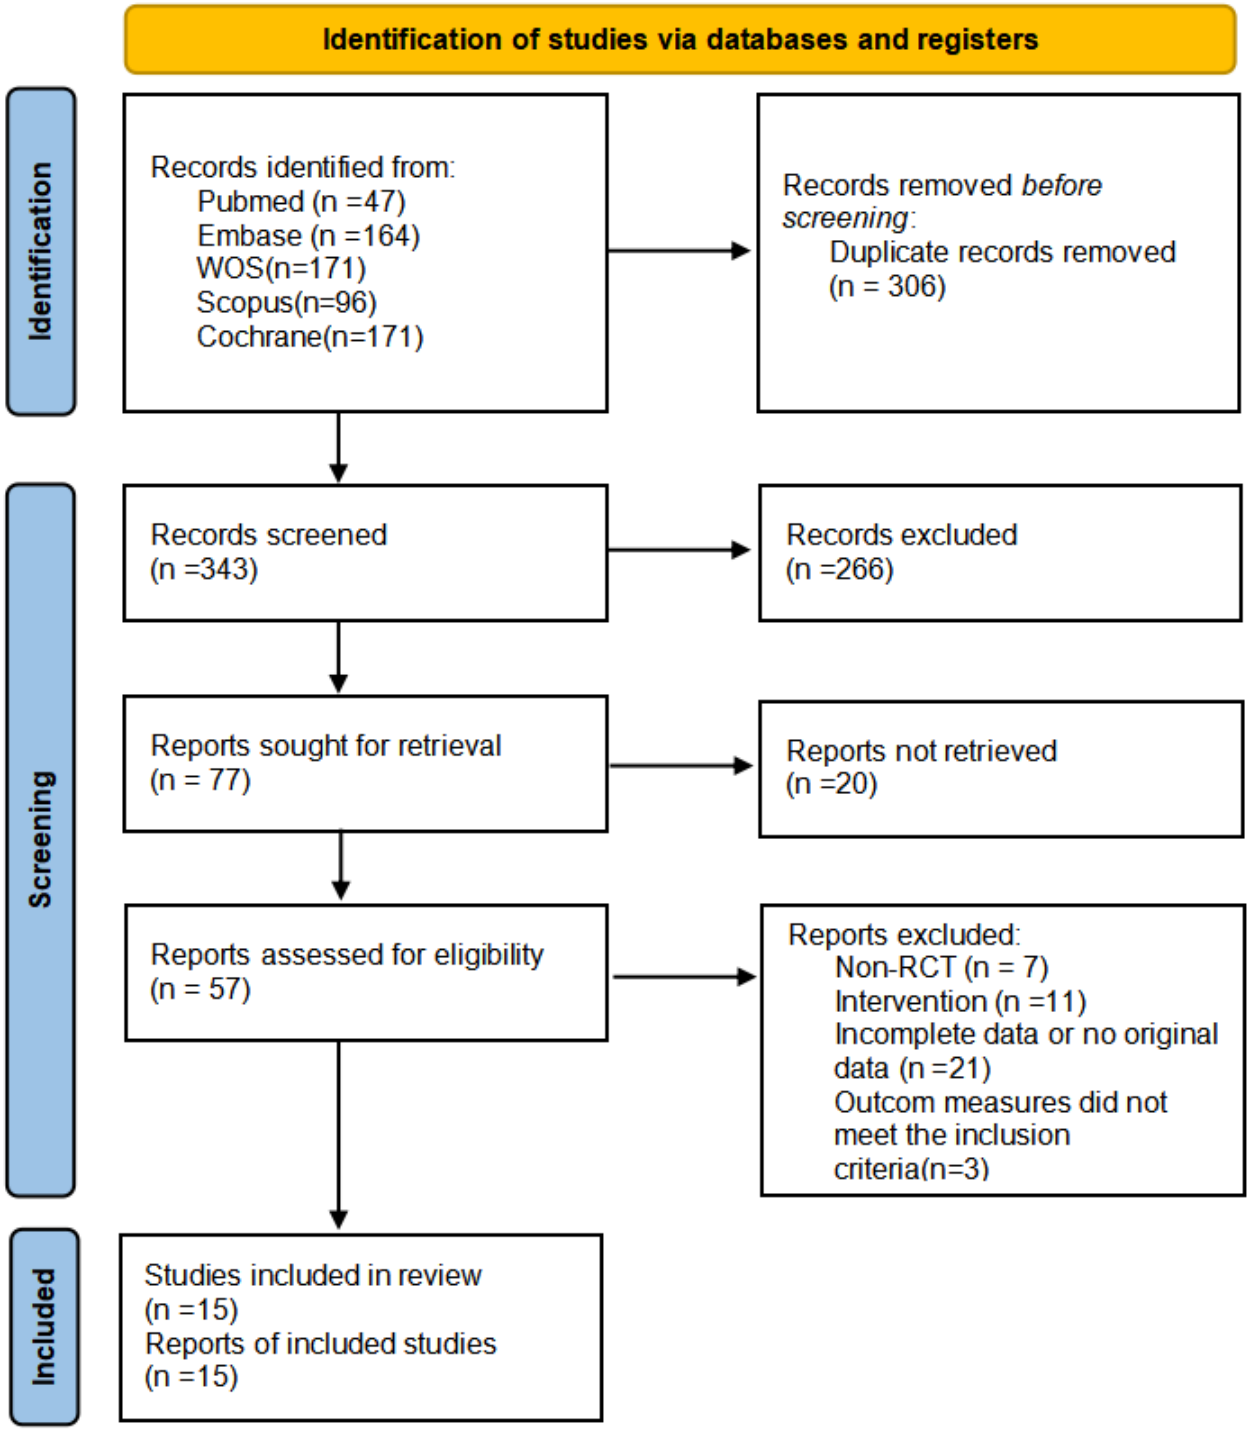
Risk of Bias

Two researchers (MS and FT) independently assessed the methodological quality and potential bias of included studies using the Cochrane Collaboration's Risk of Bias tool [33]. Disagreements were resolved through discussion with a third reviewer (Luomin) to achieve consensus. The tool systematically evaluates several dimensions of bias, including random sequence generation, allocation concealment, blinding of participants and personnel, handling of incomplete outcome data, and selective outcome reporting. Each study was assessed for potential selection, performance, detection, attrition, and reporting biases. Risks in each domain were categorized as low (unlikely to significantly affect results), high (likely to significantly undermine confidence), or unclear.

Statistical Analysis

All meta-analyses were conducted using random-effects models, based on the conceptual assumption that true effects vary across studies due to inherent differences in populations, interventions, and settings, rather than on statistical metrics such as I^2. A dual analytical approach incorporating the Hartung-Knapp-Sidik-Jonkman (HKSJ) adjustment was used to obtain more accurate and conservative interval estimates: for studies providing a single effect size, the HKSJ method was used to calculate 95% CIs; for studies with multiple dependent effect sizes, a 3-level random-effects meta-analysis was performed in R software using the *metafor* package (version 4.5.1; R Foundation for Statistical Computing) using t-distribution–based inference. This model accounts for sampling variance (level 1), within-study variance (level 2), and between-study variance (level 3), with t-distribution inference being analogous to the HKSJ correction for multilevel models. Heterogeneity was quantified with the τ^2 statistic. Although 95% prediction intervals were initially planned to illustrate the expected range of true effects in similar future studies, they were not calculated due to the limited number of studies for each outcome (all $k<10$), as such intervals are unreliable with small samples. The I^2 statistic is reported for descriptive purposes only, acknowledging its limited pragmatic use in conveying the magnitude of true effect variation across settings. Prespecified subgroup analyses examined intervention type (digital vs traditional telehealth) and follow-up duration. Sensitivity analyses were conducted using leave-one-out elimination. Small-study effects (for which publication bias is one possible explanation) were assessed with funnel plots and multilevel Egger tests. Statistical significance was set at 2-tailed $P<.05$. Complete analysis code is provided in Multimedia Appendix 3.

Results



Study Selection

Figure 1 shows the PRISMA flowchart detailing the study selection process for this systematic review and meta-analysis.

XSL•FO
RenderX

The initial electronic database search yielded 649 records. After removing duplicates, 343 articles remained. Following title and abstract screening, 266 articles were excluded, leaving 77 articles eligible for full-text review. Among these, 20 articles (conference abstracts, reviews, or research protocols) were unavailable in full, leaving 57 articles for detailed evaluation. Ultimately, 15 articles met the inclusion criteria and were included in the final analysis.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart detailing the identification and selection of randomized controlled trials (RCTs) on telehealth interventions for people with Parkinson disease. WOS: Web of Science.

Study Characteristics

This systematic review included 15 RCTs [20,28-31,34-43] with a total of 765 participants. The studies were conducted across various countries: 2 in Spain, 6 in the United States, 1 in Japan (Tokyo), 3 in Italy, 1 in Sweden, 1 in Brazil, and 1 in Australia. These studies were published between 2016 and 2024. All participants were diagnosed with PD and aged 18 years or older. Sample sizes ranged from 9 to 49 participants. All trials used telehealth technologies, including telehealth systems, telephones, applications, and tablets. Follow-up durations ranged

XSL•FO
RenderX

from 1 to 12 months post intervention. Detailed study characteristics are provided in Table 1.

Risk of Bias

The methodological quality and potential biases of the included studies were assessed using the Cochrane Risk of Bias tool [33]. Figure 2 presents detailed findings. All 15 studies were confirmed as randomized, and 12 studies [20,28,30,31,34,36-41,43] clearly described methods of random sequence generation. Only 7 studies [28-30,36,38,39,41] detailed allocation concealment methods, categorizing them as having a low risk of selection bias. Regarding the blinding of participants and intervention providers, only 3 studies [36,39,41] reported adequate blinding procedures and thus had a low risk of performance bias. In contrast, 4 studies [28,37,40,43] without blinding were classified as having a high risk of performance bias. The remaining 8 studies [20,29-31,34,35,38,42] lacked sufficient information and were classified as unclear. Blinding of outcome assessors was reported in 10 studies [28,30,36-43], indicating a low risk of detection bias, while 5 studies [20,29,31,34,35] did not report this information. All studies provided complete outcome data, indicating low attrition bias. Assessment for other potential biases generally indicated low risk. Funnel plot analysis (Multimedia Appendix 4) revealed no significant publication bias among included studies.

Meta-Analysis

Quality of Life

A total of 11 studies [20,28-30,36-40,42,43] evaluated QOL following telehealth interventions, using 5 different measurement tools. Overall, 9 studies used Parkinson Disease Questionnaire (PDQ) scales (PDQ-39 [37,39,42,43] and PDQ-8 [20,28,29,38,40]), with higher scores indicating worse QOL. Additionally, 2 studies used the Medical Outcomes Study 36-Item Short Form Health Survey (SF-36) [30,36], and 1 study incorporated both PDQ-8 and Brunnsviken Brief Quality of Life Scale (BBQ) [29], with higher scores reflecting better QOL. Due to measurement variability, a standardized mean difference (SMD)–based meta-analysis was conducted following Cochrane handbook guidelines.

A 3-level random-effects meta-analysis of 8 studies (13 effect sizes) assessing QOL using PDQ scales revealed a marginal trend toward improvement after telehealth interventions (SMD –0.42, 95% CI –0.88 to 0.03; P=.07). Heterogeneity was present (τ^2=0.258; I^2=56.2%; Q_{12}=27.37; P=.007), with between-study variance accounting for 65.5% of total variability. Prediction intervals were not calculated due to the limited number of studies (k<10; Table 2; Figures S1-S3 in Multimedia Appendix 4). Subgroup analysis demonstrated significant moderation by intervention type (test of moderators=9.84; P=.002). Telephone-based interventions significantly improved QOL (SMD –0.83, 95% CI –1.22 to –0.44; P<.001), whereas digital interventions had minimal effect (SMD –0.05, 95% CI –0.58 to 0.49; P=.86). The between-group difference was 0.78 (95% CI 0.29-1.27; P=.002) points. Follow-up duration did not significantly moderate outcomes (categorical: P=.58; continuous: β=.01/month; P=.83; Table 3; Figures S4-S7 in Multimedia Appendix 4). Sensitivity analysis identified substantial influence from Ramos et al [28], whose exclusion reduced the effect magnitude by 52.2%. Multilevel Egger test suggested possible small-study effects (P=.02; Figures S8-S9 in Multimedia Appendix 4).

[n]*P*<.001.

[o]*P*<.05.

For 3 studies assessing QOL using SF-36 and BBQ (5 effect sizes), the 3-level random-effects meta-analysis indicated significant improvement after telehealth interventions (SMD 0.39, 95% CI 0.06-0.72; *P*=.03). Minimal heterogeneity was observed (τ^2=0.020; I^2=25.9%; Q_4=5.40; *P*=.25), with within-study variance contributing 27.7% of total variability. Prediction intervals were not calculated (*k*<10; Table 2; Figures S11-S12 in Multimedia Appendix 4). Subgroup analyses indicated greater effects in short-term follow-ups (<3 months: SMD 0.73, 95% CI 0.26-1.19) compared with longer-term

XSL•FO
RenderX

follow-ups (≥3 months: SMD 0.31, 95% CI –0.40 to 0.43; β=–.42; *P*=.12). A marginal negative correlation between effect magnitude and follow-up duration was observed (β=–.06/month; *P*=.09; Table 3; Figures S13-S15 in Multimedia Appendix 4). Sensitivity analysis confirmed robustness; no single-study exclusion altered significance substantially (maximum change: +33.2% when excluding Dobkin et al [36]). The Egger test indicated no significant small-study effects (*P*=.28; Figures S16-S17 in Multimedia Appendix 4).

Depression

A total of 5 studies [20,29-31,36] evaluated depression levels in patients with PD following telehealth interventions, using 4 distinct assessment tools: Hamilton Depression Rating Scale (HAM-D) [30,31,36], Beck Depression Inventory (BDI) [30,36], Hospital Anxiety and Depression Scale-Depression (HADS-D) [29], and Geriatric Depression Scale [20]. Higher scores on these scales indicate increased depression severity. Two studies used both the HAM-D and BDI to assess depression. A 3-level random-effects meta-analysis (5 studies, 17 dependent effect sizes) with t-distribution–based inference revealed a significant reduction in depression symptoms after telehealth interventions (SMD –0.64, 95% CI –0.93 to –0.34; *P*<.001). Moderate heterogeneity was observed (I^2=45.9%; Q_{16}=29.60; *P*=.02). Variance component analysis indicated that between-study differences accounted for 35.6% of total variability (τ^2=0.062), within-study variability explained 8.9% (τ^2=0.016), and sampling error contributed 55.4% (Table 2; Figures S17-S19 in Multimedia Appendix 4). Prediction intervals were not calculated because the number of studies was below the recommended threshold (*k*<10). Subgroup analysis showed significantly greater improvements with traditional telehealth (SMD –0.84, 95% CI –1.00 to –0.67; *P*<.001) compared with digital interventions (SMD –0.31, 95% CI –0.54 to –0.08; *P*=.008; β=.53; *P*<.001). Follow-up duration was not significant in categorical analysis (β=–.13; *P*=.68), but continuous analysis showed a marginal positive association (β=.04/month; *P*=.06; Table 3; Figures S20-S23 in Multimedia Appendix 4). Sensitivity analyses confirmed robustness; effects remained significant after excluding each study (SMD range –0.55 to –0.79). The Egger test indicated no significant small-study effects (*P*=.82; Figures S24-S25 in Multimedia Appendix 4).

Anxiety

A total of 3 studies [29,30,36] assessed anxiety levels in patients with PD using 2 measurement scales: Hamilton Anxiety Rating Scale (HAM-A) [30,36] and Hospital Anxiety and Depression Scale-Anxiety (HADS-A) [29]. Higher scores represent greater anxiety severity. A 3-level random-effects meta-analysis (3 studies, 5 dependent effect sizes) with t-distribution–based inference indicated significant anxiety reduction following telehealth interventions (SMD –0.64, 95% CI –0.92 to –0.35; *P*=.003). Negligible heterogeneity was observed (I^2=0%; Q_4=0.90; *P*=.92), with variance component analysis indicating that sampling error explained all variability (τ^2=0 for both inter- and intrastudy variance; Table 2; Figures S26-S28 in Multimedia Appendix 4). Prediction intervals were not calculated due to the limited number of studies (*k*<10). All studies used telephone-based interventions, thus subgroup analyses examined follow-up durations. Follow-up duration was not significantly associated with outcomes in categorical (β=–.16, 95% CI –0.66 to 0.35; *P*=.55) or continuous analyses (β=.004/month, 95% CI –0.06 to 0.07; *P*=.90; Table 3; Figures S29-S31 in Multimedia Appendix 4). Sensitivity analyses confirmed robustness, with effects remaining significant upon exclusion of individual studies (SMD range –0.67 to –0.60), and maximum deviation of –5.4% when excluding Dobkin et al [30]. Funnel plots were symmetrical, and the Egger test revealed no significant small-study effects (*P*=.68; Figures S32-S33 in Multimedia Appendix 4).

Motor Symptoms

A total of 7 studies [20,28,34,35,38,41,42] used the MDS-UPDRS-III to evaluate motor symptoms in patients with PD post telehealth interventions, with higher scores indicating greater severity. A 3-level random-effects meta-analysis (7 studies, 11 dependent effect sizes) with t-distribution–based inference demonstrated significant improvements in motor symptoms after telehealth interventions (SMD –0.46, 95% CI –0.69 to –0.24; *P*=.001). Heterogeneity among studies was negligible (I^2=0%; Q_{10}=7.85; *P*=.64). Variance component analysis showed that sampling error accounted for all variability, with negligible between-study (τ^2=0) and within-study variance (τ^2=0; Table 2; Figures S34-S36 in Multimedia Appendix 4). Prediction intervals were not calculated because the number of studies was below the recommended threshold (*k*<10). Subgroup analysis by intervention type revealed no significant difference between digital and other telehealth interventions (β=.13, 95% CI –0.26 to 0.53; *P*=.51). Follow-up duration did not significantly moderate outcomes in categorical (β=.20, 95% CI –0.21 to 0.60; *P*=.34) or continuous analyses (β=.02/month, 95% CI –0.03 to 0.06; *P*=.55; Table 3; Figures S37-S39 in Multimedia Appendix 4). Sensitivity analyses confirmed robustness, with significant effects maintained after each study's exclusion (SMD range –0.52 to –0.42), and the largest change being 11.5% when excluding Wilkinson et al [20]. Funnel plots showed symmetry, and the Egger test indicated no significant small-study effects (*P*=.88; Figures S40-S41 in Multimedia Appendix 4).

Activities of Daily Living

A total of 4 studies [34,35,38,42] evaluated the impact of telehealth interventions on daily activities in patients with PD using the MDS-UPDRS-II scale. Higher scores represent greater impairment. A random-effects meta-analysis with HKSJ correction demonstrated that telehealth interventions significantly reduced impairment in daily activities compared with controls (SMD –0.79, 95% HKSJ-adjusted CI –1.04 to –0.54; *P*=.002). Heterogeneity was negligible (τ^2=0.000; I^2=0.0%; Q_3=0.43; *P*=.93). Prediction intervals were not calculated because the number of studies was below the recommended threshold (*k*<10). Sensitivity analysis (leave-one-out) confirmed the robustness of the findings. The largest change in effect size occurred after excluding Del Pino et al [35] (–7.9% change; SMD range across exclusions –0.83 to –0.73). Egger test indicated no significant small-study effects

XSL•FO
RenderX

(intercept=–1.35; *P*=.31; Figure S42 in Multimedia Appendix 4).

Cognition

A total of 2 studies [31,35] examined cognitive outcomes in patients with PD after telehealth interventions using the Montreal Cognitive Assessment (MoCA) and Mini-Mental State Examination (MMSE), where higher scores indicate better cognitive function. One study used both the MoCA and MMSE scales to comprehensively assess cognition. A 3-level random-effects meta-analysis (2 studies, 9 dependent effect sizes) with t-distribution–based inference indicated significant cognitive improvement following telehealth interventions (SMD 1.12, 95% CI 0.03-2.20; *P*=.045). Moderate heterogeneity was detected (I^2=52.3%; Q_8=16.77; *P*=.03). Variance component analysis showed that between-study differences accounted for 38.9% (τ^2=0.275) of total variability, within-study differences accounted for 27.2% (τ^2=0.192), and sampling error explained 33.9% (Table 2; Figures S43-S45 in Multimedia Appendix 4). Prediction intervals were not calculated due to the limited number of studies (*k*<10). A follow-up duration did not significantly moderate outcomes in categorical (β=–.31, 95% CI –1.25 to 0.62; *P*=.51) or continuous analysis (β=–.30/month, 95% CI –0.79 to 0.20; *P*=.24; Table 3; Figures S46-S48 in Multimedia Appendix 4). The Egger test indicated significant small-study effects (intercept=15.17; *P*<.001). Sensitivity analysis was not feasible due to the limited number of studies (Figure S49 in Multimedia Appendix 4).

Discussion

Overview

This systematic review evaluated the effects of telehealth interventions on the QOL and associated health outcomes in patients with PD. Findings demonstrated that telehealth interventions significantly enhanced various dimensions of patient well-being, including QOL, depressive symptoms, anxiety levels, motor function, ADL, and cognitive abilities. These results differ from earlier reviews and meta-analyses [8,26,27]. The discrepancies might be due to accelerated advancements in telehealth and remote neurology after the epidemic, alongside improvements in telehealth service quality and increased research volume [22,44]. Although the effectiveness of telehealth interventions appears promising, additional studies are needed to establish more conclusive evidence.

Effectiveness of Telehealth Interventions on QOL in Patients With PD

Our meta-analysis identified complex patterns regarding telehealth's effect on QOL in patients with PD. Interventions assessed by the SF-36/BBQ demonstrated a significant improvement, whereas those assessed using PDQ scales indicated only marginal benefit. This difference likely stems from the fundamental distinctions between scales: PDQ scales specifically measure PD-related deficits, whereas SF-36/BBQ assess general well-being [45,46]. Notably, telephone-based interventions substantially improved PDQ-based QOL, while digital interventions showed negligible effects. This distinction explains inconsistencies in prior meta-analyses [1,26,27] that did not account for intervention modality. Significant heterogeneity in PDQ analyses was primarily attributed to between-study differences, suggesting methodological variations. Sensitivity analysis highlighted substantial influence from Ramos et al [28], and potential small-study effects were noted. These factors necessitate cautious interpretation of PDQ outcomes. Conversely, SF-36/BBQ analyses exhibited minimal heterogeneity and robust sensitivity. Differences in results may also reflect variations in intervention type, therapeutic intensity, assessment timing, methodological quality, and sample sizes [27]. Follow-up duration did not moderate effects, contradicting assumptions that longer interventions yield superior outcomes. Instead, the intervention modality emerged as the critical moderator, highlighting the importance of direct human interaction in managing PD-specific QOL concerns. This aligns with telehealth's capacity for dynamic therapeutic engagement [47,48], particularly beneficial for isolated patients [10], although our findings indicate that these advantages depend on modality.

Telehealth provides more dynamic, immersive methods for treatment, education, and counseling compared to traditional medical approaches, enhancing patient engagement and interaction [47,48]. Such enhancements assist patients with PD and their families in comprehensively understanding and managing disease-related challenges, thus promoting independence, motivation for self-care, and improved life quality [49]. Patients with PD require consistent engagement with health care teams for effective management of disease progression and treatment complexity [8]. A primary advantage of telehealth lies in serving patients in isolated or underserved areas, addressing health care provider shortages, and offering timely, high-quality care to improve patient outcomes [10]. Additionally, economic burdens and logistical difficulties substantially reduce patients with PD's QOL [50,51]. By reducing health care–related costs and travel demands, telehealth can expand home-based medical services, further enhancing life quality for patients with PD [10,22].

Effectiveness of Telehealth Interventions on Depression in Patients With PD

Our meta-analysis demonstrated a significant antidepressant effect of telehealth interventions. Traditional approaches (telephone or cognitive behavioral therapy [CBT]–based) showed nearly 3 times the efficacy compared to digital interventions. This advantage aligns with neurobiological evidence linking depression in PD to dysfunction in serotonergic pathways and frontostriatal circuits [52], suggesting human-mediated therapies more effectively modulate emotional processing compared to automated digital tools. This finding notably diverges from earlier studies, which primarily emphasized motor symptoms and physical rehabilitation, often neglecting depressive symptoms [10,27]. The distinct focus of 3 specific studies [29,30,36] included in this meta-analysis may explain this difference. These studies emphasized cognitive and behavioral aspects of patient care, integrating telehealth with CBT, a method recognized for effectively reducing depression levels [53,54]. Moderate heterogeneity mainly resulted from

XSL•FO
RenderX

between-study methodological differences, likely reflecting variations in measurement tools and intervention protocols. Contrary to expectations, categorical follow-up duration showed no significant moderating effect, although continuous analysis revealed a marginal positive association. This result suggests sustained engagement—particularly through telephone-based CBT [53,54]—might progressively reinforce neuroplastic changes in emotion-regulation networks. These findings reconcile previous contradictions in the literature [1,26,27]. Whereas earlier reviews primarily targeted motor symptoms, our analysis confirms telehealth's antidepressant benefits when including behavioral interventions tailored to PD-related psychopathology.

Our findings align with those of Dou et al [55], indicating that telehealth interventions (tele-CBT and telerehabilitation training) significantly improve depressive symptoms in patients with PD. Feasibility has been verified internationally; for example, a cross-sectional study in Brazil showed effective telehealth implementation in resource-limited settings with high patient satisfaction [56,57]. Regarding specific methods, tele-motor training significantly enhanced patients' motor function and indirectly alleviated depressive symptoms [55]. In contrast, tele-CBT directly targeted depressive and anxiety symptoms, showing greater effectiveness compared to other teleinterventions [31]. Teleconsultation had relatively limited efficacy in alleviating depressive symptoms but significantly improved access to medical resources [58]. From a neurobiological standpoint, PD and depression share common pathological mechanisms, including gut microbiota dysregulation, neuroinflammation, and reward-processing dysfunction [52]. Telehealth, especially through behavioral interventions such as CBT, may modulate these pathological processes and consequently alleviate depressive symptoms [59]. However, existing evidence suggests telehealth's effectiveness may be weaker for chronic, nonepisodic mental disorders (eg, depression in PD) compared to primary depression [60]. To optimize telehealth potential, future research should investigate long-term outcomes, standardization of techniques, and cybersecurity considerations [61,62]. In summary, telehealth effectively reduces depressive symptoms in patients with PD, especially via tele-CBT, which overcomes geographical barriers and improves treatment accessibility. Nevertheless, individualized plans and sustained follow-up are necessary to achieve optimal therapeutic outcomes.

Effectiveness of Telehealth Interventions on Anxiety in Patients With PD

Our meta-analysis demonstrated robust anxiolytic effects of telephone-based telehealth interventions, with remarkable consistency across studies. This homogeneity suggests that telephone-delivered CBT provides a reliably standardized approach for managing PD-related anxiety. Notably, these benefits remained stable irrespective of follow-up duration, indicating sustained therapeutic effects without attenuation over 3-9 months. These findings resolve previous contradictions [14,26,27] by demonstrating that structured tele-CBT can effectively address PD-specific anxiety mechanisms, including fear-avoidance cycles and "off"-period distress resistant to conventional treatments. The negligible heterogeneity, with variance entirely attributable to sampling error, likely reflects 3 factors. First, interventions used standardized CBT protocols targeting PD-specific anxiety mechanisms such as hypervigilance toward motor fluctuations. Second, the uniform application of validated and sensitive scales (HAM-A/HADS-A) ensured measurement precision. Third, telephone delivery strengthened therapeutic alliances through real-time emotional interaction absent in purely digital interfaces. The integration of standardized protocols, precise assessments, and person-centered delivery resulted in methodological consistency across studies.

Although considerable evidence supports telehealth for anxiety in patients with PD, its exact mechanism and broader applicability require further investigation. Previous studies [63,64] showed comparable efficacy of telehealth and face-to-face interventions in reducing anxiety, depression, and stress scores, alongside improved heart rate variability. Anxiety reductions persisted long-term after telehealth interventions, confirming their noninferiority to in-person care. This effectiveness largely stems from multimodal interventions; for example, remote CBT overcomes movement-related barriers and, combined with exercise and biomarker monitoring, allows personalized care beneficial to underserved populations [55,64,65]. However, some research highlights intervention heterogeneity. A small study [66] indicated that telephone CBT effectively alleviated depression but not anxiety symptoms in patients with PD, suggesting anxiety may require more tailored strategies. Our analysis, in contrast, supports the long-term feasibility, effectiveness, and durability of telephone CBT effects. Earlier discrepancies might stem from small sample sizes or limitations of measurement tools. Although the revised Parkinson Anxiety Scale improved cultural adaptability, general scales (eg, HADS) may underestimate actual effectiveness due to limited sensitivity [29,67]. Future research should expand sample sizes, develop PD-specific anxiety interventions, and integrate multidimensional biomarker monitoring to improve telehealth precision and applicability.

Effectiveness of Telehealth Interventions on Motor Symptoms of Patients With PD

Telehealth interventions significantly improved motor symptoms in patients with PD. This refined estimate may reflect advancements in methodological rigor involving multilevel analyses that account for independent effect sizes, an approach not consistently used in previous meta-analyses [1,26]. Due to the standardized use of MDS-UPDRS-III assessments and similar intensities of interventions, we observed remarkably low heterogeneity among studies. Notably, digital and traditional telehealth approaches demonstrated comparable effectiveness, indicating that essential motor rehabilitation components, such as amplitude training and balance exercises, effectively translated across different treatment platforms. The temporal stability of benefits further supported telehealth as a sustainable management option, with sensitivity analyses confirming robustness to study exclusion.

A primary therapeutic objective in PD involves improving motor symptoms, wherein treatment adjustments frequently depend on accurate motor assessments [68]. The telehealth framework

XSL•FO
RenderX

enables improved and timely interactions between patients and health care providers compared to traditional face-to-face consultations, allowing for more individualized rehabilitation strategies tailored specifically to patients with movement disorders [69]. Multiple studies have confirmed the significant impact of telehealth interventions in alleviating motor symptoms in patients with PD. For instance, structured telerehabilitation programs, such as the Lee Silverman Voice Treatment BIG rehabilitation method, have effectively enhanced motor function, alleviated nonmotor symptoms, and improved the QOL for patients with PD [70]. Compared to teleconsultations alone, tele-motor interventions demonstrate superior efficacy in motor function improvement [55]. From a neuromechanism perspective, cueing techniques activate the motor cortex, thereby enhancing the stability of motor output, which provides scientific justification for using cue-based strategies in telerehabilitation [71]. Moreover, telerehabilitation is particularly suitable for patients with restricted mobility or those residing in medically underserved regions. Real-time video guidance ensures continuous rehabilitation training, effectively overcoming geographical limitations. Its safety and potential effectiveness in improving balance and functional activities have been confirmed by existing research [28,41,72]. Telehealth facilitates comprehensive monitoring of treatment effects through standardized scales (such as MDS-UPDRS) for assessing motor symptoms, combined with evaluation of nonmotor symptoms and QOL questionnaires [73,74]. Additionally, tele-motor interventions based on live-streaming have been proven feasible and safe, demonstrating high patient adherence (eg, twice a week) and thus confirming their practical use for continuous management of motor symptoms in PD [75]. Therefore, telehealth effectively enhances motor functions in patients with PD, offering advantages in personalized program design, activation of neural plasticity, and overcoming limitations in medical resource availability. With ongoing advancements in assessment instruments and technological integration, telehealth is anticipated to further improve long-term intervention outcomes.

Effectiveness of Telehealth Interventions on ADL in Patients With PD

The results of this study showed that telehealth interventions significantly improved ADL among patients with PD. This result aligns with previous research, reinforcing that remote health care interventions significantly enhance both ADL performance and motor symptoms in individuals with PD. Our analysis suggests that the significant improvements in ADL resulting from telehealth are due to multidimensional intervention strategies addressing the core symptoms of PD.

Relevant studies have shown that structured remote rehabilitation programs, delivered through real-time video instruction, enhance functional mobility and directly improve basic ADL tasks such as walking and dressing [57]. Simultaneously, high-intensity remote exercise interventions reduce motor sluggishness and freezing of gait, indirectly enhancing instrumental ADLs, such as complex daily activities like shopping and meal preparation [76]. The simultaneous improvements observed in ADLs and motor symptoms share clear pathophysiological connections; enhanced motor functions directly alleviate limitations in physical activity, enabling patients to execute daily routines more effectively [77]. Additionally, remote CBT improves executive functions, mitigating motor-related restrictions on complex ADL performance [77,78]. Telehealth frameworks achieve these synergistic effects by integrating 3 primary components: real-time video supervision ensures adherence to exercise regimens; home-based cognitive training modules restructure the prefrontal-limbic circuitry; and wearable sensors provide immediate feedback regarding movement quality [57,79,80]. Therefore, telehealth interventions positively and synergistically influence both motor symptoms and ADL performance in patients with PD. Future research should focus on optimizing intervention strategies and integrating motor and ADL training components comprehensively to further enhance the overall QOL for patients.

Effectiveness of Telehealth Interventions on Cognition in Patients With PD

Preliminary evidence shows that telehealth interventions may enhance cognitive function in patients with PD; however, these findings should be interpreted cautiously. Although statistically significant, effect sizes exhibited substantial variability, ranging from negligible to considerable clinical improvement. This observed heterogeneity primarily stems from methodological differences among studies, potentially reflecting (1) the use of varied cognitive assessments (MoCA vs MMSE), each with differing sensitivities to PD-specific cognitive deficits, and (2) distinct intervention protocols within the limited scope of available evidence. Additionally, significant publication bias and insufficient data for sensitivity analyses further limit definitive conclusions.

Overall, the efficacy of telehealth interventions for enhancing cognitive functions in patients with PD has been established. These interventions significantly improve cognitive status, particularly executive functions and memory, as well as emotional and behavioral disorders, consequently enhancing the QOL for both patients and caregivers [78,81]. Among specific intervention methods, computer-assisted cognitive training has shown potential benefits for patients with PD accompanied by mild cognitive impairment, with feasibility confirmed for home-based training modalities [82,83]. Moreover, remote virtual reality applications (telehealth virtual reality) have shown promising results for improving cognitive task performance [31]. A recent network meta-analysis further supports the beneficial effects of remote interventions, including remote cognitive training, on cognition and other nonmotor symptoms [55]. The primary advantages of telehealth interventions include high accessibility (especially beneficial for patients with limited mobility or those residing in remote areas) and flexibility, with the patient's cognitive reserve potentially enhancing treatment effect [84]. However, considerable heterogeneity exists within current evidence, aligning with our findings. This heterogeneity is largely attributed to variations in study design, inconsistencies in cognitive assessment tools, and diverse responses among patient subtypes [55,82,85]. In addition, the efficacy of telehealth interventions differed across cognitive domains. Therefore, these findings should be considered exploratory and interpreted

XSL•FO
RenderX

cautiously. In conclusion, telehealth represents a promising cognitive management approach for PD with substantial potential; nevertheless, implementation barriers must be considered, strategies tailored to individual patient needs, and larger standardized trials conducted to further substantiate effectiveness.

Strengths and Limitations

This systematic review benefits from a rigorous methodological approach, using a meta-analysis grounded in RCTs and strictly adhering to established guidelines for systematic reviews. All analyses were conducted using random-effects models based on conceptual considerations, with HKSJ or t-distribution–based corrections applied to provide more accurate and conservative CIs. This significantly enhances the credibility of the findings. Furthermore, the review assesses the impact of telehealth interventions not only on QOL but also on multiple health-related domains such as depression, anxiety, motor function, ADL, and cognitive function in patients with PD, rather than restricting its focus solely to treatment modalities.

Nonetheless, several limitations of this review should be acknowledged. First, the limited number of RCTs included in the analysis may constrain the generalizability of these conclusions to broader populations. Second, due to the small number of studies per outcome (all $k<10$), prediction intervals were not calculated, which limits the interpretation of how the true effect may vary across different settings. Third, funnel plots and Egger tests were used to assess small-study effects, but these methods have reduced accuracy when fewer than 10 studies are analyzed per outcome, and they do not specifically measure publication bias. Finally, although we applied multilevel modeling to account for dependent effect sizes, residual heterogeneity, and variations in intervention protocols may still influence the results. Therefore, additional RCTs must be incorporated into future research to enhance the robustness and reliability of the findings.

Implications for Practice

Global disparities in medical resource distribution present substantial challenges to health care service advancement. This issue is particularly pronounced in neurological care, where specialist availability is limited, notably in suburban and rural regions. Consequently, many individuals with PD struggle to receive continuous medical support, resulting in significant declines in their QOL as the disease progresses. This situation places considerable strain not only on patients and their families but also on societal resources. The emergence of telehealth, however, offers a promising solution by providing innovative avenues for managing and treating PD. Telehealth has the potential to bridge existing gaps, enabling patients with PD who previously had limited or no access to receive essential health care services.

Implications for Further Research

PD exerts substantial impacts on public health, prompting significant attention from the health care community toward preventative, diagnostic, and therapeutic strategies. As an innovative product of rapid technological advancement, telehealth represents a cost-effective, real-time, and secure platform for collecting patient data, significantly facilitating the diagnosis, monitoring, and rehabilitation of PD. Nonetheless, the efficacy of telehealth requires further validation through comprehensive and rigorous RCTs. Future research should not only evaluate functional recovery, cognitive enhancement, and health-related QOL but also examine aspects such as cost-effectiveness, patient satisfaction, and digital health literacy among older adults. Such investigations will facilitate more informed decisions and optimal tailoring of telehealth interventions for patients with PD.

Conclusion

Telehealth interventions have demonstrated the potential to significantly enhance various aspects of life among patients with PD, including alleviating symptoms of depression and anxiety, improving motor function, facilitating ADL, and enhancing cognitive performance. Despite these encouraging findings, there remains an urgent need for meticulously designed, large-scale RCTs to comprehensively evaluate telehealth's effectiveness across the full spectrum of PD management.

Acknowledgments

We would like to express our heartfelt thanks to all those involved in this study.

Abstract

Background: Type 2 diabetes mellitus (T2DM) is a prevalent chronic metabolic disorder that poses substantial challenges to global health care systems and patient management. Telemedicine, defined as the use of information and communication technologies to enhance health care delivery, has emerged as a potential tool to improve access to care and facilitate the management of T2DM.

Objective: This systematic review and meta-analysis aimed to evaluate the clinical effectiveness of various telemedicine interventions compared with usual care in glycemic control, and cardiovascular health in adults with T2DM.

Methods: A comprehensive literature search was conducted across databases such as PubMed, Cochrane Library, and Web of Science for randomized controlled trials (RCTs) published up to August 23, 2024. Eligible RCTs compared telemedicine interventions with usual care in adults with T2DM. The primary outcome assessed was hemoglobin A_{1c} (HbA_{1c}) levels, while the secondary outcomes included mean glucose, fasting blood glucose, BMI, weight, systolic blood pressure, diastolic blood pressure, high-density lipoprotein cholesterol, and low-density lipoprotein cholesterol. The quality of the included studies was examined via the Cochrane risk-of-bias tool. Data were extracted and analyzed using a random-effects model, and meta-regression was performed to explore potential moderators. The quality of the evidence was assessed via the Grading of Recommendations, Assessment, Development, and Evaluation approach.

Results: A total of 58 RCTs, encompassing 13,942 participants, were included in the analysis. Our findings showed that telemedicine interventions significantly improved HbA_{1c} levels compared with usual care (mean difference [MD] –0.38, 95% CI –0.49 to –0.27; Z=6.94; P<.001), despite high heterogeneity (I^2=96%). Significant effects were also found for fasting blood glucose (MD –11.29, 95% CI –17.65 to –4.93; Z=3.48; P<.001), weight (MD –1.33, 95% CI –2.23 to –0.44; Z=2.91; P=.004), BMI (MD –0.43, 95% CI –0.72 to –0.13; Z=2.84; P=.004), systolic blood pressure (MD –2.14, 95% CI –3.02 to –1.26; Z=4.76; P<.001), and diastolic blood pressure (MD –1.24, 95% CI –2.02 to –0.46; Z=1.10; P=.002). No significant between-group differences were found in high-density lipoprotein cholesterol and low-density lipoprotein cholesterol improvement. Subgroup analyses revealed that telemedicine delivered by physicians, dietitians, and researchers achieved the most significant reductions in HbA_{1c} levels. Short-term and long-term interventions showed significant HbA_{1c} improvements, while medium-term interventions did not achieve statistical significance. Meta-regression analysis did not identify any statistically significant moderators.

XSL•FO
RenderX

Conclusions: This review highlights telemedicine's superior effectiveness over usual care in improving HbA_{1c} levels in patients with T2DM, regardless of the type of intervention. Telemedicine led by physicians, dietitians, and researchers showed the greatest efficacy in managing blood glucose levels. Furthermore, telemedicine interventions show promise for monitoring weight and cardiovascular health in patients with T2DM.

KEYWORDS

telemedicine; type 2 diabetes mellitus; systematic review; meta-analysis; metaregression

Introduction

Diabetes is a chronic metabolic disorder with increasing prevalence worldwide, placing a significant burden on global health care systems [1]. Currently, it affects more than 537 million adults, a number projected to increase to 783.2 million by 2045 [2]. Type 2 diabetes mellitus (T2DM) accounts for 90% of all diabetes cases [3]. T2DM not only poses a significant burden on individuals and society but also leads to reduced life expectancy and impaired quality of life [3,4]. Poor glycemic control in T2DM increases the risk of complications such as retinopathy, nephropathy, neuropathy, and cardiovascular diseases, leading to disability and premature mortality [5,6].

The management of T2DM is challenging and requires personalized, lifelong care [7,8]. Key aspects of T2DM management include glycemic control, weight management, and cardiovascular health monitoring, all of which are critical for preventing and managing the condition [9-11]. Researchers have identified 5 essential components of diabetes care: nutrition, physical activity, glycemic control, medical care, and patient education [12]. As such, continuous management and regular follow-up are imperative [13]. Global digitalization offers innovative digital opportunities for intensive diabetes management [14]. Telemedicine, which has proven effective in managing chronic diseases [15], holds particular promise for improving health care access for underserved populations. First conceptualized in the 1970s, telemedicine refers to the "use of [information and communication technologies] to improve patient outcomes by increasing access to care and medical information" [16]. In diabetes management specifically, telemedicine interventions have shown promise in enhancing glycemic control outcomes [14,17]. However, a recent review indicated that mobile health (mHealth) tools within telemedicine have shown only modest effectiveness [18].

Existing reviews often focus on specific types of telemedicine tools [19-21], settings [22], or providers [23], which limit generalizability across broader diabetes care contexts. This highlights the need for a more comprehensive and inclusive systematic review that synthesizes findings across various contexts [20,22,24]. With the onset of the COVID-19 pandemic, outpatient services for patients with diabetes have been limited, creating an opportunity for health care providers to implement telemedicine for diabetes management. Consequently, a substantial number of recent studies may have been published, warranting an updated review. This study aims to evaluate the impact of various telemedicine interventions on clinical outcomes in patients with T2DM compared with usual care through a systematic review and meta-analysis, providing valuable insights for future clinical practice and research.

Methods

This systematic review followed the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses; checklist provided in Multimedia Appendix 1) guidelines and was registered in the PROSPERO database (CRD 42024608130).

Search Strategy

We searched the following databases from inception to August 2024 to identify eligible randomized controlled trials (RCTs): Embase, PubMed, Scopus, CINAHL, and Web of Science. The search strategy was optimized to capture studies in telemedicine, people with T2DM, and glycemic control. Telemedicine is a broad and evolving field encompassing various aspects of remote health care delivery. While our search strategies primarily focused on the MeSH (Medical Subject Headings) term "telemedicine," it is important to acknowledge that this field includes a wide range of related terms, such as "telemonitoring," "telehealth," "mobile health," "mHealth," "eHealth," "teleconsultation," and "telemetry." The full search strategy is shown in the Multimedia Appendix 2 [25-82].

Eligibility Criteria

RCTs that compared telemedicine interventions with usual care in adults (aged 18 years and older) with T2DM were included. The primary outcomes include an assessment of effectiveness based on clinical indicators, such as changes in hemoglobin A_{1c} (HbA_{1c}) levels, mean glucose, fasting blood glucose (FBG), BMI, weight, systolic blood pressure (SBP), diastolic blood pressure (DBP), high-density lipoprotein cholesterol (HDL-c), and low-density lipoprotein cholesterol (LDL-c).

Here, telemedicine is defined as a form of health care delivery using electronic information and telecommunications, telemedicine facilitates information exchange, education, counseling, monitoring, and management between health care professionals and patients [83,84]. The usual care refers to face-to-face care, standard care, or traditional care.

Studies were excluded if they (1) reported findings from pregnant patients, patients with type 1 diabetes mellitus, and patients with prediabetes or other comorbidities; (2) reported populations at high risk only for diabetes or prediabetes; (3) not reported primary outcomes (changes of HbA_{1c} levels); (4) were

XSL•FO
RenderX

published as conference abstracts, case reports, reviews, posters, comments, letters, and research protocols; or (5) were published in languages other than English.

Outcomes

The primary outcome measure was a change in HbA_{1c} levels, while the secondary outcomes measure included changes in mean glucose, FBG, BMI, weight, SBP, DBP, HDL-c, and LDL-c. Telemedicine interventions were categorized into four types based on the mode of delivery [85]: (1) synchronous, involving real-time communication (eg, video or telephone consultations); (2) asynchronous, involving "store-and-forward" technologies such as messaging or email; (3) hybrid, defined as interventions that combined 2 or more telemedicine modalities, for example, in the study by Yang et al [25], patients uploaded daily records and received feedback and reminders through an application (asynchronous), in addition to receiving monthly telephone consultations (synchronous), thus meeting the criteria for hybrid telemedicine; and (4) unspecified, referring to studies that did not clearly report the telemedicine modality used and could not be classified as synchronous, asynchronous, or hybrid telemedicine.

In addition, the telemedicine interventions were categorized into 9 distinct content types: monitoring, counseling, education, reminders, training, feedback, medication management, treatment, and supervision [86]. The duration of interventions was also classified into 3 categories based on their length: short-term interventions (lasting up to 3 months), midterm interventions (lasting between 3 and 6 months), and long-term interventions (lasting 6 months or more) [87].

Study Selection and Data Extraction

Duplicate studies were identified and removed using EndNote. The remaining studies were screened independently by 2 authors (JSJ and GXR) in a sequential manner of title, abstract, and full-text screening. Conflicts were settled by consulting a third author (LGY). Our data extraction included publication details (title, author, and year), study characteristics (country, purpose, blinding and randomization method, and year of publication), participant demographics, intervention details, comparison details, and results (primary and secondary outcomes with their SDs, SEs of the mean, and 95% CIs).

Quality Assessment

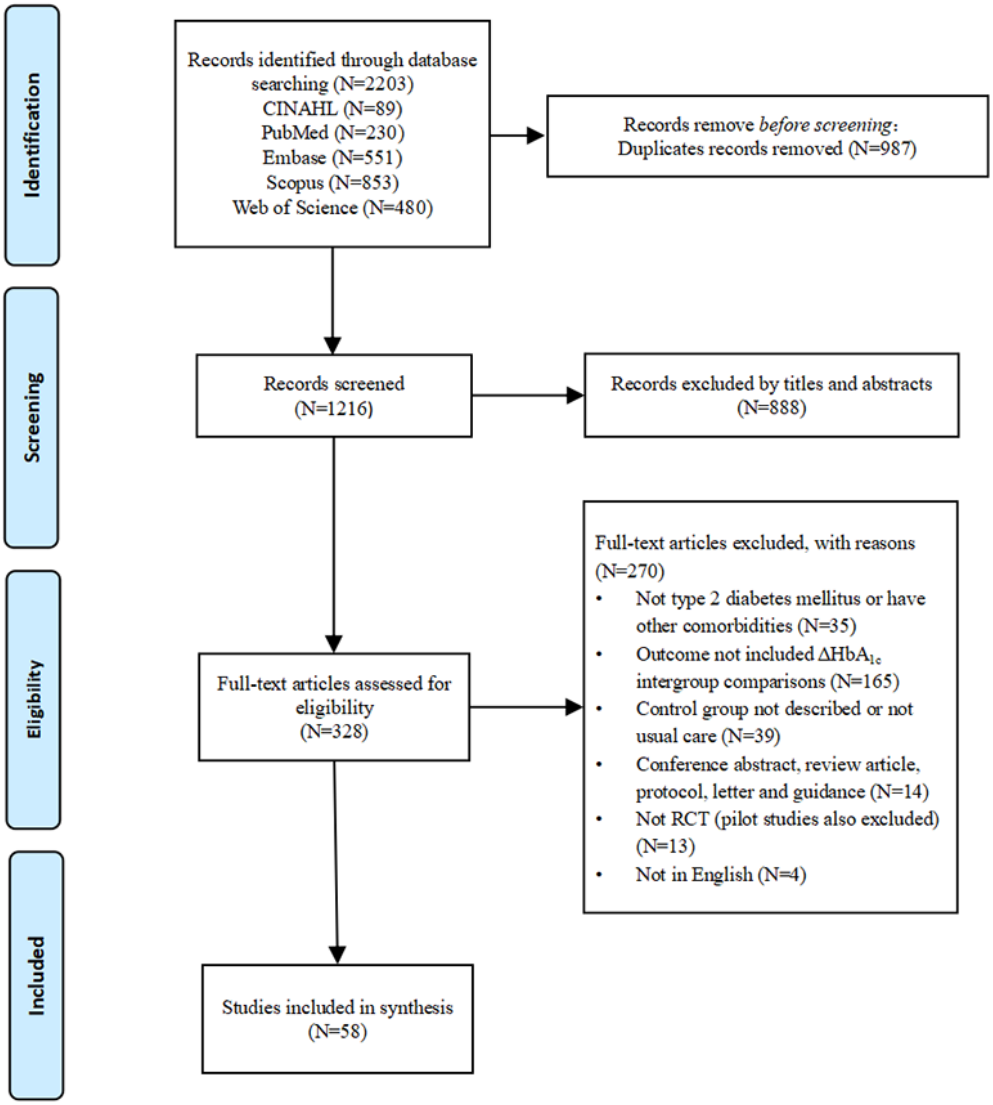
The quality of the included RCTs was evaluated using the Grading of Recommendations Assessment, Development, and Evaluation (GRADE) approach [88]. This method is widely used to assess the certainty of evidence and the strength of recommendations. It provides a structured framework for judging the quality of evidence in systematic reviews. The GRADE system categorizes the certainty of evidence into 4 levels: high, moderate, low, and very low (Table S1 in Section 4 in Multimedia Appendix 2). Using the Cochrane risk-of-bias tool for RCTs, we evaluated the risk of bias and classified each trial as having a low, high, or unclear risk of bias for each area. Six bias domains are included in the tool: selection (random sequence generation and allocation concealment), performance, detection, attritions, reporting, and other biases [89]. Each trial's risk of bias was evaluated independently by 2 reviewers (JSJ and XRG). In the event of a disagreement, consensus decision-making was used to achieve the most agreeable decision to all.

Data Synthesis and Analysis

All outcomes were reported as means and SDs. If SDs were not reported and could not be obtained from study authors, they were estimated using available information such as SEs, 95% CIs, or *P* values, in accordance with the Cochrane Handbook. HbA_{1c} values were presented as percentages in accordance with the National Glycohemoglobin Standardization Program [90]; therefore, the values from studies that reported HbA_{1c} in millimoles per mole were converted to HbA_{1c} %. Likewise, mean glucose, FBG, HDL-c, and LDL-c reported in millimoles per liter were converted to milligrams per deciliter.

All statistical analyses were performed in Review Manager (version 5.4.1; Cochrane Collaboration) and Stata 16 (Stata Statistical Software: Release 16, StataCorp 2019; StataCorp LLC). Reported medians, IQRs, ranges, and CIs were transformed to means and SDs by traditional methods [91,92]. An overall treatment effect was estimated with a meta-analysis of the pool of included studies based on the mean difference (MD). Heterogeneity was assessed statistically using I^2 tests. The results were combined with a random-effects model (due to heterogeneity, ie, an I^2 statistic >50%). Subgroup analyses were conducted based on the characteristics of the intervention, including the type of telemedicine, the telemedicine provider, and the duration of the intervention. Univariate a priori subgroup analyses based on meta-regression of the telemedicine characteristics were conducted in Stata and combined with post hoc analyses of the association of study and patient characteristics with the treatment effect of telemedicine. Publication bias was evaluated using visual inspection of the funnel plot and the Egger test, both performed in Stata.

Ethical Considerations



This study is a systematic review and meta-analysis based on previously published RCTs. No new human participants were involved, and no new data were collected. Therefore, ethics approval and informed consent were not required. All data used in this review were extracted from publicly available articles, and no identifiable personal information was involved.

Results

A total of 2203 studies were retrieved from 5 databases. After removing 987 duplicates, 1216 studies remained. Titles and abstracts were screened to determine eligibility, resulting in the exclusion of 888 studies. The full text of the remaining 328 studies was reviewed (Section 3 in Multimedia Appendix 2), and 58 studies were ultimately deemed eligible for analysis (Figure 1).

Basic Characteristics of the Included Studies

A total of 58 RCTs, encompassing 13,942 participants, were included in the analysis. The detailed basic information, sample characteristics, type of telemedicine used, and clinical outcomes of the included studies are summarized in Table S2 in Section 4 in Multimedia Appendix 2.

The number of published studies has shown a steady increase over recent decades, with the most studies in the last 5 years accounting for 41% (24/58). Geographically, the studies were primarily conducted in Asia (18/58, 31%), Europe (18/58, 31%), and North America (17/58, 29%). Additional studies were conducted in Africa (1/58, 2%), South America (1/58, 2%), and Oceania (2/58, 3%; Figure S1 in Section 5 in Multimedia Appendix 2). Notably, 72% (42/58) of the studies originated from the high-income countries (Table 1). The most common settings for these studies were hospitals (20/58, 34%) and primary health care facilities (20/58, 34%).

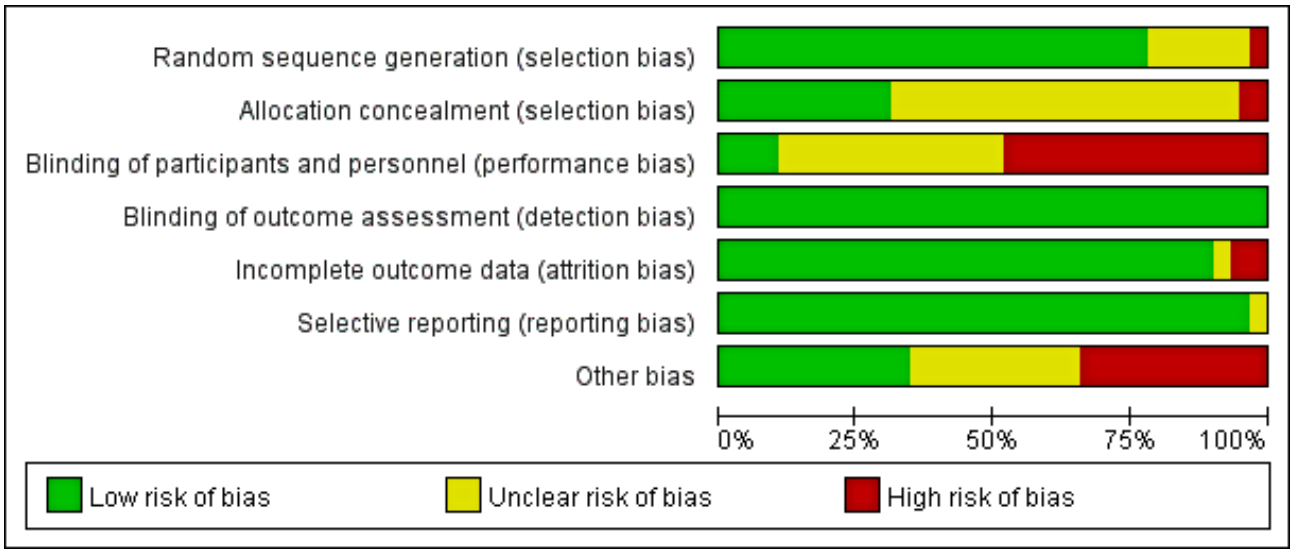
Description of Telemedicine Interventions

Among the included studies, synchronous telemedicine, remote monitoring, and hybrid telemedicine were equally prevalent, with each accounting for 29% (18/63) of studies. Asynchronous telemedicine was used in 11% (7/63), and 3% (2/63) of studies did not specify the type of telemedicine used (Figure S3A in Section 5 in Multimedia Appendix 2). The most frequently implemented intervention components were monitoring (29 studies), counseling (29 studies), and education (24 studies; Figure S3B in Section 5 in Multimedia Appendix 2). Tools commonly used in telemedicine included telephone calls (42%),



XSL•FO
RenderX

remote monitoring devices (39%), apps (36%), and text messages (32%; Figure S3C in Section 5 in Multimedia Appendix 2).

Risk of Bias in the Included Studies

The risk-of-bias assessment for the 58 included studies is summarized in Figure 2. All studies reported random sequence generation, with 47 (81%) studies assessed as low risk and 11 (19%) as unclear risk. For allocation concealment, 18 (31%) studies were judged as low risk, while 37 (64%) were unclear and 3 (5%) were rated as high risk. Blinding of participants and personnel was the most frequently identified source of bias. Only 6 (10%) studies were considered low risk, whereas 22 (38%) were unclear and 30 (51%) were at high risk. In contrast, all studies were rated as low risk for blinding of outcome assessment, as most primary outcomes were objective laboratory measures such as HbA_{1c}. With respect to incomplete outcome data, 52 (90%) studies had a low risk of bias, 2 (3%) were unclear, and 4 (7%) were considered high risk due to missing data without adequate explanation. Selective reporting bias was generally low across the studies, with 56 (97%) studies judged to be low risk and 2 (3%) as unclear. For other sources of bias, 20 (34%) studies were considered low risk, 18 (31%) were unclear, and 20 (34%) were rated as high risk. Common issues included potential conflicts of interest, such as sponsorship from device companies or external funding sources. Overall, the methodological quality of the included studies was considered moderate. Details of the evaluation process are shown in Table S4 in Section 4 in Multimedia Appendix 2.

Figure 2. RoB assessment: summary plot. RoB: risk of bias.

Effects of Telemedicine on the Clinical Indicators of Patients With T2DM

Among the 58 included studies, 4 [26-29] used 2 types of telemedicine interventions, leading to a total of 62 intervention groups. Detailed intergroup comparisons for primary and secondary outcomes are shown in Table 3. Of the 58 studies, 47 provided sufficient quantitative data (eg, MDs with SDs, CIs, or SEs) to be included in the meta-analysis of HbA_{1c} outcomes. The remaining 11 studies, although included in the systematic review, did not report complete statistical information and were therefore not included in the quantitative synthesis for HbA_{1c}. Overall, all trials demonstrated a positive impact of telemedicine on glycemic control (including changes in HbA_{1c}, mean glucose, and FBG), weight management (change in weight and BMI), and cardiovascular health monitoring (including changes in SBP, DBP, LDL-c, and HDL-c).

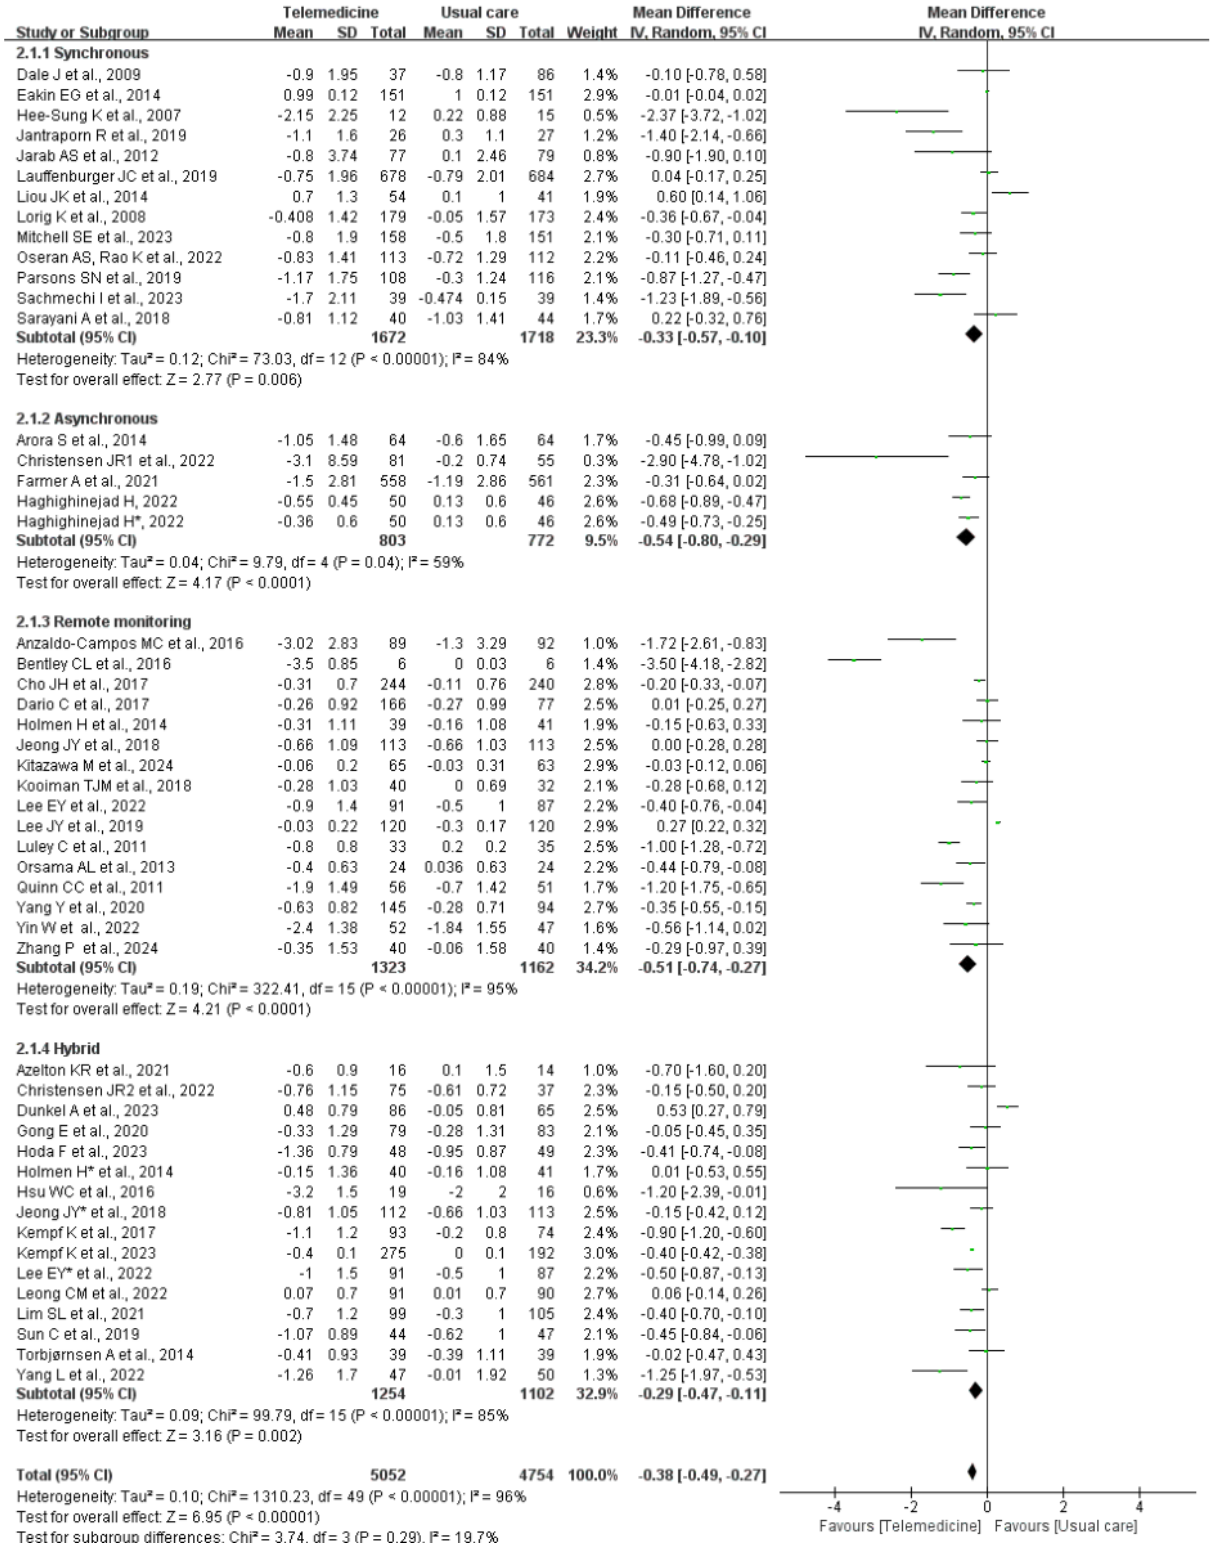
Meta-Analysis of the Effects of Telemedicine on Primary Outcome ($\triangle HbA_{1c}$)

Overall Meta-Analysis of $\triangle HbA_{1c}$ Between Intervention and Control Groups

A total of 47 studies [25-71] reported data on the change in HbA_{1c} levels between groups following telemedicine interventions, with 4 [26-29] studies including 2 types of telemedicine. The analysis revealed a high level of heterogeneity (I^2=96%). Consequently, a random-effects model was used. The pooled results showed a significant reduction in HbA_{1c} levels in the telemedicine group compared with the control group (MD –0.38, 95% CI –0.49 to –0.27; Z=6.94; $P<.001$; Figure 3 [25-71]).

XSL•FO
RenderX

Figure 3. Forest plot of the overall meta-analysis of the change in HbA_{1c} between the telemedicine intervention group and the control group (47 studies [28,36-81]). *A study used 2 different telemedicine tools for the intervention, which are used here to differentiate. HbA_{1c}: glycated hemoglobin.



Subgroup Meta-Analysis of $\triangle HbA_{1c}$ by Type of Telemedicine, Duration of Telemedicine Intervention, and Telemedicine Provider

For subgroups based on telemedicine type—synchronous, asynchronous, remote monitoring, and hybrid—telemedicine interventions consistently showed a greater reduction in HbA_{1c} compared with usual care. However, substantial heterogeneity was observed in all subgroups (Figure 4 [25-32,34-71]). The test for subgroup differences was not statistically significant ($^2_3$=3.74, *P*=.29; I^2=19.7%).

XSL•FO
RenderX

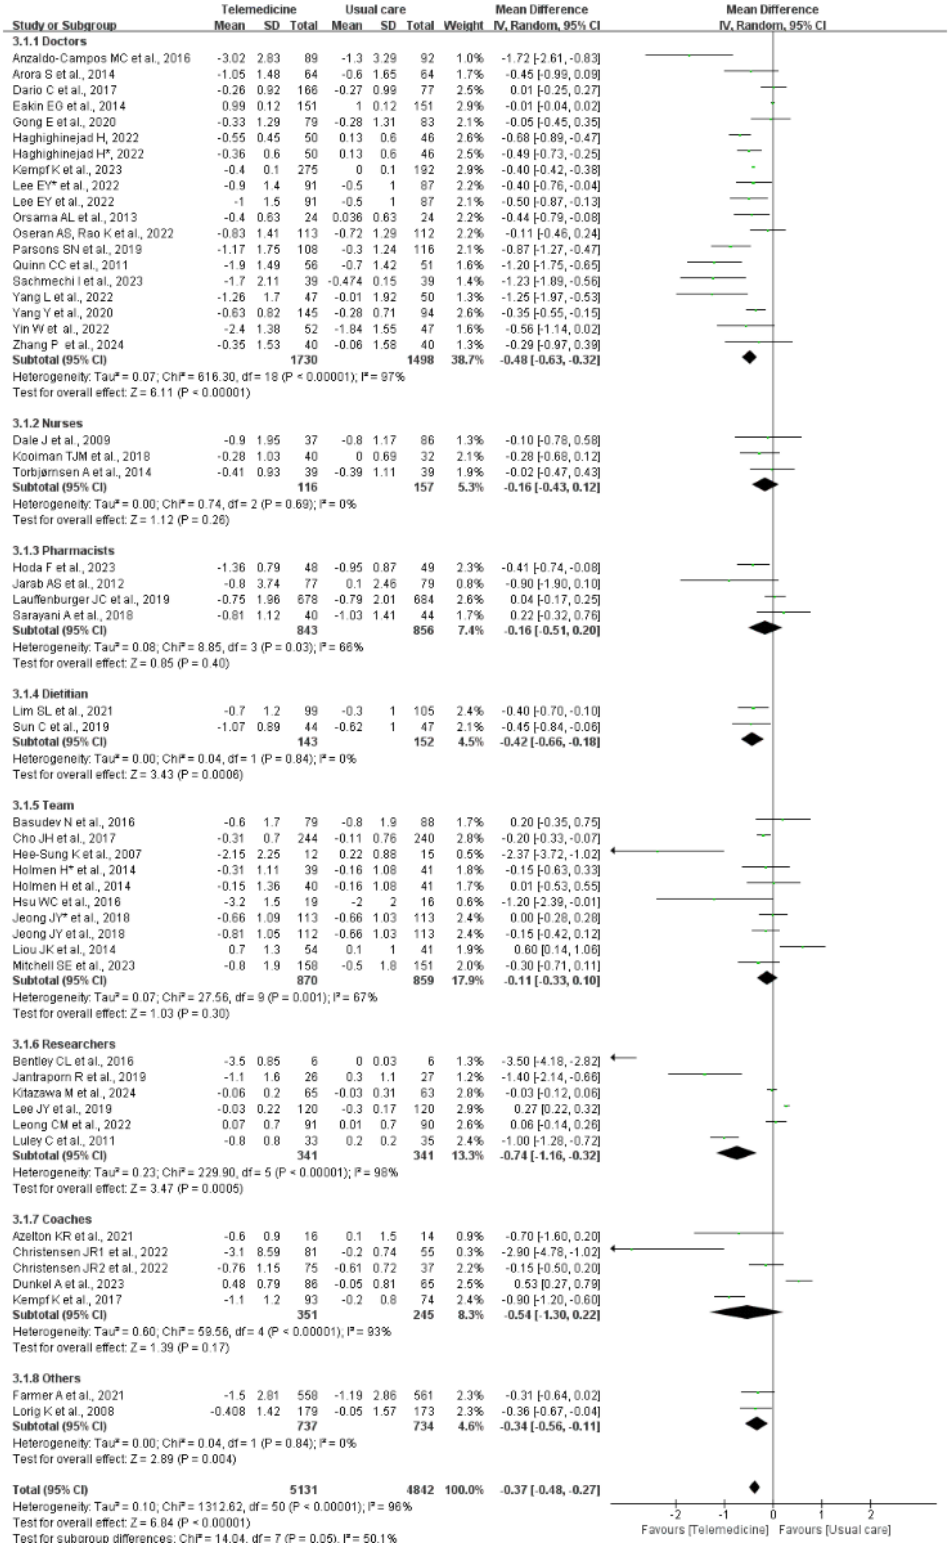


Figure 4. Forest plot of the subgroup meta-analysis of the change in HbA_{1c} by type of telemedicine intervention (46 studies [28,36-42,44-81]). *A study used 2 different telemedicine tools for the intervention, which are used here to differentiate. HbA_{1c}: glycated hemoglobin.

Eight subgroups were identified based on telemedicine providers (Figure 5 [25-71]). Telemedicine delivered by physicians, dietitians, and researchers showed a significantly greater reduction in HbA_{1c} levels compared with usual care but with very high heterogeneity in the physician and researcher subgroups. However, telemedicine delivered by nurses, pharmacists, medical teams, and coaches did not show statistically significant differences between the intervention and control groups. The between-subgroup difference approached statistical significance ($^2_7$=14.04, P=.05; I^2=50.1%).

XSL•FO
RenderX

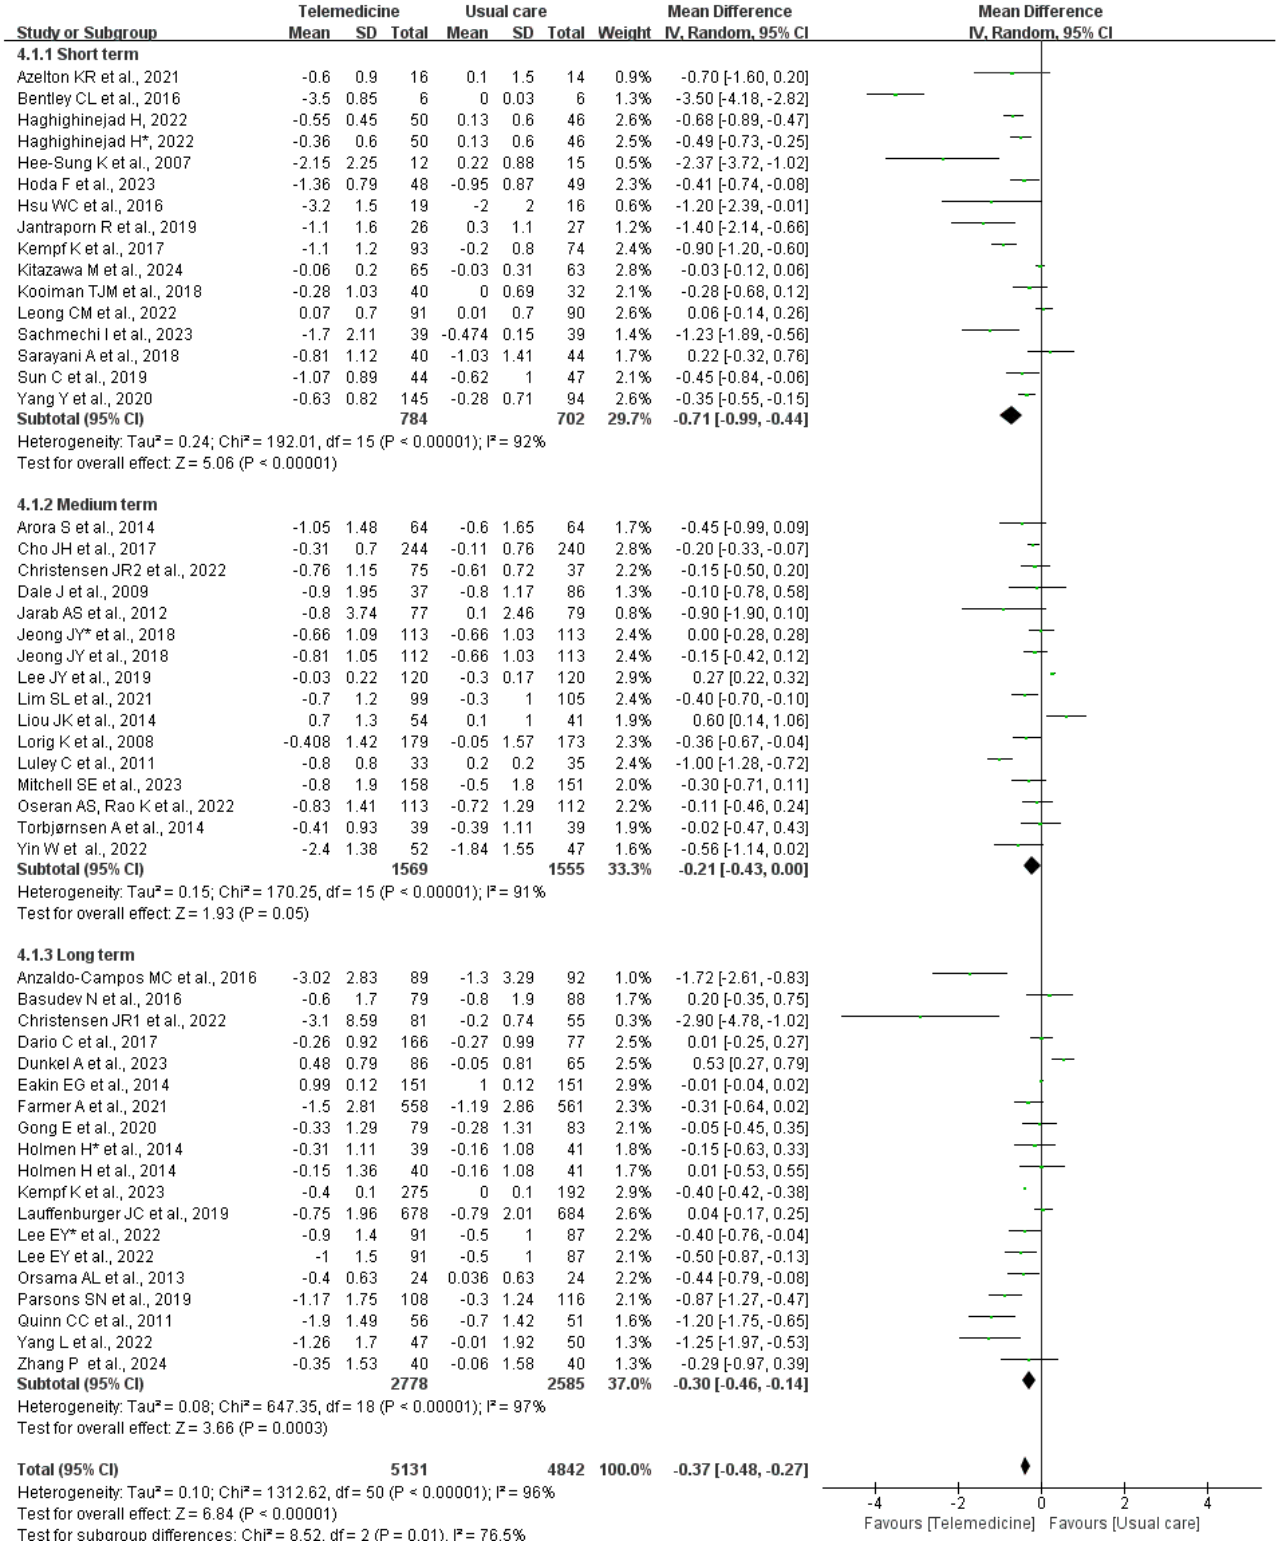

Figure 5. Forest plot of the subgroup meta-analysis of the change in HbA_{1c} by telemedicine provider (47 studies [28,36-81]). *A study used 2 different telemedicine tools for the intervention, which are used here to differentiate. HbA_{1c}: glycated hemoglobin.

Subgroup analysis by intervention duration revealed significant reductions in HbA_{1c} levels for both short-term and long-term interventions. In contrast, medium-term interventions showed no statistically significant difference in HbA_{1c} changes between telemedicine and usual care (Figure 6 [25-71]). The test for subgroup differences indicated significant variation across durations ($^2_2$=8.52, *P*=.01; I^2=76.5%).

Meta-Analysis of the Effects of Telemedicine in Secondary Outcomes

Meta-Analysis of △FBG Between Intervention and Control Groups

A total of 13 studies [25,26,28,29,35,44,47,48,53,55,68-70] provided data on changes in FBG between groups, comprising 16 group comparisons (Figure S4A in Section 5 in Multimedia Appendix 2). A high level of heterogeneity was observed (I^2=99%), prompting the use of a random-effects model. The analysis revealed a significant reduction in FBG levels in the intervention group (MD –11.29, 95% CI –17.65 to –4.93; Z=3.48; P<.001).

XSL•FO
RenderX

Meta-Analysis of △Weight Between Intervention and Control Groups

Nineteen studies [25,27-29,34-37,41,48-51,55,58,60,62,70] reported data related to weight change between groups (Figure S4B in Section 5 in Multimedia Appendix 2). The results showed high heterogeneity (I^2=97%), and a random-effects model was applied. The pooled analysis indicated a significant reduction in weight in the intervention group (MD –1.33, 95% CI –2.23 to –0.44; Z=2.91; P=.004).

Meta-Analysis of △BMI Between Intervention and Control Groups

The BMI data (Figure S4C in Section 5 in Multimedia Appendix 2) were derived from 20 group comparisons across included studies [25,28-30,33,37,40,42,47-51,55,56,58,62,68,70], indicating high heterogeneity (I^2=93%). Using a random-effects model, the intervention group exhibited a significant reduction in BMI (MD –0.43, 95% CI –0.72 to –0.13; Z=2.84; P=.004).

Meta-Analysis of △SBP Between Intervention and Control Groups

Data from 20 group comparisons on SBP changes [7,25,28,30,32,33,35,37,41,42,49,50,53,55,56,60,63,68-70] showed moderate heterogeneity (I^2=64%; Figure S4D in Section 5 in Multimedia Appendix 2). Analyses showed more significant changes in SBP levels in the intervention group (MD –2.14, 95% CI –3.02 to –1.26; Z=4.76; P<.001).

Meta-Analysis of △DBP Between Intervention and Control Groups

Nineteen studies [25, 28, 30, 32, 33, 35, 37, 41, 47, 49, 50, 53, 55, 56, 60, 63, 68-70] provided data on DBP changes (Figure S4E in Section 5 in Multimedia Appendix 2). The results showed a moderate level of heterogeneity with an I^2 value of 50%. Analyses showed more significant changes in DBP levels in the intervention group (MD –1.24, 95% CI –2.02 to –0.46; Z=1.10; P=.002).

Meta-Analysis of △LDL-c Between Intervention and Control Groups

A total of 8 studies [28-30,47,55,68-70] reported data related to LDL-c changes between groups (Figure S4F in Section 5 in Multimedia Appendix 2). The results showed a very high degree of heterogeneity (I^2=100%). Analyses showed more significant changes in LDL-c levels in the intervention group (MD –0.69, 95% CI –11.69 to 10.31; Z=0.12; P=.90).

Meta-Analysis of △HDL-c Between Intervention and Control Groups

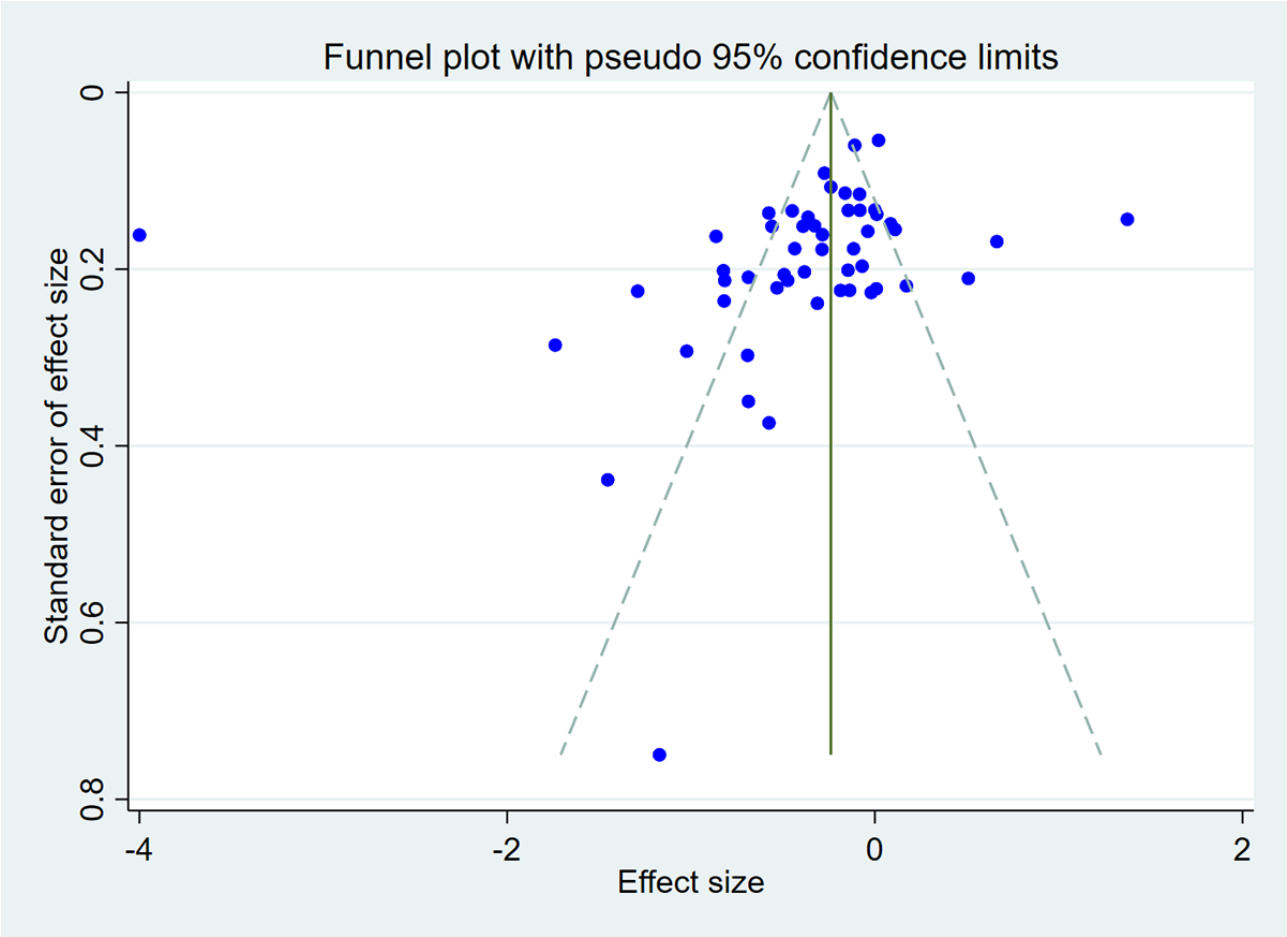
A total of 7 studies [28,30,47,55,68-70] reported data related to HDL-c changes between groups (Figure S4G in Section 5 in Multimedia Appendix 2). The results showed very high heterogeneity with an I^2 value of 99%. The analysis showed more significant changes in HDL-c levels in the control group (MD –3.41, 95% CI –2.67 to 9.49; Z=1.10; P=.27).

Meta-Rregression Analysis of Telemedicine

In this meta-regression analysis, none of the variables, including study location, whether the study was conducted in a high-income country, study setting, type of telemedicine, provider, and duration of intervention, significantly influenced the effect of telemedicine on HbA_{1c} levels (P>.05). Although the provider variable approached statistical significance (P=.084), no clear associations were found overall (Table 4).

Table 4. Association between study covariates and effect of telemedicine on HbA_{1c}[a]% (meta-regression).

Variable	Coefficient	SE	Two-tailed *t* test (*df*)	*P* value > |t|	95% CI
Study location (continent)	0.031	0.141	0.220 (44)	.826	–0.254 to 0.317
Whether the study site is in a high-income country	0.112	0.275	0.410 (44)	.687	–0.442 to 0.666
Study setting	–0.072	0.101	–0.710 (44)	.480	–0.274 to 0.131
Type of telemedicine	–0.124	0.116	–1.070 (44)	.291	–0.357 to 0.110
Provider of telemedicine	0.084	0.048	1.770 (44)	.084	–0.012 to 0.180
Duration of telemedicine	0.142	0.134	1.070 (44)	.293	–0.127 to 0.412
Intercept	–0.815	0.836	–0.970 (44)	.335	–2.500 to 0.871



[a]HbA_{1c}: hemoglobin A_{1c}.

Publication Bias

Publication bias was assessed through both visual inspection of the funnel plot and formal statistical methods (Figure 7). Egger regression analysis showed borderline significance (t=–1.98; P=.054), suggesting potential asymmetry. To further assess this, we performed a trim-and-fill analysis using a random-effects model. When imputing missing studies on the left side, the method suggested 14 potentially missing studies, resulting in an adjusted effect size of –0.607 (95% CI –0.800 to –0.414), compared with the observed –0.379 (95% CI –0.579 to –0.180). In contrast, no studies were imputed on the right, and the effect estimate remained unchanged. This asymmetry indicates that publication bias may be present, possibly underestimating the true effect. Therefore, findings should be interpreted with caution.

XSL•FO
RenderX

Figure 7. Funnel plot of effect size versus standard error for change in HbA_{1c}.

Sensitivity Analysis

In the primary meta-analysis of HbA_{1c} outcomes, significant heterogeneity (I^2=96%) was observed. Despite this, sensitivity analysis indicated that the overall effect remained robust, as no single study had a disproportionate impact on the results (Figure S5 in Section 5 in Multimedia Appendix 2).

Discussion

Principal Findings

This systematic review and meta-analysis synthesized data from 58 RCTs to evaluate the effectiveness of telemedicine interventions in managing glycemic control, weight, and cardiovascular health in patients with T2DM. The results showed that telemedicine was more effective than usual care, especially in improving HbA_{1c} levels. All types of telemedicine—synchronous, asynchronous, remote monitoring, and hybrid—significantly reduced HbA_{1c} levels. Interventions delivered by physicians and dietitians had a greater impact on HbA_{1c} than those delivered by other providers, suggesting that provider expertise may affect outcomes. In addition, telemedicine demonstrated greater effectiveness in short- and long-term interventions, while mid-term interventions showed no statistically significant difference compared with usual care.

This review found that the use of telemedicine in patients with T2DM has been more extensively studied in high-income countries. Consistent with previous findings [87,93], the majority of the evidence (72%) originates from high-income countries, with the United States contributing the highest proportion (28%). Telemedicine remains in the early stages in low-income countries. Several factors may explain this trend, including the digital divide, legal barriers, and reimbursement challenges. The digital divide, characterized by differences in access to telecommunications technologies based on geographic and socioeconomic factors (eg, rural areas, low income, and low education levels), is a major barrier to the adoption of telemedicine [94]. In addition, legal barriers such as national licensing, practice laws, certification requirements, and liability issues also limit the use of telemedicine [94]. Legal and policy changes regarding reimbursement can ensure that the convenience and benefits of telemedicine are equitably accessible and enjoyed by the public, especially vulnerable groups. Limited reimbursement policies constrain the adoption of telemedicine, especially for underserved populations. Legal and policy reforms that ensure equitable reimbursement can enhance the accessibility and benefits of telemedicine for vulnerable groups [94,95]. National and local-level advocacy is needed to support legislation that can address reimbursement challenges and improve access to telemedicine.

The included studies exhibited substantial heterogeneity (I^2=94%), a common finding in telemedicine reviews, where heterogeneity typically ranges from 65% to 99% [17,22,86,93]. Hence, this level of large heterogeneity found in the present

XSL•FO
RenderX

review is not unexpected when compared with similar reviews. Several factors may account for the observed heterogeneity. First, differences in intervention characteristics—including provider type, modality (eg, synchronous, asynchronous, and remote monitoring), and intensity—likely contributed to variability in outcomes. Previous evidence has suggested that moderate- and high-intensity interventions tend to be more effective than low-intensity ones [96]. Second, differences in patient characteristics, such as comorbidities, digital health literacy, or engagement levels, may have influenced the effectiveness of interventions [97]. Only a few included studies explicitly assessed digital literacy, with most only including basic criteria such as the ability to read or operate a device. Finally, the inclusion of studies conducted in the early 2000s may have added to the heterogeneity, as telemedicine technologies and approaches have evolved significantly over the past 2 decades [98].

Based on the pooled analysis of the included trials, telemedicine emerges as a promising approach for providing effective consultation, monitoring, and management for patients with T2DM. The finding demonstrated that telemedicine interventions positively affect glycemic management, consistent with previous studies [14,99]. HbA_{1c} is an important indicator of long-term blood glucose control, and lower HbA_{1c} levels are linked to reduced risks of diabetes-related complications. Evidence suggests that a 1% decrease in HbA_{1c} is associated with a 37% reduction in microvascular complications, a 21% reduction in diabetes-related mortality, and a 14% decrease in the risk of myocardial infarction [100]. In this meta-analysis, telemedicine interventions were associated with a greater reduction in HbA_{1c} compared with usual care (MD –0.38, 95% CI –0.49 to –0.27; P<.001). These findings indicate that telemedicine has the potential not only to match, but in some aspects exceed, the clinical benefits of usual care in the management of T2DM.

Telemedicine may also provide broader benefits for managing metabolic and cardiovascular risk factors in patients with T2DM. Compared with usual care, telemedicine interventions showed greater improvements in FBG, body weight, BMI, SBP, and DBP. Although slight improvements in LDL-c and HDL-c levels were observed in the intervention group, no significant differences were found. This finding is consistent with a previous meta-analysis conducted in primary care settings, which also reported no significant differences between telemedicine and usual care in lipid-related outcomes [22]. However, the absence of significant effects on lipid profiles does not necessarily imply a lack of cardiovascular benefit. One possible explanation is that most telemedicine interventions for T2DM primarily focused on glycemic control, with fewer targeting lipid management specifically. Cardiovascular disease remains the leading cause of death among patients with T2DM [101]. This highlights that, beyond glycemic control, managing cardiovascular risk factors is also essential in T2DM population [102]. This review suggests that telemedicine plays an important role in improving glycemic control and cardiovascular-related health indicators in patients with T2DM. They also underscore the need for more standardized, comprehensive intervention protocols and better integration of multidisciplinary teams to enhance the overall effectiveness of telemedicine in future research and practice [103].

This study observed that different intervention modalities—including synchronous, asynchronous, remote monitoring, and hybrid models—were significantly more effective in improving HbA_{1c} levels compared with usual care, aligning with findings from prior reviews [20,104,105]. However, some studies suggested that synchronous and asynchronous interventions did not consistently outperform usual care. For instance, an earlier review indicated that synchronous and asynchronous teleconsultations did not lead to statistically significant reductions in HbA_{1c} levels [106]. Furthermore, while synchronous teleconsultations showed more substantial HbA_{1c} improvements, no significant benefits were observed in BMI, blood pressure, or cardiovascular health [20,105]. These discrepancies may be attributed to advancements in telemedicine technology, the enhancement of platform functionality, and the increasing standardization of service content. Differences in study design, including intervention frequency, methodology standardization, and varying content, could also play a significant role in influencing the outcomes observed across studies. Further research is needed to better understand these variations and optimize telemedicine interventions for more consistent and comprehensive clinical benefits.

The effectiveness of telemedicine interventions may vary depending on the type of health care provider involved. This review found that interventions led by doctors, dietitians, and researchers were significantly effective in improving HbA_{1c} levels compared with usual care. However, no significant differences were observed in the subgroups involving nurses, pharmacists, and coaches when compared with usual care. This discrepancy may be attributed to the limited ability of these providers to adjust treatment and management based on patients' evolving conditions, highlighting the critical role of doctor involvement, guidance, and supervision in telemedicine interventions. Moreover, remote monitoring requires more complex operations, relying on the accuracy of devices and patients' skills [107]. A previous study emphasized the importance of pretraining both patients and health care providers to enhance the reliability of remote monitoring [108]. Therefore, health care professionals need appropriate training, technical support, and clear guidelines to seamlessly integrate telemedicine into existing electronic health systems.

Although meta-regression analysis did not identify any statistically significant moderators of effect size, some variables showed trends that may have practical implications and warrant further investigation. For example, interventions delivered by physicians, dietitians, or researchers showed a trend toward greater improvements in HbA_{1c} (coefficient=0.084; P=.084), suggesting that provider expertise may influence outcomes. This is consistent with findings from subgroup analyses. Similarly, longer intervention durations (coefficient=0.142; P=.293) also demonstrated a nonsignificant positive trend, aligning with the notion that sustained engagement may enhance the effectiveness of disease management. A previous review has suggested that low-intensity telemedicine interventions are

XSL•FO
RenderX

less effective than moderate- or high-intensity ones in supporting self-management among patients with type 2 diabetes [96]. The lack of statistically significant associations may be due to the complex nature of telemedicine interventions, residual confounding, and the predominantly categorical format of moderator variables, which may limit the sensitivity of meta-regression models to detect subtle effects. These observations highlight the importance of designing tailored telemedicine strategies that consider provider qualifications, intervention duration, and delivery context—that is, the health care setting, technological infrastructure, and patient engagement environment where telemedicine is implemented [103].

Implications for Telemedicine Use on Future Public Health Emergencies

Beyond routine disease management, telemedicine also holds substantial potential in maintaining continuity of care during public health emergencies. It has already been used to manage disruptions in medical services caused by disasters such as the wildfires in Australia and Hurricane Harvey [109,110]. While the exact timing of natural disasters or infectious disease pandemics may be unpredictable, disruptions to medical services are certain to recur in the future [108]. This review focused on comparing telemedicine with usual care and demonstrated that telemedicine interventions achieved superior outcomes in patients with T2DM. These findings highlight the potential of telemedicine not only as a complementary strategy but also as an effective alternative to conventional care in situations where usual services are disrupted. To optimize the implementation of telemedicine in clinical practice, careful coordination with in-person health care systems is essential. This includes developing structured workflows involving health care professionals (eg, physicians, pharmacists, and dietitians) and support services (eg, scheduling departments, laboratories, and pharmacies). Patient stratification based on clinical needs is also crucial, as certain individuals—such as newly diagnosed patients or those starting therapies requiring specific training (eg, insulin injections)—may benefit more from hybrid care models that combine virtual assessment with in-person visits. Finally, establishing a robust, well-integrated telemedicine management system is critical to ensuring the continuous delivery of high-quality care for individuals with chronic conditions such as diabetes, particularly during emergencies.

Strengths and Limitations

This meta-analysis has several advantages. First, to our knowledge, it is the first systematic review and meta-analysis of the management of T2DM that does not restrict the types of telemedicine interventions, tools, providers, or settings, and includes a wide range of important clinical outcomes. Second, we performed several important subgroup analyses based on the type of telemedicine, intervention content, and providers. Third, our study includes a sufficient number of long-term studies. In addition, we did not impose a time limit on published studies to ensure that earlier studies were not overlooked.

However, several limitations must be considered. First, a high level of heterogeneity was observed in the results, likely due to variations in the content of telemedicine interventions, types of media used, providers, and intervention durations. While heterogeneity is common in large meta-analyses, it remains a factor that could impact interpretation [111]. Second, due to the nature of telemedicine, blinding was not possible, which may have influenced the quality of the included studies and introduced potential bias. Third, in our subgroup analyses, the number of studies was limited and displayed high heterogeneity, so the findings should be interpreted cautiously. Further research is needed to strengthen the reliability of these results. Finally, the exclusion of non-English studies could be a potential source of publication bias.

Conclusions

The results of this review demonstrate that telemedicine interventions, regardless of the type, are more effective than usual care in improving HbA_{1c} levels in patients with T2DM. In addition, telemedicine interventions led by physicians, dietitians, and researchers showed greater effectiveness in managing blood glucose levels. While the evidence for the impact of telemedicine on FBG, mean glucose, BMI, weight, blood pressure, LDL-c, and HDL-c is not as robust as for HbA_{1c}, some studies have already highlighted the potential benefits of telemedicine for these outcomes.

Acknowledgments

The authors would like to express their sincere gratitude to Professor Guangyu Lu for her valuable guidance and technical assistance with the comprehensive literature search. The authors also thank the researchers from their research team for their constructive input during study design, data extraction, and analysis discussions. The authors confirm that no generative artificial intelligence tools were used in the writing or preparation of this manuscript.

Data Availability

All data generated or analyzed during this study are included in this published article and its Multimedia Appendices.

Funding

This study was supported by Jiangsu Provincial Health Commission New Technology Introduction and Evaluation Project (grant M2022044), the Open Project Program of Key Laboratory of Big Data Analysis and Knowledge Services, Yangzhou City, Yangzhou University (grant YBK202202), Jiangsu Provincial Science and Technology Programme Special Funds (Key R&D Programme for Social Development) (BE2022775), and Yangzhou Science and Technology Development Project (YZ2024068).

Abstract

Background: Resource limitations in public hospitals may hinder timely monitoring and management of rehabilitation in patients with nasopharyngeal carcinoma (NPC) after radiotherapy.

Objective: This study developed and evaluated the telemedicine app "Open Care," which integrates the Efficient Fully Convolutional Neural Network with Residual Network (EffiFCNN-ResNet) model and computer vision to monitor facial training exercises and provide real-time feedback, aiming to improve outcomes in patients with restricted mouth opening.

Methods: Initially, the EffiFCNN-ResNet model underwent 5-fold cross-validation, expert validation, and robustness testing to assess its reliability and clinical applicability in complex real-world environments. Subsequently, to evaluate the telemedicine app, a parallel-group, 2-arm randomized controlled trial was conducted with 109 patients, who were randomly assigned to either the intervention group (n=55) or the control group (n=54). The intervention group performed mouth-opening exercises under the supervision and guidance of the telemedicine app, whereas the control group followed traditional video-based instructions. Primary outcome measures included maximum mouth opening, mouth-opening symmetry, exercise frequency, and rehabilitation-related health beliefs. Secondary outcomes included fatigue (Brief Fatigue Inventory), health-related quality of life (Assessment of Quality of Life—6 Dimensions), and system usability scores. Data were analyzed using 2-tailed (unpaired) independent-samples *t* tests and chi-square tests, and the Mann-Whitney U test was used to assess intra- and inter-group differences before and after the intervention.

Results: The "Open Care" system leverages a lightweight fully convolutional neural network (FCNN) depth model integrated with network communication to enable real-time capture, recognition, and correction of nonrigid facial training movements. It also provides visual feedback and supports automated rehabilitation assessment. The model demonstrated strong generalization ability (macro-averaged F1-score, mean 0.96, SD 0.01) and clinical-grade stability (performance degradation: mean 5.2%, SD 0.6%, under lighting disturbances and challenging pathological cases; n=160 video segments). Compared with the control group, the intervention group showed significant improvements in maximum mouth opening (*P*=.04), exercise frequency (*P*=.001), perceived severity (*P*=.007), perceived benefits (*P*=.04), perceived barriers (*P*=.001), self-efficacy (*P*=.04), cues to action (*P*=.001),

XSL•FO
RenderX

health behavior (*P*=.03), and fatigue (*P*=.04). Participants also reported favorable training experiences, with a mean system usability score of 74.3 out of 100.

Conclusions: This telemedicine approach was more effective than traditional methods, improving patient engagement and rehabilitation outcomes while providing a more objective and precise monitoring tool. Future apps may benefit patients with NPC and other head and neck cancers.

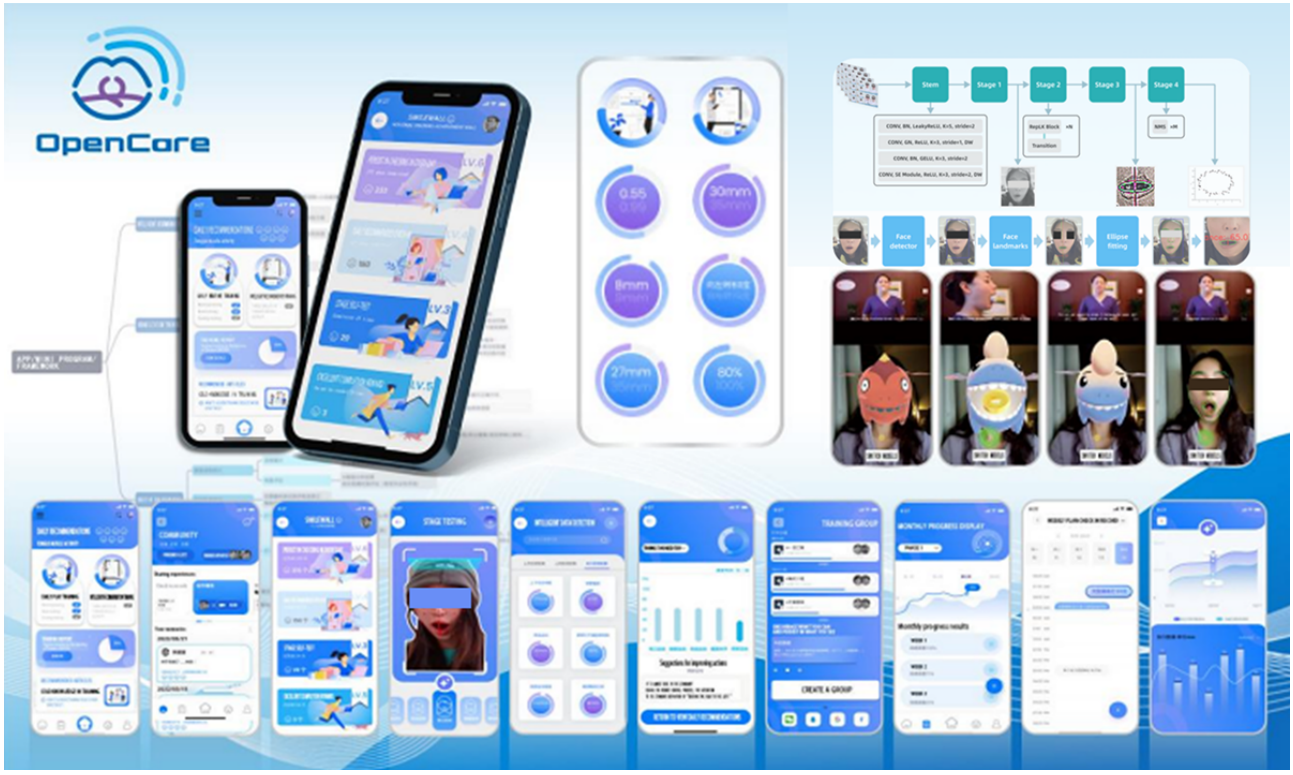
Introduction

Background

Nasopharyngeal carcinoma (NPC) is a common malignant tumor of the head and neck, with a high prevalence in Eastern and Southeast Asian countries. Comprehensive treatment, primarily based on radiotherapy, is the preferred therapeutic approach for NPC [1]. Trismus is a common complication of radiotherapy [2,3], with an incidence ranging from 12.0% to 58.5% [4]. This complication is primarily caused by radiotherapy-induced fibrosis of the masticatory muscles and temporomandibular joint, muscle atrophy, and neural injury. It may also act synergistically with dysphagia, posing long-term challenges to patients' nutritional intake and psychosocial well-being [5] and significantly affecting patients' quality of life [6]. Current research on mouth-opening training and intervention for patients with NPC primarily focuses on the content, timing, methods, and tools of such exercises. Traditional clinical interventions commonly employ cork resistance training; however, patients often report significant pain perception [7]. To address this issue, a recent literature review [8] proposed a novel therapy combining hardware-assisted passive mouth-opening traction with transcutaneous neuromuscular electrical stimulation. However, contact-based training may exacerbate symptoms in patients with radiation-induced dermatitis or skin fibrosis [9]. Therefore, there is an urgent need to explore alternative approaches, particularly noncontact, visually interactive supportive interventions for patients with NPC after radiotherapy, to improve prognosis. Studies have demonstrated that early implementation of active mouth-opening exercises can effectively prevent the onset of trismus [10,11]. Moreover, Samarah et al [12] confirmed that targeted mouth-opening training interventions play a significant role in reducing the incidence of trismus, improving patient adherence, and enhancing quality of life in patients with NPC undergoing radiotherapy and chemotherapy [13]. Despite the proven efficacy of mouth-opening exercises, long-term treatment outcomes remain inconsistent [14], likely due to the high health care burden associated with training, movement correction, and supervision [15].

Digital health interventions can provide scalable health education and self-management support for patients with NPC through apps or web-based platforms [16,17], offering high coverage, low cost, and easy accessibility to mitigate constraints related to time and resources [18-21]. However, the effectiveness of some digital interventions varies. For instance, although physiotherapy programs and online apps have demonstrated efficacy in improving physical function [22], their long-term effectiveness declines due to a lack of precise, individualized support [23]. Additionally, a physical activity counseling program based on wearable devices reported no prognostic benefits, as it lacked accurate monitoring and feedback on training movements [24,25]. This limitation reduces the effectiveness of telemedicine apps in facilitating patient rehabilitation behaviors. A meta-analysis further highlighted that precise movement monitoring and targeted feedback are critical factors in enhancing the effectiveness of digital health interventions for patient health management. Therefore, future digital health interventions should prioritize advancements in personalized, intelligent, real-time monitoring and feedback technologies to enhance intervention efficacy [26,27].

In clinical practice, evaluation of jaw training in patients with limited mouth opening mainly relies on direct observation and manual measurements [28], which are limited in objectivity and real-time applicability. Recently, machine learning has shown promise in intelligent assessment and quantitative rehabilitation [29], integrating neural networks with medical imaging, treatment planning, patient simulation, quality assurance, and radiation dose delivery to provide objective monitoring in clinical care [30]. However, patients with NPC undergoing radiotherapy may experience skin fibrosis, inflammation, swelling, and mandibular deformities, which complicate facial motion analysis [31]. Additionally, factors such as head movement and lighting variations exacerbate nonrigid facial deformations, making accurate motion tracking difficult [32]. Existing methods that rely on contact-based markers are prone to causing facial trauma and patient discomfort and provide insufficient real-time tracking accuracy. Thus, developing a deep learning–based, noncontact, real-time monitoring system is crucial for enhancing NPC rehabilitation [33,34]. Recent advancements in artificial intelligence have enabled machines to automatically analyze and interpret complex data, supporting more personalized treatment strategies. For instance, He et al [35] explored dense facial tracking sequences using convolutional neural network (CNN) networks combined with nonrigid iterative closest point algorithms to address frame-to-frame relationships in 3D facial analysis. Durga et al [36] employed a hybrid deep learning algorithm, including MtCNN (multitask cascaded convolutional neural network) and DeepFace, to overcome nonrigid facial changes, such as



XSL•FO
RenderX

variations in size, shape, and color. The authors proposed the Tiefes fully convolutional neural network (FCNN) model, achieving high accuracy in microexpression recognition for nonrigid facial movements, demonstrating the feasibility of CNN-based deep networks. Relatedly, Le et al [37] applied deep learning for human segmentation and tracking, whereas Singh et al [38] used a deep network to reduce the joint image–motion parameter search to a search limited to rigid motion parameters.

Objectives

To address the challenges in rehabilitation training for patients with NPC, we developed Open Care, a remote health care app designed specifically for NPC jaw rehabilitation (Figure 1). By utilizing an Efficient Fully Convolutional Neural Network with Residual Network (EffiFCNN-ResNet) model, Open Care enables noncontact, real-time facial motion tracking, measurement, and automated feedback. This system offers a novel solution for personalized and efficient NPC rehabilitation. A randomized controlled trial was conducted to evaluate its effectiveness in improving patient adherence and rehabilitation outcomes.

Figure 1. The overall design of Open Care.

Methods

Tasks and Process: Involvement

All participants, regardless of group assignment, received initial standardized, equally timed exercise instruction from researchers to ensure consistent foundational guidance. Researchers provided detailed instructions on the key components of the training video and informed participants of the benefits of regular mouth-opening exercises.

The core component of standard care for the control group consisted of routine mouth-opening exercise guidance delivered through a 15-minute educational video, meticulously designed by radiation oncology professionals and validated by a multidisciplinary expert team. The video provided step-by-step demonstrations of active mouth-opening exercises, and participants were instructed to perform them twice daily, consistently within a pain-free range. An ancillary app was provided to the control group solely for video playback and for recording daily maximum mouth opening, symmetry, and training frequency.

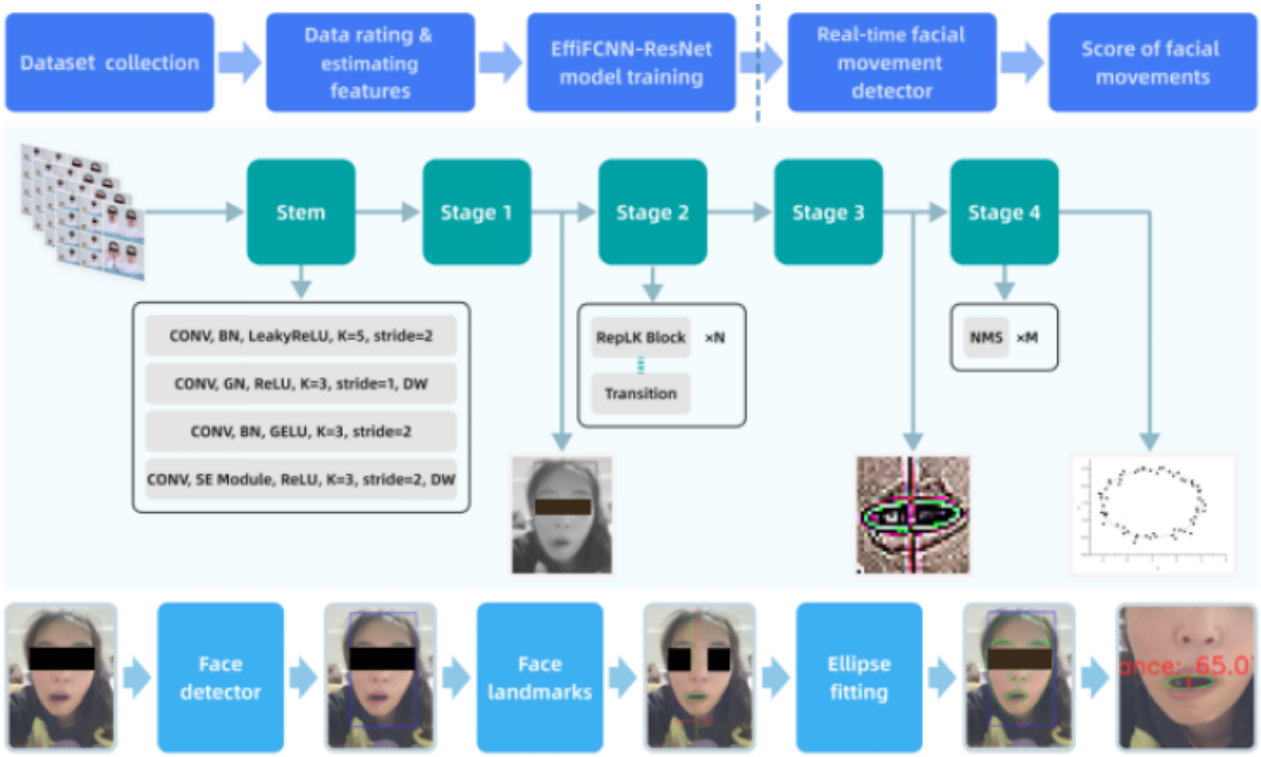
Conversely, the experimental group used the OpenCare health app, which, while integrating the identical instructional videos, was augmented with an EffiFCNN-ResNet model. This advanced functionality enabled real-time facial movement recognition, monitoring, and automated feedback, providing users with intuitive visualizations of exercise completion, rehabilitation progress, and maximum mouth-opening values through graphical representations. The OpenCare app further incorporated structured, gamified guidance, featuring an interactive module that displayed both standard demonstrations and the participant's live facial video for comparison. It provided immediate feedback, verbal cues for insufficient movement (eg, "Please try to increase the range of motion, hold longer"), and visual reinforcement, such as completion percentages and gamified animations. Beyond these advanced functionalities, OpenCare's video materials and data-recording features were strictly identical to those used by the control group.

To clearly delineate the intervention's impact, participants in both groups received weekly phone follow-ups of consistent content and duration to assess progress and address questions.

XSL•FO
RenderX

Crucially, participants in both groups were strictly prohibited from engaging in any additional training beyond the prescribed regimen, thereby minimizing confounding factors.

Procedure



Overview of the EffiFCNN-ResNet-Based System for Precise Training Monitoring and Assessment

We developed the EffiFCNN-ResNet architecture to address the complex task of recognizing a large number of nonrigid facial landmarks [39-41]. Typically, increasing network depth or input image tensors is a common approach to overcoming challenges posed by strong environmental conditions and substantial facial structural changes during facial landmark monitoring [36]. However, this strategy often increases computational complexity and execution time. Our backbone network leverages the inherent advantages of FCNN in spatial data processing and incorporates a lightweight EffiResNet backbone designed for real-time applications requiring rapid and accurate facial detection and keypoint localization [42]. The underlying principle is rooted in a single-stage object detection framework, integrating a carefully designed detector with a lightweight backbone network to achieve fast and accurate facial recognition [40], as shown in Figure 2. The advantages and contributions of our model are summarized as follows:

- Custom training on the large-scale public movie dataset Acted Facial Expressions in the Wild (AFEW) using FCNN to detect facial landmarks in complex scene settings [43].
- Replacing the FCNN backbone with a rescaled EffiResNet backbone and utilizing large-kernel depthwise convolutions to expand the receptive field of the output feature map [44].
- Integrating the backbone network with channel separation and multinetwork landmark detection modules, followed by a linear spatial channel attention module combined with nonmaximum suppression to further optimize and filter features [45].

Specifically, our model consists of the components listed in the following subsections.

Figure 2. Architecture overview of the EffiFCNN-ResNet model for real-time facial landmark detection. BN: batch normalization; DW: depthwise; GELU: Gaussian error linear unit; EffiFCNN-ResNet: Efficient Fully Convolutional Neural Network with Residual Network; GN: group normalization; LK: large kernel; NMS: nonmaximum suppression; ReLU: rectified linear unit.

Backbone Network

A lightweight backbone network based on ResNet was used to extract salient features from input images. Its core component is the residual block, which addresses the vanishing gradient problem in deep networks by introducing skip connections, thereby improving training efficiency and overall model performance. The ResNet architecture demonstrates strong hierarchical feature extraction capability, enabling efficient capture of multiscale features from low to high levels. Designed according to the structural reparameterization principle, the backbone network consists of multiple residual blocks, each incorporating convolutional layers, batch normalization, and rectified linear unit activation functions. Skip connections allow each layer to directly receive input features from the preceding layer, enhancing training stability. The primary objective is to decouple the multibranch topology used during training from the simplified structure applied during inference. This backbone design achieves a balance between computational efficiency and feature expressiveness by separating the multibranch topology at training time from the streamlined architecture used at inference time.

XSL•FO
RenderX

Neck Network

The model integrates the classic spatial pyramid pooling (SPP) module and an improved path aggregation network (PAN), enhancing feature fusion capability and multiscale perception. The SPP layer performs multiscale pooling operations to integrate features across different scales, overcoming the limitation of fixed input image sizes and enabling the capture of multiscale contextual information to improve target region perception. After the SPP module, the feature map is transformed into a fixed-length output, providing richer contextual information for the subsequent PAN. The improved PAN uses a bottom-up routing fusion strategy, effectively reducing information loss during the transfer of deep-layer features to shallow layers. Adaptive feature pooling dynamically integrates feature maps, ensuring that information from different levels is fused across all feature scales. As a result, the features passed to the detection head contain comprehensive and semantically rich information, contributing to improved target detection accuracy.

Anchor Generation Module

This module generates dense anchors (proposed bounding boxes) at different scales and aspect ratios to detect nonrigid facial structures of varying sizes and shapes within the image. It is responsible for merging semantic features from deep layers with texture features from shallow layers and relies on an efficient decoupled head with an appropriate loss function.

Face Detection Head and Keypoint Localization Head

The detection head performs classification and regression of candidate boxes to optimize their positions and sizes. Meanwhile, the keypoint localization head accurately identifies facial landmarks, enhancing the algorithm's applicability in tasks requiring detailed facial analysis while maintaining a balance between inference time and accuracy.

Dilated Convolution and Basic Block

These components are used to expand the receptive field during feature extraction while preserving spatial resolution.

Multiscale Detection

A key feature of the model is its multiscale detection strategy, which utilizes anchors generated on different feature maps to accommodate facial structures of varying sizes.

Concatenate (C) and Upsampling (U)

By combining low- and high-level features through feature fusion and upsampling, the model integrates features from different resolutions, ensuring robustness across a wide range of facial scales. This capability is critical for real-world deployment scenarios.

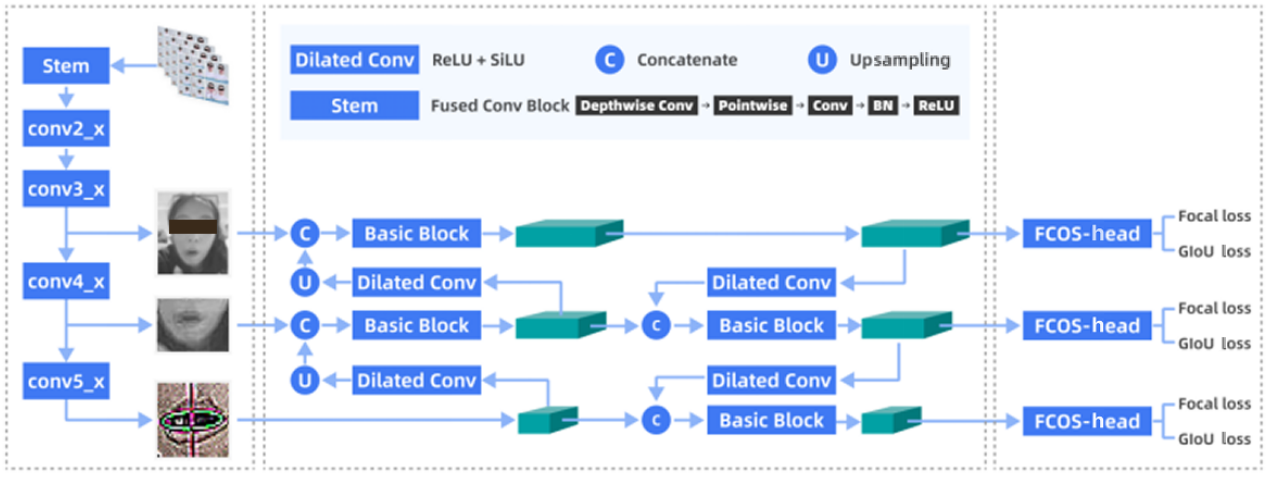
Joint Loss Function and FCOS Head

As the final detection head, the fully convolutional one-stage object detection (FCOS) head combines focal loss and generalized intersection over union (GIoU) loss to achieve efficient object classification and bounding box regression. The objective of the joint loss function is to simultaneously minimize classification error (facial region classification) and regression error (bounding box regression and keypoint localization), thereby optimizing network learning and improving the accuracy of both facial detection and keypoint localization. During deployment, the predicted probability labels for each sample are input to compute the focal loss, which is then averaged across all samples as the classification loss. GIoU is calculated to evaluate the intersection over union (IoU) between the predicted and ground truth bounding boxes. Subsequently, keypoint bounding box errors are removed, squared errors between predicted and true coordinates are calculated, and the results are averaged to obtain the keypoint localization loss. Self-monitoring of both losses constitutes a self-distillation technique, in which knowledge is transferred from the teacher model to the student model during training. The overall loss can be explained as follows:

where $-\alpha_t(1-p_t)^{\gamma}\log(p_t)$ represents the action recognition loss, $1-\mathrm{GIoU}(B_p, B_g)$ represents the facial region localization loss, and  represents the anatomical keypoint precision loss. λ_1, λ_2, and λ_3 are the corresponding adjustable weight coefficients for each term, used to balance the contribution of different tasks to the total loss, thereby adapting to varying optimization priorities during the rehabilitation training process. The term λ_1 is designed based on an improved focal loss, primarily addressing the inherent challenge of severe class imbalance in rehabilitation training data, specifically between positive and negative samples. The modulating factor γ strengthens the weight assigned to hard-to-classify samples. Specifically, the $(1-p_t)^{\gamma}$ in the formula markedly amplifies the loss contribution of low-confidence samples (ie, when the predicted probability p_t for the correct class approaches 0), while conversely reducing the contribution of easily classified examples (where p_t approaches 1). Furthermore, α_t serving as a class-balancing factor mitigates training bias arising from the disparity in the number of mouth-opening action frames versus nonaction frames. The term λ_2 employs the GIoU loss, replacing the traditional IoU loss, with the aim of significantly enhancing the bounding box regression accuracy for dynamic facial regions, particularly the perioral area. The calculation of GIoU requires the simultaneous input of the coordinate parameters for both the predicted bounding box B_p and the ground truth bounding box B_g, as detailed in equation 2:

$$\mathrm{GLoU} = \mathrm{LoU} - [|C\backslash(B_p \cup B_g)|]/|C| \quad \textbf{(2)}$$

Even in cases where the predicted and ground-truth bounding boxes are nonoverlapping, the GIoU loss can provide informative gradients by penalizing the difference between the smallest enclosing convex object (C) and the $B_p \cup B_g$. For instance, when minor rotations of a patient's head or variations in camera angle cause the predicted bounding box for the oral region to deviate from the ground-truth box without intersecting, GIoU still yields a directional gradient. This characteristic enhances the model's robustness to changes in camera pose, distance, and subtle patient head movements. The term λ_3 directly constrains the spatial deviation of facial anatomical keypoints through the mean squared error (MSE) formulation,



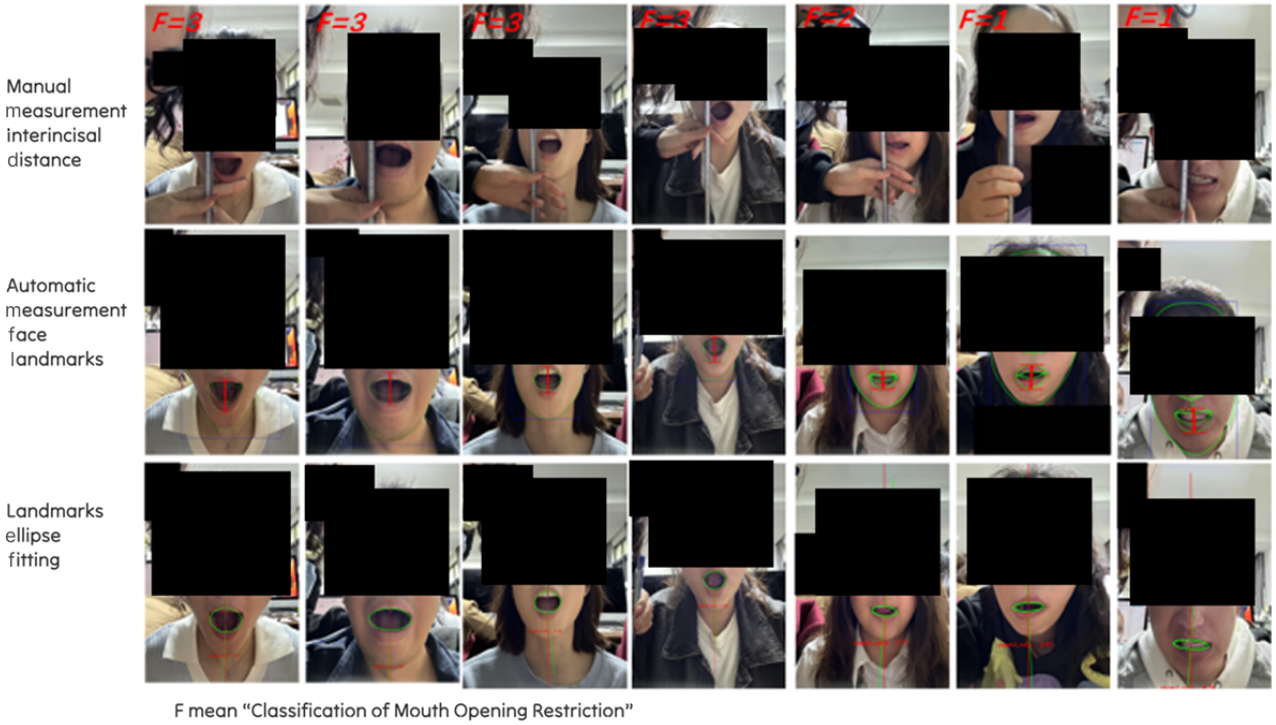
XSL•FO
RenderX

ensuring high-precision landmark localization. Specifically, for the *i*th keypoint, the squared Euclidean distance between the predicted coordinate vector P_i and the expert-annotated ground truth coordinate vector G_i is computed, with the squared Euclidean distance calculated as  for each keypoint. Subsequently, the error is averaged over N keypoints using the formula . This process ensures the model's simultaneous and consistent optimization of all annotated points, including the upper lip, lower lip, and other crucial landmarks. This loss term directly prompts the model to precisely optimize the spatial localization consistency of all annotated points, including the upper lip, lower lip, and mouth corners.

Real-Time Capture

To enable rapid inference, the model employs multiscale preprocessing and multiscale detection, supplemented by optimization techniques such as nonmaximum suppression, making it suitable for real-time applications. Through the architecture described above, FCNN preserves spatial relationships across the entire network, enabling the generation of dense prediction maps. The lightweight ResNet extends convolutional layers throughout the network, facilitating direct correspondence between input pixel positions and their feature representations. Compared with traditional landmark detection methods, this approach captures a greater number of facial landmarks with higher accuracy while mitigating disturbances in texture and shape caused by nonrigid facial deformations, as illustrated in Figure 3. For rapid inference, the model adopts a lightweight ResNet-based object detection network enhanced with dilated convolutions. The core architecture uses multilevel dilated convolutions to expand receptive fields and capture contextual information, while integrating a stem module with lightweight pointwise convolutions and hybrid sigmoid linear unit/rectified linear unit activations to reduce computational complexity. Cross-level feature fusion is achieved through concatenation and upsampling operations to enhance detail retention. The FCOS head addresses class imbalance using focal loss and optimizes bounding box regression with GIoU loss, making it suitable for dense scenarios and small-object detection. Overall, the unified framework emphasizes 3 critical aspects: receptive field expansion through hierarchical dilation, multiscale feature interaction, and lightweight deployment capability, thereby balancing detection accuracy with computational efficiency.

Figure 3. Real-time facial landmark detection with multiscale preprocessing and nonmaximum suppression optimization. BN: batch normalization; FCOS: fully convolutional one-stage object detection; GIoU: generalized intersection over union; ReLU: rectified linear unit; SiLU: sigmoid linear unit.



Training Action Classification and Evaluation

Taking the mouth-opening action as an example, a more precise evaluation of movement is achieved by introducing a 4-level grading system that incorporates both the degree of mouth opening and its symmetry. This grading system simultaneously considers 2 key aspects: maximum mouth opening and mouth shape symmetry. Maximum mouth opening is defined as the vertical distance between the highest point of the upper semicircle and the lowest point of the lower semicircle, derived from the elliptical fitting of the mouth region. Symmetry is assessed based on the rotation angle of the fitted ellipse. To compute the elliptical equation of the oral region, we use a facial landmark detection and oral-region keypoint elliptical fitting algorithm based on the aforementioned model, utilizing more than 10,000 keypoints. This algorithm provides intelligent, automated evaluation of mouth-opening performance for each patient, as illustrated in Figure 4.

XSL•FO
RenderX

Figure 4. Action evaluation output results for a subset of the patient dataset.

Through these steps, the keypoints obtained using the deep learning–based facial landmark localization algorithm can be further analyzed to assess the morphological characteristics of the oral region, thereby quantifying the degree of mouth opening and symmetry. The elliptical equation of the oral region can be expressed in the following general form:

$$(x - x_0)^2/a^2 + (y - y_0)^2/b^2 \textbf{(3)}$$

where (x_0, y_0) are the coordinates of the center of the ellipse, and a and b denote the lengths of the major and minor axes, respectively. Subsequently, the vertical distance between the highest point (u) of the upper semicircle and the lowest point (d) of the lower semicircle is calculated. The grading criteria were defined by oncologic medical experts. F4 indicates the normal range (35-50 mm), F3 represents mild restriction (25-35 mm), F2 represents moderate restriction (15-25 mm), and F1 represents severe restriction (<15 mm).

At the same time, the rotation angle of the ellipse is used to assess mouth symmetry. The rotation angle of the ellipse can be calculated using the following formula.

$$\theta=\arctan(b\sin[\Phi]/a\cos[\Phi]) \textbf{(4)}$$

where Φ represents the inclination angle of the ellipse. The grading criteria for symmetry are defined as follows: F4, rotation angle <5° (good symmetry); F3, rotation angle 5°-10° (mild asymmetry); F2, rotation angle 10°-15° (moderate asymmetry); and F1, rotation angle >15° (severe asymmetry).

To correct for variations in the distance between the user and the camera, the 2 feature points at the inner corners of the eyes are connected to form a reference line. A standard value of 3.5 cm is defined, and a real-time scaling factor is derived by calculating the ratio between this reference distance and the actual measured value to perform distance correction, thereby facilitating subsequent data analysis. The corresponding code is shown below.

"# Input: Facial landmarks detected via EffiFCNN-ResNet

leftEye = (landmarks.part(39).x, landmarks.part(39).y) # Left eye corner (point 39)

rightEye = (landmarks.part(42).x, landmarks.part(42).y) # Right eye corner (point 42)

Calculate Euclidean distance between eyes

eyeDistance = np.linalg.norm(np.array(leftEye) - np.array(rightEye)) # $||p_left - p_right||_2$

Compute scale factor using reference eye distance

scale = 3.5 / eyeDistance # d_reference = 3.5 (anthropometric mean)"

Intelligent recognition and evaluation of other training actions follow a similar approach.

Dataset

General Facial Representation Pretraining Phase

This phase used the AFEW dataset for training [46]. The AFEW dataset comprises 1200 video segments from real movies and clips, from which approximately 48,000 representative facial image frames were extracted. These frames include a wide range of individuals displaying diverse expressions under varying lighting conditions, poses, and background environments. The data modality consisted of RGB (red-green-blue) video frames and their corresponding emotional category labels. Optimization was performed using the AdamW optimizer with an initial learning rate of 1×10^{-4}. A cosine annealing learning rate schedule, coupled with a warm-up phase, was applied. The model was trained for 80 epochs with a batch size of 32,

XSL•FO
RenderX

incorporating gradient accumulation and various data augmentation techniques. Hyperparameters were determined through a combination of grid search and Bayesian optimization. This foundational training aimed to enhance the model's generalization capability and prepare it for subsequent fine-tuning, particularly to achieve robust facial feature extraction in patient-specific scenarios.

Dataset Training Phase

The formal training dataset used in this study was derived from video data of real patients with NPC undergoing postradiotherapy rehabilitation training. The dataset comprised 800 video segments, from which approximately 12,000 keyframe images were extracted. Together with their corresponding annotations, this process generated 85,000 image-annotation pairs and 65,000 video-annotation pairs. To ensure robustness and generalizability of the developed model (EffiFCNN) in real-world clinical applications, the dataset was designed with a strong emphasis on diversity. Environmental diversity was achieved through simulated or real recordings of patients performing exercises at home using smartphones or tablets. These recordings encompassed a wide range of lighting conditions (eg, strong light, low light, side light), background complexities, camera angles (eg, frontal, top-down, bottom-up, side view), and shooting distances, thereby enhancing adaptability to complex daily environments. In terms of action content diversity, the dataset focused not only on the core mouth-opening rehabilitation exercise, comprehensively documenting maximal active mouth opening, sustained holding, and relaxation, but also included samples reflecting different degrees of mouth opening classified according to clinical F1-F4 grades and varying levels of symmetry quantified by the elliptical rotation angle θ. In addition, auxiliary rehabilitation exercises, such as neck movements, ocular movements, and cheek puffing (quantification methods are detailed in Multimedia Appendix 1), were incorporated to support a comprehensive rehabilitation assessment. Patient state diversity was a central characteristic of the dataset, with particular attention to challenges unique to postradiotherapy patients with NPC. The dataset covered all levels of mouth-opening restriction, ranging from severe restriction (F1, <15 mm) to normal function (F4, 35-50 mm). Special emphasis was placed on collecting samples from patients with moderate to severe restrictions (F1-F3), as this population represents the primary target group for intervention. The dataset also included samples exhibiting common postradiotherapy sequelae, such as skin hyperpigmentation, fibrosis, edema, facial asymmetry, and subtle jaw deformities, all of which pose significant challenges for nonrigid facial deformation analysis. To address class imbalance, the synthetic minority over-sampling technique was applied to augment minority class samples within the feature space, thereby improving recognition performance for rare categories. Within ethical and privacy constraints, efforts were made to include patients across diverse age groups, genders, and body types to enhance model generalizability. During data preprocessing, all patient-identifiable information was deidentified (Figure 4), and strict adherence to ethical guidelines was maintained, with approval obtained from the Institutional Review Board (approval number 2404294-Exp8). Finally, the dataset was partitioned into training, validation, and test sets (70%:15%:15%) using stratified sampling based on key clinical features. This approach ensured sample independence and distributional consistency, providing a robust foundation for model training and evaluation.

Despite concerted efforts to ensure diversity in its design, the dataset remains susceptible to potential biases. These are explained in the following sections.

Sampling Bias

This bias may arise from the participant recruitment process, which primarily involved voluntary patients capable of using smart devices. Such an approach may lead to the underrepresentation of patients who are critically ill, severely mobility-impaired, digitally illiterate, or socioeconomically disadvantaged. In addition, the concentration of data sources within specific hospitals or regions may introduce bias related to variations in medical practice patterns.

Annotation Bias

Annotation bias may result from the inherent subjectivity in clinical experts' assessments of mouth-opening grades (F1-F4) and symmetry (rotation angle θ). Moreover, precise keypoint annotation becomes substantially more challenging in patients with severe postradiotherapy facial sequelae, such as pronounced edema or deformity.

Temporal Bias

This type of bias reflects variations associated with different postradiotherapy recovery phases (eg, acute, subacute, chronic) or heterogeneous baseline conditions, such as initial mouth-opening capacity.

Validation of Precision

To ensure rigorous and objective evaluation of the proposed EffiFCNN-ResNet model, we implemented a comprehensive validation strategy combining stratified 5-fold cross-validation with an independent test set. The dataset, comprising 800 video segments from patients with NPC, was first stratified by patient ID and mouth-opening restriction grade (F1-F4) into 560 (70%) segments for training, 120 (15%) segments for validation, and 120 (15%) segments for testing. The cross-validation procedure employed Scikit-learn's StratifiedGroupKFold method to ensure that all 448 (80% of the training set) segments were used for model training in each fold, while 112 (20%) segments served as validation data. This approach prevented patient-level data leakage across folds and maintained balanced-grade distributions throughout the validation process.

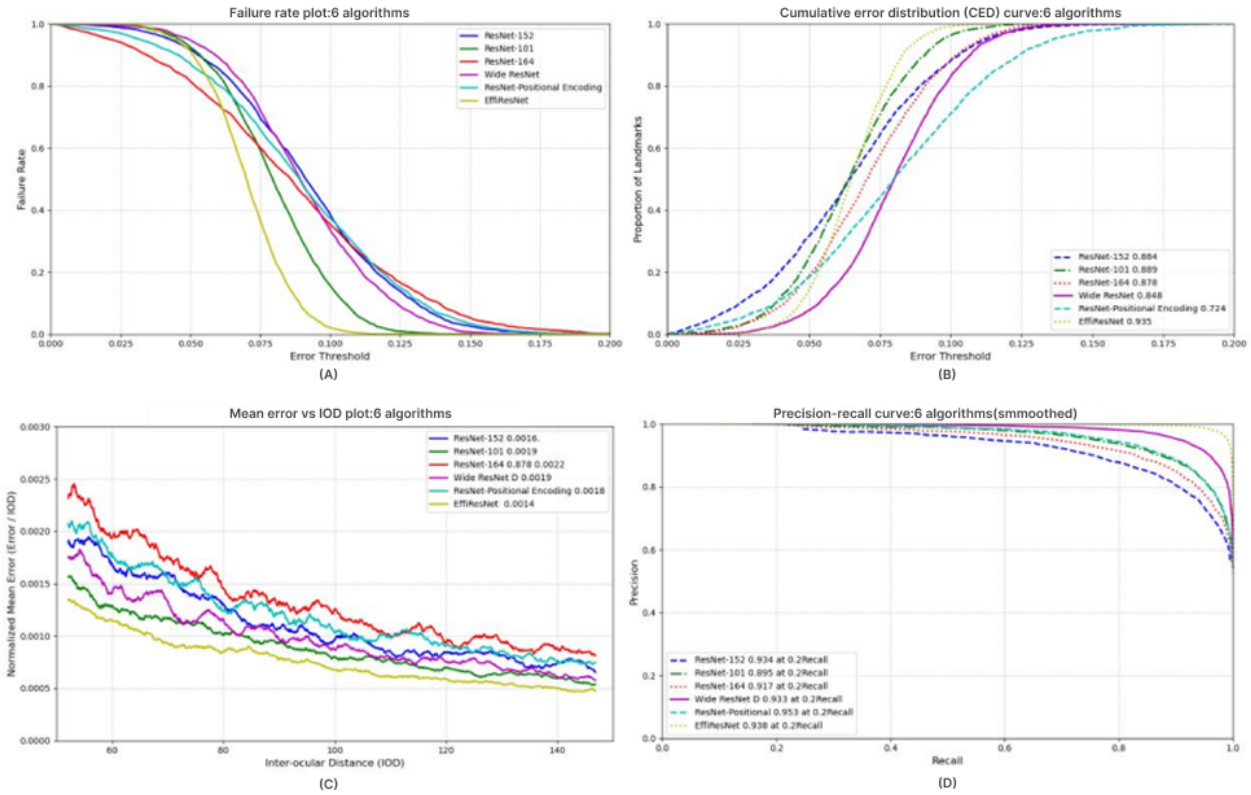
The model demonstrated consistent performance across all validation metrics. In classification tasks, it achieved a mean accuracy of 89.2% (SD 2.4%; 95% CI 86.8%-91.6%) for mouth-opening restriction grades (as detailed in equation 5), with a macro-averaged F_1-score of 0.875 (SD 0.031) and an area under the receiver operating characteristic curve of 0.934 (SD 0.018). For regression tasks, the mean absolute error for mouth-opening distance was 1.23 mm (SD 0.15 mm; 95% CI 1.08-1.38 mm), as detailed in equation 6, while the rotation angle θ showed a mean absolute error of 2.15° (SD 0.32°; 95%

XSL•FO
RenderX

CI 1.83°-2.47°). Keypoint detection achieved a normalized mean error of 0.043 (SD 0.006), with a failure rate of 3.8% (SD 1.2%; 95% CI 2.6%-5.0%). On the independent test set comprising 120 video segments from 45 patients, the model achieved an accuracy of 98.3% (118/120 correctly classified segments; 95% CI 97.6%-98.8%), with particularly strong performance on severely restricted F1-grade samples (96.4% recall; 27/28 cases correctly identified). In robustness testing involving patients with significant postradiotherapy sequelae, the model maintained 94.4% accuracy (151/160 challenging samples correctly classified). Expert annotations established a reliable gold standard with excellent interrater reliability (intraclass correlation coefficient 0.942; 95% CI 0.925-0.956) among 20 clinical oncologists. The Bland-Altman analysis demonstrated excellent agreement with expert measurements (mean difference −0.14 mm; 95% limits of agreement −1.86 to 1.58 mm), and the intraclass correlation coefficient reached 0.968 (95% CI 0.953-0.979), confirming the model's clinical reliability and readiness for deployment in diverse rehabilitation settings.

$$\text{Accuracy} = (TP + TN)/(TP + TN + FP + FN) \quad \textbf{(5)}$$

where TP is true positive, which represents the number of actual positive samples correctly predicted as positive; TN is true negative, which represents the number of actual negative samples correctly predicted as negative; FP is false positive, which represents the number of negative samples incorrectly predicted as positive; and FN is false negative, which represents the number of positive samples incorrectly predicted as negative.



where *C* denotes the number of classes (F1-F4), emphasizing the model's balanced evaluation of performance across all individual categories.

To rigorously evaluate the clinical applicability of the EffiFCNN-ResNet system, comprehensive robustness testing was conducted under simulated challenging conditions encompassing both environmental and patient-specific variations. Environmental perturbations were introduced through structured image transformations, including +30% or –30% linear and gamma-adjusted illumination shifts in the hue-saturation-value color space and affine transformations simulating +15° or –15° viewpoint deviations in pitch, yaw, and roll angles. A dedicated subset containing 160 video samples (20% of the test set; N=800), consisting exclusively of postradiotherapy patients with NPC exhibiting pronounced sequelae such as skin fibrosis, edema, and facial asymmetry, was used to assess performance under clinically relevant morphologic distortions. The model demonstrated exceptional stability, with an overall performance degradation of 5.2% (SD 0.6%) under combined disturbances. Specifically, there was a 0.007 increase in normalized mean error for landmark detection (SD 0.002), a 0.4 mm increase in mouth-opening distance mean absolute error (SD 0.1), and 94.5% accuracy retention across F1-F3 restriction grades (SD 2.1%). These findings confirm the model's ability to maintain high accuracy and reliability under real-world variability, underscoring its suitability for deployment in clinical and home-based rehabilitation settings.

In the final validation stage, the superiority of the proposed method was objectively evaluated through systematic comparative experiments against multiple ResNet architecture variants, including ResNet-101, ResNet-152, ResNet-164, Wide ResNet, and ResNet-Positional Encoding. These comparisons were conducted on both the public AFEW dataset and a self-collected mouth-opening training dataset from patients with NPC, with standardized environments and data preprocessing to ensure fairness. Four evaluation metrics were employed: failure rate, cumulative error distribution, average error relative to interocular distance, and precision-recall curves. All models were assessed using identical hardware configurations and datasets. The performance of the proposed model is presented in Figure 5. The comparison of EffiResNet with other mainstream ResNet variants demonstrates its superior ability to balance accuracy, robustness, and computational efficiency. In terms of failure rate, EffiResNet shows a markedly faster decline as the error threshold increases compared with other models, indicating stronger robustness and adaptability when handling tasks with larger error tolerances. This characteristic enables stable performance in complex and dynamic computational environments. Regarding cumulative error distribution, the EffiResNet curve is smooth and approaches the cumulative error distribution performance of ResNet-152, suggesting stable behavior across varying error magnitudes. Compared with other ResNet variants, EffiResNet more effectively balances the influence of different error scales during accumulation, thereby ensuring overall performance stability. From a spatial awareness perspective, the relationship between average error and interocular distance demonstrates that the EffiResNet curve remains relatively stable, highlighting its advantage in spatial perception. This enables more accurate capture and analysis of spatial information in tasks involving spatial positioning. In classification tasks, EffiResNet also exhibits strong performance. Precision-recall curve comparisons indicate that, relative to ResNet-Positional Encoding, EffiResNet maintains high recall while achieving comparatively high precision. This reflects its ability to accurately identify target categories while minimizing misclassification.

Personalized Real-Time Feedback

In designing the virtual avatar for patients with nasopharyngeal cancer, we considered potential deficiencies in the sensory integration system while avoiding the uncanny valley effect [47]. A series of brightly colored, soft, rounded dinosaur-themed virtual headgear avatars with simple structures was developed [48]. These avatars are linked to mouth-opening training movements through gamification based on skeletal keypoint capture, providing real-time visual and auditory feedback (eg, swallowing coins) when the required movement is achieved (Figure 6). As training scores accumulate, users can unlock additional virtual avatars as rewards. This design aims to stimulate patients' intrinsic motivation during training and create an immediate, supportive, and personalized rehabilitation environment. The remote mouth-opening data tracking function was developed using the Unity3D engine (Unity Technologies) and Python (Python Foundation), with communication implemented through SocketTools.cs. Upon user authorization, the mobile device camera is used for facial landmark detection, enabling the system to collect mouth-opening data over a specified period, including maximum mouth opening, opening frequency, and symmetry. These data are transmitted to the backend via transmission control protocol/IP sockets for processing, with serial communication facilitating data exchange between devices and enabling real-time monitoring of patient movements. Data transmission is secured using encryption protocols to ensure privacy protection. The collected data support long-term daily monitoring of mouth-opening rehabilitation progress and provide actionable feedback to both patients and health care professionals regarding training patterns and behavioral habits.

Furthermore, personalized feedback is provided according to each patient's functional level. Before each training session, an initial mouth-opening test is conducted to categorize patients into specific levels. Based on this classification, the performance thresholds required to complete the prescribed training tasks are individualized and progressively adjusted according to the severity of the condition, enabling a more flexible and targeted rehabilitation approach. This strategy ensures that the training protocol is tailored to the unique needs of each patient, thereby facilitating more effective recovery and sustained progress.

Figure 6. Training virtual headgear and its development program demonstration.

Individuals Involved

The study participants comprised patients with nasopharyngeal cancer who had completed radiotherapy and were preparing for discharge from the oncology department. Participants were recruited through posters and questionnaire screening.

The inclusion criteria were as follows: (1) a pathology or histologic diagnosis of nasopharyngeal cancer with a prescribed course of radiotherapy; (2) age 18-65 years; (3) awareness of their medical condition; (4) provision of informed consent and willingness to participate in the study; (5) access to a smartphone and related apps; and (6) Functional Status Score (Karnofsky performance status) of 80-100 [49] and Eastern Cooperative Oncology Group performance status of 0-5 [50].

The exclusion criteria were as follows: (1) a history of prior radiotherapy; (2) inability to participate in physical activity due to underlying cardiac, neurological, muscular, or joint disorders; and (3) previous engagement in relevant mouth-opening exercises (eg, as part of routine daily care, follow-up video guidance, or other structured rehabilitation programs).

The withdrawal criteria were defined as follows: (1) voluntary decision to discontinue participation in the trial; (2) development of a severe illness that precluded continuation of the study; (3) occurrence of an adverse event related to mouth-opening exercises or routine physical activity; and (4) requirement for additional surgical interventions, such as mandibular resection.

Following Testing

After the 4-week intervention period, all participants underwent a comprehensive assessment, including measurement of maximal mouth opening as well as other predefined outcome measures and relevant clinical indicators. All data were collected using the same measurement procedures as those employed during the baseline assessment, ensuring methodological consistency. This approach enabled reliable quantitative analysis for both within- and between-group comparisons.

Size of Sample

In our previous comparative study, the sample size was calculated based on the change in perceived benefit scores measured 1 week after the intervention. Pilot data demonstrated that the intervention group showed a mean increase of 0.8 points

XSL•FO
RenderX

(from mean 10.5, SD 2.6 to mean 11.3, SD 2.4), corresponding to a Cohen *d* effect size of 0.33. Using G*Power (Heinrich Heine University Düsseldorf) for sample size estimation, we determined that a total sample of 108 participants (54 per group) would be required to achieve 80% statistical power [51] at a 2-tailed significance level of 5% [52].

Blind Method, Randomization, and Allocation Concealing

This study rigorously employed a stratified block randomization approach to allocate eligible participants to either the experimental or control group, ensuring balanced distribution of key baseline characteristics while preserving allocation unpredictability. An independent statistician generated the randomization sequence using R (version 4.4.x; R Foundation). Stratification variables included age (<45, 45-60, and >60 years), gender (male or female), and cancer stage (stage II and below, stage III, and stage IV). These factors were selected based on their clinical relevance and prognostic significance, while avoiding excessive stratification that could result in sparse subgroup sizes [53]. To further enhance allocation concealment, varying block sizes (4 or 6) were applied [54]. Each group assignment was placed in an opaque, sealed, and consecutively numbered envelope prepared and safeguarded by the independent statistician. Envelopes were opened sequentially by unblinded study personnel only after completion of participant screening and informed consent procedures. This process ensured that recruiting staff, intervention providers, and outcome assessors remained unaware of group allocation prior to assignment, thereby effectively minimizing selection bias [55]. Additionally, a triple-blind design was implemented, whereby participants, outcome assessors, and statisticians were blinded to group allocation. This strategy reduced the risk of performance and ascertainment biases, substantially enhancing the internal validity, objectivity, and reliability of the study findings.

Documents of Safety

No adverse events were reported in association with this app during the study period. Participants were instructed that if they experienced significant respiratory distress, palpitations, or any other form of physical discomfort during the intervention, they must immediately discontinue the training session and return to a resting position. If symptoms were severe or persisted, participants were advised to seek prompt medical evaluation. All serious adverse events were reported to the institutional ethics committee in accordance with regulatory requirements, while any unexpected or nonserious adverse events were documented and reported to the research team for further evaluation and follow-up.

Outcomes Measures

Questionnaire

A validated questionnaire, administered either online or in person, was completed by each participant at baseline and again 4 weeks after the intervention. No financial compensation or other incentives were provided for participation in the study. The collection of baseline demographic data and related variables is described in detail later.

Primary Outcomes

Maximum Mouth Aperture Measurement

To evaluate the effectiveness of the intervention app on mouth-opening function, participants' maximum mouth aperture was measured and compared before and after the intervention. This comparison enabled assessment of functional improvement attributable to the training program. During measurement, participants were instructed to open their mouths as widely and steadily as possible to reach their individual maximal range. Once the maximum opening position was achieved, a 3-second stabilization period was maintained. Five data points were collected during the middle 1-second interval to minimize transient fluctuations. The average of these 5 values was calculated and recorded as the final maximum mouth-opening measurement.

Evaluation of Mouth Aperture Symmetry

To assess the impact of the intervention on oral motor function, the symmetry of participants' mouth-opening movements was documented and compared before and after the intervention. Symmetry was evaluated by analyzing bilateral movement patterns during mouth opening, allowing identification of deviations or asymmetries in mandibular motion. Changes in symmetry measurements between baseline and postintervention assessments were used to determine the effectiveness of the app in improving coordinated oral function.

Number of Exercises Per Week

Adherence to the prescribed training behavior was quantitatively evaluated by recording and comparing the participants' weekly exercise frequency before and after the intervention. The total number of completed mouth-opening training sessions per week was documented to assess behavioral implementation and engagement. Changes in weekly training frequency served as an indicator of intervention adherence and behavioral improvement.

Health Belief Model Questionnaire Inquiry Form

The Health Belief Model Questionnaire is widely used to assess health-related behaviors [56]. The version developed by social psychologists in the United States comprises 7 core constructs of the Health Belief Model: perceived susceptibility (3 items), perceived severity (7 items), perceived benefits (3 items), perceived barriers (7 items), self-efficacy (5 items), cues to action (3 items), and behavior (3 items) [57]. For all subscales except the behavior domain, responses were rated on a 5-point Likert scale ranging from "completely disagree" (0) to "completely agree" (4). Participants were asked to evaluate statements reflecting their health beliefs across the 6 domains. The behavior subscale, designed with strong psychometric properties, assesses the frequency of relevant health behaviors (eg, mouth-opening exercises) using a scale ranging from "never" (0) to "always" (4). Higher scores indicate greater engagement in the targeted health behavior.

Secondary Cognitive Outcomes

Borg Rating of Perceived Exertion Scale

The Borg Rating of Perceived Exertion Scale [58] is used to quantify self-reported physical exertion during exercise. The

XSL•FO
RenderX

scale score ranges from 6 (no exertion at all) to 20 (maximal exertion). Participants rate their perceived intensity of effort during mouth-opening training, providing a subjective measure of exercise load.

Assessment of Quality of Life—6 Dimensions

Health-related quality of life was assessed using the Assessment of Quality of Life—6 Dimensions (AQoL-6D) [59] instrument. Scores range from −0.04 to 1.00, with higher scores indicating better quality of life. This measure captures multiple domains of well-being to evaluate the broader impact of the intervention.

System Usability Scale

Perceived usability of the app was evaluated using the System Usability Scale (SUS) [60]. After completing the designated training tasks, participants completed the SUS questionnaire to obtain an overall usability score. Higher SUS scores indicate better perceived system usability and user satisfaction.

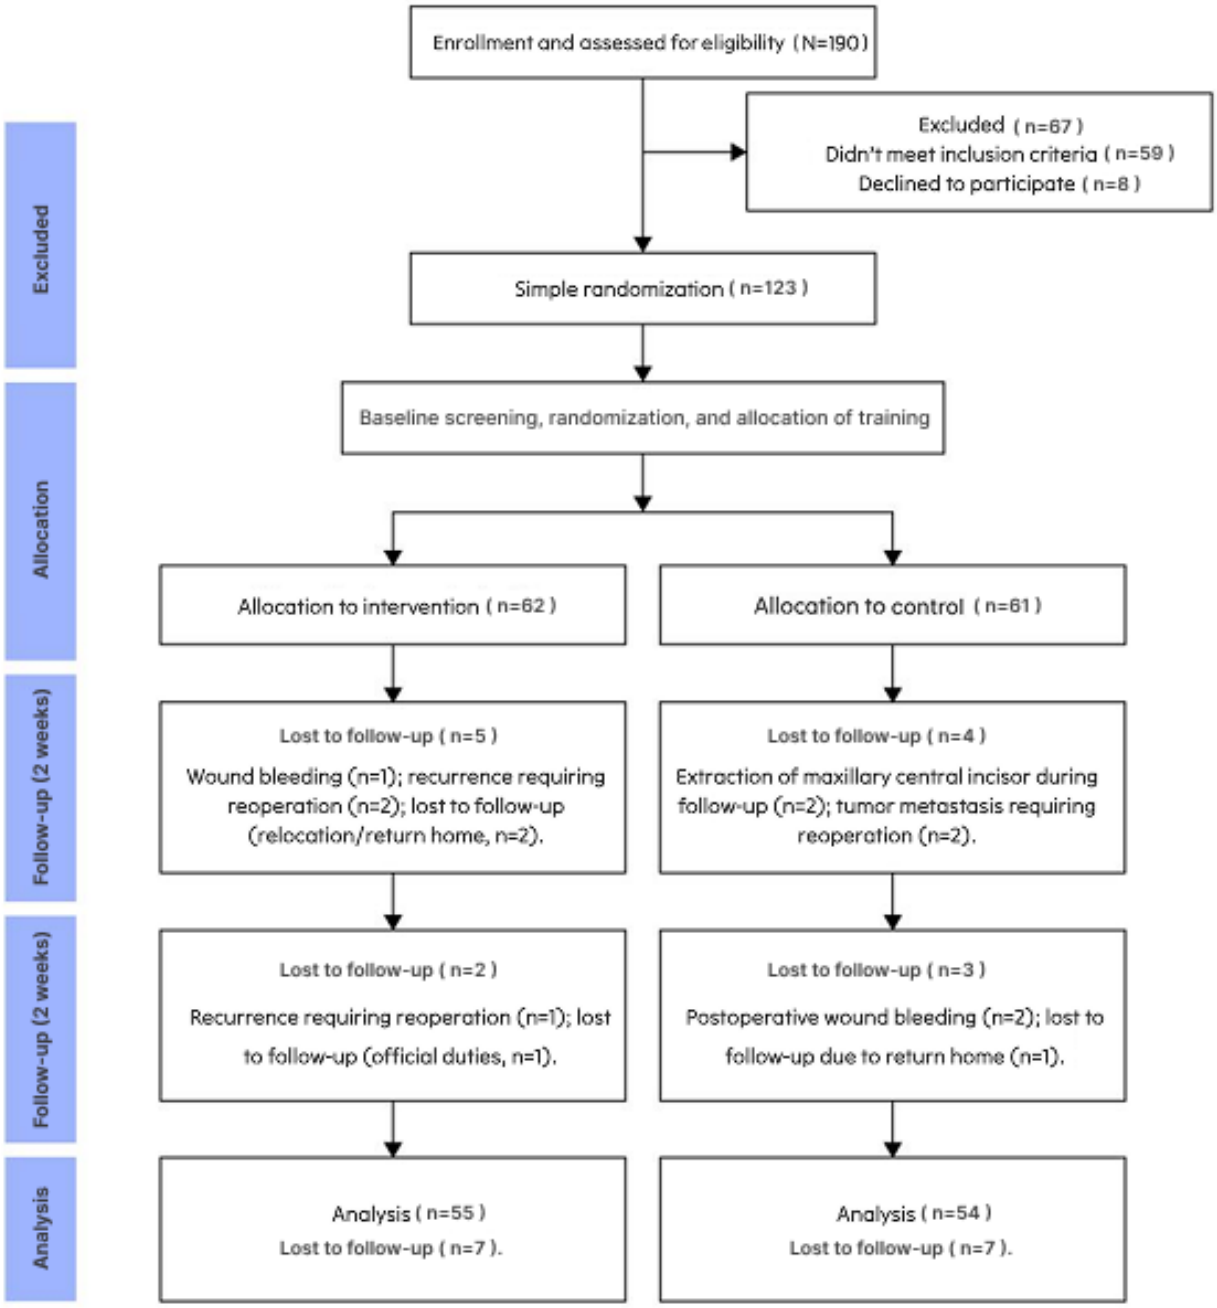
Data Analysis

Data were analyzed using SPSS (IBM Corp.). Descriptive statistics were presented as means with SDs for continuous variables, and as frequencies (n) with percentages (%) for categorical variables. Baseline characteristics of participants who completed the study were compared with those who did not using 2-tailed (unpaired) independent-samples *t* tests or chi-square tests, as appropriate. Given the distribution characteristics of the variables, the Mann-Whitney *U* test was used to evaluate differences between groups, and within-group comparisons before and after the intervention were also conducted accordingly. Comparisons were performed between the intervention and control groups to determine the effectiveness of the intervention. For all statistical analyses, inter- and intragroup differences were expressed as means with 95% CIs. The significance level (α) was set at .05, and a *P* value ≤.05 was considered statistically significant.

Ethical Considerations

This study was conducted in accordance with the ethical principles outlined in the Declaration of Helsinki and received approval from the institutional Human Research Ethics Committee (protocol number: 2404294-Exp8; reference number: H20240007I). All participants provided written informed consent before enrollment after receiving a detailed explanation of the study's objectives and procedures. They were explicitly informed that participation was entirely voluntary and that they could withdraw from the study at any time without any negative consequences. To ensure privacy and confidentiality, all collected data were fully anonymized before analysis, and no personally identifiable information was collected or retained. Additionally, no financial compensation or other incentives were provided, thereby maintaining a transparent and voluntary recruitment process.

Results



Characteristics at Baseline

A total of 190 patients were screened for eligibility, of whom 67 did not meet the inclusion criteria and were excluded. Written informed consent was obtained from all participants. During the study, 7 participants in the app-based intervention group were excluded for the following reasons: postoperative wound bleeding (n=1); postoperative recurrence requiring reoperation (n=3); and loss to follow-up due to relocation, official duties, or return to hometown (n=3). In the routine care control group, 7 participants were excluded for the following reasons: extraction of the maxillary central incisor during follow-up (n=2), tumor metastasis requiring reoperation (n=2), postoperative wound bleeding (n=2), and loss to follow-up due to return to hometown (n=1). Ultimately, 109 valid cases were included. In accordance with the CONSORT (Consolidated Standards of Reporting Trials) flow diagram (Figure 7; see also Multimedia Appendix 2) [61], participants in both groups were analyzed according to their original allocation (intervention group: n=55; control group: n=54).

Before beginning the intervention, disease-related data (cancer type, treatment method, course of disease, number of mouth-opening recovery exercises per week, and household residence), as well as name, gender, age, and education level, were collected from all participants. Baseline measurements were conducted 1 week before the commencement of the intervention, focusing on maximum mouth opening and other scores (Table 1). Males comprised the majority of the sample (75/109, 68.8%), with a mean age of 47.31 (SD 8.47) years, which was consistent with the prevalence of NPC. Table 1 presents outcomes related to NPC-related indicators, maximal mouth opening, mouth-opening symmetry, weekly training frequency, gender, age, education level, and the Shapiro-Wilk test. There were no significant differences between groups (see Table 1), indicating comparability and suitability for subsequent experiments and analyses. At baseline, based on the evaluation of participants' cancer-related function and the potential impact on quality of life after radiotherapy, mouth-opening training was supported.

Outcomes

Primary Outcomes

Table 2 shows changes in the Health Belief Model subscales and clinical indicators of improved jaw clenching from baseline to the 4-week trial period after the intervention. For perceived susceptibility, although changes in both the intervention and control groups did not reach statistical significance (*P*=.07), the intervention group score increased from 6.0 at baseline to 7.5, indicating a certain degree of positive change. This contrasted with the small change observed in the control group (from 5.8 to 6.1). For perceived severity, the mean value in the intervention group increased from 23.3 to 27.8, with a difference of 4.5 (95% CI 3.6-5.4; *P*=.007), indicating a significant difference, whereas the control group showed little change, increasing only from 24.6 to 25.4. For perceived benefits, the mean score in the intervention group increased from 11.2 to 11.9 (difference 0.7; 95% CI 0.2-1.2), which was statistically significant (*P*=.04). At the same time, the reduction in perceived impairment was particularly significant (from 15.5 to 8.5; difference −7.0; 95% CI −8.1 to −5.9; *P*=.001). In addition, self-efficacy increased from 5.4 to 6.4 (difference 1.0; 95% CI 0.6-1.4; *P*=.04), and action cues increased from 7.5 to 11.2 (difference 3.7; 95% CI 3.2-4.2; *P*=.001), indicating that the intervention successfully improved individuals' confidence and motivation to adopt healthy behaviors. The increase in maximum mouth opening (from 36.98 to 39.05; difference 2.07; 95% CI 1.49-2.61; *P*=.04) and improvements in physical indicators related to oral health demonstrated the potential benefits of the intervention in promoting specific health behaviors. The intervention group performed significantly more exercises per week (mean 10.0, SD 3.5) than the control group (mean 6.7, SD 2.3; *P*=.001). However, small changes in mouth-opening symmetry (−0.014; 95% CI −0.024 to 0.005; *P*=.15) suggested that the intervention was not equally effective across all outcomes.

Table 2. Primary and secondary intervention results.

Results	Intervention (n=55)			Control (n=54)			*P* value
	Baseline, mean (SD)	Follow-up, mean (SD)	Difference (95% CI)	Baseline, mean (SD)	Follow-up, mean (SD)	Difference (95% CI)	
Primary outcome							
Perceived susceptibility	6.0 (3.4)	7.5 (1.8)	1.5 (0.4 to 2.6)	5.8 (3.4)	6.1 (2.9)	0.3 (–1.2 to 1.8)	.07
Perceived severity	23.3 (3.8)	27.8 (2.6)	4.5 (3.6 to 5.4)	24.6 (3.6)	25.4 (2.7)	0.8 (0.3 to 1.9)	.007
Perceived benefits	11.2 (1.2)	11.9 (1.4)	0.7 (0.2 to 1.2)	10.9 (1.3)	10.8 (1.6)	–0.1 (–0.7 to 0.5)	.04
Perceived barriers	15.5 (5.5)	8.5 (5.2)	–7.0 (–8.1 to –5.9)	15.4 (6.4)	15.5 (5.9)	0.1 (–3.5 to 3.7)	.001
Self-efficacy	5.4 (1.1)	6.4 (1.2)	1.0 (0.6 to 1.4)	5.9 (1.1)	5.5 (1.2)	–0.4 (–0.9 to –0.1)	.04
Cues to action	7.5 (1.8)	11.2 (2.9)	3.7 (3.2 to 4.2)	7.7 (1.6)	7.2 (1.4)	–0.5 (–1.1 to 0.1)	.001
Action (behavior)	6.6 (2.7)	8.1 (2.8)	1.5 (0.9 to 2.1)	6.4 (2.6)	5.9 (2.8)	–0.5 (–1.3 to 0.3)	.03
Number of exercises per week	4.2 (2.6)	10.0 (3.5)	5.8 (4.8 to 6.8)	3.4 (2.6)	6.7 (2.3)	3.3 (1.9 to 4.6)	.001
Maximum value of mouth opening (mm)	36.98 (1.61)	39.05 (1.38)	2.07 (1.49 to 2.61)	37.05 (1.63)	38.02 (1.54)	0.97 (0.49 to 1.41)	.04
Evaluation of mouth opening symmetry	0.836 (0.086)	0.822 (0.048)	–0.014 (–0.024 to 0.005)	0.841 (0.079)	0.838 (0.076)	–0.003 (–0.023 to 0.017)	.15
Secondary cognitive outcomes							
Borg Rating of Perceived Exertion Scale score	11.85 (1.11)	12.98 (0.76)	1.13 (0.81 to 1.45)	11.65 (0.66)	13.43 (1.13)	1.78 (1.33 to 2.23)	.04
Assessment of Quality of Life—6 Dimensions	0.46 (0.19)	0.48 (0.18)	0.02 (–0.04 to 0.08)	0.55 (0.17)	0.52 (0.21)	–0.03 (–0.09 to 0.03)	.18

Secondary Cognitive Outcomes

The control group experienced a significant increase in perceived exertion, with a mean difference in Borg Rating of Perceived Exertion Scale score of 1.78 (95% CI 1.33-2.23; *P*=.04), indicating a notable rise in fatigue levels compared with the intervention group. By contrast, changes in quality of life, as measured by AQoL-6D, were not significant in either group (*P*=.18). System availability was evaluated using the SUS, and the experimental group achieved a mean usability score of 74.3 out of 100. Scores exceeding 70 were classified as good, indicating high system availability.

Discussion

Principal Findings

This study evaluated Open Care, a telemedicine app based on a deep learning model integrated with computer vision, for real-time monitoring and feedback of facial training exercises. The app aims to enhance rehabilitation outcomes in patients with nasopharyngeal cancer following radiation therapy. By leveraging the lightweight EffiFCNN-ResNet deep learning architecture and integrated network communication technologies, Open Care effectively captures and corrects

XSL•FO
RenderX

nonrigid facial training movements in real time. It also provides intuitive visual feedback and automated rehabilitation assessments through computer vision. The results indicate that, following use of the app, patients with nasopharyngeal cancer showed significant improvements in clinical metrics, including maximum mouth opening, training frequency for mouth opening, perceived severity, perceived benefits, perceived barriers, self-efficacy, action cues, behavior, and perceived fatigue, compared with the control group. These findings suggest that the Open Care app holds substantial potential for replicating successful rehabilitation interventions in patients with nasopharyngeal cancer. Consistent with existing literature, this study reinforces the critical role of structured, feedback-driven rehabilitation in alleviating trismus and improving quality of life for patients with NPC [62,63]. Our findings align with recent remote intervention studies, which highlight that integrating motivational elements and structured feedback significantly enhances patient exercise adherence and functional recovery outcomes [64-66]. This research further validates the positive impact of guided, regular training on symptom amelioration.

However, the "Open Care" methodology and technological pathway employed in this study diverge significantly from existing work. Most current related research predominantly relies on contact sensors or hardware devices (eg, wearable sensors or specialized rehabilitation equipment) coupled with periodic remote health education for intervention [67,68]. Outcome assessment in these approaches is largely based on manual measurements (eg, caliper measurement of mouth opening) and patient self-report questionnaires. While these traditional methods possess certain value, they generally exhibit inherent limitations: self-reported measurements are susceptible to subjective bias [69], real-time continuous monitoring of movement quality is challenging [70], intervention in daily patient training is often delayed [71], and hardware dependence elevates the barrier to entry and cost [72]. By contrast, "Open Care" facilitates entirely contactless, computer vision–based real-time motion analysis and immediate corrective feedback. It leverages high-efficiency deep learning models to automatically extract facial movement features and quantify similarity to standard movements for scoring, thereby mitigating human measurement error, minimizing intervention invasiveness, and significantly enhancing patient engagement and enjoyment [73]. This is likely a key reason why the experimental group in this study demonstrated more pronounced improvements in objective metrics [74]. Thus, unlike previous studies solely focused on remote follow-up education or single-assessment dimensions, the assessment methodology of "Open Care" demonstrates distinct innovation and advantages. It enables multimodal data fusion assessment, integrating objective training data (eg, movement accuracy and adherence) with subjective patient-reported outcomes, providing a more scientific and comprehensive quantification of rehabilitation efficacy [75]. Furthermore, Open Care represents an advancement in technological integration and interaction paradigms, innovatively incorporating real-time computer vision feedback into the clinical practice of remote rehabilitation for NPC. By offering an immersive and gamified training experience, the system effectively enhances patients' long-term adherence [73], a feat that is challenging to achieve with traditional remote education or simple video guidance [76].

Further in-depth analysis of the intervention data indicates that, in terms of objective clinical indicators, our clinical trial reported significant differences in maximum mouth opening and frequency of mouth-opening exercises, a promising finding that demonstrates better clinical outcomes than those reported in previous remote support studies [77-79]. After the intervention, maximum mouth opening increased from 36.98 to 39.05, corresponding to improvements in physical indicators related to oral health. In the intervention group, the mean increase in maximum mouth opening was 2.07 mm, with a median increase ranging from 1.5 to 2.6 mm. In addition, within 4 weeks after discharge, the number of patients with clenched jaws decreased, and the magnitude of this change was comparable to findings from previous studies involving patients with head and neck cancer [80,81], indicating the potential benefits of the intervention in improving specific health behaviors. Furthermore, treatment adherence is a critical determinant of the success of any preventive exercise program [15,82]. We observed that the intervention group performed significantly more exercises per week (mean 10.0, SD 3.5) than the control group (mean 4.2, SD 2.6), demonstrating the significant impact of our developed app on improving patient adherence to home rehabilitation exercises. However, despite the significant improvement in maximum mouth opening, 11 of 109 (10.1%) participants in the experimental group still exhibited clenched jaws during follow-up, suggesting that a longer intervention period may be required [66]. In addition, our study did not find that the app was associated with improvement in mouth-opening symmetry, which contrasts with previous studies. This discrepancy may be partly attributable to differences in study duration and in the type and level of functional support provided [83]. A comprehensive strengthening of the facial nerve structure and musculature is required for symmetry to improve, and short-term interventions are ineffective [84].

In terms of improvements in rehabilitation training behaviors, the remote health care intervention group in this study, compared with the standard care control group, demonstrated significant enhancements in patients' perceived benefits and self-efficacy. These findings are consistent with previous studies [85-87], including one by Schlieter et al [88], which examined the impact of remote health care–based educational programs on improving oral health training behaviors in pregnant women. The results of that randomized controlled trial showed significant improvements in oral health beliefs and clinical training indicators, similar to our study, suggesting that remote health care interventions can effectively improve individuals' health cognition and behavior change [89]. This supports the rational use of such models to improve health behaviors across a wide range of environments and populations [90,91]. The remote health care tool developed in this study provides patients with real-time supervision of training movements, corrective prompts, and periodic visual training score reports. This semisupervised, freely accessible intervention appears to be an effective approach for enhancing perceived benefits and self-efficacy [92]. Compared with traditional educational methods, it is more cost-effective and offers greater penetration [93]. The significant

XSL•FO
RenderX

improvements in Perceived Severity and Perceived Benefits further validate the effectiveness of the intervention. Our app, using the EffiFCNN-ResNet deep learning model and computer vision, tracks participants' mouth-opening movements to facilitate appropriate exercise and training plans while providing personalized feedback for patients at different levels. This may also effectively promote the growth of self-efficacy among patients [94], thereby contributing to clinical evidence for personalized health care design indicators in remote health care, as reported in a meta-analysis [95].

This study yielded more substantial changes in action cues and perceived barriers than previous research. In addition, there was a significant increase in the frequency of weekly mouth-opening training behavior. This confirms the promising potential of health apps that use computer vision for personalized training correction and feedback [96]. These apps overcome the spatial limitations of traditional methods and provide more effective interaction and facilitation for monitoring, feedback, and motivation in rehabilitation training [73]. Integrating the activation of behavioral cues into digital intervention tools aims to guide patients with nasopharyngeal cancer to implement training as a health behavior by prompting and facilitating modifications to their decision-making framework [97]. This finding is consistent with previous studies [98-100]. The implementation of multiple strategies can effectively bridge the gap between patients and professional rehabilitation knowledge, reduce training costs, diminish perceived barriers to mouth training as a health behavior, narrow the gap between training cognition and practice, and encourage patients to demonstrate commitment to health behaviors through mouth training. Consistent with the findings of Tore et al [101], telerehabilitation yields a considerably higher standard of physical therapy than self-management. This may be attributable to the duration and quality of training tasks [101,102]. However, there was no statistically significant increase in perceived susceptibility. This may be attributable to the fact that participants in the sample shared a common disease group, which tends to result in more consistent perceptions of specific health hazards [103]. Nonetheless, perceived susceptibility continued to increase after the intervention, which may indicate the intervention's potential.

Furthermore, we propose a reliable and objective intelligent assessment method for mouth-opening rehabilitation in clinical practice. A deep learning model, EffiFCNN-ResNet, was developed to address the needs of nonrigid, markerless, real-time facial capture, tracking correction, and automated assessment for patients with nasopharyngeal cancer. By combining the spatial processing strengths of FCNNs with a lightweight EffiResNet backbone [104], our model achieves fast and accurate facial detection, addressing the trade-offs between computational complexity and execution time. Performance analysis shows that EffiResNet demonstrates strong robustness, quickly reducing failure rates as the error threshold increases, in contrast to other ResNet variants [105,106], which are less adaptable in error-prone environments. The model shows stable performance across varying error magnitudes and excels in dynamic spatial changes [107]. In classification tasks, EffiResNet outperforms other ResNet variants in recall without sacrificing precision. Overall, EffiFCNN-ResNet excels in robustness, stability, and spatial awareness, offering an efficient solution for real-time facial landmark detection in complex environments. Its design enhancements, including the rescaled ResNet backbone and large-kernel depthwise convolutions, significantly contribute to its performance, positioning it as a promising tool for advanced facial recognition tasks. However, it is important to note that, due to certain objective factors such as limited data availability, the model may occasionally exhibit errors in specific situations. These errors primarily result from insufficient diversity in the training data or a lack of specific facial action samples, which can affect the model's accuracy when encountering rare or abnormal actions. Nonetheless, these occasional errors are not substantial enough to notably degrade overall model performance. With continued data collection and model training, these errors are expected to diminish, thereby further enhancing the model's precision.

It is noteworthy that participants reported positive feedback regarding their training experience with the Open Care app, along with a significant reduction in fatigue levels. This positive user experience not only attests to the app's utility and user-friendliness but also highlights its important role in promoting sustained patient engagement in rehabilitation training. Because of the potential presence of uncontrolled external factors during the intervention period, such as other treatments received by participants and changes in lifestyle habits, these elements may have interfered with the study outcomes, particularly for indicators closely related to daily quality of life, such as AQoL-6D [108]. Nevertheless, based on responses from the user experience questionnaire, the researchers confirmed that the app successfully achieved its objectives of precise training movement monitoring and targeted feedback. The majority of respondents regarded the electronic exercise intervention as beneficial. They believed that incorporating interactive design and real-time feedback into exercise programs enhances enjoyment while also encouraging individuals to take the initiative to engage in this healthy behavior. Regarding comfort, most participants reported that the electronic exercise intervention was more personalized and better aligned with their individual rehabilitation needs. Thus, patients with NPC who have undergone radiotherapy may benefit from telemedicine apps that use deep learning and computer vision technologies [109], and this potential should not be overlooked.

Furthermore, Open Care offers substantial advantages in terms of comprehensive benefits and clinical utility. Compared with conventional rehabilitation models that primarily rely on outpatient visits and manual supervision, this app, through its automated real-time monitoring and feedback mechanisms [110], significantly reduces dependence on specialized rehabilitation therapists. This, in turn, minimizes long-term human resource investment and associated costs, aligning with current health care policy orientations toward efficient, accessible, and intelligent services [111], and serving as an important decision-making factor for health care providers when considering new therapeutic interventions [112]. At the same time, because training and assessment can be completed remotely, the frequency of patient hospital visits is substantially reduced. This not only saves transportation, escort, and

XSL•FO
RenderX

time-related costs for patients but also alleviates patient load on health care institutions [113]. From a broader health system perspective, this standardized and scalable intervention approach is particularly well-suited for resource-limited regions. It enables expanded service coverage and equity while maintaining rehabilitation quality by leveraging digital means to enhance high-quality service delivery and decentralize health care resources, thereby optimizing overall resource allocation efficiency [114]. More importantly, through continuous and objective data collection, Open Care offers the potential for early intervention and dynamic adjustment of rehabilitation plans. This proactively mitigates the risk of secondary health complications and additional medical expenditures that may arise from improper or delayed rehabilitation [115]. From the perspective of health care payers, such preventive, data-driven health management tools help control overall health care expenditures, consistent with the ongoing policy shift from treatment-centric to health-centric approaches [116]. Consequently, Open Care not only provides immediate cost-saving benefits but also, in the long term, strengthens the resilience and value proposition of health care services, addressing the shared objectives of multiple stakeholders, including patients, health care institutions, payers, and governmental bodies.

Limitations and Future

However, our investigation is not without limitations. First, the sample size was limited and comprised individuals from several nearby tumor departments. This may have resulted in population clustering, which is not ideal for deriving generalizable conclusions. Furthermore, during the pre-experiment phase, some patients with limited digital health proficiency were unable to independently troubleshoot the equipment used in the experimental procedure. In addition, as an intervention app based on an augmented reality environment, the system may be unsuitable for patients who are sensitive to sensory stimulation at the design level. Moreover, although the trial demonstrated short-term user engagement, the long-term sustainability of engagement and activity remains uncertain. The advancement of tools for capturing, monitoring, and evaluating nonrigid facial models must contend with a wide range of human facial expressions and movements, including complex mouth movements and subtle eye and eyebrow motions. The recognition accuracy of the model we developed still has room for improvement. Precisely capturing and tracking these subtle variations is particularly challenging under low-resolution or real-time conditions. Resource limitations may also affect system response time and user experience [117]. The experiment lasted only 4 weeks; moving forward, it will be essential to extend the intervention duration and further refine the app design to optimize outcomes. In conclusion, future research should investigate the applicability of Open Care for patients with NPC living in diverse and complex environments and at different stages of rehabilitation. Furthermore, in light of ongoing technological advances and integration of user feedback, continuous refinement and expansion of app functionalities will be critical to ensuring sustained effectiveness and broad applicability.

Conclusion

This study successfully developed “Open Care,” a novel telemedicine app using the EffiFCNN-ResNet deep learning model and computer vision for real-time facial motion tracking and assessment in NPC rehabilitation. Our randomized controlled trial demonstrated significant efficacy in improving objective clinical metrics, such as maximum mouth opening and training frequency, as well as a comprehensive range of patient-reported outcomes, including perceived severity, perceived benefits, perceived barriers, self-efficacy, action cues, enhanced training behavior, and reduced perceived fatigue. These findings highlight the substantial potential of “Open Care” to enhance patient adherence, functional recovery, and quality of life in NPC rehabilitation, offering an accessible, cost-effective, and scalable digital solution for clinical practice, particularly in resource-limited settings. Future research will focus on refining model accuracy, extending intervention duration, and exploring applicability to broader head and neck cancer populations, further strengthening the role of artificial intelligence–driven telemedicine in oncological supportive care.

Acknowledgments

The authors thank the anonymous reviewers and the Human Subjects Research Ethics Committee for granting access to patients, as well as all participants for their collaboration in this study. This study was supported by the National Natural Science Foundation of China (72471140), the National Key R&D Program (grant 2022YFB3303303, First label), and the Fundamental Research Funds for the Central Universities (grant YG2023ZD10). In addition, the authors gratefully acknowledge the valuable support provided by Master Yang Yange, Master Wu Hantian, Master Liu Yongzhi, Master Yuan Yuyi, and Dr. Wang Luyao during the software interface design stage. During the preparation of this work, the author(s) conducted all research and writing manually, ensuring the accuracy and quality of the content. After completion, the author(s) reviewed and edited the manuscript as needed and take full responsibility for the content of the publication.

Abstract

Background: Use of effective contraceptive methods (ECMs) reduces maternal mortality. Person-centered counseling increases uptake, but barriers to high-quality counseling persist. Telehealth may improve access to comprehensive contraceptive care, but its effectiveness remains unclear.

Objective: This study assesses the effectiveness and acceptability of tailored, interactive telehealth contraceptive counseling (TECC) compared with in-person counseling.

Methods: We conducted a systematic review and meta-analysis of English-language randomized controlled trials (RCTs) comparing TECC with in-person counseling for women and girls of any age and setting. We searched MEDLINE, Embase, Web of Science, and the Cochrane Library from inception through October 15, 2025. Outcomes were use of ECM less than 6 months from intervention (primary outcome); use of ECM at 6-12 months; use of long-acting reversible contraception (LARC); choice of ECM; choice of LARC; satisfaction with counseling; and method switching. Two researchers assessed risk of bias (RoB) using Cochrane RoB 2, certainty of evidence using GRADE (Grading of Recommendations Assessment, Development, and Evaluation), and performed meta-analysis using a random-effects model. The protocol was registered with PROSPERO (International Prospective Register of Systematic Reviews) a priori (CRD42023404402). No specific funding was received.

Results: Eight RCTs (RoB: low, n=4; moderate, n=2; and high, n=2) and 1 cluster RCT (moderate-to-high RoB) were included in the review, with 5353 participants across all included studies. Eight studies evaluated TECC as an adjunct to in-person care (hybrid model) and 1 as a standalone model, of which 7 and 1, respectively, contributed outcome data for the meta-analyses. Certainty of evidence was low to very low. The pooled effect of 4 studies of TECC on ECM use less than 6 months showed no clear evidence of an effect (relative risk [RR] 1.10; 95% CI 0.95-1.29). The pooled effect of 4 studies of TECC on choice of ECM (RR 1.07; 95% CI 0.96-1.18) likewise showed no clear effect. The pooled effect of 4 studies of TECC on ECM use at 6-12 months showed a small but statistically significant (*P*=.04) effect in favor of TECC, narrowly excluding the null (RR 1.07; 95% CI 1.002-1.130). Because of high statistical and clinical heterogeneity (I2=87%-96%), results for LARC choice (2 studies) and LARC use at 0-6 months (2 studies) and 6-12 months (2 studies) were narratively described. The evidence for these outcomes was very uncertain. Narrative analysis of satisfaction across 2 studies showed no difference in effect. There were no data on method switching to support the analysis.

Conclusions: Current evidence suggests, with low certainty, that adjunct TECC, when delivered alongside in-person care, shows little to no effect on contraceptive use compared with in-person care. For use at 12 months, method choice, LARC use, and satisfaction compared with in-person care, the evidence is very uncertain. Future research should prioritize adequately powered

evaluations of standalone models and assess how tailoring, timing, and delivery influence effectiveness, including long-term use and method switching.

(JMIR Mhealth Uhealth 2026;14:e88887) doi:10.2196/88887

KEYWORDS

contraceptive counseling; systematic review; telemedicine; randomized controlled trials; meta-analysis; long-acting reversible contraception; mobile health

Introduction

Contraception is one of the most cost-effective public health strategies for reducing maternal mortality and improving reproductive, perinatal, and child health. Many unintended pregnancies and maternal deaths globally could be averted by satisfying the unmet need for modern contraceptives [1-3]. Women and girls continue to face barriers to access due to misconceptions and concerns about side effects, social stigma, provider bias, geographic barriers, and health system constraints [4]. Barriers disproportionately affect already vulnerable populations. Person-centered contraceptive counseling (CC) aims to support informed contraceptive decision-making by addressing misconceptions and side effects and tailoring counseling to the individual's preferences, values, needs, medical eligibility, and reproductive life goals. High-quality counseling has been shown to improve the use and continuation of effective modern contraception [5].

The core components of person-centered CC, such as eliciting individual preferences and addressing misconceptions and side effect concerns, could in principle be delivered remotely through interactive telehealth formats. The WHO defines telehealth as the use of electronic information and communication technologies for the "delivery of health care services, where patients and providers are separated by distance" [6]. Telehealth can offer a convenient, low-cost, and private alternative to in-person care. It can also expand access to person-centered care in settings where geographic or system constraints limit access through messaging, web-based tools, mobile apps, or virtual consultations [7].

Telehealth contraception services have been used for more than a decade, with commercial services expanding in response to technological advances and the COVID-19 pandemic. These digital services range from prescription and delivery services, 1-way messaging, and decision aids to more comprehensive counseling delivered by telephone or video. Several US-based observational studies report high acceptability, but evidence of effectiveness remains limited and heterogeneous [8-12]. Previous reviews have grouped heterogeneous digital contraceptive services, including 1-way messaging and nontailored models. However, none have specifically examined tailored and interactive telehealth contraceptive counseling (TECC) [11-15].

Our definition of TECC entails bidirectional communication and individualized content aligned with users' preferences, reproductive goals, and medical eligibility. Although TECC can conceptually function as a standalone counseling modality, most existing telehealth contraception trials have evaluated hybrid models delivered as an adjunct to in-person care, and the extent to which TECC can substitute for in-person counseling remains unknown. We aimed to systematically assess the effectiveness and acceptability of standalone and hybrid TECC compared with any form of standard in-person contraceptive care, including verbal or written information delivered individually or in a group setting.

Methods

Search Strategy

We followed the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines (see Multimedia Appendix 1) [16]. The protocol was registered a priori with PROSPERO (International Prospective Register of Systematic Reviews; registration number CRD42023404402) [17]. We searched MEDLINE, Web of Science, Embase, the Cochrane Library from inception to October 15, 2025, using MeSH (Medical Subject Headings) and free-text terms, with a validated randomized controlled trial (RCT) filter. A snowball search was conducted to identify references cited by and citations of eligible studies identified through the database searches. The full search strategies for all databases are available in Multimedia Appendix 2.

Eligibility Criteria

We included single and cluster RCTs comparing TECC with routine in-person CC among women and girls of any age or setting. Only full, published, English-language reports were eligible; abstracts and study protocols were excluded. Intervention eligibility required meeting 3 core domains: telehealth delivery modality, interactivity, and tailoring. Telehealth delivery modalities included phone or video calls, voice or SMS text messaging, mobile apps, and websites. Interactivity implied bidirectional communication to some degree, excluding, for example, unidirectional information delivery or reminders. Tailoring meant that interventions were individualized to users' input, generating adapted output based on at least one of the following domains: contraceptive preferences, reproductive goals, medical history, or method-specific information on benefits, side effects, and effectiveness. Interventions could be delivered in real time or asynchronously, with or without human involvement. Interventions could be delivered before, during, or after a clinical visit and could complement or substitute for in-person clinical care. We categorized models in which TECC was delivered as an adjunct to in-person care as hybrid models. Hybrid models were eligible if the telehealth component independently met the tailoring and interactivity criteria. Shared decision-making tools used in provider-led consultations were excluded. Our

XSL•FO
RenderX

comparator was any form of routine CC delivered in person as verbal or written information, provided individually or in groups. Studies using telehealth as a comparator were excluded. The rationale for excluding other digital interventions as comparators was to assess the effect of the telehealth component on CC. An overview of the concepts in our definition of TECC is provided in Multimedia Appendix 3.

Outcomes

Our primary outcome was the use of any effective contraceptive method (ECM) up to 6 months after the intervention. We distinguished use from continuation or adherence to a specific method. ECM was defined as long-acting reversible contraception (LARC), including the progestin implant and hormonal or copper intrauterine devices; combined oral contraceptives; progestin-only pills; progestin injections; the contraceptive patch; the contraceptive ring; and sterilization—methods with typical-use failure rates of less than 10% per year [18]. Additional outcomes were (1) ECM use at 6-12 months; (2) LARC use at less than 6 months; (3) LARC use at 6-12 months; (4) choice of ECM at the time of counseling; (5) choice of LARC at the time of counseling; (6) satisfaction with counseling at less than 6 months; and (7) method switching.

"Use" was assessed based on self-reported or recorded use in follow-up surveys or clinical records. Where multiple time points were reported, we prioritized the time point that enabled comparison across the greatest number of studies or, secondarily, the latest time point within the specified range. "Choice" was defined as documented intention to use a specific method immediately after counseling. We defined "switching" as a documented change from no method or a less effective method to a more effective ECM. "Satisfaction" included any reported measure of satisfaction with counseling up to 6 months after the intervention.

Study Selection

After deduplication of the final search results, we imported records into Rayyan for screening. Three reviewers (MW, AK, and ME) independently screened titles and abstracts. We unblinded the selection process after the initial screening and resolved discrepancies through discussion. We retrieved and assessed full-text articles against the inclusion criteria, and disagreements were resolved through discussion until consensus was reached. Records excluded at the full-text review stage and the reasons for exclusion are provided in Multimedia Appendix 4.

Data Collection and Quality Assessment

Data on publication year, study design, setting, participant characteristics, intervention, comparator, and raw data for each outcome were extracted by one reviewer (MW) from full-text articles, supported by GPT-4o (OpenAI, May 2024) as a preliminary extraction tool for nonoutcome study characteristics (population, setting, intervention, and comparator descriptions). All AI-assisted outputs were reviewed and corrected against the source articles by MW and then verified by ME. Studies in which data relevant to our outcomes were grouped in a way that did not permit the extraction of stratified data, or in which outcome data were missing, were excluded from the analysis.

Risk of bias (RoB) was assessed independently by reviewers MW and ME for each outcome using the Cochrane RoB 2 tools for RCTs and cluster RCTs, respectively [19]. Five domains were evaluated, including (1) bias arising from the randomization process, (2) bias due to deviations from intended interventions, (3) bias due to missing outcome data, (4) bias in outcome measurement, and (5) bias in the selection of the reported result. Discrepancies were resolved through discussion until consensus was reached.

Assessment of the overall certainty of evidence was performed using the GRADE (Grading of Recommendations Assessment, Development, and Evaluation) approach for each outcome. GRADE ratings were independently assessed by MW and ME; discrepancies were resolved through discussion until consensus was reached [20]. As we included only RCTs, the certainty of evidence started as high and was downgraded based on RoB, inconsistency, imprecision, indirectness, and publication bias. Statistical heterogeneity was quantified using the I^2 statistic in accordance with the Cochrane Handbook for Systematic Reviews of Interventions, with 50%-90% potentially representing substantial heterogeneity and 75%-100% representing considerable heterogeneity. Our interpretation was informed by the magnitude and direction of effects, the number and size of contributing studies, and the plausibility of clinical or methodological diversity. We considered downgrading for inconsistency if I^2 exceeded 50%. Imprecision was assessed using the optimal information size (OIS) criterion, in accordance with GRADE guidance for systematic reviews [21]. For each outcome eligible for meta-analysis, OIS was determined using the reference values reported by Guyatt et al [21], applying the observed pooled control event rate and the GRADE-recommended default relative risk (RR) reduction of 25%, with α=.05 and power of 80%. Certainty of evidence was downgraded by 1 level for imprecision when the total sample size contributing to the pooled estimate fell below the corresponding OIS threshold. Where the OIS threshold was met but the 95% CI of the pooled effect crossed or narrowly excluded the line of no effect, we additionally considered whether the CI excluded an appreciable effect, using the GRADE default RR reduction threshold of 25% for appreciable benefit or harm. For outcomes not eligible for meta-analysis (LARC use at 6-12 months, choice of LARC, and satisfaction with counseling), imprecision was judged by comparing the combined sample size across contributing studies with the OIS reference and by inspecting the width of individual study CIs in relation to the line of no effect. Imprecision judgments for each outcome are documented in the footnotes to Table 3.

Data Synthesis

We grouped studies for each synthesis according to outcome and follow-up time point. Studies reporting data in a comparable format were included in random-effects meta-analyses when at least 2 comparable studies were available. We calculated RRs with 95% CIs for all outcomes based on available data from intention-to-treat study groups, deriving them from raw data or alternative effect measures, and presented pooled results as forest plots. Heterogeneity was assessed using the I^2 statistic and interpreted in relation to the direction and consistency of

XSL•FO
RenderX

effects across studies. For outcomes for which data quality or heterogeneity did not support meta-analysis, we reported results descriptively and interpreted them exploratorily. Prespecified exploratory subgroup analyses were performed by country income level (low- and middle-income countries [LMICs] versus high-income countries [HICs]). One included cluster RCT (Dehlendorf et al [22]) was randomized at the provider level (28 providers; mean cluster size of ≈27). Raw event counts per study arm were extracted from the published article. As the reported provider-level intracluster correlation coefficient was approximately 0, the corresponding design effect was ≈1.0, and no design-effect adjustment was applied. Sensitivity analyses examined the effect of publication year (before vs after 2015), which stratifies the approximately 20-year period during which telemedicine has been used for reproductive health, and low versus moderate or high RoB. Where meta-analysis was not feasible, we summarized findings narratively using incidence ranges. We conducted analyses using SPSS (version 30; IBM Corp) and Review Manager (RevMan 5, desktop version).

Ethics Considerations

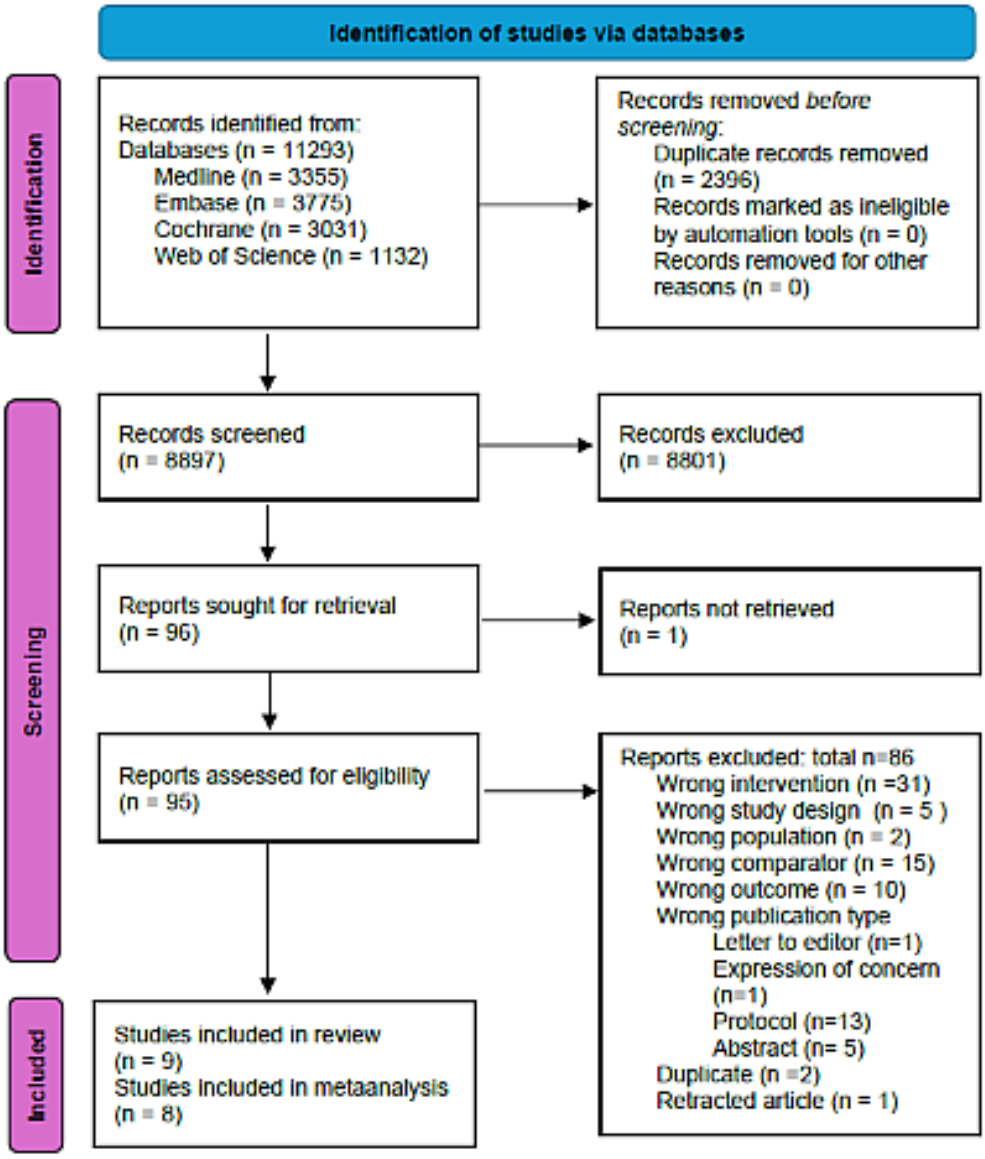
This review used only publicly available data and required no ethical approval. There was no funding source for this study. GPT-4o (OpenAI, May 2024) was used as a preliminary tool for data extraction of setting, population, intervention, and comparator characteristics from full-text articles; for the generation of a conceptual figure; and to support language editing. All AI-assisted data extraction outputs were verified and corrected against the source articles by reviewer MW and subsequently by ME. All analyses, interpretations, and conclusions were independently conducted by the authors. Outcomes related to potential harms were not prespecified, which we acknowledge as a limitation of the protocol.

The initial protocol was amended in the following ways before data extraction: outcomes were reorganized to specify a single primary outcome; the population eligibility criterion was clarified to restrict inclusion to women and girls of any age (including adolescents); men and couples were excluded; and subgroup and sensitivity analyses were added. The revised protocol also clarified our a priori intent to restrict the search to English-language publications.

Patient and Public Involvement

Patients or members of the public were not involved in the design, conduct, reporting, or dissemination of this systematic review.

Results



Study Selection and Characteristics

From 8897 records screened, 8 individual RCTs and 1 cluster RCT met the inclusion criteria, involving 5353 participants from 5 HICs and 4 middle-income countries. The PRISMA flowchart illustrates the selection process (Figure 1), and Table 1 presents the study characteristics and sample sizes. Included studies were conducted in antenatal care [23,24], postabortion care [25-27], and routine contraceptive services [22,28-30]. Sample sizes ranged from 86 to 1475 participants.

All interventions fulfilled the 3 core components of our definition of TECC—telehealth delivery modality, interactivity, and tailoring—but the degree of interactivity and tailoring varied. Eight were hybrid models, delivered in addition to, before, during, or after an in-person clinical visit. Only one study [27] tested a standalone model that substituted for in-person care using telephone calls, but recruitment was terminated after only 125 of the 1222 (10.23%) planned enrollment due to changes in the comparator condition in response to the COVID-19 pandemic. The TECC modality and degree of interactivity ranged from potentially interactive voice [25,26] or SMS text messaging [23] with interaction on demand; asynchronous, self-guided computer- [28,29] or tablet-based modules [22,30]; to video or telephone calls delivered in real time [24,27]. Provider involvement in the TECC component, therefore, ranged from minimal to high. Tailoring also varied, ranging from SMS text or voice messages tailored to an already chosen method [23,25,26] to decision aids limited to life preferences and excluding medical criteria [29], comprehensive tailored decision aids [22,28,30], and real-time individualized assessments [24,27].

Table 1. Study characteristics.

Study[a]	Country (income classification)[b]	Setting	Population	Study design	Total sample size, n	Participants per arm, n
Reiss et al [25]	Bangladesh (lower middle income)	Public postmenstrual regulation services	Women aged 18-49 following menstrual regulation, with access to a personal mobile phone	RCT[c] (2 arms)	969	Intervention: 485 and control: 484
Stephenson et al [29]	United Kingdom (high income)	Sexual and reproductive health clinics and online booking system	Women aged 15-30 with current or future contraceptive needs	RCT (2 arms)	927	Intervention: 464 and control: 463
Harrington et al [23]	Kenya (lower middle income)	Kenyan public hospitals (antenatal to postpartum)	Women and girls aged >14 years, pregnant ≥28 weeks' gestation, and HIV negative, with daily phone access (partners optional)	RCT (2 arms)	260	Intervention: 130 and control: 130
Garbers et al [28]	United States (high income)	Urban family planning clinics	Women aged >16 years at risk of unintended pregnancy and attending family planning visits	RCT (3 arms)[d]	1475	Intervention: 985 and control: 490
Saglam Aksut and Inam [24]	Turkey (upper middle income)	Antenatal primary care	Pregnant women registering for antenatal care and using smartphones	RCT (2 arms)	86	Intervention: 43 and control: 43
Smith et al [26]	Cambodia (lower middle income)	Marie Stopes abortion clinics in peri-urban and rural settings	Women aged >17 years seeking abortion services, with access to a personal or predominantly private smartphone	RCT (2 arms)	500	Intervention: 249 and control: 251
Dehlendorf et al [22]	United States (high income)	Urban family planning centers, public health centers, college student health centers, and hospital outpatient clinics	Women aged 15-45 seeking contraception and not planning pregnancy within the next 7 months	Cluster RCT (2 arms)	Providers: 28; participants: 758	Providers—intervention: 15 and control: 13; participants—intervention: 407 and control: 351
Madden et al [30]	United States (high income)	Obstetrics/gynecology clinics at academic centers	Women aged 18-45 at risk of unintended pregnancy and planning to discuss contraception	RCT (2 arms)	253	Intervention: 167 and control: 86
Reynolds-Wright et al [27]	United Kingdom (high income)	Public abortion care center in Edinburgh	Pregnant individuals aged >16 years seeking medical abortion at home	RCT (2 arms)	125	Intervention: 63 and control: 62

[a]Studies are listed in the order in which the data were first extracted.

[b]Country income classes according to The World Bank classification.

[c]RCT: randomized controlled trial.

[d]Only 1 intervention arm met the inclusion criteria and is reported in this review.

Comparators were standard in-person CC, with or without printed materials. In 1 trial [29], controls were offered delayed access to TECC after study completion. Table 2 outlines the intervention and comparator characteristics. Studies grouped by outcome and RoB assessment are presented in Figure 2 (also see [22-30]). Multimedia Appendix 5 details study outcomes and findings, and Multimedia Appendix 6 details how each intervention met the tailoring and interactivity criteria, as well as additional intervention characteristics that may have modified effects. GRADE-assessed certainty of evidence ranged from low to very low across outcomes. The GRADE assessment is presented in the summary of findings (Table 3), and a breakdown of each GRADE assessment is provided in Multimedia Appendix 7; 7 hybrid models and 1 standalone model contributed outcome data to the meta-analyses. One hybrid model contributed data for the outcome of satisfaction, which was reported descriptively [24].

XSL•FO
RenderX

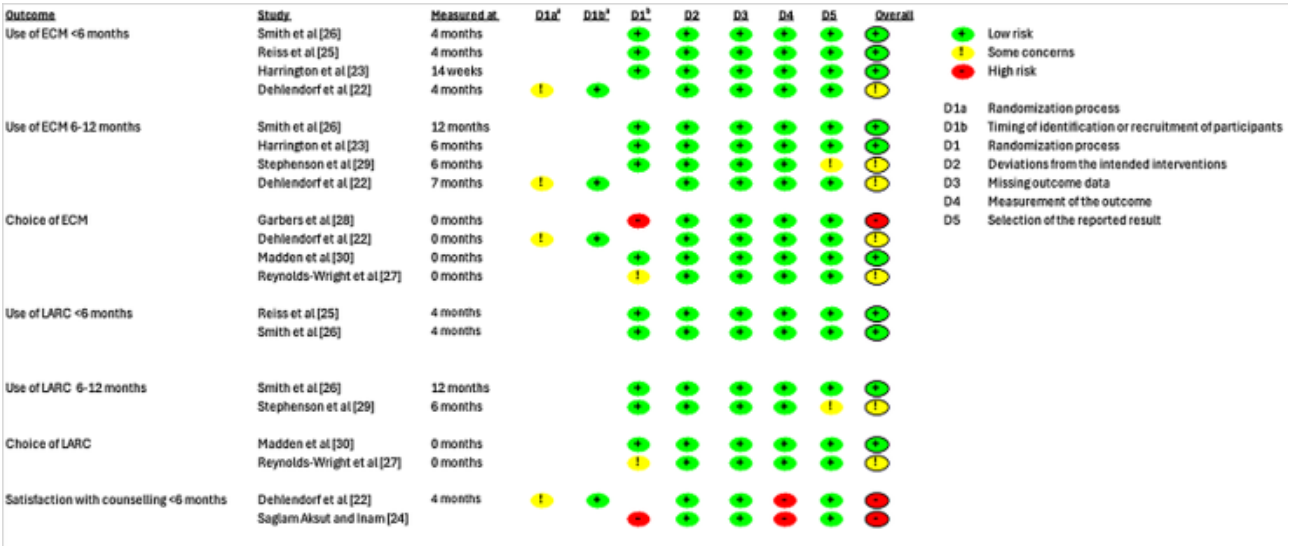

Table 2. Intervention and comparator characteristics.

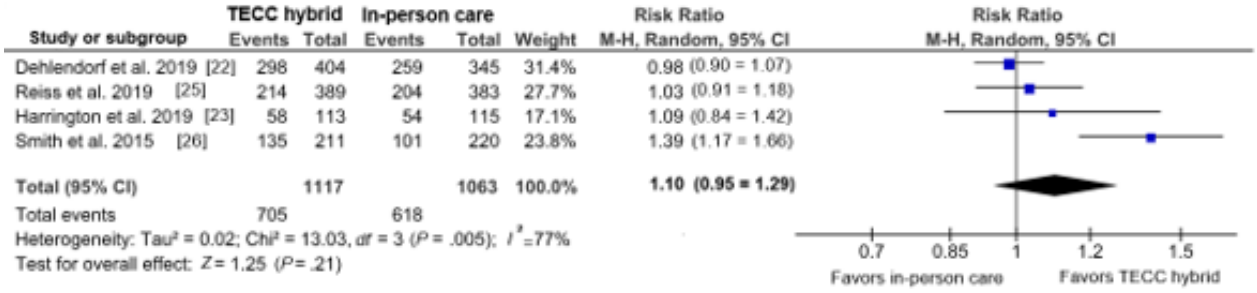
Study[a]	Relation to clinical care	Intervention	Timing and duration	Comparator
Reiss et al [25]	Hybrid/adjunct	Automated interactive voice messages delivered to mobile phones providing contraceptive method information and addressing concerns; messages tailored to the method chosen at menstrual regulation and updated if the method is switched; option to request callbacks for additional individual counseling	Delivered during the 4 months following in-person menstrual regulation; included 7 weekly messages and 4 fortnightly messages over 4 months	Routine in-person menstrual regulation counseling care without digital follow-up
Stephenson et al [29]	Hybrid/adjunct	Mobile-optimized website with videos, frequently asked questions, and a tailored decision aid generating 3 matched contraceptive methods based on user-reported preferences; designed to support informed choice before in-person counseling	Self-directed use before a clinical appointment	Routine in-person contraceptive counseling; website access offered after study follow-up
Harrington et al [23]	Hybrid/adjunct	SMS text messages tailored to user language and gestational age/postpartum stage, prompting user responses; nurses engaged in asynchronous 2-way communication; optional partner enrollment included	Weekly automated messages delivered from 28 weeks of gestation to 6 months postpartum	Routine in-person antenatal and postpartum care with no SMS text message follow-up
Garbers et al [28]	Hybrid/adjunct	Audio-assisted touchscreen decision aid eliciting user preferences and medical history, producing a traffic-light classification of contraceptive methods (green=most suitable; yellow=less effective or less suitable; and red=medically contraindicated methods); designed to support precounseling decision-making	Self-directed, 1-time use on a touchscreen laptop in the waiting room before a clinical appointment	Routine in-person contraceptive counseling and attention-matched control (demographic survey on laptop and generic printed handout)
Saglam Aksut and Inam [24]	Hybrid/adjunct	Video counseling calls using a structured handbook and visual demonstration of contraceptive methods before in-person visits; real-time tailored information provided with opportunity for user questions; partners included where possible	Provided in the third trimester of pregnancy as 2 sessions of approximately 50 minutes each, delivered 2 weeks apart	Routine in-person contraceptive counseling during antenatal visit at 24 weeks of gestation
Smith et al [26]	Hybrid/adjunct	Automated interactive voice messages providing tailored contraceptive information based on current method use; optional reminders for method adherence and option to request counseling callbacks	Initiated within 1 week after abortion and continued up to 3 months after abortion; fortnightly messages	Routine in-person postabortion care; no digital follow-up
Dehlendorf et al [22]	Hybrid/adjunct	Web-based interactive decision aid incorporating educational content, user preferences, reproductive life goals, and medical eligibility criteria; generates a personalized summary report with recommendations for shared decision-making during consultation	Self-directed, 1-time use on a tablet in the waiting room before a clinic visit	Routine in-person contraceptive counseling
Madden et al [30]	Hybrid/adjunct	Tablet-based interactive decision aid assessing user preferences, reproductive and medical history, prior contraceptive use, and preferences; generates top 3 tailored contraceptive recommendations and provides printed personalized information	Self-directed, 1-time use on a tablet in the waiting room before a clinic visit	Routine in-person contraceptive counseling with attention-matched control (demographic and reproductive survey on tablet plus generic handout)
Reynolds-Wright et al [27]	Standalone	Telephone counseling providing abortion-related counseling and postabortion contraceptive information; tailored real-time discussion during the call	Delivered at booking or another chosen time; replaced in-person counseling; followed by in-person ultrasound and medication provision; 1-time session	Routine in-person counseling

[a]Studies are listed in the order in which the data were first extracted.

XSL•FO
RenderX

Figure 2. Studies grouped by outcome and Risk of Bias (RoB) related to outcome. [a]: Cluster-randomized trial domain. [b]: Individual randomized trial domain.

Risk of Bias



RoB assessments for each outcome are presented in Figure 2. Four studies [23,25,26,30] had low RoB across all domains and outcomes. The most frequent concerns related to the randomization process, including sequential allocation to control and intervention arms, imbalanced distribution of study groups across study sites, changes to the randomization procedure [28], and small but potentially meaningful baseline imbalances [22,24,27,28].

Stephenson et al [29] had moderate RoB in domain 5 (selection of the reported result) due to post hoc changes in study outcomes when the trial expanded from a feasibility study to an effectiveness trial without a prespecified analysis plan. We therefore judged this outcome to have moderate RoB. We classified the studies by Saglam Aksut and Inam [24] and Dehlendorf et al [22] as having high RoB for satisfaction with counseling outcomes because outcome measurement was conducted by study staff, creating a risk of social desirability bias.

Use of ECMs

Four studies (n=2180) reported on our primary outcome, use of ECM less than 6 months after the intervention. The meta-analysis indicated a small positive but nonsignificant (P=.21) effect of TECC compared with standard care (SC; RR 1.10; 95% CI 0.95-1.29; I^2=77%; Figure 3; see also [22,23,25,26]). The certainty of evidence was low, downgraded for inconsistency and imprecision (Table 3).

Figure 3. Forest plot of four studies comparing hybrid telehealth contraceptive counseling (TECC) with in-person care for effective contraceptive method use within 6 months of the intervention. M-H: Mantel–Haenszel method.

Table 3. Summary of findings and GRADE[a].

Outcome and follow-up	Patients (studies), N	Relative effect, risk ratio (95% CI)	Absolute effects (95% CI)			Certainty	What happens
			Standard care	TECC[b]	Difference		
Use of ECM[c] <6 months	2180 (4 RCTs[d])[e]	1.10 (0.95-1.29)	582 per 1000	646 per 1000 (553-751)	64 more per 1000 (from 29 fewer to 169 more)	Low[f,g]	TECC may result in little to no difference in use of any effective contraceptive method at 0-6 months.
Use of ECM at 6-12 months	2043 (4 RCTs)[e]	1.070 (1.002-1.130)	646 per 1000[e]	685 per 1000 (648-730)[e]	39 more per 1000 (from 1 more to 84 more)	Low[h,i]	TECC may result in a slight increase in use of any effective contraceptive method at 6-12 months.
Use of LARC[j] <6 months	1203 (2 RCTs)	1.62	129 per 1000	210 per 1000	81 more per 1000	Very low[k,l]	The evidence is very uncertain about the effect of TECC on use of LARC at 0-6 months.
Use of LARC 6-12 months	1042 (2 RCTs)[e]	Not estimable	N/A	N/A[m]	N/A	Very low[n,o,p]	The evidence is very uncertain about the effect of TECC on use of LARC at 6-12 months.
Choice of ECM	2590 (4 RCTs)	1.07 (0.96-1.18)	564 per 1000	603 per 1000 (547-660)	39 more per 1000 (from 17 fewer to 96 more)	Very low[g,q,r]	The evidence is very uncertain about the effect of telemedicine on the choice of effective contraceptive methods.
Choice of LARC	366 (2 RCTs)	Not estimable	N/A	N/A	N/A	Very low[n,s]	The evidence is very uncertain about the effect of telemedicine on the choice of LARC.
Satisfaction with counseling <6 months	749 (2 RCTs)	Not estimable	N/A	N/A	N/A	Very low[t,u,v]	The evidence is very uncertain about the effect of TECC on satisfaction with counseling up to 6 months.
Use of ECM <6 months in LMIC[w] or low RoB[x]	580 (2 RCTs)[e]	1.20 (1.03-1.30)	500 per 1000[e]	600 per 1000 (515-695)[e]	100 more per 1000 (from 15 more to 195 more)	Very low[y,z]	The evidence is very uncertain about the effect of TECC on use of any effective contraceptive method at 0-6 months in LMICs.

[a]GRADE: Grading of Recommendations Assessment, Development, and Evaluation.

[b]TECC: telehealth contraceptive counseling.

[c]ECM: effective contraceptive method.

[d]RCT: randomized controlled trial.

[e]Numbers calculated from percentages, rounded to whole numbers.

[f]Heterogeneity I^2=0.77.

[g]Optimal information size adequate. Downgraded for imprecision because the effect estimate CI overlaps with no effect.

[h]Moderate RoB in 2/4 studies.

[i]Optimal information size is adequate, but the lower bound of the effect estimate CI (1002) fails to reliably exclude no effect.

[j]LARC: long-acting reversible contraception.

[k]Heterogeneity I^2=0.96.

[l]Optimal information size not met. Very wide CI of the effect estimate. Lower bound below 1; fails to exclude no effect.

[m]N/A: not applicable.

[n]Moderate RoB in 1/2 studies

[o]Heterogeneity I^2=0.87.

[p]Results not pooled. Smith et al [26] showed a very wide CI of effect estimate, whereas for Stephenson et al [29], the lower bound of the CI fails to exclude no effect.

[q]High and moderate RoB in 2/2 studies, respectively.

[r]Heterogeneity I^2=0.53.

[s]Total sample sizes are small. The lower bound of the effect estimate CI fails to exclude no effect.

XSL•FO
RenderX

[t]High RoB in 2/2 studies

[u]Data cannot be pooled due to different measurement methods. One study showed no difference, and the other study suggested higher satisfaction in the intervention group.

[v]Data cannot be pooled. The lower bound of the effect estimate CI (Dehlendorf et al [22]) fails to exclude no effect.

[w]LMIC: low- and middle-income country.

[x]RoB: risk of bias.

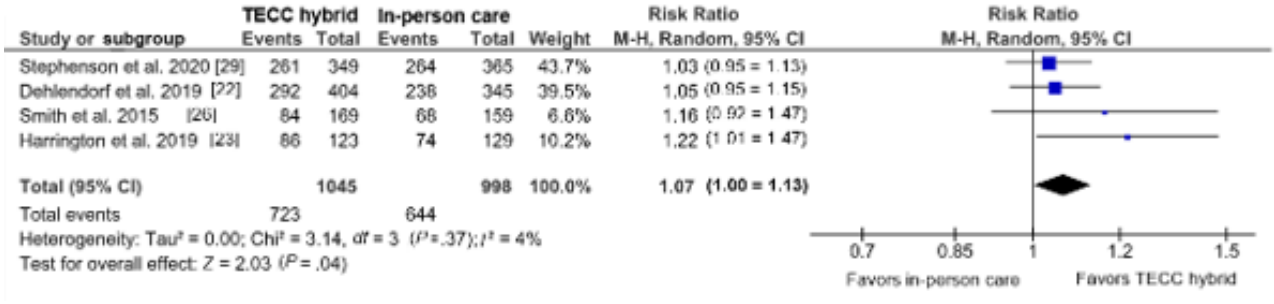
[y]Heterogeneity I^2=0.7.

[z]Wide CI of effect estimate. Lower bound below 1.

Four studies (n=2043) reported data on ECM use at 6-12 months after the intervention. The meta-analysis showed a small positive effect that reached statistical significance (*P*=.04), although the CI only narrowly excluded the null (RR 1.07; 95% CI 1.002-1.130; I^2=4%; Figure 4; see also [22,23,26,29]). The certainty of evidence was low, downgraded for RoB and imprecision (Table 3).

Our subgroup and sensitivity analyses assessed whether the effect of TECC on ECM choice and use varied by country income level, RoB, and publication period. Two subgroups overlapped: studies evaluating ECM use in LMICs also had low RoB. These analyses included a small number of studies, and the results should be interpreted with caution. Pooled results for ECM use at 6-12 months among studies conducted in LMICs with low RoB (n=580) showed that TECC significantly (*P*=.02) increased use (RR 1.20; 95% CI 1.03-1.30; I^2=0%; Figure 5; see also [23,26]). The certainty of evidence was low, downgraded for serious imprecision (Table 3). We found no evidence of an effect on ECM choice or ECM use at 6-12 months in studies from HICs with moderate-to-high RoB, or on ECM use less than 6 months in LMICs. Comparisons by publication period (pre- versus post-2015) showed no differences in ECM choice or use. Subgroup analyses based on geographic region and ECM use less than 6 months in HICs were not possible because of the small number of studies.

Figure 4. Forest plot of four studies comparing hybrid telehealth contraceptive counseling (TECC) with in-person care for effective contraceptive method use at 6-12 months after intrevention. M-H: Mantel–Haenszel method.



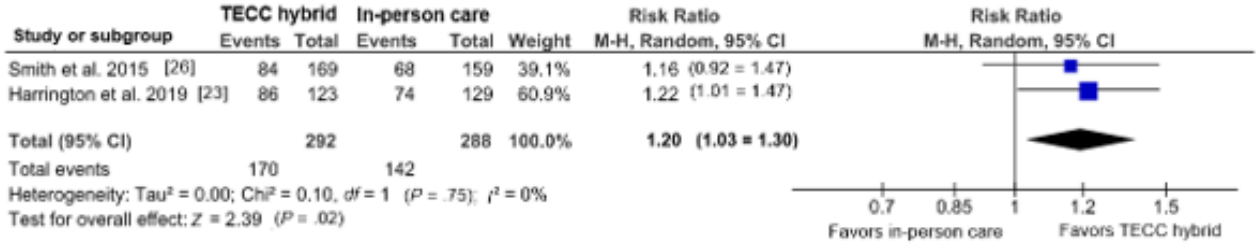


Figure 5. Forest plot of two low-risk-of-bias studies conducted in low- and middle-income countries, comparing hybrid telehealth contraceptive counseling (TECC) with in-person care for effective contraceptive method use at 6-12 months after intervention. M-H: Mantel–Haenszel method.

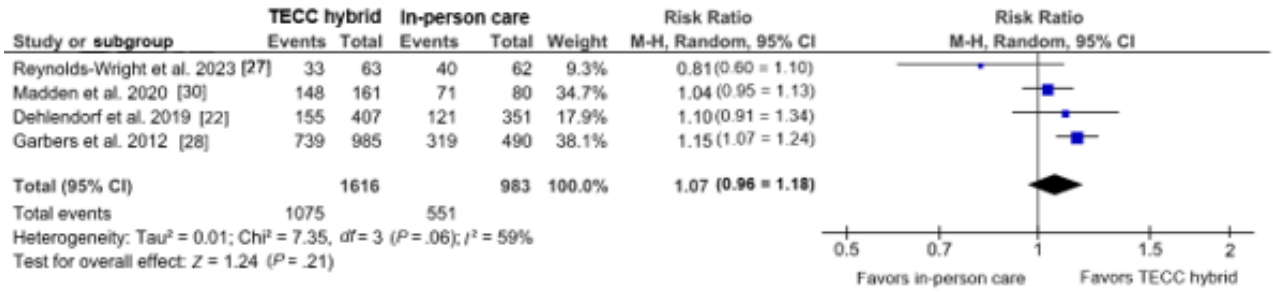
LARC Use

Two studies (n=1203) reported on LARC use at 0-6 months. Both studies were conducted in low-income settings in a postabortion context and used interactive voice messaging for TECC. However, statistical heterogeneity was high (I^2=96%), and pooled estimation was not considered appropriate. Reiss et al [25] reported no significant difference between groups (RR 0.80; 95% CI 0.56-1.14), whereas Smith et al [26] found an effect in favor of the telehealth intervention (RR 3.35; 95% CI 2.07-5.40). The certainty of evidence was very low, downgraded for moderate RoB and serious imprecision (Table 3).

Two studies (n=1042) reported LARC use at 6-12 months (Smith et al [26] and Stephenson et al [29]). Statistical heterogeneity was very high (I^2=87%) across 2 studies with different populations (postabortion care in Cambodia vs routine sexual health clinic attendees in the United Kingdom) and delivery modalities. Given these differences, pooled estimation was not considered appropriate. Smith et al [26] reported higher LARC use in the intervention group at 6 months compared with in-person care (RR 2.08; 95% CI 1.27-3.42), whereas Stephenson et al [29] reported no difference at 12 months (RR 0.98; 95% CI 0.79-1.22). The certainty of evidence was very

XSL•FO
RenderX

low, downgraded for RoB, inconsistency, and serious imprecision (Table 3).



Method Choice

Four studies (n=2599) assessed the choice of ECM immediately after the intervention. The meta-analysis showed no clear evidence (*P*=.21) of an effect of TECC compared with SC (RR 1.07; 95% CI 0.96-1.18; I^2=59%; Figure 6; see also [22,27,28,30]). The certainty of evidence was very low, downgraded for RoB, inconsistency, and imprecision (Table 3).

Two small studies (n=366) assessed the choice of LARC: 1 was conducted in a postabortion setting in the United Kingdom and was terminated early, and the other was conducted in general gynecologic clinics in the United States. Pooled analysis was not considered appropriate because the total sample size did not meet the OIS threshold and clinical heterogeneity was high across study populations, interventions, and contexts. Neither study showed increased choice of LARC at the time of counseling after TECC compared with in-person care: Reynolds-Wright et al [27] (RR 0.77; 95% CI 0.30-1.93) and Madden et al [30] (RR 1.04; 95% CI 0.74-1.47). The certainty of evidence was very low, downgraded for RoB and imprecision (Table 3).

Subgroup and sensitivity analyses examining whether the effect of TECC on ECM choice varied by publication period (*P*=.52) or RoB (*P*=.55) showed no significant effects. Subgroup analyses of LARC choice could not be performed because of the small number of studies.

Figure 6. Forest plot of four studies comparing hybrid telehealth contraceptive counseling (TECC) with in-person care for choice of effective contraceptive method at the time of counseling. M-H: Mantel-Haenszel method.

Satisfaction With Counseling

Two studies (n=749) reported on satisfaction with counseling (Saglam Aksut and Inam [24] and Dehlendorf et al [22]). Madden et al [30] noted no difference in satisfaction but did not report data suitable for extraction. Meta-analysis was not possible because of differences in outcome measurement and reporting. Saglam Aksut and Inam [24] reported significantly higher satisfaction scores for TECC compared with SC (mean 174.86, SD 7.71 vs mean 154.63, SD 26.54; *P*<.001). However, both groups scored well above the predefined threshold for high satisfaction (142 on the 185-point scale used). Dehlendorf et al [22] found no difference in overall satisfaction between groups (odds ratio [OR] 1.11; 95% CI 0.74-1.67), but a higher proportion of TECC users assigned the highest quality ratings (266/404, 65.8% vs 198/345, 57.4%; OR 1.45; 95% CI 1.03-2.05), suggesting that TECC improved perceived counseling quality. The certainty of evidence was very low, downgraded for high RoB, inconsistency, and imprecision (Table 3).

Method Switching

One study reported on method switching following TECC, but did not provide sufficient detail on the methods switched from and to; therefore, the outcome could not be analyzed [29].

Adverse Events and Safety

Only 2 studies explicitly evaluated potential harms as prespecified outcomes. Reiss et al [25] found a statistically significant increase in self-reported physical intimate partner violence (IPV) in the intervention arm compared with the control arm after menstrual regulation (11% vs 7%; adjusted OR 1.97; 95% CI 1.12-3.46). Menstrual regulation is a pragmatic term used for abortion care in Bangladesh, where abortion is illegal. This finding was detectable only when closed questions naming specific acts of violence were used; the open adverse event question (Did anything happen to you as a result of being in this study?) yielded no reports of violence in either arm. Smith et al [26] found no evidence of adverse outcomes, including domestic abuse or road traffic accidents. Other studies did not prespecify or systematically report unintended consequences, representing a gap in the evidence.

Heterogeneity and Publication Bias

We observed 2 forms of heterogeneity. Clinical heterogeneity was considerable, arising from differences in intervention design, including timing, delivery modality, provider involvement, and study setting. Studies were conducted across a range of care settings, including antenatal, postpartum, abortion, family planning, and general gynecologic clinics. Given the small number of studies available for each outcome, stratified analyses by clinical setting were not feasible. Although all interventions met our inclusion criteria for tailoring and interactivity, the extent of user engagement and integration with clinical care varied. Second, statistical heterogeneity was considerable for some outcomes (I^2>85%), as reflected by the wide CIs around pooled effect estimates. The scarcity of positive effect sizes did not suggest publication bias; however, the small number of studies per outcome limited the ability to detect asymmetry, and imputation-based analyses were not conducted.

Discussion

Principal Findings

This review identified 9 RCTs comparing TECC models with in-person care, 8 of which were hybrid models, and the remaining 1 was a standalone model that was terminated early. We found no clear evidence of an effect of TECC on ECM use less than 6 months. We found a small, statistically significant increase in ECM use at 6-12 months (RR 1.07; 95% CI 1.002-1.130). However, this finding is fragile: the lower bound of the CI only narrowly excludes no effect, meaning that a small shift in events could render the result nonsignificant, and the certainty of evidence is low. Given that the pooled estimates for method use were derived from trials with heterogeneous interventions and low-certainty evidence, the small effect observed at 6-12 months should be interpreted with caution. For other outcomes, including choice of ECM, choice of LARC, LARC use at less than 6 months and 6-12 months, and satisfaction with counseling, the evidence was very uncertain compared with SC. Method switching was assessed in 1 trial [29] but was not reported in sufficient detail to permit analysis. Across outcomes, the certainty of evidence ranged from low to very low. Hybrid interventions dominated the included studies; therefore, no conclusions could be drawn regarding the effectiveness of standalone TECC models.

The included trials were designed to evaluate the superiority of TECC over standard in-person care, not its noninferiority. In contexts where geographic, financial, or structural barriers limit access to in-person CC, a telehealth alternative that achieves equivalent outcomes could still represent a clinically meaningful advance by enabling access to care that would otherwise be unavailable. The current evidence base cannot exclude the possibility that TECC is noninferior to standard in-person care; however, formally demonstrating noninferiority would require adequately powered noninferiority trials with prespecified margins.

Comparison With Prior Work

In this review, we included only RCTs of tailored, interactive TECC, a definition that has not been used in any previous systematic review. Three previous systematic reviews, all published before 2020 and before the rapid expansion of telehealth during the COVID-19 pandemic, have assessed the effect of telehealth interventions on contraceptive use or choice [11,12,15].

Our primary outcome, ECM use, has been investigated in 1 previous review [11], which included 7 RCTs conducted in LMICs, 3 of which overlapped with our review [23,25,26]. Their meta-analysis showed no overall benefit of telehealth on ECM use compared with SC, but found a small effect in favor of telehealth in a subgroup analysis of 4 studies that evaluated ECM use as a primary outcome. Unlike our review, they included noninteractive interventions and excluded telephone-based interventions. Broader contraceptive use and continuation outcomes have been investigated in a review of telehealth decision aids [12], which included 11 RCTs, 4 of which overlapped with our review [22, 28-31]. Of the remaining 7 studies, 6 did not use SC comparators, and 1 intervention was not tailored. Their meta-analysis showed a small increase in use of any contraceptive method following telehealth contraceptive services compared with controls. Additionally, a recent cluster RCT among Latinx adolescents in the United States showed increased contraceptive uptake with a tailored TECC intervention, but the study was excluded from our review because not all controls received CC [32].

Contraceptive method choice has been evaluated in 1 review that included 5 RCTs, none of which were included in our review because they evaluated noninteractive interventions, such as video-based interventions, and defined their outcome as choice of any contraceptive method [15]. Consistent with our findings, their narrative synthesis showed that telehealth had no effect on method choice in 4 of the 5 trials.

Evidence on satisfaction with and acceptability of telehealth contraceptive services comes predominantly from observational studies conducted in the United States during the COVID-19 pandemic, which consistently report high acceptability, with users valuing convenience and rating counseling quality as comparable to in-person care [8-10,33]. However, a recent evidence map of telehealth sexual and reproductive health studies in high-income settings found that all observational and quasi-experimental studies demonstrated a very high susceptibility to confounding and selection bias, with many relying on convenience samples likely to overestimate acceptability and effectiveness [34]. These findings may also not reflect the experiences of populations with limited digital access or those who prefer in-person care. In LMICs, promising results regarding acceptability have been reported in pilot studies of telehealth communication for contraception among postabortion women in South Africa and among men and their spouses in Uganda [35,36].

Strengths and Limitations

This review has several strengths, including adherence to a preregistered protocol, rigorous application of RoB 2 and GRADE, and an exclusive focus on RCTs of interactive and tailored interventions to examine the causal effect of the telehealth counseling modality compared with in-person care. One limitation is the restriction to English-language publications, which may have introduced language bias and excluded relevant non-English-language trials. A further limitation is the exclusion of observational evidence. Prespecification of RCT-only inclusion strengthens causal inference regarding the effect of the telehealth counseling modality but constrains external validity and excludes a substantial body of real-world implementation data that have grown since the expansion of telehealth during the COVID-19 pandemic. Observational studies provide important insights into who accesses telehealth contraceptive services and how these services are experienced, but they are less suited to answering the specific effectiveness question addressed in this review because patients who select telehealth differ systematically from those who attend in-person care with respect to age, language, insurance status, income, and digital literacy. In addition, observational designs in this field have been shown to be highly susceptible to confounding and selection bias [34,37].

XSL•FO
RenderX

We used the standard DerSimonian-Laird random-effects approach in our meta-analysis. The Hartung-Knapp-Sidik-Jonkman method should be considered in future systematic reviews, particularly when the risk of spurious positive findings (type I error) is greater than it was in our analysis. The evidence has important limitations. We did not contact the study authors for additional or clarifying information. Interventions differed widely in content, delivery, timing, degree of provider involvement, and clinical context, potentially contributing to substantial heterogeneity in the results. Outcomes were often self-reported, and group allocation was unblinded, increasing RoB for subjective outcomes such as satisfaction. Some studies were excluded because outcome data did not distinguish between any contraceptive method and ECM as defined in our review. The small number of trials limited subgroup analyses and reduced power to explore sources of heterogeneity through sensitivity analyses. In line with Cochrane guidance, we did not present funnel plots to assess publication bias because fewer than 10 studies were included. We do not suspect publication bias, as most trials showed no effect in favor of the intervention.

Despite our focus on comprehensive TECC, tailoring and interactivity were only partially implemented in most included trials, highlighting a gap in TECC intervention design that may have limited effectiveness. Our review did not assess which components of TECC were most influential in determining outcomes. Previous reviews have attempted to identify the most effective features and have suggested that the incorporation of behavior change techniques and motivational interviewing may increase effectiveness [11,13,14]. However, none were able to determine which specific components were most effective.

The included trials were conducted across antenatal, postabortion, and routine contraceptive care settings, and in both high- and middle-income countries, supporting the generalizability of our findings to some extent. However, important gaps remain: no trial was conducted in a low-income country, and adolescents were represented in only 2 trials [22,28]. These gaps limit the generalizability of the findings to populations with a high unmet need for contraception. Furthermore, only 1 trial [27], which was terminated early, evaluated standalone TECC, highlighting the evidence gap regarding standalone TECC.

Safety outcomes were seldom assessed. One trial reported increased IPV following a mobile-based intervention in Bangladesh [25]. The intervention explicitly encouraged women to discuss contraception with their partners and included content aimed at increasing partner engagement in contraceptive decision-making. Mobile-based interventions that generate records or notifications may inadvertently increase the risk of IPV. This finding underscores the critical importance of prospective safety monitoring, harm-informed design, and safeguard protocols in all TECC evaluations, particularly in settings with a high prevalence of IPV. Although this finding may reflect context-specific factors related to postmenstrual regulation services in a setting with a high prevalence of IPV, it should not be dismissed as an isolated observation. Future TECC trials should consider incorporating routine baseline IPV risk screening, prespecified adverse event monitoring protocols, and context-sensitive content design that avoids prompting partner communication when doing so may increase risk.

Observational studies conducted in the United States have shown that food and housing insecurity, language barriers, lack of insurance, and race are associated with reduced access to telehealth contraceptive care [37,38]. Equity dimensions were not systematically addressed in the included trials, underscoring the need for equity-focused implementation and evaluation in diverse and underserved populations, including individuals with low literacy and limited digital access.

Implications

Although the evidence on adjunct TECC is inconclusive, it does not appear to substantially improve use, method choice, or satisfaction in settings where in-person counseling is already available. Our review assessed hybrid TECC in comparison with in-person counseling, which is not available in all contexts. If TECC were noninferior to SC in whatever form that takes, it may offer benefits in settings with limited trained providers, geographical or social barriers to care, or in overburdened health systems. In such settings, even modest effects might translate into population-level impact. The effectiveness of standalone TECC remains unknown, and its clinical relevance would depend on demonstrating that TECC is no less effective, safe, or acceptable than SC.

Future Research

Future research should prioritize adequately powered evaluations of standalone TECC, including low-income settings and adolescents, and assess long-term outcomes such as continuation, switching, and unintended pregnancy. Noninferiority designs could establish clinical relevance in settings with limited access to in-person care. Mixed-methods approaches are needed to capture user experiences, equity implications, and unintended harms. Standardized and validated measures of contraceptive use, satisfaction, and decision quality would improve comparability. Complementary real-world effectiveness evidence could be generated through rigorous quasi-experimental designs, such as propensity score–matched cohort studies in routine care populations and interrupted time-series analyses that treat system-level changes, such as the COVID-19 telehealth expansion, as natural experiments. The rapid growth of online contraceptive platforms and AI-driven communication requires rigorous evaluation of their effectiveness, safety, and implementation. Evidence is needed to guide decision makers in integrating TECC into routine contraceptive services amid ongoing digital health system transformations.

Conclusions

Current evidence suggests, with low certainty, that adjunct TECC delivered alongside in-person care shows little to no effect on contraceptive use compared with in-person care. For method choice, LARC uptake, and satisfaction compared with in-person care, the evidence was very uncertain. The effectiveness of standalone TECC remains unknown. High acceptability and scalability warrant further rigorous and equity-focused evaluations to inform integration into routine contraceptive services.

Data Sharing

All data used in this article are from publicly available published sources. Extracted data are provided in the article and its multimedia appendices. Additional outcome data, risk-of-bias assessments, and statistical calculations for meta-analyses will be made available on reasonable request to the corresponding author (ME). The PROSPERO protocol (CRD42023404402) is publicly available.

Acknowledgments

We thank Lovisa Liljegren and Emma-Lotta Säätelä, librarians at Karolinska Institutet University Library, for assistance with developing and documenting the search strategies. During the preparation of this work, the authors used GPT-4o (OpenAI, May 2024 release) to perform preliminary data extraction from full-text articles, generate a conceptual figure, and support language editing. After using this tool, 2 authors (MW and ME) reviewed and edited the content as needed and take full responsibility for the content of the published article.

Authors' Contributions

MW and ME conceived the study and designed the protocol. MW, AK, and ME screened titles and abstracts. Initial outcome data were extracted using GPT-4o (OpenAI, May 2024 release) by MW, and the data were verified and corrected if needed by MW and ME. MW and ME independently assessed the risk of bias. MW conducted the data analyses with input from WJAG and ME. WJAG provided statistical guidance and interpretation of the meta-analyses. MW drafted the initial manuscript. ME supervised the project. ME and WJAG contributed to the interpretation of findings and provided critical revisions. MW, ME, and WJAG had full access to all study data. All authors had final responsibility for the decision to submit for publication.

Artificial intelligence–generated conceptual framework of telehealth contraceptive counseling (TECC). The framework includes 3 core domains: (1) telehealth delivery via a user interface on a phone, laptop, or tablet; (2) interactive, bidirectional communication; and (3) personalization based on users' preferences, reproductive goals, or medical eligibility. Additional characteristics may vary by degree of automation and by whether communication is delivered and responded to in real time or asynchronously. TECC may be integrated before, during, or after clinical visits and may serve either as a standalone substitute for, or a hybrid adjunct to, in-person counseling.

Abstract

Background: Chronic heart failure (CHF) imposes a dual and dynamically interrelated burden on patients and family caregivers, whose health and illness management behaviors are interdependent. Exercise interventions that actively engage the patient-caregiver dyad as the unit of rehabilitation in the home setting remain underdeveloped.

Objective: This study aimed to develop a home-based, digitally assisted, dyadic tai chi (HDTC) intervention and evaluate its feasibility, acceptability, safety, and preliminary effects among dyads of patients with CHF and their caregivers.

Methods: This sequential, multiphase study comprised intervention development followed by a single-center, assessor-blinded, parallel-group pilot randomized controlled trial. Phase 1 integrated literature review, theoretical frameworks, and stakeholder focus group interviews to develop and refine the HDTC intervention. In phase 2, eligible adults with CHF (aged 18-75 years; New York Heart Association class I-III) and their primary caregivers were recruited from a tertiary medical center in Qingdao, China, from October 14 to November 12, 2024, and followed for 12 weeks. Forty dyads were allocated 1:1 to the 12-week HDTC intervention plus usual care or usual care alone (n=20 per group). Outcome assessors and the data analyst were blinded to group allocation. Feasibility, acceptability, and safety were the primary focus of the pilot trial. Patient, caregiver, and dyadic health outcomes were preliminarily explored at baseline and 4 and 12 weeks. All 40 randomized dyads were included in the intention-to-treat analyses.

Results: The HDTC intervention comprised an online educational seminar, nurse-led dyadic coaching, preliminary face-to-face tai chi training, and supervised HDTC practice. The recruitment rate was 83.3% (40/48), mean session attendance was 73.7% (SD 8.6%), and 70% (14/20) of participants achieved high adherence rate (≥75% attendance). All intervention dyads rated the intervention as acceptable. No intervention-related adverse events were identified. Exploratory generalized estimating equation analyses suggested greater improvements from baseline to 12 weeks in the intervention group than in the control group in functional capacity (β=38.858; *P*=.001), together with greater reductions in Minnesota Living With Heart Failure Questionnaire scores (β=−1.850; *P*=.002), sedentary time (β=−1.025; *P*=.01), and fear of activity (β=−6.550; *P*=.01). Caregiver burden also decreased (β=−4.350; *P*<.001), while mutuality improved more for both patients (β=10.508; *P*<.001) and caregivers (β=6.450; *P*<.001).

Conclusions: The HDTC intervention was feasible and acceptable, with preliminary improvements across patient, caregiver, and dyadic outcomes. By integrating shared patient-caregiver participation with digitally supported home-based tai chi, the HDTC

XSL•FO
RenderX

intervention extends patient-centered rehabilitation toward a dyad-oriented model. If confirmed in a fully powered trial, this approach may offer a practical strategy for expanding home-based cardiac rehabilitation.

Trial Registration: ClinicalTrials.gov NCT06876441; https://clinicaltrials.gov/study/NCT06876441

KEYWORDS

heart failure; caregivers; home-based rehabilitation; tai chi; dyadic intervention

Introduction

Heart failure (HF) remains a prevalent and burdensome chronic condition worldwide [1,2]. Patients with HF commonly exhibit high levels of sedentary behavior, which are associated with increased risks of hospitalization and mortality [3]. Although exercise-based cardiac rehabilitation is recommended to improve functional outcomes and prognosis [4], participation in center-based programs remains low because of travel, scheduling, and service capacity barriers [5]. Digitally supported home-based exercise rehabilitation offers a potential alternative, although evidence regarding its safety, feasibility, and effects in HF remains limited [6].

Within the home setting, exercise is embedded in the family context, with caregivers often providing encouragement, safety monitoring, scheduling support, and reinforcement of continued participation [7]. Meanwhile, caregivers experience substantial caregiving burden that can adversely affect their own physical and psychological health [8,9], which may in turn influence patient outcomes [10]. This reciprocal influence supports conceptualizing the patient-caregiver dyad, rather than the patient alone, as a target of intervention [11,12]. However, dyadic intervention research in HF remains limited [13], and existing interventions have focused primarily on self-care and psychosocial support, with relatively little attention to structured exercise jointly undertaken by patients and caregivers [14,15].

Dyadic exercise extends conventional patient-centered rehabilitation by engaging both members of the dyad in a shared health behavior [16]. Consistent with the theory of dyadic illness management, which emphasizes reciprocal influences within the dyad [17], this approach moves beyond targeting patient behavior alone. It also differs from caregiver-supported self-care, in which caregivers primarily facilitate patient disease management; shared exercise actively involves both members and may benefit both while strengthening mutual support and dyadic relationship quality [11].

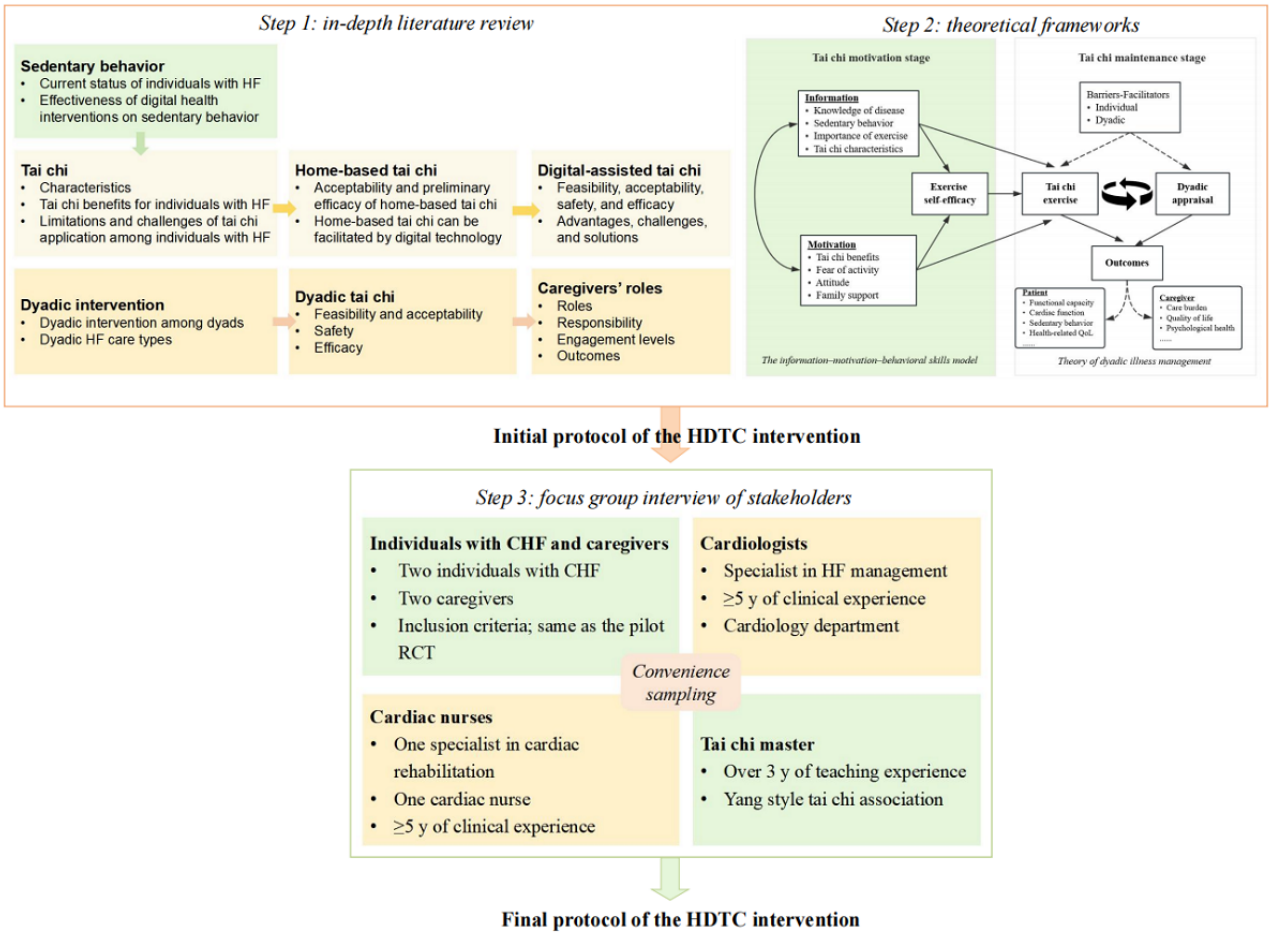
Tai chi, a moderate-intensity aerobic exercise, is recommended as an adjunctive therapy in international HF management guidelines [18,19]. Prior studies suggest that it may enhance exercise capacity, psychological well-being, and quality of life (QoL) in patients with chronic HF (CHF) [20,21], but practical barriers, including travel demands, time constraints, self-discipline challenges, and limited access to qualified masters, hinder patients' access to center-based practice [22], underscoring the need for home-based, digitally assisted tai chi. Previous evidence has revealed that digitally assisted tai chi, in which all components are delivered through an online platform without face-to-face instruction, is feasible and effective among other frail populations [23]. To date, however, the integration of tai chi into dyadic management models remains largely unexplored.

To address these gaps, this study aimed to systematically develop a home-based, digitally assisted, dyadic tai chi (HDTC) intervention for patients with CHF and their family caregivers. Then, a pilot randomized controlled trial (RCT) was conducted to evaluate its feasibility, acceptability, and safety and explore preliminary effects on patient, caregiver, and dyadic outcomes.

Methods

Study Design and Setting

This sequential multimethod study guided by the Medical Research Council framework comprised 2 stepwise phases [24]. Phase 1 developed the HDTC intervention for dyads through (1) iterative evidence synthesis (literature review, systematic review of digitally assisted interventions, and scoping review of caregiver roles), (2) application of theoretical frameworks to inform a stage transition model for sustained dyadic exercise, and (3) focus group interviews with key stakeholders (physicians, nurses, patients with CHF, caregivers, and tai chi master) to refine the digital implementation of the intervention. Phase 2 was a prospective, 2-arm pilot RCT conducted at a tertiary medical center in Qingdao, China, evaluating the feasibility, acceptability, and preliminary effects of the HDTC intervention. This pilot RCT was reported in accordance with the CONSORT (Consolidated Standards of Reporting Trials) 2010 extension for randomized pilot and feasibility trials [25] (Multimedia Appendix 1).



Phase 1: Development of the HDTC Intervention

The intervention was developed through 3 sequential steps. First, an iterative evidence synthesis via literature review identified key components informing the HDTC intervention protocol: sedentary behavior, digital health interventions, home-based tai chi, dyadic tai chi, and caregiver roles. Second, 2 theoretical frameworks guided the transition from sedentary behavior to sustained tai chi exercise: the information-motivation–behavioral skills model and theory of dyadic illness management. The information-motivation–behavioral skills model was used primarily to structure the initial transition from sedentary behavior to exercise participation (*tai chi motivation stage*) [26,27]. The educational seminar addressed exercise-related information, the dyadic coaching session explored motivation and shared goals, and introductory tai chi training was used to develop the behavioral skills required for safe home practice. The theory of dyadic illness management informed the

XSL•FO
RenderX

subsequent maintenance phase (*tai chi maintenance stage*) [17]. In this phase, patients and caregivers were encouraged to view exercise as a shared rehabilitation task, coordinate participation and support, monitor progress, and address exercise-related challenges collaboratively. Digital communication, shared reminders, and professional feedback were incorporated to support continued dyadic engagement. Third, focus group interviews were conducted with key stakeholders, comprising 2 dyads (2 patients and their respective caregivers), 2 cardiologists and 2 nurses with more than 5 years of experience in HF management, and 1 tai chi master with 11 years of teaching experience from the Yang Style Tai Chi Association. The interview guide was designed based on the nonadoption, abandonment, scale-up, spread, and sustainability framework (Multimedia Appendix 2) to enhance the practicality and adaptability of the digital intervention [28]. The intervention was subsequently refined based on stakeholder feedback. The flow diagram of the intervention development is shown in Figure 1.

Figure 1. The home-based, digital-assisted, dyadic tai chi (HDTC) was systematically developed through 3 steps: literature review, theory-guided intervention design, and stakeholder consultation. CHF: chronic heart failure; HF: heart failure; RCT: randomized controlled trial.

Phase 2: Pilot-Testing of the HDTC Intervention

Participants and Sample Size

A convenience sample of 40 dyads of patients with CHF and their caregivers was recruited from the Affiliated Hospital of Qingdao University. The inclusion criteria for patients with CHF were (1) age of 18 to 75 years with a diagnosis of CHF [29]; (2) New York Heart Association class I, II, or III and 6-minute walk test distance of more than 150 m [29]; (3) ability to perform the prescribed tai chi movements without physical assistance, as assessed during pre-enrollment screening; (4) smartphone ownership; and (5) voluntary participation and informed consent. Exclusion criteria were as follows: planned surgery within 6 months; severe comorbidities such as cancer, liver or kidney failure, and diagnosed psychiatric disorders; planned relocation to care facilities; regular exercise in the prior 3 months; or concurrent trial participation. Caregiver inclusion criteria were age of 18 years or older, being primary caregivers for patients with CHF [30], ability to practice tai chi without help, and voluntary participation and informed consent.

On the basis of pilot trial recommendations, at least 15 participants per group were required to detect a medium effect size assuming a 90% power with a 2-sided 5% significance level [31]. Accounting for 20% attrition, 18 dyads per group were targeted.

Recruitment of Dyads of Patients With CHF and Their Caregivers

Potential patients with CHF were recruited through electronic advertisements with QR codes displayed in the HF clinic and cardiology department and via electronic questionnaires disseminated to 30 WeChat groups of discharged patients. After

XSL•FO
RenderX

initial prescreening, eligible patients underwent a comprehensive assessment followed by screening of their caregivers. Informed consent was obtained from all dyads prior to enrollment.

Randomization, Allocation Concealment, and Blinding

Randomization was performed by an independent individual using the Sealed Envelope online tool [32]. Allocation used a 1:1 ratio with stratification by New York Heart Association class (I, II, and III) and block sizes of 4 and 6. Allocation concealment was ensured through sequentially numbered, opaque, sealed envelopes opened only after baseline assessments. Owing to the nature of the behavioral intervention, blinding of intervention providers and participants was not feasible [33]; only outcome assessors and the data analyst were blinded to group allocation.

Interventions

HDTC Intervention

Dyads in the intervention group participated in the HDTC intervention plus usual care. The intervention was delivered over 12 weeks, consistent with the duration commonly used in previous tai chi studies among patients with CHF [16]. The contents of the intervention are detailed in the Results section.

Control Group

Dyads in the control group received usual care, including online comprehensive education and nurse-led telephone consultations. Consultations addressed symptom management, medication adherence, dietary and exercise suggestions, psychosocial support, and regular follow-ups. Caregivers served as both partners and facilitators, assisting patients with CHF in implementing these recommendations.

Intervention Fidelity

The Behavior Change Consortium framework was adopted to guide fidelity assurance [34]. First, the initial HDTC protocol was developed through a rigorous 3-stage process to ensure design integrity. Second, a tai chi master received standardized training from a cardiac rehabilitation nurse on intervention delivery, safety protocols, and participant characteristics, with ongoing researcher supervision throughout all sessions to maintain protocol adherence. Third, all tai chi sessions were delivered by a single master from the Qingdao Yang Style Tai Chi Association with 11 years of teaching experience. The master was scheduled to deliver all sessions throughout the 12-week intervention to ensure consistency in intervention delivery. If the master was unavailable, the affected session was rescheduled to maintain continuity of the intervention. Upon completion of the tai chi form learning, the master assessed participants' skill mastery. Additionally, all online classes were recorded, with an independent expert conducting a random audit of 20% of recorded classes to evaluate intervention fidelity.

Outcomes

Assessments were conducted at baseline (T0) and 4 weeks (T1), and 12 weeks (T2) of the intervention to evaluate the feasibility, acceptability, and preliminary effects of the HDTC intervention.

Feasibility

Feasibility was assessed through the recruitment period, recruitment rate, attendance rate, adherence rate, and attrition rate. Adherence was calculated as the proportion of completed tai chi classes to total prescribed classes, with high adherence defined as attendance to at least 75% of classes, consistent with previous studies [35].

Acceptability

Acceptability was assessed after the intervention using separate patient and caregiver questionnaires based on the theoretical framework of acceptability, covering affective attitude, burden, ethicality, perceived effectiveness, intervention coherence, self-efficacy, opportunity costs, and overall acceptability [36]. Each domain was rated using domain-specific ordered response options. Responses were dichotomized as favorable or unfavorable according to the positive response categories for each domain; for overall acceptability, "acceptable" and "completely acceptable" were classified as favorable. The intervention was considered acceptable if 80% or more of the participants provided a favorable overall rating [37].

Adverse Events

Consistent with the CONSORT Harms statement [38], adverse events were defined as any possible adverse consequences attributable to the intervention. Potential adverse events, including dyspnea, palpitations, chest pain, arrhythmia, myocardial infarction, falls, and other unexpected symptoms, were recorded by a nurse and subsequently assessed by a physician to determine their relationship to the intervention.

Preliminary Effects

Outcomes of Patients With CHF

The functional capacity of patients with CHF was assessed using the 6-minute walk test through the Walker Doctor Intelligent 6-Minute Walk Test Monitoring and Analysis System [39,40]. Sedentary behavior and fear of activity were evaluated using the International Physical Activity Questionnaire–Short Form [41] and Fear of Activity in Patients With Chronic Heart Failure [42], respectively. Confidence in exercising was assessed using the Self-Efficacy for Exercise Scale [43]. The Minnesota Living With Heart Failure Questionnaire was used to measure patients' health-related QoL [44].

Outcomes of Caregivers

The Chinese version of the Zarit Caregiver Burden Interview was used to measure caregivers' perceived caring burden [45], and their QoL was assessed using the Chinese Family Caregiver Quality of Life Scale [46].

Outcomes of Dyads

Mutuality, the relationship between patients with CHF and their caregivers, was measured using the Chinese Mutuality Scale [47], with higher scores denoting better mutuality.

Data Analysis

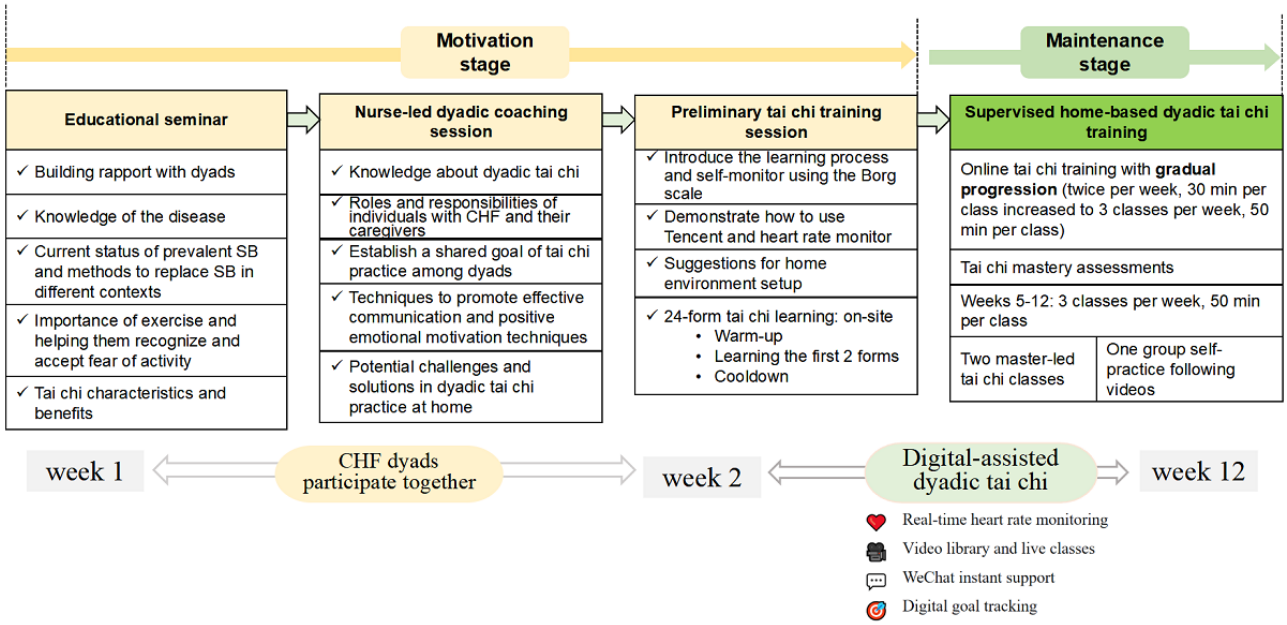
Statistical analyses were performed using SPSS Statistics (version 26; IBM Corp). Descriptive statistics summarized participant characteristics and assessed feasibility and

XSL•FO
RenderX

acceptability outcomes. Normality was evaluated using the Shapiro-Wilk test. Preliminary effects were examined using 2-tailed paired *t* tests or Wilcoxon signed-rank tests for within-group comparisons and independent *t* tests or Mann-Whitney *U* tests for between-group comparisons. Generalized estimating equation models with an independence working correlation structure and robust SEs were used to assess between-group differences across multiple time points. Missing data were assessed using the Little missing completely at random (MCAR) test to evaluate the missingness pattern. All analyses followed the intention-to-treat principle. Effect sizes were calculated using the Cohen *d* (small effect size: $d \leq 0.2$; medium effect size: $d \leq 0.5$; large effect size: $d \geq 0.8$) [48].

Ethical Considerations

This study was approved by the ethics committees of Hong Kong Polytechnic University (HSEARS20240904005) and the Affiliated Hospital of Qingdao University (QYFYWZLL29400). Written informed consent was obtained from all participating patients and caregivers before enrollment. To protect participants' privacy and confidentiality, study data were deidentified and stored securely, with access restricted to authorized research personnel. Participants received no financial compensation for taking part in the study. No identifiable images of participants are included in the manuscript or supplementary materials.



Results

HDTC Intervention Protocol

Intervention Components and Delivery

The HDTC intervention was informed by multiple sources: a systematic review on digital health interventions for sedentary behavior [49], a scoping review of caregiver roles and engagement levels [50], and focus group interviews with stakeholders (Multimedia Appendix 3). The final intervention comprised 4 components delivered in a structured sequence: an online educational seminar and a nurse-led online dyadic coaching session in week 1, an introductory face-to-face training session of 24-form Yang-style tai chi in week 2, and nurse-supervised HDTC classes (Figure 2). The tai chi sessions were delivered by a master from the Qingdao Yang Style Tai Chi Association with 11 years of teaching experience. During weeks 2 to 4, dyads attended live online tai chi classes, with the frequency and duration progressively increasing from two 30-minute sessions to three 50-minute sessions per week. During weeks 5 to 12, dyads participated in 2 master-led online sessions and 1 video-guided group practice session each week, with each session lasting 50 minutes. During supervised online sessions, a cardiac nurse monitored participants' exercise-related symptoms and heart rate and provided safety guidance as needed.

Figure 2. Protocol for the home-based, digital-assisted, dyadic tai chi intervention. The intervention comprised 4 components delivered across 2 stages: the motivation stage and the maintenance stage. Digital support included real-time heart rate monitoring, instructional videos, live online classes, WeChat-based support, and goal tracking. CHF: chronic heart failure; SB: sedentary behavior.

Digitally Assisted Features

The HDTC intervention was supported by a multifunctional digital infrastructure. Synchronous live video sessions and an on-demand video library delivered structured, progressive tai chi instruction. Real-time heart rate monitoring enhanced safety by enabling continuous oversight of patients during home-based practice. Asynchronous communication via WeChat offered ongoing access to nursing support and peer interaction, thereby reinforcing adherence. Meanwhile, digital goal-tracking features, such as shared progress updates and reminders in the online community via WeChat group, fostered shared accountability and motivation within the dyad. Together, these digitally enabled components created a supportive and interactive remote environment that effectively extends clinical supervision into the home and enhances both engagement and safety.

RenderX

Feasibility, Acceptability, and Effects of the Intervention

Baseline Characteristics of the Dyads

The dyads were recruited from a tertiary medical center in Qingdao, China, from October 14 to November 12, 2024. A total of 85 patients (62 online; 23 in person) were referred to this study. During initial screening, 37 patients were excluded. Of the 48 eligible dyads, 8 declined participation due to scheduling conflicts (caregivers: n=4; patients with CHF: n=2) or lack of interest (n=2). The remaining 40 dyads were randomly assigned to the intervention or control group. All dyads completed the 4-week assessment. However, 3 dyads (1 in the intervention group and 2 in the control group) did not complete the 12-week follow-up because of perceived recovery, lack of interest, or returning to work (Figure 3) [51]. No item-level missing data were identified among completed questionnaires. The Little MCAR test was not statistically significant (χ^2_{16}=13.1; *P*=.66), providing no evidence against the MCAR assumption. Baseline characteristics of dyads were comparable between groups (Table 1).

Figure 3. CONSORT (Consolidated Standards of Reporting Trials) 2025 flow diagram of recruitment, randomization, follow-up, and analysis in the pilot randomized controlled trial [51]. GEE: generalized estimating equations; HDTC: home-based, digital-assisted, dyadic tai chi.

Feasibility Outcomes

Of the 85 patients referred for screening (average recruitment rate: 2.8 dyads per day; n=85, 100% response rate), 48 were eligible, and 40 dyads were enrolled and randomized, corresponding to a recruitment rate of 83.3% (40/48). Among interested patients (n=85), primary motivators for participation were perceived benefits (68/85, 80%), convenience of home-based delivery (47/85, 55.3%), and insufficient postdiagnosis exercise knowledge (38/85, 44.7%; Table S1 in Multimedia Appendix 4). Retention rates were 100% (40/40) at 4 weeks and 92.5% (37/40) at 12 weeks. Mean attendance to online tai chi classes was 80.6% (SD 14.9%) at 4 weeks and 73.7% (SD 8.6%) at 12 weeks, with 70% (14/20) of participants demonstrating high adherence (≥75% attendance).

Acceptability Outcomes

The detailed responses from the dyadic perspective were shown in Table S2 in Multimedia Appendix 4. Notably, dyads reported positive appraisals of the HDTC intervention. Overall, 100% (20/20) of dyads rated the intervention as acceptable, with 60% (12/20) deeming it completely acceptable.

Safety of the Intervention

During each tai chi class, the dyads' physiological responses were closely monitored and documented by a cardiology nurse. Classes began with warm-up exercises and concluded with cooldown stretches to minimize musculoskeletal injury risk. No intervention-related adverse events were reported during the 12-week intervention, suggesting that it was well tolerated in this pilot sample.

Preliminary Effects of the HDTC Intervention

Effects of the HDTC Intervention for Patients With CHF

Compared to the control group, patients with CHF in the intervention group exhibited significant improvement in 6-minute walk test distance at both 4 weeks (β=12.300, 95% CI 8.733-15.867; *P*<.001) and 12 weeks (β=38.858, 95% CI 15.691-62.025; *P*=.001; Table S3 and Figure S1 in Multimedia Appendix 4). Significant reductions were observed in sedentary time (T1: β=−0.975, 95% CI −1.338 to −0.612; *P*<.001; T2: β=−1.025, 95% CI −1.617 to −0.433; *P*=.01), fear of activity (T1: β=−2.050, 95% CI −3.865 to −0.235; *P*=.03; T2: β=−6.550, 95% CI −11.548 to −1.552; *P*=.01), and Minnesota Living With Heart Failure Questionnaire scores (T2: β=−1.850, 95% CI −3.045 to −0.655; *P*=.002). Effect sizes for these outcomes ranged from moderate to large (Table 2).

Effects of the HDTC Intervention for Caregivers

Caregivers in the intervention group demonstrated significant reduction in Zarit Caregiver Burden Interview scores compared to controls at both 4 weeks (β=−1.750, 95% CI −2.499 to −1.001; *P*<.001) and 12 weeks (β=−4.350, 95% CI −5.765 to −2.935; *P*<.001), with effect sizes ranging from small to moderate (Table 2). However, no significant between-group differences were observed in Family Caregiver Quality of Life scores (β=1.300, 95% CI −1.644 to 4.244; *P*=.39; Table S3 and Figure S2 in Multimedia Appendix 4).

Effects of the HDTC Intervention for Dyads

Both patients with CHF and caregivers in the intervention group showed significant improvements in mutuality scores at 4 weeks (patients with CHF: β=5.700, 95% CI 1.126-10.274; *P*=.02; caregivers: β=3.850, 95% CI 1.961-5.739; *P*<.001) and 12 weeks (patients with CHF: β=10.508, 95% CI 5.534-15.482; *P*<.001; caregivers: β=6.450, 95% CI 3.652-9.248; *P*<.001; Table S3 and Figure S3 in Multimedia Appendix 4).

Discussion

Principal Findings

The potential therapeutic benefits of tai chi have been increasingly investigated [52,53], but dyadic tai chi interventions among patients with CHF and their caregivers remain under-studied [13]. This study developed and evaluated an HDTC intervention that engaged patients and caregivers as active participants in a shared rehabilitation process, thereby extending conventional patient-centered exercise toward a dyad-oriented model. The intervention demonstrated satisfactory recruitment, retention, attendance, and acceptability, providing initial evidence that this approach is feasible in the home setting. No intervention-related adverse events were reported during the 12-week intervention, although the small sample size limits conclusions regarding safety. Exploratory analyses also indicated preliminary improvements across patient, caregiver, and dyadic outcomes. However, this study was not powered to establish clinical effectiveness. If confirmed in a fully powered trial, this model may offer a practical strategy for expanding home-based cardiac rehabilitation while addressing the needs of both patients and caregivers.

Feasibility of the HDTC Intervention Among Dyads

The HDTC intervention demonstrated encouraging recruitment, with enrollment completed within 1 month. The overall recruitment rate was 83.3% (40/48), comparable to the 75.1% reported in a previous dyadic study [14]. Although dyadic interventions often face recruitment challenges because of the need to coordinate participation by both members [54,55], recruitment in this study may have been facilitated by multiple recruitment pathways and close collaboration with the Department of Cardiology at the Affiliated Hospital of Qingdao University.

Notably, the relatively low refusal rate may have been due to nurses' extensive experience with patients with CHF [54], stakeholder-informed tailoring of the intervention, and its home-based delivery [56]. Participant feedback also suggested that dyads perceived the intervention as beneficial, and more than half valued the home-based convenience. Feasibility was further supported by complete retention at 4 weeks and a satisfactory retention rate at 12 weeks. Free access, convenient home-based practice, and social support from caregivers and nurses may have contributed to sustained engagement and retention [57]. Mean attendance was consistent with findings from a previous tai chi study [58], while adherence was comparable to that reported in a previous home-based cardiac rehabilitation study (14/20, 70% vs 73%) [59]. Collectively, these findings support the feasibility and acceptability of the HDTC intervention in this pilot setting.

Acceptability of the HDTC Intervention Among Dyads

All dyads in the intervention group rated the HDTC intervention as acceptable, with 60% (12/20) rating it as completely acceptable. This high acceptability may reflect the intervention's dyadic tailoring and home-based delivery, which may also have promoted participant engagement and adherence [60]. Findings align with evidence that tai chi has been reported to be feasible and well tolerated among patients with frailty [61-62]. Its acceptability may have been further enhanced by caregiver involvement, which could provide encouragement and reinforce patients' motivation to engage in regular exercise [63].

Regarding engagement, 45% (9/20) of patients with CHF reported that the intervention required substantial effort, whereas 70% (14/20) of caregivers described it as moderately effortful.

XSL•FO
RenderX

Informal telephone follow-up suggested that difficulties in learning tai chi forms contributed to the perceived effort, a challenge also reported in previous studies involving older adults [64]. This highlights the need for refinements in a full-scale RCT. Suggested strategies include (1) enhanced instructional support with clearer, more detailed demonstrations; (2) incremental learning of new forms; and (3) pretraining videos coupled with regular review sessions. Together, these approaches aim to ease skill acquisition, foster independent practice, and support long-term retention.

Preliminary Effects of the HDTC Intervention

For patients with CHF, the intervention showed favorable preliminary effects on exercise tolerance, sedentary time, fear of activity, exercise self-efficacy, and health-related QoL, generally consistent with previous evidence on tai chi and home-based rehabilitation [21,49]. These changes may reflect the gradual, low-impact nature of tai chi and the intervention's emphasis on replacing sedentary behavior with structured home exercise, while supervised practice and progressive skill acquisition may also have supported confidence and reduced fear of activity [65,66]. Given the pilot design, these findings should be interpreted as preliminary signals rather than definitive evidence of efficacy.

For caregivers, the intervention was associated with reduced caregiver burden, whereas QoL did not show a significant improvement, possibly because broader QoL is influenced by multiple factors, including caregiving distress and competing social and family demands, and may therefore be less responsive over a short intervention period [13,67,68]. At the dyadic level, both patients and caregivers showed improved mutuality, which may reflect the intervention's emphasis on joint decision-making, shared exercise participation, and mutual encouragement, in contrast to dyadic interventions focused primarily on patient self-care [69]. These findings suggest that dyadic exercise may influence not only individual outcomes but also the relational processes within the patient-caregiver pair.

Strengths and Limitations

A key strength of this study was its explicit focus on dyads of patients with CHF and their caregivers throughout intervention conceptualization, development, and evaluation, addressing an important gap in previous research [13]. The HDTC intervention was developed through an evidence-based approach incorporating a comprehensive literature review, theoretical frameworks, and stakeholder consultation, thereby enhancing its conceptual foundation and contextual relevance.

Several limitations should be considered. First, the pilot sample was small and was not powered for definitive between-group testing of clinical outcomes; consequently, effect estimates are imprecise and exploratory. Second, the 12-week follow-up does not establish whether engagement or outcome changes are sustained after intervention completion. Third, participants were recruited from a single tertiary medical center and through voluntary recruitment pathways, which may limit generalizability to other health care settings and may have preferentially enrolled dyads who were more motivated to exercise or use digital technology. Fourth, requiring both members of the dyad to participate may have further selected families with greater caregiver availability and relational capacity. Fifth, although both patient and caregiver outcomes were measured, the small sample limited the ability to reliably estimate dyadic interdependence. Finally, feasibility estimates such as recruitment and adherence are context dependent and require confirmation in larger, multicenter settings.

Conclusions

The HDTC intervention demonstrated feasibility and acceptability among dyads, with preliminary evidence suggesting potential to improve dyadic health outcomes. These findings support further evaluation of this dyad-oriented, digitally supported home rehabilitation model in a sufficiently powered multicenter RCT with longer follow-up.

Acknowledgments

The authors express their sincere gratitude to the physicians and nurses of the Department of Cardiology, Affiliated Hospital of Qingdao University, for their professional support and to the tai chi master for providing expert instruction. They further extend their deep appreciation to the patients with chronic heart failure and caregivers for their participation in this study. The authors declare the use of generative AI in the manuscript preparation and revision process. According to the Generative AI Delegation Taxonomy (2026), the following tasks were delegated to generative AI tools under full human supervision: proofreading and editing, adapting and adjusting emotional tone, and reformatting. The generative AI tool used was ChatGPT (GPT-6; OpenAI). Responsibility for the final manuscript lies entirely with the authors. Generative AI tools are not listed as authors and do not bear responsibility for the final outcomes.

Abstract

Background: Pediatric ear, nose, and throat (ENT) surgery is common, but generates perioperative anxiety for caregivers and distress in children. Limited time for perioperative education and reliance on unverified online information can reduce family preparedness and increase stress. Few studies have evaluated co-designed mobile health (mHealth) apps to support and engage families in the perioperative ENT journey.

Objective: This study aimed to compare caregiver anxiety between an mHealth app-supported care pathway and standard supportive and educational care alone in the perioperative ENT context. Secondary objectives explored between-group differences in caregiver anxiety at follow-up, family preparation, child distress, and social-impact indicators.

Methods: A 2-arm, parallel-group, open-label randomized controlled trial (RCT) enrolled caregivers of children undergoing ENT surgery (tonsillectomy, adenoidectomy, tympanostomy tube insertion). The intervention was an mHealth app co-designed through a user-centered participatory approach and developed following Schnall and colleagues' Information Systems Research Framework, with content based on caregivers' informational needs. RCT participants were recruited at the hospital during their presurgery visit, when a health care provider introduced the study and provided instructions on how to use the app. No additional human support was scheduled thereafter. A sample size of 180 participants (90 per group) was estimated to detect the expected between-group difference in caregiver anxiety. Participants were randomly assigned in a 1:1 ratio to app use or standard care alone. The primary outcome was the between-group difference in caregiver state anxiety (State-Trait Anxiety Inventory [STAI-Y]). Secondary outcomes included between-group differences in child distress (modified version of the Yale Preoperative Anxiety Scale [mYPAS]), child preparation for surgery, family preparation for hospital admission and surgery, and social impact indicators. Outcomes were assessed online through questionnaires, which included both self-reported measures and evaluations completed by a nurse on the day of surgery. App engagement metrics were also collected. Reporting followed the CONSORT-EHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and Online Telehealth) guidelines.

Results: The study enrolled 227 caregivers, with 111 allocated to the control group (CG) and 116 to the experimental group (EG), achieving the target sample size. No statistically significant differences were observed between the groups for the primary or secondary outcomes (all $P>.05$). In the EG, 75% (n=87) of the participants accessed at least 1 item of in-app content. Higher baseline anxiety was linked to lower app use ($\rho=-0.22$, 95% CI –0.39 to –0.04; $P=.02$), while greater use was linked to lower child distress ($\rho=-0.23$, 95% CI –0.40 to –0.04; $P=.02$).

Conclusions: Although the hypotheses were not confirmed, these findings provide valuable insights for future perioperative mHealth research. The lack of effectiveness may reflect limited exposure to the intervention, outcome selection and timing, and contextual factors such as caregivers' independent information-seeking. These findings support a greater focus on implementation processes and on identifying the caregivers most likely to benefit from mHealth-supported education.

Introduction

Background

Pediatric ear, nose, and throat (ENT) surgery has undergone substantial advances over recent decades, with the introduction of innovative surgical techniques and standardized clinical pathways. In this context, elective procedures, such as tonsillectomy and/or adenoidectomy, with or without tympanostomy tube insertion, remain among the most frequently performed surgical interventions in children [1-5].

These procedures are typically delivered in high-pressure clinical settings characterized by short hospital stays and limited time for structured education. For children and their caregivers, the perioperative pathway is often unfamiliar and information-dense, leaving little opportunity to adequately address the different phases of the process, potential intraoperative risks, and common postoperative complications [6]. Postoperative sequelae may include pain, bleeding, nausea, vomiting, infection, swallowing difficulties, and prolonged discomfort after discharge. These complications can reduce oral intake, lead to dehydration, disrupt sleep, and, in more severe cases, result in hospital readmission and repeated school absences with potential academic consequences, thus placing considerable emotional and organizational demands and burden on families [5-8]. In addition, emotional factors play a key role in shaping perioperative outcomes in children, influencing both preoperative preparation and postoperative management and recovery [9]. In particular, perioperative anxiety has been consistently associated with adverse postoperative outcomes. Evidence shows that children who experience higher levels of anxiety before surgery are more likely to report increased postoperative pain and face a higher risk of complications [10,11]. Elevated preoperative anxiety in young children is also associated with increased sleep disturbances and higher levels of postoperative anxiety during recovery [10]. From a behavioral perspective, children may also exhibit problematic behavioral changes and temporary limitations in daily activities in the immediate postoperative period following ENT surgery [12].

Consistent with the family-centered approach, which considers family caregivers as key partners throughout the perioperative pathway, parental emotional responses represent another critical component of the pediatric perioperative experience. In fact, parental anxiety has been consistently identified as a significant predictor of children's anxiety prior to surgery [13] and appears to play a decisive role in shaping postoperative outcomes. Several studies have shown that higher levels of preoperative parental anxiety are associated with increased postoperative pain in children, a longer duration of analgesic use, and a higher number of analgesic administrations following tonsillectomy with or without adenoidectomy [4]. Similarly, children undergoing adenotonsillectomy whose parents report elevated anxiety levels have been found to experience higher rates of postoperative pain and complications [5]. Therefore, addressing parental anxiety before and during hospitalization is crucial not only to improve children's postoperative recovery but also to reduce emotional distress in both children and caregivers throughout the perioperative process. Interventions aimed at supporting parents' coping strategies and self-efficacy, including the provision of clear, timely, and tailored information, have been recognized as particularly relevant in pediatric surgical care [14-17].

Considering the complexity of the ENT perioperative process and its multiple clinical, emotional, and organizational implications, the provision of effective preoperative and postoperative education for both children and their family caregivers represents an essential component of care. In this context, parents' health literacy (HL), defined as "the knowledge, motivation, and competencies to access, understand, appraise, and apply health information in order to take judgements and take decisions in everyday life concerning health care, disease prevention and health promotion" [18], plays a pivotal role in how families navigate the perioperative surgical pathway. Evidence indicates that a substantial proportion of parents and caregivers of pediatric surgical patients have limited HL, which may negatively affect their understanding of surgical conditions, perceived risks and benefits, adherence to preoperative and postoperative instructions, and the quality of informed consent, while also contributing to higher levels of anxiety during surgical consultations [19-21]. These difficulties may be exacerbated by time constraints during consultations and the use of medical terminology that caregivers may find difficult to understand or feel uncomfortable questioning [22].

Moreover, the literature has revealed that parents tend to self-educate by relying on available online health care information, quickly seeking answers to their questions directly and anonymously from home [23,24]. These practices expose them to the risk of accessing information that, coming from very heterogeneous sources, is unreliable and not scientifically validated [25].

Within this framework, addressing these educational and communicative challenges requires structured perioperative preparation strategies that support both children and families throughout the ENT surgical pathway. Evidence suggests that nonpharmacological and digital interventions, including educational and immersive approaches aimed at familiarizing children with the hospital environment, equipment, and planned procedures, can reduce anxiety and emotional distress in pediatric surgical patients, particularly when integrated into perioperative preparation [15-17].

Building on these findings, perioperative digital interventions have been increasingly implemented across pediatric surgery. These interventions range from apps to text-messaging systems that support education, symptom monitoring, and reminders for medications or follow-up appointments. Overall, the available evidence suggests potential benefits in outcomes such as

XSL•FO
RenderX

follow-up adherence, postoperative monitoring, and user satisfaction, although study quality is variable and several trials show limitations (eg, inadequate controls, lack of blinding, and unequal attention to the experimental group [EG] and control group [CG]) [26].

Evidence syntheses also indicate that digital and distraction-based strategies, particularly virtual reality and other interactive formats, can reduce children's preoperative anxiety and may improve immediate perioperative outcomes, supporting their broader adoption in practice [15-17,27]. However, much of the literature focuses on single time windows (eg, preoperative anxiety reduction, postoperative follow-up or monitoring) rather than supporting families across the full perioperative pathway in a coherent way [15,26]. Recent evidence indicates that perioperative programs integrating multiple interventions across different time points, rather than focusing on a single moment of care, may achieve greater effectiveness in reducing parental and child distress [28].

Moreover, parental anxiety has been recognized as a relevant and modifiable target, with reviews describing multiple approaches (eg, education, audiovisual tools, preparation programs, and parental presence strategies), but with heterogeneity in content and delivery and limited clarity on which components work best for which families [28]. Furthermore, prior randomized controlled trials (RCTs) and meta-analyses include heterogeneous surgical populations, limiting conclusions specific to tonsillectomy and/or adenoidectomy with or without tympanostomy tube insertion [15].

Importantly, parents report valuing information provided directly by the hospital, suggesting that institution-endorsed digital tools may be particularly acceptable and useful for addressing practical issues such as pain management and fasting discussions at home [29]. Within this framework, there is a need for a condition-specific, hospital-based mobile health (mHealth) intervention designed to support family caregivers across milestones of the pediatric ENT perioperative process, using a user-centered participatory approach, with outcomes assessed through a rigorous trial design [30].

The Study: Rationale and Objectives

Considering the gaps in the literature, the aim of the current study was to evaluate the effectiveness of an mHealth app in supporting family caregivers of pediatric patients undergoing tonsillectomy and/or adenoidectomy with or without tympanostomy tube insertion, compared with supportive and educational methods related to standard care, in an RCT. Building on existing evidence, the present study focuses on the implementation of an mHealth system tailored to a specific pediatric surgical context and a clearly defined group of end users, considering the multiple phases of the ENT perioperative process. The mHealth app used in the intervention was a custom-designed, disease-specific, accessible tool, capable of providing validated scientific information, complying with current safety and privacy regulations, and designed to accompany children and their family caregivers throughout the perioperative process [31].

In line with the general aim, we intended to pursue 2 objectives. The primary objective was to explore the effect of using the mHealth app on the level of anxiety experienced by caregivers compared with standard care. The secondary objectives of the RCT were to evaluate the impact of using the mHealth app, compared with standard care, on 3 educational-emotional-organizational aspects, including (1) child preparation for hospitalization and surgery, (2) child distress before surgery, and (3) social impact such as postdischarge management. The study is based on the hypothesis that the possibility of using the mHealth app could help both reduce caregivers' state anxiety (primary outcome) and improve child preparation for hospitalization and surgery, child distress, and social impact related to postdischarge management at home (secondary outcomes).

Methods

Study Design and Setting

A full description of the design and methods used is contained in the study protocol [32]. The study used a 2-arm, parallel, open-label RCT involving family caregivers of pediatric patients aged between 2 and 10 years, who were scheduled for tonsillectomy and/or adenoidectomy with or without insertion of a tympanostomy tube. The study was conducted within a superiority framework, aiming to determine whether the EG yields better outcomes compared to the CG.

Blinding of participants, nurses, and researchers involved in the study was not feasible due to the nature of the intervention. Caregivers allocated to the EG were required to download and actively use the mHealth app and could seek support from nurses throughout the perioperative pathway, whereas those in the CG received standard care alone. In addition, nurses and researchers were involved in participant enrollment and data collection activities within the clinical setting, and app use could become apparent during routine clinical interactions, making concealment of group allocation impracticable.

The monocentric study was conducted at a 136-bed maternal and child health hospital (MCHH) in Northern Italy, where approximately 450 tonsillectomies or adeno-tonsillectomies are performed each year. The participant enrollment process, which took place in the consulting rooms of the hospital's pediatric ENT surgery department, began in December 2022 and concluded in December 2024. The random allocation sequence was generated independently by the hospital's expert statistician from the Clinical Epidemiology and Public Health Research Unit using computer-generated randomization with a block size of 4. Allocation concealment was ensured through sequentially numbered, opaque, sealed envelopes. Personnel involved in participant enrollment did not have access to the allocation sequence.

Nursing staff responsible for enrollment were in charge of providing eligible family caregivers with information about the study and obtaining signed informed consent from those wishing to participate in the RCT. Participation was voluntary, and caregivers could withdraw from the study at any time. The nurses, previously adequately trained in the mHealth app

XSL•FO
RenderX

content, features, and functionalities, were also responsible for instructing the EG caregivers both on how to download the app onto their smartphones or tablets and on how to use its contents and functionalities. During this training session, the nurses also showed the EG participants a 3-minute video presentation of the app on a tablet.

This trial is reported in accordance with the CONSORT-EHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and Online Telehealth) checklist (Checklist 1) [33].

Participants

Eligible participants were caregivers of children aged 2 to 10 years scheduled for tonsillectomy and/or adenoidectomy, with or without tympanostomy tube insertion. Caregivers were required to be able to communicate in spoken and written Italian and to have access to a smartphone and an internet connection. Exclusion criteria included cognitive or visual impairment in caregivers, cognitive impairment and/or chronic pain conditions in the child, previous surgery within the last month, and lack of previous experience with smartphone apps among caregivers. A formal assessment of reading comprehension was not performed during recruitment. However, eligibility was verified through direct interaction with caregivers, including confirmation of their ability to communicate in spoken and written Italian. HL was assessed as a study variable rather than used as an eligibility criterion, as the aim was to evaluate the intervention in a caregiver population representative of routine clinical practice.

After enrollment, participants were recruited in person at the hospital, on the day of their pre-surgery visit. Participants were not required to pay to access the app. Participants were randomly assigned in a 1:1 ratio by opening a sequentially numbered opaque and sealed envelope to either the EG, which received access to the mHealth app in addition to standard care, or the CG, which received standard care only. Standard care comprised oral information and education on the ENT perioperative pathway, supplemented by printed brochures provided by physicians and nurses during preoperative visits and throughout the hospitalization period.

Intervention Description

The intervention tested in this study was a purely app-based intervention. It allowed participants in the EG to access and use an mHealth app on their smartphones to acquire information and education about the ENT perioperative process related to 2 specific surgical procedures, namely tonsillectomy and/or adenoidectomy with or without insertion of a tympanostomy, in addition to receiving information and education on standard perioperative care provided by the ward's health care professionals. The EG was allowed to access the mHealth app from the day of the presurgery visit or preadmission consultation—when the enrollment took place—until the day of the scheduled follow-up visit, about 7 days after surgery. There was no mandatory minimum number of content views.

The contents, features, and functionalities of the mHealth app have been designed and developed by adopting a user-centered participatory design approach, in line with the Information System Research (ISR) framework [34], through the exploration of the informational or educational needs and preferences of both family caregivers (ie, primary end-users) and health care providers (ie, secondary end users) toward the mHealth app itself. A detailed description of the participatory design approach has already been published [30]. This co-design and codevelopment process involved the MCHH, which hosted the RCT and a public research institution, both situated in northern Italy.

Regarding content, the mHealth app contained 116 PDF documents covering the following six different thematic areas corresponding to 6 key informational or educational moments in the ENT perioperative process identified by primary and secondary end users who were directly involved in the participatory development process of the mHealth app: (1) the first inpatient ENT surgical consultation; (2) the phone call from the ENT surgical planning office to the family caregiver to communicate the date of the planned surgery and a list of necessary documents to bring on the day of preadmission consultations; (3) the day of preadmission consultations when caregivers are responsible for delivering the documents necessary for hospital admission and nursing, during which the anesthesiological and surgical consultations and examinations are also conducted; (4) the day of the family's admission to the hospital and where the surgery is performed; (5) discharge from the hospital and preparation for postoperative care at home, generally on the same day as the surgery (in the absence of complications); and (6) the follow-up visit in the hospital which takes place approximately 7 days after surgery. The app's contents were validated by the research team and the MCHH Scientific Director. Screenshots of the app have been published elsewhere [30].

The app's content was delivered in accordance with a timing principle, ensuring that information relevant to the specific stage in the ENT perioperative process was presented to the caregiver at the appropriate moment. In particular, depending on the child's stage in the perioperative process (eg, the day of preadmission consultation, the day of hospital admission and surgery, or postoperative recovery at home), the relevant content was suggested to the family caregiver through pop-up notifications as newly available content to consult within the app.

All the proposed content included validated medical information and reliable scientific references. All documents were provided in Italian and in text format. Depending on the specific topic covered, documents could include images, hyperlinks, graphical representations, and/or links to in-depth videos designed to facilitate caregivers' understanding. To access specific information content, caregivers had to open the corresponding PDF document in the app. Although the educational content was designed to be conveyed to the study participants progressively, reflecting the evolution of the ENT perioperative process, family caregivers still had access to all the documents throughout the period between enrollment and the follow-up visit, since they were available to end users at any time in a dedicated section of the mHealth app called Library in a consumable format and in line with the "just in time" principle [35].

XSL•FO
RenderX

As anticipated in the *Study Design and Setting* section, both participants in the EG and CG benefited from the supportive educational methods of standard care provided by health care personnel (ie, physicians and nurses), both orally and through the delivery of printed brochures. This education on the ENT perioperative process was comparable to that conveyed to the EG via the mHealth app, including content on strategies for preparing children for the experience of hospitalization, the specific surgical procedure selected, the type of anesthesia chosen, or managing postoperative pain in children at home after discharge. During the RCT, neither the EG nor the CG was prevented from seeking and using further information from books or other print materials, consulting other health care professionals, or web or social media sources. This approach was intentionally adopted to reflect routine clinical practice, where caregivers are exposed to and may actively seek information from multiple sources. The intervention was therefore evaluated as an adjunct to usual information-seeking behaviors rather than as a replacement for them.

Measures Used to Evaluate the Outcomes

The measures were taken at 4 different times, including T0 (ie, the enrollment), T1 (ie, the day of preadmission consultations), T2 (ie, the day when the surgery was performed), and T3 (ie, the follow-up visit). The timing, administration, and scoring methods for each measure are indicated below.

Sociodemographic Questionnaire

A sociodemographic questionnaire was self-assessed by participants at T0 to collect information on the family caregiver's age, gender, education level, occupational status, type of relationship with the child (ie, mother, father, other guardian), possible employment as a health professional, and any previous experience in caring for others with health problems. The questionnaire also asked caregivers about the child's age and sex, the surgical procedure planned during the current hospitalization, and any previous surgical experiences the child had undergone.

HL

Caregivers' level of HL was assessed at T0 using the 16-item self-assessment version of the European Health Literacy Survey Questionnaire (HLS-EU-Q16) [36]. This tool provides 5 possible answers on a 4-point Likert scale ranging from 1 (very difficult) to 4 (very easy), with a fifth possible answer equivalent to "I don't know." The expected score range is 0 - 16 and, depending on the total score obtained, 3 levels of HL can be distinguished, that is inadequate (0 - 8), problematic (9–12), and sufficient HL (13–16).

Caregiver's Preparation for Hospital Admission and Surgery

At T1, administrative nurses assessed caregivers' preparation for hospital admission and surgery using a checklist to verify the completeness of the necessary documentation provided by parents when they arrived at the hospital. The number of missing documents (eg, identity card or health care card) was recorded.

Child's Preparation for Surgery

At T2, a nurse in the surgical department assessed whether all the instructions provided by the staff for standard child surgical preparation had been followed, including proper hygiene, fasting, and not wearing nail polish or jewelry.

Caregiver's Anxiety

Caregivers' anxiety was evaluated using the Italian version of the State-Trait Anxiety Inventory questionnaire [37], consisting of 2 self-report scales for assessing state anxiety and trait anxiety, respectively: (1) the STAI Form Y-1 (STAI-S), including 20 statements aimed at measuring how the family caregiver feels "now, at this moment" on a 4-point Likert scale ranging from "not at all" to "very much", and (2) the STAI Form Y-2 (STAI-T), comprising a further 20 statements aimed at assessing how the participant feels "generally" on a 4-point Likert scale ranging from "almost never" to "almost always." The total score ranged from 20 to 80 points, and lower scores corresponded to higher levels of trait and state anxiety. Family caregivers were administered both scales at T0 to establish baseline levels of state and trait anxiety. The STAI-S scale was then further administered to caregivers in the hospital's ENT surgical department at both T2, before the surgery was performed, and T3, at the follow-up visit, approximately 7 days after surgery.

Child's Distress

To assess the child's distress at T2, a modified version of the Yale Preoperative Anxiety Scale (m-YPAS) [38] was used. This is an observational tool consisting of 27 items that explore five specific areas: (1) child activity, (2) child emotional expressiveness, (3) child arousal state, (4) child vocalization, and (5) caregiver engagement. The total score ranged from 23.33 to 100 points, and higher scores corresponded to higher levels of distress. Since a validated Italian version of the scale was not available, the tool was administered only by English-speaking nurses, in line with Liguori et al [39].

Social Impact Indicators

This area was self-assessed by family caregivers at T3, by answering questions about aspects such as how often caregivers called the hospital for further information, experienced and managed complications at home after discharge (eg, child pain or bleeding), or accessed the pediatric emergency department of the hospital.

mHealth App Usage

Data relating to the use of the mHealth app by family caregivers in the EG (eg, number of app accesses, the number and type of documents consulted, time spent exploring the app) were collected.

mHealth App Satisfaction

A satisfaction survey regarding the app was administered at T3. Participants were asked (1) to rate the app's completeness, usefulness, and ease of understanding; (2) to indicate whether they had sought additional information online due to dissatisfaction with the app's content; (3) to report any technical

XSL•FO
RenderX

issues experienced while using the app; and (4) to provide an overall satisfaction rating.

The STAI Forms Y-1 and Y-2, the HLS-EU-Q16, and the m-YPAS are validated instruments. However, the questionnaires administered online have not been specifically validated for online use.

The questionnaires administered at T0 and T2 were completed online in the ENT surgical department via a tablet provided by nurses to the EG and CG family caregivers. The T1 assessment was completed instead in paper form. Furthermore, the T3 evaluation was conducted online, after sending caregivers an email with a link to complete the relevant questionnaires. The latter approach was chosen since not all caregivers bring their children for follow-up at the MCHH promoting the study, sometimes preferring to refer and consult their general pediatrician.

Before the study began, nurses in the ENT surgical department involved in enrollment and subsequent measurements were adequately trained on the use of the assessment tools through the provision of standardized instructions. The training was conducted by a nurse from the research team and took place in a meeting room of the department.

Sample Size

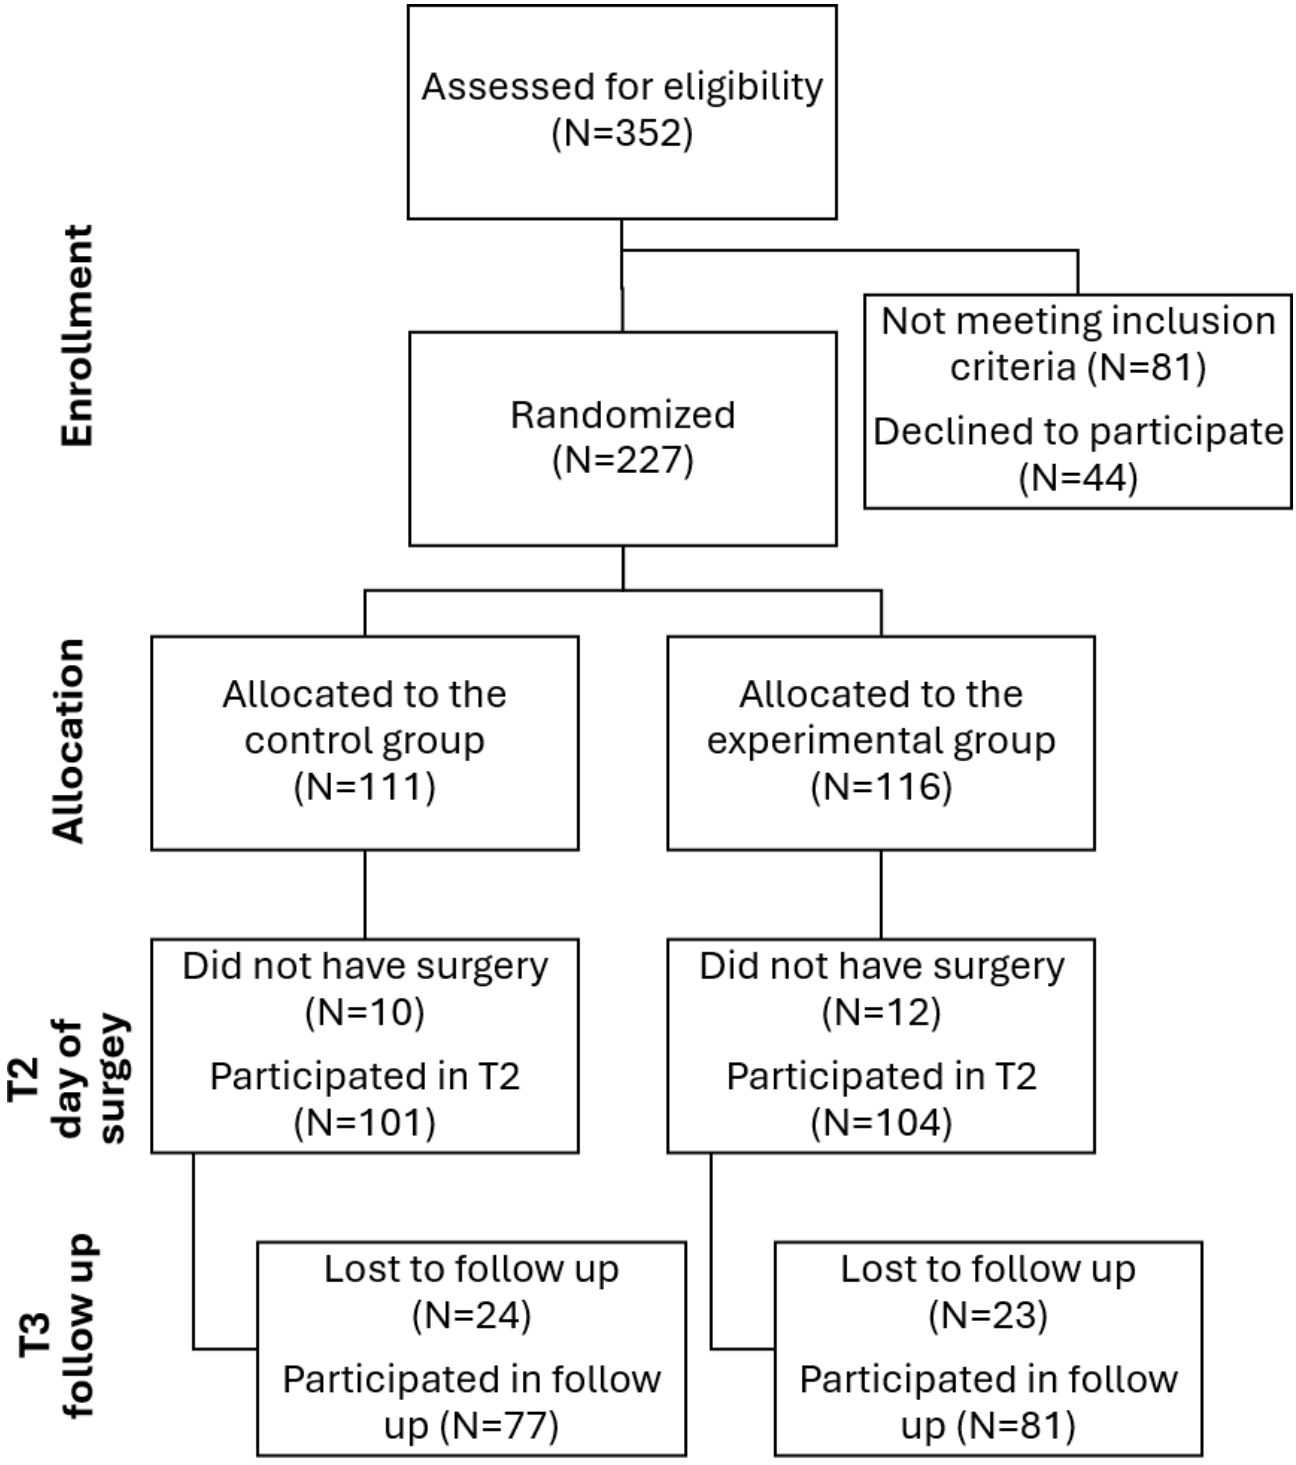
The sample size was estimated considering preoperative anxiety as the primary outcome. The sample size was estimated considering parental preoperative anxiety as the primary outcome, assessed using the Italian version of the State-Trait Anxiety Inventory (STAI-Y) [37]. The expected mean anxiety score, informed by data previously reported in an Italian pediatric surgical population [40], was 50 (SD 13) in the CG and 45 (SD 10) in the EG, corresponding to an effect size of 0.43. Based on these assumptions, a total sample of 180 participants was required, with 90 participants allocated to each group. The calculation was performed using G*Power for a 2-group Wilcoxon-Mann-Whitney test, assuming a significance level of 0.05 and a power of 80% (β=.20).

Data Analysis

Description of the sample was based on frequency and percentage for categorical variables and on median and IQR for continuous variables. The standard statistical analysis was for intention-to-treat, and the balancing of baseline characteristics of the sample between the 2 groups of intervention was tested. The chi-square test or the exact Fisher test, as appropriate, was used to assess the association between 2 categorical variables. The nonparametric Wilcoxon-Mann-Whitney test was applied to evaluate the difference in the distribution of a continuous variable between 2 modalities of a categorical variable. The nonparametric Wilcoxon signed-rank test was calculated to test the difference between 2 paired continuous variables. Correlation was evaluated with the Spearman coefficient; a *P* value <.05 was considered statistically significant. SAS (version software 9.4 (SAS Institute Inc.) was used to conduct all statistical analyses. All randomized participants were analyzed in the group to which they had originally been assigned, regardless of intervention adherence. Reasons for study withdrawal were documented and recorded. Missing data were not imputed, and analyses were conducted using available data only. Data from the EG were analyzed in detail using the Wilcoxon rank-sum test and Spearman's rank correlation coefficient.

Ethical Considerations

This study received approval from the local ethics committee (CEUR-2022-Sper-26). As the intervention consisted exclusively of providing information and educational content through a smartphone app, it was intended as a low-risk intervention, and no serious adverse events were expected. Written informed consent was obtained from all caregivers through an offline, paper-based procedure, and no compensation was provided. Participants indicated their choice by selecting either a box confirming their willingness to participate or a box declining consent. Participants were informed that they could withdraw from the study at any time without the need to provide a reason. Children over 6 years of age were also asked to assent to participate in the study, signing a simplified, age-appropriate document that explained the study and what their agreement entailed. All personal data were processed in accordance with applicable data-protection regulations, and anonymization procedures were implemented prior to analysis.



Results

Participant Characteristics

A total of 352 caregivers were screened between December 2022 and December 2024. Of these, 125 were excluded due to ineligibility or refusal to participate, resulting in the enrollment of 227 family caregivers of pediatric ENT patients, which met the target sample size. The participant flow diagram is detailed in Figure 1. As some questionnaires were not completed by all participants, only the available data were included in the analyses.

XSL•FO
RenderX

Figure 1. Participants' flow diagram.

Participants were randomly assigned to either the EG (n=116) or the CG (n=111). In both groups, women represented the clear majority (CG: n=90, 82.57%; EG: n=92, 79.31%). Their educational backgrounds spanned a wide range, from lower-secondary to postgraduate levels, with upper-secondary schooling being the most common (CG: n=61, 55.96%; EG: n=59, 50.86%). The majority were employed (CG: n=90, 82.57%; EG: n=94, 81.03%), often in clerical or office-based roles (CG: n=50, 45.87%; EG: n=57, 49.14%), though various occupational categories were represented. Caregivers were generally in mid-adulthood, with most falling between 30 and 49 years of age. The most common surgical procedures among children in both groups were adenoidectomy alone and tonsillectomy combined with adenoidectomy, which together accounted for 82.56% (n=90) of surgeries in the CG and 80.17% (n=93) in the EG.

At baseline, caregivers showed a distribution of HL levels ranging from inadequate to sufficient, with the majority classified in the sufficient category (CG: n=69, 62.73%; EG: n=72, 62.07%). The initial anxiety median scores in the CG were 37 (IQR 30 - 44) for the STAI-S and 36 (IQR 32 - 43) for the STAI-T scores, while the initial anxiety median scores

XSL•FO
RenderX

were 36 (IQR 31 - 44) for the STAI-S and 36 (IQR 31 - 42) for the STAI-T in the EG.

A complete set of participants' characteristics is reported in Table 1.

[a]Some questionnaires were not completed by all participants. In the control group, 3 sociodemographic questionnaires and 1 STAI Form Y-2 or State-Trait Anxiety Inventory questionnaire were not submitted. Furthermore, 1 control group participant did not provide a valid age value.

Caregiver Anxiety (Distribution of STAI Scores)

Total STAI-S scores changed significantly over time (P<.0001). The median score increased from 36 (IQR 31 - 42) at T0 to 38 (IQR 33 - 46) at T2, indicating a temporary rise in anxiety following baseline, since at T3, the median score decreased to 32 (IQR 28 - 39), reflecting a longer-term reduction in anxiety. All changes were statistically significant (P<.0001).

No difference in the distribution of caregiver state anxiety was found between T2 and T0 when comparing the EG and CG. The same result emerged between T3 and T0 and between T3 and T2. Table 2 presents the distribution of changes in caregivers' state anxiety levels (STAI-S) at the different measurement time points by study group.

Table . Distribution of the difference in the caregiver state anxiety levels (STAI Form Y-1 [STAI-S]) between T0, T2, and T3 by study group[a].

Difference in STAI-S between T0, T2, and T3	CG[b]		EG[c]		
	Participants, n	Median (IQR; min-max)	Participants, n	Median (IQR; min-max)	*P* value
STAI-S at T2—STAI-S at T0	98	2 (−2 to 7; −19 to 22)	96	3 (−1 to 7; −24 to 25)	.38
STAI-S at T3—STAI-S at T0	77	−2 (−11 to 1; −33 to 14)	81	−1 (−8 to 3; −25 to 24)	.08
STAI-S at T3—STAI-S at T2	75	−5 (−15 to 0; −43 to 12)	76	−6 (−12 to 0; −35 to 23)	.82

[a]Group differences were assessed using the nonparametric Wilcoxon Mann-Whitney test. Statistical significance was defined as P<.05.

[b]CG: control group.

[c]EG: experimental group.

From T0 to T2, both the CG and the EG showed a statistically significant increase in anxiety. In the CG, the median change was 2 (IQR −2 to 7), while in the EG it was 3 (IQR −1 to 7). From T0 to T3, the CG showed a median decrease of –2 (IQR −11 to 1), and the EG reported a median change of –1 (IQR −8 to 3). Nonetheless, the EG reported significantly more favorable scores than the CG for the statement "I feel comfortable" (item 10) of the STAI-S at T2 (P=.04; Table 3).

Table . Distribution of responses of item 10 of STAI Form Y-1 (STAI-S) at T2.

STAI-S at T2	CG[a], n (%)	EG[b], n (%)	*P* value
Item 10: "I feel confident"			.04
1	17 (17.35)	12 (12.50)	
2	60 (61.22)	57 (59.38)	
3	13 (13.27)	25 (26.04)	
4	8 (8.16)	2 (2.08)	

[a]CG: control group.

[b]EG: experimental group.

Caregiver's Preparation for Hospital Admission and Surgery

The data collected at T1 were lost due to the renovation of the hospital's administrative Welcome Point, which resulted in the displacement of the stored materials.

Child Distress (M-YPAS)

No statistical difference in child distress m-YPAS score at T2 emerged between the groups (*P*=.10), with equal median values (CG: 23.40; EG: 23.40) and overlapping IQRs (CG: 23.40 - 38.40; EG: 23.40 - 29.20).

Child's Preparation for Surgery

Both groups demonstrated consistently high compliance with preoperative instructions, such as arriving fasting (CG: n=97, 100%; EG: n=97, 99.0%), maintaining hygiene (100% in both groups, n=97 and n=98, respectively), and removing nail polish (CG: n=97, 100%; EG: n=93, 94.9%) or jewelry (CG: n=95, 97.9%; EG: n=97, 99.0%). Overall, no statistically significant differences were observed between the CG and EG regarding any aspect of the child's preparation for surgery (all *Ps*<.05).

Social Impact Indicators

Most social impact indicators did not show significant differences between the CG and EG. For the item "On a scale from 1 to 10, how adequate was the in-person time allocated by the medical and nursing staff at the MCHH throughout your child's surgical care pathway?", however, a significant difference emerged in the score distribution (*P*=.03). A larger proportion of parents in the CG assigned the maximum score of 10 (n=30, 39.0% vs n=17, 21% for the CG and EG, respectively), whereas the EG ratings were more concentrated around intermediate values (6 - 7: n=8, 10.4% vs n=21, 25.9% for the CG and EG, respectively).

mHealth App Usage and Satisfaction (EG Only)

The median duration of app use in the EG was 6 (IQR 5 - 7) days. Overall, 87 (75%) out of 116 caregivers in the EG viewed at least 1 content item, with a minimum of 13 contents opened and a maximum of 120. In particular, 35.3% (n=41) viewed fewer than 5 items. The 10 topics that attracted the most caregivers were, in decreasing order of number of views, the following: "Postoperative pain management (n=171)," "Postoperative diet at home (n=161)," "Postoperative home-care instructions (n=125)," "Items to bring to the hospital on the day of admission and surgery (n=117)," "How to prepare my child for outpatient visits, hospital admission, and surgery (n=102)," "The operating room (n=102)," "Can my child eat whatever they want? (n=102)," "From the ward to the operating room (n=100)," "On the ward after surgery (n=89)," and "Can my child bathe/wash? (n=87)."

A detailed analysis of the data from the EG, conducted using the Wilcoxon rank-sum test and Spearman's rank correlation coefficient, did not reveal a significant association between HL score and the number of viewed contexts (ρ=0.13, 95% CI –0.05 to 0.31; *P*=.16). A significant negative correlation emerged between the number of app contents opened and both the mYPAS child distress score (ρ=–0.23, 95% CI –0.40 to –0.04; *P*=.02) and the STAI-S caregiver state anxiety score at T0 (ρ=–0.22, 95% CI –0.39 to –0.04; *P*=.02), indicating that higher engagement with app contents was associated with lower child distress at T2 and with lower caregiver state anxiety levels at T0 in the EG, respectively.

The app was evaluated through a satisfaction questionnaire completed by 46.55% (n=56) of the users. Overall, respondents rated the app as "very" or "completely" complete (n=46, 85.18%), useful (n=48, 88.89%), and easy to understand (n=29, 53%). Most participants reported "never" having searched for additional information online due to dissatisfaction with the app's content (n=36, 66.67%) and indicated that they did not experience technical issues while using the app (n=47, 87.04%). Regarding overall satisfaction, the majority of users were "completely" (n=14, 25.93%) or "very" (n=26, 48.15%) satisfied with the app. Users' overall satisfaction was not significantly associated with baseline characteristics, HLS-EU-Q16, STAI, or m-YPAS scores.

Discussion

Principal Findings

This RCT evaluated whether a co-designed mHealth app could reduce caregiver anxiety during the pediatric ENT perioperative pathway. Contrary to our hypothesis, no significant differences in anxiety were found between caregivers who received the mHealth app in addition to standard care and those who received standard care alone. Likewise, no significant between-group differences were observed for child distress, child preparation for hospitalization and surgery, and postoperative management at home. This lack of detectable effects of using the mHealth app may appear disappointing, yet it aligns with a growing body of evidence showing limited effectiveness of app-based

XSL•FO
RenderX

interventions in pediatric perioperative care, particularly regarding caregiver anxiety [15]. Overall, while mHealth tools have shown promise in reducing distress among children [15,41], evidence of benefits for caregivers' anxiety remains weak [15,42]. In this light, the null findings reinforce the need for critical reflection on both methodological and contextual factors that may have influenced the effectiveness of the intervention. First, even if the baseline characteristics of the CG and EG overlapped, over one-third of the sample of family caregivers in the EG had a low HL level**,** which may have reduced their ability to understand, appraise, or use the health information provided through the app [18]. Moreover, although the language of the content was simplified, 1 in 6 of caregivers in the EG spoke a different native language. Therefore, the extent to which linguistic or literacy-related barriers influenced the EG's ability to use the app remains unknown [43].

A further factor that may have influenced the findings is that participants in the CG may have independently sought information online, consistent with the phenomenon known as "contamination by informal information-seeking," which is now well documented in the literature [44], thereby blurring the differences between the 2 groups.

Another contributing factor may relate to the timing of anxiety measurement, which occurred shortly before surgery, a moment that may reflect an expected physiological peak in parental stress rather than a modifiable psychological state [40]. This calls into question whether state anxiety is the most sensitive or appropriate outcome to capture the effects of digital tools that may operate more subtly, by improving knowledge, emotional preparedness, or perceived control. Notably, anxiety levels increased for both groups between baseline and the day of surgery, reflecting expected surgery anticipatory stress [44]. Following surgery, anxiety levels decreased in both groups, consistent with previous findings [41]. This pattern suggests that perioperative anxiety may evolve over time according to the natural course, regardless of the specific support tool used.

Finally, the time available to engage caregivers in using the app before surgery may have been insufficient. With a median usage period of only 6 days, caregivers may have had limited opportunities to explore and interact with the tool and related content and functionalities, given competing responsibilities and the demands of daily life.

Regarding app use, a notable share of caregivers either did not access the app or used it only minimally. Several factors may account for this limited use. One plausible factor is variation in individual preferences for how educational content was delivered. A systematic review of pediatric pretonsillectomy education programs found that interventions using smartphone apps, brochures, text messages, and videos all showed variable levels of engagement and efficacy, depending on the modality used and the target audience selected, suggesting that engagement may be influenced more by preferred learning styles than content quality alone [13]. Consistent with previous literature, another contributing factor may have been that some caregivers preferred direct human interaction and information delivered by health care professionals [45,46]. This interpretation is also supported by the findings on social impact indicators, as only 1 item showed a significant difference between the groups: parents in the CG rated the adequacy of in-person time provided by staff more highly than those in the EG. This pattern may suggest that reliance on face-to-face communication increased the perceived value of direct interaction, whereas access to the app may have shifted expectations toward digital support, influencing perceptions of in-person contact rather than actual staff time. This interpretation is consistent with evidence that technology-based preparatory tools can modify caregivers' expectations about interpersonal communication and shape how they appraise and value face-to-face interactions [47].

Another barrier to app use may have been that some family caregivers perceived it as difficult to navigate and engage with it because of the volume and density of the content provided, which may have led to information overload [47]. Although overall satisfaction with the app was high among approximately half of the participants who completed the app satisfaction evaluation survey, our results show that caregivers with higher baseline anxiety were less likely to engage with the app. This finding is consistent with Zhuo et al [48], who distinguish "monitors" (active seekers) from "blunters" or "avoiders." These different information-seeking behaviors suggest that those experiencing higher anxiety at preadmission, and who presumably would have needed the most support in managing it, were less inclined to use the app. Such behavioral heterogeneity, typical in nonstratified samples, may have diluted observable group differences.

Usage patterns also led researchers to hypothesize that usability barriers may have emerged from the document format: materials were indeed provided as PDFs and did not adapt to screen size, resulting in a text font size that was too small to read, necessitating frequent zooming and panning on mobile devices.

Despite the general null findings, a dose-response effect was observed in the EG: caregivers who accessed more than 5 pieces of content had children who appeared less stressed preoperatively, supporting the findings of Wang et al [44].

Moreover, a slightly higher level of preoperative comfort was found in the EG. This small advantage may reflect the reassuring effect of clearer procedural and orientation information provided through the app, consistent with evidence that preoperative education can reduce parental anxiety [28].

Beyond the specific findings of this study, it is important to acknowledge that null results can provide valuable contributions to the evidence base. Reporting studies that do not demonstrate significant effects helps prevent publication bias and offers a more balanced understanding of the effectiveness of digital health interventions [49,50]. Such results can also inform the refinement of app design and implementation strategies, as well as help recalibrate unrealistic expectations regarding the potential impact of digital health solutions in complex clinical contexts. More broadly, making these findings available supports research transparency, improves the accuracy of future systematic reviews and meta-analyses, and ultimately contributes to cumulative scientific progress [49,50].

RenderX

Limitations

This study has several limitations. First, caregivers and nurses were not blinded to group allocation, which may have introduced expectation- and assessment-related biases, respectively. Furthermore, the RCT findings may have been affected by contamination bias resulting from caregivers' informal information-seeking from multiple additional sources [25], including health care professionals, printed materials, websites, and social media. Future studies could assess information-seeking behaviors more systematically (and stratify the sample accordingly) to explore their influence on intervention effectiveness [48].

Another limitation concerns the variability in engagement with the intervention. Many caregivers only accessed a limited portion of the app content and therefore did not receive the intended intervention "dose", which may have affected the ability to detect significant effects. Future studies should explore alternative and more engaging content delivery formats, such as videos, podcasts, and gamification features (eg, feedback, challenges, or rewards), which may enhance accessibility, usability, and user engagement with digital interventions [51,52].

Moreover, caregivers' reading fluency and comprehension competencies as well as document or digital literacy were not assessed in this study, although these skills affect the ability to navigate written materials, particularly when delivered in PDF files that are not optimized for mobile devices.

Furthermore, the timing of the measurement of anxiety, taken shortly before surgery, is another limitation, as it coincides with an expected peak of anticipatory stress. This may have reduced the sensitivity for detecting short-term changes attributable to app use.

Moreover, the app's navigability and information architecture, such as the length or text density of written materials, may not have fully supported ease of use for all users. These considerations are addressed in the Guide to Implementing the Health Literacy Universal Precautions Toolkit and its communication-design guidance, although this resource was not incorporated into the app's design and development process [53].

A further limitation was the loss of data collected at T1 regarding caregivers' preparation for hospital admission. However, this did not affect the study's primary or key secondary outcomes.

Finally, the single-site study design limits the generalizability of the findings, as participants may not be representative of broader linguistic, cultural, or sociodemographic populations.

Conclusions

The findings of this RCT suggest that adding an mHealth app to standard care did not significantly reduce caregiver anxiety. Beyond its clinical outcomes, this study provides a methodological contribution through the development and rigorous evaluation of a user-centered mHealth intervention for family caregivers of pediatric surgical patients. The trial also underscores key challenges associated with the implementation of digital health interventions in real-world clinical settings, including variability in user engagement, the timing and duration of intervention exposure, and the potential influence of information-seeking behaviors. These factors should be carefully considered when interpreting intervention effectiveness and when designing future trials.

Rather than questioning the value of mHealth interventions, these findings highlight that future research should shift its focus from developing and evaluating digital tools alone to understanding how they can be effectively implemented, integrated into routine care, and how engagement with digital interventions can be optimized across the perioperative pathway. This will require implementation strategies that promote meaningful and sustained engagement, while identifying which caregivers are most likely to benefit from mHealth-supported education. Optimizing caregiver support throughout the perioperative pathway remains an important objective, given its potential to positively influence the perioperative experience of both caregivers and children.

Acknowledgments

The authors would like to express their sincere gratitude to the nursing staff who contributed to the data collection process: Bartoli Araya, Cantoro Marco, Colautti Marzia, Culqui Betty Roxana, Cvetkovic Valentina, Damato Giulia, De Cesco Beatrice, Ferluga Rosita, Iacobelli Giulia, Ieracintano Nicole, La Macchia Renata, Mauri Tanja, Mele Francesco, Migliozzi Maria, Moretti Annamaria, Muzzachi Antonio, Pertot Federica, Rinaldi Lucia, Vatta Mascia, Zariali Metka, and Zecchin Alice.

The research team is grateful to the staff of CGM TELEMEDICINE S.R.L. (a CompuGroup Medical company) for developing the app that was tested in this study, Fablab S.R.L. (a CompuGroup Medical Italia company) for improving the legibility of the app's content, and Quality S.R.L. (a start-up spin-off of the University of Trieste, Italy) for developing the questions for the social impact survey.

The authors used ChatGPT to improve the readability and language of the manuscript. All outputs were reviewed and edited by the authors, who take full responsibility for the final content.

Funding

The development of the mHealth app experimented in this study was funded by "PROTOCOLLO DI INTESA TRA IL MINISTERO DELL'UNIVERSITA' E DELLA RICERCA E IL MINISTERO DELLO SVILUPPO ECONOMICO E LA REGIONE

Abstract

Background: Fetal alcohol spectrum disorders (FASD) affect 1.1% to 5% of the general population. Yet, most children with FASD and their families cannot access evidence-based interventions. Mobile health (mHealth) interventions have the potential to increase access to care on a broad scale. While numerous self-directed parenting apps exist, none have been tested for FASD. The FMF (Families Moving Forward) Connect app is a self-directed intervention derived from an empirically supported intervention for caregivers raising children with FASD. FMF Connect is the first self-directed parenting app for FASD, and also one of the first parenting apps to be systematically developed and tested.

Objective: This study aimed to test the efficacy of FMF Connect for caregivers raising children with FASD on targeted primary (child behavior, caregiver attributions, parenting efficacy and satisfaction, FASD knowledge, and family needs met) and secondary (child adaptive behavior, caregiver self-care, and app satisfaction) outcomes.

Methods: This study involved a 3-arm randomized controlled trial with equal allocation to groups (1) FMF Connect+coaching, (2) FMF Connect, or (3) waitlist control. Participants from the United States were recruited online through an open access website. Recruitment materials were distributed by the Collaborative Initiative on FASD, FASD listserves, and social media. In total, 129 caregivers of children (aged 3 - 12 y) with FASD or prenatal alcohol exposure (PAE) were enrolled. Online surveys were administered at baseline, 6 weeks, and 12 weeks. Data were analyzed with linear mixed modeling, linear regressions, and structural equation modeling using SPSS (version 29.0; IBM) and Mplus 8 (Muthén & Muthén).

Results: A total of 43 participants were randomized to each group. Caregivers were predominantly White adoptive mothers. Of the total, 64% (n=83) of participants were retained through the 12-week follow-up. Groups did not differ in terms of demographic characteristics, baseline levels of functioning, or attrition. Usage patterns were similar across groups, suggesting coaching did not increase engagement. Given a few differences, app intervention groups were combined for analyses. Relative to the waitlist group, caregivers in the FMF Connect group evidenced greater improvements in FASD knowledge, child behavior attributions, family needs met, and self-care after 12 weeks (P=.01-.048). After controlling for multiple comparisons, differences in FASD knowledge, self-care, and family needs met approached significance (P=.06-.07). Groups did not differ in parenting satisfaction, child behavior problems, or adaptive functioning. More app usage is related to greater changes in parenting efficacy. Caregiver behavior attributions at 6 weeks did not mediate intervention effects.

Conclusions: This study demonstrated initial efficacy of the FMF Connect app for targeted caregiver outcomes, with small to medium effect sizes. As an mHealth app, the FMF Connect intervention has potential for scalability and accessibility. This could lead to a substantial public health impact, particularly for families who face challenges accessing evidence-based resources or encounter other barriers to care.

Introduction

Fetal alcohol spectrum disorders (FASD) are highly prevalent developmental disabilities. Studies estimate that FASD affects 1.1% - 5% of the population [1]. Yet, most people with FASD remain undiagnosed and have inadequate access to services [2]. Diagnosis of FASD focuses on evidence of prenatal alcohol exposure (PAE) and neurobehavioral impairment. Additional symptoms, such as microcephaly, seizures, subtle characteristic facial features, and growth delays, are present in approximately 10% of individuals with FASD [1,3-5]. Individuals with FASD often require lifelong, multidisciplinary, community-based services in order to receive appropriate diagnosis, treatment planning, and daily-living supports [6-9]. Caregivers of children with FASD experience high rates of stress, feelings of isolation, and relationship strain between child and caregiver [7,10,11]. Despite higher needs, individuals with FASD and their families report substantial barriers to services due to limited availability of knowledgeable providers, societal stigma, lack of policy-based supports, and insufficient availability of appropriate, evidence-based services [9,12]. These systematic barriers emphasize the need for evidence-based interventions that are both accessible and tailored to the needs of families managing FASD, presenting an opportunity to apply innovative methods and new implementation strategies.

One method to surmount these barriers is mobile delivery of services or app-based interventions. There has been an increase in technology-augmented parenting programs that have been shown to support intervention engagement, caregiver skill building, and positive child behavior outcomes [13-15]. While promising, these programs require additional live therapeutic services and many are web-based. This trend does not reflect current accessibility and preference patterns, which indicate higher preference for mobile devices compared with desktop services [16]. Most adults have access to smartphones and demonstrate consistent understanding and use of phone-based apps [17]. Mobile health (mHealth) apps provide self-paced access to material, services, and supports that can be more easily scaled to larger populations than in-person or telehealth programs [18]. A recent meta-analysis documented that health behavior apps can result in significant improvement in behavior change across a variety of settings [19]. This suggests that app-based interventions are a promising way to solve problems of intervention accessibility.

Despite the promise of app-based interventions, there have been very few mHealth apps with evidence-based review that follows recommended mental health app guidelines [20]. A meta-review of parenting-based technological interventions by David and colleagues [13] indicated that of the 53 usable parenting-focused apps available in app stores, few offered personalized content or focused on caregiver functioning, and none have yet been evaluated in a randomized controlled trial (RCT).

As mHealth apps offer a promising solution to many barriers faced by families and providers when trying to access FASD-informed care, the FMF (Families Moving Forward) Connect app was developed to provide accessible, evidence-based support for caregivers of children with FASD. The FMF Connect app is the first known stand-alone, self-directed parenting app to be empirically evaluated for efficacy for caregiver and child outcomes [21-23]. The app was derived from the FMF Program, a 14- to 17-session program for caregivers of children aged 3 - 12 years with FASD and challenging behavior problems delivered by a trained specialist [24-26]. This program was developed and tested by Olson and colleagues [24-26] at Seattle Children's Research Institute and the University of Washington, with funding from the Centers for Disease Control and Prevention. The FMF Program was designed to address the needs of diverse family structures, socioeconomic status, and racial and ethnic identities, in clinic, home-based, or, recently, telehealth settings. Derived from developmental and family systems theories, the FMF Program integrates positive behavior support, motivational interviewing, and cognitive behavioral techniques. The FMF Program helps caregivers to understand their child's strengths and challenges and alter cognitions and attitudes toward child behavior from that of willful disobedience to a neurodevelopmental "reframed" approach. Using this neurodevelopmental viewpoint, families are encouraged to focus on accommodations to support their children's needs and are also helped to understand behavior management. Research has shown that the FMF Program offers benefits for both caregivers and children [24,27,28] (personal communication by HCO, March 5, 2016, and March 2, 2017). Among other findings, caregivers experience improvements in their knowledge of FASD and advocacy skills, parenting efficacy, and some specialized parenting practices. Additionally, they report better self-care and a greater sense of their family's needs being met. For these developmentally complex children, the program leads to positive changes in behavior immediately post treatment. A growing number of innovative programs are being derived from the FMF Program to meet the diverse needs of families, affected children and youth of different ages, and various settings [21-23,29,30]. This includes the FMF Connect caregiver app, which is the focus of this study.

The FMF Connect app incorporates core content, principles, and methods of the standard FMF Program while also adding new features and content to support caregivers using the app in a self-directed, digital format. FMF Connect consists of 5 primary components, as illustrated in Figure 1, Learning Modules, Library, Notebook, Family Forum, and Dashboard. A coaching component was also trialed in this study to see if text-based coaching could increase engagement with the app and improve family outcomes.

XSL•FO
RenderX

Figure 1. The 5 main components of the Families Moving Forward (FMF) Connect app: Learning Modules, Library, Notebook, Family Forum, and Dashboard.

The systematic user-centered design approach to develop and test the FMF Connect app has been relatively rare in the field of mHealth apps. This approach, detailed in the study by Petrenko et al [22], emphasizes iterative feedback at each stage of development from community members who represent target users for the app. This process has included focus groups with caregivers on the initial design and functionalities of the proposed app [23], interviews with caregivers and providers following beta testing of initial app prototypes [22], and surveys and interviews with caregivers during a larger-scale feasibility trial [21]. This study represents the next critical phase of our systematic evaluation, which is to test the efficacy of the app in an RCT. The primary objective of this study was to determine if the FMF Connect app was related to improved targeted caregiver and child outcomes over a 12-week period. This study was conducted in the United States and involved a 3-arm parallel RCT with equal allocation to 3 study groups who received (1) FMF Connect app plus text-based coaching to support app engagement, (2) FMF Connect app without coaching, and (3) waitlist control (WLC) group who received the app after study conclusion. Relative to the waitlist control group, we hypothesized that assignment to the FMF Connect groups would be associated with increases in caregiver FASD knowledge, improvements in parenting efficacy and satisfaction, reductions in caregiver attributions of willful child behavior, increases in family needs met, and improved child behavior. We hypothesized that the addition of text-based coaching would result in greater app usage and, in turn, greater change across outcomes. A 6-week time point was also included to test whether improvements in caregiver attributions of child behavior would mediate intervention effects on child behavior and caregiver self-efficacy and satisfaction. We also assessed caregiver perceptions of app quality, consistent with previous feasibility trials [21].

Methods

Ethical Considerations

This study was registered at ClinicalTrials.gov on August 24, 2021, before study initiation. The full study protocol and study consent document are publicly available within the ClinicalTrials.gov study record. All study procedures and materials were reviewed and approved by the University Institutional Review Board (STUDY00006555). Deidentified data were coded by participant number and identifying information was securely stored separately. There were no costs to participants for participating in the study. They received payments for completing surveys (US $40 at baseline, US $20 at 6 weeks, and US $40 at 12 weeks).

Trial Design

This study involved a 3-arm parallel RCT with equal allocation to the following conditions: (1) FMF Connect+Coaching, (2) FMF Connect without coaching, and (3) waitlist control. Quantitative survey data were collected at 3 time points—baseline, 6 weeks, and 12 weeks. The 6-week time point involved an abbreviated battery designed to allow for tests of statistical mediation hypotheses. App usage was recorded through Amazon Web Services (AWS) during the study period. After 12 weeks, study participants in the waitlist control group

XSL•FO
RenderX

received the FMF Connect app. No changes were made to the trial design after initiation.

Participants

The participant population included caregivers of children (aged 3 - 12 y) with FASD or PAE who live in the United States. To be eligible, caregivers needed to be a biological parent or other primary caregiver (eg, foster or adoptive parent, relative, or legal guardian) who was at least 18 years old, living in the United States, and had a smartphone or iPad (Apple Inc) with iOS operating system. Caregivers needed to have a child between the ages of 3 and 12 years with a diagnosis of FASD or confirmed PAE. As part of study registration, caregivers completed a survey about the child's PAE and uploaded diagnostic records, if available. If there was more than 1 child in the family with FASD or PAE in this age range, the caregiver was instructed during screening to choose 1 child as the target of study surveys. The child needed to have lived with the caregiver for at least 4 months and was expected to remain in the home for at least 1 year. Exclusion criteria included the caregiver not being fluent in English (the FMF Connect app and measures were only available in English). Caregivers were also excluded if there was another caregiver of the same child or living in the home who was already enrolled in the study (couples are excluded to prevent dependence in the data), the caregiver participated in a previous trial of the FMF Connect app as part of earlier development phases of this project [21-23], or the family had previously received or was currently receiving the specialist-led standard FMF Program.

Recruitment, informed consent, and data collection procedures were conducted online. Study recruitment strategy and materials were developed through consultation with the University's Clinical and Translational Science Institute, with considerations to engage a diverse participant pool. These considerations included materials representing diverse caregivers and families across race, ethnicity, age, and family structures and strategies to leverage partnerships and social media (ie, Facebook [Meta] and Twitter [subsequently rebranded as X]) outlets across the United States. Participants were recruited through a variety of mechanisms by our study team and collaborators within the Collaborative Initiative on FASD (CIFASD; [31]) and community partners. These included disseminating recruitment materials on social media, through national and regional FASD listserves (eg, FASD United's Weekly Round-up), at relevant conferences, and to participants or patients with whom the study team or collaborators had routine access and/or had agreed to contact about new research opportunities. We aimed to enroll about 150 participants in this study. Power analyses were conducted before recruitment using GPower3. This analysis determined that with a sample size of 120 and assuming α=.05, there will be a power of 0.97 to detect medium effects (f^2=0.15) and power >0.99 to detect large effects (f^2=0.35). We anticipated about 20% attribution based on the previous feasibility trial [21].

Study recruitment materials included links to the study website [32], where potential participants could access study information and link to the study's consenting and screening module. All surveys were administered via REDCap (Research Electronic Data Capture), hosted by the University of Rochester [33,34], and REDCap's eConsent package was used to document participants' informed consent. Participants had the option to review study consent information by video or text and were required to answer several questions to ensure comprehension. Participants were also offered the opportunity to ask questions via direct contact with the study coordinator before proceeding to other parts of the survey.

After completing informed consent, participants were directed in REDCap to answer screening questions to assess for study eligibility, including information about PAE, FASD diagnostic records, and demographic information. The study team determined eligibility using a study-created eligibility verification form in REDCap to carefully review the criteria and records provided. No evidence of bots or fraudulent participants was detected. A globally unique identifier [35] was then assigned to each eligible caregiver participant and child to facilitate data sharing within CIFASD or future studies. Eligible participants then received an email inviting them to complete baseline study surveys.

Outcomes

Table 1 lists all study surveys administered per timepoint. Primary study outcomes included child behavior problems (the Eyberg Child Behavior Inventory [ECBI]), attributions of child behavior (the Reasons for Children's Behavior Scale [RCB]), parenting self-efficacy and satisfaction (the Parenting Sense of Competence Scale [PSOC]), family needs met (the Family Needs Met [FNM] Questionnaire), and caregiver FASD knowledge (the FASD Knowledge and Advocacy [K&A] Questionnaire). Secondary outcomes included child adaptive functioning (the Everyday Life Scale [ELS]) and caregiver use of self-care. We also examined participant ratings of app quality (the User Version of the Mobile Health Application Rating Scale [uMARS]) and patterns of app usage (from AWS). Additional measures of family background and services were included to characterize the sample. There were no changes in measurement after study initiation.

Everyday Life Scale (ELS)	✓	✓	✓
Self-Care and Support Assessment	✓		✓
Family Background & Services Survey	✓		✓
User Version of the Mobile Health Application Rating Scale (uMARS)			✓

ECBI

The ECBI [36] is a 36-item caregiver-report scale measuring frequency (Intensity scale) and perception (Problem scale) of disruptive behavior in children aged 2-16 years. Items are rated on a 7-point scale indicating frequency of the behavior. Scores are presented as T-scores (mean 50, SD 10), with higher scores indicating more frequent behavior problems (Intensity) or greater caregiver perception that behavior is problematic. T-scores of ≥60 are viewed as clinically elevated. Internal consistency in the current sample was high (baseline: α=.90 for Intensity and α=.88 for Problem, follow-up: α=.92 for Intensity and α=.91 for Problem).

RCB

The RCB [37] is a 30-item scale assessing caregiver attributions for children's behavior. The RCB includes 7 subscales measuring neurodevelopmental and willful attributions across multiple areas of behavior, including task completion, sensory seeking and avoiding, and dysregulated or disruptive behavior. Items are rated on a 6-point Likert scale ranging from strongly disagree to strongly agree. Higher scores indicate greater agreement with the attribution. Internal consistency across subscales in the current sample was adequate to high (baseline ranging from α=.68 to α=.92, follow-up ranging from α=.67 to α=.95).

PSOC

The PSOC [38] is a 16-item self-report measure of the caregiver's sense of parenting efficacy (ie, perceived competence, problem-solving ability, and capability) and satisfaction (ie, the extent to which the individual enjoys the parenting role or experiences parenting frustration and anxiety). The items in the PSOC are answered on a 6-point scale ranging from "strongly disagree" to "strongly agree." Higher scores on the Efficacy scale indicate lower efficacy, and higher scores on the Satisfaction scale indicate higher satisfaction. Internal consistency in the current sample was high (baseline: α=.80 for satisfaction and α=.80 for Efficacy, follow-up: α=.84 for Satisfaction and α=.80 for Efficacy).

FMN Questionnaire

The FMN Questionnaire [39] includes 19 items relating to potential needs of caregivers of children with FASD or PAE and assesses the degree to which caregivers perceive these needs have been met. It is based on a measure developed for traumatic brain injury [40] and has been used in several previous studies testing FMF and derivative products [21,24,27,28]. Each need is rated on a 4-point scale (1=not at all met and 4=a great deal met) and is scored by computing the average response across items. Higher scores reflect caregivers' perceptions of more needs being met. Internal consistency in the current sample was high (baseline α=.90 and follow-up α=.93).

FASD Questionnaire

The K&A Questionnaire [39] was developed for use in the FMF Program. The version of the K&A used in this study was adapted to emphasize the content most relevant to the FMF Connect app and was informed by response patterns in the larger feasibility trial [21]. It includes 28 core items testing knowledge of FASD, advocacy, and key FMF Program principles. It is scored by calculating the number of items answered correctly. Furthermore, 8 items are rated on a true or false scale, and 20 items are multiple choice. For this study, a total score was computed by summing correct answers. Higher scores indicate higher levels of knowledge of FASD and advocacy. Internal consistency was not calculated for this measure as it measures content mastery targeted by the app versus a unified construct.

ELS

The ELS was developed for this study to measure caregiver-reported child adaptive functioning. The ELS includes 20 items that are each rated twice by the caregiver, yielding 2 scales, Responsibility and Smoothness. Sample items include "getting ready in the morning," "making a transition between tasks," and "calming down when upset." The Responsibility scale, rated on a 5-point Likert scale, assesses to what degree

XSL•FO
RenderX

the child and/or adult is responsible for the behavior. Lower scores reflect that the adult takes full or most responsibility for the behavior, whereas higher scores reflect that the child takes greater responsibility and independence in the behavior. The Smoothness scale, rated on a 5-point Likert scale, assesses how smoothly the behavior goes, ranging from "rarely goes well" to "almost always goes well." Higher scores reflect greater smoothness. Internal consistency in this study's sample was high (baseline: α=.92 for Responsibility and α=.88 for Smoothness, follow-up: α=.94 for Responsibility and α=.90 for Smoothness).

Self-Care Assessment

The Self-care Assessment (SCA) [24,41] was administered at follow-up. Caregivers were asked how their self-care changed over the past 3 months, rated on a 5-point scale (1=a lot less self-care, 2=somewhat less self-care, 3=no change in level of self-care, 4=somewhat more self-care, and 5=a lot more self-care).

uMARS

The uMARS [42] is a 26-item survey measuring user perception of the quality of mHealth apps. It includes 6 subscales—Engagement, Functionality, Aesthetics, Information, Subjective Quality, and Perceived Impact, and a total App Quality score (summary of first 4 subscales). The uMARS was completed at follow-up only. Caregivers rated the items on a 5-point scale that was specific to each question; higher scores indicate more positive impressions of the app. Internal consistency in this study's sample was adequate (α=.62 for Engagement, α=.76 for Functionality, α=.82 for Aesthetics, α=.66 for Information, α=.72 for Subjective Quality, α=.93 for Perceived Impact, and α=.93 for App Quality).

Interventions

FMF Connect Intervention

FMF Connect includes cloud infrastructure and an innovative, multilayered mHealth app. It incorporates tailored content for caregivers of children (aged 3 - 12 y) with FASD or PAE. The target age group for the FMF Connect app was selected to be the same as the standard FMF Program, from which the app was derived. Content and methods of these programs were designed with caregivers of preschool and school-aged children in mind. The FMF Connect app integrates five main components, (1) Dashboard, (2) Learning Modules, (3) Family Forum, (4) Library, and (5) Notebook (Figure 1). Weekly emails were also sent to support motivational engagement.

App education, derived from the standard FMF Program, is packaged in easily digestible learning modules, including text, exercises, and videos tailored for the child's age and presenting behaviors. The FMF Connect app includes videos and examples of diverse children across ages 3 - 12 years. In the first module, families are asked to provide the age of their child and the main behaviors that concern them. Videos throughout the app are selected from a larger library to be most relevant to the age and primary behavior concerns of the caregiver. The Learning Modules are organized into three levels: (1) Getting Started, (2) Taking Action, and (3) Taking It to the Next Level. The Library provides access to additional optional videos and content that can be downloaded and printed to use in advocacy and skill development. The Notebook is a personalized section that organizes caregivers' responses to learning activities in a convenient location for later easy access.

The Family Forum serves to (1) engage and facilitate caregivers' continued usage of the app, (2) support and extend caregivers' implementation of new knowledge and skills, and (3) provide peer support, encouragement, and understanding of the caregiver's own needs. Trained peer moderators moderated discussion in the Family Forum to ensure safety. They also provided support and prompt skills or content areas to consider.

The Dashboard displays caregiver progress in Learning Module completion, use of the Family Forum, and daily and weekly ratings inputted by the caregiver. It also includes the "Tip of the Day" feature.

Complementing the app is a Cloud infrastructure to transparently but securely distribute information, including storing and retrieving data, managing notification and messaging, and synchronizing data on all devices. A local datastore protects the mobile app against network failures and connectivity issues. This local datastore is transparently synchronized with the Cloud database so that all querying and security features are constantly available regardless of network connectivity. Updates are automatically pushed so users have the latest version.

Furthermore, 4 minor updates were made to the app during the first 2 months of the trial. These included small wording changes, optimization of the connection with the backend system, adding banners to the Family Forum to easily identify moderators, fixing an issue with the behavior tracker tool affecting some users, adding a new notification management system, and minor bug fixes for performance improvements.

Coaching Module

A coaching module was developed within the FMF Connect app to help engage caregivers and support continued use and individualized goal setting within the app. The coaching module was activated for caregivers in the FMF Connect+Coaching group only. This module allowed an assigned coach to exchange text-based messages with caregivers through the FMF Connect app's notification system. Coaches had access to a dashboard of their participants' progress and use of the app, which aided in tailoring messages and supporting caregivers in their identified goals. The coach's interface also provided a secure way to provide text-based messages to the participant within the app.

Coaches were graduate students on the project familiar with FMF Program principles and knowledgeable about FMF Connect content and features. They had training in motivational interviewing (MI), which is a key therapeutic technique used in the FMF Program. Coaches used the spirit and skills of MI to evoke the participant's own motivation to learn more about FASD and skills taught in FMF Connect. They also aimed to support caregiver goals by helping link them with content and features within FMF Connect.

XSL•FO
RenderX

Randomization

Randomization was conducted using REDCap's Randomization package. The allocation sequence was developed by a biostatistician at the University not affiliated with the project to randomly allocate participants equally across the 3 study arms. No stratification or blocking was used. The University Research IT department implemented the allocation table in the REDCap Randomization package, and the research team did not have access to the sequence. Once the study coordinator determined a participant was eligible and baseline measures were complete, the study randomization form would determine the participant's group status. The coordinator then informed the participant of their group status and sent instructions on next steps (ie, how to install the app or wait time) via email. Participants in the intervention groups were given a username and password and were given instructions on how to install the app from the Apple App Store. The research assistant processing survey data and payments could not access the REDCap Randomization package and was blind to group status.

Statistical Methods

Data analyses were conducted using SPSS (version 29.0; IBM Corp) and Mplus 8 (Muthén & Muthén). All variables were assessed for outliers, skew, and kurtosis. No extreme outliers or skew or kurtosis were detected. Missing data in SPSS were handled using multiple imputation. Missing data in Mplus used Full Information Maximum Likelihood (FIML).

Demographic variables were analyzed using descriptive statistics in SPSS. Group differences in demographic variables were assessed using 1-way ANOVAs for continuous variables and Pearson chi-square analysis for categorical variables.

Attrition analysis involved analyzing demographic differences at baseline, 6 weeks, and 12 weeks between those who did complete each timepoint and those who did not. For demographics, these differences were conducted using 1-way ANOVAs including all 3 timepoints. Pearson correlations (r) were used to detect relationships between baseline variables, demographic variables (caregiver age and child age), and attrition at all timepoints. App usage and perceived app quality were assessed using descriptive statistics and independent samples t tests grouped by FMF Connect+Coaching and FMF Connect.

Intervention change analyses were intent-to-treat, including all participants assigned to their respective randomly assigned groups whether or not they completed the FMF Connect program, and involved 2-sided hypothesis testing. Analyses used linear mixed modeling in SPSS for variables collected at the 3 timepoints (RCB, ELS, and PSOC). False discovery rate (FDR) corrections for all P values are reported. Simultaneous linear regression was used in Mplus for variables collected at baseline and 12-week follow-up. For regressions, group status and baseline levels were entered in step 1. All regressions were predicting outcomes at 12-week follow-up. FDR correction was used and reported for all regressions. Cohen d effect sizes were calculated for each outcome to demonstrate the magnitude of the intervention change. Additionally, simultaneous linear regressions were carried out to assess whether app usage within the FMF group predicted 6-week change scores and 12-week change scores.

Point-biserial correlations between group (FMF Connect vs WLC) and change scores (6-wk timepoint−baseline) were conducted to see if mediation was plausible. For those significant correlations, mediation analyses were conducted in Mplus using change scores as the mediator and the ECBI (child behavior) and PSOC (parenting efficacy or satisfaction) as the outcomes, controlling for baseline levels.

Results

Sample Characteristics

Recruitment for this study began on January 6, 2022, with enrollment ending on August 31, 2022. The study was completed on December 31, 2022, after all participants had the opportunity to complete follow-up surveys. Baseline sample demographics can be found in Table 2. No harms or unintended effects were identified for participants.

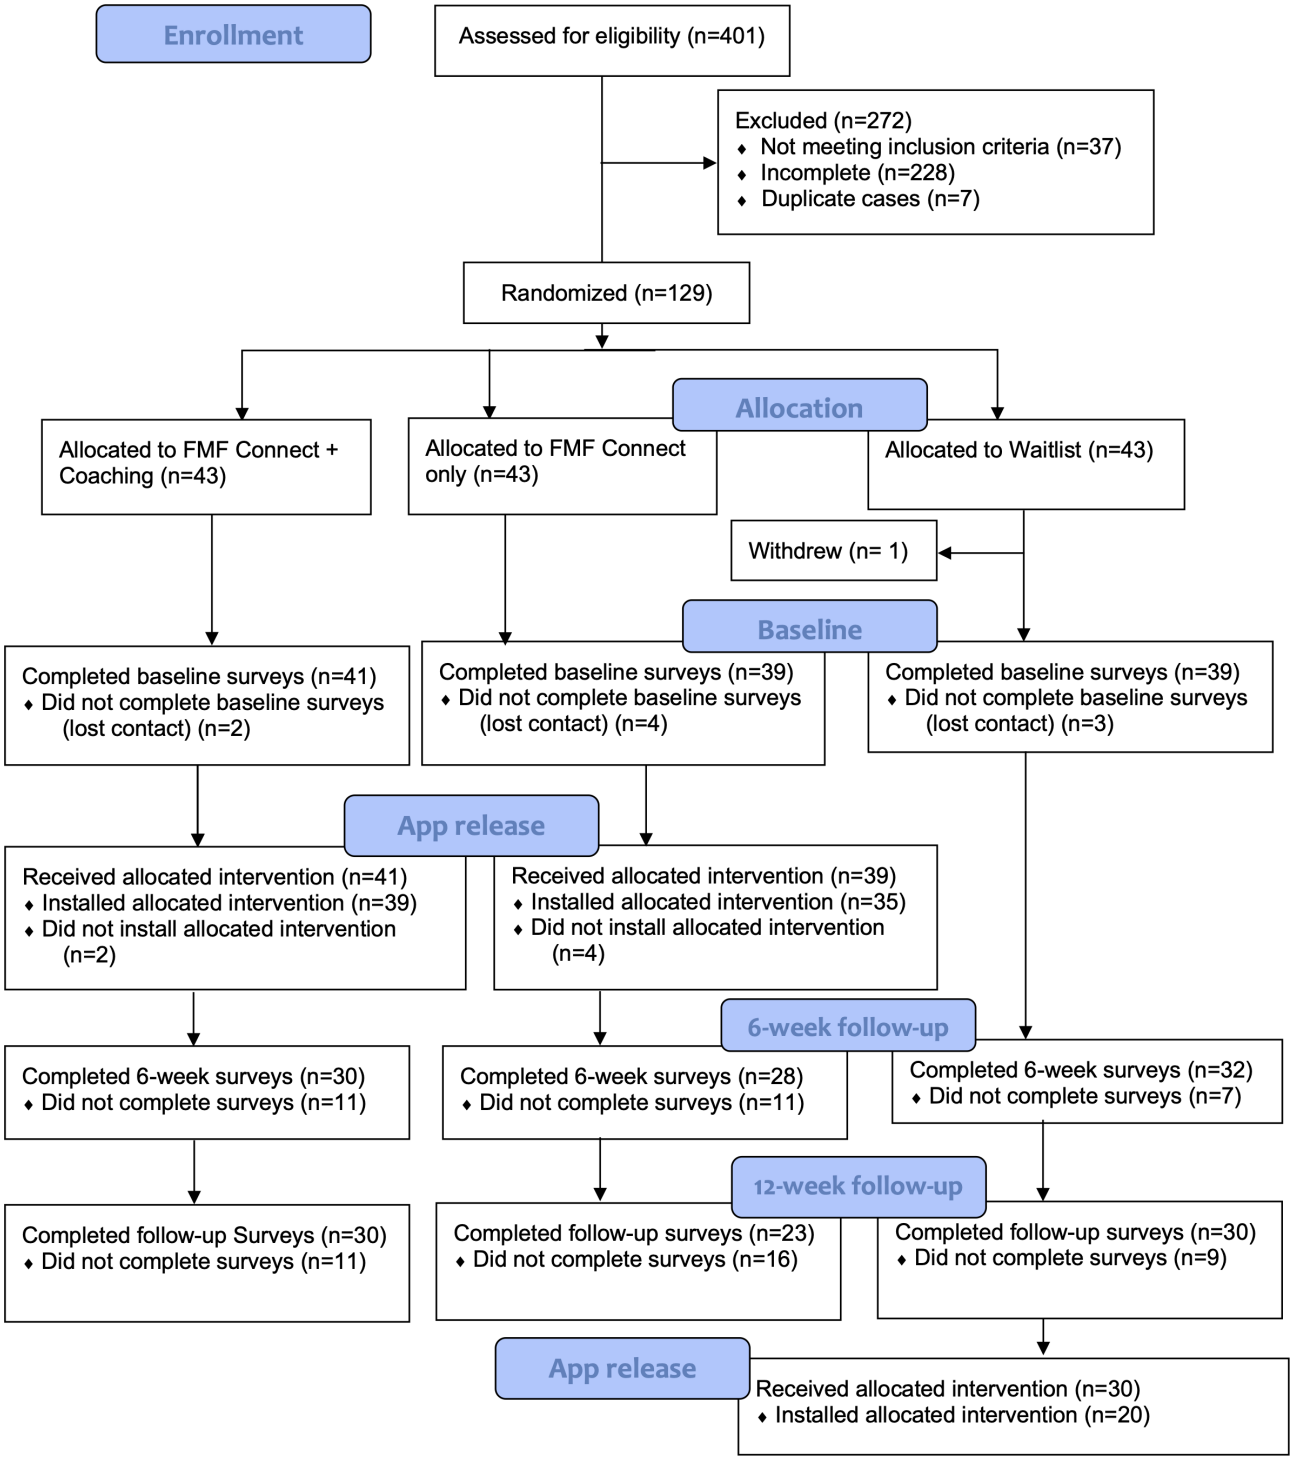
[a]FMF: Families Moving Forward.

[b]WLC: waitlist control group.

Baseline correlations by group can be found in Multimedia Appendix 1.

Demographic Group Differences



There were no significant differences between the FMF Connect+Coaching, FMF Connect, and WLC groups on any continuous variables (age, income, and household structure), nor were there significant group differences among the majority of categorical variables (gender, race, ethnicity, and relationship to child). There was a significant group difference on variables characterizing caregiver marital status. However, given the small size of marital status subgroups, this variable was not controlled for in further analyses. Given the absence of group differences, no other demographic factors were controlled for.

Attrition Analysis

The trial CONSORT (Consolidated Standards of Reporting Trials) diagram is presented in Figure 2. There were no significant differences in demographic characteristics (caregiver's gender, caregiver's race or ethnicity, caregiver's education level, comfort with technology, knowledge of FASD, income, child's gender, child's race or ethnicity, and caregiver type) between those who did and did not complete data collection at the 6-week or 12-week timepoints. Caregiver's age and child's age were not correlated with attrition. *t*-tests resulted in no significant difference in attrition by number of children in the home.

XSL•FO
RenderX

Figure 2. Study CONSORT (Consolidated Standards of Reporting Trials) diagram for the FMF Connect mobile health intervention randomized controlled trial. FMF: Families Moving Forward.

Differential attrition was also assessed for in baseline levels of functioning across groups. Greater attrition was identified among caregivers who, at baseline, reported lower child responsibility for daily tasks on the ELS for completion at 6 weeks (t_{117}=−2.85; P=.003) and 12 weeks (t_{117}=−2.69; P=.004). No other baseline scores were found to correlate significantly to attrition.

Perceived App Quality

Table 3 provides means, SDs, and score ranges on the uMARS measure of perceived app quality by users in the 2 intervention groups with data at 12 weeks. Consistent with a past feasibility trial [21], users reported high perceived quality and satisfaction with the app, with nearly all scores averaging at or above 4 (maximum 5). The quality of information provided remains the highest rated domain across groups, consistent with the goal of the FMF Connect app. This scale alone was significantly different across groups. The FMF Connect+Coaching group reported slightly lower mean ratings on quality of information than did the FMF Connect app group.

XSL•FO
RenderX

Table . App quality assessment by intervention group at 12 weeks.

	FMF Connect+Coaching (n=29[a]) mean (SD; range)	FMF Connect (n=22[a]) mean (SD; range)	Group differences, *P* value
Engagement	3.8 (0.5; 3.0-4.8)	3.9 (0.3; 3.2-4.4)	.49
Functionality	4.2 (0.5; 3.3-5.0)	4.2 (0.48; 3.0-5.0)	.53
Aesthetics	4.1 (0.6; 3.0-5.0)	4.2 (0.6; 2.7-5.0)	.59
Information	4.5 (0.4; 3.8-5.0)	4.7 (0.3; 4.3-5.0)	.03
App Quality	4.1 (0.4; 3.4-5.0)	4.2 (0.3; 3.6-4.8)	.26
Subjective Quality	4.1 (0.6; 2.8-5.0)	4.1 (0.8; 2.5-5.0)	.99
Perceived Impact	4.0 (0.8; 1.3-5.0)	4.3 (0.6; 3.0-5.0)	.26

[a]Number corresponds to all participants with data on the respective measures at that time point. Participants are included in their assigned group irrespective of app usage patterns. Some participants used the app but did not complete the uMARS at 12-week surveys.

App Usage

App usage in the FMF Connect groups was measured through number of app openings, number of modules completed, number of fact sheet openings, and number of videos watched. Table 4 provides means, SDs, and ranges for participants in each of the intervention groups who registered usage in the app (which is higher than the number who completed follow-up surveys).

Table . App usage by intervention group.

	FMF Connect+Coaching (n=39[a]), mean (SD; range)	FMF Connect (n=35[a]), mean (SD; range)	Group differences, *P* values
App openings	27.18 (26.53; 2-111)	42.23 (143.60; 1-861[b])	.52
Learning Module sections opened (out of 131 maximum[c])	67.54 (54.46; 0-165)	55 (47.47; 0-175)	.30
Learning Module sections completed	61.23 (50.52; 0-148)	49.14 (42.98; 0-138)	.27
Fact sheets opened	7.69 (11.03; 0-50)	7.37 (12.15; 0-65)	.91
Videos started	1.46 (6.78; 0-41)	2.8 (10.21; 0-53)	.51
Videos completed	1.15 (5.95; 0-37)	2.31 (9.26; 0-49)	.52

[a]Number corresponds to all participants with data on the respective measures at that time point. Participants are included in their assigned group irrespective of app usage patterns.

[b]The participant with 861 app openings in the FMF Connect group was an extreme outlier. When this outlier is removed, app opening descriptives are as follows: 18.15 (18.28), 1-75. Group differences are still non-significant (*P*=.10).

[c]While there were 131 maximum learning module sections, modules could have been initiated or completed more than once resulting in a range larger than 131.

For those assigned to coaching, participants messaged their coach an average of 2.95 (SD 2.72) times. The number of messages sent from the participant to their coach ranged from 0 to 10, with 10 participants never using the coaching feature. Coaches messaged participants an average of 6.55 (SD 3.61) times. The number of messages sent from coaches to the participant ranged from 1 to 17.

App usage was not significantly different between the FMF Connect+Coaching and FMF Connect only groups on any of the usage measures, which suggests coaching did not significantly impact app engagement as hypothesized. Pearson *r* correlations were used to see if demographic and baseline data were related to app usage across FMF Connect groups. In terms of demographic factors, older caregivers opened the app (r=0.39, P<.001) and fact sheets (r=0.31, P=.009) more than younger caregivers. Caregivers who had less comfort with technology opened fewer PDFs in the Library (r=−0.23, P=.048). No other demographic factors were associated with app usage.

In terms of baseline measures, caregivers with lower parenting efficacy opened the app (r=−0.31, P=.007) and fact sheets (r=−0.30, P=.01) more. Caregivers with fewer family needs met opened the app (r=−0.25, P=.03) and fact sheets (r=−0.25, P=.03) more than families with greater needs met at baseline. Caregivers with lower baseline FASD knowledge (K&A) finished fewer Learning Modules (r=0.24, P=.04). Caregivers who rated everyday life tasks as less smooth (ELS) opened the app (r=−0.27, P=.02) and fact sheets (r=−0.27, P=.02) more. Caregivers with higher sensory seeking attributions (RCB) opened the app (r=−0.26, P=.03) and fact sheets (r=−0.26, P=.03) less often. Those with higher ability-based task attributions watched fewer videos (r=−0.23, P=.046). In summary, these score patterns suggest that caregivers reporting greater difficulties (eg, less smooth daily tasks, lower efficacy,

XSL•FO
RenderX

and fewer needs met) generally engaged with the app more than those with relatively fewer difficulties.

Intervention Change

The FMF Connect+Coaching and FMF Connect groups were aggregated for analyses examining intervention change, given minimal group differences across demographic characteristics, baseline and follow-up measures, and app usage. Analyses conducted with 3 separate groups, as documented on clinicaltrials.gov, can be found in Multimedia Appendix 2. These analyses did not use intent-to-treat or multiple imputation methodologies; therefore, they should be interpreted with caution.

Table 5 reports linear mixed models for all intervention outcomes with 3 time points (RCB, PSOC, and ELS). Pairwise comparisons for significant models are further discussed in this study.

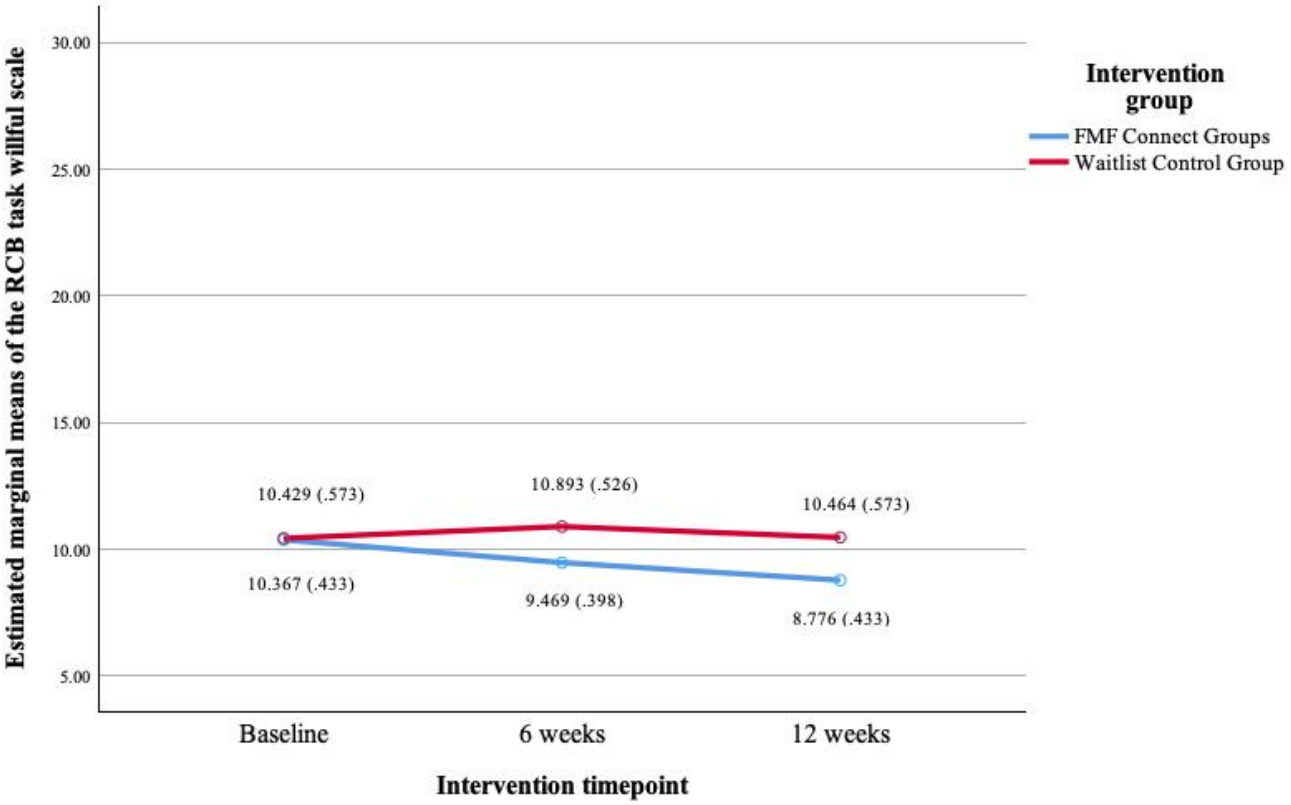
Table . Linear mixed modeling for intervention change.

Measure	F test (*df*)	*P* value	FDR[a]
Primary outcomes			
RCB[b] Sensation Avoiding attributions	0.65 (2)	.52	0.60
RCB Sensation Seeking attributions	0.61 (2)	.55	0.89
RCB Task Willful attributions	4.60 (2)	.02	0.14
RCB Task Ability attributions	0.78 (2)	.46	0.89
RCB Disruptive attributions	2.54 (2)	.08	0.46
RCB Emotion Seeking attributions	0.04 (2)	.96	0.96
RCB Dysregulated attributions	1.70 (2)	.19	0.52
PSOC[c] Parenting Efficacy	0.38 (2)	.68	0.82
PSOC Parenting Satisfaction	2.08 (2)	.13	0.48
Secondary outcomes			
ELS[d] child or caregiver Responsibility of everyday tasks	0.61 (2)	.54	0.75
ELS Smoothness of everyday tasks	0.30 (2)	.74	0.82

[a]FDR: false discovery rate correction.

[b]RCB: Reasons for Child Behavior.

[c]PSOC: Parenting Self-Efficacy and Satisfaction.



[d]ELS: Everyday Life Scale.

RCB (Primary Outcome)

There was a significant group×timepoint interaction on the RCB Task Willful measure (F_2=4.60, *P*=.01; Figure 3). Pairwise comparisons indicate significant group differences at the 12-week timepoint (mean difference=0.86, *P*=.002), with the FMF Connect group demonstrating lower endorsement of task willful attributions (mean 9.63, SE 0.30) compared with the control group (mean 10.13, SE 0.43). Interactions are no longer statistically significant when applying FDR correction.

XSL•FO
RenderX

Figure 3. Intervention group differences by timepoint on the Reasons for Child Behavior Scale Task Willful subscale (FMF Connect vs waitlist control). FMF: Families Moving Forward; RCB: Reasons for Child Behavior Scale.

No differences were detected for parenting efficacy and satisfaction or child adaptive behavior.

Linear regression analyses were conducted for all outcome measures collected at baseline and 12-week follow-up timepoints only (ECBI, FNM, K&A, and SCA). Baseline and FMF Connect group status were entered into the regression model simultaneously. The dependent variable entered was the measure at the 12-week follow-up to determine treatment effects (Table 6). Covariates were not included in analyses as there were minimal correlations or group differences on any of the demographic variables assessed (Table 2). Significant findings are summarized further in this study. FDR corrections for all *P* values are reported.

[a]FDR: false discovery rate correction.

[b]ECBI: Eyberg Child Behavior Inventory.

[c]K&A: Knowledge & Advocacy Questionnaire.

[d]FASD: fetal alcohol spectrum disorders.

[e]SCA: Self-Care Assessment.

FMF (Primary Outcome)

Group status (FMF Connect: n=80 and control: n=39) significantly predicted the FNM summary score at 12 weeks (*b*=0.21, *P*=.04), when accounting for scores at baseline and accounting for the interaction. The FMF Connect group showed significantly higher scores on the FNM post intervention (mean 47.56, SD 11.06) compared with WLC (mean 42.30, SD 11.29), indicating more family needs met. This prediction approaches significance when adjusting for multiple comparisons (*P*=.06).

K&A (Primary Outcome)

Group status (FMF Connect: n=80 and control: n=39) significantly predicted the K&A summary score at 12 weeks (*b*=0.18, *P*=.04), when accounting for scores at baseline. The FMF Connect group showed significantly higher scores on the K&A post intervention (mean 21.28, SD 3.28) compared with the WLC group (mean 20.33, SD 2.69), meaning they acquired greater knowledge about FASD, advocating for their child, and core FMF Program concepts. This prediction approaches significance when adjusting for multiple comparisons (*P*=.06).

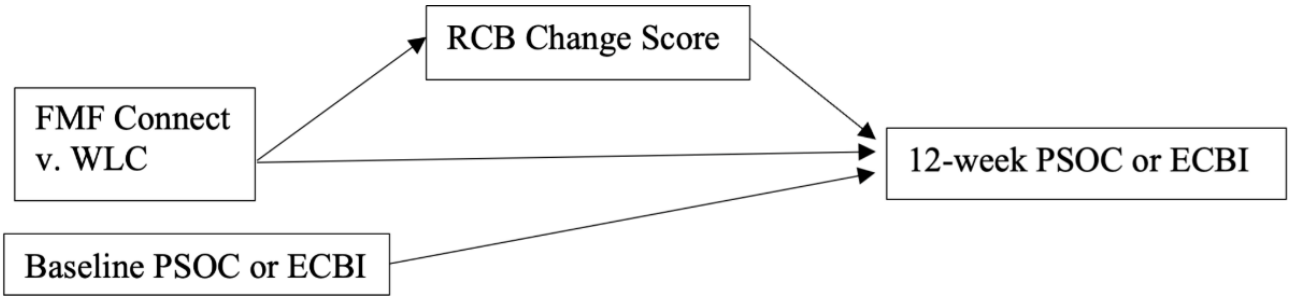
Self-Care (Secondary Outcome)

Group status (FMF Connect: n=80 and control: n=39) significantly predicted the SCA score at 12 weeks (*b*=0.17, *P*=.048), when accounting for scores at baseline. The FMF Connect group showed significantly higher scores on the SCA post intervention (mean 5.38, SD 2.46) compared with the WLC group (mean 4.401, SD 2.59), meaning they acquired more self-care skills compared with waitlist controls. This prediction approaches significance when adjusting for multiple comparisons (*P*=.07).

Group status did not predict child behavior (ECBI) at 12 weeks when controlling for scores at baseline.

App Usage and Intervention Change (Secondary Outcome)

Learning module completion and app opening were entered into a simultaneous regression model to predict change scores at the 6-week and 12-week timepoints (Multimedia Appendix 3). Learning module completion (*b*=−0.20, *P*=.02) and app openings (*b*=0.79, *P*=.02) had an effect on PSOC Efficacy change scores over 12 weeks, in that those who completed more learning modules and opened the app more had greater levels of parenting



XSL•FO
RenderX

efficacy after 12 weeks. Caregivers who opened the app more showed more improvement on RCB Emotion Seeking at the 12-week timepoint (b=0.76, P=.03) and PSOC Efficacy at the 6-week timepoint (b=0.35, P=.002).

Mediation Hypotheses

Point-biserial correlations between group (FMF Connect vs WLC) and change scores (6-week timepoint−baseline) were conducted to see if mediation was plausible. Group status was correlated with 6-week change scores on the RCB Disruptive Behavior (r=−0.24, P=.03) and RCB Task Willful (r=−0.26, P=.02) scales. Mediation analyses were conducted in Mplus using the model illustrated (Figure 4) looking at both the RCB Disruptive Behavior and Task Willful scores as the mediator and the ECBI and PSOC as the outcome. No significant mediation was found.

Figure 4. Mediation model testing whether caregiver attributions at 6 weeks (measured by the Reasons for Child Behavior scale) mediate the intervention effect of receiving the Families Moving Forward Connect app versus the waitlist control on parenting self-efficacy or satisfaction at 12 weeks (measured by the Parenting Sense of Competence scale). ECBI: Eyberg Child Behavior Inventory; FMF: Families Moving Forward; PSOC: Parenting Sense of Competence scale; RCB: Reasons for Child Behavior scale; WLC: waitlist control.

Discussion

Primary Findings

Families raising children with FASD experience poor access to evidence-based care in their communities given multiple systems-level barriers. These include limited professional training in FASD, long waitlists and provider shortages, and pervasive stigma [9,12,43]. Complementing efforts to build workforce capacity, this study tested the efficacy of FMF Connect, a first of its kind—a caregiver self-directed mHealth intervention. Results from this RCT provide initial support for the efficacy of the FMF Connect app for caregivers raising preschool and school-aged children with FASD or PAE. Relative to the waitlist group, groups that received the FMF Connect app had greater increases in FASD knowledge, reductions in willful attributions of child behavior, improved self-care practices, and more family needs met. These changes in caregiver outcomes are notable given the low intensity, self-directed nature of the intervention. Contrary to hypotheses, no significant group differences were found for child outcomes assessed. Consistent with our previous feasibility trial [21], caregivers gave high ratings for app quality, with the quality of information rated highest among indicators. App usage was relatively greater for caregivers reporting more difficulties with parenting efficacy, completing daily tasks with their children, and meeting family needs. Higher app usage was also related to greater changes in parenting efficacy scores across the 12-week intervention period.

The systematic development and testing of the FMF Connect app is particularly notable given that a 2024 review of parenting apps found that none of the available apps in app stores had been empirically tested [13]. The FMF Connect app is also part of a growing continuum of products, all derived from the standard FMF Program to meet the varying needs of children and youth of different ages, the families who care for them, and different settings in which they are treated. Similar to the standard specialist-led FMF Program, the FMF Connect app is related to important changes in caregiver and family functioning [24,27,28]. The magnitude of effect sizes for the FMF Connect app (small-medium) is generally smaller than the standard FMF Program (many medium-large), which is not surprising given the difference in duration (12 wk vs 9 mo) and format (self-directed vs specialist implemented) of the interventions. Dosage of content is also much more variable with the FMF Connect app (intervention groups averaging 56 of 131 core Learning Module sections; range 0 - 148, including repeated content); past trials with the FMF Program have had nearly all families complete the full program. Across studies, the FMF Program and FMF Connect app result in consistent improvements in FASD knowledge and family needs met. Changes in caregiver attributions of child behavior have also been found across studies, although measurement approaches have been variable. Interestingly, studies testing the standard FMF Program have found medium to large effects in parenting efficacy, whereas this study did not find significant group differences after access to the FMF Connect app. However, higher levels of app usage did relate to greater change in parenting efficacy scores, suggesting greater dosage of content is important for this outcome. Caregivers across studies have reported a high level of satisfaction with both interventions. While the magnitude of effects for the FMF Connect app is more modest, the potential for scalability creates the possibility of a broad public health impact. This impact and reach could potentially be leveraged as additional products in the FMF continuum of care are developed, continuing to increase accessibility and capacity to provide evidence-based care.

Unsupported Hypotheses

In contrast to our hypothesis, text-based coaching did not result in improved app usage or outcomes for families. Across a broad range of mHealth apps designed to manage health conditions in adults, a positive correlation has been found between app engagement and the level of personal support provided [44].

XSL•FO
RenderX

However, there is a high level of heterogeneity in methods and outcomes for mHealth interventions using coaching, and many studies did not directly assess the effect of coaching on outcomes [45]. Another possible explanation for the pattern of findings in this study is that user engagement in coaching was lower than anticipated. Study team observations noted that a few users reported difficulty finding or navigating the coaching messaging component. It is also possible that the users turned off app notifications that would have alerted them to new messages or were not interested in this feature. A future direction could explore whether peer coaches (vs graduate students) increase engagement.

We also predicted that more app usage would relate to greater improvement in outcomes. However, this hypothesis was not generally supported; usage did not correlate with greater effects for the majority of outcomes, with the exception of parenting efficacy noted above. Possibly, there is a threshold effect after accessing a certain amount (or type) of content. Alternatively, change may be related to more individualized patterns of usage or needs based on caregiver and family circumstances. Future larger-scale investigations may allow for greater power and ability to use machine learning techniques to explore usage patterns in more nuanced ways.

Finally, based on the theorized logic model for the FMF Program, this study hypothesized that caregiver attributions of behavior would mediate changes in caregiver efficacy and satisfaction and child behavior outcomes. Results of this study did not support this hypothesis. While the intervention group was correlated with 6-week change on 2 scales, mediation was not significant. In addition, the app was not associated with change in parenting efficacy, satisfaction, or child behavior over the 12-week evaluation period. Given intervention effects are seen on these outcomes in the longer duration follow-ups for the specialist-led FMF program [24,27,28], it is possible that more intensive intervention and/or follow-up is needed for these outcomes.

Strengths and Limitations

Results from this study should be interpreted in the context of several notable strengths and limitations. First, this study empirically tested one of the first stand-alone, self-directed mHealth interventions targeting parenting. Although the FMF Connect app is tailored to caregivers raising children with FASD, findings from this study have broader relevance for parenting programs and use of mHealth interventions more generally. Much of the content and form of FMF Connect could be adapted and trialed with other related populations. The FMF Connect app was rigorously developed and tested using a systematic user-centered design approach [21-23]. The app was derived from an evidence-based intervention with a strong theoretical foundation and adapted for self-directed administration on a mobile platform. Our approach is consistent with best practices in mental health app development and broader principles of user-centered design [20,46].

The generalizability of study findings may well be impacted by characteristics of study participants who enrolled in the study and other design features. Although careful attention was paid to participant reach in previous feasibility trials [21] and efforts were made to recruit a diverse participant pool, enrolled participants were largely White, relatively wealthy, adoptive mothers. Caregiver education and income were higher than national averages. Our study was also limited to participants with Apple iOS devices, which may have influenced patterns of participant demographics. For example, commercial survey data indicate iOS users tend to have higher average income, longer duration of smartphone use per day, and be younger in age than Android users [47]. The decision to limit the study to iOS devices was made given poorer stability of our Android prototypes across user devices in previous feasibility studies [21,22]. This decision likely eliminated about 40% of potential participants based on rates of Android users in our past studies and current market share in the United States [47]. Expanding the app to the Android platform and further engagement or co-design work with demographic groups not well-represented in this study are important future steps to address this limitation. Since this trial, we have subsequently rebuilt the app on Flutter (Google), which allows seamless development and refinement across iOS, Android, and web platforms. We are also in the process of commercializing the app for broad distribution. Some families may not be interested in participating in research due to barriers or mistrust but might be more likely to download the app from the app store and use it outside of the research context. It is possible these steps will increase the diversity of users. Additionally, targeted outreach and collaboration with community organizations serving underrepresented populations could help address this generalizability gap.

As with most behavioral intervention studies, participants were aware of their treatment condition, which could have potentially biased follow-up responses. FMF Connect targeted multiple child and family outcomes. As a result, multiple analyses were run to assess the range of possible intervention effects targeted. The number of analyses may have increased the likelihood of false positive intervention effects, as suggested by FDR corrections.

Conclusions and Future Directions

This study provided initial evidence for the efficacy of the FMF Connect app for targeted caregiver outcomes, with effect sizes in the small to medium range. As an mHealth app, the FMF Connect intervention has potential for scalability and accessibility. Even with modest effect sizes, this potential for scalability could result in a sizeable public health impact, especially for families who may have difficulty accessing evidence-based resources in their communities or have other barriers to care. The FMF Connect app is not intended to replace diagnostic and treatment services delivered by providers. Yet, given the severe lack of FASD-informed providers in the United States, this resource can help provide families with easy access to evidence-based information and ideas for how to access and advocate for services in their communities. Beyond that, through the Family Forum, the app can provide connections with other families with similar experiences, providing peer support.

Building on this work, our team is developing and testing a new program called FMF Connect Pro to further expand the continuum of care for families based on the FMF Program. This effort aims to train mental health providers in how to screen for

XSL•FO
RenderX

PAE, diagnose FASD (using Neurobehavioral Disorder Associated with Prenatal Alcohol Exposure in the *DSM-5* [*Diagnostic and Statistical Manual of Mental Disorders* {Fifth Edition}] [3]), and support families using the FMF Connect app within their clinical practice. This middle tier between the self-directed FMF Connect app and the standard specialist-led FMF Program has the potential to increase identification of FASD in settings with increased prevalence [48,49] and enhance access to FASD-informed treatment for families. It could also provide clinicians with easy-to-use tools and a lower training investment option to gain competencies with this population across a range of mental health settings. It is also possible that caregiver-professional relationships may increase engagement and use with families, especially those less likely to use technology on their own. Engagement with FMF Connect Pro could also increase future provider uptake of the standard specialist-led FMF Program, which may often be the best fit for higher-acuity children and families.

Acknowledgments

The authors appreciate the Collaborative Initiative on Fetal Alcohol Spectrum Disorders (CIFASD) collaborators who assisted with recruitment, as well as FASD United. Seattle Children's Research Institute (SCRI) and the University of Washington are recognized for their contributions to intellectual property from the standard Families Moving Forward (FMF) Program. The standard FMF Program was developed, tested, and materials refined by a team led by Heather Carmichael Olson, PhD, based at and sponsored by these institutions (led by SCRI), with funding via multiple grants from the Centers for Disease Control and Prevention.

We would also like to thank Alicia Roth, Shuo Zhang, Molly Arnold, and Alesia Richardson for their contributions to this study and additional staff at Mt. Hope Family Center for their support throughout the project. The authors appreciate all the families who made time in their busy schedules to participate in this study. This research would not have been possible without their valuable insights.

All or part of this work was done in conjunction with the Collaborative Initiative on Fetal Alcohol Spectrum Disorders (CIFASD, [30]), which is funded by grants from the National Institute on Alcohol Abuse and Alcoholism (NIAAA). Additional information about CIFASD, including information describing available data, can be found at [30]. The data presented in this manuscript was specifically funded under grant U01AA026104 "Development and Evaluation of an Evidence-Based Mobile Health Caregiver Intervention for FASD." Data from this study are part of CIFASD Phase 4 (2017-2022).

Authors' Contributions

All authors contributed to the preparation of this study. CP conceived of the study, oversaw the study team, led app content development, obtained necessary approvals, and led manuscript preparation and revision. MR and JM contributed to data analysis, manuscript preparation, and revision. CT led technological development of the app and contributed to manuscript revisions. CKT assisted in data analysis and contributed to manuscript revision. ES assisted in manuscript revision. ZL assisted in data analysis. LC contributed to app content review and manuscript revision. HCO is the developer of the standard FMF Program, from which the app and original assessment battery are derived. She made significant contributions to intellectual property exchange, app content adaptation and development, and assisted with manuscript revisions. All authors reviewed and edited the manuscript and approved the final version of the manuscript.

Abstract

Background: Bystander cardiopulmonary resuscitation (CPR) and automated external defibrillator (AED) use are critical for improving survival after out-of-hospital cardiac arrest. Although conventional training methods are initially effective, they are often hampered by rapid skill decay over time. Game-based mobile apps have emerged as a promising and scalable alternative for CPR and AED education; however, evidence of their long-term efficacy remains scarce.

Objective: This study aimed to evaluate the integration of a game-based mobile app into traditional CPR and AED training. We assessed its impact on university students' theoretical knowledge, practical skills, and theoretical knowledge retention, as well as their willingness to perform CPR and their awareness of disseminating these skills.

Methods: A nonrandomized controlled trial was conducted among university students in China from March 21 to September 21, 2024. Participants were assigned to either an experimental group, which received game-based mobile app training supplemented with traditional training, or a control group, which received traditional training only. The game-based app featured a simulated scenario that required users to execute the correct sequence of resuscitation procedures and operate a virtual AED under time constraints. The intervention period lasted for 6 months. Participants' theoretical knowledge and practical skills were assessed immediately after training (baseline) and at the 7-day follow-up. Long-term retention of knowledge, willingness to perform CPR, and dissemination awareness were evaluated at the 6-month follow-up. Data were analyzed using SPSS software (IBM Corp), employing the chi-square test, Mann-Whitney *U* test, and Wilcoxon signed-rank test.

Results: A total of 481 participants completed the entire survey (n=241 in the experimental group and n=240 in the control group). In the short-term (7-d) assessment, the experimental group demonstrated significantly higher scores in both theoretical knowledge (P=.02) and practical skills (P<.001) compared to the control group. This advantage was maintained in the long term, with the experimental group showing superior knowledge retention at the 6-month follow-up (median score: 9/10 vs 8/10; P<.001). Furthermore, a majority of all participants expressed willingness to perform CPR on strangers (70.9%, 341/481) and to disseminate first-aid knowledge (92.1%, 443/481). However, no significant intergroup differences were observed for these latter 2 outcomes (P=.85 and P=.97, respectively).

Conclusions: Despite the methodological limitations inherent in this nonrandomized study, our findings indicate that supplementing traditional training with the game-based mobile app significantly enhanced short-term acquisition of theoretical knowledge and practical skills and promoted sustained knowledge retention. This supports the app's potential as an effective and promising complement to conventional CPR and AED training programs.

Introduction

Out-of-hospital cardiac arrest (OHCA) is an important global public health problem with poor outcomes [1]. The worldwide incidence of OHCA among apparently healthy adults younger than 40 years of age ranges from 4 to 14 per 100,000 person-years [2]. Of an estimated 350,000 to 450,000 total annual OHCA cases in the United States, only approximately 10% survive [3]. Similarly, in Europe, the annual incidence of OHCA is between 67 and 170 per 100,000 inhabitants, with a mean survival-to-hospital discharge rate of 8% [4]. The crude incidence of emergency medical service–assessed OHCA in China is 95.7 per 100,000 population, with a low rate of resuscitation attempts (31.8%). The outcomes of emergency medical service–treated nontraumatic OHCA are unsatisfactory, with only 1.2% surviving to hospital discharge or 30 days [5]. However, the population in mainland China is approximately 1.41 billion [6], representing a substantial public health burden. Early bystander cardiopulmonary resuscitation (CPR) and rapid public access defibrillation are critical determinants of survival. Unfortunately, the bystander CPR rate in China is suboptimal compared with rates reported in the United States, Europe, and Japan [7,8]. One contributing factor may be the limited coverage and insufficient dissemination of bystander CPR training and retraining in China [9,10]. Therefore, extensive public education in basic life support is essential to improve OHCA outcomes [11].

Recently, technological advancements have become increasingly pivotal in promoting awareness and training for CPR and automated external defibrillator (AED) use [12]. Most studies focus on the initial acquisition and retention of CPR and AED knowledge and skills following training [13]. Initiatives such as the International Liaison Committee on Resuscitation World Restart a Heart Initiative are instrumental in fostering a culture of preparedness and encouraging widespread layperson CPR training, thereby helping to save countless lives [14]. Despite these efforts, key barriers—including uncertainty regarding correct CPR and AED procedures, fear of causing harm, and concerns about legal liability—continue to hinder public willingness to act during cardiac emergencies [15,16]. This underscores a critical need not only to raise public awareness and disseminate information on the importance of CPR and AED but also to develop and provide more innovative and accessible training methodologies [17].

In response to this need, we designed and developed a game-based mobile app for CPR and AED training. This study aimed to investigate whether integrating this app with traditional training could improve the acquisition and retention of CPR and AED knowledge and skills compared with traditional training alone. A nonrandomized controlled trial involving 481 participants from 2 Chinese universities was conducted to evaluate this hypothesis.

Methods

Study Design

We conducted a prespecified posttraining survey to compare the effectiveness of incorporating a game-based mobile app into traditional training methods on CPR and AED theoretical knowledge, practical skills, willingness, and dissemination awareness of CPR and AED among university students. The participants received unified theoretical and operational training. Participants in the experimental group used a game-based mobile app for simulation exercises, whereas those in the control group received no additional intervention. In this study, we strictly followed the Consolidated Standards of Reporting Trial (CONSORT)-EHEALTH (V 1.6.1) guidelines for reporting mobile health intervention trials, as detailed in Checklist 1.

Participants

Using a convenience sampling method, 2 universities in the researcher's city with comparable curricula were selected as research sites. Based on a natural grouping design, School A—which had similar curriculum systems, student compositions, and teaching resources—was assigned as the control group, while School B was designated as the experimental group. The inclusion criteria were as follows: adults aged 18 years or older, ownership of a smartphone (iOS or Android), and no prior participation in any CPR and AED training course. The exclusion criteria included physical limitations that would prevent the performance of CPR and AED techniques (including back or joint conditions).

Ethical Considerations

This study was approved by the Medical Ethics Committee of the Affiliated Hospital of Qingdao University (QYFYWZLL29327). All participants took part voluntarily and provided written informed consent. Participants were informed of their right to withdraw at any time. To ensure privacy, all data were anonymized such that no individuals could be identified in any published results. In addition, no financial compensation was provided to participants.

Features of the CPR and AED Gamification App

The gamified app was designed based on the CPR and AED procedure guidelines provided by the Red Cross Society of China Training Center. Game scenarios were developed accordingly by the research team. Software engineers used the Cocos2D game engine and the C++ programming language for development, which helped reduce costs while maintaining professional quality and achieving high visual realism in operational scenes. The app is compatible with multiple operating systems, including Windows, Android, and macOS, and can be installed on devices such as laptops, tablets, and smartphones via a downloadable installation package. This enables users to operate the app anywhere, even without an internet connection.

The CPR and AED gamified app is divided into 2 portals: a student portal and an administrator portal. The student portal comprises 4 modules: Personal Information, Operational Practice Guidance, Game Module, and System Settings. The administrator portal includes 2 modules: Information Review and Data Statistics. By integrating CPR and AED operational content with game elements, the app is designed to enhance student engagement and learning interest.

XSL•FO
RenderX

Students activated the game by registering with their mobile phone numbers. During gameplay, users interact directly with on-screen elements—such as the shoulder, neck, center of the chest, AED storage compartment button, and AED electrode pad switch—by clicking on the relevant parts and following prompts to complete each step. When moving objects, such as a battery or an electrode plug, users can either click the object and then the target location or drag the object directly to the desired position. Students were required to correctly perform the CPR and AED procedure within a specified time limit. The practice scenario consisted of 6 sequential stages that had to be completed in the correct order. Screenshots illustrating the practice process in the CPR and AED gamification app are provided in Multimedia Appendix 1 (screenshots of the CPR and AED gamification app).

1. Ensure scene safety
   - Approach the scene with caution and confirm that the environment is safe for both rescuers and the person.
2. Check for responsiveness
   - Assess responsiveness by tapping the person's shoulders and shouting (eg, "Are you okay?"). If no response is obtained, immediately check the person's breathing.
3. Check breathing
   - Check for absence of breathing or only gasping while simultaneously checking the carotid pulse. Confirm whether a pulse is definitely palpable within 10 seconds.
4. Activate emergency response system and retrieve AED
   - Send someone for help and to retrieve an AED. If alone, activate the emergency response system (eg, call the local emergency number) and get the AED if immediately available.
5. Begin high-quality CPR: follow the C-A-B sequence
   - C—Chest compressions
     - Position: Heel of one hand on the center of the chest.
     - Technique: Arms straight, shoulders directly over the hands.
     - Depth: 5 to 6 cm.
     - Rate: 100 to 120 compressions per minute.
     - Recoil: Allow complete chest recoil.
     - Minimize interruptions in compressions.
   - A—Open the airway
     - After 30 compressions, open the airway using the head-tilt or chin-lift maneuver.
   - B—Rescue breaths
     - Give 2 breaths, each delivered over about 1 second, ensuring visible chest rise.
     - Compression-to-ventilation ratio: 30:2.
     - Note: If unable or unwilling to give rescue breaths, perform compression-only CPR.
6. Early defibrillation with AED
   - Once the AED arrives:
     - Turn on the device and attach the electrode pads to the person's bare chest.
     - Ensure that no one is touching the person during rhythm analysis.
     - If a shock is advised, clear all individuals from contact with the person and deliver the shock promptly.
     - Resume CPR immediately after shock delivery, beginning with chest compressions.
     - Continue repeated cycles of approximately 2 minutes of CPR followed by AED rhythm analysis as instructed.

Intervention

This study was conducted between March 21 and September 21, 2024. The training sessions were delivered by instructors certified by the Red Cross Society of China. To ensure standardization, all instructors first underwent a researcher-led briefing to ensure a comprehensive understanding of the CPR and AED program and its key learning objectives. On March 21, 2024, a 30-minute theoretical training session on CPR and AED was conducted, followed by a theoretical test. Subsequently, a 30-minute practical demonstration was performed by the researchers in accordance with the standard procedure. Each instructor was assigned to train 10 students, allowing 1 hour for independent practice and question-and-answer interaction. Finally, a training supervisor carried out the skill assessment based on unified evaluation criteria.

Subsequently, the researchers provided the installation package to participants in the experimental group and ensured that each student successfully completed the download and installation process. They also explained the app's usage procedures and module functions to ensure that all students were familiar with its features. Students were permitted to use the game program freely at any time over the following 6 months, without needing to perform any additional operations. Each student was required to spend a cumulative duration of at least 30 minutes per week using the app and to complete at least 1 in-game level during that period. If a student failed to meet the level-completion requirement, the instructor was responsible for identifying the reasons and providing relevant guidance—addressing difficulties and questions raised during gameplay—until the student mastered the corresponding knowledge point and successfully passed the level. Instructors could access students' learning data by searching for their names directly through the management portal.

No additional intervention was provided to the control group during the study period. However, these participants were offered access to the game-based mobile app after they completed the postintervention survey.

Data Collection

Prior to the commencement of the study, all data collectors and CPR and AED skill assessors received standardized training from the investigators. An electronic questionnaire was administered immediately after the theoretical training session

XSL•FO
RenderX

to evaluate participants' knowledge acquisition. Following practical skill training, participants were invited in batches to a unified testing center for CPR and AED skills assessment. Assessors were explicitly instructed that they would evaluate participants from any study group and were required not to inquire about or speculate on group assignments throughout the process. In line with the study protocol and consistent with the structure of our team's first-aid courses at the university, both theoretical and practical tests were repeated 7 days later. Six months after completing the CPR and AED training, all participants were asked to complete a follow-up electronic questionnaire. This survey aimed to compare the 2 training methods in terms of long-term retention of theoretical knowledge, willingness to perform CPR, and dissemination of CPR-AED awareness.

Questionnaires

The study used several questionnaires. First, a general information questionnaire was used to collect demographic data, including age, sex, and major. Second, the CPR and AED Theoretical Knowledge Questionnaire, developed by the Red Cross Society of China, was used. This instrument comprises 10 items covering key aspects of CPR and AED application, with total scores ranging from 0 to 100. The next section assessed participants' attitudes and willingness to perform CPR and AED in cardiac arrest scenarios. The Willingness to Perform CPR and AED Questionnaire was developed by the research team based on a review of relevant literature [18,19], and the final version contained 6 items. Additionally, participants completed a modified version of the Dissemination of CPR Awareness Questionnaire, originally developed by Nas et al [20]. This modified instrument included 4 items specifically designed to evaluate the dissemination of CPR and AED awareness and was used to assess participants' knowledge sharing in this domain.

Sample Size and Power

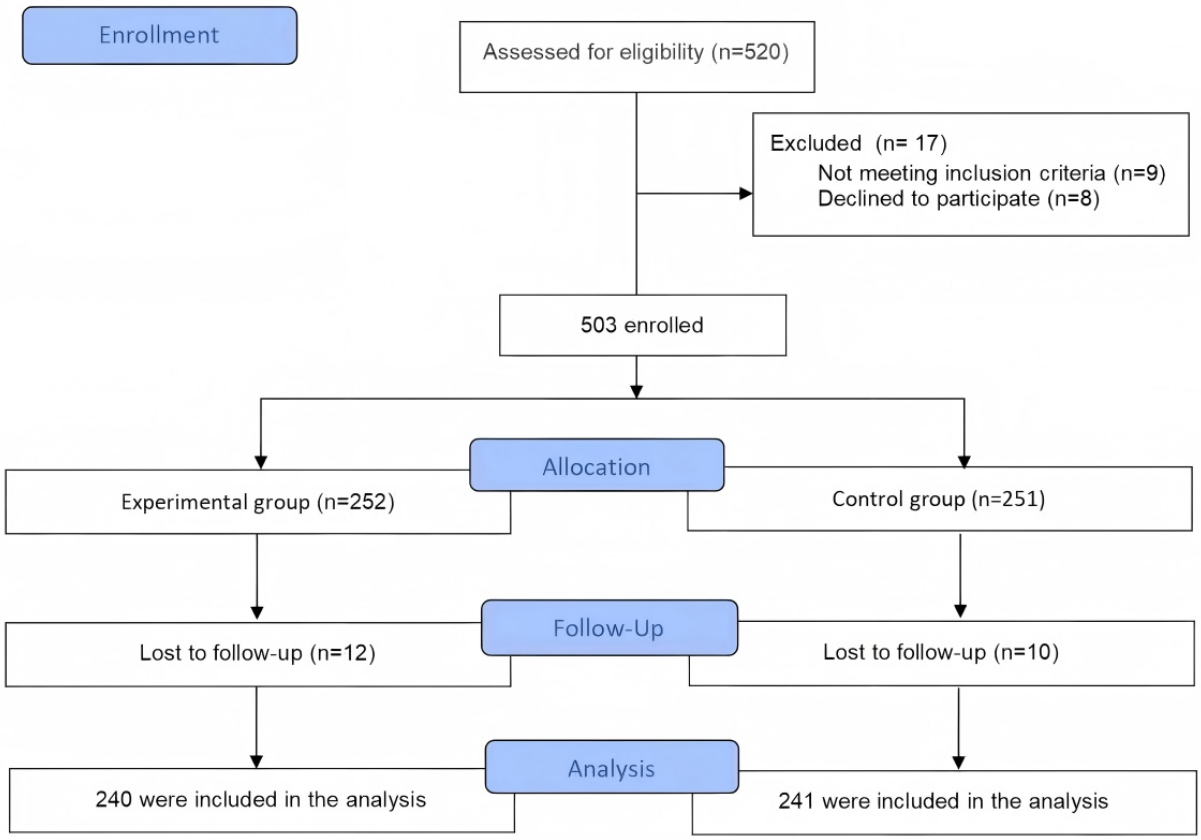
The sample size calculation was based on a previous study [21], which reported significant differences in CPR compression depth and frequency compliance rates between a VR training group and a traditional training group (51% vs 75%; 50% vs 63%). Using these proportions (p_1 =0.50, p_2 =0.63), a 2-sided α of .05, and a statistical power (1 – β) of 80% (β=.20), the calculated sample size was 227 participants per group. To account for a potential 5% invalid response or attrition rate, the minimum required sample size was adjusted to 239 per group. Accordingly, this study enrolled 241 participants in the control group and 240 in the experimental group.

The formula used to calculate the sample size is as follows:

$$(1)N=(Z1-\alpha/22\bar{p}(1-\bar{p})+Z1-\beta p1(1-p1)+p2(1-p2))2(p1-p2)2$$

Statistical Analysis

All statistical analyses were performed using SPSS version 27.0 (IBM Corp). Descriptive statistics were presented as means with SDs or as numbers and percentages, as appropriate. The normality of the data distribution was assessed using the one-sample Kolmogorov-Smirnov test. Since the skill scores deviated significantly from a normal distribution (*df*=481, *P*<.001), nonparametric tests were used for subsequent comparisons. The Mann-Whitney *U* test was used to compare outcomes between the 2 independent groups, whereas the Wilcoxon signed-rank test was applied for within-group comparisons across different time points. Categorical variables, expressed as numbers and percentages, were compared using the chi-square test or Fisher exact test, depending on the expected frequencies. All *P* values were 2-sided, and statistical significance was set at *P*<.05.



Results

Analytical Sample

A total of 503 participants were enrolled in this study (n=252 in the experimental group and n=251 in the control group). After the 6-month intervention, which included 2 follow-up assessments, 4.8% (12/252) of participants in the experimental group and 4% (10/251) of participants in the control group were lost to follow-up or withdrew. Consequently, the final analysis included 240 and 241 participants in the experimental and control groups, respectively (Figure 1).

Figure 1. Flowchart of included participants.

Participant Characteristics

Table 1 presents the baseline characteristics of the participants. A total of 481 university students were included in this study, comprising 253 men and 228 women, with a median age of 20 (IQR 19-20) years. Regarding academic major, the proportion of medical students was comparable between the control group (38/241, 15.8%) and the experimental group (32/240, 13.3%). No statistically significant differences were observed in any baseline characteristics between the 2 groups (all $P>.05$).

Table . Participants' characteristics at baseline.

Variable	Total (N=481)	Control group (n=241)	Experimental group (n=240)	Z/χ^2 (*df*)[a]	*P* value
Age (y), median (IQR)	20 (1)	20 (1)	20 (1)	1.598	.11
Sex, n (%)				0.051 (1)	.82
Female	228 (47.4)	113 (46.9)	115 (47.9)		
Male	253 (52.6)	128 (53.1)	125 (52.1)		
Major, n (%)				0.573 (1)	.45
Medical specialty	70 (14.6)	38 (15.8)	32 (13.3)		
Nonmedical specialty	411 (85.4)	203 (84.2)	208 (86.7)		

[a](df) indicates the degrees of freedom of the chi-square test.

Theoretical and Practical Skills Tests

At baseline, no significant differences were found in the theoretical and practical skills tests for CPR and AED between the control and experimental groups ($P=.50$ and $P=.63$, respectively; Tables 2 and 3). After 7 days, the experimental group achieved significantly higher scores than the control group in both theoretical knowledge and practical skills ($P=.02$ and $P<.001$, respectively).

XSL•FO
RenderX

Table . Difference in theoretical scores between the control and experimental groups.[a]

Time point	Control group, median (IQR)	Experimental group, median (IQR)	Z	*P* value
First theoretical scores	90 (10)	90 (10)	0.678	.50
7-day theoretical scores	80 (10)	90 (10)	2.323	.02

[a]Within-group comparisons (Wilcoxon signed-rank test): control group: $Z=-6.214$, $P<.001$; experimental group: $Z=-6.9$, $P<.001$.

Table . Difference in skill performance scores between the control and experimental groups.[a]

Time point	Control group, median (IQR)	Experimental group, median (IQR)	Z	*P* value
First practical skill scores	84 (6)	85 (8)	0.481	.63
7-day practical skill scores	84 (7)	87 (4)	7.703	＜.001

[a]Within-group comparisons (Wilcoxon signed-rank test): control group: $Z=-1.241$, $P=.22$; experimental group: Z=5.261, $P<.001$.

In the control group, the theoretical score significantly decreased from the immediate posttest to the 7-day follow-up ($P<.001$; Table 2). In contrast, the observed decline in operational skills was not statistically significant ($P=.22$; Table 3).

In the experimental group, theoretical scores exhibited a statistically significant change between the immediate posttest and the 7-day follow-up ($Z=-6.9$, $P<.001$). Although the median scores remained constant at 90, the distribution of the data changed. This indicates a substantial redistribution in knowledge retention that is not reflected by the median alone (Table 2). Furthermore, practical skills demonstrated a significant improvement at the 7-day follow-up compared with the initial assessment ($P<.001$; Table 3).

Theoretical Knowledge Retention

The responses to individual CPR and AED theoretical knowledge questions are detailed in Table 4. The experimental group achieved a significantly higher total theoretical knowledge score than the control group (9 vs 8 points; $P<.001$). Notably, the experimental group also demonstrated superior performance on several key items: a higher proportion of the experimental group correctly identified the initial step as assessing scene safety (204/240, 85% vs 184/241, 76.3%; $P=.02$), the correct chest compression rate (200/240, 83.3% vs 174/241, 72.2%; $P=.003$), the appropriate compression depth (186/240, 77.5% vs 166/241, 68.9%; $P=.03$), and the correct compression-to-ventilation ratio (189/240, 78.8% vs 169/241, 70.1%; $P=.03$). No significant differences were found for the remaining items (Table 4).

Willingness to Perform CPR and AED

Participants' self-reported willingness to perform CPR and use an AED is summarized in Table 5. Overall, 34.1% (164/481) of participants felt capable of performing both CPR and using an AED. Of these participants, 29.9% (144/481) attributed this capability directly to the training received in the study, and this proportion did not differ significantly between groups (*P*=.53). When asked about assisting a stranger, a strong majority of participants (341/481, 70.9%) expressed willingness, with no significant difference observed between the control group (168/241, 69.7%) and the experimental group (173/240, 72.1%) (*P*=.85).

[b]CPR: cardiopulmonary resuscitation.

[c]AED: automated external defibrillator.

The vast majority of participants (461/481, 95.8%) reported that they would perform CPR and use an AED on a relative or friend, and no significant difference was found between the control group (232/241, 96.3%) and the experimental group (229/240, 95.4%) (*P*=.90). Overall, 56.3% (271/481) of participants felt capable of performing these skills, and 51.8% (249/481) reported confidence in recalling and applying first-aid skills when needed; neither measure differed significantly between groups (*P*=.96 and *P*=.94, respectively). In contrast, 42% (202/481) of participants reported fear of performing CPR and using an AED, with comparable levels between the control group (99/241, 41.1%) and experimental group (103/240, 42.9%) (*P*=.68).

Dissemination of Awareness

The willingness to disseminate first-aid knowledge was high among participants, with 92.1% (443/481) expressing this intention.

Overall, 66.3% (319/481) of participants indicated that they would tell their family or friends about the importance of CPR, and this proportion did not differ significantly between the control group (66.8%, 161/241) and the experimental group (65.8%, 158/240) (*P*=.85). Similarly, 61.3% (295/481) of participants had already communicated with relatives or friends about the importance of CPR and AED training, with comparable rates between the control group (147/241, 61%) and the experimental group (148/240, 61.7%) (*P*=.94).

In total, 7.5% (36/481) of participants reported that their family members or acquaintances took concrete action, such as searching for CPR and AED training information, applying for a course, or attending a course. Although the proportion was higher in the experimental group (20/240, 8.3%) than in the control group (16/241, 6.6%), this difference was not statistically significant (*P*=.77). Detailed responses regarding the dissemination of CPR and AED awareness are provided in Table 6.

Table . Dissemination of cardiopulmonary resuscitation and automated external defibrillator awareness.

Question and answers	Participants, n (%)			χ^2 (*df*)[a]	*P* value

Discussion

Principal Findings

Integration of the game-based mobile app into training led to greater short-term mastery of both theoretical knowledge and practical CPR and AED skills compared with traditional methods. These findings are consistent with our previous research on other skill training [22] and are supported by preliminary studies indicating that gamification enhances learning outcomes in CPR training [23,24]. The app integrates game design elements into animated procedural simulations, which likely helps maintain learner engagement. Furthermore, its accessibility on mobile phones and computers allows for flexible, repeated practice in various settings. While these features position gamified mobile learning as a flexible, practical, and scalable tool—particularly when integrated with high-fidelity simulation—further rigorously designed studies are needed to confirm its long-term effectiveness and potential for optimizing CPR and AED training.

The follow-up assessment prioritized the evaluation of CPR and AED knowledge retention over practical skills, taking into account some participants' upcoming internships or graduation. Results from the 6-month follow-up indicated a high level of knowledge retention, which is consistent with the findings reported by Nas et al [20]. In this study, the experimental group achieved marginally higher scores across the 10 CPR and AED knowledge items, and this difference was statistically significant. This outcome may be attributed to the game-based app's emphasis on key procedural elements through a clear and visually engaging interface, which likely facilitates comprehension and long-term memory encoding. These observations suggest that a gamified mobile app could play a valuable role in supporting the sustained acquisition of CPR and AED knowledge. It is widely recognized that CPR and AED practical skills are prone to decay over time—a concern highlighted in the European Resuscitation Council Guidelines 2021 [25], which emphasize the need for regular retraining to sustain competency. These guidelines recommend distributing resuscitation training over time and maintaining competencies through frequent retraining. In this context, game-based mobile apps, given their accessibility and self-paced format, could effectively complement traditional training approaches, potentially extending reach and supporting ongoing skill maintenance.

Willingness to perform CPR and use an AED was generally high in both study groups. Compared with the control group, a greater proportion of participants in the experimental group expressed willingness to initiate CPR and AED procedures, and a slightly higher percentage reported feeling capable of assisting a person with cardiac arrest. This may be attributed to the game-based mobile app, which enabled repeated, low-stakes practice in diverse settings, thereby enhancing learners' familiarity and self-efficacy. The self-paced learning feature likely reduced anxiety and fostered incremental confidence—advantages not typically offered by single-session training. Furthermore, the gamified environment may have contributed to a more engaging learning experience, potentially reducing the perceived dread and complexity associated with emergency scenarios [26]. Additionally, the app's design, which breaks down the rescue process into clear, sequential steps with immediate feedback, may have helped users develop a structured mental model for responding in an actual cardiac arrest situation. Such clarity could alleviate the fear of making errors, a commonly reported barrier among lay responders [27]. However, the specific mechanisms underlying these effects require confirmation through studies specifically designed to establish causality. Notably, over 42% of participants across the study reported fear of performing CPR and using an AED, primarily due to concerns about causing secondary harm and facing legal consequences. These are widely documented barriers among laypersons, as also reflected in the study by Daud et al [15]. Together, these findings underscore that improving bystander willingness to act remains a critical challenge for future training initiatives.

Bystander-initiated CPR and rapid public access defibrillation are known to significantly improve survival outcomes after OHCA, with their combination exhibiting a synergistic effect [28]. A primary goal of resuscitation education for the public is, therefore, to raise awareness, train as many laypersons as possible, and develop innovative strategies to save more lives [29]. As is well known, the most common location for OHCA is the home or residence [30]; therefore, training that influences household members is of particular importance. In the present study, over 60% of the participants reported sharing information on the importance of CPR and AED with their family members or friends, indicating a potential diffusion of training awareness beyond the immediate learners. Some of these family members or friends took further active steps, such as searching for related materials, watching demonstration videos, or enrolling in formal courses, in response to participants' encouragement.

This gamified mobile app was developed based on standardized CPR and AED training scenarios. Unlike traditional approaches such as on-site training or video-based instruction, it offers more flexible and accessible learning opportunities. The app incorporates game-like elements to promote interactive and intuitive engagement, as well as active participation among learners and their peers [31]. It also enables repeated, self-directed practice in diverse environments, which may strengthen familiarity with operational procedures. Furthermore, by breaking down the rescue process into sequential steps supported by real-time feedback, the app helps users establish a clear and actionable mental model for responding to an actual cardiac arrest. We propose that integrating this gamified CPR and AED training tool with conventional methods could serve as an effective complementary strategy for broadening the dissemination of CPR and AED knowledge and skills.

Limitations and Future Study

This study has several limitations. First, the use of a nonrandomized controlled trial design represents a key methodological constraint. The lack of random assignment to the experimental or control group may have introduced selection bias, thereby limiting the strength of causal inferences that can be drawn. Future research should employ randomized controlled trials to validate these findings. Second, although high

XSL•FO
RenderX

theoretical knowledge retention was observed, the study did not assess the retention of practical skills. Thus, it remains unclear how well retained knowledge translates into actual CPR and AED performance in real-world settings. Subsequent studies should incorporate longitudinal evaluations of both knowledge and hands-on competencies in simulated or real cardiac arrest scenarios. Third, the absence of a preintervention survey prevented comparisons between baseline and postintervention outcomes, which similarly applies to measures such as willingness to perform CPR and dissemination of awareness. Finally, the generalizability of the findings may be limited by the study population, which consisted predominantly of young, highly educated participants with relatively high information technology literacy. The effectiveness of this game-based mobile app may vary among older adults, individuals with lower digital literacy, or those in different cultural settings. Future studies involving more diverse populations are needed to assess the broader applicability and effectiveness of this approach.

Conclusion

This study evaluated the integration of a game-based mobile app with traditional CPR and AED training. We assessed participants' short-term acquisition of theoretical knowledge and practical skills, as well as long-term knowledge retention, willingness to act, and dissemination awareness after 6 months. The results indicate that supplementing traditional training with the game-based app may improve short-term mastery of both knowledge and practical skills and sustain knowledge retention over 6 months. Overall willingness to perform CPR and disseminate related knowledge was high, with no significant differences between groups. Despite the methodological limitations inherent in this nonrandomized study, the findings indicate that this accessible, interest-stimulating mobile learning tool may serve as a useful complement to existing CPR and AED training paradigms.

Acknowledgments

The authors would like to thank Professor Dejun Lin for his assistance in developing the game-based mobile app. The authors also thank all participants in this study for their contributions. No generative artificial intelligence tools were used in the writing, analysis, revision, or any other process of this manuscript preparation. All content of the paper was independently completed by the authors. The authors take full responsibility for the accuracy, originality, and integrity of the entire manuscript.

Funding

This project was supported by the Qingdao Outstanding Health Professional Development Fund, the Qingdao Philosophy and Social Science Planning Project (grant QDSKL2401066), the Chinese Medical Association Press Nursing Research and Development Project 2025 (grant CMAPH-NRD2025003), and the Affiliated Hospital of Qingdao University "Clinical Medicine+X" Research Program (grant QDFY+X2023205).

Abstract

Background: Access to oral health promotion for older adults is globally limited, especially in rural, low- and middle-income settings. Digital research often lacks theoretical foundation and focuses primarily on younger cohorts, yielding few randomized trials evaluating accessible tools for oral health education in older adults.

Objective: This study aimed to develop a telehealth reinforcement strategy for oral health promotion to improve knowledge, attitudes, and self-efficacy in community-dwelling older adults.

Methods: A single-center, parallel-group randomized controlled trial was conducted in 4 municipalities (2 urban and 2 rural) in La Araucanía, Chile. Eligible participants were functionally independent adults aged ≥60 years with smartphone and internet access; those with cognitive impairment, complete edentulism, or inability to use WhatsApp were excluded. Participants were recruited from regional databases and assessed using the Geriatric Dental Specialties Tele-platform, a teledentistry tool for older adults. Participants were randomized (1:1) to face-to-face instruction (comparator) or the same instruction plus 2 weeks of social cognitive theory–informed telehealth reinforcement (4 validated videos via WhatsApp). Clinicians and statistical advisors were blinded. Primary outcomes (oral health knowledge, attitudes, and self-efficacy) were measured via telephone-administered questionnaires at baseline and 6 weeks post intervention. Secondary outcomes included acceptability and self-reported behaviors. Analyses included hypothesis testing, multiple correspondence analysis, and k-means clustering.

Results: A total of 120 older adults were randomized (comparator: n=59; telehealth: n=61), with 103 analyzed (comparator: n=51; telehealth: n=52). Both groups showed substantial within-group improvements in oral health knowledge (comparator: Cohen *d*=0.93, 95% CI 0.52-1.34; *P*<.001; telehealth: Cohen *d*=1.07, 95% CI 0.66-1.48; *P*<.001) and self-efficacy (comparator: *r*=0.59, 95% CI 0.38-0.74; *P*<.001; telehealth: *r*=0.62, 95% CI 0.43-0.77; *P*<.001). In per-protocol analysis, telehealth improved

XSL•FO
RenderX

dental caries knowledge (*P*=.03) and attitudes (*P*=.004), with no between-group differences in other domains (*P*>.05). In intention-to-treat analysis, telehealth showed a significant between-group difference for attitudes only (adjusted mean difference=0.91, 95% CI 0.34-1.48; *P*=.002), with no differences for overall oral health knowledge (*P*=.11) or self-efficacy (*P*=.59). Exploratory analyses indicated only the rural telehealth subgroup showed significant gains in attitudes (*P*=.003) and flossing (*P*<.001). Clustering suggested greater improvements among participants with higher baseline needs, predominantly rural, with fewer teeth. Telehealth demonstrated acceptability across multiple indicators (>80% for most measures) with no clinical adverse events; minor video-access issues occurred.

Conclusions: Telehealth reinforcement provided significant advantages in oral health attitudes compared with face-to-face instruction. The intervention was acceptable and showed benefits among older adults with higher preventive needs, commonly seen in rural settings. By integrating theory-informed strategies into a familiar digital platform, this study adds evidence from rural and urban contexts, extending prior work on mobile oral health. It offers insights to address service gaps in underserved areas and highlights potential for feasible, context-aligned implementation. Future research should evaluate long-term effects, adaptability, and cost-effectiveness.

Trial Registration: ClinicalTrials.gov NCT05917548; https://clinicaltrials.gov/study/NCT05917548

Introduction

Oral Health Context in Older Adults

As global life expectancy continues to rise, promoting healthy aging has become a critical public health priority, with the older population projected to more than double by 2050 [1]. However, significant oral health disparities persist among this population, who are disproportionately affected by preventable conditions—dental caries, periodontal disease, dry mouth, and tooth loss, among others [2-4].

Despite global efforts, significant disparities in oral health promotion remain, especially in low- and middle-income countries, where older adults face unique barriers such as limited access to health care and lower health literacy [5]. Additional barriers include insufficient health coverage, scarcity of tailored programs, declining overall health, and social determinants such as income, educational level, and rural residence [6-10]. Rural communities, home to 43% of the world's population, are especially underserved [11,12]. In Chile, 14.1% of older adults live in rural areas—a proportion that continues to grow—highlighting the urgent need to address territorial inequities in oral health and to develop more equitable strategies [12,13].

Oral Health Promotion and Strategies Based on Behavioral Change Theories

Health promotion empowers individuals to improve their well-being; health education is its core instrument for enhancing knowledge, motivation, and self-management skills [14]. Reinforced educational interventions can prevent disease, support well-being, and foster informed decision-making [15]. In oral health, educational interventions have shown to improve plaque control, gingival health, and salivary function by targeting knowledge, attitudes, and self-efficacy—key predictors of behavioral change [16-18].

By addressing psychosocial determinants, interventions based on psychological theories, such as Bandura's social cognitive theory (SCT), can support behavioral change [19-21]. SCT emphasizes the role of self-efficacy, observational learning, and reinforcement in promoting behavior change [22]. Among older adults, fostering self-efficacy, the belief in one's ability to perform a specific behavior to achieve a desired outcome, is key to promoting autonomy and long-term well-being, as it strengthens their physical abilities and fosters a sense of active participation in addressing daily challenges [23-25]. This psychological resource plays a pivotal role in influencing long-term oral health behaviors, linking knowledge and healthy actions such as toothbrushing and overall oral care, which are associated with healthy aging lifestyles [26-31].

Innovations in Oral Health for Older Adults: The Role of Digital Technologies

Persistent inequities in health demand a fundamental shift in how care is conceptualized and delivered. Information and communications technologies (ICTs) play a central role in advancing several Sustainable Development Goals (3, 4, 5, 9, and 17) by strengthening health systems and promoting universal health coverage [32-34]. For older adults, ICTs offer notable benefits—such as improved access to care, fewer in-person visits, lower costs, and enhanced overall quality of life [35-39]. However, adoption remains uneven due to age-related barriers, including physical limitations, resistance to change, low digital literacy, and privacy concerns—challenges known collectively as the "gray digital divide" [37,40,41].

In dentistry, ICT-based solutions have improved knowledge, promoted self-care, facilitated early disease detection, and enabled timely referrals to specialized care [41]. Some oral health promotion strategies, known as telehealth education [42], have been implemented among community-dwelling older adults through web platforms, text messages, and mobile apps [31,43-45]. A promising innovation within this field is mobile oral health (m-oral health), which uses mobile devices to

XSL•FO
RenderX

promote and maintain oral health [42]. This strategy could prove particularly effective as technology use among older adults is increasing, using it not only for communication but also to seek health-related information—such as diseases, symptoms, treatments, nutrition, and health promotion [46-48]. Current internet usage among this population ranges from 32% to 99%, with higher rates observed among individuals with greater educational attainment and those living in urban settings (91% vs 76% in rural areas) [13,49]. Since the COVID-19 pandemic, smartphone adoption has also grown, reaching 60% among adults aged 60 years and older, although adoption remains significantly lower (20%) among individuals aged 80 years and older [50,51]. Additionally, 55.5% of individuals aged 60 years and older report using social media platforms—such as WhatsApp, Facebook, YouTube, and Instagram—for both information and interaction [51]. Although still underexplored, mobile health (mHealth) and social media are gaining traction and hold great potential to support older adults, particularly as many seek additional health information after clinical encounters but often lack guidance on where to find it [52,53].

When integrated with telehealth education, social media allow on-demand access to instructional content, enhancing their comfort and independence [52,54]. WhatsApp in particular has been increasingly used in health education interventions, demonstrating positive outcomes and highlighting its potential for supporting chronic disease management and health promotion [55]. It has shown effectiveness in reinforcing behaviors related to medication adherence [56], chronic disease management [57], and increasing the uptake of cervical cancer screening [58]. In oral health, social media-based interventions have improved knowledge and reduced gingival index scores, mainly in younger cohorts [46]; extending these approaches to older adults offers a promising way to integrate tailored oral health promotion into daily routines, potentially enhancing their well-being and benefiting their families and communities [36].

Therefore, this randomized controlled trial aims to develop and evaluate a theory-informed telehealth educational reinforcement intervention delivered via WhatsApp, assessing its impact on oral health knowledge, attitudes, and self-efficacy among community-dwelling older adults living in rural and urban areas of the La Araucanía Region, Chile. We hypothesize that participants receiving the intervention will demonstrate greater improvements in these outcomes compared with the comparator group.

Methods

Ethical Considerations

Ethics approval was obtained from the Research Ethics Committee of the Universidad de La Frontera, Temuco, Chile (Folio 082/22), prior to study initiation. The study was conducted in accordance with institutional guidelines, national regulations, and the Declaration of Helsinki. Study activities began on March 3, 2023; participant enrollment occurred between March and August 2023, and the trial concluded on October 14, 2023. The trial was retrospectively registered at ClinicalTrials.gov (NCT05917548) on June 6, 2023, due to an administrative delay in completing the registry process. Primary and secondary outcomes and the statistical analysis plan were prespecified prior to participant enrollment and were not modified thereafter. No deviations from the original study protocol were made during the conduct of the trial. Although these documents were not publicly posted at that time, all prespecified methodological and analytical procedures are transparently and comprehensively reported in this manuscript.

Participants first provided verbal consent by phone to be contacted and screened for eligibility. All participants then signed written informed consent after explaining study procedures (educational activities, survey administration at 3 points), voluntary participation, the right to withdraw at any time, and potential benefits and harms of participation. The anticipated benefits included improvements in oral health knowledge, attitudes, and self-efficacy; however, to minimize bias, the specific study aims were withheld in accordance with the Council for International Organizations of Medical Sciences guideline 10 [59]. No physical harm was anticipated due to the noninvasive nature of the intervention; potential risks were limited to minor discomfort from survey completion or digital content delivery. Data were anonymized prior to analysis, and no financial or material incentives were provided. This study did not collect or include any identifiable images of participants; therefore, no image-related consent was required.

Patient and Public Involvement

Participants were not involved in study design, conduct, or reporting; they participated only in the recruitment, consent, and data collection phases. The intervention procedures and outcomes were developed by the research team based on evidence and expert consensus in geriatric oral health and telehealth.

Trial Design

This single-center, parallel-group, randomized controlled clinical trial used a 1:1 allocation ratio to compare the impact of 2 health education interventions: one delivered face-to-face and the other through ICT as an educational reinforcement. The trial followed a superiority framework to evaluate whether the ICT-based reinforcement produced greater improvements in oral health knowledge, attitudes, and self-efficacy than standard face-to-face education. The report follows the CONSORT (Consolidated Standards of Reporting Trials) 2025 statement and CONSORT-EHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and Online Telehealth) checklist (Multimedia Appendix 1) [60,61].

Trial Setting

The study was conducted in the La Araucanía Region in southern Chile, selected for its high proportion of population aged ≥60 years (18.9%) [62], and its combination of rurality and social vulnerability, which contribute to health inequities and low frequency of routine and preventive oral health care [9,63]. Through a presidential social grant, our team provided oral health care to 480 older adults in the Region via a teledentistry workflow [64,65]. Participants were recruited by telephone from the regional National Senior Citizen Service (Chile) branch and local community organization databases and invited if eligible to attend appointments at a mobile dental

XSL•FO
RenderX

clinic in the municipalities of Temuco (the regional capital, urban), Angol (urban), Freire (rural), and Los Sauces (rural).

Eligibility Criteria

The inclusion criteria were adults aged 60 years or older, of any gender, functionally independent (Barthel index ≥90), cognitively able to follow instructions, and with access to a smartphone with internet connectivity. Exclusion criteria included cognitive impairment (Mini-Mental State Examination score of <25), complete edentulism, or inability to use WhatsApp.

Sample Size

Sample size was calculated using G*Power (version 3.1.9.7; Heinrich Heine University Düsseldorf) for Windows, to assess differences between 2 independent means with unequal variances. The calculation was based on a prior study comparing oral health knowledge gains in adolescents who received face-to-face health promotion (SD 0.66) versus those who received additional video reinforcement via mobile app (SD 0.52), showing a knowledge difference of 0.42 points and an effect size of 0.7 [66]. Given the differences between adolescents and older adults in terms of cognitive processing, health literacy, and digital engagement, a more conservative effect size of 0.5 was selected. With a significance level of 0.05 and a power of 0.80, the minimum required sample size was 102 participants. Accounting for potential attrition, and in line with average withdrawal rates in clinical trials [67], the final sample included 120 participants randomly assigned to each group.

Stratified random sampling was conducted based on age categories (60-69 years, 70-79 years, and ≥80 years) and geographic sector (urban/rural by province), adjusted based on the percentage of older adults with access to a smartphone within each age group [51].

Randomization and Blinding

Participants were randomly allocated to the comparator or the telehealth education group in a 1:1 ratio using the EPIDAT random number generator (version 4.2) [68], stratified by age group. Randomization was managed by an independent researcher not involved in recruitment or intervention delivery. After confirming eligibility and obtaining written consent, the principal investigator contacted the independent researcher to receive each participant's group allocation.

To prevent contamination and crossover, the general dentist, outcome assessor, and data analysts were blinded to group assignments. Although participants were aware of the intervention during the reinforcement phase, they signed an agreement committing not to share the videos with family or friends if they received them.

Development of Educational Materials

A pilot study in rural La Araucanía (n=76) identified knowledge gaps that informed the development of 4 educational modules: self-care, dental caries, periodontal disease, and oral cancer. Guided by SCT, materials were designed to model desired behaviors, build behavioral capability, offer verbal persuasion from professionals, and present positive outcomes to foster self-efficacy [22]. Content followed clinical guidelines [69-72] and focused on oral hygiene practices (toothbrushing and flossing), disease prevention, and symptom recognition.

Quality was evaluated by 8 academic reviewers using the Item Content Validity Index (I-CVI≥0.83) and the Patient Education Materials Assessment Tool for Audiovisual Materials (adequacy threshold ≥70% for both understandability and actionability) [73,74]. Existing videos on oral hygiene and oral cancer prevention already met these criteria (understandability: 91% and 87%; actionability: 100% for both). Revisions improved readability, clarity of clinical terms, and the use of informative headings. Newly developed scripts on dental caries and periodontal disease achieved full content validation (I-CVI=1.0), except for the "periodontal disease risk factors" item (I-CVI=0.88). Final videos scored 97% and 98% in understandability and 100% in actionability for dental caries and periodontal disease, respectively [74].

Videos combined peer narratives and demonstrations by older adults with expert guidance from a dental specialist. A standardized Microsoft PowerPoint presentation was also developed to align with video content.

Intervention and Comparator

Comparator Group (Face-to-Face Only)

Participants received a 15-minute individual session delivered by a trained general dentist. The session incorporated key SCT components including behavioral capability (clear instruction and live demonstrations of toothbrushing, flossing, and recognition of early oral disease signs), observational learning (dentist modeling and hands-on practice using a dental model and participants' own mouths), verbal persuasion (personalized encouragement), self-efficacy (personalized feedback), and outcome expectations (discussion of benefits of preventive behaviors and potential consequences of untreated oral conditions). Environmental facilitation was provided through a standardized Microsoft PowerPoint presentation, protected instructional time, and direct professional support.

Telehealth Education Group

In addition to the face-to-face session, participants received 4 educational videos sent via WhatsApp over 2 weeks (2 videos per week, approximately 5 minutes each, linked to YouTube). Participants were asked to watch the videos and informed that their opinions would be requested later; however, no specific viewing instructions were provided. Videos reinforced SCT components by offering environmental facilitation (on-demand access to educational content), behavioral capability (clear demonstrations of practical oral hygiene skills, explanations of early signs and symptoms of oral diseases, and guidance on preventive behaviors and risk factor management), observational learning (peer modeling—older adults performing target behaviors such as toothbrushing, flossing, seeking dental care, inspecting the oral mucosa for signs of disease, choosing healthy foods, maintaining hydration, and avoiding risk factors like smoking). The intervention also emphasized mastery experience (indirectly by encouraging participants to try the behaviors themselves after viewing the demonstrations), verbal persuasion (motivational messages and actionable recommendations from dental professionals), and outcome expectations (positive results

XSL•FO
RenderX

of maintaining oral health and the benefits associated with the recommended behaviors).

Procedures

Participants were enrolled and managed using the Geriatric Dental Specialties Tele-platform (TEGO), which supported data collection and clinical evaluations. The study followed four phases: (1) enrollment and baseline (pretest) assessment conducted via telephone, (2) clinical evaluation and face-to-face education at a mobile dental clinic by a trained general dentist, (3) telehealth educational intervention via WhatsApp for the intervention group, and (4) follow-up assessments conducted by telephone 6 weeks post intervention.

TEGO System

Overview

The TEGO is a web-based system supporting oral health assessment and education for older adults, integrating an electronic dental record and interactive 3D models. Its protocol and workflow are detailed in prior publications [64,75,76].

Module 1: Enrollment

Collects sociodemographic information, including age, sex, place of residence [77], socioeconomic status via the Social Registry of Households [78], educational level, and smartphone usage. It also serves as the entry point for administering questionnaires, detailed in the "Outcomes" section.

Module 2: Medical-Geriatric Anamnesis

Conducted by a dentist, assessing cognitive status (Mini-Mental State Examination), psychological well-being (Short Geriatric Depression Scale), functional capacity (Barthel Index and Fried's Frailty Phenotype), and medical conditions (eg, multimorbidity, defined as the presence of 2 or more comorbidities [79]). All instruments are validated in Spanish and commonly used in primary care [80-83].

Module 3: Odontogeriatric Anamnesis

Collects self-reported oral health behaviors (eg, toothbrushing, flossing, sugar consumption, and dental service use) and performs clinical evaluation using a standardized 3D dental model to record the number and condition of teeth [76].

Outcomes

Overview

Assessments were conducted at baseline and 6 weeks post intervention. Some secondary outcomes (eg, acceptability) were measured only at follow-up, while oral hygiene behaviors were first collected during the clinical evaluation and at follow-up. The independent variable was the type of educational intervention.

Primary Outcomes

The primary outcomes were changes in oral health knowledge, attitudes, and self-efficacy, measured using the 53-item Oral health Knowledge, Attitudes, and Self-Efficacy Questionnaire, previously used in older adults' populations [17,30,31,84]. The instrument includes 3 components:

1. Knowledge (39 items): assessed understanding of dental caries, periodontal disease, and oral cancer. Items included dichotomous (yes/no) questions on signs and symptoms, and a 5-point Likert scale rating the importance of risk and preventive factors ("Very important" to "Not important at all"). Correct answers scored 1 point (maximum=39 points; subscores: caries 12, periodontal disease 14, oral cancer 13).
2. Attitudes toward oral health (7 items): evaluated beliefs about the inevitability of oral diseases in older age, perceptions of prevention, and general oral health beliefs. Responses were recorded on a 4-point Likert scale ranging from "Strongly agree" to "Strongly disagree," with higher scores indicating more positive attitudes.
3. Oral Health Self-Efficacy Scale (OHSES): The original English version of the OHSES includes 8 items divided into 2 domains: oral health self-efficacy (6 items) and general health self-efficacy (2 items) [85]. The Spanish version of OHSES, validated in older Chilean adults [86], uses a 5-point Likert scale ("Not at all confident" to "Strongly confident"). It assesses the perceived ability to prevent tooth loss (3 items) and general self-care (4 items). The scale has shown high internal consistency (Cronbach α=0.82) and acceptable test-retest reliability (intraclass correlation coefficient=0.41) [86].

Change scores were compared between intervention groups and further stratified by place of residency (urban vs rural, based on national classification [77]).

Secondary Outcomes

1. Self-reported oral hygiene behaviors: frequency of toothbrushing and dental flossing.
2. Smartphone use: categorized into four increasing levels of complexity: (1) basic communication (calls and WhatsApp), (2) informative search (adds internet browsing), (3) extended social interaction (adds other social media), and (4) advanced use (adds email).
3. Acceptability of telehealth education (intervention group only): defined as the perceived appropriateness of the intervention [87], and assessed through: (1) burden: evaluated as the perceived effort required to participate, approximated through behavioral proxies: the proportion of eligible individuals who agreed to enroll (willingness to participate) and the dropout rate (number of withdrawals divided by the total randomized × 100). (2) Affective attitude: assessed participants' feelings about the intervention, measured via a dichotomous posttest question on willingness to recommend the video-based program. (3) Perceived effectiveness: this construct examines the extent to which the intervention is perceived to achieve its purpose and was measured through the perceived use of each video using a 5-point Likert scale ("Extremely useful" to "Not useful at all").

Harms

Given the noninvasive nature of the intervention, harms were defined as any adverse events or burdens related to participation in study procedures, including difficulties with digital content delivery, frustration associated with technology use, or

XSL•FO
RenderX

discomfort during questionnaire completion. No physical harm was expected.

Harms were assessed nonsystematically, through participants' reports during follow-up contact and at each assessment point. Study staff also monitored indications of discomfort or technical burdens during phone interactions.

Statistical Methods

The per-protocol analysis was established as the primary approach, including only participants who completed all study procedures. Noncompleters were excluded from this analysis.

Descriptive statistics were computed for sociodemographic variables, clinical data, self-reported behaviors, and questionnaire variables and are presented as percentages, means, SDs, and 95% CIs. The oral health knowledge, attitudes, and self-efficacy questionnaire was also examined by domain. Normality was assessed using the Anderson-Darling and D'Agostino tests. Within-group changes were assessed using 2-tailed paired *t* tests or Wilcoxon signed-rank tests. Between-group posttest comparisons were analyzed via independent *t* tests or Mann-Whitney *U* tests, and further examined using analysis of covariance (ANCOVA), adjusting for baseline scores. Effect sizes (Cohen *d* or *r*), 95% CIs, and *P* values are reported.

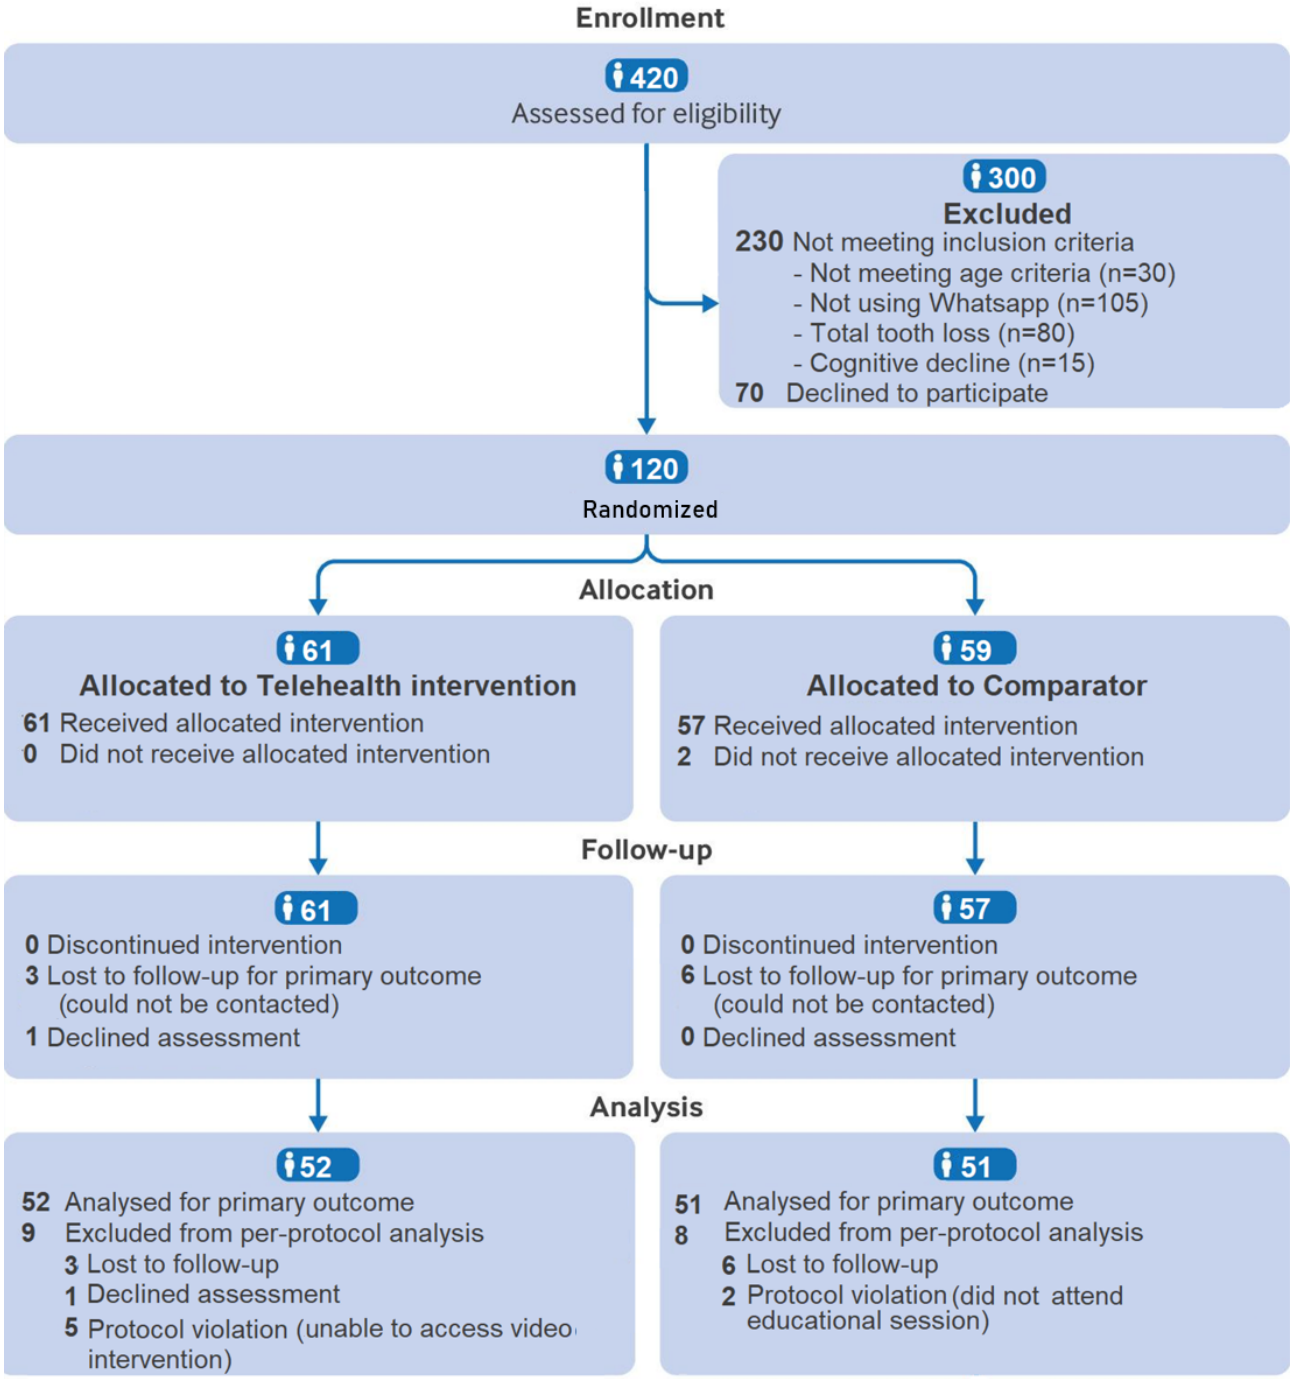
Three supplementary post hoc analyses were conducted:

1. Sensitivity analysis: an intention-to-treat (ITT) analysis was performed to preserve the integrity of randomization and minimize attrition bias. Missing data were handled using multiple imputation based on fully conditional specification, with linear regression models applied to scale variables. Five imputed datasets were generated with 10 iterations each, assuming data were missing at random. Both within-group and between-group ANCOVA analyses were conducted. A complementary Worst-Case Reasonable Scenario analysis assessed robustness under potential missing not at random (MNAR) mechanisms, assigning noncompleters in the telehealth group their baseline score (assuming no benefit) and comparator noncompleters the 75th percentile score of completers (assuming maximal benefit). This dual approach evaluates the stability of primary findings across different missing data assumptions.
2. Exploratory subgroup analysis: post hoc subgroup analysis was conducted by place of residence (urban/rural), introduced to enhance the interpretability of differential responses across settings. This includes the baseline percentage of correct responses by disease category and within-group analysis.
3. A post hoc multiple correspondence analysis and k-means clustering were performed within the telehealth group to explore associations between pre-post score changes and sociodemographic (age, educational level, place of residence, and smartphone use) and clinical variables (functional dentition, defined as ≥20 teeth vs <20 teeth). Score differences were categorized into 3 levels based on thresholds reported in previous studies [30,31,84]: significant improvement (≥50% increase), moderate improvement (20%-49% increase), and no change or deterioration (<20% improvement or decrease).

Acceptability of the telehealth intervention was assessed descriptively using percentages for perceived usefulness, willingness to recommend, and dropout rates.

Harms were assessed descriptively, including any difficulties related to digital engagement with digital content or survey procedures.

Analyses were performed using IBM SPSS Statistics (version 23.0) with supplementary visualizations in GraphPad Prism (version 8; GraphPad Software). A *P* value of <.05 was considered statistically significant.



Results

Participant Flow and Recruitment

Between March 3 and August 4, 2023, a total of 120 participants were randomly assigned to the telehealth education group (n=61) or the comparator group (n=59; Figure 1). The last follow-up was completed on September 15, 2023. All participants provided informed consent prior to enrollment. Most participants received the intervention as intended; losses and reasons for exclusion after randomization are detailed in Figure 1. Both interventions were delivered as planned, with standardized procedures to ensure fidelity. Analyses followed a per-protocol approach and included only those who completed the study procedures (n=103), with 52 in the telehealth education group and 51 in the comparator group. No additional oral-health educational activities were provided during the trial period.

XSL•FO
RenderX

Figure 1. CONSORT (Consolidated Standards of Reporting Trials) 2025 flow diagram of the study showing participant enrollment, group allocation, follow-up, and analysis.

Baseline Data

The median age of participants was 68 (IQR 63-73) years, and 64% (77/103) were female. Most had 9-12 years of education (54/103, 52%) and belonged to the most vulnerable socioeconomic category according to the Social Registry of Households classification (67/103, 65%). Overall, both groups had similar baseline characteristics (P>.05; Multimedia Appendix 2).

There were no significant baseline differences between those participants randomized and those included in the per-protocol analysis (P>.05).

Primary Outcomes

Within-Group Effects

Both the comparator and telehealth groups showed significant pre-post improvements across most oral health outcomes (Table 1).

XSL•FO
RenderX

Table 1. Baseline and postintervention scores by study group.

Variable	Comparator group (n=51)			Telehealth group (n=52)			*P* value[a]

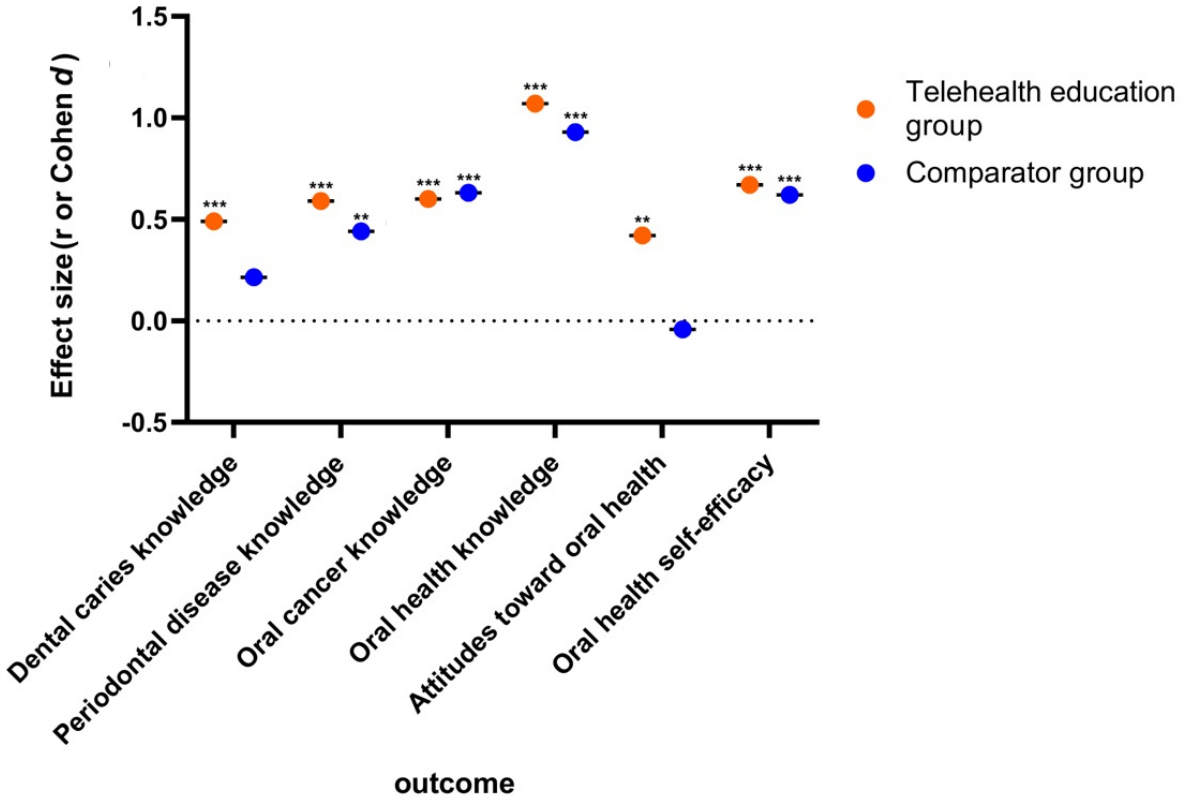
[a]Between-group comparisons at posttest (adjusted for baseline).

[b]Within-group comparisons (pre vs post).

[c]OHSES: Oral Health Self-Efficacy Scale.



Participants in the comparator group (face-to-face education; n=51) showed large effects in oral health knowledge (Cohen *d*=0.93, 95% CI 0.52-1.34; *P*<.001), oral cancer knowledge (*r*=0.63, 95% CI 0.36-0.90; *P*<.001), oral health self-efficacy (*r*=0.59, 95% CI 0.38-0.74; *P*<.001), and toothbrushing behavior (*r*=0.51, 95% CI 0.24-0.79; *P*<.001). Additionally, it had a moderate effect on periodontal disease knowledge (*r*=0.44, 95% CI 0.17- 0.71; *P*=.002). However, no significant changes were observed in attitudes (*P*=.76) or dental caries knowledge (*P*=.12).

In the telehealth education group (n=52), which combined face-to-face education with telehealth, improvements were even more marked across multiple domains. This group showed a large effect on dental caries knowledge (*r*=0.49, 95% CI 0.23-0.77; *P*<.001), attitudes toward oral health (*r*=0.42, 95% CI 0.14-0.69; *P*=.003), and periodontal disease knowledge (*r*=0.59, 95% CI 0.31-0.86; *P*<.001). Similar to the comparator group, the telehealth education group also exhibited large effects in oral health knowledge (Cohen *d*=1.07, 95% CI 0.66-1.48; *P*<.001), oral health self-efficacy (*r*=0.62, 95% CI 0.43-0.77; *P*<.001), toothbrushing behavior (*r*=0.54, 95% CI 0.26-0.81; *P*<.001), and oral cancer knowledge (*r*=0.60, 95% CI 0.33-0.87; *P*<.001).

Figure 2 visualizes the magnitude of effects across groups and outcomes, with asterisks indicating significance levels.

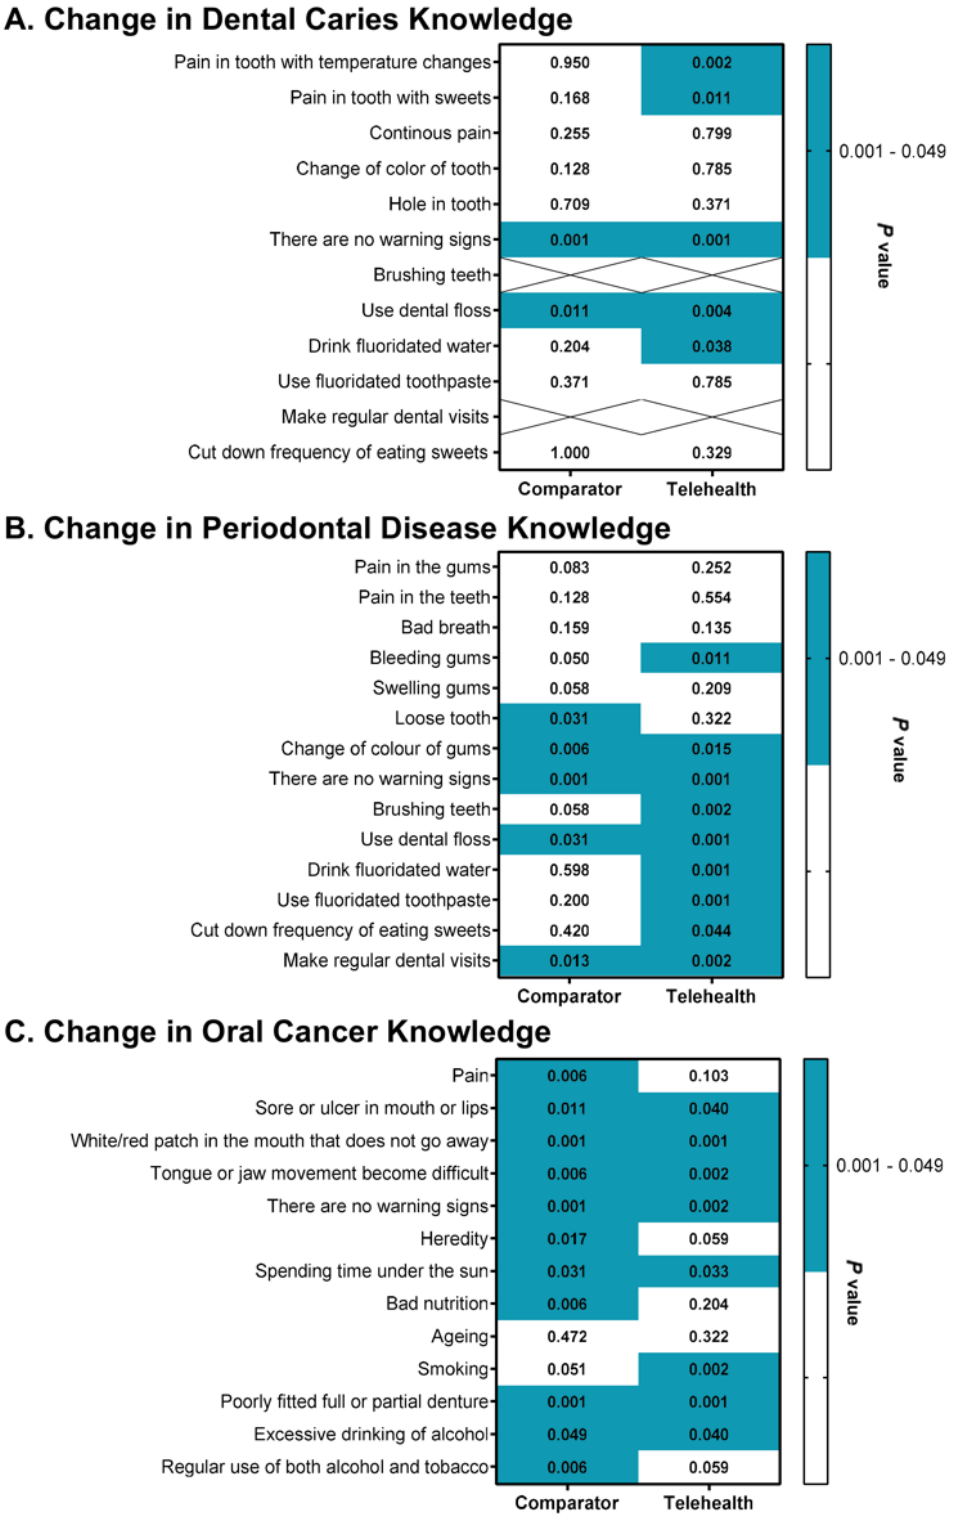
Detailed Changes in Knowledge Subdomains

Total Knowledge Score

Total knowledge scores were comparable at baseline (*P*=.93; Table 1). Following the intervention, both groups demonstrated substantial within-group improvements: the comparator group increased by 5.5 (95% CI 3.37-7.68) points (*P*<.001), and the telehealth group improved by 6.9 (95% CI 4.70-9.10) points (*P*<.001). Notably, no participant achieved the maximum possible score of 39 points.



Dental Caries Knowledge

Baseline knowledge of caries signs and symptoms was high across the sample (mean score 4.4 out of 6, SD 1.38), with no significant differences between groups (*P*=.12). The most frequently recognized signs included the presence of a cavity (92/103, 89%), and persistent pain (85/103, 82%), while tooth pain when consuming sweets was the least recognized (68/103, 66%).

Similarly, awareness of preventive measures was high overall (mean score 5.1 out of 6, SD 0.9), with no significant differences between intervention groups (comparator: mean 5.0, 95% CI 4.73-5.26; telehealth: mean 5.30, 95% CI 5.05-5.55; *P*=.09). However, the largest knowledge deficits were concentrated in 2 specific preventive measures, fluoride in water (61/103, 59%) and flossing (77/103, 79%). After the intervention, both items showed significant increases in the telehealth education group, reaching 83% (43/52; *P*=.03) and 100% (52/52; *P*=.004), respectively (Figure 3).

XSL•FO
RenderX

Figure 3. Preintervention to postintervention changes in participants' knowledge related to dental caries, periodontal disease, and oral cancer, stratified by group. Statistically significant improvements are highlighted in blue.

Periodontal Disease Knowledge

At baseline, the mean score for identifying signs and symptoms of periodontal disease was 5.5 (SD 2.6) out of 8 points. Scores were similar between groups (comparator: mean 5.6, 95% CI 4.99-6.37; telehealth: mean 5.5, 95% CI 4.70-6.33; *P*=.75). Recognition was below 80% for all signs and symptoms, except for gum inflammation (87/103, 85%). Notably, approximately 70% (72/103) of the overall sample believed that periodontal disease has no signs or symptoms.

Baseline recognition of preventive measures was generally low, mean 2.7 (SD 1.2) out of 5 points, without differences across groups (comparator: mean 2.9, 95% CI 2.54-3.29; telehealth: mean 2.48, 95% CI 2.15-2.80; *P*=.07). Most participants (77%-95%), held misconceptions about the role of fluoride in preventing periodontal disease, and these misconceptions

XSL•FO
RenderX

persisted even after the intervention. However, the telehealth group demonstrated partial improvement, with a significant decrease specifically in the misconception associating fluoride in toothpaste with periodontitis prevention (*P*<.001; Figure 3).

Following the intervention, participants showed significant improvements in identifying signs, symptoms, and preventive measures (*P*<.001). These gains were particularly evident in the telehealth education group, which demonstrated significantly better recognition of preventive measures (comparator: mean 3.3, 95% CI 3.15-3.63; telehealth: mean 3.7, 95% CI 3.52-4.04; *P*=.01).

Oral Cancer Knowledge

Baseline knowledge of oral cancer signs, symptoms, and risk factors was low across the sample, with mean scores of 1.7 (SD 1.7) out of 5 and 3.8 (SD 2.8) out of 8, respectively. Overall, 69% (71/103) of participants were unable to identify signs or symptoms, and 24% (25/103) were unaware of risk factors. The most frequently recognized sign was a persistent oral ulcer or wound (53/103, 51%), and smoking was the most identified risk factor (74/103, 72%).

At pretest, there were no significant differences between groups in the identification of signs and symptoms (comparator: mean 1.8, 95% CI 1.29-2.31; telehealth: mean 1.7, 95% CI 1.26-2.27; *P*=.92) or in awareness of risk factors (comparator: mean 3.6, 95% CI 2.86-4.34; telehealth: mean 4.2, 95% CI 3.44-5.01; *P*=.24).

Following the intervention, both groups demonstrated a significant increase in the identification of signs, symptoms, and risk factors *(P*<.001). Posttest comparisons showed no significant between-group differences in identification (comparator: mean 3.5, 95% CI 3.15-3.90; telehealth: mean 3.3, 95% CI 2.98-3.78; *P*=.60) or in risk-factor awareness (comparator: mean 5.2, 95% CI 4.72-5.74; telehealth: mean 5.5, 95% CI 5.24-6.25; *P*=.057). Across the sample, 90% (93/103) of participants could identify at least 2 signs or symptoms of oral cancer, and 96% (99/103) recognized at least 2 risk factors. Nearly all individual indicators showed statistically significant improvement (*P*<.05; Figure 3).

Attitudes Toward Oral Health

No statistically significant differences in baseline attitude scores were observed between groups (comparator: mean 4.0, 95% CI 3.59-4.44; telehealth: mean 3.9, 95% CI 3.59-4.36; *P*=.89). Following the intervention, only the telehealth group demonstrated statistically significant improvement (mean difference 0.9, 95% CI 0.37-1.51, *P*=.002; Table 1).

Notable changes were observed in the reduction of agreement with negative attitudes, with all improvements favoring the telehealth education group. Specifically, telehealth participants were less likely to agree with statements such as “As people become older, they can expect to lose their teeth” (*P*=.01), “Only people with teeth need to visit the dentist” (*P*=.01), and “Older adults must learn to live with the condition of their teeth and gums” (*P*=.02).

However, a highly prevalent negative baseline attitude—the belief that “Having dental problems is a normal part of aging” (87/103, 84%)—did not significantly change following the intervention in either group (*P*=.18).

Oral Health Self-Efficacy

At baseline, OHSES scores were comparable between groups (comparator: mean 5.2, 95% CI 4.65-5.93; telehealth: mean 5.0, 95% CI 4.54-5.53; *P*=.52). Most items were rated positively (>50%), except confidence in using dental floss (49/103, 47%), which was significantly lower in the telehealth group (*P*=.03)

Following the intervention, total OHSES scores increased significantly (*P*<.001) across all individual items (*P*<.01) and intervention groups (*P*<.001; Table 1). No between-group posttest differences were detected (*P*=.44). The proportion of participants achieving the maximum score rose from 32% (33/103) to 75.7% (78/103), and all items exceeded 80% at follow-up.

Between-Group Comparisons

When comparing the postintervention scores adjusted for baseline (Table 1), the telehealth group was significantly superior to the comparator group in 2 primary outcomes. Specifically, at 6 weeks, participants receiving the telehealth intervention (52/103) were significantly more likely than those in the comparator group (51/103) to demonstrate improved knowledge about dental caries (*r*=0.21, 95% CI 0.11-0.3; *P*=.03) and more positive attitudes toward oral health (*r*=0.28, 95% CI 0.18-0.38; *P*=.004), corresponding to small and moderate effect sizes, respectively. For all other primary outcomes, no significant between-group differences were detected at the posttest assessment (*P*>.05; Table 1).

Secondary Outcomes

Sensitivity Analysis: ITT

The ITT analysis was conducted to assess the effect of the intervention on the full randomized sample (n=120). Missing data were handled using multiple imputation, where all prespecified sociodemographic, clinical, pretest, posttest, and group assignment variables were included in the imputed model.

Between-group analysis showed that the effect on posttest dental caries knowledge was no longer statistically significant (B=0.60, SE 0.32, 95% CI -0.03-1.23; *P*=.06), whereas the telehealth advantage for oral health attitudes remained significant (B=0.91, SE 0.29, 95% CI 0.34-1.48; *P*=.002; Table 2).

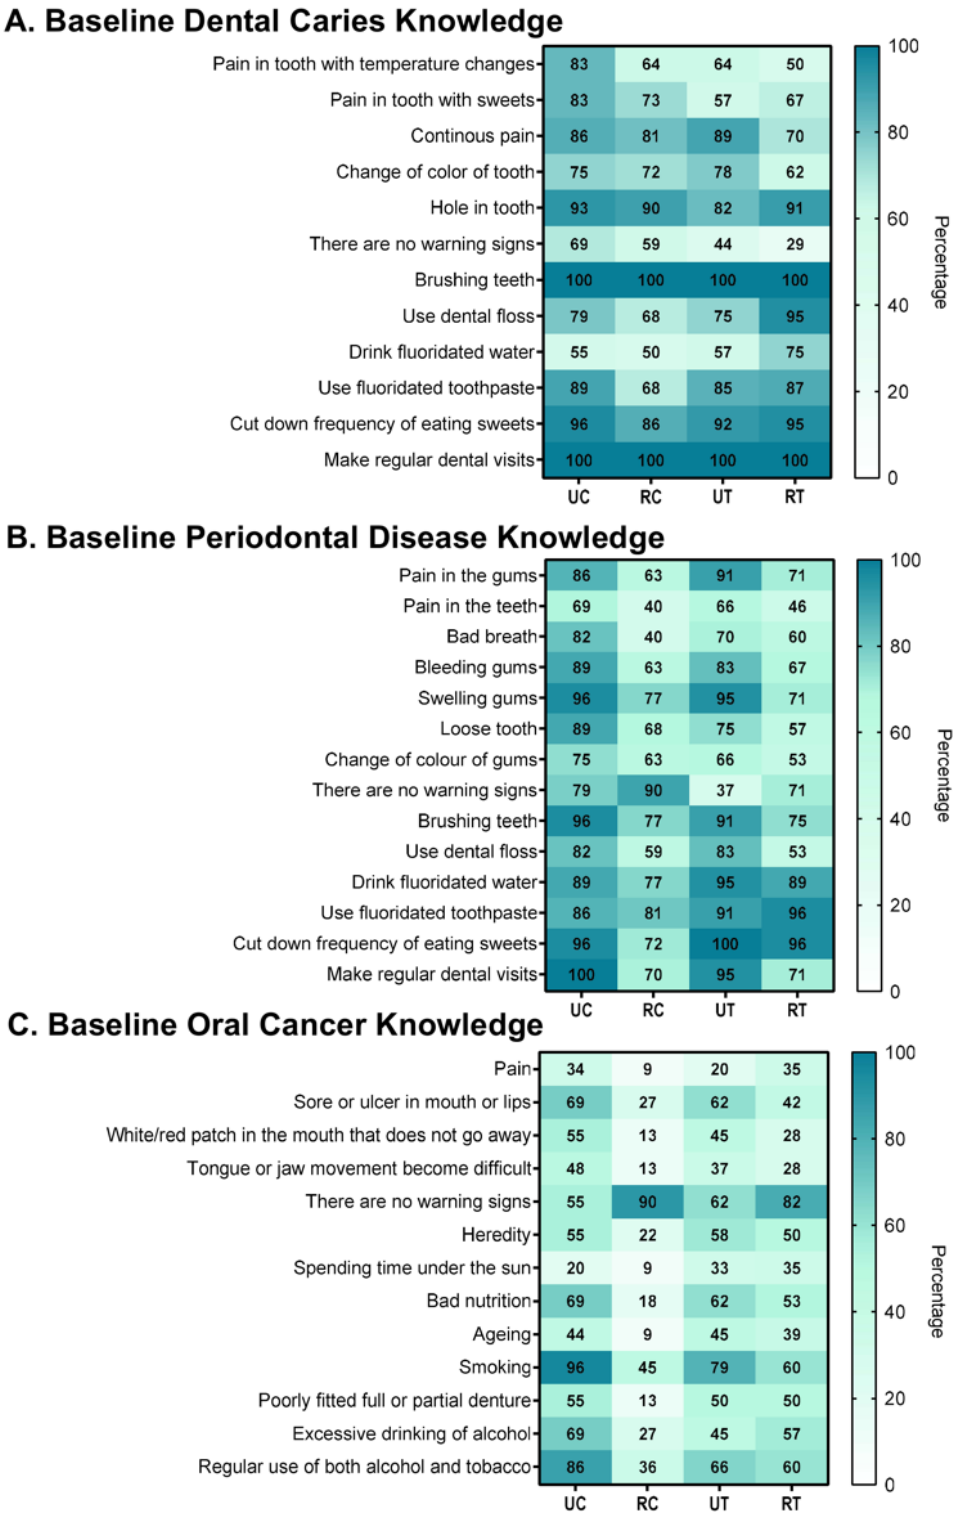
[a]Between-group comparisons at posttest (adjusted for baseline).

[b]Within-group comparisons (pre vs post).

[c]OHSES: Oral Health Self-Efficacy Scale.

To assess the stability of the primary conclusion regarding attitudes against potential MNAR mechanisms, a Worst-Case Reasonable Scenario sensitivity analysis was conducted. Between-group difference in oral health attitudes remained significant under the MNAR mechanisms assumption (*P*=.02). This finding confirms the stability of the telehealth intervention's effect on attitudes, despite potential attrition bias.

Subgroup Analyses by Place of Residence



Secondary exploratory analyses examined response patterns by place of residence (rural vs urban). Rural participants accounted for 50% (60/120) of the randomized sample, with no significant differences between intervention groups (*P*=.85) or in the final analyzed sample (*P*=.27).

At baseline, rural participants showed greater vulnerability, including differences in smartphone use (*P*=.002), higher multimorbidity (*P*=.01), and fewer number of teeth present (rural: mean 16.24, SD 7.15; urban: mean 19.20, SD 7.16; *P*=.03), and consistently lower knowledge across all domains (all *P*<.05; Multimedia Appendix 3).

Urban participants demonstrated significantly higher baseline knowledge of dental caries (*P*=.04), periodontal disease (*P*<.001), and oral cancer knowledge (*P*<.001). Item-level percentages illustrating these baseline disparities are presented in Figure 4, while Table 3 summarizes the corresponding pre-post differences by group and place of residence. At baseline, a substantial proportion of rural participants were unable to identify key signs of periodontal disease (12/50, 24% rural vs 1/53, 1.8% urban; *P*=.01) or oral cancer; specifically 86% (43/50) of rural participants could not identify any signs or symptoms of oral cancer, and 40% (20/50) were unaware of risk factors, compared with 9% (5/53) among urban participants (*P*=.003).

[a]Wilcoxon signed-rank test.

[b]Paired *t* test.

[c]OHSES: Oral Health Self-Efficacy Scale.

[d]McNemar test.

Across both study arms, rural participants exhibited larger within-group pre-post improvements than urban participants. In the telehealth group, rural participants showed significant gains across all knowledge domains (all *P*<.001), OHSES (*P*<.001), and were the only subgroup to show significant improvements in attitudes (*P*=.004) and flossing (*P*<.001). Urban participants improved in fewer outcomes (Table 3). A similar pattern was observed in the comparator group, where rural participants improved across all knowledge components and OHSES, whereas several pre-post comparisons among urban participants were nonsignificant. Overall, improvements were more consistent and pronounced among rural subgroups, particularly in the telehealth arm. However, these findings are exploratory and reflect within-group changes only; limited sample sizes across the 4 intervention-residence subgroups do not allow for formal comparative analyses.

Self-Reported Oral Hygiene Behaviors

At baseline, nearly all participants reported brushing their teeth regularly (102/103, 99%), with 54% (56/103) brushing once or twice daily. At baseline, there were no significant differences between groups (comparator: mean 2.6, 95% CI 2.40-2.81; telehealth: mean 2.4, 95% CI 2.17-2.63; *P*=.18). Following the intervention, 75% (77/103) reported brushing 3 or more times per day, with significant within-group increases (both *P*<.001). However, baseline-adjusted posttest comparisons showed no significant differences between groups (comparator: mean 3.0, 95% CI 2.78-3.29; telehealth: mean 2.9, 95% CI 2.71-3.08; *P*=.90). The change in toothbrushing frequency showed a weak yet significant correlation with perceived self-efficacy in thoroughly brushing all tooth surfaces (*r*=0.196; *P*=.04).

At baseline, 63% (65/103) of the participants reported not using dental floss, with no significant differences between groups (*P*=.73). Pretest flossing behavior was significantly associated with baseline attitudes toward oral health (*P*=.01), oral health self-efficacy (*P*=.04), educational level (*P*=.007), and number of teeth present (*P*=.01). A moderate positive correlation was found between baseline flossing behavior and baseline flossing self-efficacy (*r*=0.41; *P*<.001), while postintervention flossing demonstrated a weaker yet significant correlation (*r*=0.29; *P*=.003).

The frequency of self-reported flossing significantly increased following the intervention (38/103, 36.9% vs 64/103, 62.1%; *P*<.001). Participants in the telehealth group showed a higher likelihood of reporting flossing compared to those in the comparator group (risk ratio=1.31, 95% CI 0.96-1.78), corresponding to an absolute increase in flossing prevalence of

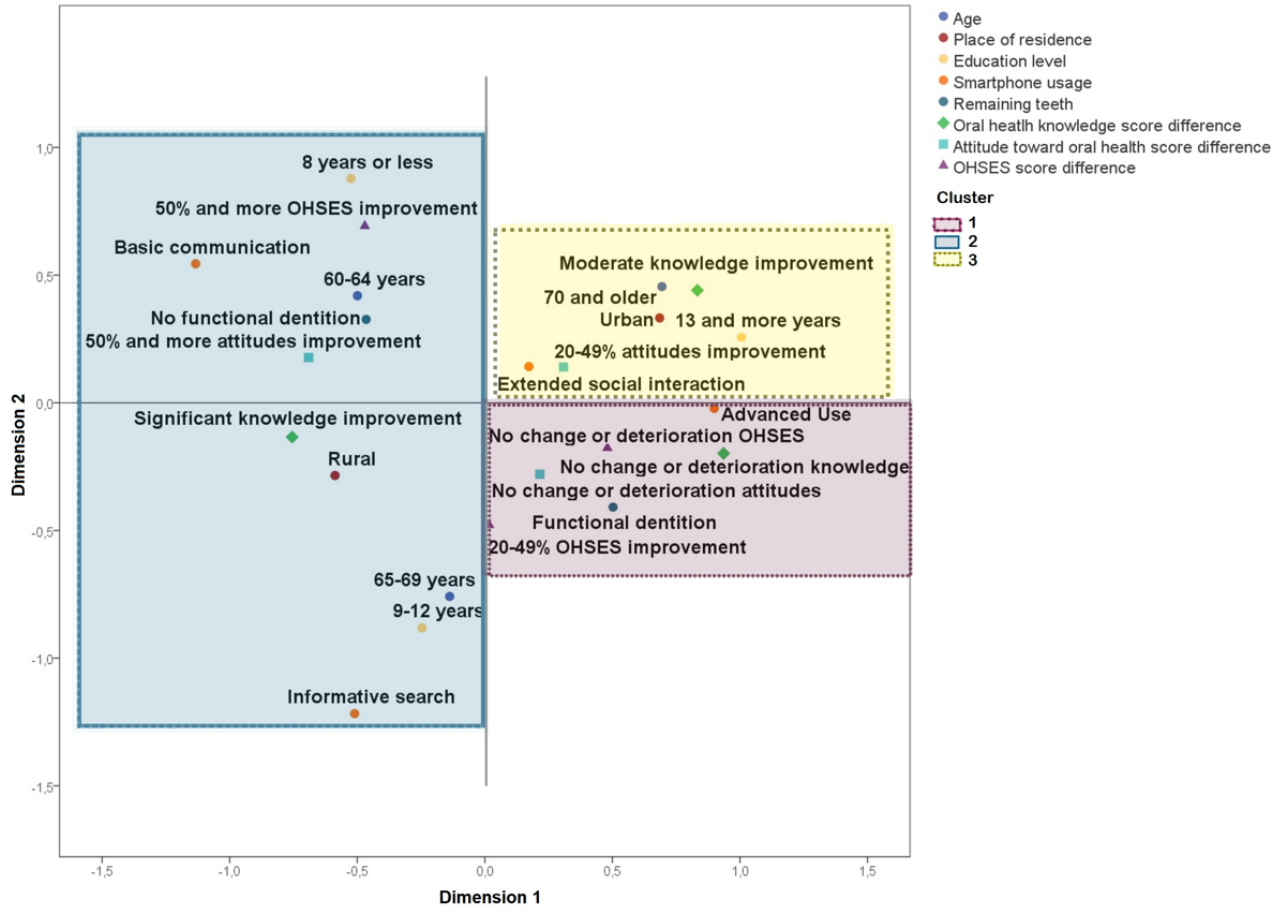
XSL•FO
RenderX

16.7% (risk difference=0.16, 95% CI –0.02 to 0.35); however, this between-group difference was not statistically significant (*P*=.08).

Smartphone Usage and Telehealth Education Acceptability

Among those assessed for eligibility, 25% (105/420) reported not using WhatsApp (Figure 1), with this pattern more pronounced in rural areas. No significant differences in WhatsApp use were found between study groups (*P*=.86). However, rural residents were significantly less likely to use online search tools (*P*=.04), other social media apps (*P*=.04), or email (*P*<.001). Advanced smartphone use—defined as use of WhatsApp, online search, social media, and email—was reported by 45% (24/53) of urban participants (Multimedia Appendix 3). Limited smartphone users (WhatsApp only) were significantly more likely to have ≤8 years of formal education and live in rural areas (*P*=.008).

Of the eligible participants, 63.1% (120/190) agreed to enroll in the intervention (willingness to participate; Figure 1). Overall, the study experienced a 14.2% (17/120) attrition rate. At 6 weeks, dropout rates did not differ significantly between the telehealth education group (9/61, 15%) and the comparator group (8/59, 13%; *P*=.85).



Most participants of the telehealth education group (48/52, 92%) stated they would recommend the use of telehealth education videos, indicating a positive attitude toward the intervention. Recommendation rates did not significantly differ by place of residence (*P*=.84), educational level (*P*=.29), or smartphone usage (*P*=.27). Perceived effectiveness of the instructional videos was high, with all participants finding the videos on dental hygiene, prevention of dental caries, and oral cancer prevention useful (52/52, 100%), and 90% (47/52) finding the periodontal disease prevention video useful.

Cluster Analysis of Demographic- and Intervention-Related Variables in the Telehealth Education Group

The analysis identified 2 main dimensions, explaining 56.5% of the total variance. Dimension 1 primarily captured the relationships between smartphone use, place of residence, and changes in knowledge and attitude scores, while dimension 2 reflected educational level and changes in oral health self-efficacy.

Subsequent k-means clustering identified 3 distinct participant profiles (Figure 5):

Figure 5. Subgroup profiles within the telehealth education group were identified using multiple correspondence analysis followed by k-means clustering. Each cluster (cluster 1: pink, square-dotted line; cluster 2: blue, solid line; cluster 3: yellow, round-dotted line) corresponds to distinct patterns of sociodemographic and clinical characteristics, including age, place of residence, education level, smartphone use, and number of remaining teeth. These clusters show differential improvements in oral health knowledge, attitudes, and Oral Health Self-Efficacy Scale scores.

XSL•FO
RenderX

- Cluster 1: participants who derived little to no benefit from the intervention. This cluster included individuals with functional dentition (12/22, 86%; χ^2_2=11.65; *P*=.003; post hoc Dwass-Steel-Critchlow-Fligner: C1>C2,*P*=.002; C1>C3, *P*=.04), who showed minimal or negative changes in knowledge, attitudes, and oral health self-efficacy.
- Cluster 2: participants who benefited the most, with most members showing high improvement (≥50%) in oral health knowledge (20/22, 91%; χ^2_2=23.24; *P*<.001; post hoc Dwass-Steel-Critchlow-Fligner: C2>C1, *P*=.01; C2>C3, *P*<.001), particularly in oral cancer knowledge (13/22, 59%; χ^2_2=17.56; *P*<.001; post hoc Dwass-Steel-Critchlow-Fligner: C2>C1, *P*=.01; C2>C3, *P*=.04), and in self-efficacy (12/22, 54%;χ^2_2=9.33; *P*=.009; post hoc Dwass-Steel-Critchlow-Fligner: C2>C1, *P*=.01; C2>C3, *P*=.04) This cluster was characterized by rural residence (16/22, 73%; χ^2_2=8.57; *P*=.01; post hoc Dwass-Steel-Critchlow-Fligner: C2>C3, *P*=.02), and limited smartphone use (11/22, 50%; χ^2_2=15.60; *P*<.001; post hoc Dwass-Steel-Critchlow-Fligner: C2>C3, *P*<.001).
- Cluster 3: participants with moderate improvements. This group consisted mainly of urban adults (12/16, 75%; *P*=.01) aged ≥70 years (13/22, 81.3%; χ^2_2=0.25.00; *P*<.001; post hoc Dwass-Steel-Critchlow-Fligner: C3>C1, *P*<.001; C3>C2, *P*<.001) and smartphone use oriented toward extended social interaction (9/16, 56.3%; *P*<.001).

Harms and Unintended Events

No clinical harms or adverse health-related events were observed. However, one unintended operational issue arose in the telehealth group: 5 (8.2%) participants of the 61 assigned to telehealth—despite initially reporting confidence using WhatsApp—were unable to access or view the educational videos, 4 of whom lived in rural areas. This usability-related limitation led to their exclusion from the per-protocol analysis but did not pose any health risks.

Discussion

Principal Findings

This randomized trial tested a WhatsApp-supported telehealth reinforcement strategy among community-dwelling older adults in the La Araucanía Region of Chile. Both study arms demonstrated significant improvements in oral health knowledge and self-efficacy. Between-group differences favored telehealth only for attitudes toward oral health and dental caries knowledge in the primary per-protocol analysis, with attitudes showing the strongest effect. No significant differences between groups were identified for total knowledge, periodontal disease recognition, or oral cancer knowledge. These findings underscore the potential of mHealth interventions in addressing disparities in preventive care, aligning with World Health Organization recommendations [88].

Intention-to-treat sensitivity analysis attenuated the between-group difference in dental caries knowledge, while superiority for attitudes remained. This outcome suggests that the added benefit of telehealth reinforcement, while present, was modest and more evident among participants with full adherence to the intervention. A plausible explanation is the high effectiveness of the face-to-face education delivered to the comparator group, which produced substantial baseline improvements, thereby reducing the margin for further short-term gains. Similar patterns have been reported in prior education trials, where reinforcement strategies yielded clearer benefits over longer follow-up periods rather than immediately post intervention [15].

From an SCT perspective, learning and behavior change are supported by reinforcement and repeated opportunities to observe, rehearse, and apply learned behaviors in supportive environments [22,25]. While face-to-face education appeared sufficient for most knowledge domains, educational research indicates that single-session interventions are vulnerable to declining retention over time in the absence of reinforcement [89,90]. In this study, telehealth operated as a structured extension of the in-person education, allowing repeated exposure to key concepts and practical application through a familiar digital platform—an approach aligned with older adults' preference for reliable postconsultation resources [46,52,53]. Although absolute knowledge gains were slightly larger in the telehealth group, no statistically significant between-group differences were observed. Notably, the magnitude of improvement observed in the telehealth arm falls at the upper range reported in prior digital interventions for older adults (3.1-5.4 points) [31,45,91], although comparisons should be interpreted cautiously given heterogeneity in study designs and outcome measures. Taken together, this combined mechanism may help explain the between-group gains observed in specific knowledge domains—particularly dental caries and periodontal prevention—among fully adherent participants.

Beyond knowledge acquisition, effective preventive behavior change requires additional mechanisms, such as self-efficacy [92]. Prior research suggests that gains in knowledge can positively influence attitudes and self-efficacy, supporting the adoption of healthier behaviors, and, over time, improvements in oral-health related quality of life [16]. Both groups demonstrated substantial improvements in self-efficacy, which were positively associated with self-reported improvements in hygiene behaviors. Exploratory subgroup analysis further suggested that rural participants receiving telehealth reinforcement experienced additional behavioral gains, specifically increased flossing. Although exploratory, this pattern is consistent with SCT-based mechanisms—such as observational learning (video-based demonstrations), verbal persuasion (via simple and supportive messaging), environmental facilitation (home-based, flexible access to content), and repetition for mastery (allowing participants to review and practice skills introduced during the face-to-face session) [22,25]. Together, these elements may have strengthened self-regulation, reinforced self-efficacy, and supported the internalization of health recommendations, thereby promoting skill development and behavior adoption [21].

The improvement in prevention-oriented attitudes may reflect changes in outcome expectancies, a core SCT construct referring to beliefs about the anticipated benefits of a behavior [22,25].

XSL•FO
RenderX

Repeated, self-paced engagement with preventive content may have strengthened participants' expectations that preventive oral health behaviors are effective and worthwhile, thereby supporting more positive attitudes toward oral health in older age. However, the persistence of fatalistic beliefs—such as viewing oral deterioration as an inevitable part of aging—highlights the resistance of deeply-rooted social narratives, particularly in socioeconomically vulnerable groups [93]. Addressing normative beliefs may require culturally sensitive messaging, accessible education, and stronger community engagement strategies to build collective efficacy and shift these deeply rooted perceptions [94].

Exploratory subgroup analyses suggested that the intervention may have helped reduce baseline knowledge disparities among rural participants. These differences aligned with underlying oral health inequalities, as rural participants had fewer teeth on average—an indicator commonly associated with limited access to preventive services and delayed diagnosis among higher-risk populations [2,95]. Findings from the multiple correspondence analysis and k-means clustering further refined this interpretation. Although the cluster showing the greatest improvements was predominantly rural, another cluster with mixed urban-rural composition and higher rates of functional dentition displayed limited responsiveness. This pattern suggests that baseline preventive need, proxied by dentition status, may play a more influential role than residence alone in shaping intervention response. Accordingly, delivering educational content through accessible digital platforms may be particularly beneficial for older adults with greater unmet preventive needs—many of whom reside in rural settings [95]—by helping mitigate structural barriers in high-need populations. This approach may be especially relevant in settings with limited access to oral health care and quality educational resources, while also representing a potentially cost-effective strategy to narrow rural-urban disparities in oral health promotion [12,95,96].

The study also highlights persistent challenges related to the "gray digital divide" [40], as a notable proportion of otherwise eligible participants were excluded due to limited WhatsApp skills. To address this, the intervention incorporated inclusive design principles by using familiar social media tools, providing basic digital guidance, and videos tailored and validated for older adults with simple language, visual modeling, and accessibility features such as large fonts, high-contrast images, clear audio, appropriate pacing, and mobile-friendly formats. Despite these actions, some telehealth participants still faced access difficulties. Although this represents a minor unintended event rather than a clinical harm, it underscores how digital competencies—unequally distributed, especially in rural areas—can limit engagement [97,98]. Combining social media use with digital literacy training can enhance eHealth engagement in older adults [99,100].

Overall, the reinforcement was well received and perceived as useful, with high willingness to recommend the intervention, regardless of sociodemographic characteristics. Incorporating older adults' perspectives in co-design may further improve relevance, usability, and equity of digital health tools [53,101]. Recent qualitative research using the Unified Theory of Acceptance and Use of Technology framework highlights the importance of understanding older adults' intentions, attitudes, and concerns to enhance telehealth uptake [102]. The TEGO enabled continuous monitoring and identification of subgroups—such as participants with functional dentition or higher baseline knowledge—who may benefit from tailored content, aligning with prior teledentistry recommendations [43].

From a public health perspective, these findings support the use of smartphone-based telehealth reinforcement as a complementary component of in-person oral health promotion programs, particularly in settings facing structural barriers to preventive care. Although effects were modest, incremental gains—especially among rural older adults—suggest that targeted telehealth interventions can improve access and reinforce learning where traditional services are limited, potentially preventing more costly oral and systemic complications over time [103-106]. Overall, telehealth reinforcement appeared feasible, acceptable, and safe; however, its impact was shaped by digital access, literacy, place of residence, and oral health status, which may limit its universal applicability.

Evidence on the cost-effectiveness of telehealth interventions in aging populations remains limited [107,108]. While economic evaluation was beyond the scope of this trial, findings highlight the importance of context-specific cost analyses, particularly for older adults with heterogeneous needs and patterns of health care use. Existing evidence indicates mixed results, with simpler mHealth approaches showing some benefit, unlike more complex smartphone-based apps [109]. Notably, cost-effectiveness varies across populations and settings, with greater savings reported in rural contexts, and more favorable outcomes for in-person care in some urban minority groups [110]. These insights underscore the need for tailored economic evaluations that prioritize high-need settings, define resource use clearly, use appropriate comparators, and adopt a societal perspective to capture both direct and indirect costs and benefits [111].

Scaling up WhatsApp-based or similar mHealth interventions in primary care will require investment in digital literacy training for health care professionals, integration of mobile-compatible tools into routine workflow, and strengthening technological infrastructure through reliable internet connectivity (eg, satellite or mobile broadband) and ensuring device availability, especially in rural areas [112,113]. Policy support is essential to promote adoption among patients, caregivers, and health teams, recognizing the role of mHealth in education, prevention, and continuity of care [114]. Moreover, safeguarding data privacy and controlling misinformation remain critical, as highlighted by recent qualitative evidence from health system decision-makers emphasizing coordinated policies across governments, clinicians, digital platforms, and the public [115].

Limitations

While the study demonstrates promising results, it is important to recognize its limitations when interpreting the findings. First, the short follow-up period precluded assessment of the sustainability of changes in knowledge, attitudes, and self-efficacy. Second, although the intervention was guided by

XSL•FO
RenderX

SCT, only self-efficacy was directly measured, whereas other constructs were embedded within the intervention design and assessed indirectly through participants' engagement, knowledge acquisition, attitudes, and behavior change outcomes. Engagement with the educational videos was not systematically monitored, limiting evaluation of dose-response relationships or specific mechanisms of change. The absence of qualitative data—such as interviews or open-ended feedback—further restricted insight into participants' subjective experiences and perceived usefulness of the intervention.

Self-reported measures were limited to secondary behavioral outcomes and may be subject to social desirability bias, warranting cautious interpretation. The relatively small sample size reduced statistical power for subgroup analyses and limited generalizability across geographic settings and levels of smartphone use. Subgroup findings, including differences by place of residence, were observational and should be interpreted as descriptive rather than causal. Finally, selection bias may have occurred at the eligibility stage due to unequal access to technology or differential motivation to participate, potentially limiting applicability to populations with lower digital proficiency.

Implications and Future Directions

Despite these limitations, this study contributes to oral health promotion for older adults in underserved regions by demonstrating a structured application of a theory-informed intervention design. While individual components are not novel [17,18,21,31,43,116], their integration into a coherent strategy explicitly informed by SCT across face-to-face and telehealth delivery provides a concrete example of theory-informed intervention design, addressing documented gaps in explicit theory operationalization in oral health interventions targeting older adults [18,117,118]. Unlike most prior m-oral health studies, which have focused predominantly on urban populations [31,43-45,91,119], this study evaluates a geographically balanced rural-urban sample and offers suggestive evidence of differential intervention response across settings, a perspective rarely examined in previous studies. Overall, the findings indicate that theory-informed telehealth reinforcement may help address service gaps in underserved settings. The intervention demonstrated consistently high acceptability across multiple indicators, together with the use of accessible digital platforms—aligned with the digital context of older adults [50,51]—supporting its feasibility and suggesting potential for scalable, context-aligned implementation in resource-limited health systems [95,96]. By generating evidence in a local context, this study offers insights relevant to context-specific policy development and contributes to the growing literature on digital health for aging populations.

Looking ahead, future research should build upon these findings by using larger and more diverse samples, extending follow-up periods, and including clinical outcomes. Given the improvements observed, particularly among rural older adults, future studies should also explore how tailoring interventions to participants' digital literacy, sociodemographic profiles, or baseline health status may enhance outcomes. Incorporating qualitative methods to capture participants' experiences, alongside in-depth analysis of their interaction with digital content (eg, process measures), will be essential to better understand the mechanisms underlying behavioral change. Furthermore, emerging technologies—such as artificial intelligence, gamification, or virtual reality—offer opportunities to enhance engagement, but must be coupled with digital literacy strategies to ensure equitable adoption.

Conclusions

This study highlights the effectiveness of both face-to-face education and telehealth reinforcement, each grounded in SCT, in improving key oral health outcomes among older adults. Per-protocol analyses showed modest benefits of telehealth in specific domains—caries knowledge and attitudes—whereas ITT analyses confirmed significance only for attitudes. Exploratory subgroup findings suggest that individuals from rural settings and those with greater baseline preventive needs may derive added benefits, though these patterns should be interpreted cautiously. The acceptability of the telehealth approach further supports the feasibility of m-oral health and social media as a scalable strategy. Future research should examine long-term effects, impact on clinical outcomes, and explore adaptation for diverse populations and settings, ensuring their relevance and cost-effectiveness for broader implementation.

By examining how telehealth can reinforce high-quality face-to-face promotion, this study adds evidence supporting digital health strategies to promote oral health, particularly among vulnerable populations, and underscores their potential to advance healthy aging and equitable access to preventive care, encouraging further work to refine and expand this approach.

Acknowledgments

The authors thank Universidad de La Frontera for logistical support and the Inter-University Center of Healthy Aging (CIES) of the Council of Rectors of Chilean Universities (CRUCH) for their collaboration. FM-S acknowledges the National Commission for Scientific and Technological Research of Chile (Comisión Nacional de Investigación Científica y Tecnológica de Chile [CONICYT]) support (Magíster Nacional/2022-22220928). Editorial Notice

This randomized study was only retrospectively registered because of an administrative delay related to internal institutional processing and coordination of clinical trial registry submission. The editor granted an exception from ICMJE rules mandating prospective registration of randomized trials because the risk of bias appears low and because the authors provided an official letter from the IRB confirming that the submitted study design is identical to the protocol assessed and approved before trial initiation. However, readers are advised to carefully assess the validity of any potential explicit or implicit claims related to primary outcomes or effectiveness, as retrospective registration does not prevent authors from changing their outcome measures retrospectively.

Abstract

Background: Mobile health (mHealth) and online video are increasingly central to cardiology education and point-of-care decision support. However, little is known about how simple design choices, such as mobile-first web layouts and captioned videos, translate into real-world practice across countries with different income levels.

Objective: This exploratory ecological study used routinely collected, cross-platform learning analytics from a francophone cardiology mHealth initiative to (1) describe how mobile web access and caption-enabled YouTube viewing varied across World Bank income groups and (2) examine whether greater reliance on mobile access was associated with poorer engagement on the website or on YouTube.

Methods: We analyzed country-level analytics from the École Numérique de Cardiologie (ENC; Saint-Denis) mobile-optimized website and its companion YouTube channel (YouTube, LLC [Google LLC]) over a two-year window (September 2023 to September 2025). Countries were grouped as high-, middle-, or low-income (World Bank, three-level classification). Country-level metrics included mobile device session share; website bounce rate; time on page; and YouTube average view duration, audience retention, and intentional views. Caption-related and demographic YouTube metrics were available only as income-group aggregates and were therefore reported descriptively as between-group contrasts; country-level inferential analyses were restricted to country-level variables. Reporting followed the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) checklist.

Results: Thirty-four countries contributed data: 13/34 (38%) high-income, 14/34 (41%) middle-income, and 7/34 (21%) low-income. Caption-enabled watch time was 18.8% in high-income countries (HICs), compared with 38.7% in middle-income countries (MICs) and 60.9% in low-income countries (LICs), representing a caption equity gap (CEG) of 42.1% between low- and high-income settings. Median website mobile share rose with decreasing income (36.5%, 63.3%, and 81.4%, respectively; Jonckheere-Terpstra $P=.01$). Across income groups, higher caption-enabled watch time coincided with a higher share of intentional views. At the country level, greater reliance on mobile access was not associated with higher bounce rate or shorter time on page, and Spearman correlations between mobile share and YouTube engagement metrics were small and nonsignificant (all $|\rho|\leq 0.28$; all $P\geq .18$).

XSL•FO
RenderX

Conclusions: In this multicountry, francophone, mHealth learning analytics case study, mobile web access and captioned video were used most intensively in lower-income settings, and greater reliance on mobile access was not associated with measurable penalties in basic engagement metrics. These findings support treating mobile-optimized design and systematic captioning as core, low-cost, access-supporting features for equitable digital cardiology education. They also suggest that routinely collected platform indicators can serve as practical equity-monitoring signals for global mHealth initiatives, while underscoring that engagement metrics are not direct measures of learning or behavior change.

mobile health; cardiology; medical education; health equity; digital divide; YouTube; learning analytics; ecological study

Introduction

Digital technologies are reshaping cardiovascular education, and many societies and academic centers now deliver teaching through online and hybrid formats alongside mobile health (mHealth) initiatives [1-4]. Within this ecosystem, online video, particularly YouTube (LLC [Google LLC]), has become a major channel for professional and patient education, although its educational contribution remains only partly characterized and is rarely examined using real-world usage data [5]. Experimental studies suggest that short videos and digital cardiology resources can improve knowledge, retention, and patient-reported outcomes [6-8].

These opportunities intersect with persistent inequities. The burden of cardiovascular disease is greatest in low-income countries (LICs) and middle-income countries (MICs), where access to guideline-based care, connectivity, and continuing education remains limited [9-12]. Global connectivity reports describe a large “usage gap”: despite widespread mobile broadband coverage, many clinicians work with unstable electricity, constrained bandwidth, and a strong dependence on personal smartphones as their primary digital device for work and learning [11-13]. In such settings, mobile-first web design and lightweight content are not optional refinements but practical access requirements.

Subtitles and transcripts represent another simple access enabler for video. Same-language captions benefit many learners, including second-language users and people who are deaf or hard of hearing, and automatically generated subtitles can support learning when sufficiently accurate [14,15]. On public platforms such as YouTube, captions and automatic translation could extend the reach of single-language cardiology content across income settings. However, little is known about how often subtitles are actually used in medical or cardiology education, how this use varies with country income, or how it relates to mobile access.

We therefore conducted an exploratory, multicountry ecological analysis of routinely collected learning analytics from a francophone, mobile-first cardiology education website and its YouTube channel. Our two prespecified objectives were (1) to describe, across World Bank income groups, the share of website sessions from mobile devices and the share of YouTube watch time with subtitles enabled and, (2) using only variables measured at the country level, to examine whether greater reliance on mobile access was associated with poorer engagement on the website or on YouTube. We hypothesized that both access indicators would be higher in MICs and LICs than in high-income countries (HICs) and that greater reliance on these access enablers would not be associated with poorer engagement metrics.

Methods

Study Design and Setting

This study was an exploratory, multicountry ecological analysis of routinely collected analytics from a French-language cardiology education website [16] and its companion YouTube channel. The website is an open-access cardiology education resource providing clinical protocols, instructional videos, and practical tools covering diverse cardiology topics. The country was selected as the natural unit of analysis because (i) the World Bank income classification used as the main stratification variable is defined at the country level, and (ii) École Numérique de Cardiologie (ENC; Saint-Denis) platform analytics aggregate user activity at the country level. The ecological design is appropriate for an equity-focused descriptive question; we did not seek to make individual-level inference and acknowledge in the Discussion that ecological associations cannot establish individual-level effects.

All metrics were aggregated over a prespecified two-year window (September 2023 to September 2025). The website was designed using a mobile-first responsive layout: core pages and PDFs were optimized and tested on smartphones (large tap targets, simplified navigation, lightweight media) to support use on small screens and variable bandwidth. No individual-level data were accessed.

Data Sources

Website Analytics

Website analytics were exported from Fathom Analytics (Conva Ventures Inc.), a privacy-focused web analytics platform. For each country, we obtained the number of sessions, unique visitors, and page views, traffic sources (organic search, direct, social, other), bounce rate, and average time on page. Device information was used to calculate the percentage of sessions from mobile devices among sessions with a known device type and the percentage of sessions with an unknown device type. We define mobile devices as smartphones and tablets combined, and this definition is used consistently in Methods, Tables, and Figure captions. For the main content categories (clinical

XSL•FO
RenderX

protocols, practical tools, video pages), we also computed the percentage of sessions from mobile devices.

YouTube Analytics

For each country, we extracted the number of views, total watch time, average view duration, audience retention, the percentage of viewers continuing beyond an introductory segment, views per viewer, and the number and percentage of views classified by the platform as intentional. Intentional views are defined by YouTube as views that the platform classifies as user-driven (eg, search-, suggestion-, or subscription-driven views) rather than impressions or auto-played starts. We selected this metric as a complement to total views because it captures viewer intent and is therefore a meaningful indicator of voluntary engagement with educational content.

A key measurement caveat applies to the caption and demographic indicators introduced here: unlike the country-level website and YouTube metrics described above, they were not available at the country level. Caption-related YouTube metrics (percentage of watch time with any subtitles enabled and percentage with French subtitles) and summary viewer demographics (dominant age band and percentage of male viewers) were available in YouTube Studio only at aggregated geographic levels that corresponded approximately to World Bank income groups, not to individual countries. For each income group (high-, middle-, and low-income) we exported these caption and demographic indicators and assigned the corresponding group-level values to all ENC countries in that group, so that web and YouTube indicators could be tabulated together. As a direct consequence, these caption-related and demographic variables took only three distinct values across the 34-country dataset and showed no within-group variability.

Country Income Classification

Countries were mapped to the World Bank's 2024‐2025 four-level income classification (high-, upper-middle, lower-middle-, and low-income economies), a widely used framework that enables standardized cross-country comparisons and reflects major disparities in digital infrastructure, resource availability, and access conditions that may influence engagement with digital health education interventions. For main analyses, upper- and lower-middle-income categories were collapsed into a single middle-income group, yielding a three-level ordinal variable (high, middle, and low income); the four-level classification was retained for descriptive sensitivity analyses.

Outcome and Access Definitions

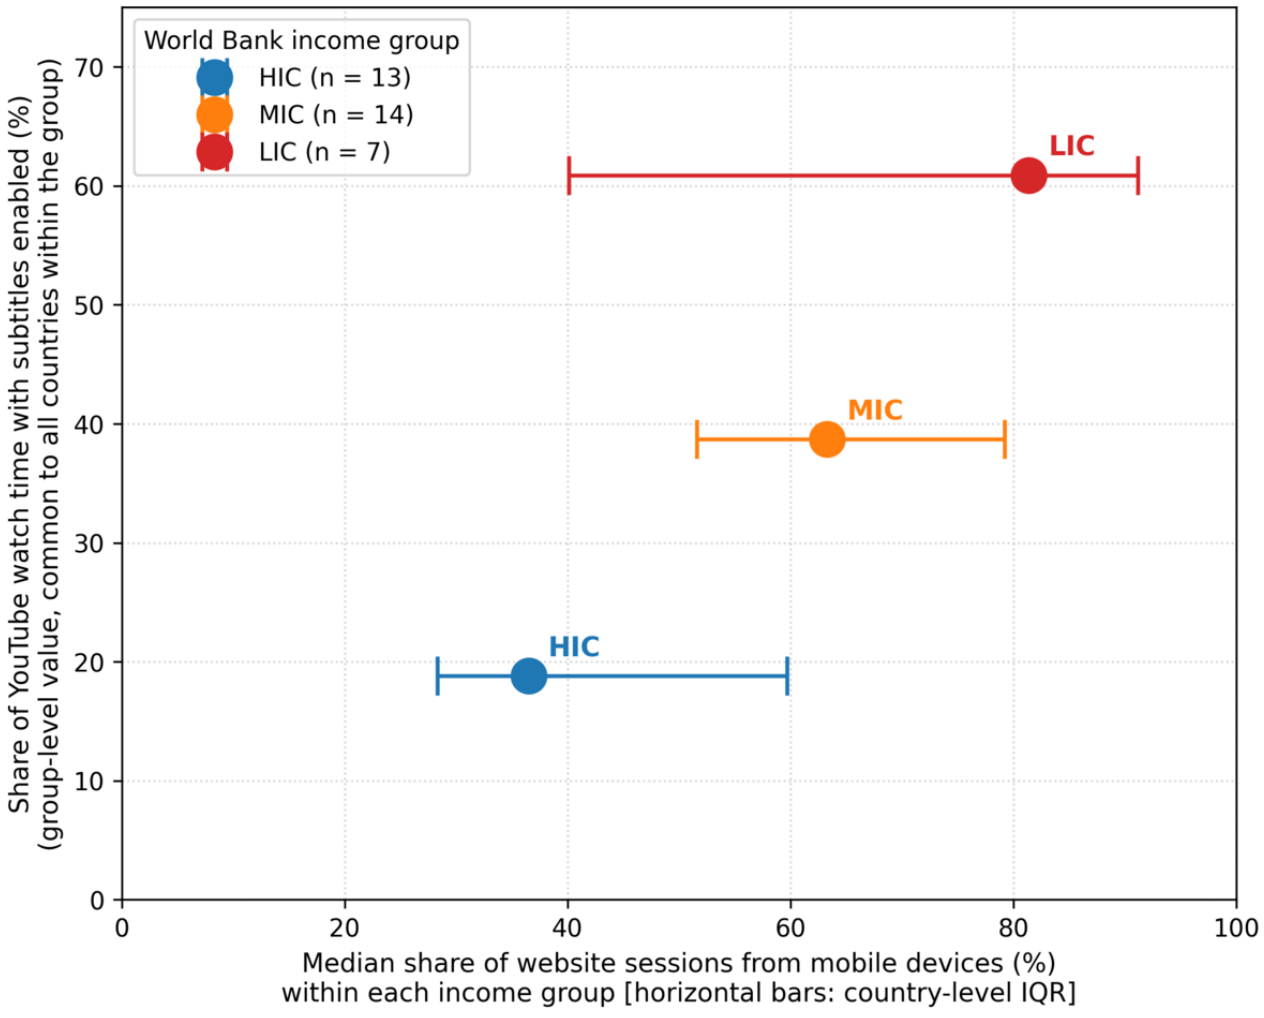
Primary access enabler indicators were website mobile access (percentage of sessions from mobile devices among sessions with a known device type) and YouTube caption use (percentage of watch time with any subtitles enabled and any language). Country-level secondary website outcomes, used as country-level proxies of engagement, were bounce rate and average time on page. Country-level secondary YouTube outcomes were average view duration, audience retention, viewer retention beyond the introductory segment, views per viewer, and percentage of intentional views. We also summarized, by income group, mobile share within each website content category, referrer structure, LinkedIn (LinkedIn Corporation) followers and visitors, and website unique visitors; these latter metrics were considered exploratory.

Caption-related YouTube metrics and demographic YouTube metrics were available only at the income-group level. We therefore treated them, throughout the analysis, as descriptive between-group contrasts and we did not include them in country-level inferential analyses. Bounce rate, time on page, average view duration, retention, viewer retention beyond the introductory segment, and intentional views are platform-defined engagement metrics; we explicitly note in the discussion that they are not direct measures of learning, comprehension, implementation, or behavior change. Demographic indicators (dominant viewer age band and percentage of male viewers) were derived from small YouTube Studio aggregates of logged-in viewers with available age and sex data and are descriptive only. In particular, the 100% male value in the low-income group reflects a very small aggregate and does not warrant inferential interpretation.

Data Preprocessing

All analyses were conducted at the country level. Raw exports from each platform were imported into a unified database, nonnumeric placeholders were removed, and percentage variables were placed on a 0‐100 scale where needed. For YouTube, country-level indicators (views, watch time, average view duration, retention, viewer retention beyond the introductory segment, views per viewer, and intentional views) were retained as such. Caption-related indicators (percentage of watch time with any subtitles enabled and percentage with French subtitles) and viewer demographics (age band code, percentage of male viewers) were available only at the income-group level; the same group-level values were therefore shared by all countries within a given income group, and there was no within-group variability in these indicators. For YouTube data, we retained all countries with at least one record and a nonmissing income group. When multiple rows were present for a given country and platform, we computed country-level medians over the observation window. For cross-domain analyses, website and YouTube tables were merged on country and income group so that each country contributed a single combined record. Country-level YouTube engagement metrics (average view duration, audience retention, intentional views, and total views) were included for a given country only when YouTube Studio exported a nonmissing country-level value for that metric over the observation window. Low-volume country accounts without an available country-level value were excluded pairwise. Country-level correlations involving these metrics were therefore based on 24 countries (9 high-, 9 middle-, and 6 low-income; 23 countries for audience retention, with one fewer low-income country), compared with all 34 countries for website-only correlations.

Statistical Analysis



Given the modest sample size and skewed country-level distributions, analyses were prespecified as exploratory and relied on nonparametric tests and robust regression, with emphasis on effect sizes and ordered gradients. For variables measured at the country level (website mobile share, bounce

XSL•FO
RenderX

rate, time on page, and country-level YouTube engagement indicators), we examined gradients across income groups using the Kruskal-Wallis test and tested for a monotonic trend with the Jonckheere-Terpstra test under the prespecified order high<middle<low income. Medians and IQRs by income group are reported for all main metrics. Because most reported percentages are country-level metrics (eg, percentage of sessions from mobile devices and percentage of watch time with captions) that are then summarized as a median or aggregate across countries, rather than proportions computed from a single numerator and denominator, a single absolute count cannot be attached to each percentage; where a discrete count and total are available (eg, number of countries per income group, sample sizes for correlations and regressions, numbers of visitors, views, or followers), both the count and the percentage or total are reported. Country-level Spearman rank correlations were computed between mobile share and engagement outcomes (website bounce rate, time on page; country-level YouTube average view duration, retention, and intentional views). Because our hypotheses were directional (a monotonic gradient across ordered income groups), the Jonckheere-Terpstra trend test was prespecified as the primary test for these ordered comparisons; it is more sensitive to monotonic trends than the omnibus Kruskal-Wallis test, which does not assume an ordering. Where the two tests diverge, the trend test therefore takes precedence.

Caption-related and demographic YouTube metrics, available only at the income-group level, were summarized descriptively as three between-group values; we did not compute country-level correlations or *P* values for these variables, and we did not include them in inferential models. To assess cross-domain coherence between platforms, we summarized, for each income group, the median website mobile share (computed across countries) and the income-group aggregate caption-enabled watch time and compared them descriptively (Figure 1, three-point income-group representation).

Figure 1. Cross-domain coherence between website mobile access and YouTube caption use, by income group (three points). Group-level summary of two access indicators across the three World Bank income groups: median share of website sessions from mobile devices (x-axis, country-level medians within each group, with horizontal bars showing the country-level IQR) and share of YouTube watch time with subtitles enabled (y-axis, group-level value common to all countries within the group). Points correspond to HIC (36.5%, 18.8%), MIC (63.3%, 38.7%), and LIC (81.4%, 60.9%). The figure shows that both access indicators increased monotonically from high- to low-income groups; because YouTube caption-enabled watch time was available only as one value per income group, this representation deliberately avoids a country-level scatter that could misleadingly suggest within-group caption variability. A country-level scatterplot of mobile share against the assigned group-level caption value is provided in Figure S1 in Multimedia Appendix 1, with an explicit note that all country dots within an income group share the same caption value. HIC: high-income country; LIC: low-income country; MIC: middle-income country.

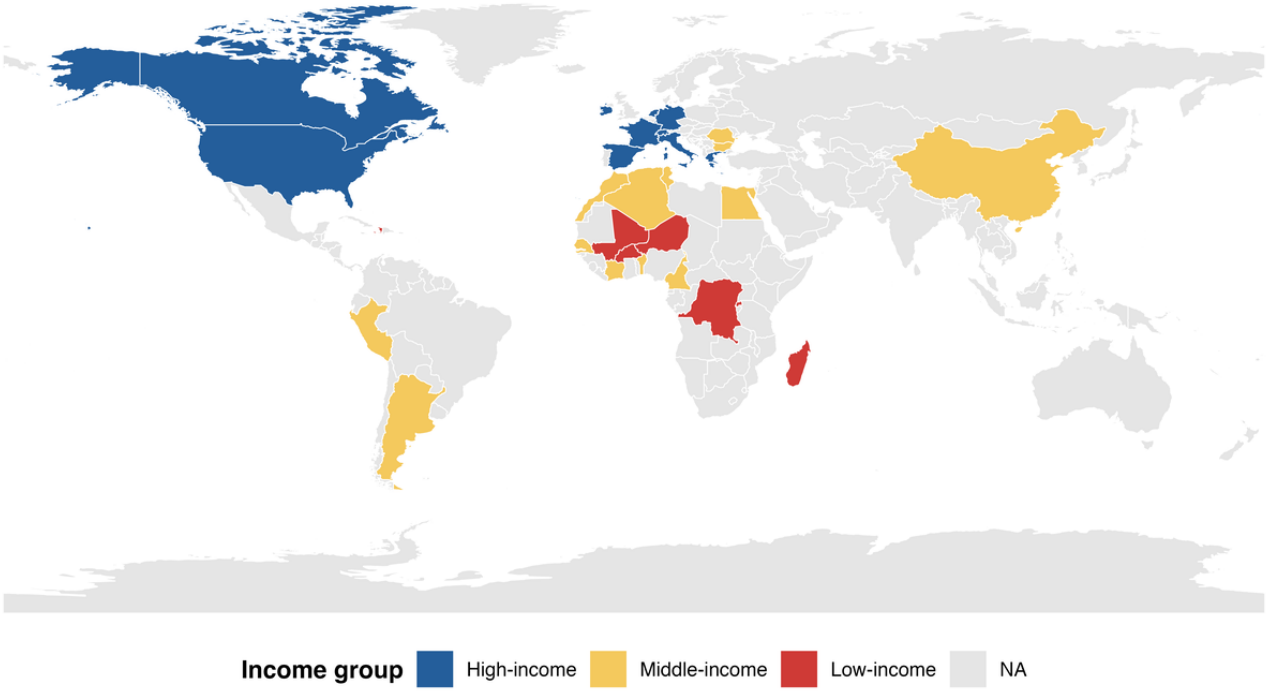
XSL•FO
RenderX

For website engagement we fitted median (τ=0.5) quantile regression models with bounce rate or average time on page as the outcome and income group plus website mobile share (proportion from 0 to 1) as predictors; interaction terms between income group and mobile share were explored in secondary models. LinkedIn followers, LinkedIn visitors, and website unique visitors were summarized by income group and compared using Kruskal-Wallis tests. Robustness of the main gradients was evaluated by repeating key comparisons under the alternative four-level income classification, in leave-one-country-out analyses, and in a sensitivity analysis excluding France (the dominant high-income contributor). *P* values are reported as *P*=.XX or *P*<.001; statistical significance was set at *P*=.05 (two-sided). All analyses were performed in R (R Foundation for Statistical Computing), version 4.5.0.

Reporting Framework

This study is reported in accordance with the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) checklist for cross-sectional observational studies. The completed STROBE checklist is provided as Checklist 1.

Ethical Considerations



The study used only aggregated, country-level web analytics without any directly or indirectly identifiable personal data and did not involve any intervention or contact with patients or health professionals. Under French law on research involving human participants ("loi Jardé") [17] and the French Public Health Code [18], such secondary analyses of fully anonymized, aggregated data do not require review by a Comité de Protection des Personnes or individual informed consent. The project complied with applicable French and European data-protection requirements, including the General Data Protection Regulation.

Results

Country Sample

Web and YouTube analytics from the ENC were available for 34 countries: 13/34 (38%) HICs, 14/34 (41%) MICs, and 7/34 (21%) LICs. The audience was predominantly but not exclusively francophone, spanning Europe, North America, Latin America, North and Sub-Saharan Africa, and Asia (Figure 2).

Figure 2. Included countries by World Bank income group. World map showing the 34 countries with École Numérique de Cardiologie (ENC) web and YouTube analytics, colored by World Bank income group (high-, middle-, or low-income). Countries without ENC data or without a mapped income category are shown in gray (not available [NA]). The map highlights a predominantly francophone yet geographically diverse reach spanning Europe, North America, Latin America, North Africa, Sub-Saharan Africa, and Asia over the fixed two-year observation window.

Income-Group Descriptive Contrasts: Caption Use and Viewer Demographics on YouTube

Caption-related and demographic YouTube metrics were available only as income-group aggregates and therefore took only three distinct values across the dataset; the contrasts below are presented as descriptive between-group differences without country-level *P* values or correlation coefficients.

Over the two-year study window, the ENC website attracted 34,340 unique visitors across 34 countries, generating 180,563 page views, while the companion YouTube channel accumulated 171,009 views and 7,451 hours of watch time.

The income-group aggregate share of YouTube watch time with any subtitles enabled increased monotonically with decreasing income, from 18.8% in HICs to 38.7% in MICs and 60.9% in LICs (Table 1, Panel A; Figure 3). As a percentage of total watch time within each income-group aggregate, rather than an

XSL•FO
RenderX

average across countries or videos, this share is inherently weighted by watch time. This corresponds to a caption equity gap (CEG) of 42.1% (60.9%-18.8%) between LICs and HICs. The share of watch time with French captions and with non-French captions varied across income groups (HICs: 2.3% French, 16.5% non-French; MICs: 0.3% French, 38.4% non-French; LICs: 17.5% French, 43.4% non-French), with non-French captions accounting for the largest share of caption-enabled watch time in middle- and low-income groups (Table 1, Panel A).

Across income groups, dominant viewer age band was older in HICs (≥65 years) than in MICs (25 - 35 years) and LICs (45 - 55 years); however, this pattern was not monotonic with caption-enabled watch time, as LICs had a higher caption-enabled watch time than MICs but an older dominant age band (Table 1, Panel A bis; see Limitations).

Table . Caption use, viewer demographics, mobile web access, and engagement by World Bank income group.[a]

Income group	Panel A[b]—income-group-level YouTube indicators			Panel A bis—income-group-level demographic indicators		Panel B[c]—country-level indicators, median (IQR); n countries					
	Caption-enabled watch time (any subtitles), %	French captions, %	Non-French captions, %	Dominant viewer age band, years	Male viewers, %	Mobile share, %	Bounce rate, %	Time on page, s	YouTube AVD[d], min	YouTube retention, %	n countries
High-income (HIC[e])	18.8	2.3	16.5	≥65	62	36.5 (28.3 - 59.7)	65.5 (60.8 - 68.5)	43.2 (39.2 - 49.4)	2.30 (2.05 - 2.82)	36.0 (27.0 - 40.0)	13
Middle-income (MIC[f])	38.7	0.3	38.4	25 - 35	46	63.3 (51.6 - 79.2)	58.5 (49.0 - 66.3)	46.4 (33.8 - 70.9)	2.55 (2.28 - 2.78)	36.0 (34.0 - 45.0)	14
Low-income (LIC[g])	60.9	17.5	43.4	45 - 55	100[h]	81.4 (40.1 - 91.2)	51.2 (43.5 - 59.0)	74.2 (52.8 - 103.6)	3.56 (3.31 - 4.44)	49.0 (37.0 - 53.0)	7

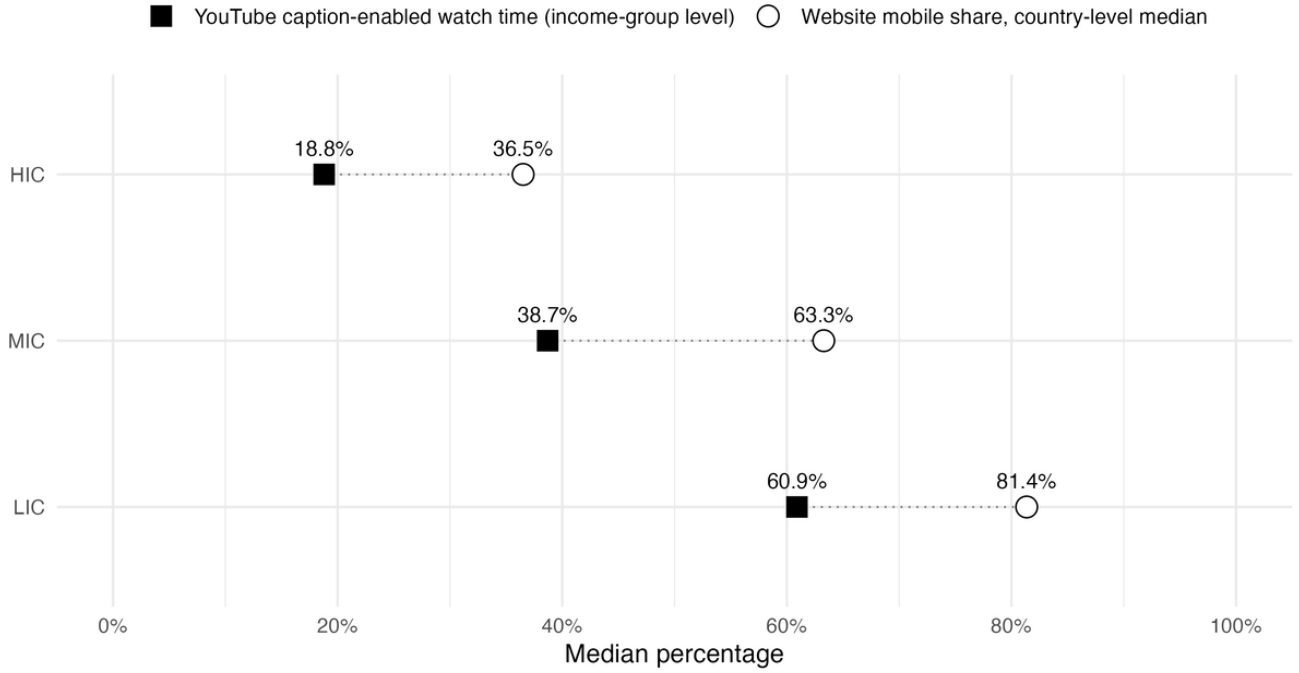
[a]Demographic values are derived from small YouTube Studio aggregates of logged-in viewers and are descriptive only (see *Methods*, *Outcome and Access Definitions* section).

[b]Panel A reports YouTube indicators that were available only at the income-group level in YouTube Studio and were assigned to all countries within an income group; these values are therefore identical across all countries of the same group and are reported descriptively, without country-level *P* values or correlation coefficients.

[c]Panel B reports country-level medians and IQRs. Mobile share: percentage of website sessions from mobile devices (smartphones or tablets) among sessions with a known device type. Bounce rate: proportion of single-page sessions, expressed as percentage. Time on page: average time spent on a page (seconds). YouTube AVD: average view duration (minutes); retention: average percentage of each video watched. The “n countries” column applies to mobile share, bounce rate, and time on page (13 HICs, 14 MICs, 7 LICs; 34 total). YouTube AVD was available for a smaller subset of countries (9 HICs, 9 MICs, 6 LICs; 24 total) and YouTube retention for a further reduced subset (9 HICs, 9 MICs, 5 LICs; 23 total) (Table S1 in Multimedia Appendix 2 for per-metric denominators).

[d]AVD: average view duration.

[e]HIC: high-income country.



[f]MIC: middle-income country.

[g]LIC: low-income country.

[h]The low-income value is based on a very small aggregate; see *Method*s section.

XSL•FO
RenderX

Figure 3. Access enablers by income group: YouTube captions and website mobile access. Income-group aggregate share of YouTube watch time with subtitles enabled (square marker, weighted by watch time within each income-group aggregate) and median share of ENC website sessions from mobile devices among sessions with a known device type (open circle) for each World Bank income group (HIC, MIC, LIC). The dotted line within each income group is provided for visual comparison only between two distinct indicators (caption-enabled watch time and website mobile share); it does not represent an uncertainty interval, a temporal change, or any modeled relationship. Caption-enabled watch time was 18.8%, 38.7%, and 60.9% in HICs, MICs, and LICs, respectively, corresponding to a caption equity gap of 42.1% between LICs and HICs. Website mobile share showed a similar gradient (36.5%, 63.3%, and 81.4%, respectively). Caption-related metrics were available only at the income-group level (one value per group, common to all countries in the group). HIC: high-income country; LIC: low-income country; MIC: middle-income country.

Country-Level Analyses: Mobile Web Access and Engagement

Website mobile share, measured at the country level, increased with decreasing income (Table 1, Panel B; Figure 3). The median mobile share of ENC website sessions was 36.5% (IQR 28.3 - 59.7) in HICs, 63.3% (IQR 51.6 - 79.2) in MICs, and 81.4% (IQR 40.1 - 91.2) in LICs. The prespecified ordered trend test supported a monotonic increase in mobile share from HICs to MICs to LICs (Jonckheere-Terpstra P=.01; Kruskal-Wallis H=5.11; P=.08). The proportion of website sessions from devices of unknown type was negligible (median 0% in HICs, MICs, and LICs; range 0% - 0% in each group); no country exceeded the 40% threshold used for exclusion from mobile-share analyses, so the mobile-share denominator effectively comprised all sessions and could not materially bias the observed gradient.

Country-Level Spearman Correlations Involving Mobile Share

Country-level Spearman correlations between website mobile share and country-level engagement outcomes were small in magnitude and not statistically significant (mobile share vs bounce rate: ρ=−0.05, P=.76, n=34; vs time on page: ρ=0.07, P=.71, n=34; vs YouTube average view duration: ρ=0.05, P=.80, n=24; vs YouTube audience retention: ρ=−0.03, P=.88, n=23; vs YouTube intentional views: ρ=0.28, P=.18, n=24). For reference, bounce rate and time on page were inversely correlated at the country level (ρ=−0.48, P=.004, n=34; Table 2).

XSL•FO
RenderX

Table . Country-level Spearman correlations between website mobile share and country-level engagement outcomes.[a]

Pair of country-level variables	Spearman ρ	*P* values	N
Website mobile share vs bounce rate	−0.05	.76	34
Website mobile share vs time on page	0.07	.71	34
Website mobile share vs YouTube average view duration (country-level)	0.05	.80	24
Website mobile share vs YouTube audience retention (country-level)	−0.03	.88	23
Website mobile share vs YouTube intentional views, % (country-level)	0.28	.18	24
Bounce rate vs time on page	−0.48	.004	34
Website mobile share vs YouTube total views (country-level)	−0.06	.79	24

[a]All variables are measured at the country level; correlations are based on country-level complete cases for each pair. Caption-related and demographic YouTube metrics are not included in this table because they were available only at the income-group level (see *Methods* and Table 1 Panel A); they are reported descriptively in the *Results*. Country-level YouTube metrics were available for 24 of 34 countries (high-income: 9/13; middle-income: 9/14; low-income: 6/7; audience retention: 23/34, with 5/7 low-income countries); website-only correlations include all 34 countries. Coverage was proportionally similar across income groups, making substantial selection bias unlikely.

Median Quantile Regression for Web Engagement

In median (τ=0.5) quantile regression models for web engagement outcomes (Table 3), income group was associated with bounce rate but not with time on page. For bounce rate, the linear contrast for income (ordered from high- to low-income) was negative (β=−0.130; 95% CI −0.219 to −0.041; *P*=.01), consistent with lower median bounce rates in lower-income countries. The quadratic contrast was small and not statistically significant (β=−0.023; 95% CI −0.119 to 0.072; *P*=.64). For median time on page, neither the linear nor the quadratic income contrasts reached statistical significance (β=21.2 s, 95% CI –11.8 to 54.1, *P*=.22; β=12.6 s, 95% CI −18.6 to 43.8, *P*=.44). Website mobile share, modeled as a 0 - 1 proportion, was not independently associated with either outcome (bounce rate: +0.072, 95% CI −0.128 to 0.272, *P*=.48; time on page:+16.0 s, 95% CI −44.8 to 76.8, *P*=.61). Overall, these analyses did not provide evidence that countries relying more heavily on mobile access experienced systematically worse website engagement.

Table . Median (τ=0.5) quantile regression of web engagement outcomes on income group (polynomial contrasts) and mobile share (n=34 countries).[a]

Outcome and predictor	Coefficient β	95% CI	*P* values
Median bounce rate (proportion of single-page sessions)			
Intercept	0.554	0.425 to 0.684	<.001
Income group (linear contrast)	−0.130	−0.219 to −0.041	.01
Income group (quadratic contrast)	−0.023	−0.119 to 0.072	.64
Website mobile share (proportion, 0 - 1)	0.072	−0.128 to 0.272	.48
Median time on page (seconds)			
Intercept	47.1	9.7 to 84.5	.02
Income group (linear contrast)	21.2	−11.8 to 54.1	.22
Income group (quadratic contrast)	12.6	−18.6 to 43.8	.44
Website mobile share (proportion, 0 - 1)	16.0	−44.8 to 76.8	.61

[a]Median (τ=0.5) quantile regression models were fitted at the country level for two web engagement outcomes: bounce rate (proportion of sessions with only one page viewed) and median time on page (seconds). Income group was entered as an ordered predictor using polynomial contrasts (high-, middle-, low-income); the “linear contrast” captures the overall gradient from high- to low-income, with negative coefficients indicating lower values in lower-income settings. Website mobile share was modeled as a proportion from 0 to 1 (0=0% of sessions on mobile; 1=100% on mobile), so the corresponding coefficients represent the expected change in the median outcome across this range. In these models, income group showed a modest association with bounce rate, whereas mobile share was not independently associated with either bounce rate or time on page (all *P*≥.48).

Sensitivity Analyses

The income-related gradient in website mobile share was robust to several prespecified checks (Table S5 in Multimedia Appendix 3). In leave-one-country-out analyses, the Jonckheere-Terpstra trend test for mobile share remained significant in all 34 reestimations (all $P<.05$; largest $P=.03$). In a sensitivity analysis excluding France, the largest high-income contributor, the gradient was essentially unchanged (mobile share Jonckheere-Terpstra $P=.02$; Kruskal-Wallis H=4.94, $P=.08$). In median quantile regression models that added an income-by-mobile-share interaction, no interaction term reached statistical significance for either bounce rate or time on page (all $P>.05$; interaction coefficients and 95% CIs are reported in Table S5 in Multimedia Appendix 3), providing no evidence of an interaction between income group and mobile share for either outcome; given the small sample size, this nonsignificant result does not establish that the absence of a mobile-access penalty is equivalent across income groups.

YouTube Engagement Metrics by Income Group

Descriptively, country-level YouTube engagement metrics tended to be higher in lower-income groups (Table S1 in Multimedia Appendix 2). Median average view duration increased from 2.30 min in HICs to 2.55 min in MICs and 3.56 min in LICs, but neither the Kruskal-Wallis test (H=4.31, $P=.12$) nor the Jonckheere-Terpstra trend test ($P=.06$) reached statistical significance. Median audience retention rose from 36% (HICs) and 36% (MICs) to 49% (LICs), but Kruskal-Wallis and Jonckheere-Terpstra tests did not show statistically significant gradients (H=1.40, $P=.50$; Jonckheere-Terpstra $P=.14$).

Cross-Domain Coherence Between Mobile Web Access and Caption Use

The income-group median of website mobile share and the income-group aggregate caption-enabled watch time both increased with decreasing income (Figure 1). To match the data structure, Figure 1 of the main paper shows one point per income group (HICs, MICs, LICs); a country-level scatterplot is provided Figure S1 in Multimedia Appendix 1 with an explicit note that caption-related values are common to all countries within an income group and that the country-level pattern therefore reflects between-group contrasts rather than within-group variability.

Mobile Access by Content Category

Mobile reliance was high across all content categories outside high-income settings (Table 4, Table S3 in Multimedia Appendix 4). In HICs, medians for the share of mobile sessions were 37.7% for protocol pages, 40% for tool pages, and 52.2% for video pages, indicating relatively greater mobile use for video content. In MICs, medians increased to 66.1% for protocols, 60.5% for tools, and 77.1% for videos. In LIC mobile shares were 72.1% for protocols, 75% for tools, and 70% for videos. Even content typically consulted from a desktop in high-income settings (protocols, downloadable tools) was predominantly accessed from mobile devices in many MICs and LICs. The four-level World Bank classification yielded a broadly similar pattern, with mobile shares exceeding 60% in lower-middle- and low-income groups across all content categories and in upper-middle-income protocol and video pages, although upper-middle-income tool pages were lower (34.8%) (Table S3 in Multimedia Appendix 4).

Table . Mobile share of web sessions by content category and income group.[a]

Income group	Protocol pages — mobile sessions (% of known devices), median (IQR)	Tool pages — mobile sessions (% of known devices), median (IQR)	Video pages — mobile sessions (% of known devices), median (IQR)
High-income (HIC[b])	37.7 (19.3-58.6)	40.0 (34.7-61.2)	52.2 (39.1-61.0)
Middle-income (MIC[c])	66.1 (43.9-86.3)	60.5 (41.4-73.7)	77.1 (64.7-91.9)
Low-income (LIC[d])	72.1 (44.3-95.6)	75.0 (31.2-88.5)	70.0 (56.6-90.6)

[a]For each country and content category (protocols, tools, videos), mobile share is the proportion of École Numérique de Cardiologie website sessions with a known device type that originated from mobile devices (smartphones or tablets). Values are medians across countries within each World Bank income group (three-level classification); only countries with at least one session in each category contribute to that median.

[b]HIC: high-income country.

[c]MIC: middle-income country.

[d]LIC: low-income country.

Referrer Mix, LinkedIn Activity, and Website Reach

Referrer patterns varied by income group but were broadly dominated by organic and direct access (Table S2 in Multimedia Appendix 5 and Table S4 in Multimedia Appendix 6). At the country-median level, organic search accounted for 33% of sessions in HICs, 38.2% in MICs, and 43.5% in LICs; direct access accounted for 39.6%, 22.7%, and 20.5%, respectively. Social referrers contributed more in MICs (median 29.1%) than in HICs (14.3%) or LICs (12.3%). Median numbers of LinkedIn followers per country were 17 in HICs, 9 in MICs, and 5.5 in LICs, with no significant differences between income groups (H=3.19, $P=.20$). Median monthly LinkedIn visitors per country were also low across all income groups (H=0.01, $P=.91$). Median counts of unique ENC website visitors per country were highest in HICs (278), followed by MICs (93) and LICs (43; Table S2 in Multimedia Appendix 5). The country-level Spearman correlation between unique visitors and website mobile share was negative but not statistically significant ($\rho=-0.28$, $P=.10$, n=34).

Discussion

Principal Findings

In this exploratory ecological analysis of country-level learning analytics from a responsive francophone cardiology education website and its companion YouTube channel, we observed marked descriptive gradients in two practical access indicators across World Bank income groups. The share of website sessions from mobile devices and the share of YouTube watch time with captions enabled were substantially higher in middle- and especially LICs than in HICs, corresponding to a CEG of approximately 40% in caption-enabled watch time between low- and high-income settings. Because caption-related metrics were available only as income-group aggregates, these gradients should be interpreted descriptively rather than as precise country-level estimates, although the pattern was consistent and large. At the country level, greater reliance on mobile web access was not associated with measurable penalties in basic engagement metrics, including bounce rate, time on page, or country-level YouTube engagement indicators (all country-level Spearman $|\rho| \leq 0.28$; all $P \geq .18$).

Interpretation in Relation to Prior Work

These findings build on previous work on digital cardiology education, mHealth, and digital health equity. Major cardiology societies have emphasized the rapid growth of online congresses, courses, and blended training, and the central role of video in modular, on-demand learning [1-3,5-7]. Digital cardiology patient education interventions have likewise improved knowledge and patient-reported outcomes, supporting the value of carefully designed digital content beyond professional training alone [8]. Reviews and bibliometric analyses of digital and blended medical education describe the broader shift toward modular, on-demand formats integrated with video and social media [19-21]. At the same time, digital health frameworks and global connectivity reports highlight a persistent usage gap. Within this context, clinicians in LICs and MICs often rely on personal smartphones, unstable electricity, and constrained bandwidth [4,10-13]. The strong gradients we observed in mobile access and caption use are consistent with this picture of a digitally connected but resource-constrained workforce. Our study contributes to this literature in two ways. First, it links routine multicountry learning analytics to these equity concerns in a cardiology-specific, predominantly francophone context. Second, it focuses on modifiable design features, namely mobile-first website design and systematic captioning, rather than on bespoke mHealth applications alone.

Our results on subtitles align with experimental and applied work showing that captions can improve comprehension and information retention, particularly for second-language users and people who are deaf or hard of hearing [14,15]. Accessibility guidelines also identify captions, transcripts, and basic player controls as core requirements for inclusive media [22]. In our project, audio was in French and non-French subtitles relied substantially on YouTube automatic captioning and translation. Caption-enabled watch time is therefore likely to reflect a mix of creator decisions, platform features, and user activation. Despite these limitations, the higher caption-enabled watch-time share in lower-income groups suggests that subtitles may be an important access enabler for clinicians and trainees in these settings, even though we could not directly assess subtitle accuracy or individual learning outcomes. Taken together, our data suggest that mobile-optimized web access and captioned video may represent access-supporting features rather than trade-offs in basic engagement metrics.

Implications for Design and Practice

From a design standpoint, these findings support treating mobile-optimized web layouts and captioned video as baseline features for cardiology education initiatives that seek international reach, rather than as optional enhancements. For clinicians and trainees in resource-constrained settings, responsive design, lightweight pages, and subtitles may reduce both technical and cognitive barriers to using educational material at the point of care [4,10,13,23]. Simple indicators such as mobile share, captioned watch time (including non-French captions), and geographic reach can be monitored as a low-cost equity dashboard alongside traditional metrics such as participation and satisfaction. For projects like ENC, practical next steps may include a lightweight mobile application with offline access to key protocols and tools, and a progressive professional translation of a core set of videos that builds upon, but does not rely solely on, automatic captioning. Professional societies and academic centers could similarly encourage contributors to provide mobile- and caption-ready content and to follow basic accessibility standards [22,24]. In HICs, the mobile gradient was milder, consistent with a dual-use pattern. Clinicians in these settings likely use desktop computers for prolonged work sessions involving protocols and tools, while relying on smartphones for quick lookups. In resource-constrained settings, however, clinicians and trainees appear to rely predominantly on smartphones as their primary device for both types of content.

Engagement Metrics as Proxies for Educational Outcomes

Bounce rate, average time on page, average view duration, audience retention, viewer retention beyond the introductory segment, and intentional views are useful, routinely available platform metrics that provide insight into how frequently and for how long users engage with educational content. They are not, however, direct measures of learning, comprehension, implementation, or changes in clinical practice. On the one hand, longer time on page may reflect engagement, but it may also reflect slower mobile loading, divided attention, or difficulty understanding the content. On the other hand, a lower bounce rate may reflect interest, while it may also reflect a search for information that was not immediately found. Caption-enabled watch time indicates that subtitles were activated, but cannot determine whether the displayed text was accurate, comprehensible, or helpful to individual viewers. We therefore interpret these metrics as exploratory indicators of equitable reach and engagement rather than as proxies for educational outcomes. Linking these platform analytics with learner-level assessments of knowledge acquisition, perceived usefulness, and impact on clinical practice should be a priority for future research.

XSL•FO
RenderX

Strengths and Limitations

This study has several strengths. It leverages routinely collected platform analytics from a real-world cardiology education initiative with a multicountry audience spanning high-, middle-, and low-income settings, and combines web and YouTube data from the same project to provide a rare cross-domain view of access enablers. Analyses were prespecified, used nonparametric methods appropriate for skewed country-level distributions, and focused on effect sizes and ordered gradients rather than solely on *P* values. By relying on simple indicators that are available on most web and video analytics dashboards, the approach is readily transferable to other mHealth and education projects with limited evaluation resources.

Important limitations must be acknowledged. The ecological design, with countries as the unit of analysis, precludes individual-level inference and is prone to ecological fallacy; we cannot identify which types of users drive the observed patterns or how usage relates to learning or clinical behavior. Caption-related and demographic YouTube metrics were available only as income-group aggregates and took only three distinct values across the dataset. They were therefore reported strictly as descriptive between-group contrasts, limiting the granularity of these analyses and precluding the inclusion of caption-related variables in country-level inferential models. The audience is self-selected and primarily francophone, which limits generalizability to other languages and likely underrepresents some large LICs and MICs. Our findings are therefore best interpreted as a francophone case study rather than a globally representative sample. Finally, web and platform metrics such as bounce rate, session duration, and caption-enabled watch time capture only limited aspects of engagement and are shaped by platform-specific definitions. In addition, the cross-sectional design did not allow us to examine temporal trends.

Country-level YouTube engagement metrics were available for 24 of 34 countries because YouTube Studio did not return stable country-level estimates for countries with fewer views. Coverage was proportionally similar across income groups (high-income 9/13, middle-income 9/14, low-income 6/7), making substantial selection bias unlikely. Nevertheless, the absolute number of LICs contributing YouTube metrics remained small. The association between caption use and viewer age was also not monotonic across income groups (older dominant age band in LICs than in MICs despite higher caption-enabled watch time in LICs), which tempers the equity narrative built around captions and should be interpreted cautiously.

Conclusions

This exploratory ecological case study examined a responsive francophone cardiology education website and its companion YouTube channel. We observed marked descriptive gradients in mobile web access and caption-enabled video watch time across country income groups. The highest values were observed in lower-income settings. A CEG of approximately 40% was identified between LICs and HICs. At the country level, greater reliance on mobile devices was not associated with meaningful penalties in basic web engagement metrics. These findings are consistent with treating mobile-optimized design and systematic use of captions, including non-French subtitles, as core, low-cost, access-supporting components of equitable digital cardiology education, while emphasizing that platform engagement indicators are not direct measures of learning. Simple platform analytics may provide useful signals about global reach and inclusiveness and should, in future work, be linked with learner-level outcomes and evaluations of mHealth interventions.

Acknowledgments

The authors thank all collaborators, colleagues, and learners who contributed to the creation, growth, and continuous development of the École Numérique de Cardiologie (ENC) platform. Their commitment and collective effort have been instrumental in expanding access to digital cardiology education across diverse regions and practice settings. The authors also thank Elise Cordonnier and Sarah Delmas for their careful English language review and helpful editorial suggestions during manuscript revision.

During revision of this manuscript, the authors used a generative AI tool (Claude [Anthropic] and ChatGPT [OpenAI]) to assist with language editing, drafting of the response to reviewers, and consistency checks across sections. All scientific content, statistical analyses, interpretation, figures, tables, and final wording were performed and verified by the authors, who take full responsibility for the content of the manuscript.

Funding

This study received no specific grant from any funding agency in the public, commercial, or not-for-profit sectors.

Data Availability

The study relied on aggregated, country-level analytics exported from the ENC website and YouTube channel. Deidentified CSV files containing the country-level dataset, the analysis scripts written in R, and the code used to produce all tables and figures are available from the corresponding author upon reasonable request, subject to platform terms of use (Fathom Analytics for the website, YouTube Studio for the YouTube channel) and institutional data-protection requirements. No individual-level data were collected, exchanged, or analyzed.

Authors' Contributions

LMD contributed to conceptualization, methodology, software, formal analysis, investigation, data curation, writing – original draft, writing – review & editing, visualization, supervision, and project administration. TR contributed to investigation, data curation, writing – review & editing, and project administration. EB contributed to methodology, investigation, writing – review & editing. LP, BM, and SV contributed to investigation (École Numérique de Cardiologie [ENC] platform development and content) and writing – review & editing. RG and PD contributed to conceptualization and writing – review & editing. ENC collaborators (JC, RV, TSM, AD, JBP, LP, GB, BM, SV, HB) contributed to the creation, implementation, and continuous improvement of the ENC platform and its educational content. All authors read and approved the final manuscript.

Multimedia Appendix 1
Country-level scatterplot of website mobile share vs assigned income-group caption value. Country-level scatterplot of École Numérique de Cardiologie website mobile share (x-axis, percentage of sessions from mobile devices among sessions with a known device type) vs the income-group caption value assigned to that country (y-axis). Each point represents one country (n=34). Caption-enabled watch time was available only at the income-group level; therefore, all country points within a given income group share the same caption value (high-income country=18.8%, middle-income country=38.7%, low-income country=60.9%). The country-level pattern in this figure reflects between-group contrasts only, not within-group variability in caption use. We do not report country-level correlation coefficients on this figure.

Abstract

Background: The Chinese National Guidelines on Diagnosis and Treatment of Gonorrhea (2020) recommend ceftriaxone 1 g intramuscularly as a single dose for the treatment of uncomplicated gonococcal infections. However, nonadherence to the guidelines remains common among physicians in China, partly due to their poor awareness of the recommendations.

Objective: This trial aimed to (1) assess the effectiveness of an app-based training tool in improving adherence to guideline-recommended treatment regimens and (2) identify reasons for nonadherence among physicians who used the training tool.

Methods: Using a cluster randomized controlled trial design, we randomly allocated 72 hospitals (clusters) from 4 provinces to the intervention (n=36, 50%) or control (n=36, 50%) arms in a 1:1 ratio. In the intervention arm, physicians received free app-based training via smartphones for 6 months, while the control arm continued routine training. The primary outcome was the proportion of prescriptions adherent to the regimens for treatment of uncomplicated gonorrhea recommended by the national guidelines. We analyzed cluster-level summary outcomes at endline using methods appropriate for stratified cluster randomized controlled trials with relatively few clusters per group, accounting for between-cluster variation. A postintervention survey was administered to all intervention-arm physicians to evaluate their experience with the app-based training module. Additionally, face-to-face interviews were conducted with 32 purposely selected nonadherent physicians from the intervention arm to explore reasons for nonadherence.

Results: A total of 715 physicians (n=343, 48% in the control arm and n=372, 52% in the intervention arm) participated in the study. Over the 6-month intervention period, the adherence to 1 g ceftriaxone for the treatment of uncomplicated gonorrhea increased from 53.6% to 54.8% in the intervention arm, whereas the rate decreased from 43.9% to 42.5% in the control arm. The mean difference (5.5%, 95% CI −7% to 18%; *P*=.37) in changes in the adherence rate between intervention and control arms was not statistically significant (risk ratio 1.12, 95% CI 0.93 - 1.35; *P*=.23). Among the 32 (19%) nonadherent physicians from the intervention arm, the primary reason for nonadherence was their concern regarding the sufficiency of the currently recommended dosage of generic ceftriaxone for treating gonorrhea.

Conclusions: In our study, the implementation of an app-based training tool did not improve adherence to treatment recommendations. Concern regarding the efficacy of generic ceftriaxone may be one of the intrinsic factors associated with nonadherence.

Introduction

Gonorrhea, caused by *Neisseria gonorrhoeae*, is a significant global public health issue, with an estimated 82.4 million cases among adults aged 15 to 49 years in 2020 [1]. Gonococcal infection predominantly involves the epithelium of the urethra, endocervix, rectum, oropharynx, and conjunctivae and can also ascend to the upper genital tract to cause pelvic inflammatory disease in women and epididymo-orchitis in men [2]. Effective control of gonorrhea relies on prevention, accurate diagnostics, and appropriate antimicrobial treatment. However, the treatment of gonorrhea is complicated by the ability of *N gonorrhoeae* to develop resistance to antimicrobials [3,4].

Due to the widespread emergence of resistant strains, only ceftriaxone is now recommended as the first-line regimen for treatment of gonorrhea in most countries [5,6]. However, isolates with decreased susceptibility to ceftriaxone, the last remaining option for first-line empiric treatment of gonorrhea, have been identified in Japan [7], the United States [8], France [9], Spain [10], the United Kingdom [11], and Australia [12]. In China, the percentage of *N gonorrhoeae* isolates with decreased susceptibility to ceftriaxone ranged between 9.7% and 12.2% from 2013 to 2016 [13].

In response to the growing threat of antimicrobial resistance, the 2020 European gonorrhea guidelines recommended high-dose ceftriaxone (1 g) for uncomplicated gonorrhea when antimicrobial susceptibility is unknown [5]. Similarly, the 2021 US Centers for Disease Control and Prevention sexually transmitted infections treatment guidelines recommended ceftriaxone 500 mg for individuals weighing <150 kg and 1 g for those weighing ≥150 kg [6]. In 2020, Chinese experts also reached a consensus to increase the ceftriaxone dose for uncomplicated gonorrhea to 1 g [14].

A major driver of antimicrobial resistance is the inappropriate use of antibiotics, particularly overprescribing, which can lead to the selection of resistant organisms. A nationwide study in China revealed a high proportion of prescription behaviors that were nonadherent to the national guidelines on diagnosis and treatment of gonorrhea in China (hereinafter referred to as the National Guidelines) [15], with excessive ceftriaxone dosing being common [16]. Lack of awareness of the National Guidelines was identified as a key factor contributing to nonadherence [15].

To address this issue, we developed a smartphone app–based training tool aimed at improving guideline adherence among physicians in China. We conducted a cluster randomized controlled trial to assess its effectiveness on improving adherence to the guidelines (ie, prescribing ceftriaxone 1 g intramuscular as a single dose for treatment of uncomplicated gonococcal infections). The secondary aim was to explore the reasons for nonadherence among physicians who used the training tool.

Methods

Ethical Considerations

This study was registered at the Chinese Clinical Trial Registry [17] (ChiCTR2000029591, registered on February 5, 2020) and approved by the Medical Ethics Committee of the Chinese Academy of Medical Sciences Institute of Dermatology (2020-LS-004). This study adhered to the principles of the Declaration of Helsinki. Participation in the study was voluntary and anonymous, and informed consent was obtained from all participants. No compensation was provided to participants.

Study Design and Setting

We conducted a parallel-group, cluster randomized controlled trial in 72 hospitals in 4 provinces (Guangdong, Hainan, Yunnan, and Zhejiang) in China to compare the adherence rate for treating uncomplicated gonorrhea with 1 g ceftriaxone between the intervention (app-based training module) and control groups.

Provinces were selected based on the reported incidence of gonorrhea in 2018, with high-incidence areas prioritized. Within each province, city-level hospitals with high reported gonorrhea cases were invited. After obtaining written consent from hospital directors, baseline data (eg, hospital category, gonorrhea case volume, physician qualifications, and drug availability) were collected. Hospitals were stratified by province and randomly assigned to intervention or control arms using a computer-generated sequence in R software (version 3.5.3; R Foundation for Statistical Computing), with allocation concealed until assignment. An internal pilot was conducted in 18 hospitals (n=9, 50% intervention and n=9, 50% control) in Guangdong province to assess feasibility. After confirming acceptability (166/241, 68.9% of physicians trained), the trial expanded to all 72 hospitals (n=36, 50% per arm), with no protocol changes between phases.

Participant and Intervention

The study was conducted from March 2022 to February 2023. In Guangdong, the 6-month intervention ran from March to August 2022, followed by a questionnaire survey in intervention hospitals in September. For Hainan and Yunnan, the intervention was implemented from April to September 2022, with the survey conducted in October. In Zhejiang, the intervention period was August 2022 to January 2023, followed by the survey in February 2023.

In China, medical graduates must complete a mandatory 3-year standardized residency training program following their undergraduate medical education (typically a 5-year program). This nationally regulated system, implemented through accredited teaching hospitals, ensures uniform clinical competency across all medical practitioners. For positions in major metropolitan hospitals (particularly tier-1 cities), competitive candidates generally require additional postgraduate qualifications beyond the mandatory training. All physicians

XSL•FO
RenderX

working in dermatology, urology, andrology, gynecology, and venereology departments at participating hospitals were eligible for study inclusion, irrespective of their educational background. After providing informed consent, physicians were guided by the local study coordinator to download the Xieshou app [18], an official platform developed by the National Center for STD Control of the Chinese Center for Disease Control and Prevention. The Xieshou platform is an electronic system routinely used for sexually transmitted disease (STD) health education and partner management in hospitals and is managed by STD control institutions at various levels. Health facilities are encouraged to integrate this platform into routine STD services. Through the platform, physicians can direct patients to scan a QR code to automatically receive an electronic intervention package containing health education materials, condom promotion information, mobilization for testing, and treatment instructions. Additionally, physicians can use the platform for academic exchanges, experience sharing, and participation in training sessions and conferences (including training videos, case discussions, and conference notices).

Technicians of the Xieshou platform distinguished between intervention and control group physicians based on hospital names provided during registration. In intervention hospitals, physicians were prompted to complete an online questionnaire collecting background information (sex, age, education level, years of practice, working department, professional title, previous training, and number of gonorrhea cases treated). After submission, they received unlimited access to a training video on the National Guidelines for the treatment of gonorrhea. Over the following 6 months, study coordinators sent monthly WeChat (Tencent Holdings Limited) reminders to physicians to watch the video, which was automatically saved in their personal learning records. At the end of the intervention, physicians in these hospitals were invited to complete another online questionnaire (Multimedia Appendix 1) via the Xieshou app to provide feedback on current treatment recommendations and their experience with the intervention. In control group hospitals, physicians were only prompted to complete the baseline questionnaire and did not have access to the training video after submission.

Outcomes

The primary outcome was the proportion of prescriptions adherent to the regimens for treatment of uncomplicated gonorrhea recommended by the National Guidelines at the cluster level. The secondary outcome was the reasons for nonadherence among physicians in the intervention arm.

Data Collection and Analyses

In each hospital, physicians' prescription records were extracted from the Hospital Information System using keyword matching (ie, gonorrhea). Prescriptions for uncomplicated gonorrhea from 6 months before (baseline) and 6 months after (endline) trial initiation were assessed for adherence to treatment guidelines. Prescriptions were excluded from data analysis if they were prescribed to patients who met any of the following criteria: (1) younger than 18 years; (2) were pregnant or lactating women; (3) received no ceftriaxone; (4) were treated with antibiotics for other infections; or (5) were diagnosed as complicated gonorrhea, such as disseminated gonococcal infection and pelvic inflammatory disease. Patient demographic data, gonorrhea diagnosis, and treatment regimens (antibiotic selection and dosage) were collected. To measure the adherence rate to the National Guidelines, a single 1 g dose of ceftriaxone was considered in line with the guidelines; deviations were classified as nonadherence. Two researchers independently reviewed the prescriptions and made the adjudication, and any discrepancies were discussed until agreement was reached.

For the secondary outcome, we purposively sampled 1 physician per intervention hospital (with ≥25% nonadherent prescriptions at endline). A total of 32 in-depth, face-to-face interviews were conducted in Chinese by local coordinators using a semistructured interview outline (Multimedia Appendix 2). Interview topics focused on intervention experiences, perspectives on antibiotic prescribing for gonorrhea treatment, and clinical practices. Interviews were audio-recorded upon written consent, and notes were taken. Participants were given the option to withdraw from the study at any point without any consequences. All interviews occurred in quiet and private locations in local hospitals.

Statistical Analysis

On the basis of a nationwide survey in China [15], we estimated that the adherence rate to the National Guidelines for the treatment of uncomplicated gonorrhea would be 37.8%, and that we could collect and process an average of 100 prescriptions per hospital. Clinical experts deemed a 10% increase in adherence clinically meaningful for the intervention arm. Under the assumption of a coefficient of variation of 0.1, 10% data loss due to illegible prescriptions, and accounting for stratification, the study required 144 clusters to detect this increase with 90% power at a 5% significance level (2-sided test). Eight provinces (Jiangsu, Shanghai, Zhejiang, Fujian, Guangdong, Guangxi, Hainan, and Yunnan) with the highest incidence of reported gonorrhea cases in China were selected in our study protocol [19]. Within each province, 9 hospitals were planned for the control group and 9 for the intervention group. However, the target number of hospitals (n=144) was not met due to COVID-19 pandemic–related restrictions in Jiangsu, Shanghai, Fujian, and Guangxi.

Participating hospital and physician characteristics were summarized using frequencies (and sample sizes) and means (SDs) as appropriate for each group. For the primary outcome, we used analysis methods appropriate for stratified, cluster-randomized trials with relatively few clusters per arm to account for between-cluster variation. We pooled both pilot and main trial data for our analysis of prescriptions, which was based on the original allocation of hospitals (ie, on an intention-to-treat basis). To deal with skewness in the distribution of cluster outcomes, we first log-transformed the proportions. We then estimated the overall risk ratio based on a weighted average of stratum-specific risk ratios, which were calculated as the difference between intervention and control arm log risks (equivalent to ratios of geometric mean risks between treatment arms), with the weights inversely proportional to stratum-specific variances. We then estimated an approximate SE for the log risk ratio and used this to calculate 95% CIs for

XSL•FO
RenderX

the risk ratio and carry out formal hypothesis testing (2 sided and at the 5% level) via a stratified 2-tailed *t* test. To adjust for covariates, we fitted a logistic regression model to the individual-level data with terms for the covariates of interest, excluding the treatment arm, and then calculated cluster-specific ratio residuals based on the ratio of observed to model-predicted values. Results were adjusted for stratum (province), cluster-level outcome at baseline, patient's sex and age, and physician's sex and department. We also calculated risk difference results using similar methods to those used to calculate the risk ratio results. In addition, we explored the associations between nonadherence and physician characteristics (age, sex, education level, years of practice, working department, professional title, number of treated gonorrhea cases, and previous training) without the intervention and added another exploratory outcome after protocol development: a physician-level indicator of nonadherence in the nonintervention group. Variables that showed significant association with the nonadherence ($P<.05$) in univariate analyses were included in the multivariate regression model to explore the association of variables with the outcome. All statistical analyses were conducted using SPSS Statistics for Windows (version 22.0; IBM Corp).

Qualitative Data Analysis

The qualitative interviews were recorded, deidentified, transcribed in Chinese, and then translated into English for analysis. The transcribed data were thematically analyzed in NVivo 11 (Lumivero). Two researchers trained in qualitative analysis methods, TTJ and YQY, analyzed several transcripts to identify themes and create codes and subcodes, which were organized into categories. This coding framework was applied to all transcripts by both researchers and modified through an iterative process.

Results

Baseline Characteristics

A total of 68 hospitals (n=33, 48.5% in the control group and n=35, 51.5% in the intervention group) provided background information. Overall, baseline hospital characteristics were well balanced between the 2 groups (Table 1). A total of 715 physicians (n=343, 48% in the control group and n=372, 52% in the intervention group) completed the baseline questionnaire survey. The intervention group had a higher proportion (n=233, 62.6%) of female physicians and included more physicians (n=213, 57.2%) from the STD department and the department of obstetrics and gynecology (Table 2).

Nonadherence to the National Guidelines

Among the 1524 prescriptions (n=747, 49% prescriptions in the control group and n=777, 51% baseline prescriptions in the intervention group) with physician demographic data, 734 (48.2%) were nonadherent to the National Guidelines for ceftriaxone treatment of uncomplicated gonorrhea.

In the multivariate analyses, the following factors were found to be significantly associated with nonadherence after adjusting for potential confounding factors: age <35 years (adjusted odds ratio [AOR] 2.61, 95% CI 1.74 - 3.92, compared with ≥35 years; *P*<.001); undergraduate degree and below (AOR 2.63, 95% CI 1.99 - 3.47, compared with postgraduate degree and above; *P*<.001), working in a department of dermatology (AOR 4.05, 95% CI 2.93 - 5.58, compared with the department of STD;

XSL•FO
RenderX

P<.001); and treating fewer gonorrhea cases (<5 cases) in the past 3 months (AOR 2.66, 95% CI 1.67 - 4.23, compared with treating ≥5 cases; *P*<.001; Table 3).

[c]*P*<.001.

Impact on Improvement of Adherence

Of the 3254 patients diagnosed with gonorrhea at baseline, 2171 (66.7%) were treated with ceftriaxone, whereas among the 3191 patients diagnosed with gonorrhea at endline, 2137 (67%) underwent treatment with ceftriaxone. We screened 2897 baseline and 2653 endline prescriptions from the intervention group, of which 1415 (48.8%) baseline prescriptions and 1391 (52.4%) endline prescriptions were eligible, respectively, for inclusion in the analysis (Figure 1). In the control group, 36.5% (1076/2946) of baseline and 42% (1240/2954) of endline prescriptions were eligible (Figure 1). The adherence rate increased from 53.6% to 54.8% in the intervention group, while the rate decreased from 43.9% to 42.5% in the control group. We also noted the variation of the adherence rate in the intervention clusters between baseline and endline was from −67% to 71% (mean difference 1.3%, 95% CI −8.5% to 11.0%; *P*=.79, paired *t* test), whereas in the control group it ranged from −50% to 100% (mean difference −1.4%, 95% CI −11.5% to 8.7%; *P*=.78, paired *t* test). After controlling for potential confounders, the online training intervention was not significantly associated with changes in the adherence rate (mean difference 5.5%, 95% CI −7% to 18%; *P*=.37; risk ratio 1.12, 95% CI 0.93 to 1.35; *P*=.23). However, when further comparing the compliance trend between the control and intervention groups, differences in trends of mean compliance of prescriptions were observed (*P*<.001; Multimedia Appendix 3). In addition, when the comparison was done by province, an obvious increase in mean compliance of prescriptions could be observed in Yunnan, where baseline compliance was substantially low (Multimedia Appendix 3).

XSL•FO
RenderX

Figure 1. Trial profile. Clusters refer to hospitals. Baseline prescriptions were issued during the 6 months before the implementation of the intervention, whereas endline prescriptions were issued during the 6-month intervention period.

Reasons for Nonadherence to the National Guidelines

A total of 64 physicians in the intervention group completed the questionnaire assessing their experience with the app-based training. Most respondents (n=54, 84.4%) reported having completed the monthly training, and 9 (14.1%) reported being unaware of the latest National Guidelines before the intervention.

In the intervention group, 168 physicians did not adhere to the National Guidelines. To investigate reasons for nonadherence, 32 (19%) physicians were interviewed. Concerns about the efficacy of generic ceftriaxone emerged as the predominant theme across all interviews:

> *We are all using generic ceftriaxone. I typically opt for a 2 g dose due to concerns regarding the efficacy of generic ceftriaxone.* [A dermatologist]

In China, the national essential medicines scheme and zero-markup policy have been instrumental in severing the connection between prescribing practices and hospital revenues.

XSL•FO
RenderX

However, these policies also restrict the availability of certain antibiotics:

> *We perceive that the efficacy of generic drugs is inferior to that of branded drugs. There appears to be a reduced selection of drugs available compared to before, with many effective branded drugs no longer accessible. The remaining generic drugs seem to be of lower quality.* [A gynecologist]

Instances have been reported in which generic antibiotics failed to effectively treat gonorrhea, further eroding physicians' confidence in generics:

> *I believe that the dosage and duration of generic ceftriaxone 1 g single dose for treating gonorrhea are inadequate. Patients treated with this regimen still experienced purulent discharge from the urethral orifice on the second and third days post-treatment, leading to a higher recurrence rate.* [A urologist]

Discussion

Principal Findings

In this study, we used an electronic platform to deliver training on gonorrhea treatment guidelines to physicians in hospital settings. The results demonstrated that the online training module did not significantly improve physician adherence to the National Guidelines for treating uncomplicated gonorrhea with ceftriaxone (P=.23). However, the intervention showed a more pronounced effect in Yunnan province, where adherence in the intervention group increased by 15%. This notable improvement may be attributed to the region's exceptionally low baseline adherence rate (4%) compared with the pooled baseline adherence rate of other provinces (65%). In contrast, areas with moderate to high baseline adherence rates (Zhejiang: 49%; Guangdong: 72%; and Hainan: 77%) showed no significant behavioral changes in the postintervention period, suggesting that nonadherence in these regions was unlikely due to a lack of guideline awareness. This hypothesis is further supported by the finding that adherence rates did not differ significantly between physicians who were aware of the updated National Guidelines (26/55, 47.3%) and those who were not (5/9, 55.6%) in the intervention group. Postintervention interviews among physicians who were not adherent to the guidelines revealed that concerns about the efficacy of generic ceftriaxone were the primary reason for deviating from the guidelines.

Comparison With Prior Work

Ceftriaxone is a broad-spectrum bactericidal agent that belongs to the third-generation cephalosporins [20]. It was patented, manufactured, and marketed in 1982 as Rocephin (Roche Pharmaceuticals). Following the expiration of the Rocephin patent, generic products became available in many countries. Compared with the brand-name (innovator) product, generics significantly reduce health care costs and enhance supply security due to their diverse sources [21,22]. Consequently, Asian markets are dominated by low-cost, locally or regionally manufactured generic medicines [23], leading to a wide availability of generic ceftriaxone for gonorrhea treatment. The efficacy and safety of these generics are theoretically assured by bioequivalence studies, making them interchangeable with innovator products [24]. However, numerous studies have found that generic ceftriaxone products often fail to meet the pharmaceutical quality standards of the branded original [25-27]. A survey of the quality of generic ceftriaxone products from Eastern Asia markets revealed high levels of impurities and microbiologic contamination, raising significant efficacy and safety concerns [28]. Physicians in this study reported treatment failures with generics in clinical practice, which may have led them to prescribe excessive doses of ceftriaxone. Overuse of antibiotics, prescription of branded antibiotics, and prescription of antibiotics not listed in the National List of Essential Medicines are prevalent in other limited-income countries [29]. Physician perceptions that branded drugs are superior to generics may contribute to both the overuse of generics and the preferential prescription of branded alternatives [29,30].

In China, ceftriaxone susceptibility testing is conducted using the innovator product rather than generics. It remains unclear whether a 1 g single dose of generic ceftriaxone is adequate for uncomplicated gonorrhea due to the lack of postmarketing surveillance and follow-up studies in China. Notably, 15.6% (10/64) of physicians in this study still considered the 1 g dose insufficient. Thus, further research is needed to generate evidence on the efficacy of currently available generic antibiotics for gonorrhea and to strengthen surveillance of resistance to these generics.

Although evidence-based guidelines have been developed, translating knowledge into practice is challenging. One potential reason for the intervention's limited success is the 6-month duration, which may have been insufficient to alter prescribing behavior. Time-trend analyses in this study demonstrated that extending the intervention period led to upward trends in appropriate antibiotic use for gonorrhea. Other studies have similarly found that discontinuing effective behavioral interventions resulted in a resurgence of inappropriate prescribing [31]. Additionally, online training alone may have a limited impact on reducing antibiotic misuse. A multifaceted approach is crucial for success. Interventions such as physician education, computerized clinical decision support, audit and feedback, punishment, and financial incentives, when implemented in combination, have resulted in lower rates of antibiotic misuse in other settings [32,33].

Strengths and Limitations

To our knowledge, this study represents the first cluster randomized controlled trial conducted in China to evaluate the impact of an innovative training program on reducing physicians' nonadherence to gonorrhea treatment guidelines.

However, several limitations should be considered when interpreting the findings. First, the COVID-19 pandemic prevented us from achieving the planned number of clusters and prescriptions per cluster, resulting in reduced statistical power. Notably, the study was conducted in only 4 of mainland China's 31 provinces, and the results should not be overextrapolated to other regions due to significant variations in guideline awareness and compliance. Future research should include physicians from more provinces. Second, the study

XSL•FO
RenderX

focused solely on adherence to ceftriaxone-based guidelines. Given the emergence of new antigonococcal antimicrobials, future training programs should incorporate guidelines for alternative antibiotics. Third, while cluster randomization ensured good balance at the hospital and physician levels, residual confounding or unmeasured contextual factors may have influenced the results. Additionally, the inability to mask physicians to their intervention group introduced Hawthorne effect bias. To mitigate this, we avoided direct observation during prescribing and collected outcome data in either group after the 6-month intervention. Finally, the qualitative component had a small sample size, and the participant sampling process and demographic characteristics were not systematically documented. This methodological gap may limit the generalizability of the findings. Future studies should prioritize multicenter, large-scale designs integrating quantitative and qualitative methods to enhance validity.

Future Directions

More robust evidence is needed on the efficacy of currently available generic antibiotics for gonorrhea treatment and their resistance surveillance. This evidence should inform the development of local evidence-based guidelines and be incorporated into training programs. With such data supporting the use of generics, physicians can be more confident in prescribing generic ceftriaxone at recommended dosages. Fortunately, postmarket evaluation of generic medicines has been included in the ROADMAP research plan to address gonococcal resistance in China [34]. In 2016, the National Medical Products Administration (NMPA), formally known as the China Food and Drug Administration, mandated that generic drugs approved before 2007 must demonstrate bioequivalence to brand-name counterparts by the end of 2021 [35]. To correct misconceptions about generic drugs, the NMPA should also ensure that generic drugs meet quality standards by using good manufacturing practices and that the generic drug approval process is rigorous and transparent to the public.

Once evidence-based guidelines are established, efforts to reduce inappropriate antibiotic prescriptions can be enhanced by training physicians via electronic platforms. Future research should also explore whether applying training long-term or adding other interventions beyond online training can further optimize antibiotic use for gonorrhea.

Conclusions

In conclusion, our study demonstrates that a 6-month intervention involving an app-based training tool with monthly reminders to physicians did not significantly improve adherence to the National Guidelines for gonorrhea treatment with ceftriaxone. A key barrier to adherence was physicians' concerns about the perceived insufficient efficacy of currently available generic ceftriaxone. Addressing these concerns will require postmarket reevaluation of generic ceftriaxone products and targeted education for physicians on the scientific evidence supporting the efficacy of generics. These steps are essential to promote appropriate prescribing behavior.

Acknowledgments

The authors thank collaborators (coordinators and physicians) who made contributions to the implementation of the trial in the 72 participating hospitals.

Funding

The study was funded by the key research and development program of Yunnan Province Science and Technology Department (grant 202403AC100011) and the Chinese Academy of Medical Sciences Initiative for Innovative Medicine (grant 2016-I2M-3-021). The funder had no role in the design, collection, analysis, and interpretation of data; in writing of the manuscript, and in the decision to submit this manuscript for publication.

Data Availability

The datasets generated or analyzed during this study are available from the corresponding author on reasonable request.

Abstract

Background: Recovery after total hip arthroplasty (THA) and total knee arthroplasty (TKA) is typically assessed with infrequent clinic-based evaluations that may not reflect patients' everyday mobility. Smartphone inertial sensors enable scalable, repeated gait measurement in real-world settings, but the extent to which prompted walking tests reflect daily life walking during recovery is not well defined.

Objective: The objective of this study was to characterize week-by-week recovery trajectories after THA and TKA using high-frequency smartphone sensor data and quantify the difference between prompted in-app walking tests and passive daily life background walking.

Methods: We analyzed longitudinal smartphone-based gait measurements from 735 patients (THA, n=350; TKA, n=385) who underwent unilateral surgery between July 2022 and October 2025. Nine spatiotemporal gait parameters were monitored over the first 15 postoperative weeks across 2 conditions: prompted "in-app" walks and passively captured "background" walks. Recovery trajectories were evaluated using Kaplan-Meier time-to-baseline analyses, linear mixed-effects models, and comparison of late-stage plateau levels (weeks 11 - 15) using estimated marginal means of the models.

Results: Across all parameters, THA patients returned to preoperative baseline levels faster than TKA patients, with mean trajectories generally approaching baseline by week 4 for THA versus weeks 6 to 8 for TKA. Linear mixed-effects models showed that surgical procedure type significantly influenced recovery trajectory for all parameters except single support of the unaffected leg. All gait parameters except stance asymmetry and single support of the unaffected leg exhibited persistent differences through the late-recovery plateau (weeks 11 - 15). We also compared prompted "in-app" walks with passively captured background walking. Prompted and passive walking showed systematic divergence in both THA and TKA; prompted assessments generally indicated faster or more complete return to baseline than passive daily life walking. Finally, preoperative gait level was strongly associated with postoperative trajectories, with baseline-stratified analyses showing distinct patterns of recovery between groups.

Conclusions: High-frequency smartphone gait assessment quantifies procedure-specific recovery dynamics and demonstrates that prompted tests and passive daily life measurements capture distinct, noninterchangeable functional signals. Parameters from prompted walks plateaued while those from passively captured walks were still changing; prompted testing alone therefore captures only one component of returning function, highlighting the additional information that passive, real-world gait monitoring can provide.

Introduction

Total hip arthroplasty (THA) and total knee arthroplasty (TKA) are highly successful orthopedic surgeries that restore mobility for millions of people with end-stage arthritis [1,2]. Their volume is substantial and growing; over 3.7 million Americans underwent THA or TKA from 2021 to 2024 [3], and projections indicate that the annual volume for THA and TKA could increase by 176% and 139%, respectively, by 2040, compared to 2019 volumes [4]. This escalating demand establishes total joint arthroplasty (TJA) as a major component of the health care system, making the optimization of postoperative recovery a critical public health priority.

Conventional methods for monitoring patient recovery after TJA have significant limitations and provide an incomplete picture of a patient's functional status [5]. The standard of care relies on infrequent, in-person clinical visits featuring practitioner-dependent assessments such as the Timed Up and Go test [6]. These appointments offer only brief snapshots of function in a controlled setting and correlate poorly with a patient's actual daily activities. This episodic model limits a clinician's insight into the patient's day-to-day progress and challenges, hindering proactive intervention. Furthermore, the common practice of limiting complication surveillance to the acute recovery phase has been shown to miss a substantial number of adverse events, revealing a systemic gap in long-term patient monitoring [7].

Another key challenge in postarthroplasty care is the discordance between subjective patient-reported outcome measures (PROMs) and objective, performance-based metrics [8]. While PROMs are vital for capturing the patient's perspective on function, pain, and quality of life, studies show that early improvements in these scores often do not align with objectively measured functional gains [9,10]. Patients frequently report feeling significantly better long before objective measures, such as walk speed or mobility, return to normal levels. This may partly reflect that patients often associate recovery with meaningful pain relief, even when objective mobility remains impaired. However, pain relief is unlikely to be the only explanation, and the broader point remains that perceived recovery and measured physical performance can differ substantially. This issue is compounded by low patient completion rates for long-term PROMs, which can introduce bias into the data [11]. This disconnect highlights the need for granular, individualized, and objective monitoring tools that can characterize function beyond self-assessment.

Previous studies have attempted to establish such recovery benchmarks and expected trajectories [12-14]. However, these efforts are often limited in scope, focusing on a single metric or joint, or on limited follow-up periods with infrequent data collection time points, which fail to capture the continuous, dynamic nature of the recovery process.

The widespread availability of smartphones with built-in inertial measurement units (IMUs) offers a validated and scalable solution to the limitations of traditional monitoring. A growing body of research confirms the reliability of smartphone-based systems for measuring key gait parameters like walk speed, cadence, and asymmetry in real-world environments [15-18]. These systems show strong correlation with gold-standard laboratory equipment. This technology shifts measurement from the clinic to the patient's daily life, enabling the continuous, high-frequency collection of objective functional data that is more representative of true mobility [19]. Digital health platforms like the OneStep system leverage these capabilities to create objective recovery benchmarks and track individual progress with unprecedented detail.

While remote monitoring provides a wealth of objective data, a critical nuance essential for understanding true recovery is often overlooked: the distinction between a patient's functional capacity—what they are capable of doing under observation or during a prompted task—and their habitual daily performance—what they actually do in an unobserved, unguarded state [20-23]. This distinction is vital, as the goal of rehabilitation is not merely to enable a patient to perform a task correctly, but to restore normal, noncompensatory movement as an automatic pattern in daily life.

This study presents week-by-week gait trajectories after THA and TKA, measured using a smartphone-based system, to guide more precise postoperative monitoring and rehabilitation. Specifically, we compare the 15-week recovery trajectories of THA and TKA patients across 9 gait parameters and quantify differences between prompted in-app walks, treated as a proxy for functional capacity, and passively captured background walking, treated as a proxy for habitual performance.

Methods

Cohort

This study analyzed deidentified data collected from commercial users (N=735) of the OneStep gait monitoring system during routine postoperative care and recovery monitoring between July 2022 and October 2025. Data were not collected specifically for this research but were generated as part of standard app use. Starting from all patients with a recorded THA or TKA, we sequentially applied eligibility criteria based on surgery type, data availability, and preoperative recording requirements.

Ethical Considerations

This study used secondary, deidentified data collected during routine use of a commercial gait monitoring platform. Users provided consent at onboarding for their deidentified data to be used in aggregate for research purposes. The authors determined that the secondary analysis met the criteria for exemption from institutional review board oversight under the US Federal Policy for the Protection of Human Subjects (Common Rule), 45 CFR §46.104(d)(4)(ii) [24]. For the research analysis, information was recorded in a manner such that the identities of individuals could not readily be ascertained directly or through identifiers linked to the data. The investigators did not contact individuals and did not attempt, and will not attempt, to reidentify them. The study was conducted in accordance with applicable privacy and ethical standards.

RenderX

Gait Data Collection

Gait was measured before and after surgery with OneStep's smartphone gait analysis system (software versions 2.18.0 - 4.0.0; Celloscope Ltd). Figure 1 shows the measurement screen of the mobile app. Patients carried their phones in a pants pocket while walking. The sensors of the phone's IMU record 3-dimensional acceleration and gyroscope data at a sampling frequency of 50 Hz and upload the data to secure servers. No calibration is required. The inertial motion data are split into individual strides, and a supervised convolutional neural network then assigns each stride to a joint (physical activity, device body position) class; strides that are not assigned to the walking class or a pants pocket body position are excluded from the analyses reported here [25]. A proprietary deep learning framework is then used to detect which side the phone was carried on and compute standard spatiotemporal gait measures for each step. This framework was trained using a gold-standard gait measurement system (the C-Mill VR+ instrumented treadmill; Motek) to generate ground truth labels for simultaneous phone measurements from a variety of healthy and unhealthy walkers; these results were then validated against a selection of gold-standard gait measurement methods [15-17]. The software is compatible with almost all modern smartphones, as most smartphones contain the necessary IMU hardware, and is compatible with both iOS and Android operating systems. Although the gait analysis system has not been validated specifically in a post-TJA population, it has been validated in cohorts with a variety of moderate to severe gait abnormalities [16,17].

XSL•FO
RenderX

Figure 1. Screenshot of the OneStep mobile app walk analysis screen.

Nine gait parameters were analyzed for this study: cadence, single support percentage of the affected (ie, the leg upon which the operation was performed) and unaffected leg; stance asymmetry; double support percentage; step length of the affected and unaffected leg; stride length; and walk speed. Stance asymmetry is defined as the difference between the stance percentage of the 2 legs; that is, the percent of stride time each leg is in contact with the ground. For this study, it was calculated as the stance percentage of the unaffected leg minus the stance percentage of the affected leg. We used the signed value of stance asymmetry, rather than its absolute value, because the direction of asymmetry is clinically relevant in TJA, where one leg is affected.

Walk Types

We used 2 kinds of recordings:

1. *In-app walks*. Patients opened the OneStep mobile app, started a recording, placed the phone in a pocket, and

XSL•FO
RenderX

walked in a straight line (with 180° turns as necessary) on a flat surface for about 60 seconds.
2. *Background walks*. With permissions enabled, the app ran in the background and automatically recorded motion when it detected pocket-carried walking during daily life.

In-App Walk Collection

In-app walks were collected before and after surgery when patients chose to initiate a recording; no fixed recording schedule or surgeon-directed reminders were used. Recordings were performed in patients' own environments. App instructions directed patients to walk on a clear, straight path, to turn around and walk back and forth if the available path was too short, and to walk at a comfortable pace. Data processing and filtering are described above in *Gait Data Collection*.

Background Walk Collection

Background walks represent a particular challenge for data collection because walks can be taken in a variety of contexts (indoors vs outdoors, with or without shoes, on various terrains, straight-line walking or curved paths, etc) and because the patient can walk with their smartphone in a position other than the pants pocket. In addition, daily walking can occur in short bursts of 5 seconds or less, which have qualitatively different attributes than more extended walking bouts.

To account for these factors, the background gait analysis pipeline performs several steps. First, only walking bouts of 30 seconds or longer are analyzed. Second, any steps taken while not walking in a straight line are filtered out before analysis, and walking bouts with too few straight strides are flagged and filtered out. Straight-line walking was identified from gyroscope-derived heading after the sensor data were oriented to the direction of motion. Third, phone position (pocket vs nonpocket) is detected by a deep learning framework that was trained on examples of motion data from phones placed in the pocket and in a variety of other locations (hand, bag, shirt pocket, etc). Any walk that is detected as not being from the pants pocket is filtered out. Finally, gait measurements may differ between prompted and background conditions, as has been shown previously for this gait analysis system [23]. Therefore, as described below, in-app and background data are normalized separately to their respective presurgery baseline values. By normalizing in-app and background walks separately, lower background values at a given postsurgery week are interpreted relative to the patient's own presurgery background walks, not relative to their in-app walks. This distinction is important because raw background and in-app values may differ for reasons unrelated to recovery, including phone position, walking environment, and walking path. The analysis therefore asks whether background gait returns to its own baseline more slowly than in-app gait, rather than whether background gait has lower absolute parameter values.

Preoperative Baseline

Inclusion required at least one in-app gait recording and one background gait recording in the 14 days before surgery; patients without such data were excluded. If multiple recordings were available, their gait measures were averaged to define that patient's baseline. Baselines were calculated separately for in-app and background walks.

Aggregation and Normalization

For each patient, postoperative walks were grouped by week since surgery (days 1 - 7, 8 - 14, etc) and averaged to create weekly values. The patient's baseline was then subtracted from each weekly value to express change from baseline. To describe population-level recovery, these normalized values were averaged across patients contributing data in that postoperative week. Analyses used available data only (weekly sample sizes varied); no temporal interpolation or imputation was performed.

Statistical Analysis

To quantify differences between recovery trajectories, 3 methods were used. First, Kaplan-Meier analysis was used to determine whether time to first observed return to preoperative baseline differed between conditions. For parameters where a higher value is considered healthier (cadence, single support, step and stride length, and walk speed), time to return to baseline was considered the first week after surgery during which the parameter value was equal to or higher than the preoperative baseline level; for parameters where a lower value is healthier (double support and stance asymmetry), the first week in which the value was equal to or lower than baseline was used. A sustained crossing was not required because consecutive weekly observations were unavailable for many participants; requiring them would have excluded a large proportion of the cohort. Concretely, the Kaplan-Meier curve for a given parameter shows, for each postoperative week, the fraction of patients who had reached their own presurgery gait level by that week; a curve that rises sooner or reaches a higher fraction indicates faster or more complete return to baseline. A log-rank test (or a multivariate log-rank test, in cases where more than 2 Kaplan-Meier curves were being compared) was used to determine significance.

Second, we used linear mixed-effects models to test whether postoperative recovery trajectories differed between conditions. For each gait parameter, we fitted a model with fixed effects for postoperative week (modeled using a B-spline basis), condition (eg, THA vs TKA; in-app vs background; preoperative baseline level), age, and gender, and included interactions between the spline basis for week and each covariate of interest to test for differences in trajectory shape (time-varying effects) rather than only overall level shifts. A patient-specific random intercept was included to account for repeated measures within individuals. Postoperative week was represented with a B-spline basis of degree 1 and 4 degrees of freedom.

To test the importance of each fixed effect, we performed nested-model likelihood ratio tests by refitting reduced models that excluded one term at a time (condition, age, or gender) and its interactions, holding all remaining fixed effects, the postsurgery week specification, and random effects constant. The likelihood ratio statistic was computed as $2(\ell_{full} - \ell_{reduced})$, where ℓ is the maximized log-likelihood, and P values were obtained by comparing this statistic to a chi-square distribution with degrees of freedom equal to the difference in the number of estimated parameters between the full and reduced models.

XSL•FO
RenderX

Third, to compare parameter levels of late-stage plateaus, we computed estimated marginal means (EMMs) from the linear mixed-effects models. We defined the plateau as weeks 11 to 15 postsurgery and, for each condition, obtained the model-predicted mean over this window with age fixed at its sample mean and gender averaged by its observed proportions. Statistical significance of the difference in means between conditions was assessed with a Wald test, from which we report *z* scores and *P* values, along with 95% CIs.

All *P* values for all tests were adjusted using Benjamini-Hochberg false discovery rate correction over all *P* values in the analysis type (Kaplan-Meier, linear mixed-effects models, and EMMs). Statistical and modeling work was performed using Python and the Python packages lifelines, statsmodels, and SciPy; R and the R packages lme4, emmeans, and splines were used for the EMM analysis.

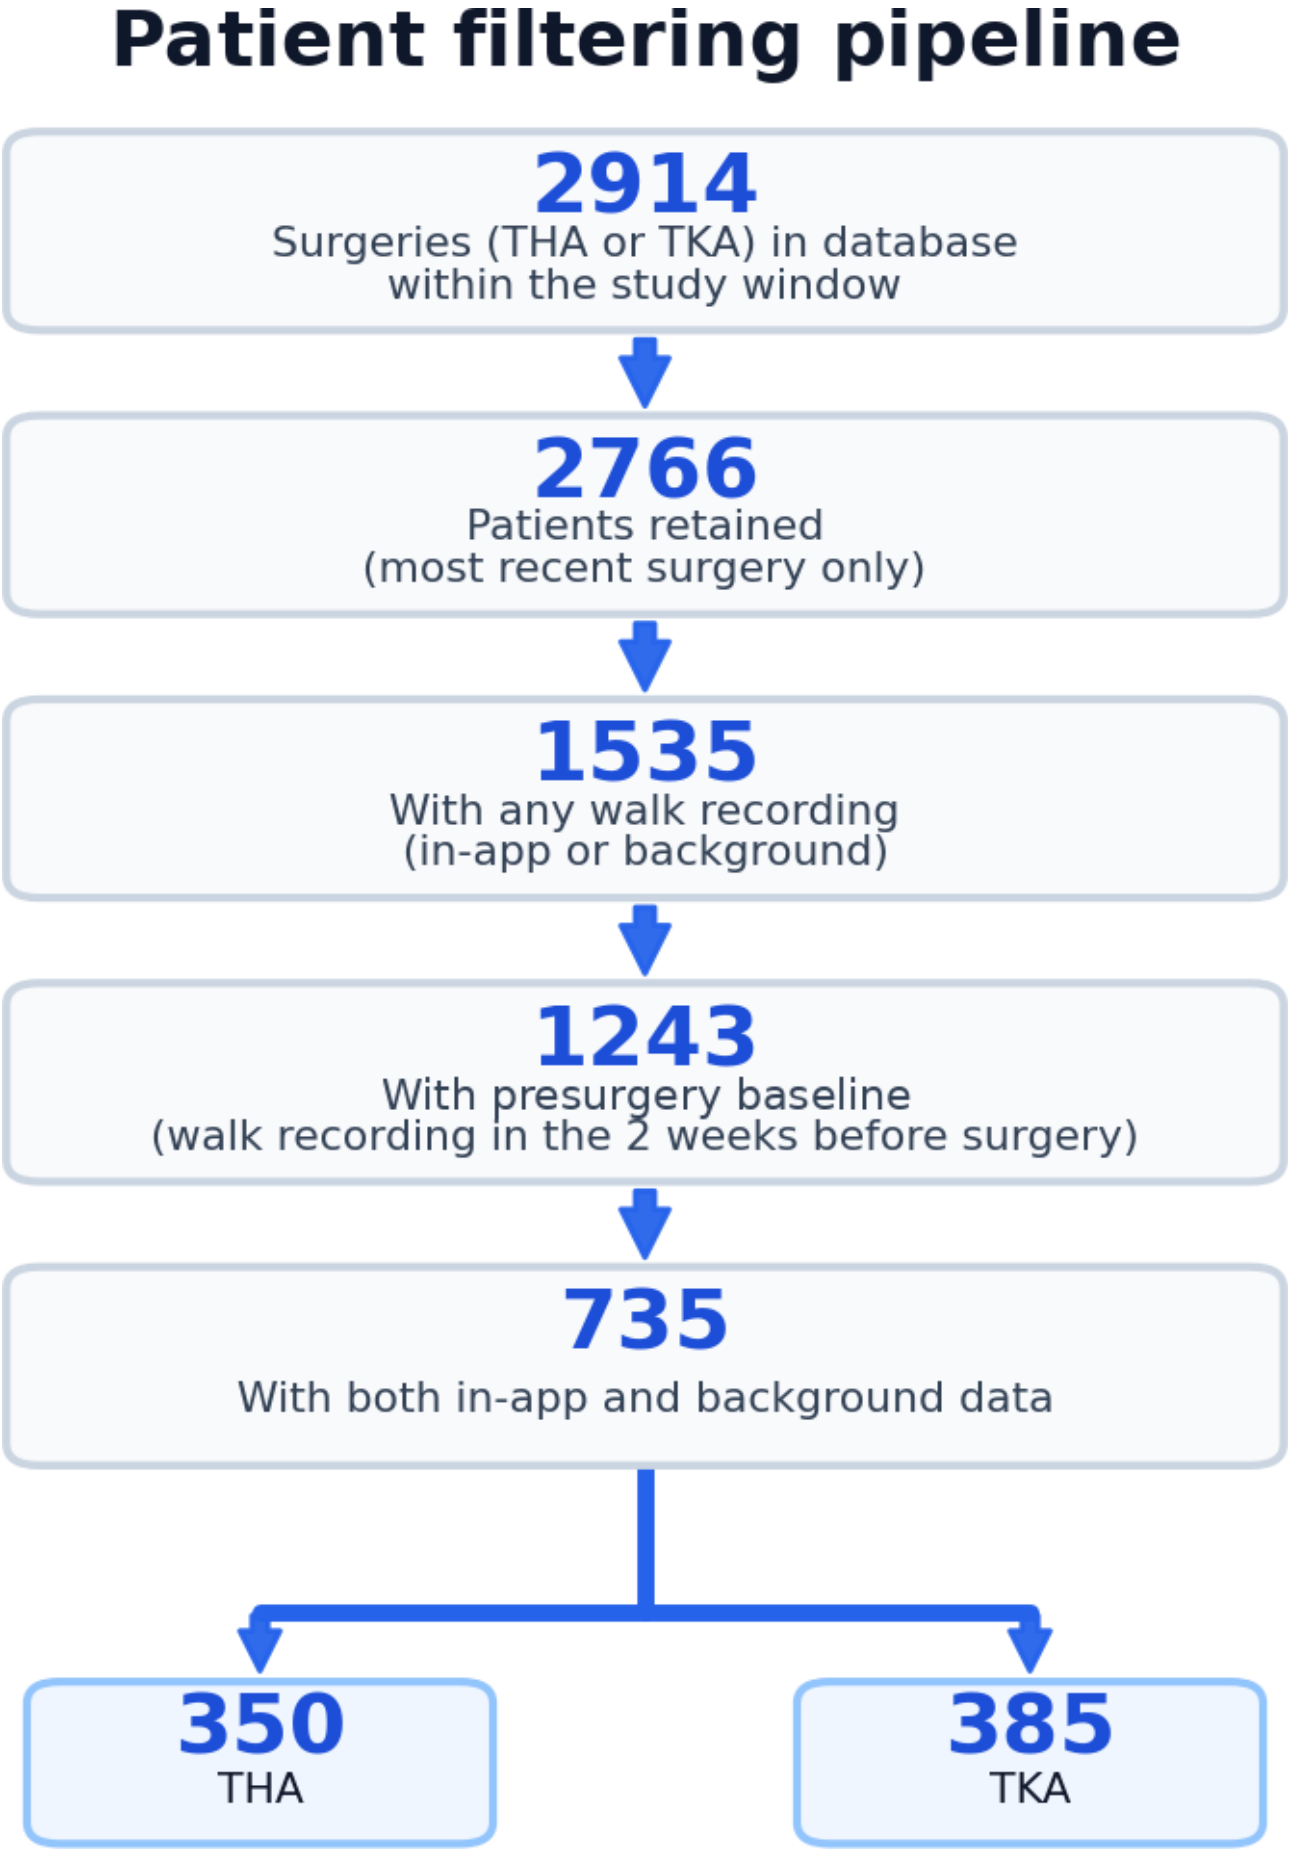
Results

Patient Demographics

Data were analyzed from 735 patients who underwent THA (n=350) or TKA (n=385). Baseline characteristics, including age distribution and gender composition used for subgroup analyses, are summarized in Table 1. The 2 cohorts had similar demographics: the THA cohort had a mean age of 69.6 (SD 7.6) years and included 56% (197/350) of women, while the TKA cohort had a mean age of 70.9 (SD 6.9) years and included 59% (227/385) of women. Figure S1 in Multimedia Appendix 1 shows the age distributions of the 2 cohorts. Preoperative baseline parameters differed slightly by gender, age, and procedure (Figure S2 in Multimedia Appendix 1). Figure 2 summarizes cohort assembly and filtering.

Table . Characteristics of total hip arthroplasty and total knee arthroplasty cohorts.

Characteristic	THA[a] (n=350)	TKA[b] (n=385)
Male participants, n (%)	153 (44)	158 (41)
Female participants, n (%)	197 (56)	227 (59)
Age (y), mean (SD)	69.6 (7.6)	70.9 (6.9)
Age of male participants (y), mean (SD)	69.2 (7.8)	70.9 (7.6)
Age of female participants (y), mean (SD)	69.9 (7.4)	70.9 (6.3)
Recorded in-app walks, n	8183	7289
Left-side surgery, n	191	214
Right-side surgery, n	159	171



[a]THA: total hip arthroplasty.

[b]TKA: total knee arthroplasty.

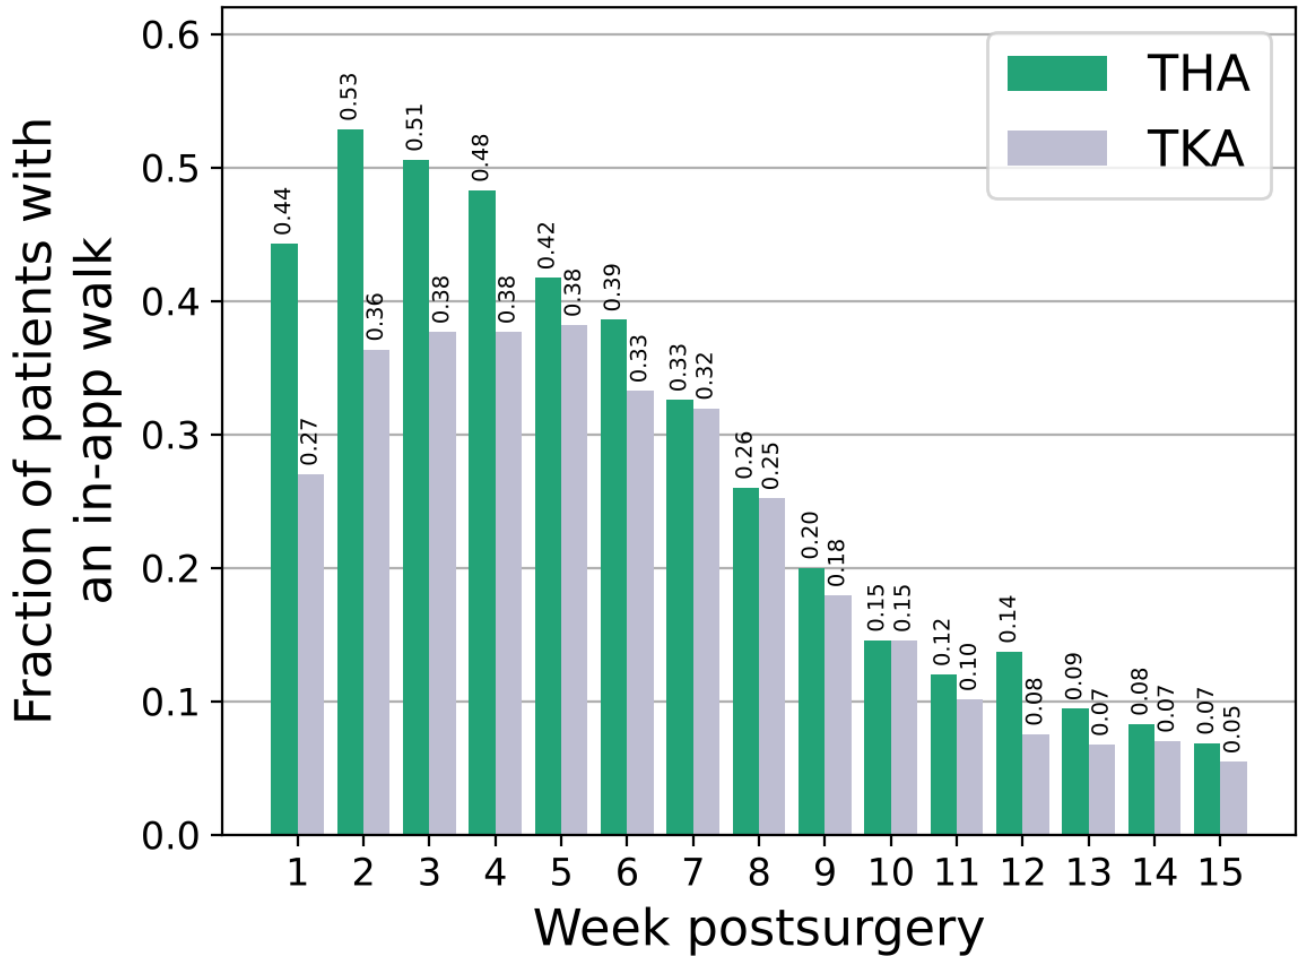
Recovery Trajectories After THA Versus TKA

Across all 9 gait parameters, average values relative to the preoperative baseline were lower after TKA than after THA in postoperative week 1. The mean THA trajectory returned to baseline by about week 4, whereas mean TKA trajectories reached baseline later, between weeks 6 to 8 (Figure 3 and Figure S3 in Multimedia Appendix 1). Kaplan-Meier analysis showed significant differences between THA and TKA in time to return to baseline for all parameters except single support of the unaffected leg (Figure S4 in Multimedia Appendix 1). Linear mixed-effects models showed that adding THA versus TKA status significantly improved fit for all gait parameters except single support of the unaffected leg (Figure S5 in Multimedia Appendix 1).

Figure 3. Recovery trajectories of in-app gait parameters after surgery in THA versus TKA. Each data point represents the mean change from all patients' preoperative baselines for that postoperative week; error bars show SE. Positive values indicate increases relative to baseline. Improvement corresponds to an increase in walk speed and a decrease in double support. For both parameters shown, THA patients returned to their preoperative gait level earlier than TKA patients, consistent with the known differences in procedural invasiveness and rehabilitation trajectory between the 2 surgeries. Weekly counts of patients contributing measurements in each group are given in Table S2 in Multimedia Appendix 1. THA: total hip arthroplasty; TKA: total knee arthroplasty.

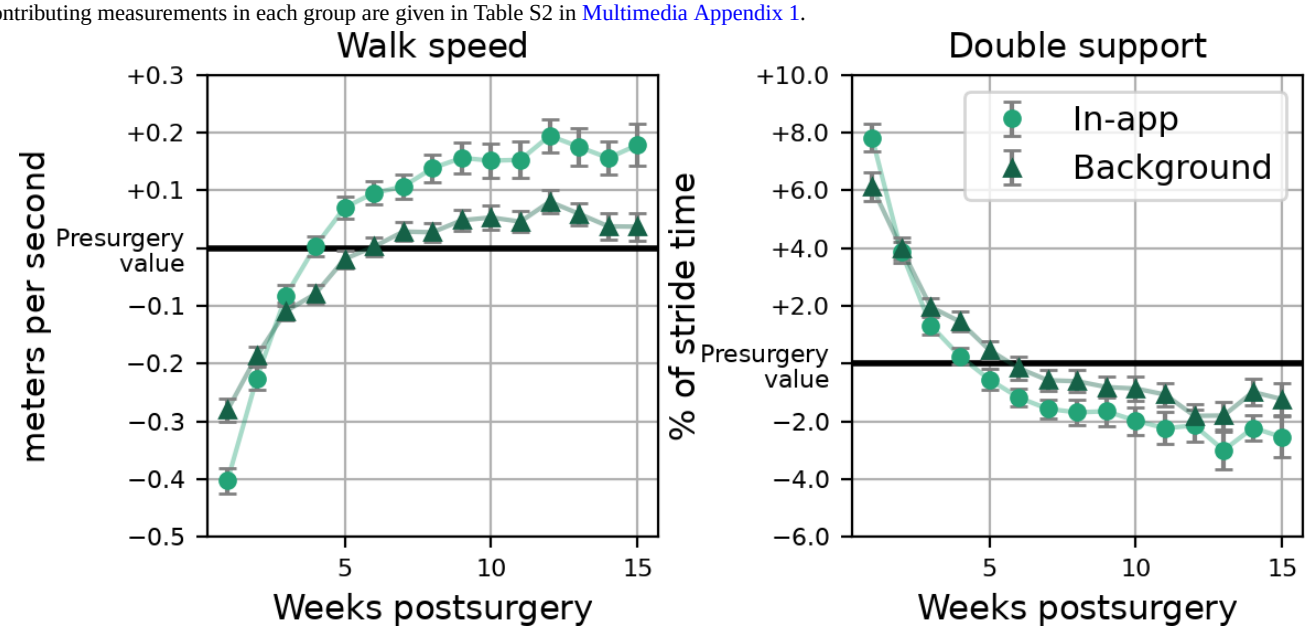


After crossing baseline, both procedures showed stable trajectories in weeks 11 to 15, with minimal week-to-week fluctuation. However, on average, THA patients reached a healthier level relative to the preoperative baseline than TKA patients at this plateau stage in all parameters except stance asymmetry and single support of the unaffected leg, and for most parameters, this difference reached an appreciable change in magnitude (Table S1 in Multimedia Appendix 1). For example, the difference in EMM at weeks 11 to 15 for walk speed was 0.14 m/s, exceeding the commonly used 0.1 m/s threshold for a clinically meaningful change in walk speed [26].

In the final weeks, some parameters showed unusual fluctuations or shifts in plateau level. This likely reflects diminishing and variable weekly sample sizes, as not every patient recorded an in-app walk each week and recordings tend to decline over time (Figure 4 and Figure S6 and Table S2 in Multimedia Appendix 1). This incompleteness may similarly affect the other analyses, including the Kaplan-Meier curves, and raises the possibility of survivorship bias if patients who continued contributing data differed systematically from those who did not; we consider these issues further in the *Discussion*.

XSL•FO
RenderX

Figure 4. Fraction of patients contributing in-app walks by postoperative week. For each postoperative week, bars show the fraction of patients in each cohort who recorded at least one in-app walk that week, out of all patients in the cohort (THA, n=350; TKA, n=385). Adherence peaks in the early postoperative weeks and falls steadily thereafter in both groups, reaching under 10% by week 15. Absolute weekly patient counts for these groups, as well as for background walks and subgroups, are given in Table S2 in Multimedia Appendix 1. THA: total hip arthroplasty; TKA: total knee arthroplasty.



Recovery Trajectories of In-App Versus Background Measurements

We next compared recovery trajectories from prompted in-app walks with those from passive background activity. In both THA and TKA, differences in recovery trajectories between these 2 types of walking were observed (Figure 5 and Figure S7 in Multimedia Appendix 1). Kaplan-Meier analysis did not show significant differences in time to return to baseline between in-app and background walking, except for walk speed and step length of the unaffected leg after THA (Figure S8 in Multimedia Appendix 1). However, linear mixed-effects models showed that adding in-app versus background status significantly improved fit for all gait parameters, most at a very high level of significance (Figure S9 in Multimedia Appendix 1). The level of the late-stage plateau differed significantly between in-app and background walking after THA for all parameters except stance asymmetry and single support of the unaffected leg. Effect sizes were generally of a lower magnitude than those of the plateau differences between THA and TKA, although the difference in walk speed was 0.14 m/s, the same as the difference between THA and TKA (Table S1 in Multimedia Appendix 1). The plateau levels after TKA differed significantly between in-app and background walking in cadence, step length of both legs, stride length, and walk speed; however, effect sizes were much lower than even those of in-app versus background walking in THA, including a difference in walk speed of 0.07 m/s (Table S1 in Multimedia Appendix 1).

XSL•FO
RenderX

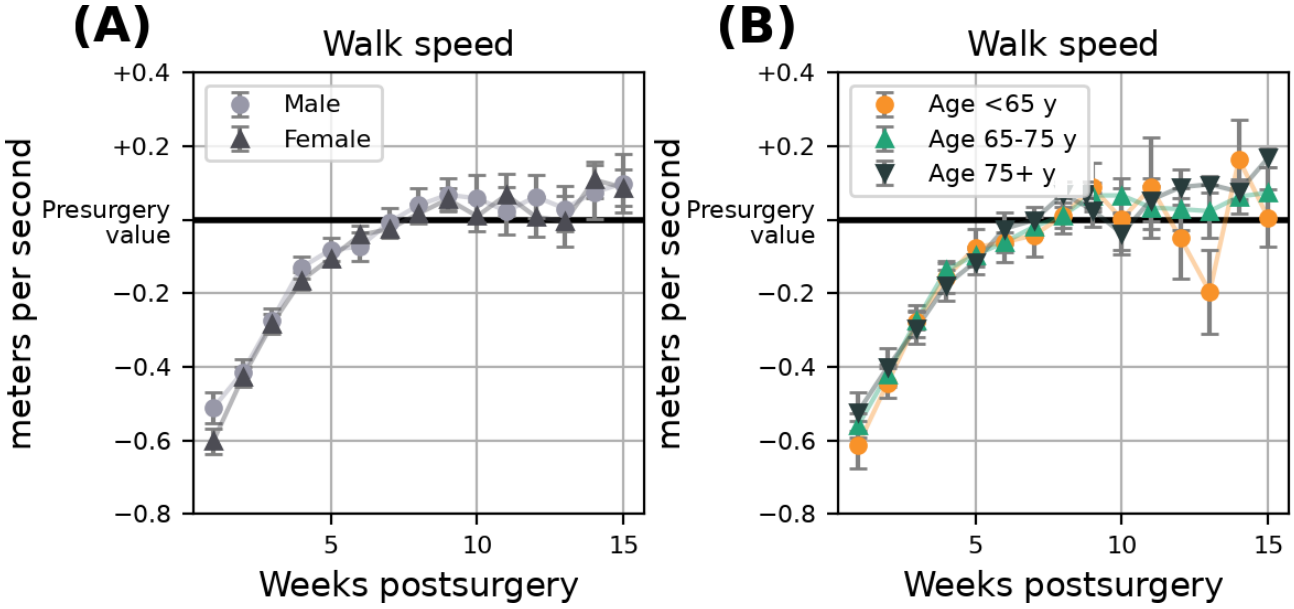


Figure 5. Recovery trajectory of in-app versus background gait parameters after surgery in total hip arthroplasty. Each data point represents the mean change from all patients' preoperative baselines for that postoperative week; error bars show SE. Positive values indicate increases relative to baseline. Improvement corresponds to an increase in walk speed and a decrease in double support. Background walking returns to baseline more slowly than in-app walking, suggesting that prompted clinical assessments may overestimate a patient's functional recovery in daily life. Weekly counts of patients contributing measurements in each group are given in Table S2 in Multimedia Appendix 1.

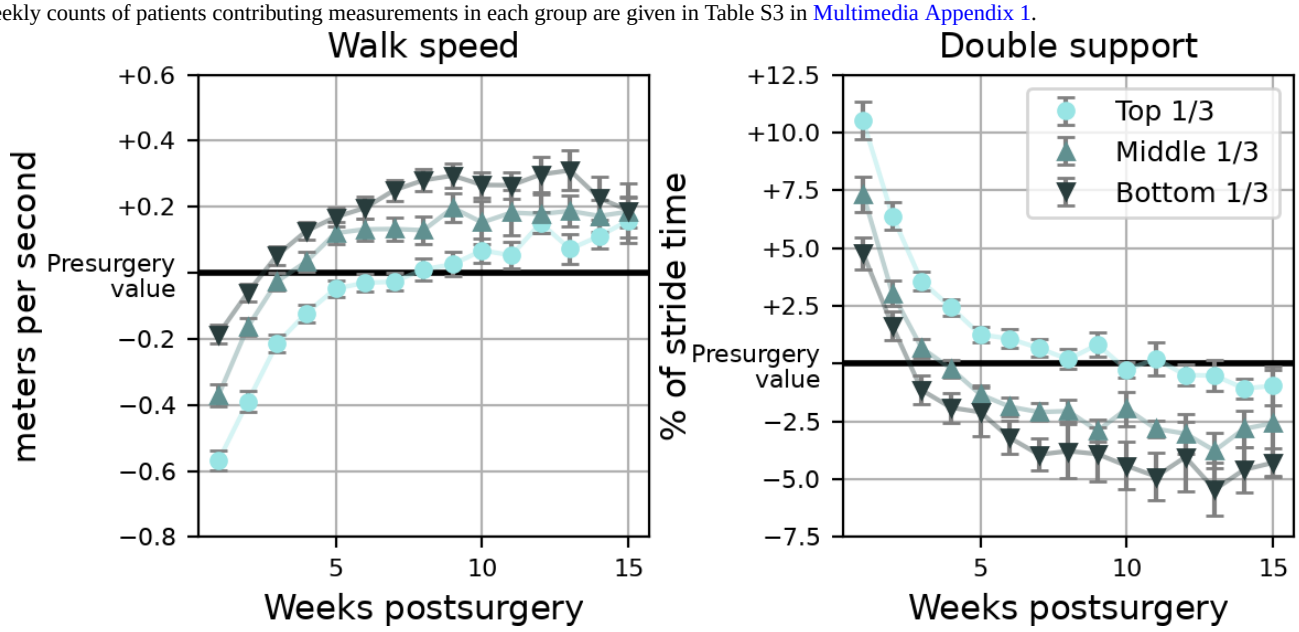
Recovery Trajectories by Age and Gender

We performed these analyses with populations stratified by gender and age (Figure 6 and Figures S10 and S11 in Multimedia Appendix 1). By gender, trajectories were visually highly similar for THA (male, n=153; female, n=197) and TKA (male, n=158; female, n=227). By age, patterns were likewise highly similar across groups in THA (<65 y: n=86; 65 - 75 y: n=173; 75+ y: n=91) and TKA (<65 y: n=76; 65 - 75 y: n=200; 75+ y: n=109). Kaplan-Meier analysis showed no difference in time to return to baseline between gender or age groups for any parameter (Figures S12 and S13 in Multimedia Appendix 1). Although adding age or gender to the linear mixed-effects models significantly improved model performance for many parameters (Figures S5 and S9 in Multimedia Appendix 1), the significance of those improvements was generally many orders of magnitude lower than that observed when adding condition (eg, THA vs TKA, in-app vs background).

Figure 6. In-app recovery trajectory in walk speed after total knee arthroplasty stratified by demographic characteristics. (A) Recovery trajectories stratified by gender (male, n=158; female, n=227). (B) Recovery trajectories stratified by age (<65 y: n=76; 65 - 75 y: n=200; 75+ y: n=109). The overlap between demographic subgroups indicates that patient age or gender play a limited role in the shape of the recovery trajectory at the population level (in contrast to the absolute level of gait parameters, which do differ between these subgroups). Weekly counts of patients contributing measurements in each group are given in Table S2 in Multimedia Appendix 1.



Weekly measurement counts by age and gender are shown in Table S2 in Multimedia Appendix 1.

RenderX

Recovery Trajectories by Preoperative Baseline

In addition to splitting patients by age and gender, we investigated whether preoperative baseline gait level was associated with postoperative recovery trajectories. Patients were split into 3 groups, representing the upper, middle, and lower thirds of preoperative baseline levels for each parameter. These splits were done independently for each parameter. Recovery trajectories varied greatly between the 3 groups (Figure 7 and Figure S14 in Multimedia Appendix 1). The highest-level walkers before surgery had the greatest decline in gait parameters in the week immediately following surgery and, by week 15, had reached only approximately their preoperative baseline on average. In contrast, the lowest-level walkers had a smaller decline immediately after surgery and, on average, reached well past their preoperative baseline by week 15. Kaplan-Meier and linear mixed-effects model analyses confirmed that these trajectories were significantly different for all parameters, in both THA and TKA and for in-app and background walking (Figures S15 and S16 in Multimedia Appendix 1). It should be noted that, in absolute terms, the highest-baseline group maintained better gait values at week 15 than the lowest-baseline group. However, the lowest-baseline group showed larger improvements relative to its own baseline (Figure S17 in Multimedia Appendix 1).

Figure 7. In-app recovery trajectory after total hip arthroplasty stratified by preoperative baseline level. Recovery trajectories were stratified by gait parameter values during a 14-day preoperative period; patients were split into 3 groups representing the upper, middle, and lower thirds of preoperative baseline levels for each parameter. These findings show that patients with poorer preoperative gait show larger relative gains but do not reach the absolute gait levels of higher-functioning patients, while high-functioning patients often do not return to their own baseline until later time points. Weekly counts of patients contributing measurements in each group are given in Table S3 in Multimedia Appendix 1.

Discussion

Principal Findings

Using longitudinal smartphone-based gait analysis, we characterized week-by-week recovery trajectories after THA and TKA across multiple spatiotemporal measures. On average, THA patients returned to their preoperative baseline by about week 4, while TKA patients did so between weeks 6 to 8, and THA patients reached a higher plateau thereafter. These differences match clinical experience and prior reports comparing postoperative mobility between procedures, which show that recovery is slower and pain persists for longer in TKA compared to THA [27,28].

A key finding is the significant difference between prompted in-app walks and passive background walking across many gait parameters. This pattern highlights the well-documented discordance between functional capacity and habitual performance [20-23], which may persist for years after surgery [29]. However, this discordance cannot be attributed solely to behavioral compensation because the 2 walking modalities are collected under fundamentally different conditions. In-app walks are performed on a flat surface under deliberate conditions, while background walks occur across heterogeneous real-world environments. Terrain type systematically influences gait parameters: energy expenditure and stride variability change substantially across surface conditions, from sidewalk to gravel to grass, and these differences are detectable by body-worn inertial sensors [30]. Walking context also matters, as indoor and outdoor walking shape distinct digital mobility signatures in ways that averaged measures can obscure [31]. Bout length is another well-established confounder of passively collected gait measures. Walking speed increases systematically with bout length, yet most real-world walking occurs in short bouts. Consequently, passive gait measures that are aggregated without accounting for bout length may not reflect gait capacity at longer sustained efforts [32,33]. This effect influences both the magnitude and reliability of extracted gait features across a range of clinical populations [33]. In the context of TKA, prearthroplasty individuals already exhibit shorter gait bouts and reduced daily walking activity compared with healthy peers [34], suggesting that passive gait measurements in this cohort are shaped not only by gait quality but also by activity patterns reflecting pain, fatigue, and behavioral avoidance.

XSL•FO
RenderX

The environmental and behavioral factors described above represent sources of structural heterogeneity in background walking that cannot be fully eliminated by algorithmic filtering. To mitigate these potential confounders, we adopted a within-person normalization approach, in which in-app and background walks were each normalized separately to their respective presurgery baselines. Any stable systematic differences between the 2 walk types arising from environmental context, walking or bout characteristics, or other persistent factors are thereby incorporated into the baseline and subtracted out. The comparison of interest is therefore not whether background and in-app parameter values differ in absolute terms: they do, and the absolute presurgery and postsurgery values for both walk types are reported here. Rather, the key comparison in this study is whether the rate and completeness of return to each condition's own baseline differ between the in-app and background walks. Using this normalized framework, background gait consistently returns to its own presurgery level more slowly than in-app gait. We cannot fully exclude the possibility that the ecological composition of background walks shifts after surgery; for instance, early recovery may involve a greater proportion of short indoor walking bouts that differ systematically from presurgery background activity. (Because our analysis included only walking bouts lasting at least 30 s, we were unable to characterize the full distribution of walking bout lengths and contexts over the recovery period.) That being said, a shift such as this would still suggest that the patient has not returned to their regular presurgery daily walking behavior, even as their conscious gait has returned to its presurgery state. Nevertheless, the normalization approach substantially mitigates the concern that the observed divergence simply reflects a fixed structural difference between walk types, and the consistency of the pattern across the gait parameters in 2 surgical cohorts supports its robustness. Collectively, these results indicate that prompted and passively captured walks follow different recovery trajectories, and that prompted testing alone would place the point at which gait parameters stabilize earlier than the passive data indicate. What stabilization in either measure represents clinically and functionally, and which trajectory better reflects meaningful recovery, will require studies anchored to patient-reported or clinical outcomes.

Surprisingly, age- and gender-stratified trajectories appeared similar across both procedures, suggesting that the overall shape and timing of recovery, when normalized to each patient's own baseline, are broadly robust at the population level. Although age and gender improved model fit for several parameters, the magnitude of improvement was small relative to procedure type and walk context, and neither factor was associated with differences in time to baseline in Kaplan-Meier analyses. This is at least partially at odds with prior literature, which has identified age and sex as meaningful predictors of post-TJA outcomes, though with important nuance. For TKA specifically, Pua et al [13] found older age to be among the strongest predictors of lower postoperative gait speed in a longitudinal cohort, and the large meta-analysis by Olsen et al [35], covering over 11,000 patients, identified better preoperative physical function as correlated with better 1-year physical function after TKA, though age and sex effects were inconsistent across the included studies. For THA, the predictor literature is less definitive: a systematic review by Hofstede et al [36] covering 35 studies and over 138,000 patients found that results for age, gender, and comorbidity were conflicting across studies, with preoperative function being the most consistently identified predictor. Examining both procedures jointly, Kennedy et al [37] followed 152 THA and TKA patients across the first 4 postoperative months and found that gender and baseline preoperative function both shaped early recovery trajectories, with women tending to present with greater preoperative disability and showing correspondingly different recovery curves. The apparent absence of age and gender effects in the current study should not be taken as evidence that these factors are clinically irrelevant. A key feature of our design likely attenuates them: because trajectories are normalized to each patient's own preoperative baseline, the analysis asks whether different groups of patients recover *relative to where they started* at a different rate, not whether they reach the same absolute gait level. Since absolute gait capacity differs systematically by age and sex at baseline, normalization effectively controls for these differences, which could explain why trajectory shapes converge even when absolute gait levels do not. The finding that older patients do not take longer to return to their own preoperative baseline, while their actual gait parameter values remain lower than those of younger patients, is meaningful in its own right: it suggests that the relative recovery process is broadly consistent across demographic groups, even if absolute functional levels diverge.

In contrast, recovery trajectories differed substantially by preoperative gait level. Patients with the poorest preoperative baseline gait performance exhibited the largest improvement relative to baseline, likely reflecting greater room for improvement. In contrast, patients with higher preoperative baseline gait performance showed smaller relative gains, likely because they began closer to their functional ceiling. Nevertheless, when postoperative gait was evaluated using absolute rather than baseline-normalized values, these higher-functioning patients still achieved higher absolute postoperative gait levels. Thus, relative improvement and absolute gait performance capture distinct aspects of recovery and should be interpreted together. These phenomena are well documented in the TJA literature. Across TKA studies, preoperative gait function, quadriceps strength, and overall physical function have consistently predicted postoperative performance-based outcomes, gait-speed recovery, and 1-year physical function, while lower baseline function and higher BMI have been associated with poorer absolute outcomes [13,35,38,39]. At the same time, patients with higher preoperative gait function may show smaller relative gains or even early functional decline, consistent with our finding that the highest-baseline group returned only approximately to its own preoperative level by week 15 [38]. Similar patterns have been reported after THA: patients with worse preoperative function often improve more, but do not reach the absolute postoperative function achieved by those who started at a higher level [36,37].

Taken together, the results of this study support recovery targets that are individualized to each patient's baseline function rather than defined by a single absolute threshold. Whether the

XSL•FO
RenderX

difference in baseline is due to demographic considerations or individual variation, valuable clinical information is lost when recovery is evaluated solely against population-based gait parameter values. A patient who walks slowly before surgery and returns to that level has a different clinical interpretation than a higher-functioning patient who fails to recover to their own preoperative level. Thus, both the absolute level of gait performance and the trajectory of recovery relative to baseline provide distinct and complementary clinical information.

Limitations

Within this observational study, we did not have access to and therefore did not control for all factors known to affect recovery, such as surgical approach, implant type, perioperative protocols, rehabilitation protocols, pain level, or comorbidities [40]. Further, no anthropometric normalization was performed (eg, normalizing stride length by patient height) because such data were also unavailable. Age was available for patients, and we grouped patients using clinically meaningful age ranges rather than equal-sized groups. This allowed us to compare age categories that are more interpretable clinically, but the resulting uneven group sizes should be considered when interpreting the age-stratified analyses.

We chose to use the return to preoperative baseline as the primary metric in this study, for the reasons described above. However, because most patients expect to achieve better function and/or less pain than they experienced in the weeks before surgery, a return to baseline should not be conflated with full recovery. In this study, the data did not allow for an analysis focused on, for example, reaching a clinically meaningful level above the presurgery baseline, since many patients had not exceeded their baseline by a noticeable margin by week 15. Future studies in this vein should aim to extend the timeline of data collection so as to be able to directly assess recovery beyond baseline.

Time to return to baseline, as calculated with Kaplan-Meier analysis, used the first week in which the patient reached their presurgery level. This definition may overestimate the speed of recovery in patients whose first crossing of baseline was transient. Functional recovery after TJA can fluctuate because of pain, fatigue, activity level, or other short-term factors, and a patient who reaches baseline in 1 week may fall below baseline in a subsequent week. The Kaplan-Meier results should therefore be interpreted as time to first observed return to baseline, rather than time to sustained recovery beyond baseline.

While smartphone-based data collection vastly increases the number of subjects it is possible to include in these types of studies, one downside compared with using dedicated hardware is that there is much more missing data within a subject's dataset. Adherence and phone-carriage behaviors (whether people carry their phones in their pants pockets while walking) influence who contributes data over time, and environmental variability can affect background measurements as well. For this reason, we do not see multiple passive walking bouts per day in many subjects, whereas previous studies using more dedicated measurement systems do find walking bouts at that frequency, although in cohort sizes more than an order of magnitude smaller than our study [31,41].

We summarized cohorts without imputing missing weeks, so missingness could relate to recovery status. Further, diminishing sample sizes in later weeks (particularly for in-app walks) reduce statistical power and make late-week estimates highly sensitive to outliers. This analysis may also be subject to survivorship bias because patients who continued contributing data at later weeks may not be representative of the original cohort. In particular, if continued participation is related to recovery status, the observed results may reflect both true recovery and the changing composition of the patients who remained under observation. Therefore, the values at later weeks should be interpreted with caution.

Passive data collection depends on the patient carrying their smartphone in a pants pocket, which may introduce selection bias. Our filtering methods for removing walks in which the smartphone was outside the pants pocket could also have failed to filter some such walks, introducing noisy and unreliable data into the dataset. In addition, as discussed above, passively collected data reflect walking undertaken in a variety of conditions, which makes such data inherently different from prompted data collection. This fact is mitigated by our normalization of the in-app and background data separately to their respective presurgery levels, but there could still be an effect; for example, if the types of passive walks undertaken after surgery differ systematically from those taken before surgery. Finally, our analysis ended at 15 weeks after surgery, so later improvements or setbacks were not captured.

Conclusions and Implications for Future Research

Despite these limitations, this study provides a robust quantitative characterization of gait-parameter recovery trajectories in the first 15 weeks after TJA at weekly resolution and demonstrates the power of smartphone-based gait analysis to generate longitudinal datasets at scale. The differences in in-app and background walking that we observed suggest that clinical decisions, such as when to taper walking aids or advance activity, could benefit from incorporating passive background metrics rather than relying solely on prompted tests. However, studies that directly assess these questions are needed before any concrete clinical recommendations can be made. Further analyses of this dataset could quantify within-week heterogeneity, identify early signals associated with delayed recovery, and cluster longitudinal trajectories to define distinct recovery trajectory profiles. Defining and validating these profiles and linking them to clinical correlates could support clearer counseling and targeted interventions. Beyond this dataset, future work should extend follow-up, link trajectories to complications and PROMs, and incorporate factors such as BMI, height, and rehabilitation exposure.

Abstract

Background: Mobile health interventions have the potential to motivate healthy behaviors. Optimal strategies for engaging patients in cardiac rehabilitation (CR) through mobile health interventions remain unclear.

Objective: This study aimed to examine patient engagement in a mobile app platform for CR across patient characteristics and by the method of delivery of nudge messages over the 12 weeks of CR.

Methods: The authors analyzed data from the ERA-Nudge (Enhancing Rehabilitation Adherence Through Optimized Nudge) study, a pragmatic randomized trial conducted at an urban safety-net hospital testing nudges (short messages designed using behavioral economics to elicit behavior change) to enhance CR adherence and log healthy activity. Trial patients were given access to a smartphone-based app. Nudges were initially sent as app notifications. Later in the study, patients received nudges as text messages. We assessed patient characteristics associated with app engagement, and we compared time spent in the CR app among patients receiving nudges as app notifications vs text messages. The trial enrolled patients who could engage with messages in either English or Spanish at an urban safety-net hospital with a qualifying CR diagnosis and a smartphone from May 2019 to May 2023. We describe minutes spent in the app across patient characteristics and by type of nudge delivery, and we compare the 2 approaches using unadjusted and multivariate negative binomial regression over the 12 weeks of CR.

Results: In total, 223 patients received nudges: 74 via app notification and 149 via text message. Overall, patients spent an average of 219 (SD 328) minutes in the app, and 3 (1.3%) patients used the app for zero minutes. Patients receiving only app nudges spent a mean of 167 (SD 365) minutes in the app, and patients receiving text messages and app nudges spent 245 (SD 306) minutes in the app (unadjusted ratio 1.5, 95% CI 1.1-2.0; *P*=.02). After adjusting for age category, sex, primary language, CR location (hospital vs home), and highest education achieved, Spanish-preferring patients, patients with some college education, and patients receiving text messages spent more time in the app. Patients receiving nudges as text messages and app notifications spent an adjusted ratio of 1.8 (95% CI 1.2-2.5; *P*=.002) times as many minutes in the app compared to those getting nudges as app notifications.

Conclusions: Among an urban safety-net population, text message nudges were associated with greater time in the app compared to nudges delivered as app notifications. These findings suggest that text messages may result in greater patient engagement for mobile health interventions.

KEYWORDS

cardiac rehabilitation; mobile health; mHealth; patient engagement; mobile health intervention; healthy behaviors; application; randomized trial; mobile app

Introduction

Disparities in access to and availability of cardiovascular care persist. Burgeoning mobile health (mHealth) technologies have the potential to augment patient care by improving care team interaction and motivating healthy behavior change. An important use case is cardiac rehabilitation (CR). CR portends immense benefits for patients [1-6], but referral rates are approximately 30%, and participation rates are even lower at 8% to 9% [1,2,5,7]. Numerous barriers to CR attendance lower adherence rates, and augmentation of CR delivery via mobile tools such as telehealth CR or a mobile app may circumvent these obstacles [2,5]. There are numerous platforms in development, but clear benefits from these mobile or hybrid CR interventions have been inconsistent [8]. Approximately half of virtual CR alternatives report improved adherence, physical activity, or functional status. Reasons for the mixed results are underexplored, and patient use of the technologies is infrequently reported. Heterogeneity in patient use across studies may be a reason for inconsistent outcomes, but strategies to best engage patients remain unclear [2,9].

A possible explanation for inconsistent improvement in outcomes of virtual CR trials could be the lack of use by patients—like medications, patients must use interventions for them to work [8]. Some studies of hybrid or remote CR have resulted in fewer adherences compared to traditional CR, and the mechanisms of this suboptimal adherence are undefined. One way to engage patients may be to send nudge messages designed to create behavior change using principles of behavioral economics [10,11]. It is not yet known how these nudge messages should be delivered or how they may impact patient engagement.

To better understand how to engage patients, the primary objective of this analysis was to identify patient characteristics associated with patient engagement and compare patient engagement in the ERA-Nudge (Enhancing Rehabilitation Adherence Through Optimized Nudge) study of an app-based CR platform based on whether patients received nudges via both text messages and app notifications or app notifications alone, as assessed by the amount of time spent in the app. While most CR studies evaluate attendance at CR or exercise sessions by CR patients, we aimed to assess not the exercise minutes or sessions, but rather patients' engagement with mobile technology as measured by time spent in the app when patients have a virtual CR option. The ERA-Nudge study aims to improve referral and adherence to CR using short messages designed to elicit behavior change or nudges [10,11]. Nudges were initially sent as notifications within a mobile phone app, Movn (Movn Health), and later also sent as text messages. We identified patient characteristics associated with app engagement and evaluated the intervention factor of text messaging to determine if it was associated with app engagement independent of patient factors, with the hypothesis that text messages may be associated with greater engagement with the app.

Methods

Population

This is a secondary analysis of the ERA Nudge study (NCT03834155). The protocol has been previously published [12]. Briefly, this study enrolled patients with a qualifying CR diagnosis who speak English or Spanish and have access to a smartphone. Patients were identified daily from the hospital census based on a qualifying diagnosis by the CR team. The trial was a single-center study conducted at Denver Health, an urban safety-net hospital with over 60% of patients identifying as minorities, and it enrolled patients from May 2019 to May 2023. The app usage data were sourced from Movn Health, the company that delivers the app, and the remainder of the data was compiled from the electronic health record and collected trial data. For the purposes of our study, we evaluated the time spent in the app by patients receiving nudges as either app notifications or text messages.

Ethical Considerations

All eligible patients provided consent prior to enrollment and randomization. The trial protocol and analysis plan were approved by the Denver Health and Colorado Multiple Institutional Review Board (18 - 1290). Data were deidentified prior to analysis. Compensation was provided to participants for completing surveys. Participants received a US $25 gift card for completing each study assessment.

Movn App

As part of the trial, all enrolled patients were given access to the Movn app on their smartphones. This platform facilitated chat-based communication between the CR team and patients, provided educational resources, and enabled patients to log exercise type and duration. The app also allowed for patient data entry of weight and vital signs such as heart rate and blood pressure. The app was intended for data logging, chat, and the provision of educational resources. The patients' time spent in the app may not have included the time they spent exercising, as these data were logged after an exercise session. These data were not required, and patients were not provided with exercise equipment, but they were able to enter this information if they had equipment. Movn Health collected data on how many minutes each patient spent in the app from the program start date to the graduation date. All patients were trained in app use upon enrollment in the trial by study staff.

Trial Design

The ERA-Nudge study consisted of a 2×2 factorial design, randomizing patients to (1) choice of hospital or home-based CR vs hospital-based CR and (2) optimized nudges vs no reminders. We developed nudges through iterative focus group sessions and designed them to encourage healthy behavior aligned with general messages around CR. The messages encouraged healthy behaviors but did not specifically include information on how to use the app. They were sent once or twice

XSL•FO
RenderX

per week, and only to patients randomized to receive nudges. Nudges were initially sent as app notifications and into the patient's inbox within the app. However, by July 2021, patients expressed to study staff that they were not seeing the nudges. In response to this feedback, study staff added text messages via a mobile messenger platform, providing the same nudges on the same schedule in both messaging formats, thereby enabling patients to view the messages as an app notification or a text message. Given that nudges were in the patients' app inboxes, the nudges were always available for viewing within the app, regardless of participants' app notification settings. Patients' settings regarding app notifications were not viewable or available to Movn or study staff. The nudge messages and schedule remained the same. We aim to evaluate whether the nudge delivery modality was associated with greater use or time spent in the app among patients receiving nudges—whether patients interacted with the app more when they received text message or app notification nudges. Apart from the switch from app notification nudges to text message notifications, all other methods were held constant, including app training protocols and trial enrollment. Based on feedback during the initial app notification nudges phase, no changes were made in the app training protocol for patients who received text message nudges. Given our study focuses on nudge message modality, our cohort comprises exclusively patients receiving nudges.

All patients referred to CR were screened for the trial. Eligible patients were then consented and enrolled by study staff. As part of the initial intake, patients also provided their educational status, employment, income, and Patient Health Questionnaire-9 (PHQ-9), an instrument used to assess depression. Clinical data, such as qualifying conditions, were collected by study staff based on the electronic health record.

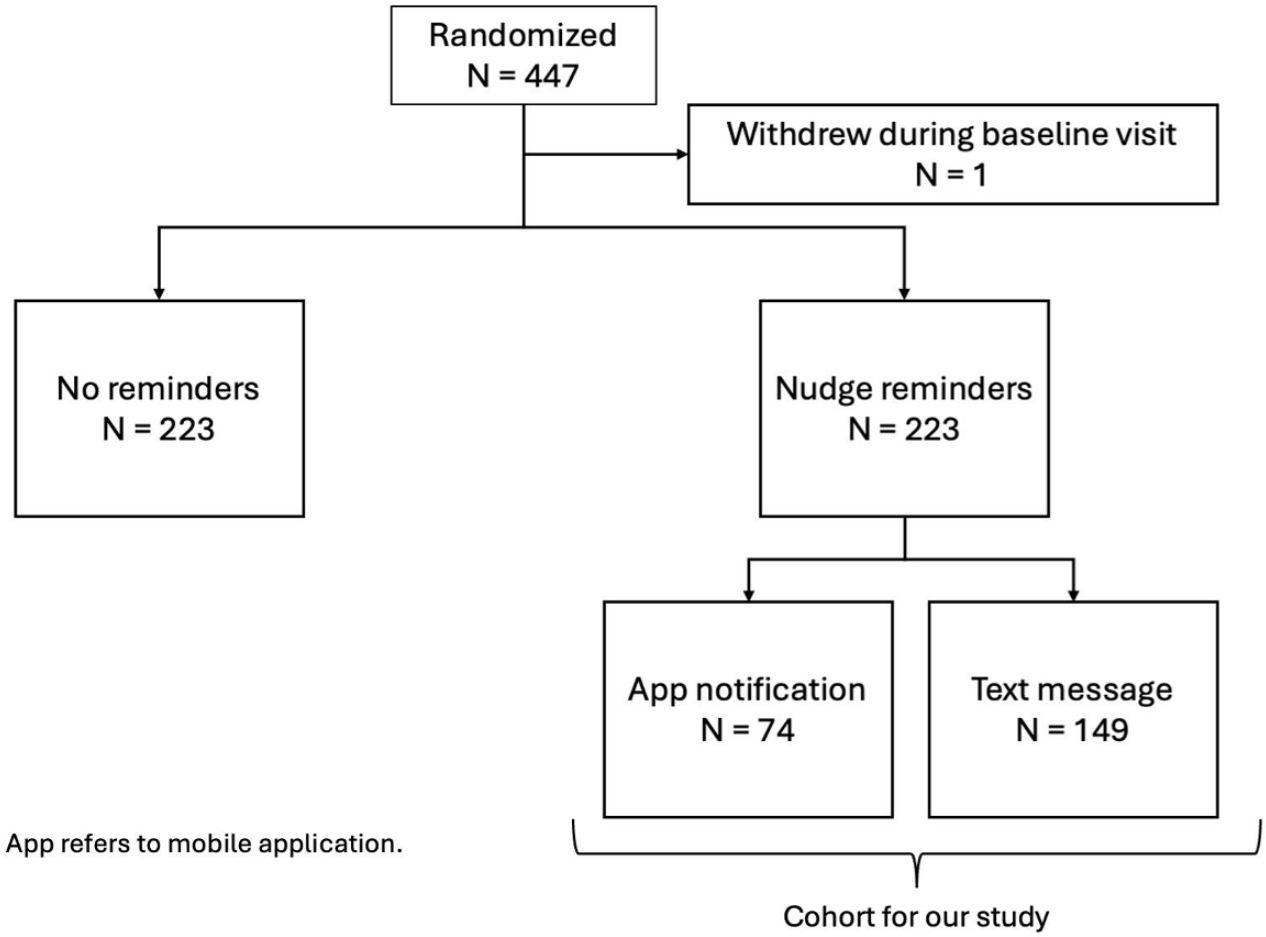
Statistical Analysis

We evaluated baseline patient factors using the mean and SD for continuous variables and proportions for categorical variables. Demographics, clinical indication for CR, and CR location were compared among subgroups using chi-square tests or Fisher exact tests, where appropriate. We performed unadjusted comparisons of each covariate with the outcome variable, minutes in the app, as well as an adjusted analysis accounting for all patient factors. We used a negative binomial regression with a log-link function to account for the zero-weighted, skewed data in the full cohort. The final multivariable model was determined based on a prespecified approach incorporating age category, sex, CR location (home vs hospital), and the primary exposure variable: text message and app notification nudges vs app notification nudges alone. Educational status, employment, and income demonstrated significant collinearity. For the determination of the final multivariable model, multivariable models incorporating educational status, employment, or income were compared using information criteria to arrive at the final multivariable model. Interaction terms were evaluated, but none were significant. The resulting ratios identify the ratio of minutes in the app between the compared groups. Results are reported according to the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) checklist (Checklist 1). All analyses were performed using SAS Studio (version 3.8.1; SAS Institute).

Results

Baseline Characteristics

Overall, in the ERA-Nudge study, 447 patients were enrolled and randomized (224 to nudges and 223 to no nudges). Among these, 1 patient withdrew during the baseline visit, resulting in a cohort of 223 patients for this analysis (Figure 1). Among our cohort of patients for this analysis receiving nudges, 74 patients received nudges as app notifications only, and 149 patients received both text message and app notification nudges.



Our cohort includes 167 (75%) male and 56 (25%) female patients. The average age of the cohort was 55.5 (SD 11.5) years. Additionally, the trial cohort included 153 (69%) White patients, 36 (16%) Black patients, and 7 (3%) patients of other races. The cohort included 88 (40%) Hispanic patients and 55 (25%) patients who preferred Spanish over English. There were 75 (34%) patients who participated in CR at home. Of note, 95 (43%) patients had an income level of US $20,000 or less, and 99 (44%) patients in the cohort were employed at least part-time (Table 1). The most common qualifying condition in our cohort was percutaneous coronary intervention (n=96, 43% in the whole cohort). Other qualifying conditions included patients with acute coronary syndrome (n=87, 39%) and heart failure (HF; n=56, 25%). Data on intake demonstrated that 87 patients (52% of 167 total PHQ-9 tests gathered at baseline) had PHQ-9 scores greater than 4, consistent with at least mild depression.

Patients receiving text messages had a mean age of 54.7 (SD 12.4) years; 73% were male (109/149), 62% were White patients (93/149), and 36% received CR at home (53/149). Patients receiving app notifications had a mean age of 57.3 (SD 9.4) years, 78% (58/74) were male, 81% (60/74) were White patients, and 30% (53/74) received CR at home (Table 1).

Overall, the distribution of minutes spent in the app among the cohort was skewed toward nonuse (Figures 2 and 3). Overall, patients spent an average of 219 (SD 328) minutes in the app. There were 3 out of 223 (1.3%) patients who used the app for zero minutes.

Figure 3. Histogram of log-transformed minutes spent in the app. Red represents patients who received app notifications only, and blue represents patients who received both text messages and app notifications. Overall, patients who received text message nudges used the app more than those who received app notifications only.

Overall Predictors of Engagement

Unemployed participants spent 308 (95% CI 224-423) minutes in the app compared to 198 (95% CI 157-250) minutes spent by employed participants (unadjusted ratio 1.6, 95% CI 1.1-2.3; *P*=.03) (Table 2). Participants who had a qualifying diagnosis of myocardial infarction, non-ST–elevation myocardial infarction, or unstable angina spent 275 (95% CI 215-352) minutes in the app compared to those without (182, 95% CI 149-222 min; *P*=.01). Patients with a qualifying diagnosis of stable HF spent 142 (95% CI 104-193) minutes in the app compared to 244 (95% CI 204-291) minutes among those with other qualifying diagnoses (including but not limited to percutaneous coronary intervention or acute coronary syndrome; Figure 2 and Table 2).

[a]Reflects least-squared mean from a negative binomial regression across levels of the covariate, with a 95% CI for the mean.

[b]Reflects the arithmetic mean and SD of minutes among participants in that subgroup.

[c]Unadjusted ratio and *P* value reflect the unadjusted analysis of time in the app across levels of that covariate.

[d]Adjusted ratio and *P* value reflect results from the adjusted negative binomial model with a log-link function, accounting for age tertile, sex, preferred language, site of CR, level of education, and app notification vs text message nudges.

[e]Not applicable.

[f]CR: cardiac rehabilitation.

[g]GED: general equivalency degree.

[h]PHQ-9: Patient-Health Questionnaire-9.

[i]SD 328.

Unadjusted App Notification vs Text Message

Patients receiving nudges as text messages spent 245 (SD 306) minutes in the app compared to patients receiving app notifications, who spent 167 (SD 365) minutes in the app (unadjusted ratio of minutes in the app among patients receiving both text messages and app notifications vs app notifications only: 1.5, 95% CI 1.1-2.1; *P*=.02).

Adjusted Analyses

In an analysis adjusted for age category, sex, primary language, CR location, and highest education achieved, patients receiving text messages and app notification nudges spent an adjusted ratio of 1.8 (95% CI 1.3-2.6; *P*=.001) times as many minutes in the app compared to those receiving only app notifications (Table 2). The adjusted model also suggested that there was greater app use among patients who preferred Spanish (261 vs 204 min among those who preferred English; adjusted ratio 1.5, 95% CI 1.02-2.26; *P*=.04) and had at least some college-level education compared to participants with less than a high school education (262 vs 172 min; adjusted ratio 2.1, 95% CI 1.3-3.3; *P*=.002).

Discussion

Principal Findings

This analysis of a pragmatic study of app-based remote CR at an urban safety-net hospital aimed to identify correlates of app use and characterize app use among patients receiving nudges as text messages and app notifications or app notification nudges only. Our analysis of 223 patients demonstrated that app use was heterogeneous and heavily skewed toward low use. In an adjusted model, we found that increased use was associated with higher education and Spanish language–preferring patients. Most importantly, nudges sent as text messages and app notifications were associated with greater app use compared to nudges sent as app notifications in both adjusted and unadjusted models.

The results of this study suggest that patients who prefer Spanish and those with higher education levels spent more time in the app. In contrast to prior work, we did not find that older patients engaged less with the intervention [13-15]. Other studies have previously identified ethnicity and education level as important influences on patient engagement in chronic disease management [14]. It is important to note that most trials underrepresent the target population of this study, as most trials enroll participants from major university centers [16-18]. While this single-center study is affiliated with a major university, the study was entirely conducted at an urban safety-net hospital, suggesting that with adequate technology training, these adversely resourced patients may be interested in and engaged with the resources available to them. In the adjusted multivariate model, patients with higher levels of education spent more time in the app. Several prior studies have identified the level of education as an important mediator of socioeconomic differences in cardiovascular disease and CR participation, and our study replicated this finding among patients participating in virtual or hybrid CR [19,20]. In addition, the finding that Spanish-preferring patients spent more time in the app could suggest 2 disparate possibilities: that patients need more time

XSL•FO
RenderX

to navigate the interface, or they are spending more time in the app to learn more about their condition. There is little prior work in this area, and this warrants further investigation.

While most studies in this realm report changes in adherence, physical activity, or quality of life, few report the use of the mHealth platform itself [8,21]. Only occasional reports exist regarding the duration of wearables worn [22], time spent in mobile apps, or web logins [23,24] for the variety of remote CR platforms tested thus far. These smaller studies demonstrate high usability and acceptability, with use metrics ranging from 20 to 120 patients and 30 days to 24 weeks [9,25]. Other digital health interventions aimed at improving patient health found baseline technology use and intent for lifestyle change to be associated with patient engagement. Multiple studies have also found dose-response effects, with higher use among patients associated with greater improvement in clinical parameters [26-30]. A multicomponent health promotion intervention to promote weight loss identified that phone calls were deemed helpful by participants, but website and app usage were low [31]. Some studies suggest self-segregating cohorts of users, including high users, high users who decline, and low users [29,30]. This suggests significant variation over time, a phenomenon that should be studied further to identify strategies to keep patients engaged. Needs assessments and surveys with engaged patients have identified personalization as a suggested strategy to maintain engagement [32]. Some qualitative studies report nonadopters among an aging population, with "forgotten passwords" and "outdated technology" reported as obstacles to use, but these studies represent a limited subset of perspectives [33,34]. A mixed methods study demonstrated low adherence across all demographic subgroups and identified fear of movement and exercise self-efficacy as major obstacles to a home CR intervention among patients with HF [13]. Significant heterogeneity is demonstrated in these studies, suggesting that much work needs to be done to understand how to best augment adherence to home-based or virtual CR alternatives.

It is crucial to study strategies that may augment use or adherence among patients to virtual alternatives, given that greater use may result in better clinical outcomes. One CR study compared changes in activity among patients receiving text message reminders for activity, finding variation in steps walked based on the device used for measurement and the number of days since study enrollment [35]. However, the majority of studies investigating strategies to augment patient engagement in mHealth are outside of CR. In a review of interventions to augment engagement with mHealth, strategies included incorporating behavior change theory, reminders, goal-setting, automatic enrollment, and provider-led strategies [26,36]. A greater number of behavior change theories incorporated may have led to greater behavior change, but few studies referenced theories, and the effects were no different from the overall studies in the review. Provider-facilitated engagement led to the greatest engagement, but no reasons were provided for this or for the high attrition with other engagement strategies. Another study identified that opt-out consent led to greater participation in a mHealth intervention to improve medication adherence among groups that have been historically underrepresented [16]. We found a higher association of app use among patients receiving text message nudges, suggesting that this intervention factor may modify use among patients. While our analysis cannot determine causality, this is hypothesis-generating regarding strategies to better engage patients in mHealth interventions. Given the lack of standard measurements, and variations in follow-up periods, it remains difficult to compare use among studies or strategies. Without examining or comparing use, it will remain unclear which patients require additional support. Mobile interventions require careful implementation and theoretical bases to ensure that we are able to reach all populations, given ongoing concerns regarding widening disparities with the increasing advent of digital health interventions [16,17,21,37-39]. To deliver CR as a mobile or remote option, quality cannot be compromised, and patients must be supported and engaged [1]. Ongoing work is necessary to determine how to best engage patients.

Limitations

Limitations of this study include that it was a single-center study that excluded patients who did not speak English or Spanish. The nonrandomized, pre-post design used in the analysis additionally precludes the determination of causation. Given the temporal differences in study arms, there are several factors that this study design could not account for, such as improved training protocols, study staff experience, or seasonality. We conclude that nudge delivery modality influences patient engagement, with text messaging being associated with greater engagement than app notifications. Furthermore, this is an intermediary assessment. The true value of increased time in the app will be determined through an analysis of patient outcomes. Strengths of this study include the 223 patients, which is a larger sample size than many studies exploring similar questions.

Conclusions

We conclude that an app-based CR platform at an urban safety-net hospital was feasible and acceptable. Spanish language–preferring patients and those with higher educational status demonstrated greater use of the app. Most importantly, nudges delivered as text messages and app notifications were associated with greater use of the app platform compared to patients who received nudges as app notifications alone. It remains to be seen how best to support and engage patients who demonstrated lower app use, and whether this will impact outcomes within the study. As we transition to incorporating hybrid or virtual CR models into care, it is crucial that we identify strategies to better engage patients who have been historically excluded. These findings inform future interventions, which may consider text messages to engage patients more effectively than app notifications. Further research remains necessary to evaluate how to support patients who engage less with the app, such as those with lower educational status, and to assess whether app use correlates with patient outcomes such as CR adherence or functional capacity.

Abstract

Background: With total hip arthroplasty (THA) volumes rising worldwide, scalable home rehabilitation strategies are needed. Home-based digital physiotherapy can improve recovery after THA, and adding wearable motion sensor feedback may further enhance exercise performance and adherence. However, the impact of sensor-augmented digital rehabilitation on patient outcomes and cost-effectiveness remains unclear.

Objective: This study aimed to evaluate the clinical effectiveness (including adherence) and cost-effectiveness of adding wearable sensor feedback to a home-based digital THA rehabilitation program compared with the same digital program without sensors.

Methods: We conducted a single-center randomized controlled trial in Shanghai from June 2023 to June 2024. A total of 240 patients who had undergone primary THA were randomized (1:1) to a 12-week home exercise program delivered via a mobile app either with wearable motion sensors for real-time feedback (intervention) or without sensors (control). Both groups received identical exercise content and weekly teleconsultations. Outcomes were assessed at 6, 12, and 24 weeks by blinded evaluators. The primary outcome was the Hip Disability and Osteoarthritis Outcome Score (HOOS) at 24 weeks. Secondary outcomes included HOOS subscales, timed up-and-go (TUG), Berg Balance Scale, 36-item Short Form Health Survey (SF-36) physical and mental scores, Hospital Anxiety and Depression Scale (HADS) anxiety/depression, patient satisfaction, adherence metrics, and total 24-week costs. Intention-to-treat analyses were used. Mixed effects models and χ^2 tests were used for group comparisons. Cost-effectiveness was evaluated from a societal perspective.

Results: The sensor-based rehabilitation group showed significantly greater improvement in the primary outcome (HOOS overall) than the control group at 24 weeks (P=.01). Early postoperative gains were larger: At 6 weeks, 4 of the 5 HOOS subscales, TUG time, and all patient-reported outcomes remained significant after Bonferroni correction for 47 secondary comparisons (adjusted P<.001). By 24 weeks, hip-specific functional differences had narrowed, but SF-36 physical and mental scores (both P<.001) and HADS anxiety and depression scores (both P<.001) remained significant after correction. Total 24-week costs were similar between the groups (¥87,967 vs ¥94,396 [US $12,879.80 vs $13,821.10] per patient; P=.32). The sensor intervention was associated with numerically lower costs on average (¥6428.98 [US $941.31] less per patient), yielding negative incremental cost-effectiveness ratios, though the cost difference was not statistically significant. Adherence was high in both groups but higher with sensors: The intervention group completed more exercise sessions (P=.002) and showed greater participation in weekly assessments and follow-up calls (both P<.001). Adverse events were uncommon in both groups (5.8% vs 7.5%) and mostly minor, with no serious events reported.

Conclusions: Augmenting home-based digital rehabilitation with wearable sensor feedback led to statistically significant improvements in the primary hip function outcome and in patient-reported quality of life and psychological outcomes that persisted after Bonferroni correction through 24 weeks. Several early hip-specific secondary outcome differences did not survive correction for multiple comparisons. The between-group HOOS differences were below the established minimal clinically important difference. Exercise adherence was significantly higher in the sensor group. These benefits were achieved with no increase in cost, suggesting the sensor-enhanced program is a safe and feasible approach to THA rehabilitation that enhances adherence and accelerates early recovery.

KEYWORDS

total hip arthroplasty; wearable sensors; telerehabilitation; cost-effectiveness; patient adherence

Introduction

Total hip arthroplasty (THA) is in increasingly high demand worldwide driven by aging populations and expanding indications. Over 1 million THAs are performed annually, and procedural volumes are projected to rise dramatically in coming decades (an estimated 174% increase in primary THA by 2030 in the United States) [1]. As the number of THA surgeries grows, there is a critical need for scalable and accessible postoperative rehabilitation strategies that can accommodate larger patient volumes without compromising outcomes. Effective rehabilitation is essential to maximize functional recovery after THA and to ensure long-term success of the procedure. However, traditional clinic-based physiotherapy can be resource-intensive and may pose accessibility challenges, especially for patients with mobility limitations or those living far from specialized centers.

Digital health interventions and home-based rehabilitation programs have emerged as promising solutions to meet this need. Recent evidence supports the efficacy of telerehabilitation and other digital home exercise programs following joint replacement. Randomized trials have shown that home-based digital rehabilitation yields postoperative functional outcomes comparable to those of conventional in-person therapy [2,3]. Even in post-THA telerehabilitation without specialized sensors, compliance with home exercise has been observed to improve relative to standard care [3]. Moreover, a digital program has demonstrated superior short-term results: An artificial intelligence–powered home exercise system with biofeedback after THA led to significantly greater gains in mobility and higher patient-reported outcome scores than traditional rehabilitation in a pilot trial [2]. These trials underscore that technology-assisted, home-based rehabilitation can expand access without sacrificing effectiveness and, in certain cases, may enhance early recovery metrics.

Wearable sensor technology offers an innovative enhancement to digital rehabilitation. By integrating inertial motion sensors into home exercise regimens, patients can receive real-time biofeedback on their exercise technique and performance. This immediate feedback loop is posited to improve the quality of exercise execution and boost patient engagement and adherence. Early data support these benefits: Sensor-based telerehabilitation systems have been shown to increase patient adherence and exercise intensity during orthopedic recovery [4,5]. In one study of a knee rehabilitation app, patients using wearable motion sensors achieved higher rates of prescribed exercise completion and greater training intensity than those undergoing usual care, with no safety concerns [5]. These observations suggest that wearable sensor feedback could further amplify the positive effects of home rehabilitation by motivating patients and ensuring exercises are performed correctly, which in turn may translate to better functional outcomes.

Beyond clinical efficacy, home-based digital rehabilitation has important health economic implications. Remote programs can reduce the burden of travel and time costs for patients and caregivers, increasing the convenience and uptake of rehabilitation. From a health system perspective, shifting rehabilitation to the home setting may help contain costs and resource utilization [6]. This reduced “time burden” with telerehabilitation reflects potential indirect cost savings (such as fewer work absences and transportation expenses) and supports digital rehab as a cost-effective, patient-centered alternative to facility-based care [6]. Additionally, decreasing reliance on in-person supervision through digital tools could alleviate workforce demands and enable broader dissemination of rehab services to underserved or remote regions [2-6].

Building on this background, this randomized controlled trial (RCT) was designed to evaluate the added value of wearable sensor feedback in home-based digital rehabilitation following THA. We hypothesized that integrating wearable sensor–mediated biofeedback into a home-based digital rehabilitation program would improve patient adherence and lead to superior recovery after THA compared with a digital rehabilitation program without sensor feedback.

Methods

Study Design and Setting

This study was a single-center, 2-arm, parallel-group RCT reported in accordance with the CONSORT (Consolidated Standards of Reporting Trials) 2010 guidelines. It was conducted at the Chinese National Medical Center of Orthopaedics in Shanghai, China (affiliated with Shanghai Sixth People’s Hospital) from June 2023 to June 2024.

Eligible patients awaiting primary THA at the study center were identified from surgical waiting lists and screened by two physicians according to predefined inclusion criteria. Patients meeting eligibility were enrolled prior to surgery. Baseline (preoperative) evaluations for all participants were performed by a single physiotherapist after consent. On the first postoperative day, participants were randomly allocated in a 1:1 ratio to the study groups by a trial coordinator (allocation details and sequence described later). Two independent physiotherapists (not involved in initial enrollment nor outcome assessment) subsequently contacted each participant to implement the allocated rehabilitation intervention. All participants then underwent a 12-week home-based rehabilitation program according to their group assignment and were followed for a total of 24 weeks postsurgery. The 24-week follow-up duration was selected to capture both the acute rehabilitation phase, during which sensor-mediated benefits were expected to be most pronounced, and the later recovery period, during which convergence of outcomes was anticipated based on prior literature in musculoskeletal rehabilitation. Outcome assessments were conducted at baseline (presurgery)

XSL•FO
RenderX

and at 6, 12, and 24 weeks after surgery by two physiotherapists in the outpatient clinic who were blinded to group allocation to minimize observer bias. These outcome evaluators, who were not involved in providing the interventions, collected all functional performance measures and assisted participants with completing self-reported outcome questionnaires using an online system during the clinic visits. Participant adherence to the digital training intervention was monitored through system usage logs; if a physiotherapist noted that a patient was not engaging with the digital rehabilitation platform as prescribed, they promptly inquired about the reasons for nonadherence to address any barriers to participation.

Ethical Considerations

Ethics approval for this study was obtained from the Ethics Committee of Shanghai Sixth People's Hospital (approval number: 2016KY-109(K)), and the study was conducted in accordance with institutional guidelines and international ethical standards, including the principles of the Declaration of Helsinki. Written informed consent was obtained from all participants prior to enrollment, and participation was voluntary. All data were anonymized to protect participants' privacy and maintain confidentiality, ensuring that no personal identifiers were included in the analytical dataset. No compensation was provided to participants.

Participants

This single-center trial enrolled patients scheduled for primary THA from the waiting list of the orthopedic surgery outpatient clinic of a tertiary hospital. Eligible patients were identified and consented preoperatively, and baseline assessments were completed before surgery. Potential participants were informed about the study 2 weeks prior to their admission and formally screened for eligibility on the same day of their admission. Those meeting all inclusion criteria were invited to participate, and written informed consent was obtained before enrollment.

The inclusion and exclusion criteria are shown in Textbox 1. Patients meeting the criteria were enrolled by the research coordinator and randomized to begin the assigned home-based rehabilitation program. All participants were recruited from a single high-volume arthroplasty center, ensuring a consistent surgical protocol and postoperative care across the study cohort. Each participant's eligibility was verified against the criteria prior to randomization, and a screening log was maintained to record any exclusions or refusals.

Textbox 1. Eligibility criteria.

Inclusion criteria

- Age: 18 years to 80 years
- Underwent a primary THA within the prior 3 weeks for a nontraumatic indication (eg, osteoarthritis or osteonecrosis)
- Able to ambulate at least 10 meters (with or without a cane or walker) by approximately 2 weeks postsurgery
- Medically cleared by the surgical team for routine rehabilitation (no wound complications and no contraindications to unsupervised exercise, such as uncontrolled cardiac issues)
- Access to a smartphone or tablet with home internet to use the digital rehabilitation app (basic tech literacy or caregiver assistance as needed)
- Willing to be randomized and to comply with study procedures (including wearing the sensor device if assigned) and able to provide written informed consent

Exclusion Criteria

- Underwent a revision hip arthroplasty or any concurrent complex hip procedure during the index surgery (eg, periacetabular osteotomy or extensive muscle repair)
- Simultaneous bilateral THA in the same hospitalization
- Severe coexisting hip or lower-limb conditions that would impede rehabilitation (such as advanced arthritis in the opposite leg or significant neurological deficits affecting mobility/balance)
- Cognitive impairment or severe psychiatric illness that would prevent adherence to the exercise program or use of the technology
- Serious postoperative complications before enrollment that precluded normal rehab (eg, unstable medical status, a surgical site infection requiring intervention, or an unplanned reoperation for complications like dislocation)
- Already engaged in formal outpatient physiotherapy prior to enrollment that they were not willing to discontinue (for example, having started or completed an intensive supervised rehab program in the first 2 weeks post-THA)
- Concurrent participation in another interventional trial or prior participation in this study (such as a pilot enrollment)

Intervention

All participants in both the intervention and control groups engaged in a 12-week home-based rehabilitation exercise program following THA. On the second postoperative day, each patient received an in-person orientation: One of the technicians assisted them with installing a dedicated mobile app (Joymotion software, Shanghai Medmotion Medical Management Co, Ltd) on their smartphone and provided instructions on its use. This app-based platform delivered a "Digital Physiotherapeutic THA-Specific Training System," following the standardized post-THA training protocol (see Multimedia Appendix 1), and it recorded each patient's exercise performance and completion rates. The supervising physiotherapist prescribed individualized

XSL•FO
RenderX

daily exercise tasks through the app and could adjust the program remotely as needed. Both groups were scheduled for weekly teleconsultation sessions; at an appointed time each week, a physiotherapist from the rehabilitation center initiated a 2-way video call via the app to monitor progress, provide coaching, and address any issues. Notably, the frequency and duration of physiotherapist contact (including teleconsultations) were identical for the two groups to ensure parity in clinical guidance and support.

Intervention Group

Participants allocated to the inertial measurement unit (IMU) intervention group received the home-based digital exercise program via the smartphone app with full telerehabilitation features. The app provided daily interactive exercise instructions, feedback on training performance, and real-time video or audio communication with the physiotherapist. The rehabilitation regimen was automatically tailored to each patient's baseline characteristics and functional status, and the physiotherapist could further fine-tune the difficulty or exercises through a clinician interface. In addition to the app-based program, this group also used a wearable inertial sensor system to enhance exercise monitoring and feedback. Five small wireless IMU sensors were affixed to the patient's body (one at the waist and one on the front of each thigh and each lower leg) and were registered and calibrated with the app during the initial setup. During each training session, these sensors captured the patient's movements and projected them onto a virtual avatar visible in the app. The system's software continuously compared the patient's avatar movements with the pre-set correct posture for each exercise. If a movement did not reach the target position or was performed with improper form, the patient received immediate feedback from the app, prompting them to repeat the motion correctly. This real-time feedback mechanism ensured that patients in the IMU group could correct their technique on the spot, helping them perform the exercises as intended. Throughout the 12-week period, the assigned physiotherapists remotely monitored the IMU group's exercise sessions via the app's data logs. The sensor system transmitted detailed performance data to the therapist interface, allowing the physiotherapist to review each patient's adherence, exercise form, and progress. Any necessary modifications to the exercise program or additional guidance were provided based on these observations.

Control Group

Participants in the control group followed the same 12-week home exercise program using the digital platform but without the aid of wearable sensors. Like the IMU group, control group patients accessed daily THA-specific exercises and instructional videos through the mobile app, which tracked their exercise completion and provided basic performance feedback such as summaries of repetitions completed or time spent exercising. They received the same schedule of weekly physiotherapist-led teleconference sessions via the app's two-way video interface, ensuring equal contact time and guidance as the intervention group. The exercise content and progression for control participants were also individualized to their baseline function and could be adjusted remotely by the physiotherapist in the same manner as for the IMU group. However, unlike the IMU group, the control group did not receive real-time motion feedback on their exercise technique. They performed the prescribed exercises with the app's guidance alone (see Multimedia Appendix 1), without the virtual avatar or sensor-based corrections. All other aspects of the rehabilitation program were kept consistent between the two groups.

Outcome Measures and Data Collection

The primary outcome was the Hip Disability and Osteoarthritis Outcome Score (HOOS), measured at 24 weeks postsurgery as a comprehensive patient-reported index of hip-related health status [7]. Secondary outcomes were assessed at follow-up visits and included the 5 HOOS subscale scores (pain, symptoms, activities of daily living [ADL], sport/recreation, and hip-related quality of life), objective functional performance tests (the timed up and go [TUG] test and the Berg Balance Scale), generic health-related quality of life measures (36-item Short Form Health Survey [SF-36] physical and mental component summary scores), and psychological status measures (Hospital Anxiety and Depression Scale [HADS] anxiety subscale [HADS-A] and depression subscale [HADS-D]) [8-11]. Patient satisfaction with the rehabilitation program was evaluated at 12 weeks and 24 weeks using a 4-item Likert-scale questionnaire addressing convenience, ease of use and access, perceived helpfulness, and communication with the care provider (each item scored from 1 to 5, with higher scores indicating greater satisfaction).

Cost outcomes were analyzed from a societal perspective capturing direct medical costs (including the cost of the wearable sensor hardware and setup for the IMU group), direct nonmedical costs, and opportunity costs (lost wages and productivity) obtained from hospital billing records and participant self-reports. All costs were converted to 2024 Chinese Yuan (¥), with costs incurred before 2024 adjusted to 2024 price levels using the national consumer price index and any costs occurring beyond 1 year postsurgery discounted at an annual rate of 3%. A currency exchange rate of ¥1=US $0.15 is applicable.

Adherence to the rehabilitation program was measured using multiple indicators collected throughout the 24-week study period. These included the number of prescribed exercise sessions completed, the number of weekly app-based assessments attended, and the number of scheduled weekly follow-up phone calls successfully completed in each group.

Adverse events (AEs) and serious AEs (SAEs) were closely tracked as part of safety monitoring from enrollment through the full 24-week trial. Participants were instructed to report any AEs or SAEs either through the study's mobile app (which included a "Report a Problem" feature) or via a phone call to the research team. For this study, an AE was defined as any untoward or unintended medical occurrence during the trial, regardless of whether it was considered related to the intervention. An SAE was defined using standard criteria as any adverse event that resulted in death, was life-threatening, required or prolonged hospitalization, caused significant disability or incapacity, or captured any other important medical event that necessitated intervention to prevent such outcomes. Follow-up assessments were conducted at 6 weeks, 12 weeks,

XSL•FO
RenderX

and 24 weeks postsurgery in the outpatient clinic. Two trained physiotherapists conducted all outcome measurements at each visit. Participants completed patient-reported outcome measures, including HOOS, HADS, and SF-36, using paper questionnaires. All performance-based outcome tests were administered in person by the physiotherapists during each follow-up visit.

Sample Size Calculation

The sample size was determined to provide sufficient power to detect a clinically meaningful difference in the primary outcome (HOOS) between groups. Based on published data in THA populations, an improvement of roughly 8 to 10 points on the HOOS represents the minimum clinically important difference in patient-reported hip function after surgery. We therefore set a 10-point difference in HOOS as the target effect size for this trial. To inform the variability estimate, we reviewed prior studies reporting HOOS outcomes and found that the SD of change scores is approximately 15 to 20 points in this context. Using these assumptions and a 2-sided significance level of .05 with 80% statistical power, we calculated that 86 patients per group would be required to detect a 10-point difference in HOOS between the intervention and control arms. This calculation was based on a 2-sample comparison of means for the primary outcome. To account for an anticipated attrition rate of about 25% (loss to follow-up and dropouts), the sample size was inflated accordingly. We aimed to recruit approximately 115 participants per arm to ensure that the study would remain adequately powered for the primary endpoint after accounting for potential dropouts. This sample size was also expected to provide sufficient power for key secondary outcomes while maintaining a feasible recruitment target.

Randomization, Allocation, and Blinding

An independent statistician generated the allocation sequence using block randomization with randomly varying block sizes (between 4 and 6), achieving a 1:1 allocation ratio to the 2 study groups. Allocation concealment was maintained by placing assignments in sequentially numbered, opaque, sealed envelopes. Randomization was implemented after participants completed baseline assessments. At that time, the enrolling investigator opened the next envelope in sequence to reveal the participant's group assignment. The allocation list was kept secure by the statistician and was not accessible to investigators or clinicians responsible for recruitment and treatment, ensuring that allocations remained concealed until the point of assignment. Due to the nature of the intervention, participants and treating physiotherapists were not blinded to group allocation; however, all outcome assessors and data analysts remained blinded to group assignments throughout the study to minimize the risk of bias.

Statistical Analysis

Baseline characteristics, outcome measures, and treatment adherence data were summarized using appropriate descriptive statistics (mean and SD for continuous variables; frequencies and percentages for categorical variables). We applied the Shapiro-Wilk test to formally evaluate normality [12]. A nonsignificant Shapiro-Wilk test ($P>.05$) indicated no evidence against normality. Any major deviations would have prompted use of transformations or nonparametric methods, but no such issues arose in this study. All hypothesis tests were 2-sided with a significance level of 5%. Intention-to-treat (ITT) analyses were primary, including all participants as randomized.

For the primary outcome (HOOS at 24 weeks postrandomization), an adjusted 2-sided analysis was conducted in the ITT population. The primary between-group comparison of HOOS at 24 weeks was based on a linear mixed effects model treating the repeated HOOS measurements as the dependent outcome. This model included fixed effects for treatment group, time, and the treatment-by-time interaction, with baseline HOOS score, age, and sex entered as covariates to improve precision. A random intercept for each participant was incorporated to account for within-subject correlation over time. As this was a single-center trial, no random center effect was needed. The adjusted mean difference in HOOS at 24 weeks between the 2 groups was estimated from this model with a 2-sided 95% CI. The primary hypothesis was evaluated using the *P* value associated with the treatment group effect (difference in outcomes between groups) at the 24-week time point. Model assumptions (such as normality of residuals and homogeneity of variance) were checked, and analyses were robust to these assumptions or used appropriate transformations if necessary.

Continuous secondary outcomes were analyzed with similar linear mixed effects models appropriate for their distribution. Each continuous outcome measured over time was examined for overall group differences and trajectory over the follow-up period. These models included the same fixed effects (group, time, and their interaction) and participant-level random intercepts, adjusting for baseline values when available. From each model, we obtained estimates of the mean outcome in each group at each follow-up time and the mean differences between groups with 95% CIs. Group differences at each time point were derived from interaction terms or post hoc contrasts. For binary categorical outcomes, comparisons between groups were made using χ^2 tests. These dichotomous results were reported as risk differences or relative risks with corresponding 95% CIs. All significance tests were 2-sided, and a *P* value $<.05$ was considered statistically significant for each individual outcome analysis. To control for inflated Type I error across secondary endpoints, a Bonferroni correction was applied to all secondary outcome comparisons. The primary outcome (HOOS overall at 24 weeks) was tested at a 2-sided significance level of .05 as the single confirmatory analysis. For secondary outcomes, the family-wise alpha was divided by the total number of secondary comparisons (47 tests across 15 secondary outcome measures at up to 3 time points, plus 2 nonprimary time points for HOOS overall), yielding a Bonferroni-adjusted significance threshold of $P<.001$. Both unadjusted and Bonferroni-adjusted significance levels are reported for transparency.

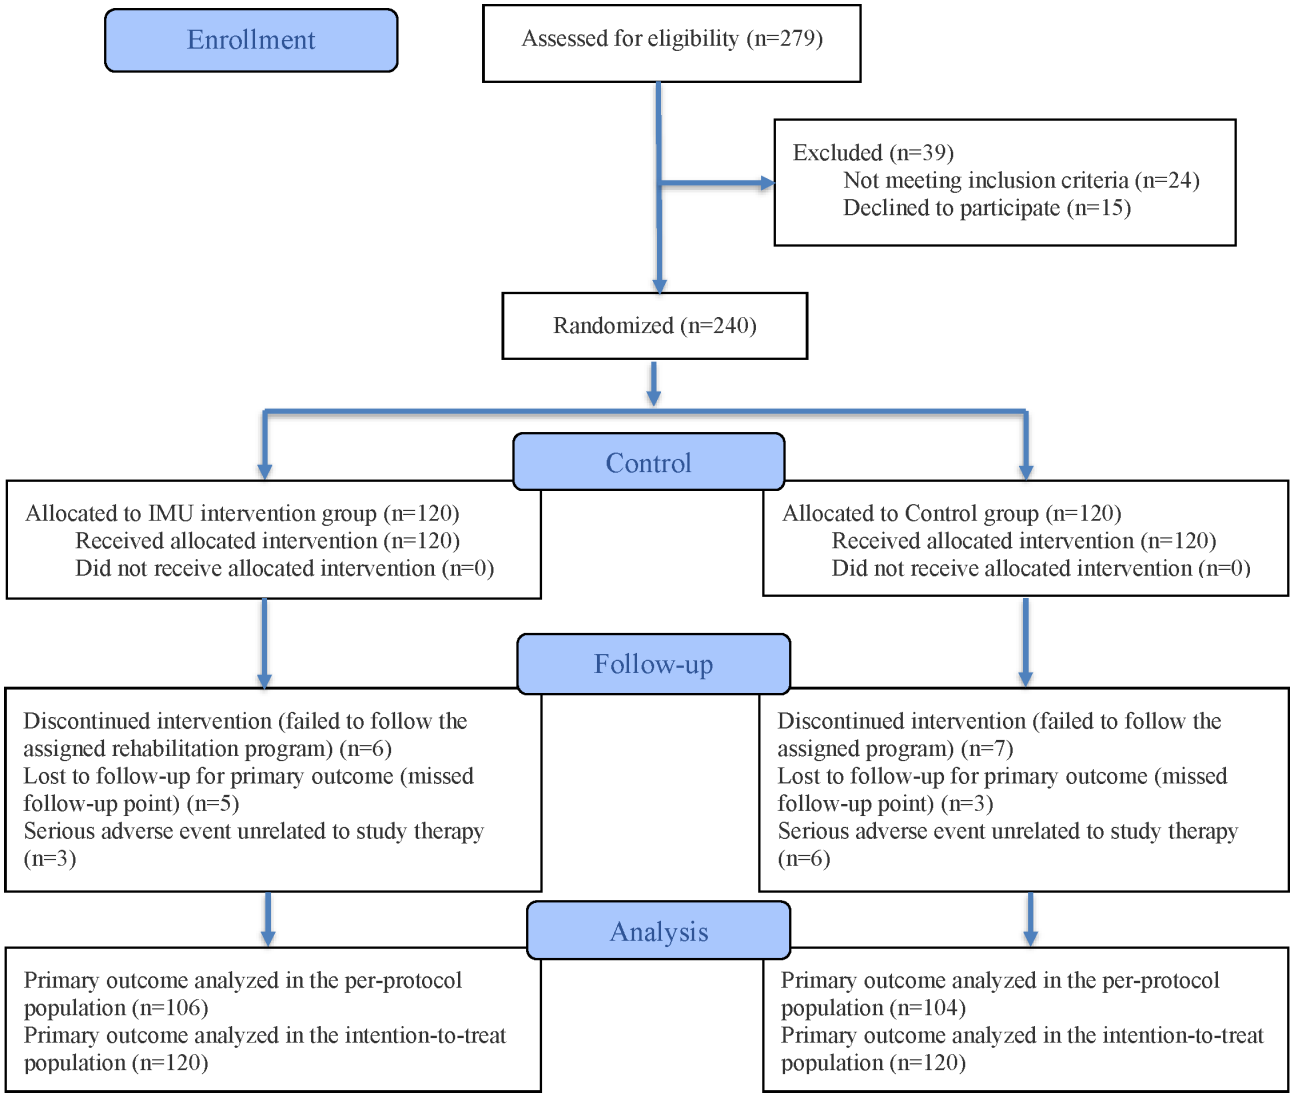
A comprehensive cost-effectiveness analysis was also performed alongside the clinical outcomes. Total health care costs for each participant over the 24-week follow-up were calculated, incorporating intervention costs and any other relevant medical expenditures. The difference in mean total cost between the 2 groups was then evaluated using appropriate between-group comparisons (with nonparametric bootstrap methods applied to account for skewed cost data). We plotted the joint uncertainty

XSL•FO
RenderX

in costs and effects on a cost-effectiveness plane to visualize the difference in mean cost against the difference in effectiveness (primary outcome improvement) for the digital rehabilitation versus control. If the digital intervention demonstrated lower average cost while yielding no worse outcome, it was considered a dominant strategy (more cost-effective). In cases where the digital program had higher cost or marginally different outcomes, an incremental cost-effectiveness ratio (ICER) was computed to quantify the additional cost per unit of benefit gained. Uncertainty in the cost-effectiveness results was explored by nonparametric bootstrapping (10,000 resamples), which produced a cloud of incremental cost-effect pairs on the cost-effectiveness plane and allowed construction of cost-effectiveness acceptability curves. These acceptability curves illustrate the probability that the digital program is cost-effective compared with the control across a range of willingness-to-pay thresholds for improvement in outcome.

Missing data were handled using both ITT and per-protocol (PP) analysis strategies. In the ITT analysis, all participants were retained in their originally assigned groups for analysis, regardless of protocol adherence or missing follow-up data. The linear mixed effects model used all available observations from each participant under a missing-at-random assumption, thereby inherently accommodating incomplete follow-up without requiring formal imputation. In contrast, the PP analysis included only those participants who completed all scheduled follow-up assessments, thereby using a complete-case approach. It is important to note that missingness in our dataset was holistic at the follow-up level: If a patient was lost to follow-up at a given time point, all variables for that visit were missing for that patient. There was no item-level missingness within an attended visit. Consequently, missing data occurred only at the participant-visit level, and all available data from each participant's other time points were still used in the mixed model under the ITT approach. Because entire follow-up visits were missing for dropouts and not selective outcome omissions, we did not perform any statistical imputation for missing values. In addition, given this pattern of whole-visit missingness, a formal test for data missing completely at random (such as the Little MCAR test) was not applicable, as that test is designed for detecting patterns of sporadic item-level missingness across variables rather than the uniform visit-level dropout observed in this trial.

Results



Participants

We evaluated 279 patients scheduled for primary THA, and 240 were randomized. The flowchart of our study is shown in Figure 1. The baseline characteristics were comparable between the IMU and control groups. Men accounted for 62 (62/120, 51.7%) participants in the IMU group and 56 (56/120, 46.7%) participants in the control group (P=.44); the mean age was 70 years versus 69 years (P=.46); mean BMI was 22 kg/m² versus 22 kg/m² (P=.31; Table 1). Paracetamol or nonsteroidal anti-inflammatory drugs were taken by 17 (17/120, 14.2%) in the intervention group versus 18 (18/120, 15%) in the control group (P=.86). In addition, 62% (74/120, 61.7% vs 72/120, 60%) had the left hip as the surgical side (P=.79). There were no significant differences in functional tests nor patient-reported outcome measures.

Sensitivity analysis using the PP population showed similar results as those of the ITT population (Table S1 in Multimedia Appendix 2).

Primary and Secondary Outcomes

The primary outcome (HOOS) improved significantly more in the IMU group than in the control group at all follow-ups. The estimated between-group difference in the overall HOOS (IMU minus control) was 2.021 (95% CI 1.445 - 2.598) points at 6 weeks (*P*<.001), 1.721 (95% CI 0.896 - 2.545) points at 12 weeks (*P*<.001), and 1.298 (95% CI 0.313 - 2.282) points at 24 weeks (*P*=.01). All 5 HOOS subscales showed a pattern of greater early improvement with the IMU intervention. At 6 weeks, 4 of the 5 subscales (pain, symptoms, sport/recreation, and hip-related quality of life) had significant between-group differences after Bonferroni correction (all *P*<.001), with coefficients ranging from 2.334 to 3.327 points. The HOOS ADL subscale difference at 6 weeks (1.208 points, 95% CI 0.283 to 2.134; *P*=.01) did not survive Bonferroni correction. At 12 weeks, none of the individual HOOS subscale differences remained significant after correction for multiple comparisons (unadjusted *P* values ranged from .002 to .047). By 24 weeks, all subscale differences had further narrowed and were not statistically significant at either the unadjusted or adjusted level (all *P*>.13), except for HOOS pain, which had a nominal difference of 1.501 (95% CI 0.084 to 2.918) points (unadjusted *P*=.04) that did not survive Bonferroni correction. In terms of objective function, the IMU group completed the TUG faster than controls by 1.198 (95% CI 0.789 to 1.607) seconds at 6 weeks (*P*<.001) and 1.131 (95% CI 0.557 to 1.705) seconds at 12 weeks (*P*<.001), both of which remained significant after Bonferroni correction. The 0.901-second (95% CI 0.237 to 1.565) difference at 24 weeks was nominally significant (unadjusted *P*=.008) but did not survive Bonferroni correction. Berg Balance Scale scores were numerically higher in the IMU group at all time points (0.300 to 0.431 points), but none of these differences reached the Bonferroni-adjusted threshold (unadjusted *P* values of .004, .02, and .16 at 6 weeks, 12 weeks, and 24 weeks, respectively). For generic patient-reported outcomes, the SF-36 physical component summary was higher in the IMU group by 3.821 (95% CI 3.315 to 4.326) points at 6 weeks, 2.626 (95% CI 1.913 to 3.338) points at 12 weeks, and 1.949 (95% CI 1.144 to 2.753) points at 24 weeks (all *P*<.001; all surviving Bonferroni correction). The SF-36 mental component summary showed a similar pattern (3.239, 95% CI 2.881 to 3.597; 2.272, 95% CI 1.771 to 2.773; and 1.726, 95% CI 1.117 to 2.334 points at 6 weeks, 12 weeks, and 24 weeks, respectively; all *P*<.001; all surviving Bonferroni correction). Psychological outcomes also consistently favored the IMU arm across all time points and remained significant after Bonferroni correction: The IMU group had lower HADS-A scores by 0.537 (95% CI 0.470 to 0.604), 0.418 (95% CI 0.310 to 0.527), and 0.363 (95% CI 0.220 to 0.506) points at 6 weeks, 12 weeks, and 24 weeks, respectively (all *P*<.001), and lower HADS-D scores by 0.501 (95% CI 0.435 to 0.566), 0.370 (95% CI 0.260 to 0.481), and 0.307 (95% CI 0.163 to 0.450) points at 6 weeks, 12 weeks, and 24 weeks, respectively (all *P*<.001). Patient satisfaction with the rehabilitation program was high in both groups, with no significant between-group differences in any domain at 12 weeks or 24 weeks (all *P*>.23). Detailed results of the primary and secondary outcomes are shown in Tables 2 and 3. Sensitivity analyses in the PP population yielded results consistent with the ITT findings, reinforcing the robustness of the observed treatment effects (Tables S2-S3 in Multimedia Appendix 2).

Cost Measurements

The mean 24-week total cost per patient was ¥87,967.32 (SD ¥8854.19) in the IMU group versus ¥94,396.30 (SD ¥10,037.74) in the control group (*P*=.32). The cost composition differed between groups: IMU participants had significantly lower in-hospital costs (¥69,534.95, SD ¥5394.69 vs ¥70,359.45, SD ¥5043.84; *P*<.001) and primary care costs (¥250.00, SD ¥38.14 vs ¥1503.18, SD ¥186.13; *P*<.001). Nonmedical expenses were lower with IMU, including paid home care (¥1178.73, SD ¥362.12 vs ¥1451.95, SD ¥357.74; *P*<.001), transportation (¥800.06, SD ¥138.89 vs ¥1968.67, SD ¥273.82; *P*<.001), and nutrition (¥4505.32, SD ¥479.00 vs ¥5093.08, SD ¥519.96; *P*<.001). Patient productivity losses were also lower (¥1599.77, SD ¥6994.72 vs ¥1829.44, SD ¥6618.91; *P*<.001). The detailed results are shown in Table 4.

The IMU intervention's incremental cost was –¥6428.98 (IMU less costly). Correspondingly, most ICERs were negative, though the overall cost difference between groups was not statistically significant (¥87,967.32 vs ¥94,396.30, *P*=.32). For the primary outcome (HOOS overall), the incremental effect was +1.298 (95% CI 0.313 to 2.282) points, with an ICER of –¥4954 per point. TUG time decreased by 0.901 (95% CI 0.237 to 1.565) seconds (ICER ¥7136.79 per second), and the Berg Balance Scale increased by 0.300 (95% CI –0.118 to 0.718) points (ICER –¥21,451.43 per point). SF-36 physical component summary and mental component summary improved by 1.949 (95% CI 1.144 to 2.753) points (ICER –¥3299.31 per point) and 1.726 (95% CI 1.117 to 2.334) points (ICER –¥3725.41 per point), respectively. The detailed results, including for the HOOS subscales, are shown in Table 5. PP sensitivity analyses (Tables S4 and S5 in Multimedia Appendix 2) yielded similar cost-effectiveness results.

Table . Average total cost per patient in the inertial measurement unit (IMU) group and control group during the 24 weeks after the surgery.

Cost category[a] (¥[b])	IMU (n=120)	Control group (n=120)	*P* value
Medical costs[c]			
Costs while in the hospital (including the hospital stay, surgery fee, medication, implants during surgery)	69,534.95 (5394.69)	70,359.45 (5043.84)	<.001
Physical therapist costs (including the instrument)	6980.00 (0.00)	8447.88 (1046.07)	.24
Primary care costs	250.00 (38.14)	1503.18 (186.13)	<.001
Nonmedical costs[d]			
Paid home costs	1178.73 (362.12)	1451.95 (357.74)	<.001
Transportation costs	800.06 (138.89)	1968.67 (273.82)	<.001
Nutrition costs	4505.32 (479.00)	5093.08 (519.96)	<.001
Opportunity costs[e]			
Lost wages for patients	1599.77 (6994.72)	1829.44 (6618.91)	<.001
Lost wages for families	3118.49 (4461.09)	3742.65 (4743.85)	.80
Total cost	87,967.32 (8854.19)	94,396.30 (10,037.74)	.32

[a]All relevant costs were captured from a societal perspective and were obtained from hospital billing records and patient self-reports where needed (wage losses). All costs are reported in 2024 Chinese Yuan, as 2024 was the end of the enrollment period; costs incurred in earlier years were adjusted to 2024 price levels using the consumer price index. Costs and outcomes occurring beyond the initial year were discounted at an annual rate of 3% to reflect time preference, consistent with standard practice in health economic evaluations.

[b]A currency exchange rate of ¥1=US $0.15 is applicable.

[c]Hospital stay; primary and secondary care; rehabilitation and physical therapy costs, including wearable sensor hardware and setup for the IMU group; and medication costs.

[d]Direct costs related to care (transportation for medical visits and any specialized nutritional support during recovery).

[e]Indirect costs due to productivity loss (lost wages for patients during recovery or disability, and lost income for family members/caregivers, if applicable).

[a]HOOS: Hip Disability and Osteoarthritis Outcome Score.

[b]ADLs: activities of daily living.

[c]TUG: Timed Up and Go test.

[d]36-item Short Form Health Survey.

[e]HADS: Hospital Anxiety and Depression Scale.

[f]Incremental effects for primary outcome measures for the 24-week follow-up under both the intention-to-treat and per-protocol analyses. A negative ICER suggests that the IMU intervention achieved numerically better outcomes at a numerically lower cost compared with the control group; however, the statistical significance of both the cost and effect differences should be considered when interpreting these ratios.

XSL•FO
RenderX

Adherence and AEs

Adherence to the intervention was high in both groups, with the IMU group completing more of the 60 prescribed exercise sessions (mean 51.6, SD 9.3 vs mean 48.7, SD 10.6; *P*=.002), attending more of the 12 weekly app-based assessments (mean 10.5, SD 1.5 vs mean 9.5, SD 1.8; *P*<.001), and completing more of the 12 follow-up phone calls (mean 10.8, SD 1.6 vs mean 9.3, SD 1.8; *P*<.001) than the control group (Table S6 in Multimedia Appendix 2). AEs were infrequent, occurring in 7 patients (7/120, 5.8%) in the IMU group and 9 patients (9/120, 7.5%) in the control group; most AEs were minor and considered related to treatment (Table S7 in Multimedia Appendix 2).

Discussion

This RCT demonstrated that integrating a wearable sensor into a home-based digital rehabilitation program after THA resulted in significantly greater improvements in patient outcomes compared with a standard digital program without sensor feedback. Specifically, the sensor group achieved significantly larger gains in the primary hip outcome measure and multiple secondary functional and quality-of-life outcomes, particularly during early recovery, although most between-group differences narrowed by the final 24-week follow-up. These statistical differences were attained without increasing health care costs. Total 24-week costs were comparable between groups. Although several individual cost components were numerically lower in the sensor arm, the overall cost difference did not reach statistical significance, suggesting that the sensor-based program was cost-neutral rather than definitively cost-saving. Adherence to the prescribed rehabilitation was high in both groups, with the sensor group completing a higher proportion of exercise sessions and assessments than the control group.

Our findings suggest that augmenting home-based digital rehabilitation with real-time sensor feedback can confer modest gains in early postoperative recovery, though the clinical significance of these gains warrants careful interpretation. The IMU‐enhanced training led to faster improvements in hip function and mobility during the initial weeks, although not all secondary hip-specific outcomes survived Bonferroni correction for multiple comparisons, which is consistent with other orthopedic populations. For example, a recent RCT with patients with diabetes who had undergone total knee arthroplasty demonstrated that adding IMU sensor feedback to telerehabilitation significantly improved functional outcomes compared with telerehabilitation alone [13]. More broadly, our results align with a growing body of evidence that technology-assisted or remote rehabilitation is at least as effective as standard physiotherapy. Meta-analyses in knee and hip arthroplasty have shown that telerehabilitation can yield equal or even superior short-term improvements in pain, range of motion, strength, and functional scores when compared with traditional in-person programs [14-16]. These early advantages are likely attributable to enhanced exercise technique, engagement, and adherence driven by the biofeedback component. Notably, the between-group differences in hip-specific outcomes narrowed by the 24-week follow-up. After Bonferroni correction, no HOOS subscale nor TUG difference remained significant at 24 weeks. However, the SF-36 and HADS differences persisted through the final follow-up even after correction, suggesting that the sensor-mediated benefits on broader quality of life and psychological well-being were more durable than the hip-specific functional gains. This trajectory mirrors prior reports of musculoskeletal rehabilitation, indicating that initial benefits of more intensive or innovative interventions may diminish over time as all patients progress through natural recovery [15]. Indeed, telerehabilitation appears to facilitate a comparable 6-month outcome to that of conventional care in many settings, supporting its use as a viable alternative without long-term trade-offs [15,16]. It is important to acknowledge that, although the improvements with sensor guidance were statistically significant, their absolute magnitude was relatively small. For instance, the HOOS overall score in the IMU group was only 2 points higher on average, a difference below the typical minimal clinically important difference reported for hip outcomes [12]. This suggests that, although sensor-based digital training accelerates early rehabilitation and subjective recovery, the clinical significance of the advantage is modest. Nevertheless, even slight early gains in function and pain relief can be valuable; achieving milestones sooner may improve patient confidence, expedite return to daily activities, and potentially reduce short-term complication risks. In summary, the interpretation of our findings is consistent with existing evidence: Wearable sensor integration enhances the quality of home exercise performance and adherence, thereby providing a small boost to early postoperative outcomes, while overall recovery at the mid-term remains comparable to traditional rehabilitation approaches [13-16].

From a clinical perspective, these findings support integrating wearable sensor–enhanced telerehabilitation into standard post-THA care. Patients in the sensor-based program achieved faster early gains in functional mobility and quality of life without compromising longer-term outcomes. This accelerated recovery can improve the early postoperative experience and potentially reduce short-term disability. Importantly, the sensor feedback substantially boosted patient adherence to prescribed exercise, a critical determinant of successful rehabilitation, echoing prior reports of higher compliance with telerehab interventions [17]. The approach was also safe and well-received, with similar patient satisfaction and no increase in adverse events compared with usual care. Furthermore, our trial's economic analysis indicates that delivering home-based digital rehabilitation with wearable sensors is feasible without added cost burden. Although the point estimate suggested numerically lower costs in the sensor group, the overall cost difference was not statistically significant, and shifting rehabilitation into the home may help reduce indirect costs (travel, time off work) and alleviate demands on in-person physiotherapy services [6,17]. With THA volumes rising globally, adopting such technology-assisted home programs could expand rehabilitation capacity, improve access for patients in remote or resource-limited settings, and enhance the value of care by providing efficient, patient-centered recovery support [17].

This study has several notable strengths, including its robust randomized controlled design (with blinded outcome

XSL•FO
RenderX

assessments) and comprehensive outcome evaluation encompassing both clinical and economic measures, which bolsters confidence in the findings. However, there are also important limitations. Methodologically, some experimental details lacked clarity or could have been more appropriately standardized, potentially affecting reproducibility. Analytically, the data analysis methods, although rigorous, involved statistical assumptions that may limit their appropriateness or introduce bias or uncertainty. Additionally, the results should be interpreted with caution, as conclusions remain contingent on the study's context and design. We also strived for scientific accuracy and consistent terminology, but minor ambiguities in usage and definitions may persist. These considerations highlight areas for improvement; future studies will address these concerns by refining methodology and analysis, clarifying terminology, and further validating our findings.

In conclusion, this RCT showed that adding wearable sensor feedback to a home-based digital THA rehabilitation program led to improved early functional outcomes, sustained benefits in patient-reported quality of life and psychological well-being, and significantly higher patient adherence compared with a similar program without sensors while incurring no additional costs. Several early hip-specific functional differences did not survive Bonferroni correction for multiple comparisons, and most HOOS subscale differences had converged by 24 weeks. Although the between-group differences in HOOS were statistically significant, their magnitude remained below the established minimal clinically important difference, tempering the clinical significance of these gains. Nevertheless, the sensor-enhanced approach provided consistent early benefits across multiple outcome domains and substantially improved exercise adherence. The intervention was cost-neutral, suggesting that integrating wearable technology in post-THA rehabilitation can enhance patient engagement and accelerate early recovery without adding to the economic burden.

Abstract

Background: The benefits of multidisciplinary rehabilitation programs on pain and function in people with chronic low back pain (CLBP) are fairly well documented in the literature. However, these positive effects tend to fade over time due to low long-term patient adherence.

Objective: The study aimed to evaluate the impact of a smartphone app on adherence to an exercise program for people with CLBP at 6 months. The secondary aims were to assess the effectiveness of the app on pain, disability, fears, and beliefs related to physical activity, physical capacity, and qualitative adherence (correctness of exercise execution) at 6 months.

Methods: A total of 110 people with CLBP were included and randomized into 2 groups: 54 in the intervention group (IG) who received education on the use of the app in addition to usual care (a 3-week multidisciplinary rehabilitation program with self-management education) and 56 in the control group (CG) who received only usual care. Part B of the Exercise Adherence Rating Scale was used as the primary outcome to assess adherence to the 6-month exercise program. Secondary outcomes were pain (Numeric Rating Scale), disability (Oswestry Disability Index), barriers and facilitators to performing physical activity (Evaluation of Physical Activity Perception), physical capacity (battery of tests), and qualitative adherence (correctness of exercise execution). Statistical analyses were performed according to the intention-to-treat principle. A linear mixed model compared the primary end point between the groups at 6 months.

Results: A total of 71 of 110 participants (n=35 in the CG vs n=36 in the IG) were evaluated at 6 months. We did not observe any significant difference in the Exercise Adherence Rating Scale score between the CG and the IG (group difference 0.01, 95% CI −2.4 to 2.4; *P*=.97). The same findings were found for pain, disability, and barriers and facilitators to physical activity, except for the motivation criterion. The 6-Minute Walk Test (group difference [log] 0.06, 95% CI 0.01-0.12; *P*=.06), cycle ergometer (group difference 9.30, 95% CI 0.48-18.13; *P*=.04), Ito (group difference [log] 0.31, 95% CI 0.01-0.62; *P*=.04), plank (group difference [log] 0.29, 95% CI 0.03-0.54; *P*=.03), and qualitative adherence (IG mean 12.6, SD 1.3 vs CG mean 11.4, SD 1.4; *P*=.02) differed between the groups in favor of the IG. All outcomes improved from baseline to 6 months in the IG but not in the CG.

Conclusions: The smartphone app did not impact adherence to an exercise program at 6 months in individuals with CLBP. Similar results were found for pain and function. Nevertheless, the app could be a useful self-management tool in view of the positive effects on physical capacity and qualitative adherence.

Introduction

Background

Low back pain is the leading cause of disability worldwide, affecting over 620 million people in 2020 [1]. Although this condition typically improves in most cases, 10% to 20% of individuals continue to experience pain beyond 3 months. Pain lasting more than 3 months is classified as chronic [1]. Chronic low back pain (CLBP) leads to significant functional limitations, impacting daily activities, productivity, and overall quality of life [2]. It imposes a heavy social burden and economic cost, representing a huge challenge to health care systems. Despite its high prevalence, effective management remains a challenge.

Global health organizations, including the World Health Organization and the Global Burden of Disease Study, emphasize the importance of nonpharmacological treatments for managing CLBP. Evidence-based recommendations prioritize physical rehabilitation, including tailored exercise programs, patient education with self-care strategies, and cognitive behavioral therapy (CBT) [1-3]. Exercise is consistently recommended as a first-line treatment to improve mobility, strength, and overall function while reducing pain. Tailored exercise programs for individuals with CLBP have demonstrated significant benefits on pain and function [4]. The National Institute for Health and Care Excellence guidelines highlight the importance of self-management, providing advice tailored to individual needs to help manage CLBP over the long term [5]. Self-management programs, incorporating multidisciplinary rehabilitation, have shown positive effects on return to work and physical activity at 6 and 12 months [6]. However, maintaining the necessary level of physical activity remains a challenge for most individuals. Despite these positive results, adherence to exercise programs is often suboptimal, with dropout rates ranging from 10% to 36% [7]. Adherence is defined as “the extent to which a person’s behavior corresponds with agreed recommendations from a healthcare provider” [8]. Medium-term and long-term follow-up data show that one- to two-thirds of individuals do not comply with the exercise recommendations [9,10], particularly for unsupervised home-based exercises [11-13]. Furthermore, adherence tends to decline over time [14]. Several studies have investigated the reasons behind poor adherence to prescribed exercises following multidisciplinary rehabilitation programs. Pain and exacerbation of low back pain (LBP) are the primary barriers, negatively influencing adherence [15]. Lack of time, weather conditions [16], and difficulty integrating physical activity into daily life have also been reported as barriers [15,17]. Factors that can improve long-term adherence to a home-based exercise program include the involvement of, and follow-up by, a physiotherapist during the multidisciplinary program, as well as a clear understanding of the exercises to be performed. These facilitators improve autonomy and increase the perception of self-efficacy [18,19]. It is also a theoretical component of behavior change used in therapeutic programs [20].

CBT has emerged as a highly effective intervention for CLBP, particularly when combined with exercise [21]. CBT is “a safe, evidence-based treatment for a range of mental and physical health problems, including chronic pain” [22]. The American Pain Society and the American College of Physicians recommend combining CBT with active functional restoration exercises within a multidisciplinary management program. This combined approach can enhance adherence and reduce disability and pain over time, providing a comprehensive strategy for managing CLBP.

Connected health devices, such as smartphones and tablets, are valuable tools that can be used to deliver CBT to promote behavior change and support the sustainable adoption of healthy behaviors. These devices provide personalized medical information, self-management tools, and remote monitoring by health care professionals, creating an optimal environment for patient care. Mobile health (mHealth) solutions, particularly through smartphones, offer a means for continuous support and follow-up [23], helping maintain the benefits of in-center care through engaging, interactive platforms [24]. With the growing prevalence of smartphones (70% of the population in 2021) and the rapid expansion of health apps (from 100,000 in 2014 to 350,000 in 2021) [25], mHealth facilitates remote rehabilitation, real-time data collection, and improved disease management. As personal and accessible devices [26], smartphones enhance patient engagement and understanding of health conditions, contributing to better self-management and health care access. The use of smartphone apps could reduce pain and disability [27,28] and improve quality of life [29] in the short term, but these effects have not been studied in the long term. However, some evidence regarding the use of smartphone apps for the self-management of CLBP is contradictory [30].

Objectives

The primary objective of this study was to assess the impact of a smartphone app on adherence to a home exercise program at 6 months in people with CLBP. The secondary aims were to assess the effectiveness of the app on pain, disability, fears, and beliefs relating to physical activity, physical capacity, and qualitative adherence (correctness of exercise execution) at 6 months.

Methods

Study Design

This was a single-center, prospective, controlled, cluster-randomized trial (trial registration: ClinicalTrials.gov: NCT04264949) with session as the unit of randomization. Sessions were performed 5 days per week for 3 weeks [31,32] and involved groups of 4 to 6 participants. Participants randomized to the intervention group (IG) participated in 3 one-hour sessions of education on how to use the app in addition to the conventional, multidisciplinary rehabilitation program and the self-management program. Those randomized to the control group (CG) participated only in the conventional multidisciplinary rehabilitation program and the self-management education program. Assessments were conducted at baseline, postprogram (3 wk), and at follow-up (6 mo). The trial protocol has been published elsewhere [33]. This trial is reported according to the CONSORT (Consolidated Standards of Reporting Trials) Statement for nonpharmacological trials [34] (Checklist 1).

XSL•FO
RenderX

Recruitment and Selection

Recruitment was conducted between March 2020 and June 2023. Following a medical consultation regarding their chronic low back pain, potential participants were invited to join a multidisciplinary rehabilitation program in our physical medicine and rehabilitation department. Participants who met the inclusion criteria (Textbox 1) and provided written consent after reading the information sheet were randomized by session into one of the 2 groups.

Textbox 1. Inclusion and exclusion criteria.

Inclusion criteria

- Adult participants (≥18 years old).
- Experiencing nonspecific chronic low back pain.
- Diagnosis confirmed according to the Haute Autorité Santé definition.

Included participants must have provided written informed consent.

Exclusion criteria

- Participants not meeting the Haute Autorité Santé diagnostic criteria.
- Participants with comprehension difficulties (questionnaire completion impossible).
- Participants with a medical contraindication to physical exercise.
- Participants under legal guardianship, curatorship, or protective supervision.
- Participants without a smartphone.

Randomization and Blinding

The unit of observation for the outcome was the participants. However, the session was the unit of randomization to avoid contamination bias. Individual randomization may lead to recruitment difficulties and feasibility and an increase in the number of individuals lost to follow-up in the CG. Participants in the same session were assigned to the same randomization group. An independent statistician performed the randomization and allocation using Stata v15 (StataCorp), taking into account the number of participants per session. The evaluator and the members of the rehabilitation team were blinded to group allocation. Participants were not blinded, as we had to explain the purpose of the study before randomization. The name of the app was not revealed to participants unless they were randomized into the IG or screened out of the study.

Interventions

Overview

Both groups participated in a conventional, multidisciplinary rehabilitation program and a self-management education program, which lasted 3 weeks (5 days a week). The only difference between the 2 groups was that the IG received the smartphone app “Mon Coach Dos” and participated in 3 one-hour training sessions on how to use it (Multimedia Appendix 1). The aim of the app was to improve adherence to the home exercise program, reinforcing the conventional care effect.

Self-Management Exercise Program Based on a Smartphone App (for the IG)

The app used was Mon Coach Dos and was developed in collaboration with the health care professionals from our physical medicine and rehabilitation department and the Thuasne group. This app aims to help individuals to better understand CLBP and enable them to self-manage their condition. It provides medical information on the pathology, messages regarding the benefits of physical activity, information on pain management, and a video of a physical exercise program. It is designed to change individuals’ representations of the pathology and their related behavior [19,35]. The Mon Coach Dos app was developed following work carried out in our department on an initial test app, “E-lombactifs,” which was evaluated by collecting opinions from people with CLBP and health care professionals through interviews (individual or focus group) [23].

The main aims of the self-management exercise program using the smartphone app are to increase individuals’ understanding of (1) the importance of practicing physical exercise; (2) when, where, and how to exercise; (3) how to adapt physical activity practices according to phenotype; and (4) how to integrate these practices into daily life over the long-term. Three educational training sessions on the use of the smartphone app were provided during the rehabilitation program (each Wednesday). Each session consisted of 1 hour of self-management education and physical exercise practice related to the content of the app. By the end of the program, each participant had developed a personalized exercise program with the assistance of the adapted physical activity specialist who led the sessions.

Conventional, Multidisciplinary Rehabilitation Program

The rehabilitation program lasted 3 weeks. Participants attended 5 days a week (Monday to Friday). Each day included 1 hour of physical therapy, 1 hour of occupational therapy, 1 hour of adapted physical activity, 1 hour of hydrotherapy, and 1 hour of self-management education (Multimedia Appendix 2).

Self-Management Education

This component of the program consisted of 6 different workshops to improve the self-management of CLBP and quality

XSL•FO
RenderX

of life, performed over 3 sessions (1 per week). The themes of the workshops were the anatomy and pathology of LBP, activities of daily living, nonpharmacological pain management (ie, relaxation, transcutaneous electrical nerve stimulation), pharmacological pain management, adapted physical activity, and return to work strategies.

Outcomes

At baseline, we collected sociodemographic data (age, sex, weight, height, education status, and socioprofessional category) and medical data (history of low back pain and treatments).

Primary Outcome

The primary outcome was the change in the Exercise Adherence Rating Scale (EARS) score at 6 months. The EARS is a self-administered questionnaire that measures adherence to a physical activity program and has good psychometric properties [36].

Secondary Outcomes

Pain intensity during the last 7 days was assessed on a Numeric Rating Scale. Self-declared functional ability was measured using the Oswestry Disability Index [37,38]. Barriers and facilitators to regular physical activity were assessed using the Evaluation of Physical Activity Perception (EPAP) score [39]. Aerobic capacity was evaluated using the 6-Minute Walk Test (6 MWT) [40] and a submaximal test on a cycle ergometer [41]. Muscle endurance was evaluated using the Shirado-Ito test for the trunk flexors [42], the Sorensen test for the erector spinae [43], and the wall-sit test for the lower limbs [44]. Lumbar mobility was assessed by measuring fingertip-to-floor distance [45]. Qualitative adherence was assessed by the good execution of 3 physical exercises carried out during treatment (squat, plank, and rowing) using a graded evaluation grid out of 15 points [46]. More details are provided in Multimedia Appendix 3.

Assessment Schedule

Study outcomes were collected at baseline, postprogram (3 wk), and at 6 months post randomization by the adapted physical activity specialist and the physician, both of whom were blinded to the group allocation.

Statistical Analysis

The sample size estimation for this pilot trial was determined according to the 2010 CONSORT Statement extension for randomized pilot and feasibility trials [47] and Cohen recommendations [48], which define effect size (ES) limits as small (ES: 0.2), medium (ES: 0.5), and large (ES: 0.8, “grossly perceptible and therefore large”). According to data reported in the literature and considering this study as a pilot, it seemed suitable to include 60 patients per group.

To achieve an ES of 0.8 at 6 months postrandomization with a type 1 error of 5% and statistical power of 90%, 33 participants are required per group. However, because of the randomization design, with session as a unit cluster of randomization, the sample size should be increased to take into account between- and within-session variability. More precisely, the assumption in randomized controlled trials that the outcome for an individual is completely unrelated to that of any other individual is violated in cluster randomized trials because individuals in any 1 cluster (session in our case) are more likely to respond in a similar manner. This similarity is known as the intraclass correlation coefficient (ICC). For an average of 5 participants per session and an ICC of 0.05, 38 participants were required in each group. Therefore, to account for losses to follow-up, we planned to include 120 individuals (n=60 per group).

All analyses were conducted before the randomization code was broken, in line with the International Conference on Harmonization Good Clinical Practice guidelines. Data storage and management were conducted according to international guidelines relevant to French institutions. All data were entered using an electronic case report form, and data accuracy was analyzed by the study data manager. Data quality control measures included queries to identify outliers and missing data.

Continuous parameters are presented as mean (SD) or median (IQR) according to the normality of the distribution (Shapiro-Wilk test).

Participant characteristics were summarized by randomization group to consider selection biases and lack of balance.

Statistical analysis was first conducted using the intention-to-treat approach. To prevent attrition bias, missing data were replaced using post hoc multiple imputation. A linear mixed model was used to compare the primary endpoint (EARS score) between randomized groups at 6 months post randomization. The randomization group was evaluated as a fixed effect and session as a random effect to consider between- and within-session variability. The normality of residuals obtained from this model was studied. The results concerning group differences were expressed as effect sizes and 95% CIs. The estimated ICC from the fitted model was reported.

Between-group comparisons for the other outcomes were performed using random-effects models, as specified for the primary analysis.

The random-effects models were also used to study longitudinal repeated data (baseline, after rehabilitation [15 days] and at 6 months post randomization), considering participant as the random effect in addition to session. The following fixed effects were studied: randomization group, evaluation time point, and their interactions.

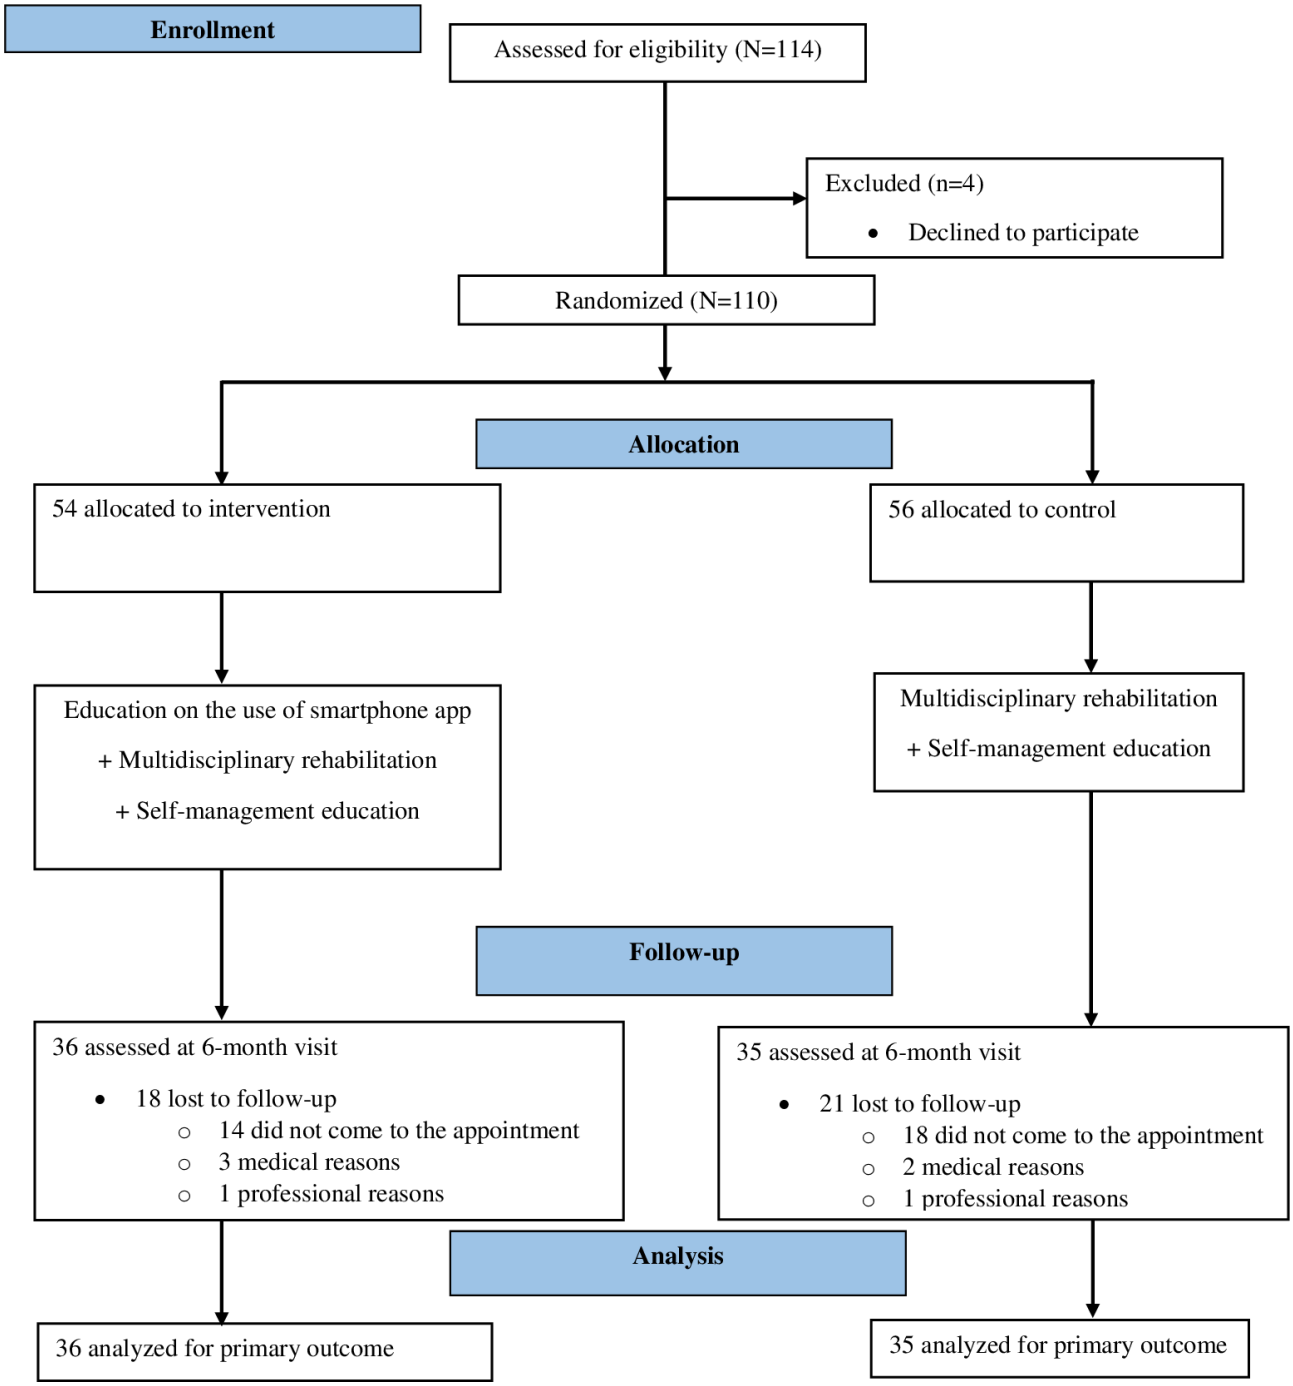
Statistical analyses were performed using Stata v15 (StataCorp). The tests were 2-sided with the type 1 error set at 5%. The widths of CIs were not adjusted for multiplicity and therefore should not be used in place of hypothesis testing, except for the primary outcome analysis. Consequently, the results for secondary outcomes were considered exploratory and were interpreted as such. The results were expressed using absolute group differences (after log transformation when appropriate), effect sizes, and 95% CIs.

Ethical Considerations

This study was conducted in accordance with the ethical guidelines outlined in the Declaration of Helsinki. The study was approved by the medical ethics committee of Ile-de-France (Ile-de-France III 3740, November 5, 2019). All participants

XSL•FO
RenderX

received both verbal and written information regarding the aim of the study and the protocol. Written informed consent was obtained before inclusion and before any specific procedure was performed. Participant data were anonymized and securely stored to ensure confidentiality. Identifiable information was removed from the dataset, and only deidentified data were used for analysis. Data access was restricted to authorized researchers. Participants were not compensated.



Results

Baseline Characteristics

In total, 110 individuals were enrolled in this study (Figure 1). They were randomized either to the app-based intervention group (n=54, 49.1%) or to the control group (n=56, 50.9%). The sociodemographic and clinical characteristics of the participants at baseline are presented in Table 1.

A total of 71 (64.5%) participants completed the study. A total of 39 (35.5%) participants dropped out between “postprogram” and “M6”: 18 (46.2%) in the IG versus 21 (53.8%) in the CG.

Primary Outcome

The EARS score did not differ significantly between the 2 groups at 6 months (group difference 0.01, 95% CI −2.4 to 2.4; *P*=.97). However, the EARS score improved significantly in both groups postprogram compared to baseline (Figure 2). These results were confirmed by the analysis that took into account the session effect as a random effect (group difference 0.1, 95% CI −2.4 to 2.4; *P*=.97). The ICC related to the session effect was 2.7%.

Pain (Numeric Rating Scale)

Pain levels did not differ between the 2 groups at 6 months (group difference −6.58, 95% CI −14.46 to 1.29; *P*=.10). Pain reduced significantly in the IG postprogram compared to baseline (mean 3.8, SD 2.3 vs mean 4.4, SD 2.3; *P*=.02), as well as at 6 months compared to baseline (mean 3.8, SD 2.2 vs mean 4.4, SD 2.3; *P*=.03) (Figure 3). These differences were not found in the CG.

XSL•FO
RenderX

Figure 3. Pain score in the 2 groups at baseline, postprogram, and at 6 months. M6: 6 months; NRS: Numeric Rating Scale. *$P \leq .05$.

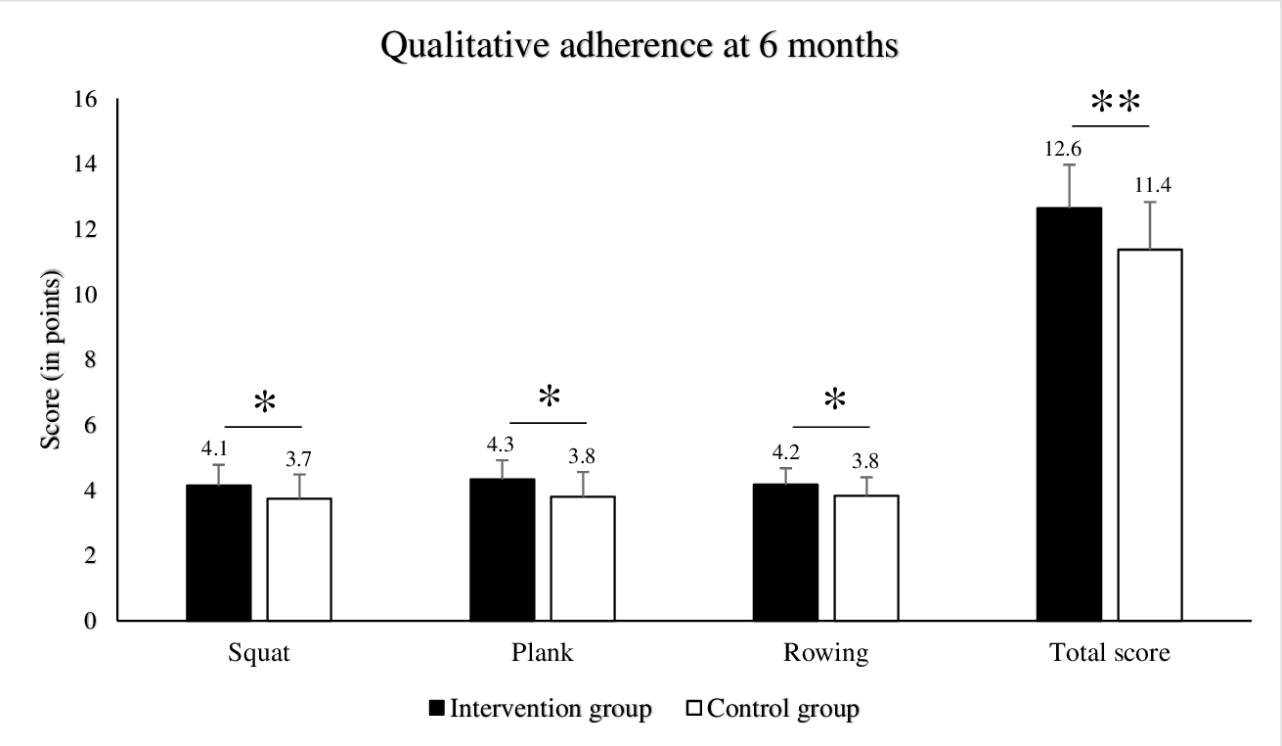
Disability (ODI)

Disability levels did not differ between the 2 groups at 6 months (group difference −2.27, 95% CI −6.50 to 1.96; *P*=.29). However, the ODI score improved significantly in both groups postprogram and at 6 months compared to baseline.

Barriers and Facilitators to Regular Physical Activity (EPAP)

The EPAP scores did not differ between the 2 groups at 6 months, except for the criterion “motivation” (group difference 8.38, 95% CI 1.12-15.65; *P*=.02). All EPAP criteria improved significantly (motivation, beliefs, barriers, facilitators) in the IG between baseline and 6 months. These differences were not found in the CG, except for the belief criterion.

Physical Capacity



At 6 months, there was a small between-group difference in the 6MWT (group difference [log] 0.06, 95% CI 0.01-0.12; *P*=.06), the cycle ergometer test (group difference 9.30, 95% CI 0.48-18.13; *P*=.04), the Ito (group difference [log] 0.31, 95% CI 0.01-0.62; *P*=.04), and the plank test (group difference [log] 0.29, 95% CI 0.03-0.54; *P*=.03) in favor of the IG. Moreover, a significant improvement in all physical capacity tests was found postprogram compared to baseline in both groups, except for the cycle ergometer test in the CG. This significant improvement was maintained at 6 months in the IG for all tests, except for the cycle ergometer test, whereas in the CG, only the 6-MWT, wall-sit test, and the fingertip-to-floor distance test showed an improvement at 6 months compared to baseline (Table 2).

Qualitative Adherence

The total qualitative adherence score differed significantly between the groups in favor of the IG at 6 months (IG: 12.6, SD 1.3 vs CG: 11.4, SD 1.4; *P*=.02; Figure 4).

XSL•FO
RenderX

Figure 4. Qualitative adherence at 6 months in the 2 groups. **$P \leq .01$, *$P \leq .05$.

Discussion

To our knowledge, this is the first study to evaluate the impact of a smartphone app on adherence to a home exercise program at 6 months in people with CLBP. The lack of a significant difference in adherence between the 2 groups at 6 months suggests that the Mon Coach Dos app did not enhance adherence compared to usual care.

Primary Outcome

Although adherence did not differ between the groups, it improved significantly postprogram in both groups, with a return to the initial score at 6 months in both groups. This aligns with previous findings on medium- and long-term adherence, demonstrating a decline in adherence levels 3 months postprogram [49,50]. However, the study by Krkoska et al [51] showed very good adherence to a home exercise program over a period of 18 weeks. In that study, 25 out of 27 participants completed the program. Adherence was measured by the frequency of completing the program (once or twice a day) and was greater in the app group than in the diary group. However, the strong adherence of both groups to the programs can be explained by the considerable number of monitoring visits carried out during the program, making it possible to maintain a strong relationship with the therapist. In a qualitative study collecting patient expectations regarding mHealth, Palazzo et al [24] found that adherence could be increased by maintaining a relationship with the provider, for example, via telephone feedback, by offering attractive exercise programs, and by improving patient performance. In our study, we did not provide feedback to the participants during the 6-month follow-up period.

Adherence is a concept that is quite difficult to define and evaluate. Adherence to mHealth interventions has been assessed by different methods and defined in various ways. For example, some studies defined adherence as the number of complete active days of app use [52,53], the average time spent using the app [54], or the number of self-management plans completed using the app during the first 12 weeks after randomization [55]. In 2013, Beinart et al [10] highlighted the lack of standardized measures for adherence to prescribed home exercises. The absence of a standardized and valid tool to quantify adherence could compromise research on the effectiveness of tools designed to improve adherence [56]. There is currently no “gold standard” [57] nor a consensus for measuring patient adherence to self-exercise programs [58]. The development of a validated measure of adherence should be a priority for the research community, as it could lead to a better understanding of the multitude of factors that affect adherence to home exercises in people with LBP [10]. Furthermore, adherence to an exercise program can be influenced by the patient’s perception and motivation and the therapist’s expectations, which further complicates its objective measurement [59]. In response to this observation, Newman-Beinart et al [36] developed the first self-administered questionnaire to assess adherence to a physical activity program, the EARS questionnaire. This questionnaire has been used and evaluated in several languages (eg, Brazilian, Danish, Nepali) and across various pathologies, and it has been shown to have good reliability and validity [60-62]. This is why we used the French version of the EARS questionnaire to measure our primary outcome. We used Part B of the questionnaire, which quantitatively measures adherence to the exercise program. Contrary to our expectation, there was no between-group difference in the EARS score. However, this scale has already been questioned by Arensman et al [63], who stated that the EARS only focuses on the quantitative properties

XSL•FO
RenderX

of adherence and not on the quality of performance of the home-based exercise program pre-established by the health care professional. For this reason, they are now developing an instrument to measure adherence in terms of frequency, intensity, and quality of performance of home-based exercise programs [63]. In our study, we were not able to collect these quantitative data (log-ins, video views, exercise completions) due to a technical problem with the app on data recovery.

Secondary Outcomes

Pain or Disability

Neither pain nor disability levels differed between the groups at 6 months, in contrast with the findings of Chaabra et al [27]. A systematic review found that the simultaneous use of mHealth and usual care interventions was more effective than usual care in reducing pain intensity and disability in people with LBP [64]. Furthermore, they found that telephone calls enhanced improvements in pain and disability, suggesting that telephone calls or the provision of sensitive feedback devices enhance the effectiveness of mHealth interventions on pain intensity and disability. They could improve patient adherence and self-management [24,51]. We found a significant, long-term (6 mo) reduction in pain and disability score in the IG, a finding that has been previously reported for the short term (3 mo) [27,28,65]. The lack of a between-group difference in pain despite the significant reduction in pain at 6 months only in the IG and not in the CG could be explained by the fact that the CG received an intervention (a 3-week multidisciplinary program, including a therapeutic patient education program). In addition, we did not provide feedback or telephone calls to the IG. A scoping review found similar results regarding the effectiveness of mHealth apps on pain and disability but concluded that the generalizability of the results was limited due to the heterogeneity of the characterization of pain by the included participants and the different intervention durations [66].

Barriers and Facilitators to Regular Physical Activity (EPAP)

We found no difference between the groups in the EPAP criteria at 6 months, except for the “motivation” criterion, which could be explained by the fact that the smartphone app included videos of the exercises. However, all EPAP criteria (increased facilitators and decreased barriers) improved at 6 months in the IG, but not in the CG. Therefore, access to this app and its content appeared to help dispel false beliefs about physical activity and LBP. Participants might have been better informed about their pathology and gained a more precise understanding of its mechanisms. This process of clarification reduces the barriers often associated with low back pain and physical exercise [15].

Physical Capacity

Few studies have evaluated the long-term effectiveness of health apps on physical capacity. Our study found a significant improvement in all physical parameters at 6 months in the IG, but not in the CG, except for the 6MWT and FFT. Moreover, the significant between-group differences at 6 months in the 6MWT, cycle ergometer, Ito, and plank tests highlight the positive impact of the app on maintaining physical capacity in the long term. The lack of significant improvement in the CG, except for the specific tests mentioned, may also suggest that the mHealth app provided added value in terms of motivation or organization of exercise practice [24], facilitating progress in the IG.

Qualitative Adherence

The IG group executed the exercises (squat, plank, rowing) more correctly than the CG at 6 months. This could be attributed to the videos provided in the app that demonstrated the correct movements to perform. These videos offered participants a reassuring visual model, helping them gain confidence in their ability to perform the exercises correctly, which could have previously been a barrier to exercise practice. Therefore, the app appears to be a useful, motivational tool to promote continued physical activity, as its dynamic content instills user confidence in the correct execution of the movements performed, reducing the fear of injury and exacerbation of pain [15]. The app also allows users to be more independent in performing the movements, potentially leading to better qualitative adherence [67]. The qualitative aspect of adherence is important to consider when defining and evaluating adherence, in alignment with recommendations regarding the quality of exercise performance [63].

Relationship Between Adherence and Secondary Outcomes

It is surprising that, although quantitative adherence at 6 months (EARS) did not differ between the groups, the secondary outcomes (pain, disability, and physical capacity) only improved in the IG. Another study found no association between adherence to home-based exercise recommendations and changes in clinical outcomes in people with LBP [68]. These findings suggest that the relationship between home-based exercise adherence and treatment outcomes is complex. Further research is needed to better understand this relationship.

Limitations

The primary limitation of our study, given the existing literature, was the lack of quantitative data on the use of the app by the users (number, frequency, duration of connections to the app), which would have allowed us to be more precise in terms of adherence and to correlate these data with the EARS score.

The metrological properties of the EARS appear limited as only 6 questions were used to assess adherence [36]. Moreover, some of these questions appear to be similar. Furthermore, the EARS does not evaluate qualitative adherence.

Furthermore, our control group did not represent a true nonintervention, as the participants in the CG were provided with a conventional program, along with a patient education program, which simultaneously offered important information to help patients better manage their condition on a daily basis. The control group was not a “true” control, as seen in the previously cited studies.

Finally, although the number of dropouts during the protocol (39/110) indicates some challenges in sustaining participant engagement over a long-term process [65], the impact on the study’s statistical power is likely limited. First, in the final

XSL•FO
RenderX

analysis, the observed ICC was 0.027, lower than the assumed 0.05, suggesting that the inflation applied in the sample size calculation was conservative. Moreover, the initial sample size calculation indicated that 38 participants per group were required. After inflating this number to account for potential missing data, a target of 60 participants per group was set. Although the final analysis included 35 versus 36 participants, this remains reasonably close to the initial requirement and is therefore unlikely to have markedly compromised statistical power.

Conclusions

The Mon Coach Dos smartphone app did not improve adherence to an exercise program at 6 months in individuals with CLBP. Similarly, it did not lead to improved outcomes in pain, function, and physical capacity at 6 months. However, the significant improvement in pain, function, and physical parameters between baseline and 6 months in the IG, as well as better qualitative adherence, highlights the usefulness of such a tool in empowering individuals in the daily self-management of CLBP.

Acknowledgments

The authors would like to thank the entire Physical Medicine and Rehabilitation department team for their direct or indirect support in this work.

Funding

This research protocol was funded by the University Hospital of Clermont-Ferrand (AOI funding DGA/AB/MFC 2019-8). No artificial intelligence tools were used in the preparation of this manuscript.

Data Availability

The datasets generated and analyzed during this study are not publicly available due to ethical and legal restrictions related to participant confidentiality and the terms of approval by the ethics committee but are available from the corresponding author upon reasonable request.

Authors' Contributions

JBL designed the protocol, trained the study personnel, maintained the study master record, monitored data collection, and cleaned and analyzed the data. EC, MP, and JBL secured funding, ethics approval, and the research contract. JBL is the guarantor, oversaw participant recruitment, and was the principal investigator responsible for all aspects of the trial. EC was the supervising investigator and oversaw the protocol at the trial site. BP wrote the statistical plan and oversaw the statistical analysis. JBL and MP maintained the study master record, monitored data collection, and cleaned and analyzed the data. EC and MP negotiated the research contract and managed the trial funds. JBL, LD, BP, MP, CL, and EC made intellectual contributions to the paper. JBL, LD, and EC drafted and revised the paper.

Abstract

Background: Accessibility barriers contribute to low participation in center-based cardiac rehabilitation. We developed an innovative, comprehensive, dual-phase telerehabilitation program to address this gap (Smartphone Cardiac Rehabilitation, Assisted Self-Management; SCRAM).

Objective: The study aimed to determine the effectiveness of SCRAM for increasing maximal aerobic exercise capacity (VO_2max).

Methods: A multicenter, parallel 2-arm randomized controlled trial recruited clinically stable adults (aged ≥18 y) with diagnosed coronary heart disease at 3 hospitals in Victoria, Australia (Melbourne, Geelong, and Bendigo) from 2018 to 2021. Participants were randomized (1:1), stratified by sex and study site, to receive SCRAM plus usual cardiovascular care (intervention) or usual cardiovascular care alone (control). SCRAM provided 24 weeks of remote exercise supervision, coaching, and behavior change support via smartphone. Usual cardiovascular care included standard medical care and advice to seek a referral to center-based cardiac rehabilitation, which was heavily impacted during the COVID-19 pandemic. Due to the nature of the treatments, participants were not blinded to allocation; primary outcome assessors and biostatisticians were blinded. The primary outcome was VO_2max at 24 weeks, analyzed on the principle of intention-to-treat, using linear regression adjusted for baseline and stratification factors on multiple imputed data.

Results: Recruitment and data collection were heavily impacted by COVID-19, although SCRAM delivery was sustained throughout. Of 220 required participants, only 123 (56%) were recruited and randomized (intervention n=63, control n=60); 45% (55/123) had missing VO_2max at 24 weeks—largely due to enforced COVID-19 restrictions. Mean VO_2max at 24 weeks favored SCRAM (26.10, SD 10.72 mL/kg/min) over control (24.65, SD 7.87 mL/kg/min), but the difference was not statistically significant (mean difference=1.61 mL/kg/min, 95% CI –1.38 to 4.61, *P*=.28). Among secondary outcomes, patients receiving SCRAM had

XSL•FO
RenderX

lower diastolic blood pressure at 24 weeks (mean difference=–5.54 mm Hg, 95% CI –10.01 to –1.06). All reported adverse events (control n=6, intervention n=16) were deemed mild or moderate, with only one deemed as possibly related to treatment. There were no deaths or hospitalizations.

Conclusions: This was an underpowered trial, but SCRAM did not lead to a clinically important difference in VO_2max compared to usual cardiac care. SCRAM was resilient to COVID-19–related disruptions that significantly impacted the delivery of cardiac rehabilitation and supervised exercise training in particular. Further research is needed to conclusively assess treatment effects and understand how virtual cardiac rehabilitation can be translated into routine practice to augment center-based delivery and enhance equity of access.

Introduction

Cardiovascular disease (CVD) is the leading cause of death and disease burden, globally [1]. Since 1990, the burden of CVD has continued to increase in most countries, with trends driven by changing exposures to harmful risk factors, population growth, and population aging [1]. For people living with CVD, secondary prevention comprising lifestyle modifications, pharmacotherapy, and cardiac rehabilitation is recommended to reduce the risk of recurrent events and is a priority of the World Heart Federation [2].

Cardiac rehabilitation has a class 1a recommendation for management of CVD, particularly for coronary heart disease (CHD) [3-5]. Cardiac rehabilitation programs deliver comprehensive support, education, and monitoring of patients after a cardiovascular event. In a meta-analysis of 85 randomized controlled trials (RCTs) involving 23,430 participants with CVD, exercise-based rehabilitation was associated with significant risk reductions in cardiovascular mortality (risk ratio [RR]: 0.74, 95% CI 0.64 - 0.86, hospitalizations [RR: 0.77, 95% CI 0.67 - 0.89], and myocardial infarction [RR: 0.82, 95% CI 0.70 - 0.96]). There was evidence that cardiac rehabilitation improved health-related quality of life (HRQoL) and was cost-effective [6].

However, low participation rates limit the benefits of traditional center-based (face-to-face) programs [7-11]. Literature shows that 50% - 70% of patients eligible for cardiac rehabilitation do not attend, and among those that do attend, 30% - 60% do not complete their program [12,13]. Barriers to use are diverse and include distance to services and time pressures caused by the need for face-to-face in-hospital or clinical-setting attendance [14]. Evidence-based alternative delivery models are needed to overcome access barriers and improve participation [15,16].

Home-based delivery models have been designed to overcome aforementioned barriers to center-based cardiac rehabilitation. A Cochrane systematic review and meta-analysis of 24 RCTs involving 3046 participants that compared center- and home-based rehabilitation programs reported similar effectiveness for improving clinical, functional, and patient-reported outcomes, and low risk of adverse events [17]. These findings are encouraging, but they also identified a lack of interaction between participants and rehabilitation professionals during home-based delivery.

A small number of trials included in the Cochrane review augmented home-based delivery with digital technologies. Often known as telerehabilitation, this approach has rapidly gained interest because it can support interaction between participants and rehabilitation professionals and enable important program components such as social support and personalization. Indeed, the European Society of Cardiology recently defined telerehabilitation as a key quality indicator for cardiac rehabilitation program accreditation and undertook a Delphi methodology to identify minimum standards for high-quality delivery [18]. Recommendations highlight the potential benefits of both synchronous and asynchronous remote monitoring of exercise training. These approaches have also been outlined by the American Heart Association [19]. Synchronous monitoring involves viewing exercise data live during training sessions and could enable higher levels of responsiveness, personalization, and feedback but is more resource-intensive to deliver. Asynchronous monitoring involves intermittently reviewing previously recorded exercise data and could provide more flexibility for participants and professionals and promote greater autonomy for reducing resource use but offers less interaction and support from rehabilitation professionals [18,20].

These attributes may make synchronous monitoring well-suited during earlier program stages (eg, phase II) and for individuals whose medical and exercise history indicates a need for closer supervision. Conversely, asynchronous monitoring may be well suited for later program stages (eg, phase III and beyond) and for individuals whose medical and exercise history is suitable for more self-directed exercise. These approaches could be combined sequentially to provide a graduated program of long-term support that emphasizes safety and personalization on entry before transitioning toward self-direction and lifelong behavior change.

We previously developed and evaluated the 12-week REMOTE-CR (remote exercise monitoring trial for exercise-based cardiac rehabilitation) telerehabilitation program,

XSL•FO
RenderX

which delivered synchronous remote exercise coaching via smartphone and wearable sensing technologies [21,22]. The effect on maximal aerobic exercise capacity (VO_2max; primary outcome) was noninferior to center-based programs (adjusted mean difference −0.51, 95% CI −0.97 to −1.98 mL/kg/min; *P*=.48; prespecified inferiority margin: −1.25) [23]. REMOTE-CR was also substantially cheaper to deliver and had high usability, acceptability, and end-user demand [23,24].

Following the REMOTE-CR trial, we extended the intervention to include asynchronous exercise and behavioral support for an additional 12 weeks (total 24 wk) and to incorporate evidence-based multifactorial support for self-management behaviors [25] (eg, diet, medication adherence). The extended intervention, named Smartphone Cardiac Rehabilitation, Assisted Self-Management (SCRAM) comprised additional modular components in the form of push notifications that were derived from our previous research studies [26-28] and expert input.

The aims of this study were to compare the effects of the SCRAM intervention on exercise capacity, lifestyle and self-management behaviors, and HRQoL with usual cardiovascular care in adults with CHD.

We hypothesized that SCRAM would augment usual secondary prevention services and improve cardiorespiratory fitness compared to controls. In addition, we hypothesized that SCRAM would have a positive effect on other lifestyle behaviors including diet and physical activity.

Methods

Trial Design

A pragmatic multicenter 2-arm parallel-group RCT was conducted between November 2018 and August 2021. Participant eligibility criteria were unchanged after trial commencement, but enforced COVID-19 restrictions affected recruitment, outcome measurement, and access to usual cardiovascular care. The trial protocol was prospectively registered (ACTRN12618001458224, August 30, 2018), published [29], and reported according to CONSORT (Consolidated Standards of Reporting Trials) guidelines (Checklist 1) [30]. Analyses were outlined in a detailed plan prior to unblinding (Multimedia Appendix 1) with postunmasking changes noted.

Changes to Trial Protocol

Enforced responses to COVID-19 at study sites required a change in the way the primary outcome was measured for some participants (see Outcomes section), and changed delivery of the control treatment (see Control section). Difficulty achieving the target sample size also resulted in changes to the preplanned analyses (Multimedia Appendix 1).

Eligibility and Recruitment

Clinically stable (no hospitalization within 6 wk) adults (≥18 y) with a recent CHD diagnosis (angina, myocardial infarction, and coronary revascularization within 6 mo) were recruited from 3 hospitals (Sunshine Hospital, Western Health; University Hospital Geelong, Barwon Health; Bendigo Hospital, Bendigo Health) in Victoria, Australia (November 12, 2018 to March 21, 2021). Research nurses identified participants from in-patient records and outpatient clinics and provided verbal and written information. Consenting participants were scheduled for baseline assessment.

Intervention

Participants received SCRAM plus usual cardiovascular care. SCRAM has been described fully elsewhere [29], according to recommendations in the Template for Intervention Description and Replication [31]. Briefly, SCRAM was a multicomponent dual-phase intervention that provided participants with a comprehensive, 24-week individualized, evidence-based program of exercise training and modular behavioral self-management support via a bespoke smartphone platform. The SCRAM platform included a Polar wearable sensor, a participant-facing app that is compatible with iOS and Android (≥v5.0) operating systems, and a health professional-facing web app, compatible with mobile and desktop web browsers (Figure 1). Behavior change strategies and education were delivered via staged modular push notifications to support the uptake and maintenance of healthy eating, physical activity, medication taking, stress management, and, if indicated, smoking cessation. Each module provided 2 - 4 notifications per week in weeks 1 - 12 and 1 - 3 notifications per week in weeks 13 - 24. As highlighted above, the additional modules were derived from our previous trials [26-28] as well as expert input from an exercise physiologist (JCR) and dietitian (ESG) to ensure relevance for the Australian context. Participants accessed the smartphone app via Apple and Google Play Stores.

XSL•FO
RenderX

Figure 1. Schematic diagram of the Smartphone Cardiac Rehabilitation, Assisted Self-Management platform.

During weeks 1 - 12, accredited exercise physiologists provided synchronous remote exercise prescription, monitoring, and coaching via the SCRAM platform. Weeks 13 - 24 transitioned participants toward independent, self-determined exercise and behavior change. Exercise physiologists provided weekly coaching phone calls informed by asynchronous review of exercise data, rather than synchronous supervision.

Control

Participants received usual cardiovascular care, including advice to seek referral to center-based cardiac rehabilitation.

Outcomes

Primary Outcome

Maximal oxygen uptake (VO_2max, mL/kg/min) was assessed at baseline and 24 weeks during an incremental treadmill test. When direct measurement (respiratory gas analysis) was precluded by COVID-19 restrictions, VO_2max was estimated from treadmill velocity and gradient using established metabolic equations for treadmill walking (<8 km/h: [velocity {m/min} * 0.1] + [velocity {m/min} * gradient {%} * 1.8]+3.5) or running (>8 km/h: [velocity {m/min} * 0.2] + [velocity {m/min} * gradient {%} * 0.9]+3.5) [32].

Secondary Outcomes

Secondary outcomes are summarized in Table 1. COVID-19 restrictions prevented objective outcome measurement for some participants. Self-reported physical activity was assessed using the Godin Leisure-time Physical Activity Questionnaire [33]. Dietary intake was assessed using the web-based, Automated Self-Administered 24-Hour Dietary Assessment Tool [34-37]. Participants completed the Automated Self-Administered 24-Hour Dietary Assessment Tool for 1 calendar weekday within 3 days of assessment appointments. Alcohol consumption was assessed using the Alcohol Use Disorders Identification Test-C [38], while the Medication Adherence Scale [39] assessed self-reported medication adherence. HRQoL was assessed using the Assessment of Quality of Life 8-Dimension scale [40]. The 8 dimensions include independent living, happiness, mental health, coping, relationships, self-worth, pain, and senses. Methods for prespecified health economic analyses have been reported in detail elsewhere [41], and the results will also be reported separately. We carried out semistructured exit interviews with trial participants, which were categorized under the themes of usability, acceptability, and satisfaction. Process evaluation outcomes using the Reach, Effectiveness, Adoption, Implementation, and Maintenance framework will also be reported as a separate paper.

Vegetable intake (servings/d) via ASA24-Australia[g] [34-37].	✓	✓	✓

[a]Randomized controlled trial, Victoria, Australia. Population: adults with coronary heart disease.

[b]BP: blood pressure.

[c]NA: not assessed.

[d]LSI: leisure score index.

[e]HRQoL: health-related quality of life.

[f]AQoL-8D: Assessment of Quality of Life-8 Dimensions.

[g]ASA24-Australia: Automated Self-Administered 24-Hour Dietary Assessment Tool.

Adverse events were reported at 12 and 24 weeks and classified for severity (mild, moderate, and severe) and likely relationship to study treatment (not related, possible, probable, and definite).

Sample Size

A total of 220 participants were required to detect a clinically important 2 (SD 6.75) mL/kg/min between-group difference in VO_2max at 24 weeks with 2-sided α of .05, 90% power, assuming preintervention and postintervention correlation of 0.8 [42], and 20% attrition [29].

Randomization

An independent biostatistician created a computer-generated randomization schedule, stratified by sex and trial site. Other researchers did not have access to the sequence. Participants were allocated to receive intervention or control treatments at a 1:1 ratio using a centralized web-based system (Research Electronic Data Capture [REDCap]; Vanderbilt University) that ensured allocation concealment until the time of randomization.

Blinding

Due to the nature of the intervention, participants could not be blinded to allocation. Primary outcome assessors and biostatisticians were blinded to allocation. Secondary outcomes were either self-reported or assessed by research nurses or researchers who were not blinded to allocation.

Statistical Analysis

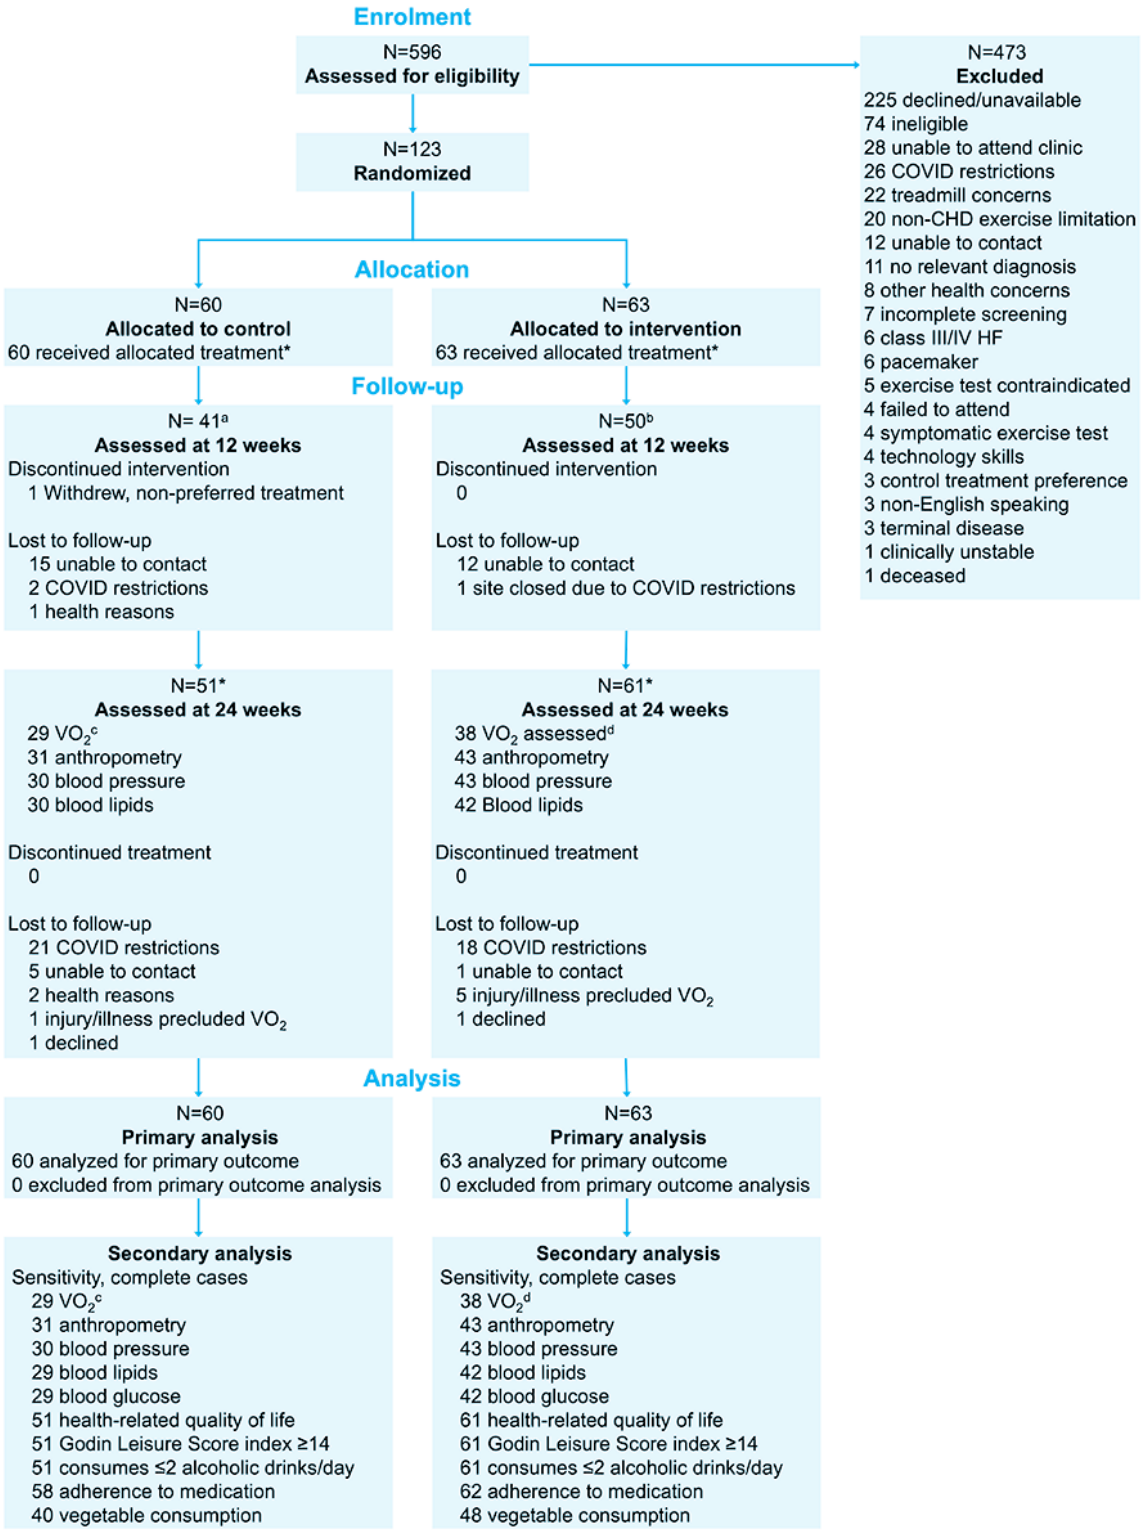
Available data were analyzed according to randomized assignment (ie, intention-to-treat). A linear regression model was fitted to estimate the absolute mean between-group difference in VO_2max at 24 weeks, irrespective of participant adherence, adjusting for baseline VO_2max and stratification factors (sex and study site). Similar analyses were undertaken for continuous secondary outcomes, except for HRQoL. A linear mixed model was fitted for HRQoL accounting for treatment arm, time, treatment arm by time interaction, baseline value, and stratification factors. Logistic regression models with generalized estimating equations were fitted for binary secondary outcomes (physical activity, alcohol consumption, and medication adherence), and an ordinal regression model with clustered standard errors was fitted for vegetable consumption; these models accounted for treatment arm, time, treatment arm by time interaction, baseline values of each outcome and stratification factors, sex, and study site.

Primary analysis used multiple imputations due to high levels of missing follow-up data. Complete case analyses were

XSL•FO
RenderX

undertaken in sensitivity analyses. Per protocol analyses excluded participants with major protocol violations or nonadherence to the SCRAM intervention (recording <12 exercise sessions via the SCRAM app during each of the intensive [wk 1 - 12] and maintenance phases [wk 12 - 24]); these data are presented descriptively by treatment arm due to low numbers. Adverse events are reported descriptively by the treatment arm.

Ethical Considerations



The trial received multisite ethical approval from Melbourne Health (HREC/18/MH/119), which was ratified by Deakin University (2018-251), in accordance with institutional and national guidelines for research involving human participants. All participants were fully informed about the study and the voluntary nature of their involvement, including their right to withdraw at any time without penalty. Written informed consent was obtained prior to participation. Privacy and confidentiality were maintained through deidentification of collected data, which were stored securely on encrypted servers with access restricted to authorized research staff. It is not possible to identify individual participants from any images in the manuscript or supplementary material. Each participant received AUD $50 (US $35.39) shopping vouchers at the completion of baseline and 24-week assessments. Intervention group participants who used their own smartphone and/or data plan received an additional AUD $60 (US $42.46) value to reimburse data use during the intervention at the 24-week assessment.

Results

COVID-19 severely affected the recruitment and collection of objectively measured outcomes. As a result, we were unable to achieve the recruitment target. Randomization and outcome assessments completed pre- and peri-COVID were comparable between groups (Multimedia Appendix 2). Overall, 123 (55.9% of the target) participants were randomized (Figure 2); characteristics are reported in Table 2. Recruitment stopped (March 21, 2021) due to COVID-19 lockdowns and health and safety measures implemented by participating hospitals. The SCRAM intervention was delivered as planned throughout the trial. Delivery of usual care cardiac rehabilitation (control) was frequently disrupted by enforced COVID-19 restrictions, which meant that in some regions, participants may not have been offered in-person, center-based contact. We were unable to quantify the level of contact for control participants.

[c]BP: blood pressure.

[d]Denominators were numbers of participants with diabetes.

[e]PCI: percutaneous coronary intervention.

[f]CABG: coronary artery bypass graft.

Enforced COVID-19 restrictions meant VO_2max could only be assessed in 67 (54.5%; intervention=38 [35 measured, 3 estimated], control=29 [27 measured, 2 estimated] participants at 24 weeks; Figure 2). Using multiple imputation, we found a between-group VO_2max difference at 24 weeks favoring SCRAM, but it was not statistically significant (mean difference=1.61 mL/kg/min; 95% CI −1.38 to 4.61, *P*=.28).

Among secondary outcomes, SCRAM demonstrated a positive effect compared to control for diastolic blood pressure at 24 weeks (mean difference: −5.54 mm Hg; 95% CI −10.01 to −1.06, *P*=.02, Tables 3 and 4). CIs included the null for between-group differences of self-reported secondary outcomes at 12 weeks (Tables 5 and 6).

Table . Primary intention-to-treat analyses of outcomes assessed at 24 wk, using multiple imputed data[g].

Sensitivity analyses, including prognostic factors and complete case analyses, were generally consistent with the primary analyses (Multimedia Appendix 3). Per protocol analyses excluded 19 participants (control n=10, intervention n=9) for eligibility criteria violations (recent CHD diagnosis n=3, clinically stable outpatients n=15, terminal disease n=1) and 42 participants for SCRAM treatment nonadherence (Multimedia Appendix 3).

Among 22 reported adverse events (control n=6, intervention n=16), all were deemed mild or moderate, and only 1 was deemed as possibly related to treatment. There were no deaths or hospitalizations (Multimedia Appendix 4).

As part of the process evaluation, we conducted interviews with 21 trial participants who completed the study (n=11 from the intervention group and n=10 from the control group), 4/21 (19%) of whom were female participants. Participants reported high levels of usability, acceptability, and satisfaction with the SCRAM intervention. Most intervention participants (9/11, 82%) indicated that the technology was simple and easy to use. All participants agreed that SCRAM provided a flexible option for cardiac rehabilitation, allowing them to exercise in locations convenient to them while retaining expert supervision. Those who found SCRAM easy to use expressed high satisfaction with the intervention, particularly valuing the expert supervision, synchronous coaching, and activity-monitoring features.

Discussion

Principal Findings

This study sought to compare the effects of the SCRAM intervention on cardiorespiratory fitness, lifestyle and self-management behaviors, and HRQoL with usual cardiovascular care in adults with CHD. Overall, we found beneficial directional effects on the primary and selected secondary outcomes that favored the SCRAM intervention, but our findings are inconclusive as we were unable to recruit the a priori target sample size.

Unfortunately, the COVID-19 pandemic severely impacted this trial. We did not achieve our desired sample size, and follow-up data were lost due to enforced closures within the Australian health care services during this trial. While beneficial directional effects were generally consistent with our previous effectiveness trial [23], a lack of statistical power renders our findings, and any comparisons to previous cardiac telerehabilitation research, inconclusive. Nonetheless, it is important to report the trial to avoid publication bias [44].

Key findings were the resilience of telerehabilitation to severe cardiac rehabilitation service disruption, and its potential to deliver multifactorial supervised exercise and self-management behavioral support regardless of participants' geographic proximity to traditional center-based cardiac rehabilitation

XSL•FO
RenderX

facilities. The COVID-19 pandemic was unforeseen at the outset of our trial but significantly impacted global center-based cardiac rehabilitation delivery during the trial period, and telehealth quickly became the only safe and preferred delivery option [45-49]. Supervised exercise training was the most impacted program component globally, with approximately 76% of center-based programs reporting moderate to high impact due to COVID-19–related safety concerns [45]. While the SCRAM telerehabilitation intervention was not originally designed for such circumstances, its design enabled continuous delivery throughout COVID-19 restrictions in one of the world's most locked down regions.

Despite these drawbacks, this trial provides insights about a number of important issues that have been highlighted for high-quality telerehabilitation. Remote exercise monitoring, such as that provided during the first phase of the SCRAM intervention, was identified as an important component of effective telerehabilitation [50] and was recently advocated as a preferred standard to optimize individualization and risk management [18]. Synchronous monitoring is desirable because it enables rehabilitation professionals to verify exercise individual responses, tolerability, and clinical stability via heart rate, electrocardiogram, and symptoms [18]. This could play an essential role in intervention effectiveness by avoiding protective risk mitigation strategies such as overly conservative exercise prescription, which has been used in the context of unsupervised home-based exercise training [51]. Indeed, rehabilitation professionals have reported synchronous monitoring could be a useful tool to mitigate adverse event risk by enabling higher quality individualization and progression of exercise training [51].

Telerehabilitation standards also highlight the use of center-based cardiopulmonary exercise testing as a gold standard component of routine pre- and postprogram assessment [18]. Our trial included cardiopulmonary exercise testing, but it was not possible for all the participants. This was related to COVID-19 during our trial but could manifest in numerous ways that contradict key aims of telerehabilitation. For example, precluding participants who are most in need of alternative delivery methods because they cannot attend clinical centers for requisite preprogram assessment. Our adapted exercise testing method removed measurement of respiratory gas exchange to manage the risk of viral transmission but was still conducted at clinical centers. A systematic review of remote exercise testing methods in cardiac rehabilitation found that this is an underexplored area, with limited evidence demonstrating the validity of the six-minute walk test [52]. While this is commonly used in many clinical settings, it does not provide comparable data to cardiopulmonary exercise testing. This highlights an urgent need for evidence-based methods for remotely measuring exercise capacity as part of preintervention and postintervention assessments.

Cardiac rehabilitation interventions should comprehensively provide all evidence-based core components, regardless of the delivery model [18]. The SCRAM intervention improved upon our earlier REMOTE-CR intervention [23] by adding multifactorial behavior change education and support. However, this was delivered via push notifications rather than more intensive teleconsultation methods that have been recommended [18], and did not provide all types of recommended support over and above exercise training [11,53,54]. The predominance of physical activity and exercise-related features is common in cardiac telerehabilitation [19]. While exercise training is a pivotal part of comprehensive cardiac rehabilitation [55], these gaps represent areas for improvement to ensure alignment with best practices in cardiac rehabilitation.

The exercise monitoring features of SCRAM were well suited for monitoring aerobic exercise performance but less capable of monitoring key aspects of strength exercise such as volume, load, and technique. Since strength exercise is also an important component of cardiac rehabilitation [55,56], this represents another area of opportunity to ensure telerehabilitation more fully aligns with best practices in cardiac rehabilitation.

Strengths and Limitations

Our trial included a robust multicenter design, an objective primary outcome [57], a large diverse geographic area (including urban and regional sites), and an intervention that aligns with contemporary standards in cardiac telerehabilitation [18]. There were several limitations of our trial. First, despite considerable effort, COVID-19 response policies enforced at trial sites meant we could not recruit the required number of participants, which meant the study was underpowered. Also, due to enforced closures at the study sites, there was a large amount of missing follow-up data. Results need to be interpreted cautiously with these considerations in mind. Second, self-reported data for some outcomes had to be collected via telephone. Third, COVID-19 restrictions impacted access to in-person center-based cardiac rehabilitation services for control group participants, although they could access other telehealth services if offered by the trial sites. As a result, our comparator of usual care changed throughout the conduct of this trial. Ours was not the only trial affected by the COVID-19 pandemic. A recent paper highlighted the need to acknowledge its impact on study conduct, and the importance of reporting findings despite this [58].

Implications

Uninterrupted delivery across a large geographic area throughout the COVID-19 pandemic demonstrated promising capability to reinforce and augment center-based cardiac rehabilitation by addressing barriers that contribute to suboptimal and inequitable access. Further research is needed to conclusively assess treatment effects and understand how the SCRAM telerehabilitation platform can be translated into clinical practice.

Conclusion

This was an underpowered trial and findings were inconclusive, but SCRAM did not lead to a clinically important difference in VO_2max compared to usual cardiac care. SCRAM was resilient to COVID-19–related disruptions that significantly impacted the delivery of cardiac rehabilitation and supervised exercise training in particular. The SCRAM telerehabilitation intervention aligns with several contemporary standards for cardiac telerehabilitation, and further research is needed to conclusively assess treatment effects and understand how cardiac

XSL•FO
RenderX

telerehabilitation can be translated into routine practice to augment center-based delivery and enhance equity of access.

Acknowledgments

The authors gratefully acknowledge their funding organization (Australian National Health and Medical Research Council), study participants, health care practitioners and providers at trial sites, and key project personnel Jessica Freeman and Emily Scanlan.

Funding

Australian National Health and Medical Research Council Project grant (1144331).

Data Availability

The datasets generated and/or analyzed during this study are available from the corresponding author upon reasonable request, subject to compliance with ethical approval.

Authors' Contributions

RM conceived the trial and procured funding. BO, CC, SAM, LG, MM, JA, VN, CN, KEL, and JCR contributed to the study design, intervention development, and trial conduct. ESG also contributed to the intervention development. PLM and KEL developed the statistical analysis plan with RM and JCR and undertook all analyses. NS, RM, and JCR drafted the manuscript. All authors critically reviewed and approved the manuscript.

Conflicts of Interest

RM and JCR are inventors of the Smartphone Cardiac Rehabilitation, Assisted Self-Management software platform. Behavior change support built on work initiated by RM and JCR at the University of Auckland's National Institute for Health Innovation, and included contribution from ESG. The authors declare no financial or competing interests.

Abstract

Background: Respiratory dysfunction frequently occurs during the acute phase of stroke and is associated with reduced ventilatory capacity, respiratory muscle weakness, and increased pulmonary complications. However, delivering standardized respiratory training during hospitalization is often constrained by staffing and service continuity.

Objective: This study aimed to evaluate the efficacy, safety, and feasibility of a hospital-based comprehensive mobile-based respiratory training program (CMRTP) added to conventional rehabilitation in people with acute stroke who are inpatients.

Methods: This single-center, assessor-blinded randomized controlled trial enrolled 40 patients within 2 weeks after stroke onset with respiratory dysfunction (forced vital capacity <80% predicted). Participants were randomized (1:1) to CMRTP plus conventional rehabilitation or conventional rehabilitation alone. The CMRTP was delivered via the WeChat-based AIRHUB platform and performed 20 minutes twice daily, 5 days per week for 2 weeks, either independently or with caregiver assistance as needed. The primary outcome was change in forced vital capacity from baseline to week 2. Secondary outcomes included forced expiratory volume in 1 second (FEV_1), peak expiratory flow, maximal inspiratory pressure, maximal expiratory pressure, and modified Barthel index. All outcomes were assessed face-to-face by a blinded senior physician, and all analyses followed an intention-to-treat principle.

Results: Of 56 screened patients, 40 were randomized, and 39 completed the study. Adherence to the CMRTP reached 96%, and no serious adverse events occurred; mild, transient events (fatigue, dizziness, and hyperventilation) were recorded. Compared with the control group, the CMRTP group demonstrated greater improvement in forced vital capacity at week 2 (mean difference 0.77 L; 95% CI 0.39 - 1.16; P<.001; η^2=0.32), with additional between-group differences in maximal inspiratory pressure (P=.001; η^2=.25), maximal expiratory pressure (P<.001; η^2=.08), and modified Barthel index (P=.001; η^2=.26). No significant group differences were found for forced expiratory volume in 1 second or peak expiratory flow.

Conclusions: A 2-week hospital-based mobile respiratory training program is feasible and safe in people with acute stroke who are inpatients and yields clinically meaningful improvements in respiratory function and daily functional performance when added to conventional rehabilitation.

Introduction

Stroke is the second-leading cause of death and the third-leading cause of disability worldwide, imposing a substantial burden on society and families [1]. Advances in acute stroke management have improved survival rates; however, most survivors experience persistent functional impairments [2]. In addition to motor, sensory, swallowing, and speech impairments, stroke frequently induces respiratory dysfunction during the acute stage [3]. Recent studies indicate that 18% to 88% of patients with stroke exhibited abnormal breathing patterns [4], while 44% to 90% present with respiratory failure syndrome of varying severity [5]. Furthermore, 7% to 38% develop pneumonia within the first week after the onset of acute stroke [6], underscoring the urgent need for effective interventions to improve respiratory function.

Clinical guidelines advocate early respiratory monitoring and intervention to mitigate poststroke respiratory complications, emphasizing an integrated care that includes physical and respiratory rehabilitation [7]. Previous studies have demonstrated that respiratory muscle training and breathing exercises, such as diaphragmatic, air-stacking, and pursed-lip breathing, can improve respiratory muscle strength, pulmonary function, and functional capacity during early stroke rehabilitation [8-12]. However, the implementation of respiratory interventions in stroke rehabilitation remains limited by multiple clinical constraints, including insufficient staffing and inconsistent service delivery [13-16]. In many health care settings, rehabilitation services are delayed or underused due to the prioritization of acute medical management, leaving survivors with stroke with inadequate support for respiratory dysfunction [17-19]. In this context, telerehabilitation may represent a promising alternative for delivering timely and accessible respiratory rehabilitation interventions.

Telerehabilitation has emerged globally as a promising approach to improving access to and continuity of stroke rehabilitation services, attracting widespread attention [20,21]. Chen et al [22] reported that telerehabilitation has been widely applied in stroke rehabilitation and provided effects comparable to conventional rehabilitation in improving motor function among survivors with stroke. Linder et al [23] demonstrated that mobile-based exercise interventions can effectively enhance quality of life and alleviate depressive symptoms among individuals recovering from stroke. In addition, Sun et al [24] found that telerehabilitation can effectively reduce caregiver burden. Moreover, a growing body of evidence from high-income countries supports the feasibility, safety, and effectiveness of telerehabilitation in the postacute and chronic phases of stroke recovery [25-27]. However, despite these encouraging findings, the application of telerehabilitation during the acute hospitalization phase of stroke remains largely unexplored.

Therefore, this study aimed to evaluate the effectiveness of a 2-week hospital-based comprehensive mobile-based respiratory training program (CMRTP) on respiratory function in patients with acute stroke, and to explore its safety and feasibility for early inpatient rehabilitation. We hypothesized that integrating CMRTP with conventional rehabilitation would yield greater improvements in respiratory function, without increasing the incidence of adverse events.

Methods

Design

We conducted an assessor-blinded, parallel group, randomized controlled trial at Sichuan Mianyang 404 Hospital (Mianyang, Sichuan, China) from September 2024 to March 2025. This study was prospectively registered with the Chinese Clinical Trial Registry (ChiCTR2400088647). The study adhered to the CONSORT (Consolidated Standards of Reporting Trials) statement guidelines (Checklist 1) [28], and all procedures complied with the Declaration of Helsinki.

Participants

Participants were recruited from the inpatient departments of Rehabilitation Medicine, Neurology, and Neurosurgery through electronic medical records screening. A physician (GQ) screened potential participants based on the eligibility criteria.

Participants were eligible if they met the following criteria: (1) aged 18 - 75 years; (2) diagnosed with stroke according to the Diagnostic Criteria of Cerebrovascular Diseases [29]; (3) first-ever unilateral ischemic stroke confirmed by neuroimaging; (4) stroke onset within 2 weeks; (5) respiratory dysfunction, defined as forced vital capacity (FVC) <80% predicted value [30]; and (6) either the participants or their caregivers were proficient in reading Chinese characters and in operating a smartphone or tablet.

Participants were excluded if they met any of the following criteria: (1) cognitive deficits (Mini-Mental Score Examination scores for patients with stroke: illiterate <17 points, primary school education <20 points, and junior high school education and above <24 points) or inability to understand the instructions provided by researchers; (2) having other diseases, surgeries, or injuries that may interfere with respiratory function training (like severe lung infections, tracheostomy intubation, myasthenia gravis, phrenic nerve paralysis, severe facial paralysis, oropharyngeal structural abnormalities, a history of chest or abdominal surgery or rib fractures within the past year); or (3) refuse or withdraw from this research.

Randomization and Blinding

Patients were randomly assigned in a 1:1 ratio to either the experimental group (the CMRTP plus conventional rehabilitation) or control group (conventional rehabilitation only) using a computer-generated randomization sequence (IBM SPSS version 29). Allocation concealment was ensured by a research assistant, who was not involved in sequence generation or participant enrollment, using sequentially numbered, sealed, opaque envelopes. Each envelope was opened only after a participant had been formally enrolled, and the assigned intervention was then revealed. Outcome assessors and data analysts were blinded to group allocation throughout the trial.

XSL•FO

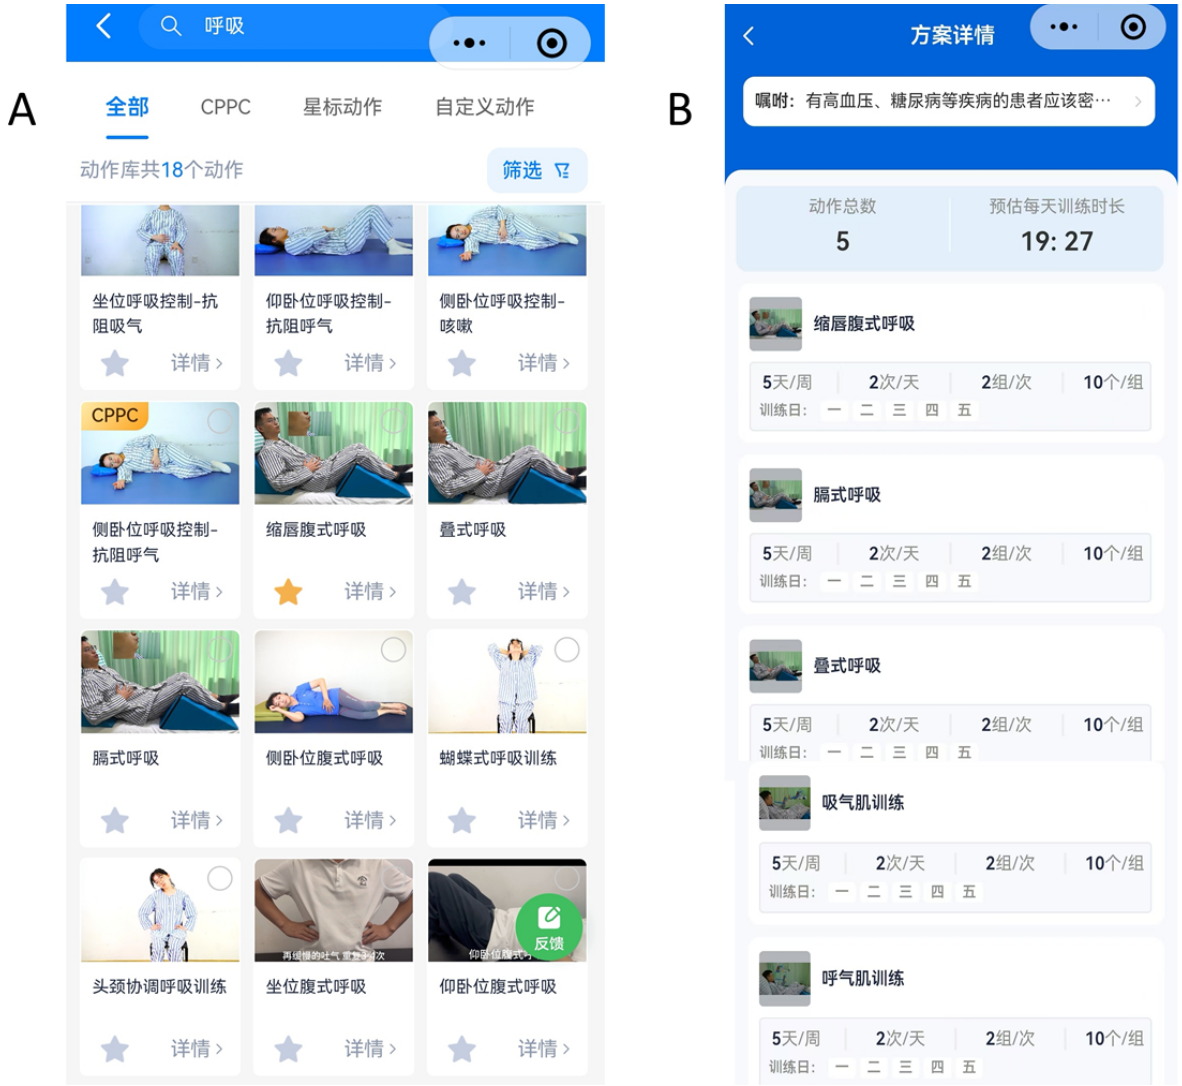
Intervention



Overview

Patients in the experimental group received the CMRTP plus conventional rehabilitation, while the control group received conventional rehabilitation alone, without specific respiratory training. Conventional rehabilitation was administered by two licensed physiotherapists for 40 minutes per session, once daily, 5 days per week, over a 2-week period. The CMRTP was delivered via the AIRHUB platform (a mobile WeChat-based applet, AIRHUB TECH) by two licensed physiotherapists (JY and Z-KM), with 20 minutes per session, twice daily, 5 days per week for 2 weeks.

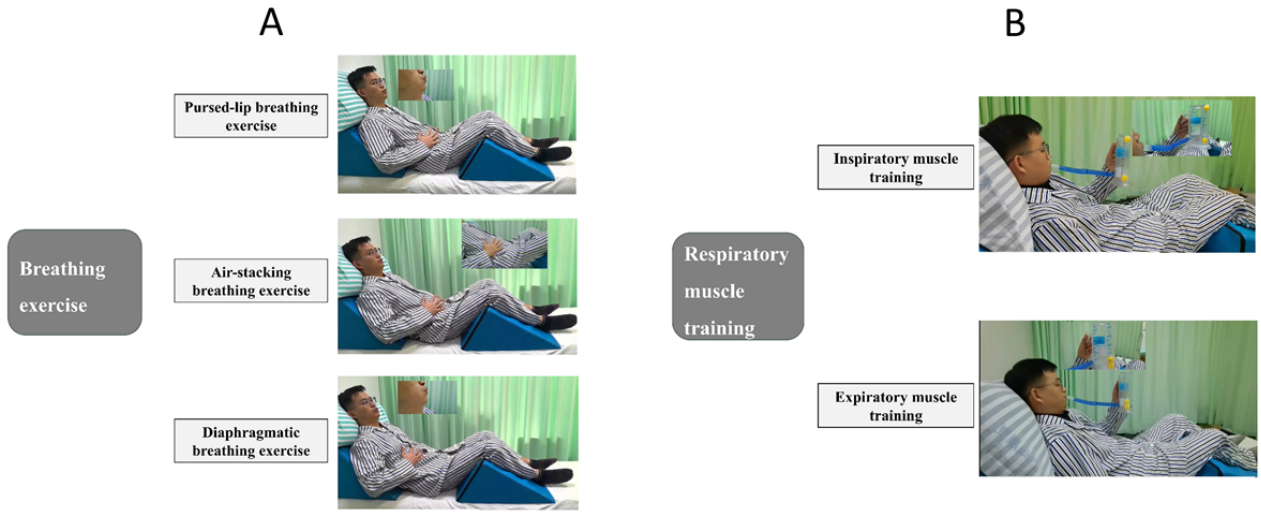
The CMRTP Intervention

The AIRHUB platform is a WeChat Applet–based telerehabilitation system consisting of a cloud-based server, a therapist interface (Figure 1), and a patient interface (Figure 2). The therapist interface provides access to an exercise video library, remote prescription and monitoring modules, and real-time feedback collection, while the patient interface allows video-guided exercises, automatic performance recording, and submission of postsession feedback. All data are synchronized securely to the cloud, enabling therapists to review adherence and feedback. The platform supports multiuser access and modular expansion, allowing integration with other rehabilitation programs and scalability to multicenter use. To protect privacy, all patient data are encrypted, deidentified, and accessible only to authorized personnel, in accordance with data protection standards aligned with the principles of the HIPAA (Health Insurance Portability and Accountability Act).

Figure 1. Therapist interface of the AIRHUB platform. (A) Video library and (B) comprehensive mobile-based respiratory training program.

XSL•FO
RenderX

Figure 2. Patient interface of the AIRHUB platform (A: exercise plan; B: feedback submission).



In the experimental group, two licensed physiotherapists (YJ and Z-KM) provided guidance to patients or their caregivers on the proper use of the AIRHUB platform for 2 hours, including the login process, conducting respiratory training, and performing movements correctly as demonstrated in the instructional videos prior to the intervention. After confirming that participants had achieved adequate training proficiency, the physiotherapists guided them to register a personal account on the patient interface using their own mobile phone number. The physiotherapist then logged into the therapist interface, selected the corresponding CMRTP videos from the motion library, and sent them to the individual patient interface.

The CMRTP consisted of 5 exercises, including breathing exercises and respiratory muscle training (Figure 3; details are mentioned in Multimedia Appendix 1), each accompanied by audio cues and written instructions. Each exercise was performed 5 times, with a 20-second rest interval between each exercise. After completing all exercises, the entire plan was repeated once. During the intervention, participants accessed the CMRTP via the patient interface, where they followed standardized demonstration videos and audio instructions to perform the exercises synchronously, and the playback speed could be adjusted as needed. Upon completion, the patient provided feedback through a platform-based questionnaire, and the therapist supervises the training remotely via WeChat or mobile video calls as they needed.

XSL•FO
RenderX

Figure 3. Breathing exercises and respiratory muscle training in AIRHUB. (A) Breathing exercises and (B) respiratory muscle training.

To ensure adherence and track progress, two licensed physiotherapists (YJ and Z-KM) reviewed the training status, such as session duration and questionnaire responses, three times weekly via the AIRHUB platform to evaluate overall completion. When potential issues were identified during monitoring, the responsible physiotherapist would promptly reach out to the participant and offer support. Moreover, the primary nurse provided supervision and reminders to patients and caregivers. If a patient did not engage for three consecutive days, the system automatically triggered a SMS text message reminder. In cases where no training activity was recorded thereafter, the physiotherapist conducted a follow-up telephone call to identify barriers and encourage continued participation.

Conventional Rehabilitation

Conventional rehabilitation [8] was provided by 2 licensed physiotherapists (QCW and HHJ), including the following exercises: (1) joint range of motion exercises in bed, (2) maintaining proper limb positioning in bed, (3) turning exercises, (4) positional transfer training, (5) sitting exercises in bed, and (6) standing exercise (if feasible). If necessary, occupational and speech therapy may also be included.

Assessments and Outcomes

All baseline evaluations were independently performed by a research coordinator after participant enrollment. Primary and secondary outcomes were assessed at baseline (T0), week 1 (T1), and week 2 (T2) following randomization. Outcome assessments were completed face-to-face by a senior physician (HHJ).

Primary Outcome

The primary outcome was the change in FVC from baseline to week 2. FVC, defined as the total volume of air exhaled during a maximal forced expiration following a full inspiration, was used to evaluate overall improvements in respiratory function for patients with acute stroke [31,32]. The minimal clinically important difference for FVC was preset at a 5% predicted increase [33,34]. FVC was measured in liters using standardized spirometry (Breath Home, Home Sun Int.) in accordance with American Thoracic Society and European Respiratory Society standard guidelines [35-38]. FVC was measured three times per assessment, with the highest value used for analysis.

Secondary Outcomes

The secondary outcomes included forced expiratory volume in 1 second (FEV_1) and peak expiratory flow (PEF) to assess airflow dynamics [39], maximal inspiratory pressure (MIP) and maximal expiratory pressure (MEP) to measure respiratory muscle strength [40], and the modified Barthel Index (MBI) to evaluate functional performance in daily activities [41]. Feasibility (adherence rate) and safety (adverse events) were also examined as secondary endpoints. FEV_1, PEF, MIP, and MEP were measured using the same spirometry device (Breath Home), and MBI was assessed using a validated scale by the same physician following standardized procedures.

Sample Size

The sample size calculation was conducted via G*power of 3.1.9.7 based on the result of the FVC in a published similar study [33,42], which indicated an estimated effect size of f=0.27. Other parameters were set as follows: a significance level of α=.05 (two tails), power (1–β)=95%, correlation among repeated measures=0.5, nonsphericity correction ε=1, number of measurements=3, and number of groups=2. Therefore, a sample size of n=32 was obtained. After allowing for a 20% attrition, a minimum total of 40 participants was needed.

Statistical Analysis

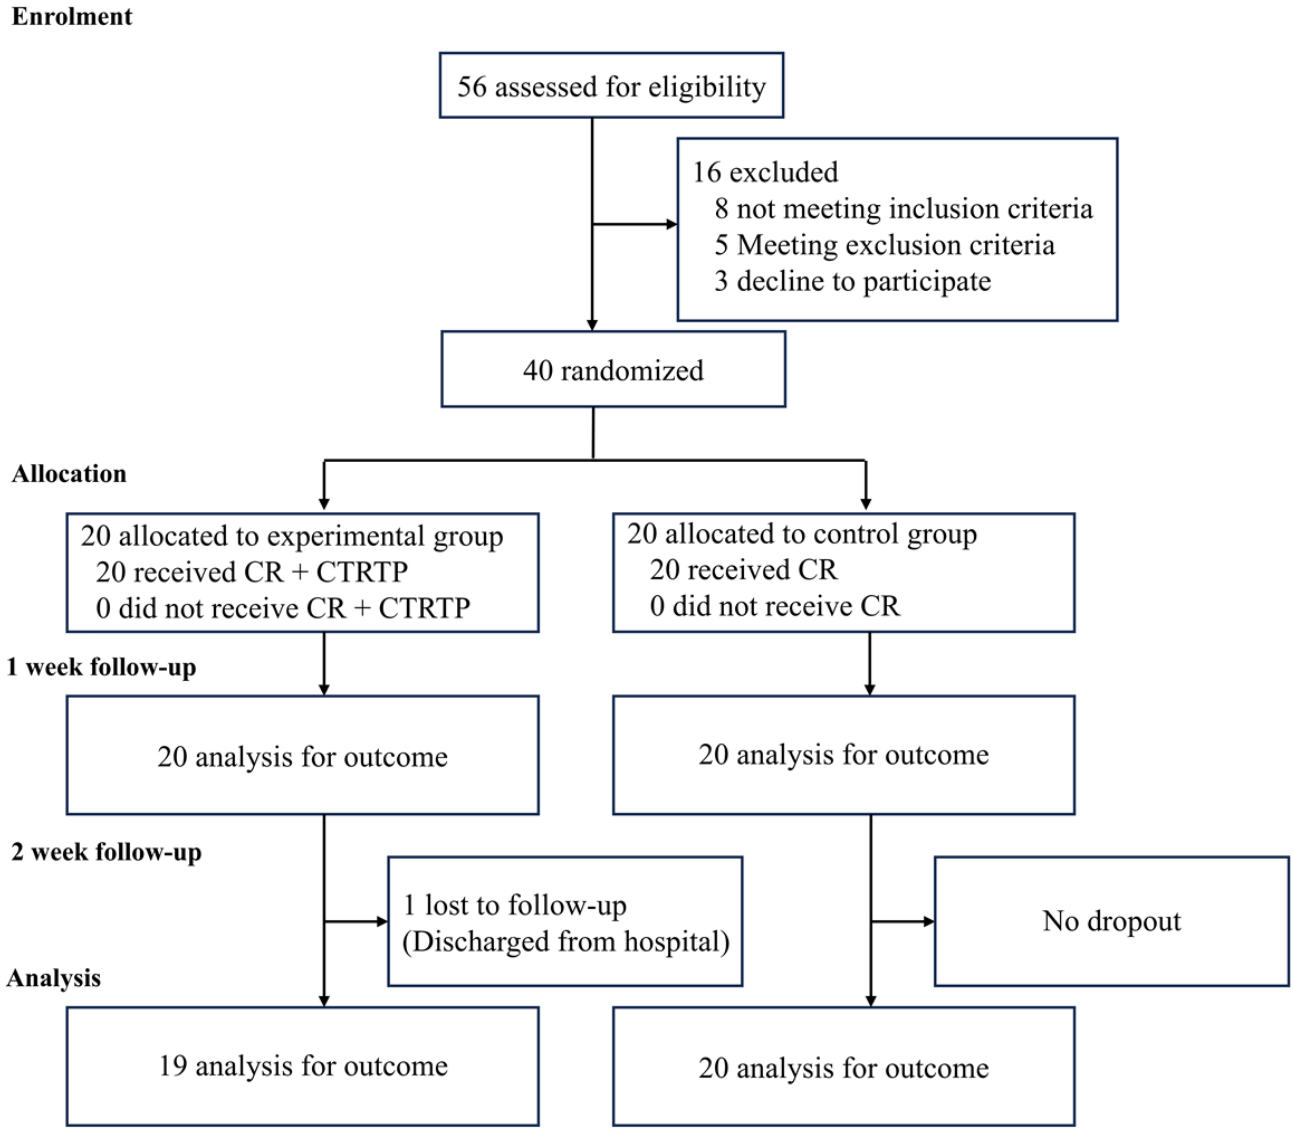
Baseline assessments included patient characteristics, FVC, FEV_1, PEF, MIP, MEP, and MBI. All data were analyzed using an intention-to-treat approach, with missing values imputed via the last observation carried forward method.

Statistical analyses used IBM SPSS version 29 (IBM Corp). The Shapiro-Wilk test assessed data normality, and the Levene test was applied to assess the homogeneity of variances. Continuous variables were reported as mean and SD values, ordinal variables as median with IQR values, and categorical variables as numbers with percentages. Baseline characteristics

XSL•FO
RenderX

were compared using *t* tests for normally distributed continuous variables, Mann-Whitney *U* tests for nonnormally distributed or ordinal variables, and chi-square tests for categorical variables. Repeated measures analysis of covariance (ANCOVA) evaluated between-group differences across time points, adjusting for baseline values, with least squares mean differences (least squares [LS] mean differences) estimated to quantify treatment effects. Fixed effects included group, time, and time× group interaction, with participant and National Institutes of Health Stroke Scale (NIHSS) as a random effect. The Mauchly test assessed sphericity, with Greenhouse-Geisser correction applied if violated. Bonferroni correction was applied only to unplanned post hoc pairwise comparisons. The primary outcome was not adjusted for multiple comparisons. For secondary outcomes, Bonferroni correction was applied to control the risk of type I error. Significance was set at $P<.05$ (2-tailed) for the primary outcome and $\alpha<.025$ (2-tailed) for others.

Ethical Considerations



The study was approved by the Ethics Committee of Sichuan Mianyang 404 Hospital (ethics reference: 2023‐051). Written informed consent was obtained from all participants prior to enrollment after they had received a full explanation of the study procedures. All data were anonymized to protect participant privacy and confidentiality. No financial compensation was provided to participants. To ensure participants' safety, all potential adverse events were predefined and explicitly described in the informed consent form. Adverse events were monitored by the physiotherapists responsible for the intervention in the experimental group. Potential adverse events associated with tele-respiratory training included fatigue, tiredness, dizziness, headache, falls, worsening neurological function, hyperventilation, hypoventilation, decreased oxygen saturation, hypertension, and tachycardia. If any adverse events occur during the intervention, caregivers or primary nurses would immediately inform the patient's attending physician and take appropriate measures. All adverse events associated with conventional rehabilitation or CMRTP were recorded on the case report form for final analysis.

Results

A total of 56 patients were screened for eligibility, and 40 were enrolled in the study. Of these, 20 were randomly assigned to the intervention group and 20 to the control group (Figure 4). One participant in the intervention group withdrew during the second week due to hospital discharge. Regarding treatment adherence, participants in the experimental group completed 192 of the 200 prescribed training sessions (96%), whereas those in the control group completed all 100 assigned sessions (100%). Outcome data for analysis were available for 100% (N=40) of participants at T1 and 97.5% (39/40) at T2. Nonserious adverse events considered reasonably or definitely related to study procedures were recorded in 10 sessions in the experimental group (including fatigue, dizziness, and hyperventilation) and in 3 sessions in the control group (including fatigue and tiredness). All events were transient and mild, and no serious adverse events occurred in either group.

Figure 4. The CONSORT (Consolidated Standards of Reporting Trials) flow diagram of the trial. CR: conventional rehabilitation; CMRTP: comprehensive mobile-based respiratory training program.

The baseline clinical characteristics of the patients, shown in Table 1, were generally comparable between the experimental and control groups. All included patients had moderate stroke with notable functional impairments affecting daily activities. The mean (SD) age was 62.5 (SD 10.57) years. The experimental group exhibited slightly greater stroke severity than the control group (mean NIHSS score 7.30, SD 1.75 vs 5.75, SD 1.97; P=.01), while other clinical features were comparable between groups.

For the primary outcome, the analysis of FVC revealed significant main effects in both the time ($F_{1,37}=41.12$; $\eta^2=0.52$; $P<.001$) and time×group interaction effect ($F_{1,37}=4.50$; $\eta^2=0.12$; $P=.008$), without group effect ($F_{1,37}=4.05$; $\eta^2=0.10$; $P=.05$; Table 2). The FVC at week 2 increased by 1.12 L (95% CI 0.43 - 1.81) in the experimental group and 0.58 L (95% CI 0.02 - 1.14) in the control group, a significant difference was observed between the groups at week 2 (LS mean 0.77, 95% CI 0.39 - 1.16; $\eta^2=0.32$; $P<.001$; Figure 5). The improvements of both groups exceeded the minimal clinically important difference (5%), but the experimental group showed a greater improvement (Table 3).

As for secondary outcome in Tables 2 and 3, there was no significant main effect of group for FEV_1 ($F_{1,37}$=2.21; η^2=0.06; P=.15), PEF ($F_{1,37}$=1.89; η^2=0.05; P=.18), whereas MIP ($F_{1,37}$=14.49; η^2=0.28; P<.001), MEP ($F_{1,37}$=10.54; η^2=0.20; P=.002), and MBI ($F_{1,37}$=7.56; η^2=.17; P=.009) reached statistical significance. The main effect of time for FEV_1 ($F_{0.83,30.71}$=6.86; η^2=0.16; P=.004), PEF ($F_{0.83,30.71}$=1.37; η^2=0.14; P=.008), MIP ($F_{1,37}$=7.66; η^2=0.17; P<.001), and MBI ($F_{1,37}$=10.07; η^2=0.21; P<.001) showed significant differences, but not on MEP ($F_{0.76,28.12}$=1.37; η^2=0.04; P=.26) at weeks 1 and 2. Significant group×time interactions were found for MIP ($F_{1,37}$=7.28; η^2=0.16; P=.001), MEP ($F_{0.76,28.12}$=4.62; η^2=0.11; P=.02), and MBI ($F_{1,37}$=3.35; η^2=0.08; P=.04), but not for FEV_1 ($F_{0.83,30.71}$=1.25; η^2=.00; P=0.29) and PEF ($F_{0.83,30.71}$=1.66; η^2=0.04; P=.20). Compared with baseline, the experimental group exhibited significant increases in FEV_1 ($F_{1.66,31.54}$=21.48; η^2=0.53; P<.001), PEF ($F_{1.66,31.54}$=19.09; η^2=0.50; P<.001), MIP ($F_{2,38}$=41.48; η^2=0.69; P<.001), MEP ($F_{1.52,28.88}$=21.59; η^2=0.53; P<.001), and MBI ($F_{2,38}$=90.42; η^2=0.83; P<.001), whereas the control group showed significant increases in FEV_1 ($F_{1.66,31.54}$=10.74; η^2=0.36; P<.001), MIP ($F_{2,38}$=8.50; η^2=0.31; P<.001) and MBI ($F_{2,38}$=90.42; η^2=0.85; P<.001), but not in PEF ($F_{1.66,31.54}$=2.99, η^2=0.14; P=.07) and MEP ($F_{1.52,28.88}$=0.48; η^2=0.03; P=.55). Compared with the control group, the experimental group had no baseline differences (P>.05 for FEV_1 , PEF, MIP, MEP, and MBI), and showed significant improvements at week 2 in MIP (LS mean 11.38, 95% CI 4.69 - 18.08; η^2=0.25; P=.001), MEP (LS mean 17.85, 95% CI 9.92 - 25.77; η^2=0.08; P<.001), and MBI (LS mean 9.92, 95% CI 3.90 - 14.53; η^2=0.26; P=.001; Figures 6 and 7), as well as in MIP at week 1 (LS mean 10.83, 95% CI 4.12 - 17.54; η^2=0.23; P=.002). No difference was found between the groups in the FEV_1 and PEF at any assessment time point, which may be due to the short intervention duration and the limited sensitivity of these measures to detect subtle respiratory changes.

Figure 7. Between-group temporal changes in modified Barthel index. Mean (SD) values are shown at baseline (T0), week 1 (T1), and week 2 (T2). The experimental group exhibited greater improvement than the control group at T2 (**P=.001). MBI: modified Barthel index.

Discussion

This randomized controlled trial demonstrated that a 2-week, hospital-based CMRTP combined with conventional rehabilitation significantly improved respiratory function and daily functional performance compared with conventional rehabilitation alone in patients with moderate acute stroke. Importantly, no serious adverse events were reported, and the mobile-based platform (AIRHUB) was feasible for implementation in inpatient acute stroke care. To our knowledge, this was the first study to establish the efficacy of a mobile-based respiratory program as a safe and effective adjunct to standard care during the acute phase of stroke.

Compared with prior studies [8,43,44], the experimental group demonstrated comparable improvements in respiratory function, respiratory muscle strength, and daily activities in patients with acute stroke. Choi et al [8] reported that a 4-week comprehensive respiratory muscle training program, incorporating air-stacking and respiratory muscle strengthening, led to significant improvements in FVC and MEP in patients with acute stroke. Similarly, Yoo et al [43] found that delivering the same protocol at the bedside over three weeks resulted in increases in FVC, FEV_1, and MBI. In another study, Wei et al [44] found that a 12-week intervention combining respiratory muscle training, pursed-lip breathing, and diaphragmatic breathing improved FVC, FEV_1, respiratory muscle strength, and MBI in patients with stroke.

FVC, as a comprehensive indicator of ventilatory capacity, was particularly sensitive to changes in respiratory muscle performance [43]. Given the prevalence and clinical relevance of respiratory dysfunction in acute stroke, FVC provided an objective and meaningful measure to evaluate the efficacy of respiratory interventions [45]. In this study, both groups showed improvements in FVC after 2 weeks of intervention, but the experimental group achieved greater gains. These intergroup differences were unlikely to be attributed to spontaneous recovery alone but were more plausibly linked to the structured and synergistic design of the CMRTP, encompassing both muscular and neurological mechanisms.

The observed improvements in respiratory function likely resulted from multilevel adaptations involving both central neural remodeling and peripheral muscular strengthening. The acute poststroke phase represented a critical window of heightened neuroplasticity [46], during which axonal sprouting and synaptic reorganization occur at an accelerated rate [47]. Previous studies showed that exercise can facilitate long-term

XSL•FO
RenderX

potentiation–like synaptic plasticity, enhancing functions such as memory and fine motor skills [48,49]. Structured and repetitive respiratory exercises—such as diaphragmatic breathing, pursed-lip breathing, and air-stacking—might elicit similar effects by providing continuous sensory and proprioceptive input to cortical and brainstem respiratory centers, reinforcing sensorimotor pathways and supporting circuit-level functional recovery [50]. In addition to synaptic mechanisms, respiratory training might promote neuroplasticity at the molecular level. Exercise was shown to upregulate the expression of mature brain-derived neurotrophic factor, a key modulator of synaptic strength and corticospinal connectivity [51,52]. These effects might enhance the cortical drive to spinal respiratory motor neurons, facilitating compensatory activation and improving voluntary control over respiratory muscles [53-55].

Peripherally, the CMRTP targeted both inspiratory and expiratory muscle groups through focused protocols. Inspiratory exercises and air-stacking primarily strengthened the diaphragm and intercostal muscles [56], whereas pursed-lip and expiratory resistance breathing enhanced the performance of abdominal and accessory expiratory muscles [57-59]. These interventions likely contributed to the significant improvements in MIP and MEP observed in the intervention group. Repeated mechanical loading and neuromuscular activation might have enhanced motor unit recruitment, firing efficiency, and muscle coordination within the respiratory system [60,61]. Together, these central and peripheral adaptations improved respiratory mechanics and endurance, which might have translated into better exercise tolerance and reduced dyspnea. As a result, participants could engage more effectively in physical rehabilitation and daily activities, reflected in the observed improvements in MBI scores.

Despite these positive findings, no significant between-group differences were observed in FEV_1 and PEF. These indices primarily reflect airway patency and expiratory flow dynamics, which are less responsive to short-term interventions and more sensitive to chronic airway function and expiratory control [62]. The 2-week duration of training may have been insufficient to elicit detectable changes in these parameters. Moreover, poststroke impairment in airway coordination—such as reduced glottic control or weakened expiratory reflexes—may further limit responsiveness to early-phase interventions [63,64]. Longer or more targeted expiratory-focused protocols may be needed to achieve improvements in these measures.

Compared with other motor telerehabilitation studies, our findings highlight the value of a simplified, focused intervention suitable for patients with acute stroke. Previous programs targeting upper limb [65], spinal stability [66], or core function [67] have shown functional gains, but often required long durations (8‐12 wk), complex protocols, or real-time supervision, which may limit adherence or scalability. Some participants in these studies reported training fatigue, reduced engagement, or low compliance [66,67]. In contrast, our 2-week respiratory protocol achieved a high adherence rate (96%) with minimal supervision, supported by an app-based system that provided clear instructions and immediate feedback. Rather than using videoconferencing or immersive visual reality [25,66,68], which required constant therapist involvement, our approach relied on routine caregiver support, enhancing feasibility in clinical settings. By focusing on a single, targeted domain—respiratory recovery—our program provided a practical and scalable model for early-phase telerehabilitation in stroke care.

Despite these promising findings, the results must be interpreted in the context of certain limitations. The intervention period was limited to two weeks due to constraints imposed by the Chinese health insurance system, whereas previous studies suggested that respiratory training typically spans at least 4 weeks to maximize benefit [8,59,69]. To address this, the CMRTP was intentionally designed as a high-intensity, twice-daily, multicomponent protocol targeting multiple facets of respiratory function simultaneously. Although the improvements observed in FVC were smaller than those reported in longer trials—for example, a recent meta-analysis reported an average FVC increase of 0.87 L in early stroke [9]—our findings suggest that a condensed, intensive approach could still yield meaningful gains, particularly for patients in the acute phase of stroke.

The AIRHUB platform significantly facilitated the delivery of this program by overcoming temporal and spatial barriers that often impede rehabilitation in the acute phase. It mitigated treatment disruptions caused by limited clinical staff availability or urgent medical needs, ensuring continuous and stable access to respiratory training. Its user-friendly interface, guided multimedia instructions, and integration with nursing oversight enabled patients to complete high-quality training sessions independently and consistently. The hybrid model, combining digital support with in-hospital supervision, likely contributed to the high adherence rate (97.5%) and absence of adverse events. Compared to home-based rehabilitation models, this approach provided greater control over intervention fidelity, which was critical in early-phase recovery.

Nevertheless, several limitations should be acknowledged. First, although outcome assessors were blinded, patient awareness of group allocation might have introduced performance bias, particularly for effort-dependent measures such as MIP and MEP. Second, the relatively short duration of the intervention limited the interpretation of long-term effects. Third, the modest sample size (N=40), while sufficient to detect primary effects, might reduce generalizability and statistical power to detect smaller but clinically meaningful differences.

Recent advances in respiratory rehabilitation included virtual reality biofeedback systems that visualized and quantified respiratory data, offering more effective and engaging training experiences [70,71]. Devices such as Acapella combined with the active cycle of breathing technique improved lung function in perioperative patients with lung cancer [72], and mobile-based intelligent trainers like AeroFit IMT enhanced respiratory muscle strength without inducing fatigue [73]. While these technologies showed promise, their use often required specialized equipment and supervision, which might limit feasibility in acute stroke care [74]. Therefore, incentive spirometry was chosen in this study for its safety, low cost, ease of training, and visual feedback–facilitated adherence [74,75].

RenderX

Future studies should investigate longer interventions, larger multicenter cohorts, and the integration of advanced or digitally enhanced respiratory devices. Comparative studies of different training intensities, configurations, and delivery models, including home-based telerehabilitation, will be essential to optimize individualized protocols and evaluate scalability in diverse clinical settings.

This randomized controlled trial demonstrated that a 2-week, hospital-based CMRTP combined with conventional rehabilitation significantly improved respiratory function and daily functional performance in patients with moderate acute stroke. The intervention was safe, well-tolerated, and achieved high adherence, suggesting good feasibility for inpatient application. These findings support the integration of mobile-based respiratory training as an effective adjunct to conventional hospital rehabilitation for early respiratory recovery after stroke. Larger multicenter studies with extended follow-up are needed to confirm the long-term benefits and cost-effectiveness of this approach.

Acknowledgments

We sincerely thank the researchers involved who work at the Departments of Rehabilitation Medicine, Neurology, and Neurosurgery of Sichuan Mianyang 404 Hospital and Department of Rehabilitation Medicine of West China Hospital at Sichuan University. Abstract

Background: Nutritional and exercise interventions have shown beneficial effects after gastrectomy for gastric cancer. While digital health tools show promise in cancer care, their long-term effectiveness in patients with gastric cancer remains unclear. In addition, large-scale studies of personalized interventions initiated in the immediate postoperative period are lacking.

Objective: This study aimed to determine whether a personalized mobile health intervention incorporating exercise and nutrition confers additional benefits in weight change, body composition, nutritional status, physical fitness, and quality of life compared with standard care when applied continuously for 12 months after gastrectomy.

Methods: This multicenter, randomized controlled trial enrolled 257 patients who had undergone curative resection for stage I-III gastric cancer. Participants were randomly assigned (2:1) to either a 12-month personalized mobile health intervention group or a standard rehabilitation control group. The digital intervention incorporated a smartphone app and wearable device, offering exercise and dietary plans tailored to clinical parameters such as BMI, surgery type, and recovery stage. Standard care, including nutritional education, was provided to all patients. The primary outcome was a change in body weight over 12 months. Secondary outcomes included quality of life (European Organisation for Research and Treatment of Cancer Quality of Life Questionnaire-Core 30 [EORTC QLQ-C30] and European Organisation for Research and Treatment of Cancer Quality of Life Questionnaire-Stomach 22), nutritional status (Mini Nutritional Assessment Score), physical fitness (grip strength, 30-second chair stand test, and 2-minute walk test), physical activity (International Physical Activity Questionnaire-Short Form), pain intensity (average Numeric Rating Scale), body composition (skeletal muscle mass, lean body mass, and fat mass), BMI, hemoglobin, vitamin B_{12}, and albumin. Assessments were conducted at baseline and at 1, 3, 6, and 12 months postoperatively.

Results: No significant group-by-time effects were observed for weight change. Secondary outcomes showed no between-group differences, except for 1 subscale of the EORTC QLQ-C30, which lacked clinical significance. The intervention group reported high satisfaction and adherence to the mobile app, and no adverse events or incidents were observed during the 12-month study period.

XSL•FO
RenderX

Conclusions: The digital health program integrating exercise and nutrition was safe and feasible, with high satisfaction and adherence among patients with gastric cancer. However, it was not superior to standard education in modifying the postoperative trajectory in patients with gastric cancer after surgery, including body weight change and related functional or nutritional outcomes. These findings suggest that future digital health programs should be precisely targeted and tailored to specific patient populations and recovery phases.

Introduction

In patients with gastric cancer (GC) undergoing gastrectomy, prevention of postoperative weight loss is a critical factor for reducing complications and improving both cancer-specific survival and quality of life [1,2]. However, malnutrition is highly prevalent, affecting more than half of patients who are affected or at risk [3]. Nutritional impairment leads to weight loss and skeletal muscle depletion, which in turn are associated with reduced activities of daily living and poorer survival outcomes [4,5]. Evidence indicates that nutritional or exercise interventions in the postoperative course of GC provide beneficial effects [6,7]. For example, randomized controlled trials have demonstrated that dietary interventions significantly attenuate weight loss, particularly in patients undergoing total gastrectomy, with benefits sustained not only at 6-8 weeks but also up to 1 year after surgery [8-10]. Likewise, exercise interventions have been shown to enhance muscular strength, cardiopulmonary function, quality of life, and emotional functioning in this population [11,12].

With recent developments in communication technology, mobile health (mHealth) apps have gained attention as supportive tools in cancer management [13-15]. However, studies of digital health interventions in upper gastrointestinal cancers have shown inconclusive efficacy [16-19]. Most previous studies on digital health with wearable devices focused on limited interventions, such as health programs applied only during chemotherapy or those focusing mainly on psychological or nutrition-related issues, often with insufficient personalization, short follow-up periods, or a small number of patients [20,21]. Offering uniform content to this population might be inefficient because patient status varies according to diverse factors such as age, surgical method, or therapeutic phase [10,22,23]. In addition, a small number of patients is not sufficiently generalizable to the broader population.

This study aimed to evaluate whether a long-term, personalized digital health intervention initiated after gastrectomy in patients with GC confers superior effects compared with conventional education in modifying the biological postoperative course.

Methods

Patients

Participants were recruited between May 17, 2021, and September 19, 2022. In total, 257 patients diagnosed with GC who underwent curative surgery were enrolled in this study. The inclusion criteria were as follows: (1) age of 19-75 years, (2) curative resection for stage I-III GC according to the American Joint Committee on Cancer staging system, (3) ownership of an Android- or iOS-based smartphone, (4) ability to use a mobile app and to attend regular outpatient follow-up visits, and (5) voluntary agreement to participate in the study. Exclusion criteria included the inability to engage in exercise or diet management due to severe comorbidities, neuromusculoskeletal disorders, cognitive or visual impairment, or communication difficulties.

Eligible patients were identified through consultations with the Departments of Surgery and Rehabilitation Medicine. Following surgery, all eligible participants were informed of the study procedures, and written informed consent was obtained from those who agreed to participate voluntarily.

Trial Design

This prospective, randomized, controlled, multicenter, open-label, 2-arm trial adhered to the SPIRIT (Standard Protocol Items: Recommendations for Interventional Trials) and CONSORT (Consolidated Standards of Reporting Trials) standards (checklist provided in Multimedia Appendix 1). Participants were recruited from 2 university hospitals in South Korea (Samsung Medical Center and Korea University Anam Hospital) and were randomly assigned (2:1 ratio) to either the digital therapeutic or control group using blocked randomization with randomly selected block sizes of 3 and 6. Patients were randomly allocated to 2 groups for 12 months of the rehabilitation program, starting immediately after the operation: a personalized digital therapeutic (intervention) group and a conventional education-based rehabilitation (control) group. Both groups received standard care and conventional dietary education on the prevention of dumping syndrome and the maintenance of muscle mass and weight.

Personalization Algorithm and Dynamic Adjustment

Participants in the intervention group (personalized digital therapeutic group) were provided with the “Gastric Cancer by a Second Doctor” mobile app (Medi Plus Solution) and the “DoFit” smart wristband (NF-B20; Medi Plus Solution).

Participants in the usual care group received regular diet management and dumping syndrome prevention training at the hospital.

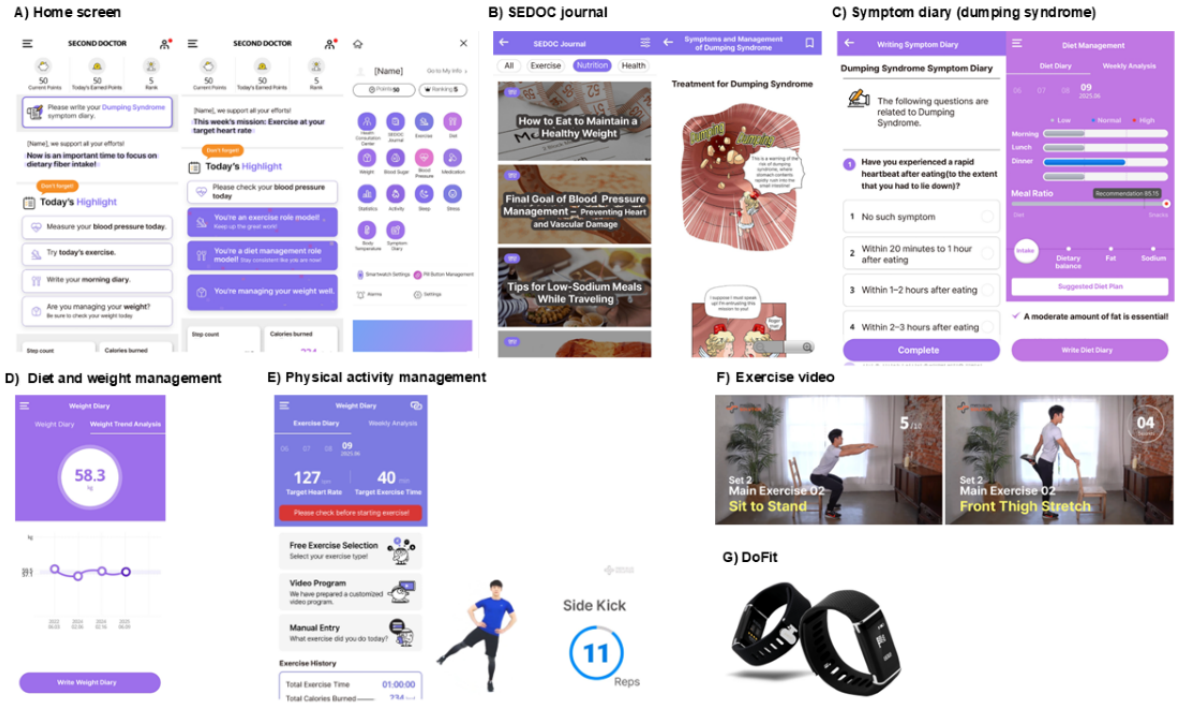
RenderX

Exercise Prescription Algorithm

The exercise component was individualized using a rule-based algorithm that incorporated patient-specific variables, including weeks since surgery and current chemotherapy status. Based on these factors, participants were categorized into an exercise stage, which determined the target intensity and duration of aerobic activity. The target heart rate (THR) was calculated using the standard formula: THR = (220 – age) × THR factor. The THR factor was defined according to cancer-specific exercise guidelines, including those from the American College of Sports Medicine (2022) and the Roundtable on Exercise for Cancer Survivors (2019), as well as previous studies involving patients with GC, such as the Postoperative Recovery Exercise Program for Gastric Cancer Patients (2018) [12,24,25]. Exercise duration was adjusted according to the assigned stage, and progression was guided by the individual's clinical recovery. The prescribed exercise program included stretching, flexibility exercises, aerobic training, and functional resistance exercises using body weight or simple equipment. These prescriptions were reviewed and adjusted biweekly based on monitored adherence, patient-reported symptoms, and physiological parameters such as heart rate and step count, allowing real-time tailoring of exercise difficulty. During chemotherapy, low-intensity exercises focused on flexibility were implemented. Additionally, the exercise stage was adjusted upward or downward based on the patient's self-reported rating of perceived exertion. Table S1 in Multimedia Appendix 2 presents the stepwise logic used for exercise stage progression and adjustment.

Nutrition Prescription Algorithm



Nutritional planning was driven by a clinical decision algorithm that considered the patient's age (<65 vs ≥65 years), extent of gastrectomy (total vs subtotal), postoperative week, and the presence of chronic diseases such as diabetes, hypertension, and dyslipidemia. Caloric requirements were calculated using the formula: ideal body weight × activity factor (26-35 kcal/kg/day). During the early recovery phase (the first 12 weeks postoperatively), calorie targets were conservatively adjusted to reduce the risk of gastrointestinal complications, such as dumping syndrome and diarrhea. After week 13, caloric targets were increased to meet 100% of estimated needs, with additional modifications based on relevant clinical guidelines—such as sodium restriction per the 2022 Korean Society of Hypertension guidelines and carbohydrate adjustment in accordance with the 2021 Korean Diabetes Association recommendations [26,27]. Protein intake was consistently recommended at 1.2 g/kg ideal body weight per day throughout the recovery and adaptation periods, while fat intake was limited to 20% of total energy during early recovery. Meal plans were adapted in real time to reflect changing caloric needs. Specifically, portion sizes and snack frequencies were automatically recalculated. For patients who underwent subtotal gastrectomy, snack frequency was adjusted to accommodate more rapid adaptation to oral intake. Nutritional care followed a phased structure. In the recovery phase (weeks 1-4), energy intake was slightly below estimated needs and focused on soft textures and small, frequent meals. In the adaptation phase (weeks 5-12), patients gradually advanced toward full caloric intake with a transition to regular textures. The maintenance phase (week 13 and beyond) included nutritional modifications based on comorbidities, with targeted adjustments for fat, carbohydrate, sodium, and cholesterol. The corresponding decision rules for energy and nutrient prescription, stratified by surgical type, recovery phase, and clinical profile, are presented in Table S2 in Multimedia Appendix 2.

Clinician Monitoring and Feedback

The program was designed to operate primarily through a rule-based algorithm, enabling fully automated adjustment of exercise and nutrition prescriptions without requiring direct input from clinicians. A secure, web-based monitoring platform was available to clinical staff (eg, nurses, dietitians, and physiotherapists), allowing access to real-time life-log data, including step count, heart rate, nutritional intake, and symptom reports. While the platform did not allow clinicians to override or alter the algorithmic recommendations manually, it facilitated patient-centered feedback. Clinicians used the data during routine outpatient visits to encourage adherence and self-management, particularly when patients exhibited low engagement or reported challenges. Based on clinical judgment, face-to-face feedback was selectively offered to patients undergoing chemotherapy approximately 3 months postoperatively—when adherence risk is typically higher—to reinforce self-care and address barriers. Screenshots of the representative functions are shown in Figure 1, and the main app functions are listed in Table S3 in Multimedia Appendix 2.

XSL•FO

Figure 1. Representative screenshots of the app and smart band interface include (A) main screen displaying today's to-do list and self-reported symptom monitoring, (B) provision of the general information (Second Doctor [SEDOC] Journal), (C) symptom diary, (D) dietary tracking module and body weight management interface, (E) physical activity tracking module, (F) instructional exercise videos, and (G) DoFit.

Outcomes

A trained clinical research coordinator conducted in-person evaluations of the outcome measures during hospital visits. An overview of baseline screening, assessment procedures, and the follow-up schedule across study visits is presented in Table S4 in Multimedia Appendix 2.

Primary Outcome

The primary outcome was the change in body weight from baseline to 12 months, assessed using a bioimpedance analysis device to compare the intervention and control groups.

Secondary Outcomes

The secondary outcomes included quality of life, cancer-specific symptoms and function, nutritional status, physical activity, physical status, pain intensity, and physical fitness over time.

Quality of Life

Health-related quality of life was assessed using the European Organisation for Research and Treatment of Cancer Quality of Life Questionnaire-Core 30 (EORTC QLQ-C30) and European Organisation for Research and Treatment of Cancer Quality of Life Questionnaire-Stomach 22 (EORTC QLQ-STO22). The EORTC QLQ-C30 consists of 30 items, covering functional, symptom, and global quality of life domains. A high EORTC QLQ-C30 score indicates a good quality of life. The EORTC QLQ-STO22, a GC-specific questionnaire, consists of 22 items across symptom domains related to GC [23,28].

Nutrition, Pain Intensity, Physical Activity, and Function

Korean Mini Nutritional Assessment

Nutritional status was assessed using the Korean version of the Mini Nutritional Assessment (MNA) long form, an internationally validated tool in patients with cancer [29]. Previous studies have shown prognostic value for treatment efficacy, health-related quality of life, mortality, survival, and cancer progression [30]. A total score of less than 17 points indicates malnutrition, 17-23.5 points indicates a risk of malnutrition, and 24-30 points represents the normal range [31].

Numeric Rating Scale

Pain intensity over the past week was assessed using an 11-point Numeric Rating Scale (NRS), where 0 indicated "no pain," and 10 represented "the worst possible pain." The participants were asked to report both their average and worst perceived pain intensities during this period [32].

International Physical Activity Questionnaire-Short Form

Self-reported physical activity was assessed using the International Physical Activity Questionnaire-Short Form (IPAQ-SF) [33]. The IPAQ-SF is a widely used self-report instrument that enables standardized measurement and comparison of physical activity levels across populations. It consists of 7 items assessing the frequency and duration of physical activities performed over the preceding 7 days, including vigorous and moderate activities, walking, and sedentary time [34]. Responses are converted into metabolic equivalent of task (MET) minutes per week, using standardized MET values (8.0 for vigorous activity, 4.0 for moderate activity, and 3.3 for walking) [34,35]. Based on total activity levels, respondents are classified into low, moderate, or high activity

XSL•FO
RenderX

categories. Only activities lasting at least 10 continuous minutes are counted [35].

In this study, we used the Korean version of the IPAQ-SF, developed and validated by Oh et al [34], which demonstrated acceptable reliability and validity in Korean adults, including older populations.

Grip Strength Test, 30-second Chair Stand Test, and 2-minute Walk Test

Physical fitness was assessed using the grip strength test [36], 30-second chair stand test [37,38], and 2-minute walk test [39], which evaluates the strength generated by the forearm muscles, strength and endurance of the lower extremities, and cardiorespiratory endurance, respectively. Grip strength of the dominant hand was assessed using a handheld dynamometer (microFET Digital HandGRIP Dynamometer; Hoggan Scientific LLC). All tests were performed using standardized measurement methods.

eHealth Literacy Scale

The eHealth literacy of the intervention group was only measured at baseline using the eHealth Literacy Scale (eHEALS), which comprised 10 items. A total of 8 questions assessed eHealth literacy on a 5-point Likert scale, with higher scores indicating greater literacy [40]. In addition, the intervention group completed a self-developed questionnaire assessing satisfaction with the mobile app and smart band at 6 months.

App-Based Adherence Measures

“Exercise log (days)” was defined as the number of days in a month on which participants recorded any exercise session—whether free-form, video-guided, or manually entered—that lasted at least 5 minutes. “Exercise duration per exercise day (min)” was calculated by dividing the total exercise time in a month by the number of exercise log days. For trend analyses, participants who had no exercise records in each month were not included in the calculation of mean values. “Step count logged (days)” refers to the total number of days on which step counts were recorded. The “step count” was calculated by dividing the total number of steps over a month by the number of step-log days. To ensure monthly data reflected typical activity patterns, step counts were counted only if data were recorded on at least 7 days within the month. For the trend analysis of step counts, zero values were excluded when calculating the average step count among users with available data. “Weight log” and “diet log” indicate the number of days with at least 1 entry, and “app access” denotes the number of days the user accessed the app at least once.

Satisfaction Survey

A customized satisfaction questionnaire regarding the use of mobile apps and Internet of Things devices was developed collaboratively by investigators from the 2 participating institutions. This survey was administered exclusively to participants in the intervention group at the 6-month follow-up and used a 5-point Likert scale, with higher scores reflecting greater levels of satisfaction.

Sample Size Calculation

Using G*Power (version 3.1.9.2; Heinrich Heine University Düsseldorf), the required sample size was calculated for the primary outcome: change in body weight from baseline to 12 months. The primary hypothesis was to test the superiority of the personalized digital intervention in attenuating postoperative percentage body-weight loss. We assumed a standardized effect size (Cohen *d*) of 0.35 (moderate), a significance level (α) of 5%, and power of 80%, based on the characteristics of the intervention described in a previous behavioral intervention study [41]. This effect size was chosen to represent a conservative estimate for the minimum clinically meaningful difference expected from a nonpharmacological, behavioral intervention in a population of cancer survivors. The attrition rate in mobile-based interventions is known to vary depending on the study design. Considering an anticipated dropout rate of 10%, the final target enrollment was set at 324 participants, with 216 assigned to the intervention group and 108 to the control group. In our previous 12-week validation study involving 203 patients with advanced gastrointestinal cancer, approximately 6% discontinued the study for reasons unrelated to changes in physical condition [13].

Data Handling and Security

Electronic data were captured using a secure web-based platform provided by the Medicallogic Company [42] for systematic and reliable data management. Access to the system was restricted to authorized study personnel.

Participant data were recorded using an electronic case report form, and relevant information from the source documents was entered into the electronic case report form by designated research staff.

Statistical Analysis

All statistical analyses were conducted using the R software (version 4.4.2; R Foundation for Statistical Computing). Statistical significance was defined as a 2-sided *P* value of <.05, and 95% CIs were calculated. The normality of continuous variables was assessed by examining histograms. For baseline comparisons between the intervention and control groups, the Student *t* test or Mann-Whitney *U* test was used for continuous variables, and the chi-square or Fisher exact tests were applied for categorical variables, as appropriate. For the primary outcome (weight), comparisons at each time point were performed using independent *t* tests, and changes over time were analyzed using mixed-effects models, with group, time, and their interaction included as fixed effects, and participant ID included as a random effect. For secondary outcomes, if the data were normally distributed, mixed-effects models with the same structure (group, time, and group × time interaction as fixed effects, and participant ID as a random effect) were used. For nonnormally distributed outcome measures, the change from 1 to 12 months was compared using the Wilcoxon rank-sum test. To assess the robustness of these findings, supplementary analyses were conducted using generalized estimating equations (GEE), which account for within-participant correlation and allow for nonnormally distributed repeated measures.

XSL•FO
RenderX

Histogram analyses indicated that the following variables were normally distributed: weight, skeletal muscle mass, BMI, skeletal muscle index, total fat mass, grip strength, 30-second chair stand test, and 2-minute walk test. These variables were analyzed using mixed-effects linear regression models, incorporating all available data points at 1, 3, 6, and 12 months, to estimate the slope trajectories.

Conversely, the following variables were nonnormally distributed and were analyzed using the Wilcoxon rank-sum test: NRS average, NRS maximum, vigorous activity, moderate activity, walking time, total METs, MNA subcomponents, and EORTC QLQ-C30 and QLQ-STO22 scores—including physical functioning, role functioning, cognitive functioning, emotional functioning, social functioning, fatigue, nausea/vomiting, pain, dyspnea, insomnia, appetite loss, constipation, diarrhea, financial difficulties, global health status/quality of life, and summary score, as well as dysphagia, reflux, eating restrictions, anxiety, dry mouth, taste alteration, body image, and hair loss. Inflammatory and nutritional biomarkers, such as hemoglobin, vitamin B_{12}, and albumin, also showed nonnormal distributions and were analyzed accordingly.

Safety Monitoring and Discontinuation Criteria

The risk level associated with this study was assessed as minimal based on evaluations conducted by the institutional review board and principal investigator. Throughout the study period, participants were allowed to contact the research team at any time to address study-related concerns. In cases of severe pain or injury, participants underwent a clinical evaluation by the principal investigator. Participants were permitted to withdraw from the study at any time they wished. Additionally, withdrawal could also be initiated by the study team in cases of serious medical conditions or noncompliance with medical instructions.

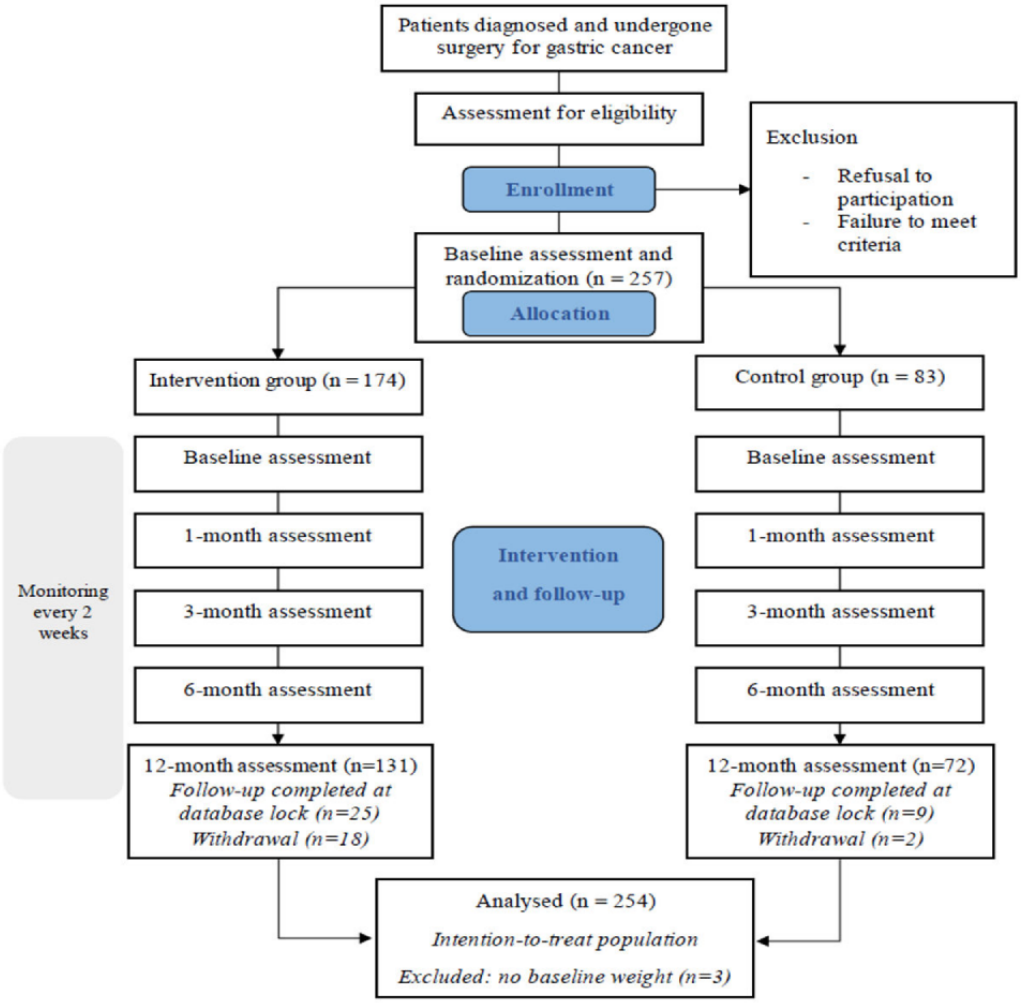
Ethical Considerations

All study procedures were reviewed and approved by the institutional review boards of the 2 hospitals (approval numbers SMC-2021-01-090 and 2021AN0104). The trial was registered at ClinicalTrials.gov (approval ID NCT04907591). The original study protocol was submitted to the Samsung Medical Center Institutional Review Board on February 1, 2021, and received approval on February 23, 2021. All collected data were retained for 3 years after study completion and were subsequently destroyed in accordance with institutional policy.

Written informed consent was obtained from all participants prior to their participation, and all participants voluntarily agreed to take part in the study. All data were anonymized and securely stored in restricted-access locations to protect personal information and ensure confidentiality. Participants received a compensation of 50,000 KRW (approximately US $34) after hospital discharge at each follow-up assessment.

Results

Patients



A total of 254 patients were included in the intention-to-treat population (131 in the intervention group and 123 in the control group). Overall, 3 participants were excluded from the final analysis due to missing baseline body weight data.

By the 12-month follow-up, several postrandomization dropouts had occurred. In the intervention group, 1 participant died due to lung and brain metastases, and another was diagnosed with non-Hodgkin lymphoma, unrelated to GC. In the control group, dropouts were primarily due to clinical deterioration and failure to attend scheduled follow-up visits. Additional reasons for early withdrawal across both groups included adverse effects from ongoing treatment, allergic reactions to the smartwatch device, and user-reported difficulties with or reluctance to use digital tools. Despite these attritions, all participants were included in the intention-to-treat analysis (Figure 2).

The baseline demographics and clinical variables of the intervention and control groups are shown in Table 1. Baseline characteristics of the participants were well balanced between the 2 groups, except for age, alcohol consumption, adjuvant chemotherapy, and grip strength. To account for baseline imbalances, demographic variables showing between-group differences were included as covariates in the outcome analyses.

Primary Outcome

No significant difference was observed in body weight change between the groups over 12 months as assessed using a linear mixed model that accounted for group, time, and their interactions (Figure 3). This result remained consistent after adjusting for age, drinking, and adjuvant chemotherapy in multivariate regression (Table 2).

XSL•FO
RenderX

Figure 3. Analysis of the primary outcome with between-group comparisons at each time point. (A) Box plot showing the change in weight from baseline to 12 months postoperatively. The box represents the median (center line) and the first and third quartiles, with whiskers representing the minimum and maximum values. (B) Weight changes over the study period. Error bars represent standard errors estimated from the linear mixed model. The reported *P* value corresponds to the group × time interaction effect. Statistical significance was set at *P*<.05. mHealth: mobile health.

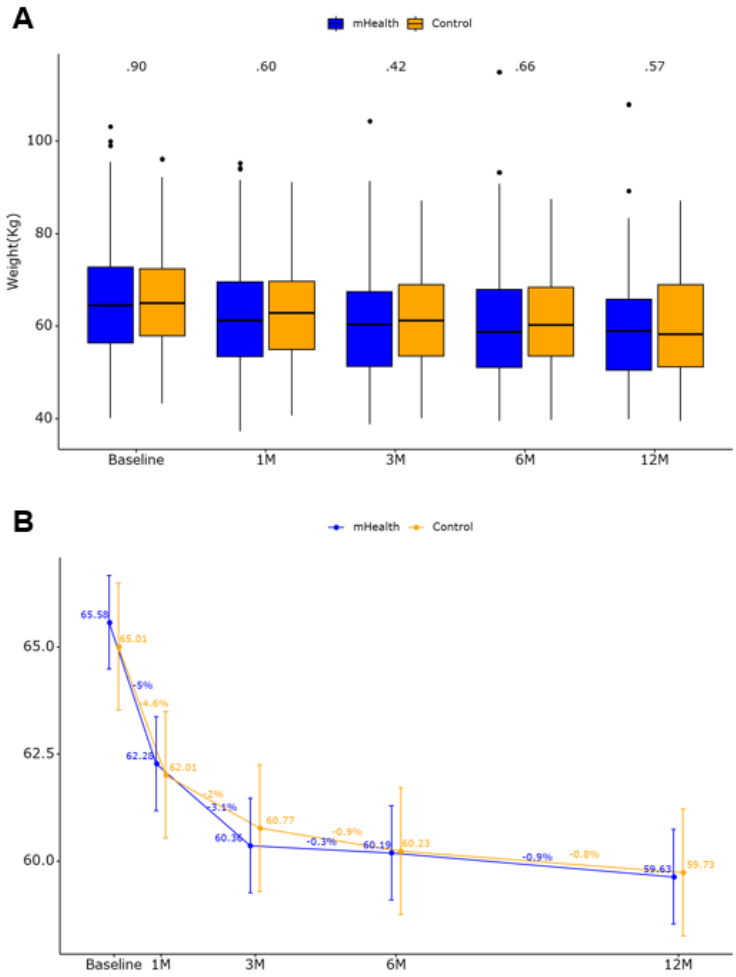

Table 2. Analysis of primary outcome.

Time point	Control	mHealth[a]	*P* value
Baseline, mean (SD)	65.54 (10.60)	65.35 (11.96)	.90
1 month, mean (SD)	62.85 (10.63)	62.05 (11.53)	.60
3 months, mean (SD)	61.46 (10.84)	60.14 (11.83)	.42

12 months, mean (SD)	60.20 (11.63)	59.18 (11.85)	.57
Within-group adjusted mean change from baseline to 12 months[b], mean (95% CI)	−5.29 (−6.22 to −4.35)	−5.95 (−6.62 to −5.28)	.26[c]

[a]mHealth: mobile health.

[b]Estimated using linear mixed-effects models adjusted for age, drinking status, and adjuvant chemotherapy. Values represent the adjusted mean change in body weight from baseline to 12 months within each group.

[c]Between-group adjusted difference in mean change (mHealth-control): 0.10 (95% CI −3.01 to 3.21). A positive value reflects a greater weight loss in the mHealth group compared to the control group. Statistical significance was set at *P*<.05.

Secondary Outcomes

The secondary outcomes of the study are summarized in Table 3. Variables analyzed included physical fitness (grip strength test, 30-second chair stand test, and 2-minute walk test), nutrition (screening and total MNA), quality of life (EORTC QLQ-C30 and EORTC QLQ-STO22), physical activity (IPAQ-SF), physical status (skeletal muscle mass, lean body mass, fat mass, BMI, hemoglobin, vitamin B_{12}, and albumin), and pain intensity (average NRS). No significant group-by-time interactions or between-group differences were observed for any of these outcomes, except for the nausea/vomiting subscale

XSL•FO
RenderX

of the EORTC QLQ-C30. Although the Wilcoxon rank-sum test indicated a statistically significant difference between groups ($P<.05$), both groups had identical medians and IQRs, suggesting that this result likely reflects subtle rank-based variation rather than a clinically meaningful difference in symptom burden. To further evaluate the robustness of the secondary outcome results and to complement the change-score analyses, additional longitudinal analyses were performed using GEE. The GEE results were consistent with the primary analyses, demonstrating no significant group-by-time interaction effects across all secondary outcomes (Table S5 in Multimedia Appendix 2).

XSL•FO
RenderX

Table 3. Analysis of secondary outcomes. For variables following a normal distribution, linear mixed-effects models were used to estimate adjusted mean changes from baseline to 12 months within each group, accounting for relevant covariates. For nonnormally distributed variables, the Wilcoxon rank-sum test was applied. "mHealth-control" indicates the estimated between-group difference in adjusted change from baseline to 12 months. A positive value reflects greater loss in the mobile health (mHealth) group compared to the control group. Statistical significance was defined as $P<.05$.

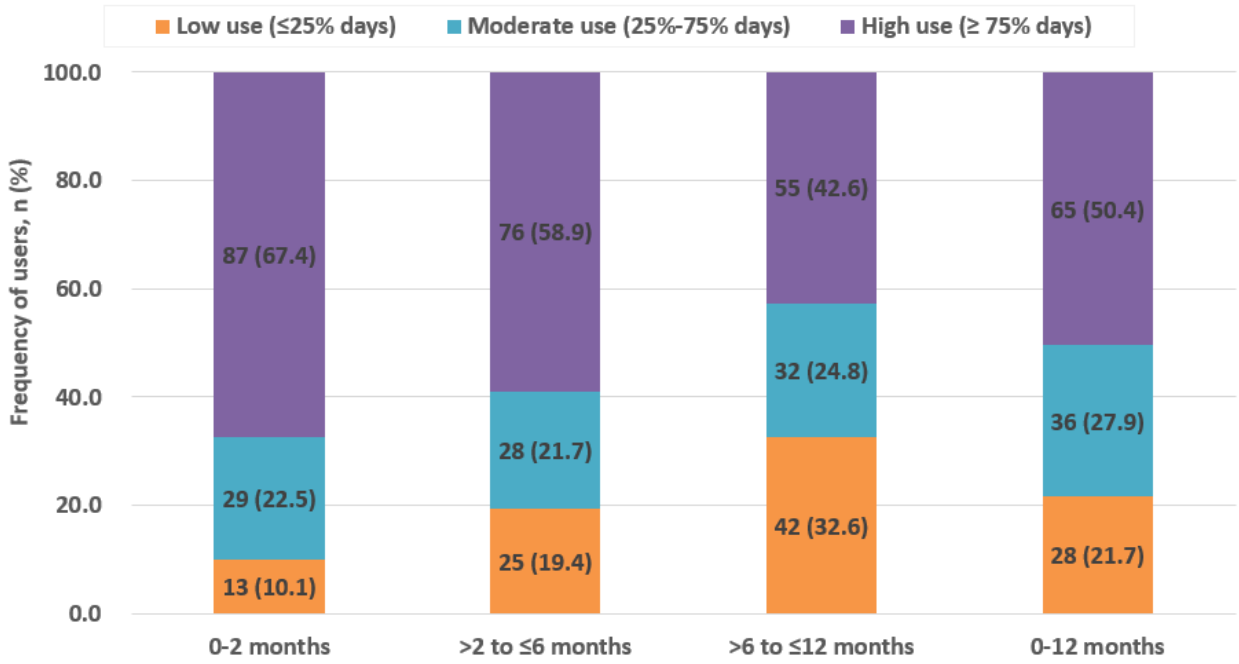
eHEALS



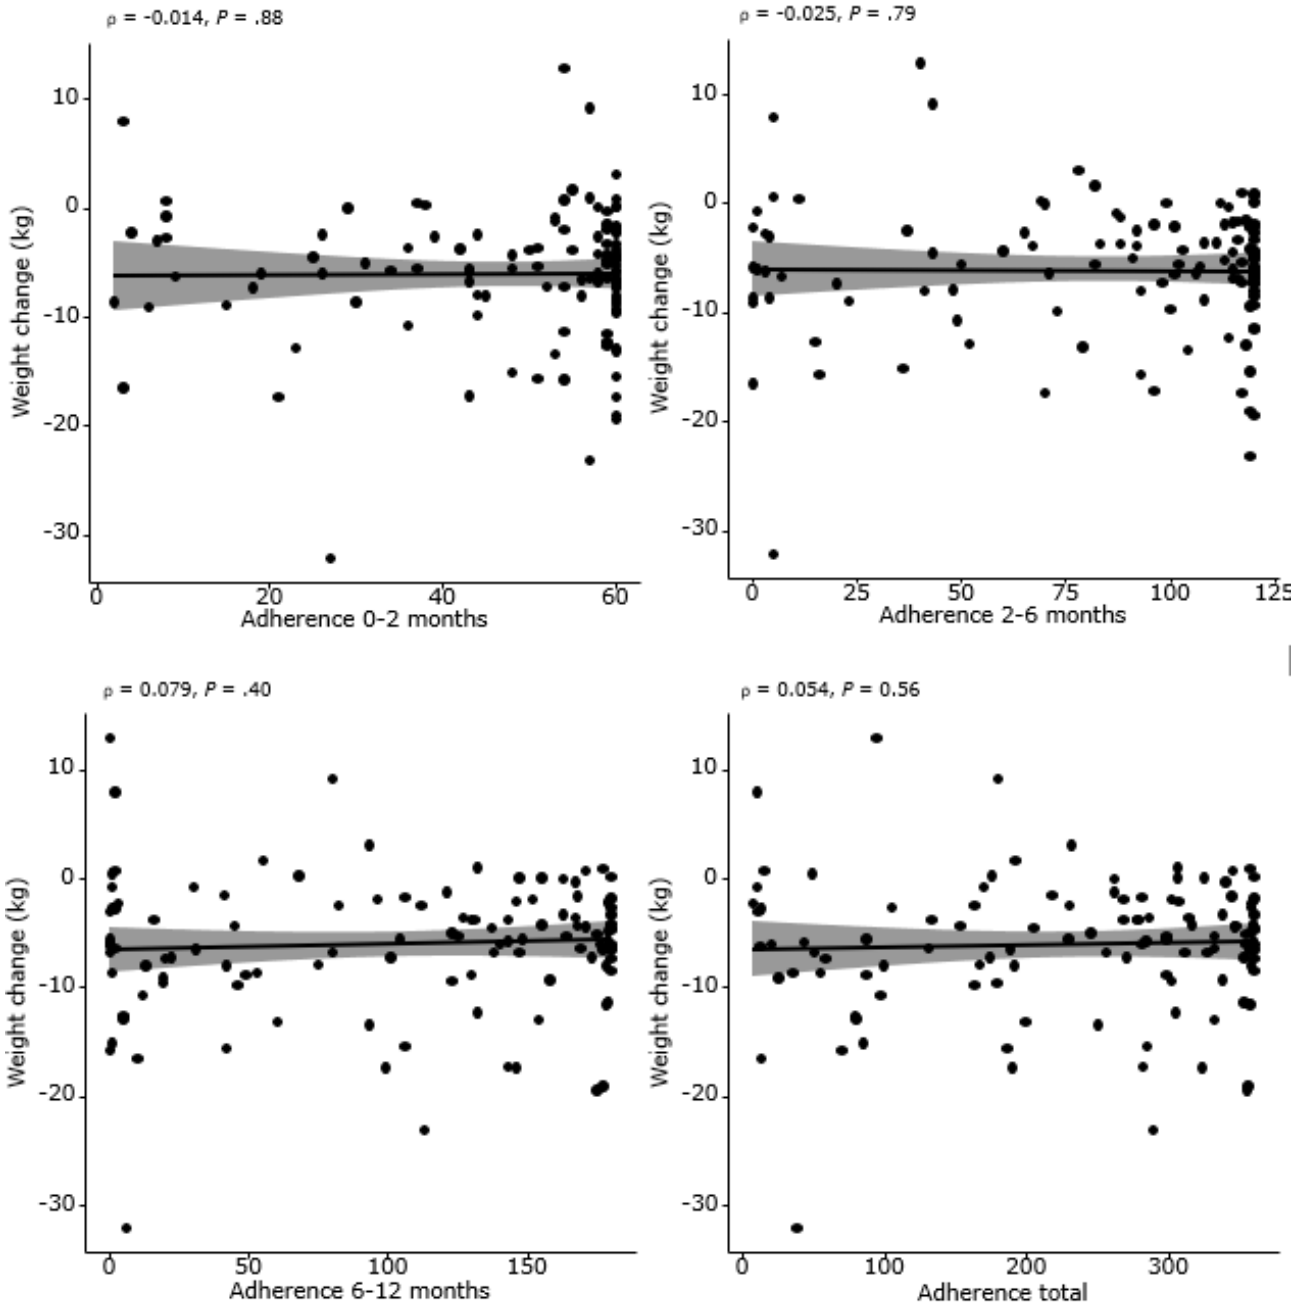
eHealth literacy was assessed only at baseline in the intervention group using the eHEALS. The mean score was 29.8 (SD 4.05) out of 40, indicating a moderate level of eHealth literacy. This suggests that while participants were likely capable of independently searching for health information online, they may have had limitations in evaluating accuracy and reliability.

Compliance

Compliance with wearable device–linked mobile app use over 12 months is presented in Figure 4. Usage was categorized as high (≥75% of days), moderate (25%-74% of days), and low (≤25% of days). Compliance was highest during the initial 0-2 months, followed by a gradual decline during the 2- to 6-month and 6- to 12-month intervals. Nevertheless, overall adherence was favorable, with approximately 78.3% (101/129) of the participants demonstrating moderate to high use throughout the study period.

XSL•FO
RenderX

Figure 4. Compliance with wearable device–linked mobile app use over 12 months. Stacked bars show the number and proportion of participants with low (≤25%), moderate (25%-74%), and high (≥75%) usage across 4 time intervals: 0-2 months, 2-6 months, 6-12 months, and the overall 12-month period.



Association Between Adherence and Weight Change

To explore a potential dose-response relationship, we analyzed the correlation between app adherence and 12-month weight change. Adherence was calculated separately for 3 time intervals (0-2 months, 2-6 months, and 6-12 months) and for the total intervention period. As shown in Figure 5, Spearman correlation analyses revealed no statistically significant associations between adherence and weight change in any period: ρ=–0.014 (*P*=.88) for 0-2 months; ρ=–0.025 (*P*=.79) for 2-6 months; ρ=0.079 (*P*=.40) for 6-12 months; ρ=0.054 (*P*=.56) for the total study period. These results suggest that higher app engagement levels were not significantly associated with attenuated postoperative weight loss in this cohort.

XSL•FO
RenderX

Figure 5. Correlation between intervention adherence and 12-month weight change from baseline.

App-Based Adherence Measures

Among the 131 participants in the intervention group who completed the 12-month follow-up, data from 129 were included in the adherence analysis. Individuals who discontinued app use or withheld consent for data access at the time of data retrieval were excluded. App usage patterns over the 12-month intervention period are summarized in Table 4. Participants recorded exercise on an average of 18.2 (SD 10.0) days per month, with a mean duration of 56.9 (SD 26.9) minutes per exercise day. The number of step count log days remained relatively stable throughout the follow-up (overall mean 24.2, SD 8.7 days per month), with an average of 8491.1 (SD 3765.5) steps per day. Weight and diet logs were entered on an average of 9.9 (SD 10.9) and 22.7 (SD 8.8) days per month, respectively. App access was recorded on 21.3 (SD 10.0) days per month. While the frequency of exercise logging was higher in the earlier months, average exercise duration per exercise day and daily step counts showed an increasing trend over time, suggesting improved engagement in physical activity among users who continued to log their data.

XSL•FO
RenderX

Table 4. Monthly digital intervention engagement: exercise, step count, weight logs, diet logs, and app use (n=129). Exercise logs include any session (free-form, video-guided, or manually entered) lasting at least 5 minutes. Aerobic exercise refers to sessions lasting ≥10 minutes. Step counts, weight, and dietary logs were self-reported via the digital platform.

Satisfaction Survey

A customized satisfaction survey was conducted with participants in the intervention group at the 6-month follow-up (n=113). Overall, responses reflected a high degree of satisfaction with the digital health care service (Table 5).

Among the assessed domains, perceived effectiveness received the most favorable ratings, with average scores ranging from 4.0 (SD 0.6) to 4.1 SD (0.7). These results suggest that participants felt the service contributed meaningfully to their efforts to monitor and manage their health. Items addressing usability also performed well (means ranging from 3.9, SD 0.8 to 4.0, SD 0.9), indicating that participants generally found the app intuitive and easy to use.

In the domain of content adequacy, scores were slightly lower, with the item evaluating whether the service included all essential features for health management receiving a mean score of 3.7 (SD 0.8). Many participants noted that the exercise and dietary management tools were especially useful. On the other hand, several respondents identified dietary tracking as an area requiring further refinement.

XSL•FO

Table 5. Satisfaction survey results at 6-month follow-up (intervention group; n=113).

Survey question	Mean (SD)
Use and access	
The service provided sufficient in-app instructions on how to use its features.	4.0 (0.9)
Understanding how to operate the service was straightforward[a].	3.9 (0.8)
I was able to easily locate and use the functions I needed.	3.9 (0.8)
Content adequacy	
The service included all the essential features required for managing my health.	3.7 (0.8)
The service offered sufficient and helpful information that supported my health management and lifestyle improvement[a].	3.9 (0.7)
Satisfaction	
Overall, how satisfied are you with the healthcare service you used?[a]	3.9 (0.7)
Do you intend to continue using the healthcare service in the future?[a]	3.8 (0.9)
Would you recommend this healthcare service to other patients?[a]	3.9 (0.8)
Perceived effectiveness	
Since using the service, have you monitored your health status more regularly?	4.0 (0.6)
Has your interest in managing your personal health increased after using the service?	4.0 (0.6)
Was the service useful in supporting your personal health management?	4.0 (0.6)
Do you consider the service a suitable method for managing your condition?	4.1 (0.7)

[a]Included a follow-up question to elaborate on their answers.

Discussion

Principal Findings

This study investigated the long-term effects of a personalized, stage-adjusted digital health program combining exercise and nutritional interventions in patients with GC, delivered for 12 months following surgery. While overall satisfaction with and compliance with the digital health intervention were relatively high, the intervention group did not show a statistically significant benefit in mitigating postoperative body weight loss compared to the control group. Secondary outcomes, including body composition, BMI, physical fitness level, nutrition, and quality of life, did not demonstrate meaningful improvements across time points. The overall consistency between the results of nonparametric tests and GEE analyses suggests that the absence of statistically significant group-by-time interaction effects is unlikely due to model selection. This concordance reinforces the robustness and validity of our findings related to the secondary outcomes.

The hypothesized mechanisms by which a digital health program combining exercise and nutrition might influence postoperative weight loss after gastrectomy can be conceptualized in 3 interrelated domains: behavioral activation, metabolic/nutritional modulation, and muscle-preserving functional support. The app and wearable device supported self-monitoring, goal setting, and feedback, promoting adherence to physical activity and dietary goals. These behavioral components are especially valuable during early recovery, when fatigue and reduced intake are common. In addition, prior studies in populations with cancer support the effectiveness of such digital tools in sustaining health behaviors [43]. Postoperative weight loss in patients with GC is a multifactorial process influenced by mechanical, hormonal, and metabolic changes (eg, increased catabolism and inflammatory responses). These alterations result in decreased oral intake, impaired nutrient absorption, and significant losses in skeletal muscle mass and body weight. Structured digital interventions can modulate these adverse trajectories by optimizing caloric intake, preserving lean body mass, and minimizing nutrient deficiencies [44,45]. Furthermore, exercise prescriptions were tailored using cancer guidelines, combining aerobic and resistance training to mitigate sarcopenia and preserve function [24]. The individualized prescriptions targeted aerobic and resistance training intensity using patient-specific maximum heart rate and stage-based progression, aiming to preserve lean mass and physical function. Digital delivery enabled sustained support during the high-risk postdischarge period, allowing flexible, remote adjustments to care without increasing burden [10].

Nevertheless, several factors may explain why the 12-month digital health intervention did not significantly alter the postoperative weight loss trajectory in patients with GC compared to conventional education-based rehabilitation.

Reach

Our trial enrolled 257 patients after curative resection for stage I-III GC. As noted in the manuscript, the study population had relatively preserved nutritional status (mean BMI 24.05, SD 3.36 kg/m^2 in the intervention group, 24.05, SD 2.79 kg/m^2 in the control group; *P*=.99), with only 2 participants (BMI 16.1 kg/m^2 and 16.2 kg/m^2) having BMI <17 kg/m^2. This indicates

XSL•FO
RenderX

that the study population predominantly comprised individuals at a relatively lower baseline risk of nutritional compromise, potentially omitting those at the highest nutritional risk who may have derived the greatest benefit from the intervention. In addition, although current clinical guidelines emphasize dietary practices to prevent complications [46,47], many patients fail to adopt them due to insufficient cognitive factors, such as limited risk perception, weak motivation, or limited expectations of benefit [48-50]. A study in patients with upper gastrointestinal cancer showed that weight loss was attenuated only with telephone counseling, while mobile app–based support alone was insufficient to ensure nutritional adequacy [51]. Moreover, a Korean survey reported that the general public perceived digital therapeutics less favorably than health care professionals [52].

Effectiveness

Although the personalized mHealth program was safe and well-received—with high early-phase adherence and no reported adverse events—it did not yield statistically significant differences in weight change or secondary clinical outcomes (eg, quality of life, physical function, and nutritional biomarkers). This highlights the importance of distinguishing between biological efficacy and intervention usability/satisfaction, especially in patient populations with a low baseline risk. GC has a unique biological trajectory compared with that of other malignancies. Patients undergoing gastrectomy typically exhibit substantial changes in body composition, characterized by marked reductions in body weight during the first 6 months, followed by gradual stabilization [10,53]. One study reported that the most pronounced weight changes occurred within 6-12 months, with stabilization or recovery extending up to 2 years after surgery [1]. This biphasic course may be resistant to reversal even with structured digital interventions. Postoperative weight loss in GC is multifactorial, driven by inflammatory responses, reduced intake, and decreased physical activity. Tumor-related malnutrition and immune dysfunction are further aggravated by radical surgery, underscoring the need for both nutritional and immune-supportive interventions [54,55]. This is consistent with findings that most oral nutritional supplementation trials in GC have not shown consistent benefits in preventing postoperative weight loss [13,43,44]. While GC and colorectal cancer share gastrointestinal origins, GC is associated with poorer survival and more aggressive progression due to differences in the underlying metabolic pathways [56-58]. Although recent randomized controlled trials in colorectal cancer showed quality-of-life improvements through mHealth, these results may not be generalizable to GC due to these fundamental biological differences.

In addition, the conservative nature of the intervention, largely driven by safety considerations, may have limited its efficacy. Unlike supervised rehabilitation programs, the current unsupervised digital program required cautious exercise prescriptions. Moreover, both groups received comprehensive standard care, narrowing the margin for additional benefit.

Another potential contributing factor is the lack of real-time symptom management and psychological support, as the program focused solely on exercise and nutrition. Psychological support is known to be critical in postoperative quality of life for patients with GC, breast cancer, and esophagogastric cancer [59-63]. However, due to the COVID-19 pandemic, it was not feasible to incorporate family or peer-based support. Future mHealth programs should incorporate humanized psychological support and caregiver-focused components [3,60,62].

Adoption and Implementation

The intervention was implemented across multiple hospitals and integrated into routine postgastrectomy care, delivered through a mobile app and wearable device. The program was initiated within 1 week after surgery and maintained for 12 months, aligning with critical recovery periods. However, we observed a progressive decline in engagement, particularly during the 6- to 12-month period—a common challenge in long-term digital interventions. While this low-touch, patient-led design ensured feasibility and safety, the absence of active supervision may have limited behavior change, particularly in patients with lower health literacy or motivation. Although exercise and nutrition prescriptions were algorithmically tailored, adherence to these prescriptions in real-world settings was not directly assessed, limiting our understanding of implementation fidelity.

Maintenance

Although the intervention spanned 12 months, true maintenance—sustained behavior changes and functional improvement—often extends beyond this time frame. Systematic reviews of web-based digital health interventions have demonstrated efficacy attenuation over extended time frames due to digital fatigue, with short-term benefits failing to translate into sustained long-term outcomes [64-67]. Therefore, further research in GC is needed to investigate strategies that can maintain high patient engagement over periods exceeding 2 years, as well as including approaches such as gamification to enhance motivation [68].

To maximize the effectiveness of digital health, it is essential to deliver the right content to the right patients at the right time. For example, an Internet of Things–based lifestyle intervention in prostate cancer demonstrated benefits among patients receiving androgen deprivation therapy or those with a high symptom burden, whereas effects were inconsistent in broader populations and across different intervention durations [69,70]. In our study, the digital health program, initiated immediately after gastrectomy and maintained for 12 months at a safe intensity, might have served mainly as supportive monitoring without conferring superior effects on the biological course of GC. Therefore, further research on precise targeting is warranted to tailor intervention content to the specific characteristics of each cancer type.

Strengths and Limitations

This study has several notable strengths. First, to the best of our knowledge, this is the largest and longest randomized controlled trial to date to evaluate a mHealth and nutrition platform in patients with GC, enrolling 257 participants with a follow-up period of 12 months. Second, the digital health program was highly personalized and dynamically adjusted based on the

XSL•FO
RenderX

patient's treatment phase and clinical condition. Third, the program was initiated within 1 week after surgery, enabling early rehabilitation and nutritional support during a critical recovery window. Fourth, the program was safe and well-received, with no adverse events and high levels of satisfaction and adherence. This reinforces its clinical relevance as a feasible and acceptable model of digital rehabilitation. Fifth, although mHealth interventions have been reported to be broadly beneficial in cancer rehabilitation, this study allowed for a focused examination of their applicability to GC. Our findings suggest a novel viewpoint that a digital health program centered solely on nutrition and exercise for 12 months may have limited effectiveness in the postoperative GC population, unlike some other cancers. Finally, our study adhered to CONSORT/SPIRIT standards.

This study has several limitations. First, this was an open-label design that was not free of bias. However, this reflects real-world clinical settings, thereby enhancing the external validity of the findings. In addition, compliance gradually declined at 2- to 6-and 6- to 12-month intervals. Nevertheless, overall adherence remained favorable. Weight change after gastrectomy for GC is most pronounced within the first 6-12 months, with subsequent stabilization or improvement observed up to 2 years postoperatively [1,71]. Given that our study was limited to a 12-month follow-up period, the long-term recovery trajectory could not be fully characterized, considering the physiology of GC. Moreover, most participants entered the study with relatively preserved nutritional status, which may have contributed to a ceiling effect and reduced the magnitude of observable benefit, particularly for nutritional outcomes. This profile likely reflects a selection bias that patients with greater frailty or poor performance status may be less likely to enroll or remain eligible. Furthermore, as the study was powered based solely on the primary outcome with an assumed moderate effect size, it may have been underpowered to detect smaller but clinically meaningful effects in secondary end points. Given the large number of secondary outcomes assessed, the absence of multiplicity adjustment may increase the risk of type I error (false positives). At the same time, because the sample size was not specifically calculated to detect effects in secondary variables, the study may also be subject to type II error (false negatives) for outcomes with small effect sizes. Accordingly, analyses of secondary outcomes were exploratory in nature, and no adjustments were made for multiple comparisons. Therefore, findings related to secondary end points should be interpreted with caution and regarded as hypothesis-generating rather than confirmatory. While adherence metrics were reported, key implementation outcomes related to intervention reach (eg, recruitment yield, refusal reasons, and population representativeness) were not quantitatively captured. This represents a limitation in fully characterizing the implementation context and may constrain the interpretation of broader applicability. Finally, participants were recruited from a single monoracial country. Future studies should aim to recruit more diverse populations to enhance global generalizability.

Conclusion

In summary, this randomized controlled trial showed that a personalized digital health program integrating exercise and nutrition is safe, feasible, and associated with high satisfaction and adherence among patients with GC in the early postoperative period. However, the intervention did not produce measurable benefits over standard education in postoperative weight change or other functional and nutritional outcomes. These results suggest that when applied broadly across all postoperative patients, digital health tools may function primarily as supportive monitoring platforms rather than interventions that biologically augment recovery. Future research is needed to identify subgroups that may benefit most, optimize intervention timing and intensity, and determine how digital programs can complement existing rehabilitation pathways.

Acknowledgments

We would like to thank Medi Plus Solution for technical support and all hospital members who devoted their efforts to the study.

Funding

This research was supported by the National IT Industry Promotion Agency, funded by the Ministry of Science and Information and Communications Technology of Korea (project numbers S2001-20-1006 and S2401-21-1001, Project Healthcare Big Data Showcase Utilization Service Support: Cancer Patient Treatment and Prognosis Management Service Development). The funder played no role in the study design, data collection, analysis, and interpretation, or writing of the manuscript.

Data Availability

The datasets used and/or analyzed in this study are available from the corresponding author upon reasonable request.

Authors' Contributions

IK was responsible for writing the original draft and for review and editing, as well as for formal analysis and conceptualization. JY Lim and SWK contributed to the investigation, data curation, resources, and methodology. JHL, TSS, SP, and SHK were involved in providing resources and in data curation and methodology. JY Lee and JHH led the conceptualization and methodology and were responsible for supervision, project administration, review and editing, and funding acquisition. All authors reviewed and approved the final version of the manuscript.

Abstract

Background: Frailty is highly prevalent in survivors of multiple myeloma (MM) after autologous hematopoietic cell transplantation and is associated with poor functional recovery and adverse clinical outcomes. Although exercise is known to improve physical function, traditional center-based rehabilitation models are often inaccessible to this population during early posttransplant recovery. Mobile health (mHealth)–supported exercise may offer a scalable alternative; however, evidence in hematologic malignancies remains limited.

Objective: This study aimed to evaluate the effects of a 16-week mHealth-supported exercise rehabilitation program on frailty phenotype and physical function in survivors of MM within 180 days after autologous hematopoietic cell transplantation.

Methods: In this single-center randomized controlled trial, participants who self-reported as prefrail or frail were randomized 1:1 to an mHealth-supported exercise group (n=16) or usual care control (n=16). Remote assessments were conducted at baseline (week 0), midpoint (week 9), and follow-up (week 17). The intervention consisted of 8 weeks of supervised tele-exercise (3 sessions/week, 50 minutes/session), followed by 8 weeks of independent home-based exercise using the same mHealth platform. Exercise intensity was prescribed using a repetitions-in-reserve–based rating of perceived exertion approach with symptom-guided progression. The primary outcome was change in the 5-component Fried frailty phenotype score (0-5). Secondary outcomes included Short Physical Performance Battery components, chair stand time, gait speed, and handgrip strength. Intention-to-treat analyses were conducted using generalized estimating equations to evaluate between-group differences over time.

Results: Participants had a mean age of 64.6 (SD 7.1) years and were enrolled a mean of 136 (SD 36.3) days posttransplant. At baseline, 94% (30/32) of participants were classified as frail. Adherence to the supervised sessions was 85% (326/384 sessions), and adherence during the unsupervised phase was 78% (298/384 sessions). The exercise group demonstrated a significantly greater reduction in frailty score compared with control from baseline to week 17 (P<.001). Between-group difference estimates showed a clinically meaningful improvement favoring exercise at both week 9 and week 17 (P<.001). Chair stand time improved significantly in the exercise group compared with control, with faster completion times observed at week 9 and sustained through week 17 (P=.002). Improvements in other Short Physical Performance Battery components and handgrip strength favored the exercise group but did not reach statistical significance. No serious adverse events occurred.

Conclusions: A 16-week mHealth-supported, progressively prescribed exercise rehabilitation program was feasible, safe, and effective in reversing frailty phenotype and improving functional mobility in survivors of MM early after autologous transplantation. This approach provides a scalable model for delivering structured rehabilitation during a high-risk recovery window. Larger trials incorporating attention-matched controls and longer follow-up are warranted.

KEYWORDS

mobile health exercise; mHealth exercise; multiple myeloma; frailty; autologous hematopoietic cell transplantation

Introduction

Background and Rationale

Autologous hematopoietic cell transplantation (HCT) improves progression-free survival in patients with multiple myeloma (MM) [1]. Advances in treatment approaches, coupled with improved access to HCT, have contributed to a growing number of patients with MM undergoing HCT annually. In fact, MM is the most common indication for HCT, with >7000 patients undergoing autologous HCT annually in the United States alone [2]. However, despite improvements in disease-related outcomes, patients with MM who undergo HCT remain at high risk of experiencing frailty after HCT, attributed to pre-HCT treatment exposures, HCT-related conditioning therapies, and post-HCT acute toxicities [3,4].

The frailty phenotype is characterized by the presence of 3 or more of the following characteristics: underweight, exhaustion, low energy expenditure, slow gait speed, and weak muscle strength [3,5,6]. Two-thirds of patients with MM are estimated to be frail at diagnosis or shortly thereafter, and the prevalence of frailty increases after HCT [7]. In an International Myeloma Working Group report, frailty was associated with significantly worse overall survival and a higher rate of treatment discontinuation (31.2% vs 16.5%) [8]. This underscores the need to develop innovative strategies to mitigate frailty in patients with MM and its associated morbidity and mortality following HCT.

Supervised exercise-based interventions have been shown to improve physical function and frailty in patients with chronic health conditions, including cardiovascular diseases and cancer [9,10]. Traditionally, supervised exercise interventions have been delivered in person at specialized centers, an approach that poses logistical challenges and limits access for many patients. Supervised prescriptive mobile health (mHealth) exercise interventions have emerged as alternatives to in-person approaches, offering the convenience of anytime and anywhere access to patients, regardless of geographic boundaries [11]. Studies in patients with other cancer types, such as the breast and endometrium, have shown that an mHealth exercise is effective in improving physical function, BMI, and health-related quality of life [12,13]. There is a paucity of information on the safety and efficacy of mHealth exercise intervention in prefrail and frail patients with MM.

Objective and Hypothesis

To address this limitation, we conducted a randomized controlled trial evaluating the effectiveness of an mHealth exercise intervention aimed at improving frailty and physical function in patients with MM shortly after undergoing HCT. We hypothesized that a 16-week mHealth exercise intervention would significantly improve frailty and physical function in these patients.

Methods

Study Design and Setting

This was a single-center randomized control trial conducted at City of Hope (COH). The trial was registered at ClinicalTrials.gov (NCT05142371) on October 29, 2021. We conducted a 16-week mHealth intervention that included baseline (week 0) and postintervention (week 9 and week 17) assessments of physical function and frailty phenotype. All study procedures, including screening, enrollment, intervention, and data collection, were performed using an mHealth-based approach, eliminating the need for participants to be assessed at a center. This study adheres to the CONSORT (Consolidated Standards of Reporting Trials) guidelines for reporting randomized controlled trials.

Participants and Eligibility Criteria

The participant eligibility criteria are shown in Textbox 1.

XSL•FO
RenderX

Textbox 1. Participant eligibility criteria.

Inclusion criteria

- Diagnosis of multiple myeloma
- Aged >18 years at enrollment
- Prefrail or frail status (ie, Fried criteria: clinically underweight [BMI <18.5 kg/m^2], exhaustion, low energy expenditure, slow walking speed, and muscle weakness), with the presence of 2 of 5 indexes classified as prefrail and ≥3 of 5 indexes classified as frail [14]
- <180 days after hematopoietic cell transplantation
- Physically able and willing to complete all study procedures
- English speaking

Exclusion criteria

- Had clinically significant or active cardiovascular disease (eg, unstable angina and uncontrolled arrhythmia)
- Had contraindications to exercise (acute infectious disease or unstable bone lesions)
- Were recovering from a recent injury or were physically injured in the past 6 months, whereby participation in rigorous exercise may not be appropriate
- Were already participating in regular, structured exercise (>60 minutes/week)

Screening, Recruitment, and Randomization

Prescreening of potentially eligible patients was performed using an established institutional review board–approved COH protocol for long-term follow-up after HCT [15]. During telephone prescreening, participants were asked simple mobility and fatigue screening questions, including whether they were able to ambulate independently without assistance and whether they experienced persistent fatigue or low physical activity. Frailty status was formally confirmed during the baseline remote assessment prior to randomization. Individuals self-reporting characteristics consistent with prefrailty or frailty were invited for formal remote assessment. Once potentially eligible patients were identified, we notified their primary hematologist to obtain clearance prior to our outreach. Potentially eligible patients were then contacted by phone to assess their willingness to participate and to screen for patient-reported symptoms related to prefrailty or frailty. If potentially eligible patients expressed interest in the study, a trained clinical research assistant conducted detailed discussions with the patients over the phone regarding the additional study inclusion and exclusion criteria. Once patients were found to be eligible for participation, they provided informed consent using a web-based consent form (DocuSign Inc). Participants were randomly assigned in a 1:1 ratio to either the mHealth exercise group or the control group using a computer-generated random allocation sequence. The sequence was prepared by an independent statistician not involved in study conduct. Allocation concealment was maintained, as participants were enrolled by the study coordinator, while group assignments were implemented by a separate investigator who was unaware of the allocation sequence.

Intervention: mHealth-Supported Exercise Intervention

Intensity Prescription and Progression

Exercise intensity during resistance training was prescribed using a repetitions-in-reserve–based rating of perceived exertion (RPE) scale [16]. Participants were instructed to perform exercises at an intensity corresponding to RPE 7 to 8, indicating that they could complete approximately 2 to 3 additional repetitions before fatigue. If participants reported that they could perform >4 additional repetitions (RPE ≤6), resistance or repetitions were increased. Conversely, if participants could perform fewer than 1 to 2 additional repetitions (RPE ≥9) or reported excessive fatigue, discomfort, or dizziness, the exercise was modified by reducing resistance, repetitions, or range of motion and increasing rest intervals. Progression followed a standardized symptom-guided approach. When participants completed all prescribed sets at RPE ≤7 for 2 consecutive sessions, exercise difficulty was progressed by increasing repetitions, adding sets, or advancing resistance band tension and balance challenge. This allowed individualized progression while maintaining safety in the early posttransplant period. Details of the intervention strategies used have been previously published [17]. Exercise equipment, including resistance bands, resistance loop bands, and exercise mats, was shipped directly to participants from COH. The exercise intervention consisted of 2 phases. The first phase offered each participant 24 supervised exercise sessions, each lasting 50 minutes and held 3 times per week for 8 weeks. All sessions in the first 8 weeks were supervised remotely via videoconferencing. Participants could reschedule or make up sessions if they were unable to attend as planned. Their adherence to the program was tracked on the platform. After completing the initial 8-week intervention, the second phase encouraged participants to continue exercising independently without direct monitoring by the exercise trainer for the subsequent 8 weeks until the follow-up physical assessment (week 17). Participants in the control group were asked to maintain their current lifestyle for 17 weeks. They were

XSL•FO
RenderX

later offered the same mHealth exercise intervention as a courtesy, though it was not mandatory for completing the study procedures.

Sample Exercise Plan

A representative example of a supervised exercise session structure, including balance, strength, and core components with repetitions-in-reserve–based RPE targets and progression rules, is provided in Multimedia Appendix 1 to facilitate reproducibility of the intervention.

Outcomes and Remote Assessments

We used a commercially available mHealth exercise platform (Moterum Technologies) that offers exercise videos, physical activity monitoring, and automatic data collection from wearable devices. We sent gait sensors (for the hip, right foot, and left foot), a hand dynamometer, measuring tape, and blue tape to each participant's home via mail. This equipment was used to assist in measuring physical function and frailty phenotype outcomes before and after the intervention in both groups.

Frailty Phenotype (Primary Outcome): Components and Cutoff Values

Frailty was assessed using the 5-component Fried phenotype (score range 0-5), with 1 point assigned for each component present and participants classified as prefrail (2/5) or frail (≥3/5). The operational definitions followed the original Fried criteria: (1) low BMI defined as BMI <18.5 kg/m²; (2) exhaustion defined as a Functional Assessment of Chronic Illness Therapy-Fatigue score ≤30, indicating clinically meaningful fatigue; (3) low physical activity defined as <600 metabolic equivalent minute/week based on International Physical Activity Questionnaire-Short Form scoring guidelines; (4) slow gait speed defined as a 4-m walk speed <0.8 m/second; and (5) weakness defined as handgrip strength <26 kg for men and <18 kg for women. All measures were obtained remotely using mailed equipment and videoconference supervision. All frailty assessments were conducted under live videoconference supervision by trained research staff to ensure standardized administration.

Physical Function

We assessed physical function remotely using the Short Physical Performance Battery (SPPB) under the supervision (through videoconferencing) of study staff. Remote administration of the SPPB has previously been shown to demonstrate acceptable validity and reliability compared with in-person assessment when standardized instructions and camera positioning are used [18,19]. SPPB included 3 lower extremity measures completed in the following order: timed balance, gait speed, and chair stand. We evaluated timed balance under three conditions: (1) side-by-side stand with both feet placed on the ground for 10 seconds or when the participant steps out of position, (2) semitandem stand with the side of the heel of one foot touching the big toe of the other foot for 10 seconds or when the participant steps out of position, and (3) tandem stand with the heel of one foot touching the big toe of the other foot for 10 seconds or when the participant steps out of position. We evaluated chair stand performance under 2 conditions: participants performed a single chair stand, and then they were asked to perform 5 repeated chair stands as quickly as possible. The time taken to complete each task was recorded.

Sample Size and Power Calculation

The original sample size calculation was based on detecting a between-group difference in frailty phenotype score at week 9, which was considered the primary early end point. Assuming a 2-sided α of 0.05, 80% power, 20% attrition, and a within-person correlation of 0.80 across repeated measures, 60 participants (30 per group) were estimated to be required to detect a standardized effect size (Cohen *d*) of 0.40. This effect size was selected based on prior exercise intervention studies demonstrating moderate improvements in frailty-related functional outcomes in clinical populations [20,21].

Owing to recruitment challenges in this specific posttransplant population, the final sample size was 32 participants (16 per group). Under the same assumptions, this sample size provided 80% power to detect a larger effect size of 0.50. Therefore, this study should be interpreted as an early-phase randomized trial with adequate power to detect moderate-to-large intervention effects but limited precision for smaller effects and generalizability.

Statistical Analysis

We generated descriptive statistics for participants' demographics, level of physical activity, and history of chronic health conditions. Assuming a 2-sided type I error of 0.05, intention-to-treat analyses were performed using all randomized participants. Changes in frailty index from baseline to week 9 and week 17 were evaluated using the Generalized Estimation Equation methods with 2 indicators of time, assuming a compound symmetry within-person correlation matrix. We included treatment by time interaction and tested its significance using a 2-*df* χ^2 test. BMI, age, and race (non-Hispanic White vs other) were included as a priori covariates for adjustment. Additionally, between-group differences in outcome values at week 17 were computed, along with 95% CIs, and compared with differences at week 9.

Ethical Considerations

The study protocol was approved by the COH Institutional Review Board (21406) and was conducted in accordance with institutional and national ethical standards for research involving human participants. All participants provided written informed consent electronically (DocuSign) prior to participation and were able to withdraw at any time without affecting their clinical care. Study data were deidentified and stored on secure institutional servers accessible only to authorized study personnel. Participants received a US $50 gift card as compensation for their time and participation. The trial was registered at ClinicalTrials.gov (NCT05142371) on October 29, 2021.

Results

Participant Flow and Retention

A total of 212 potentially eligible patients with MM were identified in the long-term follow-up program following HCT at COH (Figure 1). Of the 129 successfully contacted patients

XSL•FO
RenderX

with MM, 46 (36%) refused due to lack of interest, confidence in mHealth exercise settings, and time and 45 (35%) were deemed ineligible (Figure 2). Among the initial 33 prefrail or frail patients with MM who were enrolled, 1 individual withdrew from the study prior to randomization. This resulted in 32 patients randomized equally to either the mHealth exercise group (n=16) or the control group (n=16).

Baseline Characteristics

Baseline characteristics are presented in Table 1. All participants had received high-dose melphalan conditioning (standard dose, 200 mg/m^2), with appropriate dose reduction (140 mg/m^2) for those with renal impairment (eg, creatinine clearance <40 mL/min), per standard of care. The mean age at study enrollment was 64.6 (SD 7.1) years. Of the 32 participants, 21 (66%) were female and 18 (56%) were non-Hispanic White. The mean time from HCT to study enrollment was 136 (SD 36.3) days. At baseline, 30 (94%) participants were classified as frail and 2 (6%) as prefrail according to the Fried phenotype criteria. The most common frailty characteristics were exhaustion (n=32, 100%) and low physical activity (n=30, 94%), followed by weakness (n=23, 72%), slow gait speed (n=19, 59%), and low BMI (n=1, 3%).

Intervention Adherence and Safety

All participants (32/32, 100%) successfully completed remote physical function assessments prior to randomization and initiation of the intervention. At week 9, 2 (6%) participants were lost to follow-up, and an additional 2 (7%) were lost at week 17 (1 from each group at both time points). During the initial 8-week supervised phase, adherence to the 24 prescribed exercise sessions among participants in the intervention group was 85% (326/384 sessions). During the subsequent 8-week unsupervised phase, participants remained engaged with the mHealth platform and completed 78% (298/384 sessions) of the prescribed exercise sessions. No serious adverse events or unintended effects were reported during the intervention period.

Primary Outcome: Frailty Phenotype

Overall, the mHealth exercise intervention resulted in a significant adjusted between-group reduction in frailty phenotype at week 9 (−0.92 points; 95% CI −1.38 to −0.46 ; P<.001), which was further sustained at week 17 (−1.14 points; 95% CI −1.66 to −0.62; Table 2). Descriptively, 63% (10/16) participants in the intervention group no longer met criteria for slow gait speed or low physical activity at both week 9 and week 17, whereas 88% (14/16) participants in the control group continued to meet these frailty components across the study period.

[a]Between-group differences represent adjusted change estimates (exercise vs control) derived from generalized estimating equation models with 95% CIs based on intention-to-treat analysis.

[b]*P* values correspond to the treatment by time interaction terms from the same models.

Secondary Outcomes: Physical Function

The mHealth exercise intervention resulted in a significant adjusted between-group improvement in chair stand performance at week 9 (−2.78 seconds; 95% CI −4.66 to −0.90) that was sustained at week 17 (−3.50 seconds; 95% CI −5.58 to −1.42; Table 2). The adjusted between-group difference in handgrip strength did not reach statistical significance. However, descriptively, dominant arm strength increased within the intervention group, with 50% (8/16) participants demonstrating an increase of >1 kg by week 9 that was maintained through week 17, whereas no consistent change was observed in the control group.

Discussion

Principal Findings

The findings of this study demonstrated the efficacy of an mHealth exercise intervention in improving frailty phenotype and physical function among patients with MM who had recently undergone autologous HCT. This study is among the first to evaluate a fully remote, supervised mHealth exercise intervention specifically targeting frailty reversal in patients with MM following transplantation. This indicates the potential for mHealth interventions to provide sustainable support and benefits for individuals with MM beyond their major cancer treatments. The observed improvements in chair stand performance highlight the potential of mHealth exercise to address key aspects of physical function in patients with MM. These outcomes are clinically meaningful, as each unit increase in chair stand score has been associated with a 21% improvement in survival among older adults [22].

Comparison With Prior MM Trials

Randomized evidence supporting exercise and behavioral interventions in MM is emerging; however, prior trials have largely focused on behavioral coaching models rather than the delivery of structured, progressive exercise targeting functional recovery and frailty. The REAL-FITNESS trial randomized newly diagnosed patients to a World Health

XSL•FO
RenderX

Organization–compliant physical activity prescription during induction therapy and demonstrated improvements in fatigue, depression, grip strength, comorbidity burden, and quality of life [23]. This study importantly established that promoting guideline-based physical activity is feasible and beneficial during treatment. However, the intervention primarily emphasized adherence to aerobic and resistance activity targets rather than delivering supervised, progressive exercise with quantified intensity, and the population did not include patients recovering from the physiological stress of transplantation where frailty risk is substantially heightened. Similarly, Larsen et al [24] conducted a randomized trial of a 10-week individualized exercise program in newly diagnosed patients with MM with careful adjustment for lytic bone disease. The trial demonstrated that exercise is safe in this population and may improve functional measures such as sit-to-stand performance and aerobic capacity. However, no clear between-group superiority was observed, and the study population consisted of patients earlier in their disease trajectory rather than individuals in the high-risk posttransplant recovery phase. Moreover, neither study used frailty as a primary outcome. In contrast, Banerjee et al [25] evaluated a digital life coaching intervention during stem cell transplantation and demonstrated that sustained patient engagement and patient-reported outcomes can be maintained through a fully remote support model even during the intensive peritransplant period. While this work demonstrated the potential of digital health platforms in MM care, the intervention focused on behavioral coaching and patient-reported outcomes rather than structured exercise delivery or objective functional end points.

This trial extends this literature in several clinically meaningful ways. First, it specifically targets the early recovery window following autologous transplantation and deliberately enrolls individuals who are prefrail or frail, a subgroup central to posttransplant morbidity but underrepresented in prior MM exercise trials. Second, the intervention delivers supervised, progressive exercise with explicit intensity and progression during the early phase, followed by a sustainability phase within the same mHealth ecosystem, rather than relying primarily on activity encouragement or coaching. Third, the study pairs this intervention with remote objective functional assessments and a frailty phenotype end point, directly evaluating frailty reversal rather than changes in activity volume or quality of life metrics alone. Collectively, these features position mHealth-supported exercise rehabilitation as a scalable strategy for functional recovery and frailty reversal in survivors of MM after transplantation, complementing and extending prior MM trials conducted in earlier disease phases and coaching-focused digital models.

Interpretation and Potential Mechanisms

The observed adherence to the prescribed exercise sessions during both the supervised (326/384, 85%) and unsupervised phases of the intervention (298/384, 78%) is noteworthy. Despite the transition to unsupervised exercise sessions during the second 8-week phase, participants remained physically active and responsive to the prescribed exercise regimen. This indicates the feasibility and sustainability of mHealth exercise interventions in facilitating engagement in continuous exercise training among patients with MM, even in the absence of direct supervision. Developing a tailored exercise intervention within similar disease and treatment profiles may allow for health care professionals to address specific patient's needs or challenges and enhance the effectiveness of rehabilitation strategies. One notable aspect of the findings from this study is the absence of significant improvement in gait speed following the intervention, despite the observed improvements in other measures of chair stand performance and frailty phenotype. Gait speed is widely used to assess functional capacity, and its assessment provides valuable insights into an individual's ability to perform physical activities [26]. However, the discrepancy between self-reported improvements in gait and the lack of significant changes in objective measures of gait speed in our study may present an intriguing aspect of the study findings. While participants may have subjectively perceived improvements in their gait, as reflected in self-reported frailty phenotype assessments, these perceptions may not have translated into measurable changes in gait speed during objective assessments [27]. It is possible that participants experienced improvements in other aspects of gait performance, such as perceptions of effort or changes in overall mobility, that were not captured by the gait speed itself. Furthermore, variability in testing conditions, such as the testing environment and surface conditions, may have influenced gait speed measurements and introduced variability in the results.

Limitations

While this study represents an important step forward in exploring the potential of mHealth exercise interventions to improve frailty phenotype and physical function in patients with MM, it is important to acknowledge certain limitations. First, the sample size was modest and drawn from a single center, which limits statistical precision and generalizability. Second, the control group did not receive an attention-matched intervention; therefore, nonspecific effects related to increased contact, accountability, or health-focused reminders cannot be excluded as contributors to the observed improvements. Third, eligibility required English proficiency and familiarity with telehealth technology, which may limit applicability to non-English speakers and individuals with lower digital literacy. Finally, although remote objective assessments were incorporated, some frailty components relied on self-report measures, which may introduce reporting bias.

Conclusions
