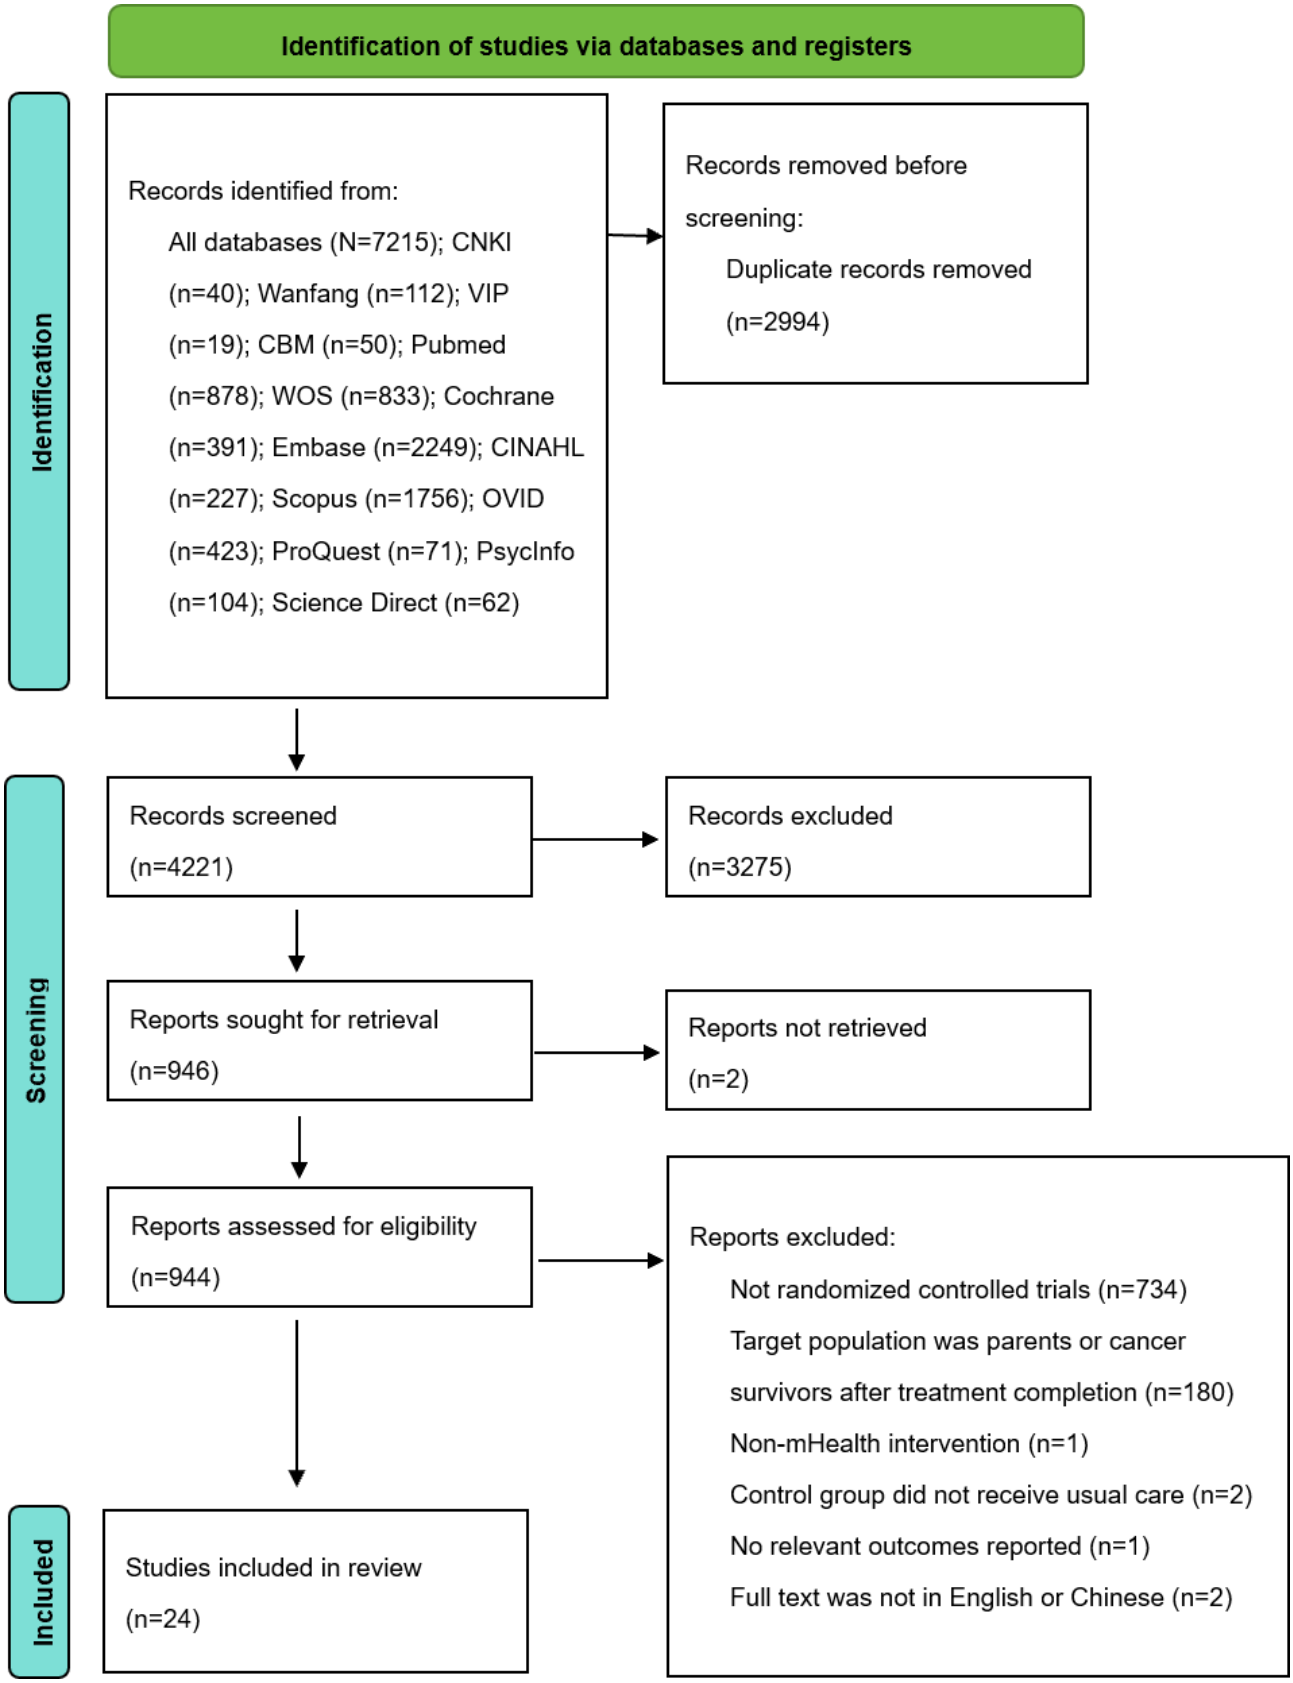
This study adhered to the Cochrane Handbook [29] for data synthesis and analysis, using RevMan 5.4 (Nordic Cochrane Center) and Stata 15.0 (StataCorp) for statistical procedures. Effect measures included standardized mean differences (SMD, 95% CI) and odds ratios (OR, 95% CI). Heterogeneity was assessed using I^2 and P values; when I^2 >50% and P<.1 (indicating substantial heterogeneity), a random-effects model was used; otherwise, a fixed-effects model was used. Sensitivity analyses were conducted using a stepwise exclusion, while subgroup analyses and meta-regression were used to explore heterogeneity. Publication bias was assessed with funnel plots and Egger's test. A P<.05 was considered statistically significant.



Results

Search Results

A total of 7215 studies were identified, with 24 meeting the inclusion criteria for the systematic review and meta-analysis (Figure 1).

Descriptions of the Included Studies

This study included 24 RCTs published between 2017 and 2025, the main characteristics of which are summarized in Table 1. Most of the studies (19) were conducted in China [30-48], while one each was conducted in America [49], Canada [50], Iran [51], the Netherlands [52], and Turkey [53]. These studies involved a total of 2645 children with cancer, with sample sizes ranging from 18 to 444 participants. The cancer types included hematologic malignancies, brain tumors, bone tumors,

XSL•FO
RenderX

neuroblastoma, sarcomas, and other solid tumors. Participants were aged 0 - 18 years. The intervention durations varied from 7 days to 2 years. The intervention settings included home-based (9 studies [30-33,35,37,41,51,52]), hospital-based (3 studies [34,50,53]), and combined home and hospital (12 studies [36,38-40,42-49]).

[a]T: experimental group.

[b]C: control group.

[c]Age is given as mean (SD), range values, and median (IQR).

[d]BCT: behavior change technique.

[e]*Goals and planning:* Personalized planning of medication, exercise, follow-up visits, disease management, and personal development.

[f]*Feedback and monitoring:* Recording medication information, disease management, assessments, and test results with data visualization, generating corresponding guidance and recommendations; providing regular reminders, alerts for critical values or risky behaviors; and enabling video consultations or scheduling in-person follow-ups.

[g]*Social support:* Establishing 2-way communication channels with other families and medical staff or offering assistance and reimbursement consultations.

[h]*Natural consequences:* Enabling individuals to understand or experience the natural consequences of their behaviors.

[i]*Reward and threat:* Using virtual tasks or gamified elements to assess the mastery of self-care knowledge and providing point-based rewards or badge recognition.

[j]*Usual care:* During hospitalization, treatments are administered according to medical orders, with face-to-face monitoring of vital signs and rehabilitation care, while maintaining a comfortable ward environment. Before discharge, guidance is provided via verbal instructions, printed materials, or health education videos, covering medication, diet, and catheter care. At home, care and record-keeping are performed by family members, with medical staff monitoring the condition and addressing questions through regular phone calls or outpatient follow-ups. This approach does not involve mobile apps or online platform support.

[k]SEAMS: Self-Efficacy for Appropriate Medication Use Scale.

[l]*Shaping knowledge:* Providing staged information delivery, search, and storage functions related to disease, symptoms, catheter care, and medication management.

[m]NRS-11: Numerical Rating Scale–11.

[n]BPI-SF: Brief Pain Inventory–short form.

[o]ET: emotion thermometer.

[p]*Comparison of outcomes:* Promoting belief enhancement and behavior change through social comparison and modeling by sharing successful cases, organizing parent communication for mutual learning, and demonstrating practical experiences and caregiving skills.

[q]PICC: peripherally inserted central catheter.

[r]KAP: knowledge, attitude, and practice.

[s]PedsQL 4.0: Pediatric Quality of Life Inventory 4.0.

[t]SCAS-C: Spence Children's Anxiety Scale—child version.

[u]ESCA: Exercise of Self-Care Agency Scale.

[v]*Repetition and substitution:* Conducting online cognitive-behavioral interventions, professional psychological counseling, or other complementary medical interventions.

[w]ARINVc: Children's Version of the Adapted Rhodes Index of Nausea and Vomiting.

[x]ARINVp: Parent Version of the Adapted Rhodes Index of Nausea and Vomiting.

[y]REDCap: Research Electronic Data Capture.

[z]AWC: adolescents with cancer.

[aa]PPUS-CC: Parent Perception of Uncertainty Scale–Child Chronic Illness version.

[ab]RHDS: Readiness for Hospital Discharge Scale.

[ac]SF-36: 36-Item Short Form Survey.

[ad]PSQI: Pittsburgh Sleep Quality Index.

[ae]*Regulation:* Helping individuals reduce negative emotions, relieve tension and stress, and maintain a more stable and positive psychological and physiological state through interventions such as stress management and music therapy.

[af]CMFS: Children's Medical Fear Scale.

[ag]Not available.

[ah]MEMS: Medication Event Monitoring System.

[ai]HAD: Hospital Anxiety and Depression Scale.

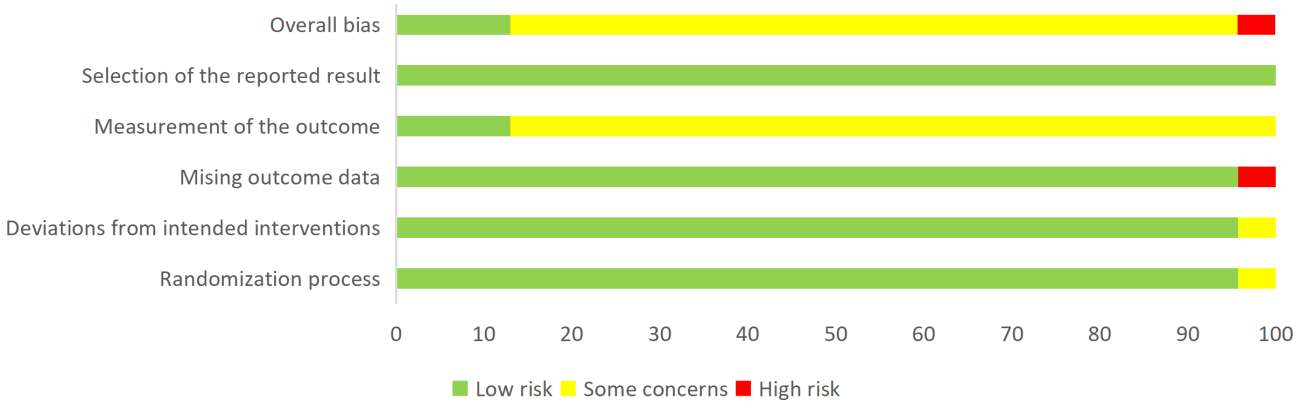
RenderX

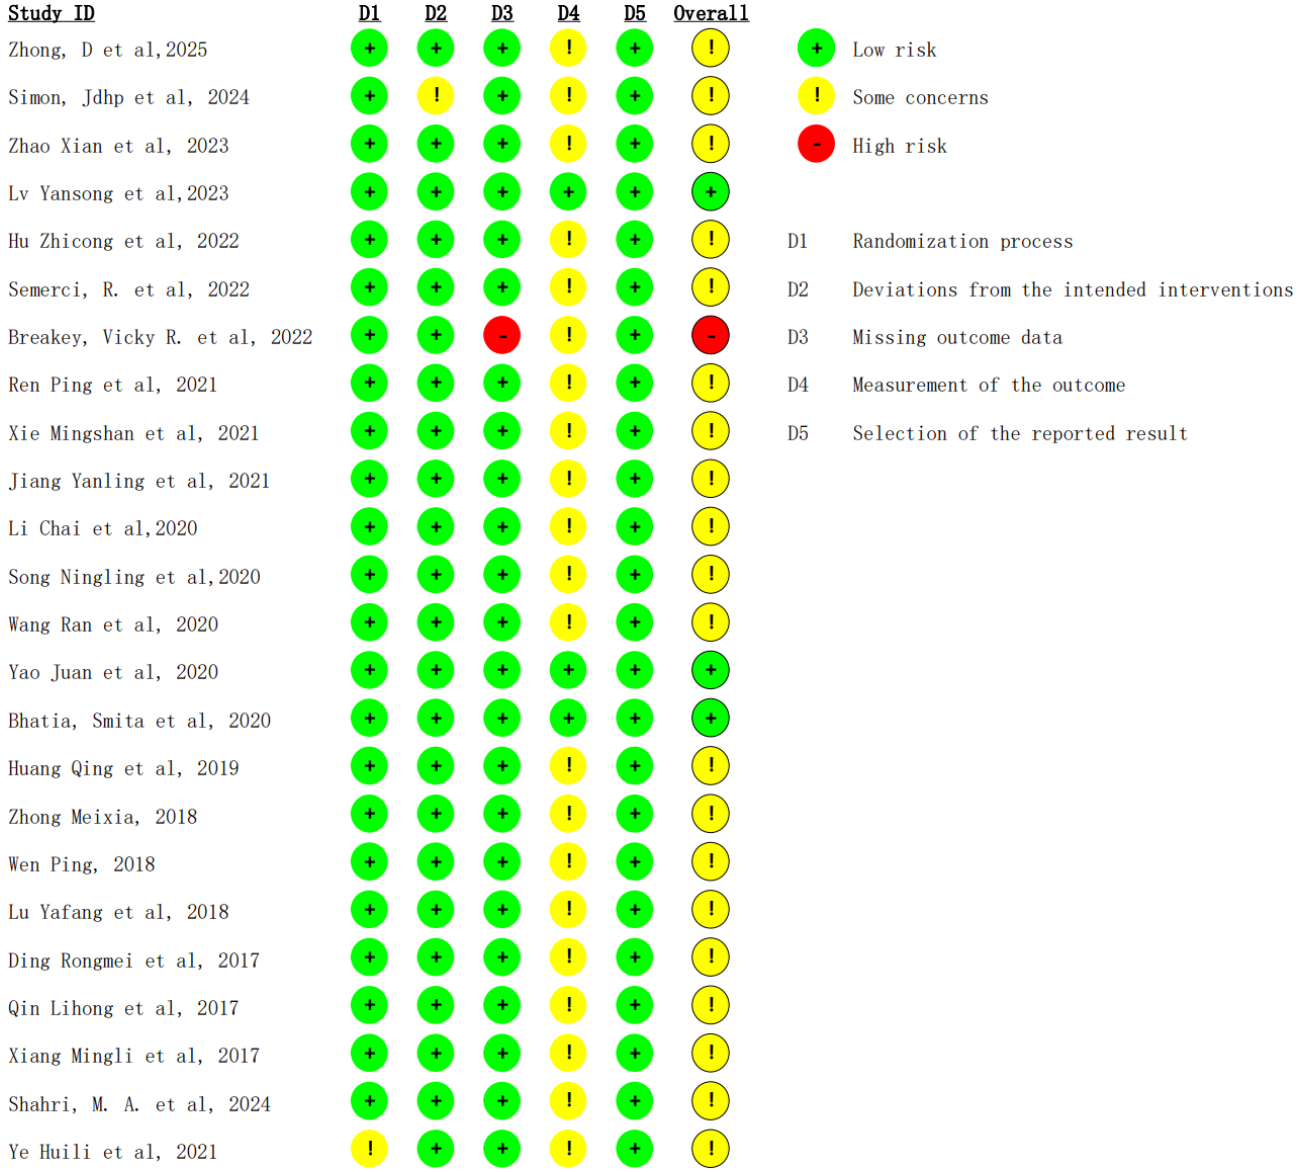
Regarding intervention platforms used for the experimental groups, 15 studies [30-33,35-39,42-47] used WeChat (a widely used mobile-based social media and communication app in China that supports messaging, group communication, and content dissemination[54]), 1 used a website [50], 3 used professional medical apps [41,52,53], and 5 used mixed platforms [34,40,48,49,51]. All interventions were conducted under the guidance of medical staff. Figure 2 shows the BCTs used in each study. A total of 13 studies involved goals and planning [30,31,34-36,38-40,42,43,45,46,50]; 19 studies included feedback and monitoring [30-35,38,39,41-43,45-50,52,53]; 21 provided social support [30-44,46-48,50-52]; 21 included shaping knowledge; 3 involved repetition and substitution [36,49,53]; 4 included reward and threat [30,32-34]; 3 conducted comparison of outcomes [31,39,47]; 16 incorporated natural consequences [30,31,34,36,39-41,43-49,51,52]; 2 involved regulation [36,44]. A total of 3 reported security measures such as password login and patient-specific data verification [41,50,51]. The control groups received usual care.

Figure 2. The behavior change techniques used in each study [30,31,32,33,34,35,36,37,38,39,40,41,42,43,44,45,46,47,48,49,50,51-53].



Quality Assessment Results

Among the 24 included studies (Figures 3 and 4), 3 were rated as low risk of bias [32,41,49]. One study had a high risk due to unaddressed missing data [50]; the remaining 20 had some concerns (1 study [52] due to potential bias in the intervention, 1 study [37] for not reporting allocation concealment, and the other 18 due to subjective outcome assessments potentially influenced by positive psychological suggestion).



XSL•FO
RenderX

Figure 3. Risk of bias graph.

GRADE evidence quality ratings are presented in Multimedia Appendix 2. Evidence for infection incidence, overall incidence of PICC complications, PICC phlebitis, PICC puncture site bleeding, PICC puncture site infection, PICC occlusion, PICC catheter dislodgement, and PICC catheter displacement was rated as moderate. In contrast, evidence quality for QoL, PICC thrombogenesis, health knowledge, children's self-management ability, and treatment adherence was rated as very low.

Figure 4. Risk of bias summary [30,31,32,33,34,35,36,37,38,39,40,41,42,43,44,45,46,47,48,49,50,51-53].

RenderX

Meta-Analysis Results

Infection Incidence

Six [31-33,39,41,44] of the 24 studies investigated the effectiveness of mHealth-based interventions in controlling infection rates among pediatric patients with cancer. The infections reported in the included studies primarily involved skin, bloodstream, catheter-related, oral, and perianal infections. The studies demonstrated homogeneity (P=.91; I^2=0%), thus enabling analysis using a fixed-effects model. The results showed that mHealth-based interventions could significantly reduce the incidence of infections (OR 0.25, 95% CI 0.10-0.60; P=.002, Figure 5).

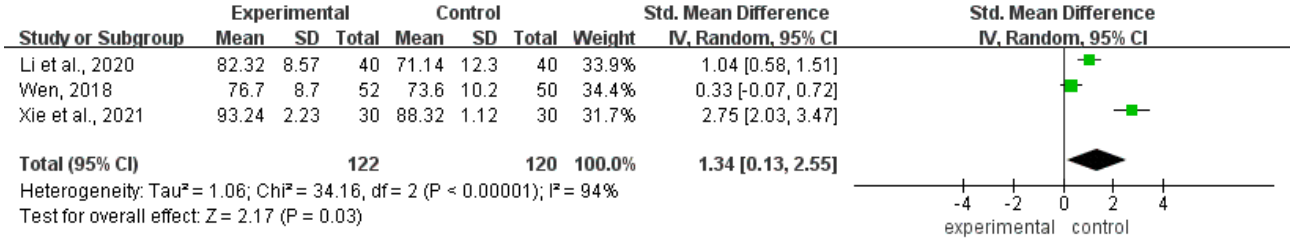

Figure 5. Forest plot of the effect of mHealth on infection incidence [31,32,33,39,41,44].

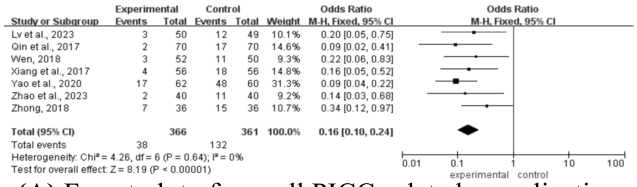
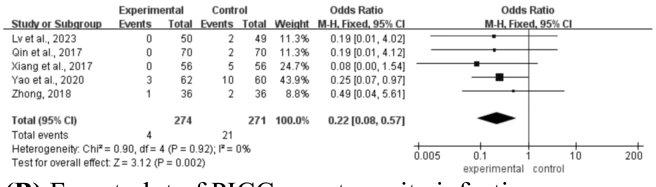
Quality of Life

Of the 24 studies included in the analysis, three [35,38,44] reported total QoL scale scores for pediatric patients with cancer who received mHealth-based interventions. Due to high heterogeneity across the studies (P<0.001; I^2=94%), a random-effects model was used for the analysis. Meta-analysis results showed that mHealth-based interventions were more effective than control in improving the QoL of children with cancer (SMD =1.34, 95% CI 0.13-2.55; P=.03, Figure 6).

Figure 6. Forest plot of the effect of mobile health on quality of life [35,38,44].



PICC-Related Complications



Among the 24 studies, 10 [31-33,40,41,43,44,46-48] reported the incidence of PICC-related complications in mHealth interventions, including the overall incidence of PICC complications (n=7) [31,32,41,43,44,47,48], puncture site infection (n=5) [32,41,43,47,48], phlebitis (n=9) [31-33,41,43,44,46-48], thrombogenesis (n=3) [33,43,47], puncture site bleeding (n=5) [32,41,43,44,47], catheter occlusion (n=8) [32,33,40,41,43,44,46,48], catheter dislodgement (n=9) [31-33,40,41,43,44,46,48], and catheter displacement (n=3) [43,46,47]. Heterogeneity tests revealed no significant heterogeneity among studies for any outcome measure (P>.1; I^2=0%), thus allowing analysis using a fixed-effect model. Meta-analysis results showed that in the mHealth intervention groups, the incidence of overall complications (OR 0.16, 95% CI 0.10-0.24; P<.001, Figure 7A), puncture site infection (OR 0.22, 95% CI 0.08-0.57; P=.002, Figure 7B), phlebitis (OR 0.30, 95% CI 0.16-0.58; P=.0003, Figure 7C), thrombogenesis (OR 0.15, 95% CI 0.03-0.82; P=.03, Figure 7D), puncture site bleeding (OR 0.28, 95% CI 0.12-0.61; P=.001, Figure 7E), catheter occlusion (OR 0.33, 95% CI 0.16-0.65; P=.002, Figure 7F) and catheter dislodgement (OR 0.29, 95% CI 0.16-0.54; P<.001, Figure 7G) were all lower than in the control groups. However, there was no significant difference in the incidence of catheter displacement (OR 0.44, 95% CI 0.15-1.29; P=.13, Figure 7H).

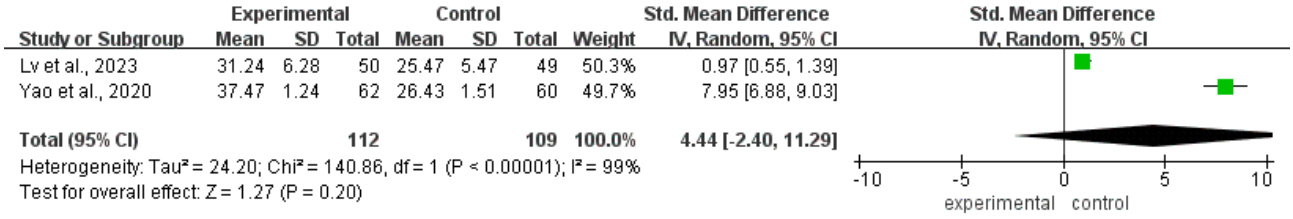
(G) Forest plot of PICC catheter dislodgement

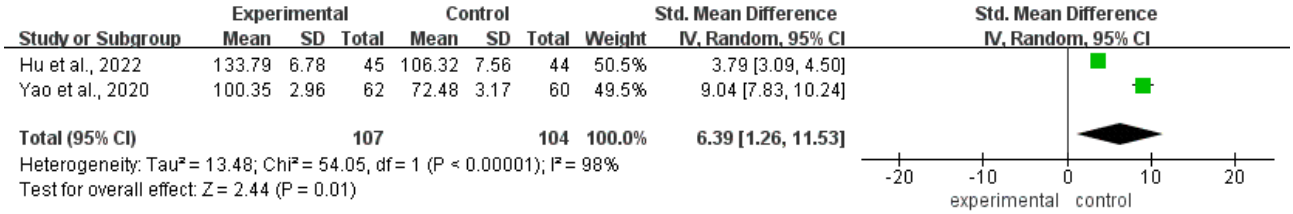


(H) Forest plot of PICC catheter displacement

Health Knowledge

Among the 24 studies, 2 [32,41] reported the effects of mHealth-based interventions on health knowledge. Owing to substantial heterogeneity (P<.001; I^2=99%), a random-effects model was used. There were no significant differences in health knowledge compared with the control group (SMD 4.44, 95% CI −2.40 to 11.29; P=.20, Figure 8).

Figure 8. Forest plot of the effect of mobile health on health knowledge [32,41].



Self-Management Ability

Among the 24 studies, 2 [33,41] reported the effects of mHealth-based interventions on self-management abilities in pediatric patients with cancer compared to usual care. Due to high heterogeneity across studies (P<.001; I^2=98%), a random-effects model was used for analysis. The results of the meta-analysis indicated that mHealth-based interventions were more effective than control in improving children's self-management abilities (SMD 6.39, 95% CI 1.26-11.53; P=.01, Figure 9).

XSL•FO
RenderX

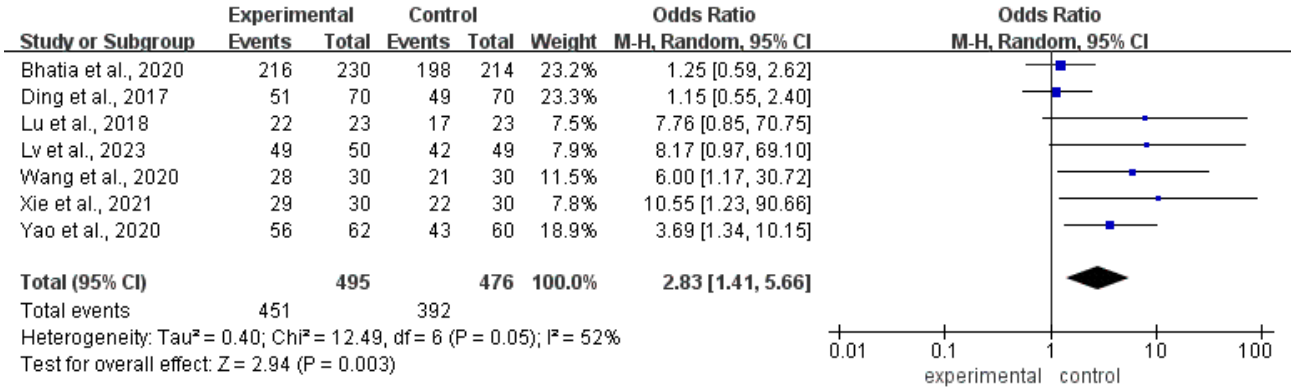


Figure 9. Forest plot of the effect of mobile health on self-management ability [33,41].

Treatment Adherence

Of the 24 studies, 10 [32,35-37,39,41,42,45,46,49] assessed the effectiveness of mHealth-based interventions compared to usual care in improving treatment adherence among pediatric patients with cancer. Two studies [36,42] were not pooled because of differences in scoring directions, and 1 study [37] was not entered into the quantitative synthesis owing to internally inconsistent and unverifiable adherence data; the remaining 7 studies reporting dichotomous adherence outcomes were included in the meta-analysis. Heterogeneity testing revealed significant heterogeneity among the studies (P=.05; I^2=52%), which prompted the use of a random-effects model. The results indicated that children in the mHealth group had higher treatment adherence than those in the control group (OR 2.83, 95% CI 1.41-5.66; P=.003, Figure 10).

Figure 10. Forest plot of the effect of mobile health on treatment adherence [32,35,39,41,45,46,49].

Sensitivity Analyses

For most outcomes, excluding any single study did not alter the effect sizes of mHealth-based interventions, indicating stable results (see Multimedia Appendix 3). Exceptions were observed for QoL, PICC complication incidence, and treatment adherence. For quality of life, excluding either study by Li et al [38] or Xie [35] led to significant changes in the overall effect size (SMD 1.52, 95% CI −0.86 to 3.90; P=.21; SMD 0.67, 95% CI −0.03 to 1.38; P=.06), indicating instability. Exclusion study by Hu et al [33] (OR 0.33, 95% CI 0.03-3.19; P=.34), substantially altered the effect estimate for thrombogenesis. In contrast, heterogeneity in treatment adherence decreased markedly after excluding the study by Ding et al [46] (P=.11; I^2=45%), while the pooled effect size remained stable (OR 3.72, 95% CI 1.68-8.22; P<.001). Two outcome indicators (health knowledge and self-management ability) were not subjected to sensitivity analysis as they were only involved in 2 studies.

Publication Bias

The assessment of publication bias in the effects of mHealth–based interventions on infection incidence, QoL, PICC-related complications, health knowledge, self-management ability, and treatment adherence in pediatric patients with cancer was facilitated by the use of funnel plots. The majority of the funnel plots demonstrated symmetrical patterns in the outcomes, with the exception of those pertaining to health knowledge and self-management ability (Multimedia Appendix 4). In addition, the Egger test was performed to evaluate the incidence of infection (t=0.56; P=.61), the QoL (t=12.12; P=.052), PICC-related complications (t=0.42; P=.69), PICC puncture site infection (t=−0.66; P=.55), PICC phlebitis (t=−1.59; P=.16), PICC thrombogenesis (t=20.91; P=.03), PICC puncture site bleeding (t=−0.39; P=.72), PICC catheter occlusion (t=−2.35; P=.07), PICC catheter dislodgement (t=−2.09; P=.08), and PICC catheter displacement (t=−0.59; P=.66), and treatment adherence (t=5.37; P=.003). The results indicated the absence of substantial publication bias, with the exception of the PICC thrombogenesis, health knowledge, self-management ability, and treatment adherence.

Subgroup Analysis and Meta-Regression

Subgroup analyses and meta-regression were not conducted because fewer than 10 studies were available for each outcome. This decision aligns with the Cochrane Handbook [55] guidelines to prevent false-positive results, insufficient statistical power, and unstable results.

Discussion

Principal Findings

This review aims to evaluate whether mHealth-based interventions are more effective than usual care for pediatric patients with cancer. The quality of the evidence for each

XSL•FO
RenderX

outcome measure in the included studies was graded using GRADEpro, with the following results:

1. Moderate certainty evidence: mHealth-based interventions significantly reduce the incidence of infections and PICC complications (including overall complications, puncture site infection, phlebitis, puncture site bleeding, catheter occlusion, and catheter dislodgement) compared to usual care in pediatric patients with cancer, with no significant effect observed for PICC catheter displacement.
2. Very low certainty evidence: mHealth-based interventions outperform usual care in improving QoL, self-management ability, treatment adherence, and reducing the PICC thrombogenesis rate among pediatric patients with cancer, but do not significantly enhance their health knowledge.

Effect of mHealth Interventions on Infection Rates

This is the first review to summarize the effect of mHealth on infection rates in pediatric patients with cancer, demonstrating a significant protective benefit. The interventions used 8 BCTs to establish effective bidirectional communication between clinicians and patients, offering practical insights for clinical implementation. Notably, the majority of interventions used WeChat, a social platform that dominates the Chinese digital landscape with over 1 billion monthly active users and preinstallation on more than 90% of smartphones across all age demographics. Its comprehensive functionality encompasses instant messaging (text, voice, and video messages), free audio and video calls, group chats (eg, interactions between health care professionals and patients or among patients), and private messaging for individualized consultation. In health care settings, WeChat is commonly used through official accounts (for health education dissemination), mini-programs (for data recording or questionnaire administration), and multimedia transmission (eg, image or video reports), offering advantages of low cost and wide reach [54]. Nevertheless, this app presents notable limitations. Interactions frequently depend on medical staff availability, potentially resulting in delayed responses [56]. In addition, current health education materials often require manual compilation and uploading, reducing efficiency and increasing clinician workload—potentially compromising care quality and safety. There is a clear need for more automated, dynamic content delivery systems.

Effect of mHealth Interventions on QoL

The results of a meta-analysis indicate that mHealth-based interventions significantly improved the QoL for pediatric patients with cancer compared to usual care. These findings address previous gaps in quantitative measurement [15] and reconcile inconsistencies attributed to confounding factors in interventions and populations [14]. The included mHealth interventions incorporated 6 BCTs, supporting psychological, social, and symptom-related needs, thereby reducing risks of psychological distress, infections, and PICC complications. However, high heterogeneity and sensitivity analyses indicate instability in these results. All studies on this outcome measure used WeChat as the platform, differing only in sample size and measurement tools. This suggests that the instability and heterogeneity of these intervention outcomes may be influenced more by methodological factors than by mHealth. In addition, the observed large effect size of QoL may be partly attributable to the elevated effect size in Xie's [35] study, which assessed outcomes at 2 months post intervention—a shorter timeframe than other studies (3 mo, 6 mo)—resulting in stronger short-term effects. Furthermore, the employment of subjective assessment scales in all studies may have resulted in an overestimation of results. Therefore, while mHealth interventions show potential for improving the QoL in pediatric patients with cancer, their long-term effects require further confirmation through more rigorous evidence-based studies before integration into routine clinical care.

Effect of mHealth Interventions on Incidence of PICC-Related Complications

This study is the first to summarize the effectiveness of mHealth-based interventions in reducing PICC-related complications within the pediatric oncology field. Results indicate that mHealth management significantly lowers overall complication rates compared to usual care, likely by mitigating recall bias and misunderstandings associated with traditional education methods (eg, demonstrations or printed manuals) [57]. The mHealth intervention in this outcome involved 8 BCTs, offering real-time monitoring and correction, scheduling and reminders, online assessment, and follow-up. Despite these advantages, the nonsignificant effect of mHealth on reducing catheter displacement may be attributed to children's growth and frequent postural changes, which increase the risk of mechanical traction [58]. Hu et al [33] implemented a reward and threat system (weekly quizzes with prizes for successful venous catheterization) that generated a more pronounced intervention advantage in the intervention group compared to the control group. In contrast, the remaining 2 studies [43,47] used health education manuals in their control groups, potentially reducing the distinction from the experimental group. This suggests that certain functions of mHealth may not necessarily offer a significant advantage over health education manuals for specific outcomes. Overall, mHealth appears effective for reducing PICC complications, though efficacy may vary by complication type and specific intervention components.

Effect of mHealth Interventions on Treatment Adherence

Similar to previous reviews [15], treatment adherence was significantly better in the mHealth group than in the usual care group. The mHealth intervention in this study integrated 9 BCTs. These strategies collectively address core aspects of treatment adherence, such as timely medication administration, maintaining appropriate lifestyle habits, and attending regular follow-up appointments and assessments [59]. Additionally, dedicated online accounts facilitate peer interaction, reducing stigma and enhancing adherence [60]. However, these results exhibit some heterogeneity and extreme effect sizes. The observed heterogeneity may be partly attributable to the 3-arm randomized controlled design used by Ding et al [46]. The extreme effect sizes may be related to the smaller sample sizes. Notably, while mHealth interventions significantly improve adherence among pediatric patients with cancer, participant attrition remains a significant issue. This may stem from limited digital literacy among children and their parents, which can

XSL•FO
RenderX

hinder the effective use of mobile devices and negatively impact adherence [61]. Therefore, clinical practice should establish timely feedback and reminder mechanisms, which may be key factors in maintaining long-term engagement among pediatric patients.

Effect of mHealth Interventions on Health Knowledge and Self-Management Ability

This review found that mHealth-based interventions did not significantly improve health knowledge scores, possibly due to a lack of age-appropriate educational content. The 4 BCT clusters used may not suffice for children's cognitive levels [62]. Future interventions should incorporate age-tailored content, interactive designs, and parental involvement to enhance learning outcomes. In contrast, mHealth interventions demonstrated favorable effects on improving children's self-management ability. This result pertains to 5 BCT clusters. Benefits likely stem from flexible, real-time education and feedback [63], empowering both children and caregivers [62]. The high effect sizes may reflect the use of subjective scales and potential Hawthorne effects.

However, Yao et al [41] used a professional medical platform for intervention, yielding effect sizes higher than those reported in studies using WeChat platforms [32,33] for both outcome measures. This discrepancy may explain the higher heterogeneity and wider confidence intervals observed, warranting cautious interpretation of the findings. Notably, Yao et al [41] was also the only study to conduct a cost-related analysis, reporting that the cost of hospital visits for PICC maintenance in the intervention group 117.50 CNY (US $17.07; IQR 105.00-132.50) was significantly lower than that in the control group 321 CNY (US $46.66; IQR 261.50-374.25), limiting the generalizability of the evidence. Therefore, balancing patient economic benefits with clinician workload remains a key challenge for health care administrators.

Strengths and Limitations

This review has several strengths. First, it provides a systematic review and meta-analysis of mHealth effectiveness in pediatric cancer, moving beyond usability to report quantitative clinical outcomes—including infection rates and PICC complications—for the first time. It also offers evidence on QoL, health knowledge, self-management, and treatment adherence, establishing a foundation for future research and practice. Second, by including only RCTs—the gold standard in clinical evidence—and restricting participants to pediatric patients undergoing treatment (excluding parents or survivors), it minimizes confounding and enhances translational potential. Third, it identifies and categorizes BCTs across studies, standardizing intervention components and improving comparability and replicability for future design. Fourth, the inclusion of Chinese databases supplements evidence from developing countries, addressing a gap in prior research.

Limitations should also be acknowledged. First, most included studies lacked the implementation of blinding, resulting in a current lack of high-certainty evidence. This may be related to the inherent difficulty of setting up blinding for mHealth interventions. Second, 79% of the included studies were conducted in China, with interventions predominantly delivered via the WeChat platform. However, the usage context of WeChat differs from that of mHealth tools commonly used in other countries, such as standalone mHealth apps or web-based platforms. The integration of daily life functions with health care services within WeChat may result in higher user engagement and retention compared with independent medical apps, potentially representing a key factor underlying the observed intervention effectiveness. Consequently, this WeChat-based model, characterized by high user engagement, may be difficult to directly replicate in other countries or regions with different health care systems and mHealth infrastructure, potentially limiting the generalizability of the findings to other linguistic and cultural contexts. Third, as a nonmedical social platform, WeChat has limitations in clinical applications. Specifically, it shows deficiencies in data encryption, regulatory compliance, liability definition, and ethical oversight during use. Simultaneously, medical staff may experience vigilance fatigue and blurred professional boundaries during specialized communications on such platforms due to unclear responsibility frameworks [64]. Moreover, it also lacks integration with clinical systems (eg, electronic health records), structured data support, and advanced algorithmic feedback [65]. Fourth, the limited number of included studies precluded subgroup analysis or meta-regression, restricting deeper exploration of heterogeneity sources, including the influence of BCT number on outcomes. Fifth, only Chinese and English articles were included due to the authors' reading limitations, which may have resulted in the omission of high-quality articles in other languages. Finally, although the initial protocol registration planned to include a range of telehealth interventions and study designs, the scope of the review was refined during the implementation phase to focus specifically on RCTs of mHealth-based interventions. This refinement improved conceptual clarity and internal validity, while also strengthening the clinical and practical relevance of the findings. However, this focused scope may limit the applicability of the conclusions to other forms of telehealth (such as telephone-based consultations or video-enabled remote care) and to nonrandomized study designs that more closely reflect real-world practice (eg, stepped-wedge or cluster-based designs).

Prospects

The findings of this study suggest that the extant evidence remains inadequate, and subsequent research may investigate the following domains.

First, future platforms could integrate ecological momentary assessment and smart biosensors to enable dynamic, predictive monitoring. Establishing automated, risk-stratified feedback mechanisms and exploring the incorporation of large language models could enhance efficiency through automated content updates and personalized information delivery. This would allow clinicians to focus more on data review and clinical decision-making [66]. Second, given the advantage of WeChat highlighted in this review, future developments should prioritize embedding mHealth modules into widely used ecosystem apps to minimize user burden, rather than developing isolated apps. Third, research quality should be enhanced. Adopting internationally recognized core outcome sets would facilitate

XSL•FO
RenderX

cross-study comparisons [67]. Large-scale, multicenter RCTs should be conducted with extended follow-up periods to observe the temporal dynamics of intervention effects and long-term clinical outcomes. Fourth, equity and safety should be prioritized. Preuse assessments of digital health literacy and preferences among patients, parents, and health care providers should be conducted, offering tailored training to ensure resource equity during mHealth implementation. Platform users should be clearly defined to mitigate the adverse effects of inappropriate mobile device use on children's vision, sleep, and other areas [68]. Finally, implementation research should be strengthened. Clear cost-benefit analyses should be conducted; barriers and facilitators to mHealth adoption should be evaluated, such as health care institutions' feasibility regarding equipment investment, technical maintenance, staffing costs, and time allocation; and how mHealth interventions integrate with existing care processes and electronic information systems should be examined to avoid additional workload, duplicate documentation, or process conflicts, thereby enhancing technology usability and sustainability.

Conclusion

This systematic review and meta-analysis synthesizes evidence from RCTs on mHealth interventions for children with cancer. The findings suggest that mHealth holds significant value in pediatric oncology care, demonstrating greater effectiveness than usual care in reducing the incidence of infection and various PICC-related complications, including overall complications, site infection, phlebitis, thrombosis, bleeding, occlusion, and dislodgement. mHealth interventions also significantly improved patients' QoL, self-management ability, and treatment adherence. However, current evidence does not show a significant advantage for mHealth in reducing PICC catheter displacement or enhancing health knowledge. Large effect sizes for some outcomes may be related to subjective measurement tools and small sample sizes. Limitations such as lack of blinding and considerable heterogeneity reduce the certainty of evidence and may lead to overestimation of effects; therefore, results should be interpreted cautiously. Despite these limitations, existing evidence supports the potential benefits and applicability of mHealth in pediatric cancer care. Future research should conduct higher-quality, multinational RCTs and use methods such as network meta-analysis to identify the most effective BCTs within mHealth platforms. Concurrently, integrating implementation science and cost-effectiveness analyses will be crucial, with a focus on aligning mHealth technologies with existing clinical workflows to improve their feasibility, scalability, and sustainable impact.

Abstract

Background: Anemia is a global health concern. It is disproportionately prevalent among pregnant women in low-resource regions, where iron deficiency is the leading cause. Given the multifactorial nature of anemia, a range of nutritional interventions is recommended. However, effective implementation is often hindered by limited health care access, poor adherence to supplementation, and gaps in nutrition knowledge and counseling. To address these challenges and optimize hemoglobin (Hb) levels among pregnant women, mobile health (mHealth)−based nutritional interventions offer a promising alternative.

Objective: The aim of the study is to review available evidence on the effectiveness of mHealth-based nutritional interventions on iron status (Hb and/or serum ferritin concentration) among pregnant women.

Methods: Searches were conducted in Embase, CINAHL, Cochrane Library, PubMed, Web of Science, and Scopus, and supplemented by snowballing to identify additional relevant studies from citation lists. The key search strings comprised 4 concepts: “mobile health,” “nutritional intervention,” “Hb, anemia or iron deficiency anemia,” and “pregnant women.” Predefined inclusion and exclusion criteria were applied during screening. The methodological quality of included studies was assessed using the Risk of Bias 2 tool. The primary end point was the change in mean Hb concentration or serum ferritin level. Effect sizes (ESs) were calculated as standardized mean differences, including Cohen *d* and Hedges *g*.

Results: Of the 14,284 studies identified, only 11 randomized controlled trials were included. These studies used various modes of delivery, including mobile phone calls (n=1), SMS text messaging (n=3), and mobile apps (n=4), with some using more than 2 modes (n=3). The effect of mHealth-based nutritional interventions on iron status varied significantly. In total, 4 studies demonstrated a large ES (>0.8), with 3 relying on WhatsApp Messenger as an mHealth delivery mode. Approximately 82% (9/11) of the included studies reported a positive effect (*P* values ranging from <.001 to .047) of the intervention on Hb level, whereas 2 studies reported no statistically significant association (*P*=.33 and *P*=.35, respectively). Notably, interventions with the largest ES achieved clinically significant improvements in Hb concentration, with within- and between-group differences exceeding 1 g/dL. However, including behavioral change theories and nutrition-sensitive components was not consistently associated with larger ESs. Due to high heterogeneity (I^2>95%), attributed to variations in mHealth delivery modes, functions, and interactive features across the included studies, meta-analysis could not be performed.

Conclusions: This review demonstrates that mHealth-supported nutritional interventions effectively optimize Hb concentration in pregnant women. While SMS text messaging was less effective in improving Hb concentration, combining it with another mHealth delivery mode, such as phone calls, improved intervention effectiveness. However, the variability in mHealth delivery modes, functions, and interactive features underscores the need for tailored strategies that account for context-specific challenges, digital literacy, and access to technology to enhance effectiveness.

KEYWORDS

mHealth; mobile health; anemia; pregnancy; systematic review; randomized controlled trials

Introduction

Anemia during pregnancy, defined by the World Health Organization as a hemoglobin (Hb) concentration below 11 g/dL, remains a critical public health problem [1,2]. Globally, anemia affects nearly 36.8% of pregnant women, with the prevalence disproportionately higher in low-resource settings [2-4]. The etiology of anemia is multifactorial, involving nutritional deficiencies, mainly caused by deficiencies in hematopoietic nutrients such as vitamins A, B_2, B_6, B_{12}, C, D, E, and folate, as well as minerals like iron, copper, and zinc; infections; chronic disease; inflammation; and genetic Hb disorders [5-7]. Iron deficiency anemia alone accounts for over half of cases, driven by increased gestational iron demands, poor dietary intake, and dietary habits such as inadequate consumption of heme iron sources (animal-based foods) and high intake of iron inhibitors, including polyphenols (tea and coffee) and phytates (whole grains) [4-7].

Maternal anemia is associated with adverse perinatal outcomes, including stillbirth, preterm birth, low birth weight, intrauterine growth retardation, and high neonatal mortality rates [8-10]. Furthermore, anemia during pregnancy is linked to neurodevelopmental disorders, attention-deficit/hyperactivity disorder, and intellectual disability in children [11]. In mothers, anemia raises the risk of pre-eclampsia, postpartum depression, and maternal mortality [3].

Recognizing the consequences of anemia, countries have been implementing both nutrition-specific and nutrition-sensitive solutions aimed at preventing and managing the condition. The nutrition-specific interventions focus on the most immediate causes of anemia, particularly inadequate intake of iron and other hematopoietic nutrients. Strategies include adhering to iron and folic acid supplementation, promoting dietary diversity, implementing iron fortification programs, and providing nutritional education and counseling. Conversely, nutrition-sensitive interventions tackle the underlying causes of anemia by addressing food security, ensuring access to adequate health services, and maintaining a safe and hygienic environment [5,12,13].

The effectiveness of iron and folic acid supplementation and dietary intake is closely associated with the dietary behavior of individuals. According to Marijn Stok et al [14], dietary behavior relates to all phenomena related to food choices, eating habits, and dietary intake patterns. Various studies have highlighted the pivotal role of nutritional education and counseling in influencing dietary behaviors, enhancing nutritional knowledge and attitudes, and promoting anemia prevention and management strategies [3,15,16]. A meta-analysis focused on the impact of nutritional education and counseling on iron status of pregnant women in low- and middle-income countries (LMICs) found that women who received nutritional education and counseling experienced an average increase of 0.88 g/dL (95% CI 0.63-1.13 g/dL; $P<.001$) in Hb concentration and a 34% lower risk of anemia compared to the control group [16].

Despite the potential of nutritional education and counseling in improving health and dietary behavior, a review targeting 4 countries (2 in Africa and 2 in Asia) found that pregnant women were not reached frequently enough, were not counseled adequately, and consequently lacked motivation, nutritional knowledge, and optimal dietary practice [17]. These gaps highlight the need for nutritional education and counseling to be supported by innovative solutions, such as mobile health (mHealth), to effectively influence dietary behavior through improving knowledge, attitudes, and dietary practices [5,18].

mHealth, defined as the use of mobile technologies in health care, has emerged as a promising tool for improving the accessibility, affordability, and effectiveness of nutrition care services in both high-income countries and LMICs [18,19]. Furthermore, nowadays, the delivery of health behavior change interventions increasingly relies on mHealth technologies due to their widespread penetration across socioeconomic levels [20]. For example, an umbrella review of 47 meta-analyses, comprising 507 randomized controlled trials (RCTs), documented an impact of mHealth on dietary behavior. According to this review, mHealth interventions have small-to-moderate improvements across various dietary outcomes [21].

However, while several reviews have explored the role of mHealth interventions in improving maternal and child health outcomes, there remains a lack of systematic reviews specifically focusing on mHealth-based nutritional interventions and their impact on the iron status of pregnant women. To our knowledge, no review has identified, appraised, and synthesized the existing evidence focused on nutritional interventions supported by mHealth in optimizing the iron status of pregnant women.

Therefore, this systematic review aims to evaluate the effectiveness of mHealth-based nutritional interventions on the iron status of pregnant women through a synthesis of evidence from existing RCTs. Additionally, this review examined the effects of mHealth-based interventions on secondary outcomes, including adherence to iron and folic acid supplementation, dietary intake, gestational weight gain, and nutritional knowledge, attitudes, and practices, as well as patient-centered implementation outcomes reported in the included studies. The findings are intended to inform and guide the development of future mHealth interventions with relevant evidence to address anemia during pregnancy.

Methods

Overview

The review protocol was registered in PROSPERO (International Prospective Register of Systematic Reviews; CRD42025627769) on January 17, 2025, with prespecified primary and additional

XSL•FO
RenderX

secondary outcomes (adherence to iron and folic acid supplementation, dietary intake, gestational weight gain, and nutritional knowledge and practice). Attitudes and implementation outcomes were introduced later as additional secondary outcomes not included in the original registration. The paper was structured following the updated guidelines for PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses; Checklist 1) statement and methodological considerations of conducting a systematic review of RCTs [22].

Search Strategy

The searches were conducted in CINAHL (via EBSCOhost), Embase, PubMed (including MEDLINE, via NCBI), CENTRAL (via Cochrane Library), Scopus, and Web of Science Core Collection using a predeveloped search strategy (Multimedia Appendix 1). A combination of indexed terms, database-specific keywords, and MeSH terms was used to improve the search. The search query retrieved all studies that included key terms such as mHealth, nutritional interventions, Hb, anemia or iron deficiency anemia, and pregnant women in either the title, abstract, or keywords. Besides, references and citation lists of all included studies and relevant systematic reviews that met our eligibility criteria were further screened through snowballing.

Eligibility Criteria

The population, intervention, comparison, and outcome scheme was used in this review to formulate the review question and define the eligibility criteria. In addition, the study design, setting, publication language, and period were prespecified as part of the inclusion and exclusion criteria (Multimedia Appendix 2). We included individual and cluster randomized controlled trials (cRCTs), as these study designs are considered the gold standard for clinical research, generating robust and reliable conclusions. This is due to the random allocation of participants to competing interventions and the analytic approaches that support causal inference [23,24]. In contrast, we excluded nonrandomized studies of interventions, including quasi-RCTs, non-RCTs, cohort studies, and case-control studies, as these designs present methodological challenges. Effect estimates obtained from nonrandomized studies of interventions are more subject to additional sources of bias, such as confounding [23,25].

Trials fulfilling the inclusion criteria and published between January 1, 2003, and February 28, 2025 (the date of the final search) were included. All pregnant women were included, regardless of gestational age, Hb level, age, or country of residence. We included studies reporting mean Hb concentration as part of their study outcomes. Thus, we described iron status in terms of mean Hb concentration (expressed in g/dL) or iron deficiency anemia, defined as Hb <11 g/dL or serum ferritin <12 µg/L) [1].

Nutritional interventions delivered either as standalone interventions (using only mHealth components) or as part of a comprehensive intervention package (mHealth combined with other non-mHealth components) were included in the review. We considered various mobile technology tools that facilitate communication in remote areas, including phone calls, video calls, SMS text messages, multimedia messaging services, mobile apps, and social media platforms (eg, WhatsApp, Facebook, Telegram, and TikTok). We also included studies comparing mHealth-based nutritional interventions with standard antenatal care, described as “usual care,” “standard care,” “routine care,” or “standard antenatal care.”

Non–peer-reviewed papers were excluded due to concerns about scientific consistency, methodological compliance, and reliability, which are better ensured in peer-reviewed publications. Nutrition interventions that were supported or delivered by any means other than mHealth technologies were also excluded. Additionally, we excluded studies published before 2003, as the widespread adoption of mHealth-based interventions and the emergence of related publications occurred after this period [26]. This criterion ensures that included studies reflect contemporary mHealth interventions using mobile technologies.

Study Selection and Data Extraction

The retrieved records were imported into EndNote (version 21; Clarivate) software for reference management and duplicate removal. After duplicates were manually verified and removed by 1 author (SAB), the remaining papers were transferred to Rayyan (Qatar Computing Research Institute) for systematic screening.

Two authors (SAB and CM) independently screened the titles and abstracts and categorized papers as relevant (met the eligibility criteria), irrelevant (did not meet the eligibility criteria), and uncertain (inconclusive information on eligibility criteria) following the removal of duplicates. Both authors then reviewed and assessed “potentially relevant” and “uncertain” papers in full text based on the eligibility criteria. Any discrepancies arising during the selection process were resolved through discussion and, when necessary, the involvement of a third reviewer (AMB).

Based on the guidelines in the Cochrane Handbook for Systematic Reviews of Interventions, a comprehensive data extraction form was developed by 1 author (SAB) and subsequently reviewed and refined by 3 authors (CM, WVP, and AMB). The form was piloted on at least 2 included studies to ensure reliability and reproducibility.

The following information was extracted from the included studies:

- Study identifiers: author details and publication details.
- Participant characteristics: age (in years), gestational age (in weeks), and anemia status (Hb concentration in g/dL).
- Study methodology: study setting, sample size and sampling procedures, study design, eligibility criteria, processes for randomization, allocation and blinding, and statistical analysis details.
- Intervention description: characteristics and components of the intervention, intervention delivery methods, duration of follow-up, and details of the comparison intervention.
- Intervention outcomes: attrition rate, continuous data (mean and SD) of Hb concentration, and any reported secondary outcomes.

XSL•FO
RenderX

Following the development of the extraction form, data were extracted by 1 author (SAB) and independently verified by 2 authors (CM and AMB). Discrepancies were resolved through consensus or, if necessary, by consulting a fourth reviewer (WVP). All relevant information was obtained from the full texts of the included studies. Corresponding authors were contacted when clarification was required or when data were missing.

Evaluation of the Methodological Quality of the Studies

Two authors (SAB and CM) independently assessed the methodological quality of the included studies using the revised Risk of Bias 2 tool [27]. In accordance with Risk of Bias 2 guidance, the risk of bias was assessed at the outcome level rather than the study level. Specifically, we evaluated the risk of bias for the results related to the primary outcome of interest.

The tool uses five domains to incorporate all types of bias currently considered to affect the results of RCTs. The domains include (1) risk of bias arising from the randomization process, (2) risk of bias due to deviations from the intended interventions, (3) risk of bias due to missing outcome data, (4) risk of bias in measurement of the outcome, and (5) risk of bias in selection of the reported result, followed by the assessment of the overall risk of bias. On this basis, studies were categorized as having a “high” risk of bias (high risk in at least 1 domain or some concerns across multiple domains), “some concerns” (some concerns in at least 1 domain without any domain rated as high risk), or a “low” risk of bias (low risk across all domains). Any disagreements during the quality assessment were resolved through discussion, involving third and fourth reviewers (AMB and WVP) as needed. Additionally, an independent reviewer (Kidu Gidey) cross-checked the risk-of-bias judgments within domains.

Dealing With Missing Data

For missing data in the included studies (eg, SDs or means), we first attempted to contact the corresponding authors via email to obtain the required information. If data could not be retrieved, we followed guidance from the Cochrane Handbook to derive missing statistics from other reported measures using the generic inverse variance method [23]. For instance, missing SDs were calculated from CIs for means, SEs, *t* statistics, or *P* values when available. In addition, when data were symmetrically distributed, reported medians were considered as a reasonable substitute for means. Studies with missing data were not directly excluded; instead, they were considered in sensitivity analyses to assess the robustness of the findings. We excluded studies with missing data that were irretrievable and judged to be at high risk of bias from effect size (ES) estimation.

Data Synthesis

The characteristics of mHealth interventions are described in terms of mHealth function, interaction feature, and delivery mode.

mHealth Function

We categorized mHealth functions in each study following the classification proposed by Knop et al [28], which outlines 12 mHealth functions. Among these, we focused on the “client education and behavior change communication” function [28]. To systematically analyze the behavior change components within this function, we mapped each intervention to the corresponding behavior change techniques (BCTs) derived from the BCT Taxonomy v1, which includes 93 hierarchically clustered techniques [29]. This approach enables integration of the mHealth function classification with specific and theory-based BCTs.

mHealth Interaction Features

In addition to describing the mHealth feature, it is crucial to examine the level of interaction between the patient or participants and these features. As reported by Knop et al [28], interactions are categorized as unidirectional (1-way communication), bidirectional (2-way communication), and multidirectional (complex interactions involving multiple stakeholders). Following the description by Donevant et al [30], which aligns with existing terminology, we described these interactions as passive and interactive features. The passive feature does not require any additional response or action from the patient within the mHealth app, including 1-way text messaging and reminders. In contrast, interactive features enable patients to respond or engage on the matter, including interactive prompts and 2-way communication via texting, email, phone calls, and other mobile apps [30].

Measures of Mean Hb Concentration (g/dL)

The primary end point of this review was the change in mean Hb concentration (g/dL). For each included study, we calculated the mean change in Hb concentration (g/dL) from baseline. We assessed within-group differences (pre- vs postintervention) and between-group differences based on postintervention mean Hb concentrations (intervention vs control).

Measures of Statistical Significance (P Value)

For the evaluation of effectiveness, an intervention was classified as effective if the mHealth-based nutritional intervention resulted in statistically significant ($P<.05$) outcomes, as compared to the control group. The intervention was classified as ineffective if there was no statistical difference between the intervention and control groups.

Measures of Intervention Effect

The standardized mean difference, a commonly used ES measure in RCTs, including 6 cRCTs and 5 individual RCTs, was calculated. For consistency across study designs, we estimated the standardized mean difference using both Cohen *d* and Hedges *g*. Cohen *d* is a standard metric for ES estimation, while Hedges *g* is similar but incorporates a correction factor to reduce bias in small sample sizes [31,32].

The ES (Cohen *d*) for continuous outcomes was calculated using the formula: $d=(M1-M2)SDp$, where M_1 and M_2 represent the mean Hb concentrations of the intervention and control groups, respectively, and SD_p is the pooled SD of the 2 groups [31]. Group-level summary statistics, which had already accounted for the study design in the original analysis, were used to estimate the ES in cRCTs. Consequently, no additional clustering adjustments were made.

XSL•FO
RenderX

We summarized the intervention's effect on iron status separately for each study. The magnitude of Hedges *g* is interpreted using Cohen convention, where an ES of <0.20 is small, 0.50 to 0.80 is medium, and scores >0.80 are large [31]. Comprehensive Meta-Analysis software was used to calculate the ES.

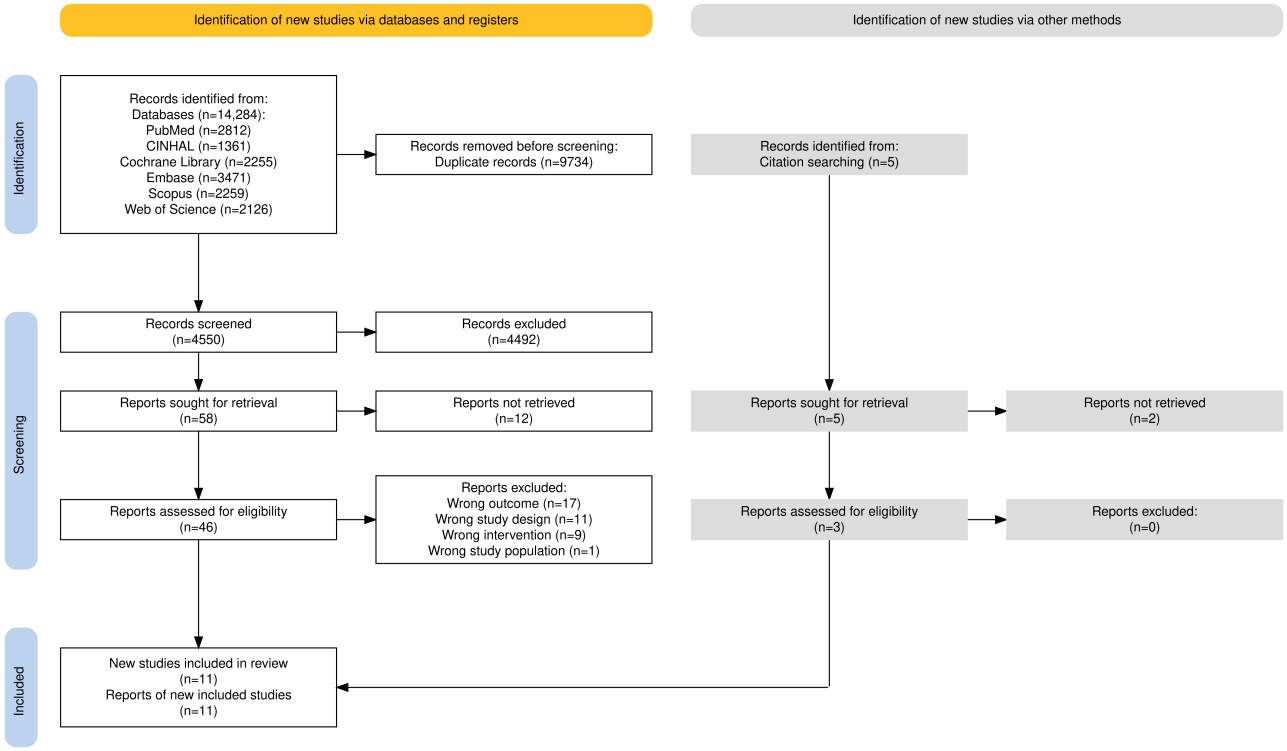
Heterogeneity

Heterogeneity was quantified using the chi-square and the I^2 statistic. These measures assess the variability in the intervention effects across studies. Following Cochrane guidelines, a chi-square greater than the *df* and a small *P* value (eg, *P*<.05) indicate evidence of heterogeneity of intervention effects (variation in effect estimates beyond chance) [23]. I^2 values were interpreted as: 0% to 40%: might not be important, 30% to 60%: moderate heterogeneity, 50% to 90%: substantial heterogeneity, and 75% to 100%: considerable heterogeneity [23]. Quantitative synthesis was considered only when heterogeneity was low to moderate. With substantial or considerable heterogeneity, results were synthesized narratively.

Secondary Outcome

Based on a review of the existing literature, we defined the following secondary outcomes. Adherence to iron and folic acid supplementation was defined as the consumption of at least 4 iron-folic acid tablets per week for the recommended period [33]. Dietary intake was defined as food and nutrient consumption at an individual, household, or population level over a period [34,35]. Gestational weight gain was characterized as the recommended range of weight a pregnant woman should gain during pregnancy to optimize maternal and child health outcomes [36]. Nutritional knowledge was defined as the knowledge of nutrition, including the ability to recall nutrition and diet-related terminology [37]. Attitude was described as an individual's feeding or eating behavior influenced by feelings, motivations, perceptions, and thoughts [37]. Practice was operationalized as an individual's actions that could affect his or her nutrition, such as eating, feeding, cooking, and selecting foods [37].

In addition, the following implementation outcomes were defined based on the framework proposed by Proctor et al [38]. Appropriateness was defined as the perceived relevance or compatibility of the intervention for the target groups to address the issue or problem. Acceptability or satisfaction was defined as the perception among the target groups that a given practice or intervention is agreeable, palatable, or satisfactory. Implementation was defined as the cost impact of an implementation effort. Feasibility was defined as the extent to which the newly developed intervention can be successfully used or carried out within a given setting. Adoption or uptake was defined as the intention, initial decision, or action to try or use the intervention. Fidelity was defined as the degree to which an intervention was implemented as intended by its developers. Sustainability was defined as the extent to which a newly implemented intervention is maintained or institutionalized within a service setting over time.



Results

Search Results

As shown in Figure 1 [39], a total of 14,284 studies were extracted from 6 databases, and 5 additional papers through citation searching. We screened titles and abstracts of 4550 papers. Of these, we assessed the full text of 46 papers against the eligibility criteria. Following the full-text assessment, 11 studies published between 2018 and 2023 were included in this review. A total of 38 records were excluded, with detailed reasons for exclusion provided in the PRISMA diagram.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram of study selection process.

Study Characteristics

Table 1 summarizes characteristics across 11 included studies. Among these, 6 studies [40-45] were individual RCTs conducted in health facility settings. Of the 5 cRCT studies, only 1 study [46] was conducted at the community level, while the remaining 4 [15,47-49] were conducted in health facilities. In terms of geographical distribution, the majority (7 studies) [15,41,43-46,48] were conducted in low- and lower-middle-income countries, while the remaining 4 studies [40,42,47,49] were conducted in high- and upper-middle-income countries, according to the World Bank classification [50]. Only 2 continents were represented in this systematic review, with Asia contributing 9 (81.8%) studies, and the remaining 2 (18.2%) studies were conducted in Africa. The sample size in the included studies ranged from 59 in Thailand [42] to 413 participants in Nepal [46], with a total of 2191 (mean 199.2, SD 104.1) study participants.

XSL•FO

				Age (years)	Gestational weeks	Hb[a] level (g/dL)	Pregnant women with the following conditions were excluded from the study
Ahmad et al (2022) [49]	Indonesia	cRCT	• n=110 • Intervention: 55 • Control: 55	—	>28	—	—
Sharma et al (2023) [43]	India	RCT	• n=250 • Intervention: 127 • Control: 123	—	14 - 24	<11	Had a history of obstetric, medical, or psychological problems.
Abujilban et al (2019) [45]	Jordan	RCT	• n=200 • Intervention: 100 • Control: 100	18 - 45	13 - 28	<10.5	Illiterate or had a history of obstetric, medical, or psychological problems.

[a]Hb: hemoglobin.

[b]RCT: randomized controlled trial.

[c]No report.

[d]cRCT: cluster randomized controlled trial.

The age range of participants at baseline was reported in 5 studies [40,42,45-47], ranging from 15 to 45 years. Except for 1 study [48], all studies provided information on the gestation age (in weeks) of the participants. Additionally, 5 studies [40,41,43,45,47] selected the participants based on their Hb levels (Hb <11 g/dL), while the remaining 6 studies did not consider the anemia status of the participants as a selection criterion.

Description of the mHealth Interventions

Descriptions of the mHealth and nutritional interventions from the reviewed studies are summarized in Tables 2 and 3. Among the included studies, 5 studies [40,43,45,47,49] used WhatsApp Messenger to deliver text, audio, and video-based educational messages to pregnant women in the intervention group. Different modes of delivery, including mobile phone calls, SMS text messaging, and mobile apps, were reported. Some studies used more than 1 mode of delivery [43,48,49]. Approximately 91.9% of the included studies used client education and behavior change communication to convey educational information to the target groups.

XSL•FO
RenderX

Table . Summary of mobile health (mHealth) characteristics[a].

Study	Delivery mode	mHealth function	Interaction feature	Intervention (mHealth group) received	Follow-up period (weeks)
Elsharkawy et al [40]	WhatsApp texts	• Education • Reminder[b] • Feedback	Interactive	One educational message, four medication reminders, and more than three participant feedback	12
Sontakke et al [41]	Phone calls	• Reminder • Feedback	Interactive	Biweekly phone calls and reminder notifications	12
Singh et al [46]	SMS or texting	• Education	Passive	One message every 2 weeks (4 - 6 months), weekly thereafter until childbirth	12
Abd Rahman et al [47]	WhatsApp video	• Education	Passive	Daily 3 - to 5-minute educational video (6 days), followed by weekly reminders (weeks 2 - 5)	12
Xuto et al [42]	SMS or texting	• Education	Passive	Two text messages per week (13 - 40 gestational weeks)	28
Sharma et al [44]	Mobile app	• Education • Reminder • Feedback	Passive	Nutritional advice, test tracking, data input, graphical or textual visualization of data, and medication reminder	Until delivery
Washington et al [48]	SMS and phone calls	• Education	Passive	Biweekly “antenatal care telereminder” texts and calls	12
Wakwoya et al [15]	SMS or texting	• Education	Passive	Weekly serial SMS messages	12
Ahmad et al [49]	Phone calls and WhatsApp text	• Education • Feedback	Interactive	Educational flyers via WhatsApp and telephonic nutrition education	12
Sharma et al [43]	SMS or texting, phone calls, and WhatsApp audio	• Education • Reminder • Feedback	Interactive	Four SMS, one WhatsApp audio message, and six weekly calls	4
Abujilban et al [45]	WhatsApp video	• Education	Passive	15-minute educational video	12

[a]All participants in the control groups received routine antenatal care.

[b]Reminder: medication reminder.

Table . Summary of mobile health (mHealth) components, nutritional interventions, and behavior change techniques (BCTs) or behavior change theory applied.

Study	mHealth component	Other components	Nutrition interventions or topics covered by mHealth		BCT taxonomy applied	Behavior change theory
			Nutrition interventions (sensitive)	Nutrition interventions (specific)		
Elsharkawy et al [40]	Educational texts	PowerPoint slides, guidelines, brochures	IFAS[a], dietary advice, and anemia prevention and management	—[b]	Knowledge shaping, prompts and cues, feedback and monitoring, social support	—
Sontakke et al [41]	Phone call reminders	—	IFAS	—	Prompts and cues, goal setting, feedback and monitoring, social support	—
Singh et al [46]	Educational texts	HCP[c] training	General nutrition advice	Health care service use	Knowledge shaping	—
Abd Rahman et al [47]	Educational videos and reminders	—	IFAS, dietary advice, and anemia prevention and management	—	Knowledge shaping, natural consequences	HBM[d]
Xuto et al [42]	Educational texts	—	Dietary advice	—	Knowledge shaping	—
Sharma et al [44]	Apps-based content	—	IFAS, dietary advice, and malaria prevention	Reproductive health care	Knowledge shaping, feedback and monitoring, prompts and cues, social support	—
Washington et al [48]	Educational texts and calls	HCPs or guideline manual	IFAS, dietary advice, malaria prevention, and intestinal parasite control	Hygiene and health care service use	Knowledge shaping, prompts and cues, social support	—
Wakwoya et al [15]	Educational texts	Face-to-face nutritional counseling and brochures	IFAS, dietary advice, use of iodized salt, malaria, and intestinal parasite prevention and control	Hygiene and health care service use	Knowledge shaping	HBM
Ahmad et al [49]	Educational calls and texts	Nutrition booklet and food monitoring card	IFAS and dietary advice	Hygiene	Knowledge shaping, prompts and cues, feedback and monitoring, social support	TPB[e]
Sharma et al [43]	Reminder calls, texts, and audio messages	—	IFAS	—	Feedback and monitoring, prompts and cues	—
Abujilban et al [45]	Educational videos	—	Iron supplementation and dietary management	—	Knowledge shaping	—

[a]IFAS: iron and folic acid supplementation.

[b]No report.

[c]HCP: health care provider.

[d]HBM: health belief model.

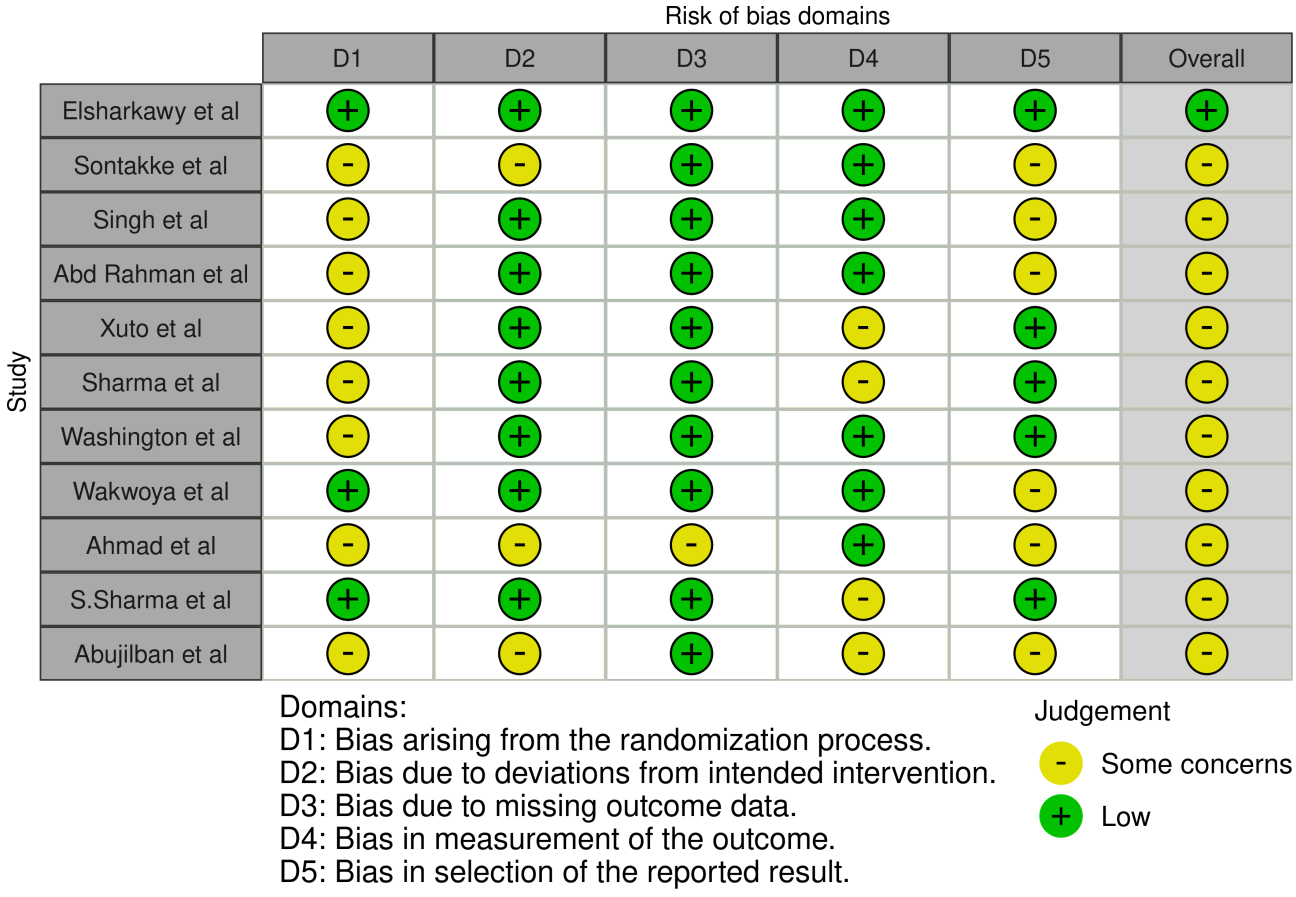
[e]TPB: theory of planned behavior.

Regarding mHealth interaction features, 7 studies [15,42,44-48] incorporated a passive feature (unidirectional communication approach), using push technology to deliver educational content or reminders to the target groups. In contrast, 5 of the studies [40,41,43,44,49] used an interactive feature (bidirectional communication; Table 2).

The follow-up duration across studies ranged from 4 weeks [43] to 28 weeks [42], with a mean of 12.8 (SD 5.9) weeks estimated from 10 studies. One study [44] did not provide a clear

XSL•FO
RenderX

intervention duration. Approximately 82% of studies implemented an intervention follow-up period of 12 weeks.



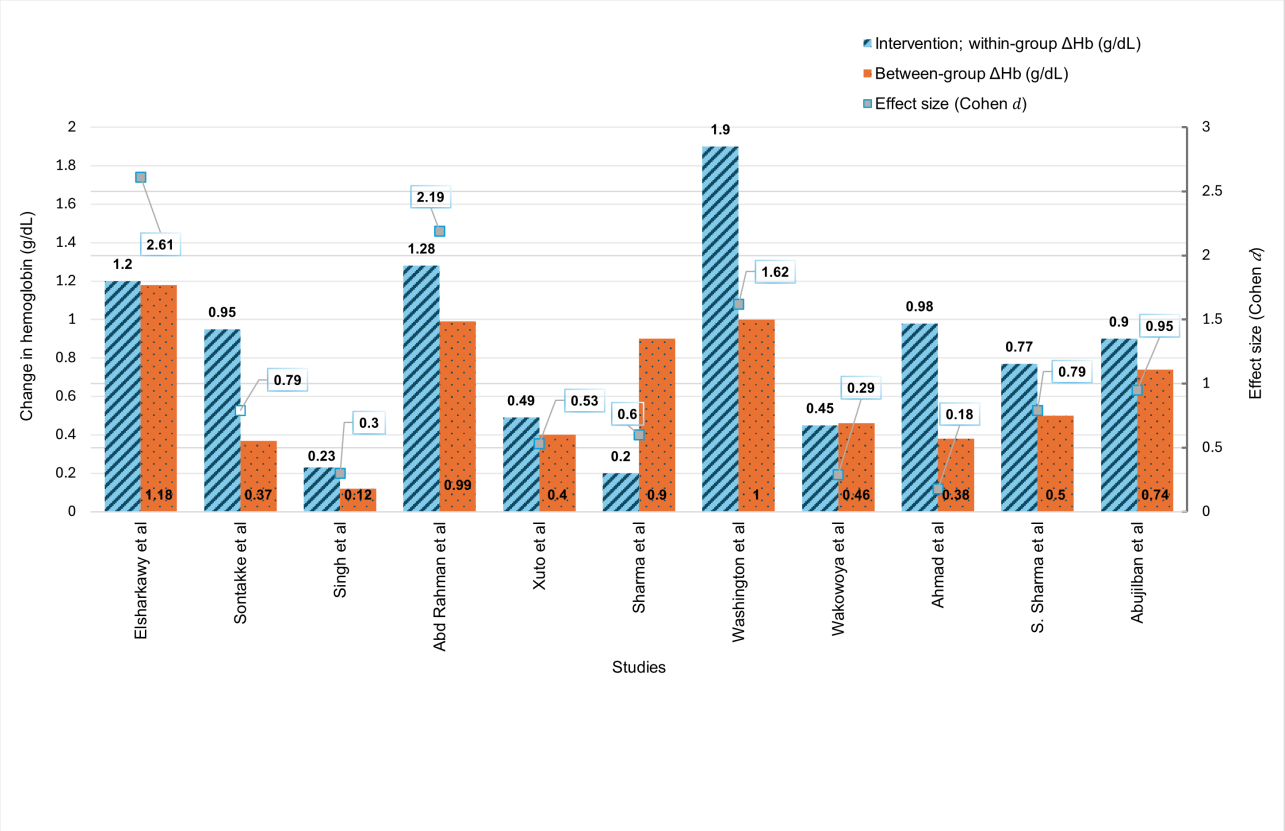
This review also identified a range of BCTs across the included studies, as presented in Table 3. Approximately 54.5% of the studies [40,41,43,44,48,49] applied 2 or more BCTs, with the most frequently used techniques including shaping knowledge, prompts and cues, and feedback and monitoring. Additionally, only 3 studies [15,47,49] incorporated a behavior change theory, such as the health belief model and the theory of planned behavior.

In total, 5 studies [15,40,46,48,49] supplemented their mHealth interventions with additional strategies such as face-to-face presentations, nutritional counseling, guideline and brochure distribution, and health care provider capacity-building training sessions to enhance intervention effectiveness. All studies incorporated nutrition-specific topics, conveying advice on key areas such as iron and folic acid supplementation, dietary intake, and strategies for preventing and managing anemia, malaria, and intestinal parasites. However, nutrition-sensitive topics related to health care service use, hygiene, and reproductive health were covered in only 5 studies [15,44,46,48,49].

Risk of Bias in Included Studies

The methodological quality of the studies varied noticeably. A total of 90.9% of studies were judged to have some concern regarding the risk of bias, with only 1 study classified as having a low risk of bias. Approximately 8 (72.7%) of the studies did not report the method used for allocation sequence concealment, and more than half (54.5%) demonstrated a bias in the selection of reported results. Blinding practice differed across the included studies. In total, 5 studies [15,40,42,47,48] were able to blind participants. The risk of bias for each included study is described in Figure 2 [51], and detailed descriptions of the risk of bias judgments are provided in Multimedia Appendix 3 [15,40-49].

Figure 2. Risk of bias plot for included randomized controlled trials [15,40-49].



Effects of mHealth-Based Nutritional Interventions

Of the 11 included studies, 10 reported participants' Hb concentration (g/dL) using mean and SD to describe iron status, while 1 study [43] used the median and IQR to report pre- and postintervention changes in Hb concentration. As Figure 3 shows, the highest mean Hb concentration difference within the intervention group (1.9 g/dL) was reported by Washington et al [48], while the smallest difference (0.2 g/dL) was observed in the study of Sharma et al [44]. The smallest between-group difference (intervention vs control) was 0.19 g/dL [49], whereas the largest was 1.18 g/dL [40]. Notably, interventions with the largest ES (eg, ES=2.61, 95% CI 2.23-3.00; ES=2.19, 95% CI 1.70-2.68; ES=1.62, 95% CI 1.25-1.99) achieved clinically meaningful improvements in Hb concentration. These increases exceeded the widely recognized 1 g/dL threshold, indicative of a positive therapeutic response to anemia in pregnant women, and are associated with significant improvements in maternal health outcomes [52,53].

XSL•FO
RenderX

Figure 3. Mean hemoglobin change (ΔHb) within and between groups (g/dL) and corresponding effect sizes (Cohen *d*) across included studies [15,40-49].

Almost 82% (9/11) of studies showed a positive association between intervention and Hb concentration. However, 2 studies [42,49] with small ES (Cohen *d*=0.5) found no association between the mHealth intervention and the Hb concentration in the intervention group (*P*=.33 and *P*=.35, respectively; Table 4).

[f]Nonsignificant *P* value ($P \geq .05$).

[g]Mapp: mobile app.

[h]PC: phone call.

[i]WAM: WhatsApp audio message.

The ES varied among studies, ranging from ES=2.61 (95% CI 2.23 - 3.00) [40] to ES=0.18 (95% CI −0.20 to 0.55) [49]. Among the studies with a small ES (Cohen *d*=0.5), the majority used SMS text messages as their mode of delivery [15,46]. Studies with the highest ESs (ES=2.61, 95% CI 2.23 - 3.00 and ES=2.20, 95% CI 1.70-2.68) used WhatsApp as an mHealth delivery mode, incorporating multiple mHealth functions [40,47]. In total, 3 studies used more than 1 mode of delivery, with ES varying across studies. A detailed description of the intervention's effect on participants' iron status is presented in Table 4.

Secondary Outcomes

As presented in Table 5, 10 studies [15,40-48] reported at least 1 of the secondary outcomes relevant to this review. Among these 10 studies, 5 showed a statistically significant effect ($P<.05$) of mHealth intervention on adherence to iron and folic acid supplements in the intervention group, with adherence ranging from 63.8% [43] to 96% [48] in the intervention group.

XSL•FO
RenderX

Table . Summary of secondary outcomes.

Outcome categories and studies	Summary of findings
Adherence to IFAS[a]	
Elsharkawy et al [40]	Higher adherence to IFAS in the intervention group (90.8%) versus the control group (66.4%), *P*<.001
Sharma et al [43]	Higher adherence to IFAS in the intervention group (63.8%) versus the control group (39%), *P*=.001
Abujilban et al [45]	Higher mean IFAS adherence in the intervention group (mean 14.13, SD 2.68) versus the control group (mean 11.45, SD 3.02), *P*<.01
Washington et al [48]	Higher adherence to IFAS in the intervention group (96%) versus the control group (84%), *P*=.02
Gestational weight gain	
Singh et al [46]	Higher mean weight in the intervention group (mean 52.36, SD 6.28 kg) versus the control group (mean 50.94, SD 5.90 kg), *P*=.02
Wakwoya et al [15]	Slightly higher weight gain in the intervention group (9.69 kg) versus the control group (7.75 kg), but not statistically significant, *P*<.27
Xuto et al [42]	Higher mean weight gain in the intervention group (mean 12.77, SD 4.92 kg) versus the control group (mean 11.98, SD 6.42 kg), but not statistically significant, *P*=.60
Dietary intake	
Abd Rahman et al [47]	Higher mean dietary intake in the intervention group (mean 20.55, SD 5.12) versus the control group (mean 15.98, SD 3.68), *P*<.001
Wakwoya et al [15]	Intervention group consumed more: dark green vegetables (mean 17.96, SD 4.23 vs mean 10.37, SD 2.27; *P*<.001), vitamin C-rich foods (mean 5.42, SD 2.01 vs mean 4.20, SD 2.26; *P*=.005), eggs (mean 4.02, SD 1.04 vs mean 3.35, SD 1.10; *P*<.01), and meat, liver, and fish (mean 22.66, SD 4.77 vs mean 18.06, SD 3.36; *P*<.001) than the control group
Washington et al [48]	Intervention group consumed more fruits (91% vs 72%; aOR[b] 3.77, 95% CI 1.49-9.54; *P*=.003), vegetables (96% vs 87%; aOR 3.69, 95% CI 0.97-14.00; *P*=.04), and fish, meat, or poultry (93% vs 83%; aOR 2.93, 95% CI 0.99-8.70; *P*=.04)
Nutritional knowledge	
Elsharkawy et al [40]	Higher mean knowledge score in intervention group (mean 54.33, SD 10.92) versus the control group (mean 24.79, SD 10.19), *P*<.001
Abd Rahman et al [47]	Higher mean knowledge score in intervention group (mean 26.41, SD 2.17) versus the control group (19.10, SD 3.44), *P*<.001
Abujilban et al [45]	Higher mean knowledge score in intervention group (mean 35.33, SD 9.55) versus the control group (mean 18.74, SD 9.55), *P*<.01
Attitude and practice	
—[c]	No included studies reported on this outcome
Implementation outcomes	
Sharma et al [44]	About 92.5% of pregnant women using the SwasthGarbh app expressed complete satisfaction

[a]IFAS: iron and folic acid supplement.

[b]aOR: adjusted odds ratio.

[c]Not available.

Among studies that evaluated the effect of mHealth intervention on gestational weight, only 1 study [46] reported a statistically significant association (*P*=.02). However, according to Wakwoya et al [15] and Xuto et al [42], although weight gain was slightly higher among pregnant women in the intervention group compared to the control group, the difference was not statistically significant (*P*=.27 and *P*=.60, respectively). Only 1 study [44] measured satisfaction levels among pregnant women adhering to the mHealth intervention. However, no studies provided data on maternal nutrition attitudes and practices or other patient-centered implementation outcomes, such as appropriateness, affordability, feasibility, acceptability,

XSL•FO
RenderX

adoption, fidelity, sustainability, or the cost of mHealth intervention.

Heterogeneity

Considerable heterogeneity was observed across studies, likely attributable to variance in participant characteristics (maternal age, gestational age, and Hb status), intervention features (mHealth delivery mode, mHealth interaction, and function), and socioeconomic and geographical contexts. Although a random-effects meta-analysis was conducted, heterogeneity was extreme (I^2=95%; χ^2_{10}=196.7; P<.01), and the wide prediction interval (−0.92 to 2.82) restricted the interpretability of pooled effect estimates. Additionally, sensitivity analyses were performed to assess the influence of outlining studies, including those with large ESs and those reporting nonstatistically significant results. However, exclusion of these did not reduce heterogeneity, which remained high (I^2>88%), nor did it substantially change the direction or statistical significance of the pooled effect. Therefore, we provided a narrative synthesis following guidance from the Cochrane Handbook for summarizing findings when meta-analysis was not feasible [23]

Discussion

Principal Findings

To the best of our knowledge, this is the first systematic review comprehensively assessing the effectiveness of mHealth-based nutritional interventions on maternal iron status. In this systematic review, 9 of 11 studies revealed a positive effect of mHealth-based nutritional intervention on Hb concentration during pregnancy. However, the ES varied from large ES (Cohen d>0.8) to small ES (Cohen d<0.5). Among the studies with a large ES, 3 used WhatsApp as an mHealth mode of delivery. These studies were conducted in high and upper-middle-income countries, where smartphone availability and access to data bundles are high, enabling mHealth interventions via WhatsApp platforms. In contrast, in LMICs, mHealth interventions mainly rely on SMS text messaging or telephone calls, as these delivery modes are more accessible through basic mobile devices [54,55]. The limited smartphone ownership, poor internet connectivity, and lower digital literacy in LMICs may contribute to reduced engagement with more interactive mHealth platforms.

According to a systematic review by Kante and Målqvist [56], the effectiveness of SMS-based interventions in LMICs varied across studies and settings, largely due to the differences in intervention type, content, frequency, and implementation approach. Some studies reported positive effects of SMS text messaging–based interventions on increasing the use of maternal and child health care services and improving adherence to iron supplementation among pregnant women [57,58]. These studies also identified SMS text messaging as a low-cost, easily personalized intervention that can be sent directly to target groups [57,58]. However, other studies found no significant effect of SMS text messaging on maternal health outcomes, including iron status during pregnancy [59].

Consistent with these findings, in our review, SMS text messaging was the most common mHealth delivery mode, used in 5 studies [15,42,43,46,48] conducted in LMICs. Despite its applicability, texting was associated with lower effectiveness than phone calls or WhatsApp-based interventions. This reduced effectiveness may be due to the limited educational content that can be conveyed via SMS text messaging and the lack of multimedia support, which could aid in information retention. Notably, the findings from this review suggest that combining SMS text messaging with other mHealth delivery modes, such as phone calls, significantly enhances intervention effectiveness. For instance, studies by Washington et al [48] and Sharma et al [43] reported ES of 1.61 (95% CI 1.25-1.99) and 0.79 (95% CI 0.53-1.04), respectively, when SMS text messaging was combined with phone calls.

Moreover, a study suggested that combining SMS text messaging with an interactive feature could improve the effectiveness of mHealth interventions [59]. Similarly, the highest ES (2.61, 95% CI 2.23-3.00) in this review was observed in a study that used text-based education via WhatsApp, supplemented by interactive features or 2-way communication [40].

In total, 3 studies [40,47,48] demonstrating the highest ES also showed clinically significant improvements in mean Hb concentration, with differences greater than 1 g/dL within- and between-group comparisons. These studies conveyed nutritional advice through different delivery modes, in which 2 studies [40,48] reported higher adherence to iron and folic acid supplements, and the third study [47] found higher dietary iron intake among intervention groups adhering to mHealth-supported nutrition interventions. Furthermore, the mean Hb concentrations observed in these 3 studies were notably higher than the pooled results from 2 meta-analyses, which found mean Hb differences of 0.46 and 0.89 g/dL in pregnant women taking iron with or without folic acid, respectively [60,61]. Similarly, a review by Engidaw et al [16] reported a mean Hb difference of 0.88 g/dL based on pooled results from 39 studies, of which only 8 used an mHealth-based approach. While it is acknowledged that comparing individual study results with pooled meta-analysis data has limitations, the higher mean Hb concentration difference observed in this review may be attributed to the nutritional interventions supported by mHealth technologies. This technological support may have improved participants' adherence to the interventions, thereby enhancing the intervention outcomes.

All 11 studies included in this review focused on nutrition-specific interventions, which address the most proximal causes of anemia, such as dietary intake and iron and folic acid supplementation. Nonetheless, 5 studies [15,44,46,48,49] incorporated nutrition-sensitive interventions, which address underlying determinants of anemia, such as maternal health care access and hygiene practices. Notably, this review found that studies incorporating nutrition-sensitive components did not demonstrate higher ES compared to those focusing solely on nutrition-specific interventions. This may be due to 2 key factors. First, the complex and multifactorial etiology of anemia may hinder the direct effects of nutrition-sensitive interventions, especially within short study time frames [6]. Second, mHealth

XSL•FO
RenderX

platforms may not be optimally suited for delivering certain nutrition-sensitive interventions, such as maternal reproductive health services that require in-depth counseling, physical demonstrations by skilled health care providers, or access to physical resources [62].

Additionally, the meta-review by Moorthy et al [13] synthesized data from 118 systematic reviews to assess the impact of nutritional interventions on Hb concentration and anemia outcomes in specific populations, including pregnant women. This comprehensive analysis highlighted the effectiveness of key nutrition-specific interventions, such as iron and folic acid supplementation and intermittent preventive treatment in pregnancy for malaria, in optimizing Hb concentration among pregnant women. However, only 5 of the 118 systematic reviews focused on the impact of nutrition-sensitive interventions on Hb concentration and anemia prevalence, indicating a knowledge gap in the evidence [13]. This paucity of data constrains our ability to draw robust conclusions about the effectiveness of nutrition-sensitive interventions in enhancing maternal iron status.

The effectiveness of mHealth-based nutritional interventions may also rely on the integration of BCTs, which refer to the specific techniques used in the intervention to promote behavior change [63,64]. However, despite their broad use in health promotion, only 3 (27.3%) studies in this review explicitly used existing behavior change theories such as the health belief model or the theory of planned behavior. Notably, one study incorporating the health belief model reported a small ES (ES=0.29, 95% CI 0.07-0.51), while another study with the largest ES (ES=2.61, 95% CI 2.23-3.00) did not apply any behavior change theories [15,40]. This discrepancy suggests that the effectiveness of mHealth interventions may not rely solely on the inclusion of a single behavior change theory or BCTs but rather on the integration of diverse theories or techniques alongside optimal mHealth delivery modes [64,65]. These findings align with systematic reviews, emphasizing that combining multiple BCTs, such as feedback and monitoring, prompts and cues, personalization, and goals and planning, enhances intervention outcomes [66,67].

Limitations of the Review

A key limitation of this review is the inability to include a meta-analysis due to substantial heterogeneity across studies, including variations in mHealth delivery modes, intervention content, and types of nutritional interventions. As a result, a formal statistical assessment of publication bias (eg, funnel plot analysis) could not be conducted. Nevertheless, studies with null or nonsignificant findings may be underrepresented due to publication bias.

This review was restricted to peer-reviewed studies published in English, potentially leading to language and publication bias by excluding relevant evidence from the gray literature. Additionally, interrater reliability statistics (eg, Cohen κ) were not calculated, as data extraction was conducted by only 1 reviewer (SAB).

Furthermore, many of the included studies (90.9%) were judged to have some concerns regarding the risk of bias, potentially limiting the quality of evidence. Finally, this review did not focus on mHealth interventions designed for health care providers, which may have influenced maternal health outcomes indirectly by enhancing maternal nutrition care and adherence to antenatal guidelines.

Conclusions

This systematic review demonstrates that mHealth-supported nutritional interventions can effectively optimize Hb concentrations in pregnant women. Interventions using WhatsApp showed the most significant impact, potentially due to their capacity to deliver multimedia-rich content, thereby facilitating better information retention. Conversely, interventions relying solely on SMS text messaging were less effective; however, combining SMS text messaging with other delivery modes, such as phone calls, improved overall effectiveness.

The integration of mHealth interventions into maternal health care for anemia prevention and management is both feasible and supported by evidence. Nevertheless, the variability in mHealth delivery modes, functions, and interactive features underscores the need for tailored strategies that consider context-specific challenges, digital literacy levels, and access to technology to increase effectiveness.

Implications for Practice and Future Research

The current evidence is predominantly generated from studies conducted in a limited number of countries, which constrains the generalizability of findings. Future research should focus on evaluating the effectiveness of mHealth-based nutritional interventions on maternal iron status across diverse geographical and socioeconomic contexts to strengthen the applicability of the conclusions. Additionally, the insights from this review can guide future researchers in understanding the impact of various mHealth delivery modes, functions, and interactive features on the iron status of pregnant women. Such understanding will assist mHealth intervention designers and implementation researchers in adopting and developing context-specific approaches and identifying implementation strategies to improve effectiveness.

Given the importance of patient-centered care, mHealth interventions must be designed with a personalized approach. Thus, future researchers should also emphasize evaluating implementation outcomes to ensure the effectiveness and sustainability of mHealth interventions in real-world settings.

Acknowledgments

The authors wish to thank Thomas Vandendriessche, Norin Hamouda, Krizia Tuand, Chayenne Van Meel, and Jaana Van Overwalle, the reference librarians of the KU Leuven Libraries—2Bergen (Leuven, Belgium), for their help in conducting the systematic literature search.

Funding

SAB received a PhD scholarship from Vlaamse Interuniversitaire Raad—Universitaire Ontwikkelingssamenwerking through the Global Minds Program, funded by the Belgian Directorate General for Development Cooperation and Humanitarian Aid. The funder was not involved in the conceptualization, analysis, interpretation, or writing of this manuscript.

Data Availability

All data generated or analyzed during this review are included within this paper and its supplementary information files.

Authors' Contributions

SAB and CM conceptualized the review, developed the initial search strategy, and conducted the study selection, data extraction, quality assessment, and data analysis. AMB and WVP contributed to the review and interpretation of the findings. SAB drafted the initial manuscript with input from CM. All authors critically revised the manuscript for important intellectual content and approved the final version. All authors had full access to all data in the study and take responsibility for the integrity and accuracy of the data and analysis.

Conflicts of Interest

None declared.

Abstract

Background: Healthy aging has emerged as a global priority. However, older adults' participation in health promotion programs remains low, and traditional health promotion models have achieved limited success in fostering sustained engagement among this population. Mobile health (mHealth)–based gamification interventions offer a promising way to address these challenges. However, no published reviews support or oppose the use of mHealth-based gamification interventions as health promotion strategies in older adults.

Objective: The study aimed to identify mHealth interventions using gamification to promote health among older adults.

Methods: Our scoping review was conducted following the Joanna Briggs Institute recommendations for scoping reviews and Arksey and O'Malley's framework. The process followed PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) guidelines and PRISMA-S (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Literature Search Extension) checklist. A comprehensive literature search was conducted across 8 databases: PubMed, Scopus, Web of Science, Embase, Cochrane Library, CINAHL, PsycARTICLES, and IEEE Xplore Digital Library, from their inception to December 10, 2025. Two reviewers independently screened titles, abstracts, and full texts via Rayyan, with disagreements resolved by a third reviewer.

Results: This scoping review identified 11 studies. Only 1 article was published before 2022. The interventions were found to improve enjoyment and motivation (n=5), cognitive function (n=3), physical activity (n=2), and digital literacy (n=2). Individual studies also reported improvements in mental health (n=1) and adherence (n=1), a reduction in suicidal ideation (n=1), improvements in physical function (n=1), the promotion of social engagement (n=1), and the identification of mild cognitive impairment (n=1). Game elements used were ranked by frequency as progress, challenges, goals, levels, reward, sensation, storytelling or narration, leaderboard, surprise, and avatar. No research was found to use the game element of "social sharing." mHealth types included augmented and virtual reality–based training systems, wearable devices, mobile phones, tablets, and Windows platforms and devices. Notably, only 4 studies applied theoretical frameworks, and 3 omitted the concrete approach to gamification.

Conclusions: As the first scoping review to identify and map mHealth-based gamification interventions for older adults, this study highlights their potential as an innovative approach to health promotion. By systematically synthesizing evidence regarding intervention designs, gamification strategies, and preliminary health outcomes, it establishes a foundation for future inquiry. However, this review is limited by the small number of included studies, precluding broad generalizations. Future research should assess long-term impacts, integrate theoretical frameworks, establish reporting guidelines, design personalized social-interactive interventions, and expand to broader health domains. Ultimately, these insights provide targeted guidance for developing age-appropriate digital health solutions, contributing to the realization of active aging.

RenderX

Introduction

Globally, the proportion of older people continues to rise. By 2050, the number of people over the age of 65 years is expected to reach approximately one-sixth of the total population [1]. The aging process often leads to cognitive and physical changes in older adults that, if not addressed, can lead to a variety of health complications, including dementia [2]. Maintaining the health of older people is not only related to the quality of individual life but also the core issue of coping with the social and economic pressure of aging.

Healthy aging has also become a global priority, with the World Health Organization identifying the promotion of older people's health as one of its sustainable development goals [3]. However, the number of older people participating in health promotion programs is small [4,5]. In addition, traditional health promotion models have had limited success in engaging older persons in sustained engagement. Therefore, there is an urgent need for innovative interventions to improve the health behaviors of older persons.

Mobile health (mHealth) is showing its unique potential as an effective way to address these challenges. As a new and rapidly growing field, mHealth enables the implementation of predefined health promotion interventions and practices through mobile devices and their applications [6]. mHealth is an ideal choice for health promotion because of its significant benefits: continuous availability of services, wider access, equity in access to services, personalization of content, lower cost, and increased service capability and efficiency [7]. In recent years, with the increasing penetration of smartphones and the overall increase in digital literacy among the public, public and private health care systems have made significant progress in using mobile apps to address public health challenges [7]. In this context, mHealth is an innovative tool that can greatly broaden access to health promotion services for older people and flexibly adapt to a wide range of health-related needs and contexts.

There is a growing interest in integrating game-like elements into mobile apps, known as gamification, to increase user engagement and enable personalization [8,9]. This review uses a definition provided by Deterding et al [10-12]. They define gamification as the use of game elements (such as goal-setting, progress bars, rewards, feedback, badges, points, competition, cooperation, leaderboards, etc) rather than mature games in nonplayable services and applications to enhance user experience and engagement [10-12]. While game elements are not always clearly distinguishable, they refer to the typical features of a game [10]. To be clear, this review focuses on gamification, not serious games, because serious games provide a pure gaming experience by creating complete and immersive games. In contrast to serious games, this article focuses not on the full game but on the fun elements.

Systems that incorporate gamification often use incentives to promote the adoption of mHealth technologies and healthy behaviors, including immediate success feedback (rewards), continuous progress feedback, and goal setting. For example, users receive badges as rewards when they win, and they can share their achievements on social networks [13]. In rehabilitation and behavioral sciences, gamification has been integrated into mHealth, virtual reality (VR) technology, and robotics and has been effective in motivating patients with cardiovascular disease [14-16], diabetes [17,18], and stroke [19-21] to participate more actively in long-term health management. Multiple studies have shown that mobile app–based gamification interventions can improve patients' adherence to medical protocols and effectively manage their health conditions [22-24]. In addition, a literature review of empirical studies on gamification further confirms the effectiveness of gamification in improving user motivation and engagement [25], which is the core goal of many established behavior change strategies [26-30]. Taken together, gamification seems to be an effective strategy for promoting health [31].

Older people are becoming a growing segment of technology users with unique needs and challenges [32]. Furthermore, in the field of health care, there is a lack of understanding of gamification as a design strategy, and its application is often restricted to the use of video games [33] or blindly incorporating game elements without discrimination to motivate certain behaviors (such as physical activity) [34]. In addition, the concept of gamification is relatively new [10], and research on mHealth-based gamification interventions for the age group 60 years and older is still in the early stages of exploration. Therefore, for older people, more in-depth investigations and customized reviews are necessary. Unfortunately, in existing literature databases, we were unable to search for an English-language scoping review that explored the current use of mHealth-based gamification interventions to promote health in older adults.

To address these gaps, this study adopted a scoping review methodology to identify mHealth interventions using gamification to promote health among older adults. To provide a comprehensive overview, this review specifically analyzes (1) intervention characteristics and the health promotion topics addressed; (2) gamification characteristics; (3) the needs and experiences of older adults regarding these interventions; and (4) current knowledge gaps to provide recommendations for future research.

Methods

Overview

This study was structured according to the framework proposed by Arksey and O'Malley [35], with our methodology being guided by the steps described in the Joanna Briggs Institute manual for key phases, including study selection; data mapping; and the collation, synthesis, and reporting of results [36]. The reporting of this scoping review aligned with the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) checklist (Checklist 1) and PRISMA-S (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Literature Search Extension) checklist (Checklist 2) [37]. To ensure methodological rigor, inclusion and exclusion criteria were predefined prior to initiating the review process.

XSL•FO
RenderX

Search Strategy

All authors discussed and decided to include the following 8 databases: PubMed, Scopus, Web of Science, Embase, Cochrane Library, CINAHL, PsycARTICLES, and IEEE Xplore Digital Library. The IEEE Xplore Digital Library is a more technology-oriented database that allows us to search for articles in the fields of informatics and engineering. A comprehensive literature search was conducted across all databases, covering the period from their inception to an initial search date of February 18, 2025. This search was subsequently updated by rerunning the same strategy on December 10, 2025, to identify any newly published relevant studies. The language of publication was limited to English to ensure an accurate understanding of the research.

The search strategy included terms across three categories: (1) mHealth (eg, telemedicine OR telehealth OR e-health OR m-Health OR eHealth OR mHealth OR "mobile applications" OR applications OR application OR app OR apps OR online OR mobile OR internet OR "web based" OR Smartphone OR "phone, smart" OR "smart phones" OR smartphones OR "smart phone" OR "phones, smart" OR "cell phone" OR iphone OR android OR iOS OR "Wearable Electronic Devices" OR website OR digital* OR system* OR electronic* OR technolog* OR device OR framework* OR "social support" OR Facebook OR "networks, social"), (2) gamification (eg, Gamification OR "game-based learning" OR gaming OR gamif* OR "game element*" OR game* OR "game mechanic*" OR gameful* OR "game design element*" OR "game-design element*" OR "game interface element*" OR "game feature" OR "game-like element*" OR "videogame element*"), and (3) older adults (eg, "older adult*" OR "older people" OR elderly OR "older population" OR "senior citizen*").

The search terms were derived from Medical Subject Headings (MeSH) and free-text words. These keywords were then combined using Boolean operators (AND, OR) to ensure a comprehensive search. All search algorithms were modified and refined for each database. For a detailed search strategy, see Multimedia Appendix 1. A supplementary manual search was conducted by reviewing the reference lists of all included articles. Additionally, ResearchGate was used as a targeted supplementary tool for two specific purposes: (1) to retrieve the full texts of potentially eligible peer-reviewed articles that were otherwise inaccessible, including directly requesting full texts from the authors; and (2) to review the publication profiles of key authors from the included studies to identify any other relevant peer-reviewed journal publications meeting our inclusion criteria. The inclusion and exclusion criteria are mentioned in Textbox 1.

Textbox 1. Inclusion and exclusion criteria.

Inclusion criteria

- This review primarily includes interventions based on "gamification" rather than "serious games," both of which are defined in the introduction. We explicitly did not exclude studies simply due to the absence of a clear definition of "gamification" or "serious games" within the text. Instead, we require that gamification be explicitly stated or at least 1 game element used in the article
- Peer-reviewed English-language journal publications with no date limit until the final search date
- Original empirical research, including qualitative and quantitative research (must be experimental research)
- Gamification is delivered through mHealth devices such as computers, smartphones, and wearables
- The purpose of gamification is to promote health in older adults, including but not limited to physical activity, cognitive function, mental health, nutritional intake, and social interaction
- The mean age of the participants included in the article is 60 years or older

Exclusion criteria

- Excluding reviews, protocols, design documents, letters, magazines, dissertations, abstracts, reviews, posters, preprints, conference proceedings, conference abstracts, nonprimary data sources, books, and book chapters
- Excludes serious or mature games (eg, video games, immersive virtual reality games, and augmented reality exergames)
- If the entire article cannot be accessed or retrieved, the study will also be excluded
- Exclude studies that only mention gamification superficially, for example, as a buzzword or as a suggestion for future research, without it being a core component of the study's intervention or analysis

Study Selection

We first used the software EndNote X21 (Clarivate) to automatically identify and remove duplicates. Then, we imported the deduplicated documents from EndNote X21 into Rayyan software and continued to perform manual deduplication in Rayyan software. Prior to the formal review, a calibration exercise was conducted on a random sample of one-fifth of the titles and abstracts. Two reviewers (XC and YZ) independently screened this sample to ensure consistency. Following a precedent set in similar reviews, an interrater agreement of nine-tenths was achieved before proceeding with the screening of the remaining articles [38]. The complete screening was performed independently by the 2 reviewers using Rayyan software. Initially, the 2 authors (XC and YZ) screened all study titles and abstracts for eligibility based on inclusion and exclusion criteria. Next, the 2 authors (XC and YZ) examined all full-text articles to determine whether they included the use of mHealth-based gamification interventions to promote health in older adults. Finally, a supplementary manual search was

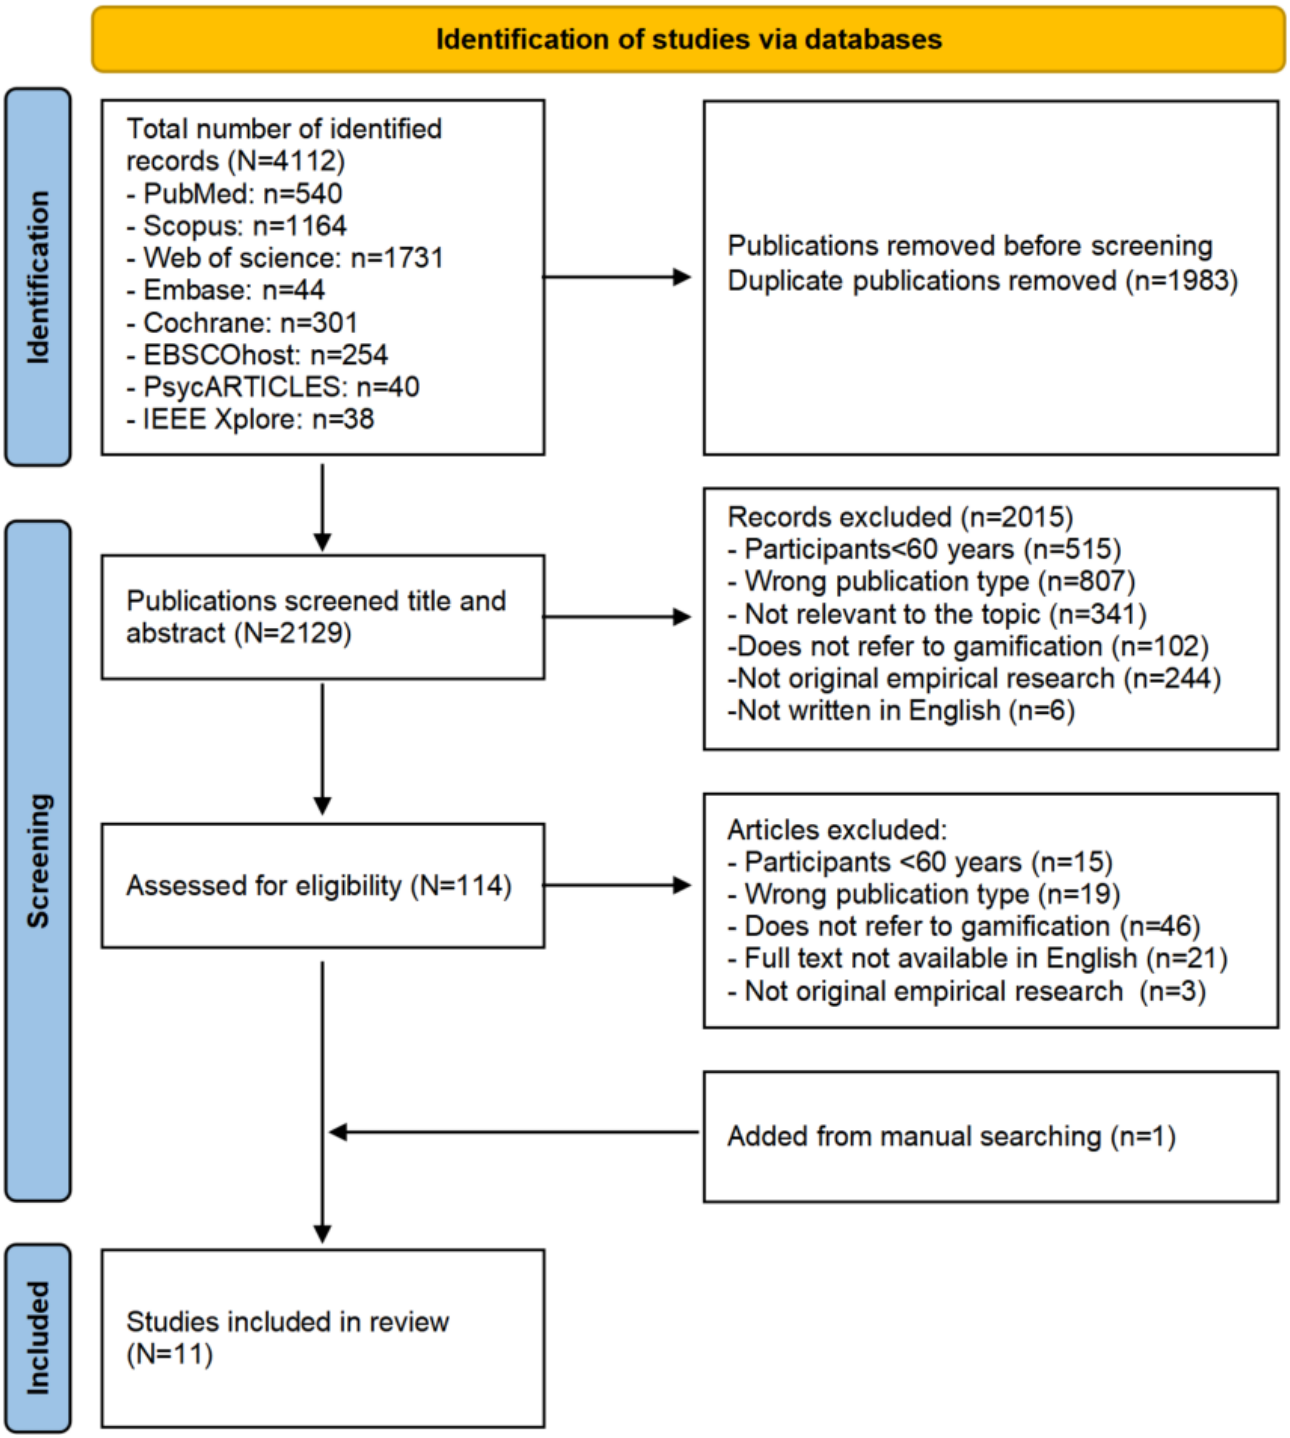
XSL•FO
RenderX

performed by looking at the list of references for the included articles and using ResearchGate. To ensure the uniformity of the screening, the authors conducted several training sessions in Rayyan with the co-reviewers. After each stage, the 2 authors (XC and YZ) cross-checked their results and discussed any differences. Any disagreements were resolved by a third researcher (HF).

Data Extraction

Two researchers (XC and YZ) independently used the data extraction table of Excel and extracted and encoded study characteristics (first author name and year of publication, country, study design, and study objectives), participant characteristics (mean age, percentage of female participants, and target population), intervention characteristics (sample size, study setting, type of mHealth used, the theory used, and duration), gamification characteristics (definition of gamification, gamification elements, reasons for using gamification elements, and the concrete approach to gamification), and the needs and experiences of older adults with mHealth-based gamification interventions, key measurements, and study results. We extracted game elements based on the classification in the research by Aschentrup et al [31], including reward, sensation, progress, challenges, surprise, storytelling or narration, social sharing, level, leaderboard, goals, and avatar.

The extracted data were cross-checked between authors (XC and YZ), and any discrepancies within data were discussed. Differences were resolved through consultation with the third author (HF). The first author (XC) synthesized the extracted data for analysis. All data were presented using the data charts suggested by Arksey and O'Malley [35].



Results

Study Selection

A total of 4112 records were found in our database. We first used the software EndNote X21 to automatically identify and delete duplicates, with 1928 duplicates removed. We then imported the deduplicated documents from EndNote X21 into Rayyan software, and continued to perform manual deduplication, which excluded 55 out of 2184 publications. The authors (XC and YZ) then used Rayyan software to screen all study titles and abstracts of these publications, achieving an interrater agreement rate of 0.978. The screening of titles and abstracts resulted in the exclusion of 2015 studies. The full texts of the remaining articles were then assessed for eligibility, resulting in the inclusion of 10 studies. An additional study was identified through a manual search of reference lists and using ResearchGate, bringing the final number of included studies to 11. The PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram (Figure 1) provides more details on the screening process and reasons for exclusion.

XSL•FO
RenderX

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram of article selection.

Study Characteristics

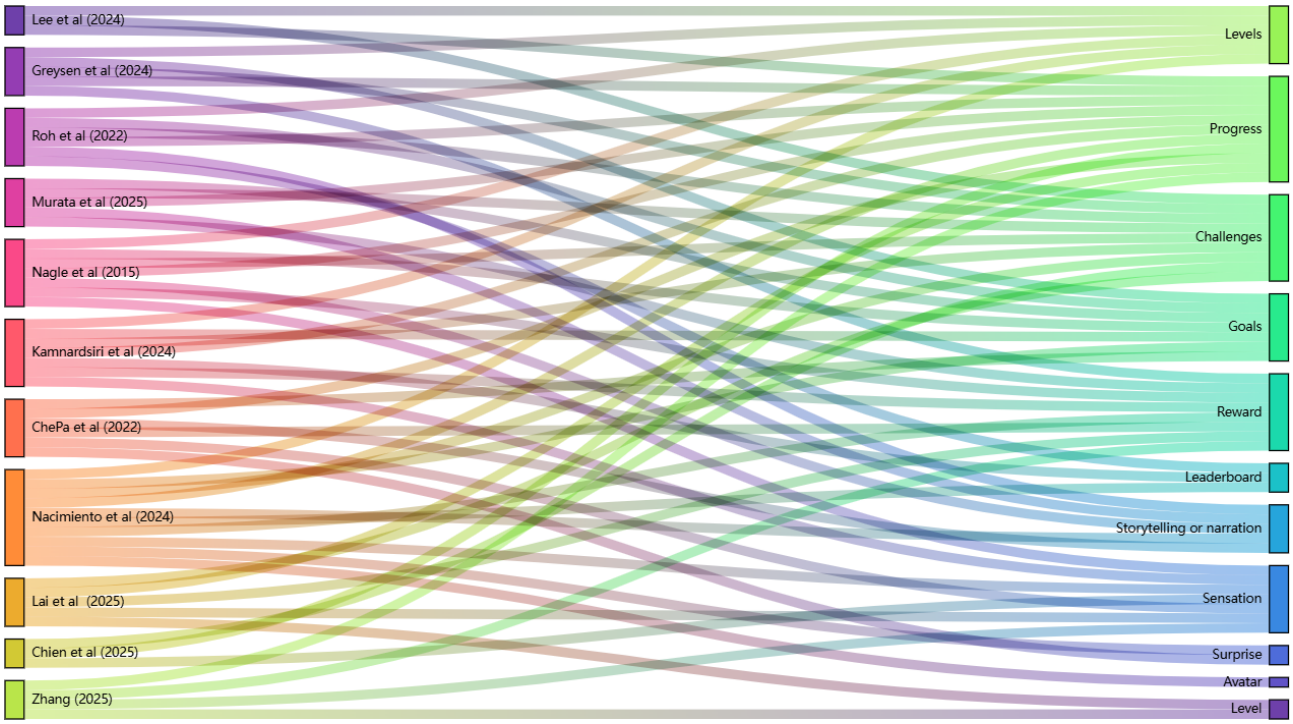
Table S1 in Multimedia Appendix 1 summarizes the research characteristics of the 11 articles included in this study. These studies were published between 2015 and 2025, with only 1 out of 8 articles published before 2022. These studies were distributed in the following 7 countries: China (3/11), South Korea (2/11), Switzerland (1/11), Spain (1/11), the United States (1/11), Japan (1/11), Thailand (1/11), and Malaysia (1/11). The research design included the following 3 types: 4 randomized controlled trials (RCTs), 4 quasi-experiments, 2 mixed methods studies, and 1 qualitative study. The research objectives of the included studies focused on developing mHealth-based gamification interventions for the older population and exploring their acceptability, feasibility, usability, safety, and effectiveness among older adults.

Participant Characteristics

All included studies provided detailed reports on the female proportion, which was relatively high, ranging from 0.476 to 1.000. The 11 included studies recruited diverse populations of older adults. Three studies focused on participants with specific cognitive conditions, including those with early symptoms of memory disorders [39], individuals at risk for Alzheimer disease and related dementias [40], and older adults with no diagnosed cognitive impairments [41]. Another 2 studies targeted

XSL•FO
RenderX

participants with specific physical or mental health statuses: high-risk, postdischarge patients with chronic pulmonary disease [42], and older women experiencing suicidal ideation [43]. A further study recruited hospital inpatients without specifying their condition [44]. The remaining 5 studies did not explicitly specify the health status of their participants.



Intervention Characteristics

A total of 545 participants were included in this review, with sample sizes ranging from 12 to 138. The study setting covered communities (n=3), hospitals (n=3), homes (n=2), care centers (n=1), and universities (n=1). One study did not explicitly specify the study setting. The mHealth types comprised augmented and VR-based training systems, wearable devices, mobile phones, tablets, and Windows platforms and devices. Some studies used a single device, while others used a combination of technologies. Furthermore, only 4 studies used theory. These included the application of behavioral economic principles [40], gamification theory [45], technology acceptance model [41], and human-centered design framework [42]. Among all the studies, only 4 studies provided the duration of a single intervention, ranging from 5 minutes to 60 minutes. Three studies provided the intervention frequency, all of which were 3 times a week. Seven studies provided the total duration of the intervention, ranging from 3 to 14 weeks. For detailed information, please refer to Table S1 in Multimedia Appendix 1.

Gamification Characteristics

Of the 11 included studies, only 5 provided a definition of gamification and were consistent with this review. The number of game elements used in these studies ranged from 1 to 11. Multimedia Appendix 2 illustrates the frequency of each game element across the included studies. Interestingly, no research was found to use the game element of "social sharing." Figure 2 presents a Sankey diagram illustrating the specific many-to-many relationships between each study and the elements it used. Overall, each included study integrated at least 3 game elements, with the study by Nacimiento-García et al [2] using the highest number of game elements (n=10). The primary reasons cited for incorporating game elements were to promote engagement and motivation (n=7), enhance adherence (n=3), and increase enjoyment (n=3). Other reasons for using game elements are detailed in Table S2 in Multimedia Appendix 1. Additionally, 7 studies described "the concrete approach to gamification," indicating that reporting on this aspect requires strengthening in future research.

Figure 2. Sankey diagram illustrating the distribution and flow of game elements across the included studies. The left column represents the individual studies, while the right column lists the identified game elements. Each colored flow connects a study to the specific game elements it used [2,39-48].

Needs and Experiences

Three included studies reported on user needs and experiences through qualitative methods. Positive user experiences, reported across the studies, included high acceptability, satisfaction, emotional satisfaction, enhanced enjoyment, motivation to continue use, a refreshing experience, perceived cognitive benefits, and improvements in physical activity, memory, and sleep quality, alongside practical design aspects such as clear instructions, good design, suitability for personal preferences, and accessibility for play at any time [2,48]. The interventions' social and collaborative aspects were also described as valuable for fostering a sense of community [2].

Reported challenges and negative experiences included technical issues such as system freezes, difficulty with game mechanics, relatively small character and object sizes, and misalignment between in-game and actual movements, as well as experiences of stress and initial physical fatigue [2,48]. Furthermore, user needs and preferences were found to differ by gender, with men

XSL•FO
RenderX

valuing cognitive challenges, while women emphasized practical memory support [41].

Health Promotion Domains and Recommendations

Overview

The 11 included studies reported several positive outcomes. The interventions were found to improve enjoyment and motivation (n=5), cognitive function (n=3), physical activity (n=2), and digital literacy (n=2). Individual studies also reported improvements in mental health (n=1) and adherence (n=1), a reduction in suicidal ideation (n=1), improvements in physical function (n=1), the promotion of social engagement (n=1), and the identification of mild cognitive impairment (n=1).

Improve Physical Function

One RCT by Lee et al [46] compared the efficacy of an 8-week mHealth-based gamification intervention against conventional exercise in 40 community-dwelling older adults (aged 60 - 85 years). The study found significant improvements in physical function in both groups, concluding that the gamified intervention produced comparable exercise effects to conventional exercise. Notably, the study examined mHealth-based gamification interventions as an integrated whole rather than evaluating individual game elements. Future research is needed to identify specific game elements most effective in enhancing older adults' physical function.

Improve Adherence

In a 3-week home-based trial with 21 healthy older adults, Nagler et al [47] investigated the impact of user control over game design elements (difficulty adjustment, reward selection, and visual theme customization) on adherence to a memory training game. The study compared a "user-control" mode to an "automatic" mode and found that the user-control group demonstrated significantly higher play frequency, total engagement duration, and memory task accuracy. These findings suggest that user-driven gamification enhances adherence and performance. However, the study combined 3 game elements, preventing identification of individual effects, and its small sample of healthy, motivated participants limited generalizability, while the nonrandomized design hindered causal inference. Additionally, the research did not specify the concrete approach to gamification, leaving unclear how exactly game mechanics were integrated into the mHealth intervention.

Promote Physical Activity

Greysen et al [40] conducted a 12-week RCT with 94 older adults at risk for Alzheimer's disease. They found that an mHealth-based gamification intervention with a support partner led to a significant increase in physical activity (1699 steps/day; $P<.001$) compared to controls (step goals with daily feedback), a gain that was partially sustained at a 3-week follow-up. However, the authors noted several limitations, including the short intervention and follow-up periods and the exclusion of nine participants post randomization, which could introduce bias.

The RCT by Roh et al [45] targeted older adults to evaluate a gamification-based smartphone app for promoting brain health. Over 8 weeks, 40 older adults were randomized to the app intervention or control group, with outcomes measured via physical activity questionnaires, cognitive scores, and the Situational Motivation Scale. The intervention group showed significant improvements in moderate-intensity physical activity ($P=.01$) and an 8-week physical activity difference ($P=.04$) versus controls. However, the study faced challenges, including a small sample size and a short intervention period, which may limit generalizability to long-term behavior change in older adults.

Identify Mild Cognitive Impairment

Murata et al [44] developed and tested a gamified mobile app, based on the N-back task, to screen for mild cognitive impairment in 138 older adults. The study found significant correlations between gameplay performance metrics (eg, swipe time, accuracy) and cognitive function (Mini-Mental State Examination scores). The authors concluded that their gamified app could identify mild cognitive impairment with an accuracy comparable to standard dementia screening tests. However, the study did not address participants' past smart device experience, which may confound motor-based metrics. Additionally, reliance on device-specific factors (eg, swipe time) raises cross-device reproducibility concerns.

Improve Cognitive Function and Promote Digital Literacy and Social Engagement

Nacimiento-García et al [2] developed a tailored mHealth-based gamification intervention, with games targeting memory, attention, and problem-solving. A pilot study found the intervention effectively promoted cognitive function, digital literacy, and social engagement. However, the authors noted that advanced tools like VR glasses posed initial usability barriers for some older users, and they recommended that future research should expand participant diversity and conduct longitudinal controlled studies to assess long-term impacts.

ChePa et al [39] used an mHealth-based gamification intervention for older individuals with memory disorders and found that it led to significant cognitive improvement, enhanced memory recall, and improved digital literacy. A key limitation noted was the lack of a specific description of how the gamification was implemented.

In a qualitative study by Lai et al [41], participants reported perceived cognitive benefits from using a Cantonese-language gamified mobile app. However, the reported cognitive benefits were based on self-reported experiences only; no objective cognitive or usage data were collected, and the small sample size limits the generalizability of findings across different demographic subgroups.

Improve Enjoyment and Motivation

Nacimiento-García et al [2] found that gamified experiences were enjoyable in mHealth-based interventions. Roh et al [45] demonstrated that such interventions significantly enhanced intrinsic motivation ($P=.01$), which subsequently promoted physical activity ($P=.01$). Kamnardsiri et al [48] reported comparable benefits in a home-based, low-intensity, gamification-based interactive physical-cognitive training pilot; participants showed a significant increase in enjoyment ($P=.001$)

XSL•FO
RenderX

over 4 weeks. However, this study focused on prototype usability and did not evaluate clinical physical or cognitive outcomes, nor did it specify the concrete approach to gamification.

Lai et al [41] reported that participants experienced emotional satisfaction and expressed motivation to continue using a gamified application; however, the study did not assess enjoyment or motivation using quantitative measures. Given that the study was exploratory and based on voluntary participation, potential self-selection bias should be taken into account when interpreting the results.

Chien et al [42] reported that participants in a home-based pulmonary telerehabilitation program using the Intelligent Pulmonary Rehabilitation Exercise System experienced increased engagement, motivation, and enjoyment through personalized feedback, collaborative goal-setting, and gamified exercise modules. However, the study used a single-group design with a modest sample size, evaluations were primarily conducted during hospitalization, and the absence of a control group or comparison with other treatment modalities limits generalizability.

Improve Mental Health and Reduce Suicidal Ideation

Zhang [43] conducted an RCT involving 120 older women with suicidal ideation to evaluate a gamified group-based VR physical activity intervention. The study concluded that this approach serves as a promising strategy to enhance psychological well-being and mitigate suicide risk. However, the intervention lacked a guiding theoretical framework. Critically, the study design did not allow for the identification of the specific effects of individual game elements. Furthermore, the reliance on indirect indicators rather than direct suicide assessment, combined with the absence of blinding and longitudinal follow-up, presents methodological limitations.

Discussion

Summary of Key Findings

This is the first scoping review to examine mHealth-based gamification interventions for health promotion among older adults. This scoping review identified 11 studies. We provide a comprehensive overview of mHealth-based gamification interventions for older people's health promotion in countries like China, Korea, and the United States. Only 1 article was published before 2022. These studies demonstrated the interventions' effectiveness in improving physical and cognitive function, adherence, enjoyment, motivation, and mental health; promoting physical activity, digital literacy, and social engagement; identifying mild cognitive impairment; and reducing suicidal ideation.

Game elements used were ranked by frequency as progress, challenges, goals, levels, rewards, sensation, storytelling or narration, leaderboard, surprise, and avatar. However, due to insufficient information in these studies, it remains unclear whether intervention outcomes should be attributed to single game elements or synergistic effects of multiple elements. mHealth types included augmented and VR-based training systems, wearable devices, mobile phones, tablets, and Windows platforms and devices. Notably, only 4 studies applied theoretical frameworks (behavioral economic principles and gamification theory, technology acceptance model, and human-centered design framework), and 3 omitted the concrete approach to gamification. Given these findings, there is substantial potential for wider adoption of mHealth-based gamification interventions for clinicians and patients in future health promotion among older adults.

Intervention Characteristics

First, all included studies in this research had relatively short intervention periods, with the longest lasting only 14 weeks [39], and 1 study even involved a single intervention lasting just 5 to 10 minutes [44]. This finding aligns with Aschentrup et al [31], where only 2 studies had a 12-week intervention period. In reality, the long-term effects of interventions are one of the most critical aspects for evaluating intervention efficacy. Additionally, most studies did not report specific details of intervention dosage, particularly intervention frequency and the duration of single sessions. Therefore, future research should explore long-term effects and report intervention dosage details to facilitate study reproducibility.

Second, the mHealth types involved in the studies included augmented and VR-based training systems, wearable devices, mobile phones, tablets, and Windows platforms and devices, with mobile phones and tablets being the most commonly used. This contradicts the findings of Xu et al [49], whose study indicated that most research used wearable devices. A possible reason for this discrepancy is that their study focused solely on physical activity in participants, and wearable devices can provide real-time feedback on daily steps and energy expenditure through specially designed algorithms [50,51]. Thus, when using mHealth-based gamification interventions to promote physical activity among older adults in the future, we recommend prioritizing wearable devices as the mHealth type.

Finally, in terms of theoretical applications, only 4 studies applied theoretical frameworks: 1 used behavioral economic principles to select gamification elements [40], 1 used gamification theory to guide intervention design [45], 1 used the technology acceptance model to explore older adults' experiences with the gamified mobile app, and 1 adopted a human-centered design framework to guide the development of an mHealth-based gamified intervention system. This finding differs from previous research. For example, Montagni et al [52] noted that almost all included studies were grounded in robust theories, which were proven effective in promoting understanding and evaluating information related to vaccines and behavioral change end points. Literature reviews also show that theory-driven interventions are more effective than non–theory-based ones [53]. Therefore, we advocate that future designs of mHealth-based gamification interventions for older people's health promotion should be closely integrated with theoretical frameworks.

Gamification Characteristics

First, in this study, the most frequently used game element was progress, followed by challenges and goals. The most commonly used game elements align with a previous study [49]. Notably,

XSL•FO
RenderX

goals serve as a key technique for behavioral change [54]. When combined with progress and feedback, they can significantly boost intrinsic motivation [55]. The only game element unused in all included studies was social sharing, which contradicts prior findings. For example, Xu et al [49] showed that when using mHealth-based gamification interventions for physical activity, the second most common game element was social interaction, which not only enhanced users' enjoyment but also promoted motivation for physical activity through social incentives. The discrepancy might be attributed to differing inclusion criteria for gamification elements across studies [56,57]. Additionally, Mahmoudi et al [38] emphasized the importance of considering user preferences and personalized game elements, which was not reflected in our study. Thus, developers and researchers are encouraged to integrate social interaction, user preferences, and personalized gamification elements into interventions to enhance user engagement and, in turn, their effectiveness in health-related outcomes.

Second, gamification is one of the most critical components of mHealth-based gamification interventions. However, it is worth noting that among the 11 included studies, 3 failed to describe how gamification was specifically implemented in mHealth. This could undermine the reproducibility and comparability of research findings, thereby hindering the accurate evaluation of intervention efficacy and the formulation of evidence-based guidelines. Such oversight also aligns with previous review studies [31,38,58]. Thus, future research is recommended to establish corresponding reporting guidelines, emphasizing the need to strengthen this aspect of reporting for field advancement.

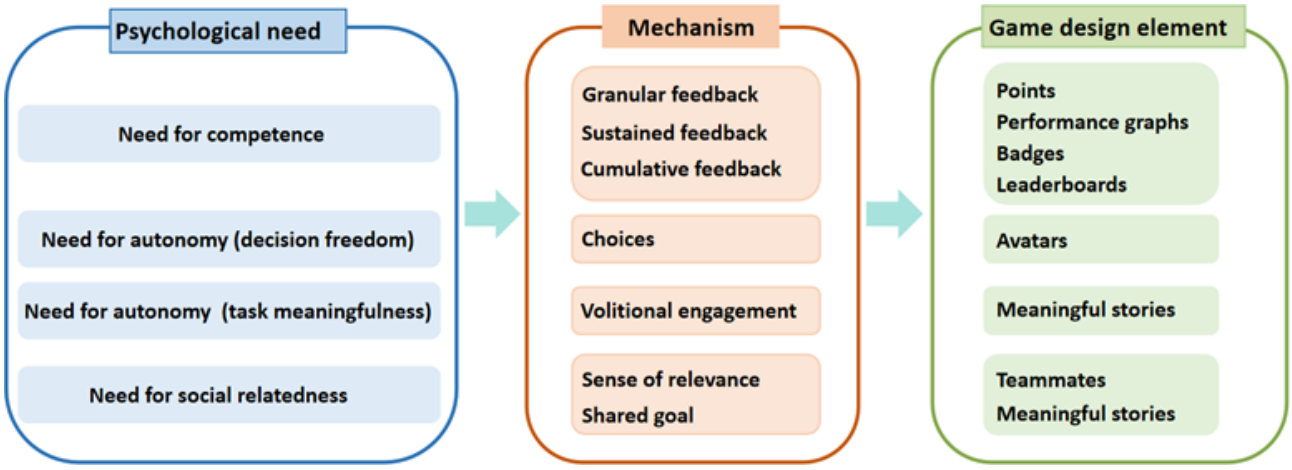
Finally, it is noteworthy that each study explained the reasons for using game elements, primarily, including promoting engagement and motivation, enhancing adherence, increasing enjoyment, and improving intervention efficacy. These findings are consistent with previous studies. For example, Mahmoudi et al [38] noted that most studies included in their research aimed to use game elements to enhance the adherence and motivation of children with disabilities. Additionally, a study has found that introducing gamified applications can improve intervention effectiveness by encouraging users to use them continuously and frequently [59].

Needs and Experiences

Only 3 studies collected older users' needs and experiences. The positive feedback can be categorized into 4 main aspects: first, the attributes of interventions, covering practical design aspects such as user-friendly design, personalization, and accessibility for play at any time; second, user engagement and subjective experience, which included high acceptability, satisfaction, emotional satisfaction, enhanced enjoyment, motivation to continue use, and a refreshing experience; third, health and functional benefits, such as perceived cognitive benefits and improvements in physical activity, memory, and sleep quality; and fourth, social and cultural elements, where the interventions' social and collaborative aspects were described as valuable for fostering a sense of community. Possible explanations include that game elements enhance enjoyment and self-efficacy among participants. Additionally, integrating immersive and gamified elements provides dual benefits of cognitive and emotional stimulation, enhancing the overall user experience [2]. These results are also supported by previous studies [60,61].

Key issues included usability and technical flaws, including system freezes, difficult game mechanics, small character and object sizes, and movement misalignment, alongside reports of stress and initial physical fatigue. Usability is a critical aspect of improving acceptability and intervention adherence [48]. A prior study has shown that user-friendly interfaces, in particular, are a key factor in promoting positive acceptance among older users unfamiliar with new technologies [62]. Thus, future research should prioritize investigating needs and experiences, as this is crucial for designing mHealth-based gamification interventions. And more attention should be paid to user-centered design principles to ensure high acceptability and usability.

Health Promotion Domains and Recommendations



Our study demonstrates that mHealth-based gamification interventions effectively improve physical and cognitive function, enhance adherence, promote physical activity, identify mild cognitive impairment, promote digital literacy and social engagement, improve mental health, reduce suicidal ideation, and enhance enjoyment and motivation among older adults.

These findings are consistent with previous studies. A study by Luo et al [63] showed that mHealth-based gamification interventions effectively improve pre-exposure prophylaxis adherence among men who have sex with men. Xu et al [49] found that mHealth-based gamification interventions may increase participation in physical activity. Huang et al [64] noted that using gamification to promote self-management among patients with chronic diseases has been widely recognized, including promoting physical exercise and rehabilitation training, enhancing motivation for symptom management, providing psychological support, improving cognitive function, and improving medication adherence. Additionally, research has indicated that when gamification is combined with emerging technologies, the findings may be more promising [65]. This could be attributed to digital tools being unconstrained by time and space [66], and gamification elements potentially enhancing their appeal and acceptability. Thus, future intervention designs should consider the integration of new technologies and gamification.

The motivational effects of game elements can also be explained theoretically. Sailer et al [67] constructed a relationship between various gamification elements (such as points, leaderboards, and badges) and Ryan and Deci's self-determination theory [68] (Figure 3). It is a theory of motivation that identifies 3 universal basic psychological needs that determine human behavior: competence, autonomy, and social inclusion [68]. If 1 or more of these needs are met (eg, through gamification elements), there is a positive impact on human behavior and the factors that influence it [67].

XSL•FO
RenderX

Figure 3. Psychological needs with matching game design elements.

Beyond the topics identified in our review, prior research has demonstrated the potential of mHealth-based gamification interventions across other health domains. For example, Montagni et al [52] showed that digital gamification enhances vaccination knowledge and ultimately expands vaccination coverage. Another study highlighted its potential in promoting positive oral health behaviors [69]. To guide this future work, key methodological findings should also be considered. Xu et al [49] found that combining multiple game elements in mHealth-based gamification interventions is more effective than single elements, and theory-guided interventions outperform those without theoretical grounding. Therefore, we recommend that future empirical research should not only explore broader health domains but also (1) systematically compare the effects of single versus combined game elements and (2) ensure that the design and implementation of interventions are grounded in established theoretical frameworks.

Practical and Research Implications

Our study suggests that mHealth-based gamification interventions are a promising approach for enhancing older adults' health. Although this review identifies potential benefits, given the limited number of included studies, these findings should be interpreted with a cautious and critical perspective. We propose several recommendations for future research and practice:

First, to expand the innovative capacity outlined above, determining long-term impacts is crucial. Future studies should standardize research settings, increase sample sizes, extend intervention and follow-up periods, and conduct high-quality RCTs. They should also report intervention dosage details to facilitate study reproducibility.

Additionally, most existing studies lack theoretical frameworks. Thus, we advocate for integrating theoretical frameworks into future designs of mHealth-based gamification interventions for older health promotion, as theory-guided interventions may be more effective than nontheoretical ones.

Furthermore, future research is needed to explore whether intervention outcomes can be attributed to single game elements or synergistic effects of multiple elements.

Moreover, future research should establish corresponding reporting guidelines, particularly focusing on how gamification is specifically implemented in mHealth, thereby advancing the field and enhancing the reproducibility of studies.

Additionally, developers and researchers are encouraged to integrate social interaction, user preferences, and personalized gamification elements to create tailored, older-friendly interventions, thereby enhancing user engagement and health-related effectiveness.

Subsequently, future studies should prioritize investigating users' needs and experiences, which are critical factors in designing mHealth-based gamification interventions.

Finally, empirical research for older adults should also expand mHealth-based interventions to broader health domains, such as exploring their impacts on the mental health of older populations.

Limitations

We acknowledge several limitations in this review. First and foremost is the limited number of included studies, many of which were pilot studies or used small sample sizes. Consequently, the current evidence primarily supports the feasibility and preliminary potential of mHealth-based gamification rather than definitive broad effectiveness. Although we searched 8 databases to ensure comprehensiveness, the application of gamification in geriatric health remains a relatively emerging field.

Second, a major limitation of this scoping review is the overreliance on published peer-reviewed research, which may introduce publication bias and limit the comprehensiveness of the mapping. Relying solely on published works explicitly excludes gray literature such as technical reports, institutional documents, theses, dissertations, and government publications. These materials often provide valuable insights into early-stage developments and practical implementations. Although these contents may not have entered the formal academic literature, their contribution to this field is crucial. The absence of these perspectives may lead to an incomplete understanding of the overall landscape and real-world applications. While the focus of this review was deliberately on published and accessible peer-reviewed empirical evidence to ensure a high baseline of

XSL•FO
RenderX

methodological rigor, future reviews should incorporate gray literature to capture a broader range of evidence, particularly for this emerging field.

Third, the protocol for this scoping review was not prospectively registered, which may diminish transparency and increase the potential for unintentional bias in our review process. To mitigate this, all authors critically reflected on the different steps. Fourth, restricting the search to English-language literature may have excluded relevant studies from non–English-speaking countries, potentially affecting the comprehensiveness and generalizability of our findings. Fifth, this review focused on describing effects and did not conduct a meta-analysis. Sixth, all included studies were conducted in high- or middle-income countries, limiting the generalizability of findings to low-income contexts. Furthermore, restrictions due to the specific definition of gamification adopted (ie, excluding serious games) may have limited the scope of relevant interventions included in this review. Finally, given the rapidly evolving digital landscape, the temporal limitation of the search period necessitates cautious interpretation as new research continues to emerge.

Conclusion

As the first review to systematically scope this specific area, our study identifies mHealth-based gamification as a novel and viable strategy for fostering healthy aging. Although the findings are preliminary and require cautious interpretation due to the limited number of studies, the synthesized evidence highlights the capacity of these interventions to enhance enjoyment, motivation, cognitive function, physical activity, digital literacy, and other aspects among older adults. By bridging the gap between geriatric health needs and emerging digital technologies, this review provides a much-needed baseline for the field. However, to transform these emerging interventions into scalable real-world solutions, future research must prioritize rigorous, theory-driven, and long-term evaluations, alongside standardized reporting and personalized, socially interactive designs. Ultimately, this work lays the groundwork for developing more effective, age-tailored digital health tools that can tangibly improve the quality of life for the aging population.

Acknowledgments

The authors declare the use of generative artificial intelligence (GAI) in the research and writing process. According to the GAIDeT (Generative AI Delegation Taxonomy; 2025), the following tasks were delegated to GAI tools under full human supervision: proofreading and editing. The GAI tool used was Gemini 3 Pro Preview. Responsibility for the final manuscript lies entirely with the authors. GAI tools are not listed as authors and do not bear responsibility for the final outcomes. Artificial intelligence (Gemini 3 Pro Preview) was used for minor language refinement and editing, specifically to improve grammar, spelling, verb tense, sentence flow, and English idiomatic expression. All outputs were reviewed and modified by the authors, and the authors take full responsibility for the final content. This declaration was submitted by the authors.

Abstract

Background: Prediabetes is a growing global health concern. Lifestyle modification is the cornerstone of management, yet scalable delivery strategies are needed. SMS text messaging is a promising mobile health approach for behavior change, but its effectiveness for metabolic outcomes in prediabetes remains uncertain.

Objective: This study aims to evaluate the effectiveness of text message–delivered lifestyle programs for BMI among adults with prediabetes and, secondarily, for weight, waist circumference, hemoglobin A_{1c} (HbA_{1c}), total cholesterol, and diabetes incidence.

Methods: We conducted a PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses)-guided systematic review and meta-analysis of randomized controlled trials (searching the PubMed, MEDLINE, CINAHL, Embase, Web of Science, and the Cochrane Library databases; from April 2005 to March 2025). Three reviewers independently screened studies, extracted data, and assessed risk of bias (using the Cochrane Risk of Bias tool), and random-effects meta-analyses were performed.

Results: In total, 7 randomized controlled trials (n=4632) met the inclusion criteria. SMS text messaging did not significantly affect BMI compared with standard care (mean difference [MD] −0.17 kg/m², 95% CI −0.85 to 0.25; I^2=32%). Secondary outcomes were similarly nonsignificant: weight (MD −0.46 kg, 95% CI −1.74 to 0.83; I^2=27%); waist circumference (MD −0.36 cm, 95% CI −1.09 to 0.36; I^2=13%); HbA_{1c} (MD −0.05%, 95% CI −0.17 to 0.07; I^2=89%); total cholesterol (standardized MD −0.00, 95% CI −0.06 to 0.06; I^2=0%); and diabetes incidence (odds ratio 0.84, 95% CI 0.63-1.12, I^2=51%; n=3515 across 3 trials). Estimates were small and, for several outcomes, notably HbA_{1c} and diabetes incidence, were imprecise and heterogeneous, indicating substantial between-study variability.

Conclusions: In adults with prediabetes, lifestyle programs incorporating SMS text messaging showed no meaningful effect on BMI or other metabolic outcomes; pooled estimates were near null with considerable uncertainty and heterogeneity for some end points. Variability in intervention design, dose, and tailoring likely contributed to these results. Future trials should extend follow-up, report body composition outcomes in addition to BMI, and test tailored, interactive, closed-loop SMS text messaging strategies with adequate power to resolve heterogeneous effects.

Introduction

Prediabetes affects approximately 374 million adults aged 20 to 79 years worldwide and is projected to increase to 730 million by 2045 [1,2]. It is defined by impaired fasting glucose or impaired glucose tolerance, with blood glucose levels elevated but below the threshold for a type 2 diabetes diagnosis [3,4]. Prediabetes is associated with increased risks of cardiovascular disease, microvascular complications, and all-cause mortality, and approximately 5% to 10% of individuals with prediabetes progress to type 2 diabetes annually [1]. Due to its asymptomatic nature, prediabetes often remains undiagnosed until significant disease onset, underscoring the need for early preventive strategies.

Lifestyle modification is the first-line approach for prediabetes management, demonstrating efficacy in delaying or preventing

XSL•FO
RenderX

type 2 diabetes [5]. Compared with pharmacological interventions, lifestyle programs are preferred by individuals and focus on dietary changes, increased physical activity, and behavioral support [6]. Adopting healthy eating patterns, such as the Mediterranean diet, improves glycemic control [7], while enhanced physical activity improves insulin sensitivity and reduces diabetes risk [8]. Behavioral strategies, including goal setting and self-monitoring, are critical for sustaining lifestyle changes [9]. Given that an elevated BMI is a strong risk factor for diabetes progression, targeting BMI through lifestyle interventions is central to prediabetes prevention efforts [10].

Mobile health (mHealth) technologies have emerged as scalable tools for delivering lifestyle interventions. Numerous studies have demonstrated that mHealth interventions, including mobile apps, wearable devices, and SMS text messaging, can effectively support behavior change and reduce the incidence of type 2 diabetes [11-14]. Among these mHealth interventions, SMS text messaging stands out for its simplicity. SMS text messaging, in particular, is widely accessible, cost-effective, and convenient, leveraging ubiquitous mobile phone use to promote health behaviors [15-17]. Messages can be retained, accessed flexibly, and tailored to individual needs, which may enhance engagement and adherence [11-14].

SMS text messaging interventions, guided by behavior change theories such as self-determination theory, offer motivational support and personalized feedback that facilitate sustainable behavior change [18-20]. Compared with other mHealth modalities, SMS text messaging imposes minimal user burden and provides an efficient, scalable approach to lifestyle modification [21]. These advantages are particularly relevant for individuals with prediabetes, who often face barriers to program participation, including socioeconomic constraints, time limitations, and low motivation [16,22].

Despite growing interest in SMS text messaging interventions for lifestyle modification, evidence specific to adults with prediabetes remains limited. Prior reviews have predominantly focused on populations with diagnosed diabetes or obesity, which may differ in baseline awareness, motivation, and response to interventions. As prediabetes continues to rise globally, understanding the effectiveness of SMS text messaging–based interventions in this specific population is critical.

This systematic review and meta-analysis aimed to evaluate the effectiveness of lifestyle modification programs using SMS text messaging on BMI reduction among adults with prediabetes, compared with standard care. Secondary outcomes included changes in weight, waist circumference, hemoglobin A_{1c} (HbA_{1c}), total cholesterol, and incidence of diabetes. By synthesizing available evidence, this study addresses the lack of targeted evidence for digital interventions in prediabetes management, a distinct group often underrepresented in diabetes prevention research. The findings are expected to directly inform the development of mHealth strategies tailored to the population with prediabetes, optimizing early intervention efforts. Furthermore, by identifying the role of SMS text messaging in BMI reduction and metabolic improvements, this review provides a foundation for implementing scalable, low-cost digital solutions to curb diabetes progression at both clinical and public health levels.

Methods

Overview

This systematic review and meta-analysis was conducted in accordance with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 guidelines (Checklist 1). It was registered in PROSPERO with the number CRD420251055972. A protocol for this systematic review was not prepared.

Search Strategy

A comprehensive literature search was performed by 3 independent reviewers (TTYC, CYF, and AKCW) across 6 electronic databases: PubMed, MEDLINE, CINAHL, Embase, Web of Science, and the Cochrane Library. Studies published between April 1, 2005, and March 31, 2025, were included. The reference lists of included studies were also hand-searched independently by the 3 reviewers (TTYC, CYF, and AKCW) to identify additional eligible studies. Any disagreements among the reviewers were resolved through discussion.

Only peer-reviewed articles were considered; gray literature and review articles were excluded to ensure the inclusion of high-quality evidence. Search strategies were developed using key terms including “prediabetes” and “text messaging” and were expanded using Medical Subject Headings (MeSH) terms where appropriate. Detailed search strategies for each database are provided in Multimedia Appendix 1.

Study Selection

Studies were eligible for inclusion if they met the following criteria: randomized controlled trials (RCTs), participants aged ≥18 years diagnosed with prediabetes, interventions consisting of lifestyle modification programs (ie, diet control, exercise, or behavioral therapy), and use of text messages—defined as SMS, multimedia messaging service, or instant messaging via mobile apps—as the primary intervention delivery channel.

The exclusion criteria were as follows: participants diagnosed with type 2 diabetes mellitus (DM) or gestational diabetes, participants taking medications known to affect glucose tolerance, and studies without complete analytical outcome data.

Outcome

The primary outcome of interest was change in BMI. Secondary outcomes included changes in body weight, waist circumference, HbA_{1c}, total cholesterol, and incidence of DM.

Quality Assessment and Risk of Bias

The risk of bias for the included studies was assessed using the Risk of Bias tool (Cochrane Collaboration). This tool evaluates the following five domains: (1) bias arising from the randomization process, (2) bias due to deviations from intended interventions, (3) bias due to missing outcome data, (4) bias in the measurement of outcomes, and (5) bias in the selection of reported results. Any disagreements among the 3 reviewers were resolved through discussion. As there were fewer than 10

XSL•FO
RenderX

included studies, a funnel plot to assess publication bias was not constructed.

Certainty of Evidence (Grading of Recommendations, Assessment, Development, and Evaluation)

Beyond study-level risk of bias, we appraised the outcome-level certainty of evidence using the GRADE (Grading of Recommendations Assessment, Development and Evaluation) approach for each meta-analyzed outcome (BMI, body weight, waist circumference, HbA_{1c}, total cholesterol, and diabetes incidence). Because all included studies were RCTs, each outcome began at high certainty and could be rated down for risk of bias, inconsistency, indirectness, imprecision, and publication bias. The domains were assessed as follows:

- Risk of bias; considered the risk of bias domain ratings contributing to each outcome
- Inconsistency; considered heterogeneity (I^2 and between-study variability) and overlap of study CIs
- Indirectness; assessed population, intervention, comparator, and outcome alignment with the review question
- Imprecision; considered 95% CIs (including whether they crossed the line of no effect) and optimal information size
- Publication bias; formal tests were not performed given <10 studies; we qualitatively considered small-study effects and selective reporting.

We present GRADE ratings and explicit downgrading rationales in a summary of findings table (Table S1 in Multimedia Appendix 2) and detailed footnotes (Multimedia Appendix 2). No outcomes were upgraded.

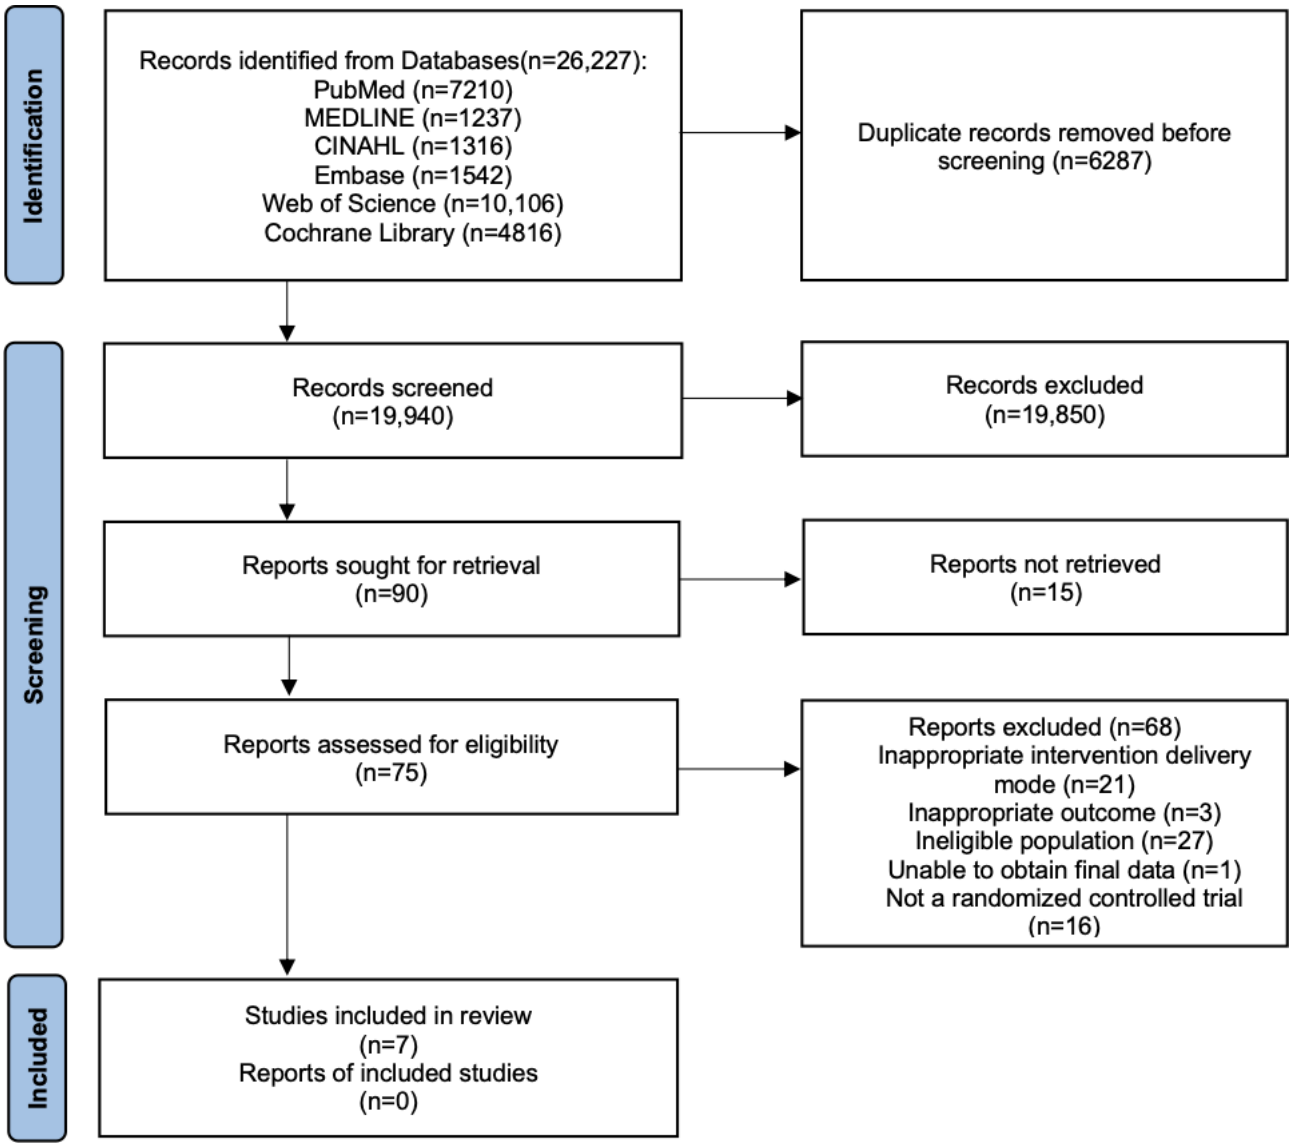
Data Extraction

Data from the included studies were retrieved and independently entered into a Microsoft Excel spreadsheet by 3 independent reviewers (TTYC, CYF, and AKCW). Additional variables—including author, study location, study population, study duration, intervention and control details, data collection time points, outcome measures, and results—were also extracted from the selected studies (Multimedia Appendix 3).

Data Synthesis and Analysis

Meta-analyses were conducted using Review Manager (version 5.4.1; Cochrane Collaboration). Outcomes were analyzed at the longest reported follow-up time point and illustrated by forest plots. For continuous variables, mean differences (MDs) with 95% CIs were calculated under a random-effects model. The meta-analysis was conducted using the postintervention values reported by the individual studies. For dichotomous variables, odds ratios and 95% CIs were computed using the inverse variance method.

Statistical heterogeneity was assessed using the chi-square test, the I^2 statistic, and associated P values ($P<.05$ was considered statistically significant). I^2 values were interpreted as follows: unimportant (0% - 40%), moderate (30% - 60%), substantial (50% - 90%), or considerable (75% - 100%) heterogeneity. Given the limited number of included trials (<10), subgroup analyses, meta-regression, and sensitivity analyses were not conducted.



Results

Study Selection

A total of 19,940 publications were identified after duplicate removal. Title and abstract screening excluded 19,850 (99.5%) publications. Of the remaining 90 publications, 75 (83.3%) were available for full-text review and assessed for eligibility. In total, 68 (90.7%) publications were excluded, primarily due to inappropriate intervention delivery modes, ineligible populations, or study designs other than RCTs. Only 7 (9.4%) publications met the eligibility criteria and were included in this review [16,23-28] (Figure 1).

XSL•FO
RenderX

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 flowchart.

Risk of Bias Assessment

Risk of bias among the 7 included RCTs, assessed using the Cochrane Risk of Bias tool, ranged from “some concerns” to “high risk.” All included studies demonstrated low risk in the domain “bias in selection of the reported result.” However, 3 of 7 included studies were rated as “some concerns” for the domains of bias arising from the randomization process, missing outcome data, and measurement of outcomes. All included studies were rated as “some concerns” for bias due to deviations from intended interventions, likely reflecting the nonblinded nature of the interventions. A summary of the risk of bias assessments is presented in Table 1.

XSL•FO
RenderX

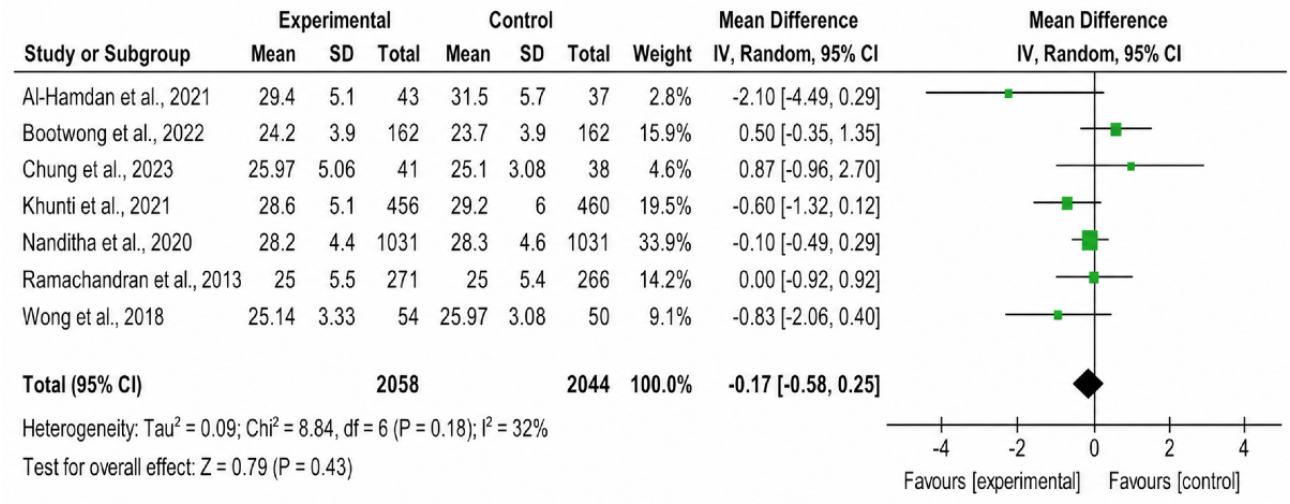
Table . Risk of bias of the included studies.

Study	Randomization process	Deviation from intended intervention	Missing outcome data	Measurement of outcomes	Selection of the reported result	Overall risk of bias
Al-Hamdan et al [26]	Some concerns	Some concerns	Low	Low	Low	Some concerns
Bootwong and Intarut [16]	Some concerns	Some concerns	Low	Low	Low	Some concerns
Chung et al [27]	Low	Some concerns	Some concerns	Some concerns	Low	High
Khunti et al [28]	Low	Some concerns	Some concerns	Some concerns	Low	High
Nanditha et al [23]	Low	Some concerns	Some concerns	Low	Low	Some concerns
Ramachandran et al [24]	Low	Some concerns	Low	Some concerns	Low	Some concerns
Wong et al [25]	Some concerns	Some concerns	Some concerns	Low	Low	High

Certainty of Evidence (GRADE) Summary

Outcome-level certainty ratings and rationales are reported in Table S1 (summary of findings) in Multimedia Appendix 2. In brief, certainty was most commonly rated down for inconsistency (between-study heterogeneity) and imprecision (wide CIs and limited sample size per outcome). Publication bias could not be formally assessed due to fewer than 10 studies, and no outcomes were upgraded.

Characteristics of Participants and Studies



The 7 included RCTs enrolled a total of 4632 participants diagnosed with prediabetes. All participants owned smartphones and were free of major comorbidities. The mean age of participants ranged from 43.5 to 54.2 (SD 5.6) years. Of 4632 participants, 2843 (61.4%) were male.

Among the participants, 2056 (44.4%) individuals received lifestyle modification programs incorporating SMS text messaging, while 2576 (55.6%) individuals received comparable programs without SMS text messaging support. Intervention durations ranged from 12 to 48 months, with 24 months (n=2) and 48 months (n=2) being the most common durations. Delivery formats varied: 4 studies delivered regular text messages promoting lifestyle modification [16,23-25], 2 studies combined mHealth apps with SMS text messaging support [26,27], and 1 study integrated face-to-face sessions with text message follow-ups [28]. For the control group, usual care included related education (n=4), paper-based health information materials (n=2), and physical activity management (n=1). Characteristics of all included studies are summarized in Multimedia Appendix 3.

Quantitative Synthesis

The forest plots of both primary and secondary outcomes are shown in Figures 2-7.

RenderX

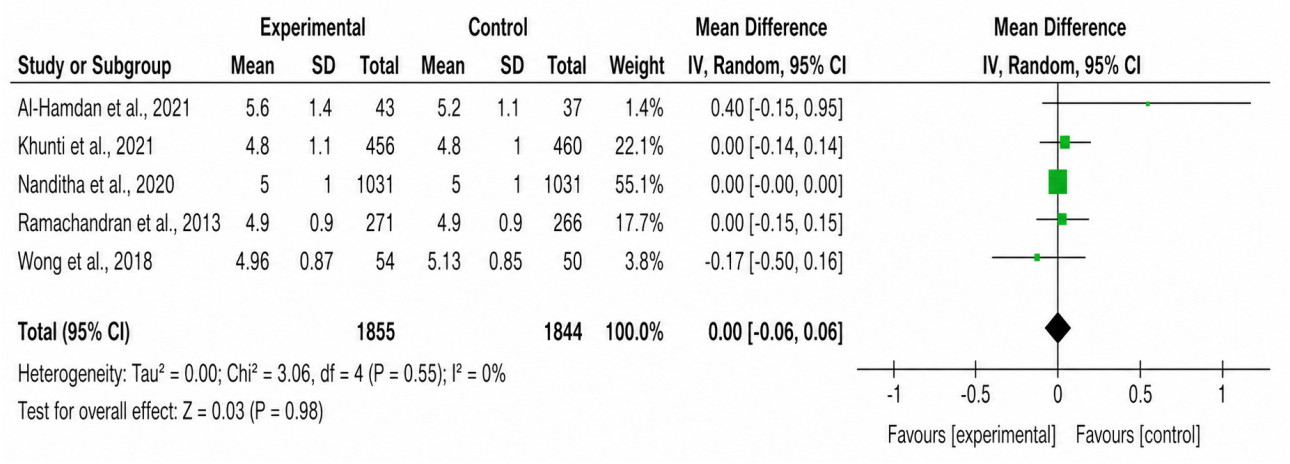
Figure 6. Forest plot of the effect of SMS text messaging interventions on total cholesterol [23-26,28].



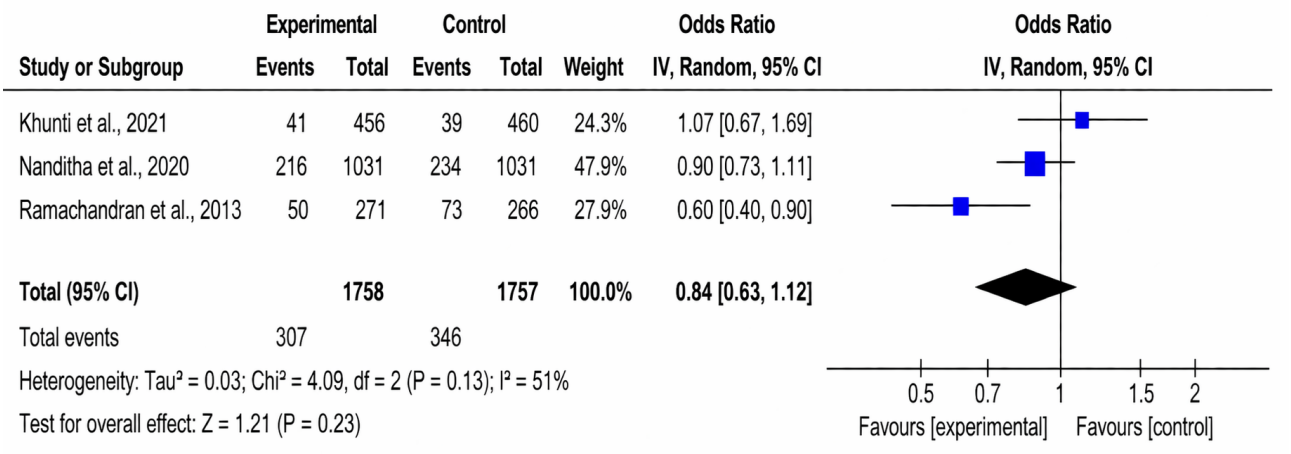


Figure 7. Forest plot of the effect of text messaging interventions on diabetes incidence [23,24,28].

Primary Outcome: BMI

All 7 studies assessed BMI (4102/4634, 88.5% participants). The pooled MD in BMI change was not statistically significant between intervention and control groups (MD –0.17, 95% CI –0.85 to 0.25; *P*=.43), with low heterogeneity observed (χ^2_6=8.8; I^2=32%; *P*=.18).

Secondary Outcomes

Weight

Of the 7 studies, 5 (71.4%) reported weight outcomes. The pooled MD was –0.46 (95% CI –1.74 to 0.83; *P*=.48), indicating no significant difference in weight change between groups. Low heterogeneity was observed (χ^2_5=5.49; I^2=27%; *P*=.24).

Waist Circumference

In total, 6 (85.7%) studies assessed waist circumference. The pooled MD was –0.36 (95% CI –1.09 to 0.36; *P*=.33), with low heterogeneity (χ^2_5=5.74, I^2=13%; *P*<.001).

HbA_{1c}

Overall, 4 studies assessed HbA_{1c} levels. Only 1 study reported a significant improvement favoring the SMS text messaging group. The pooled MD was –0.05 (95% CI –0.17 to 0.07; *P*=.41), with high heterogeneity across studies (χ^2_3=3.06, I^2=89%; *P*=.49).

Total Cholesterol

A meta-analysis of 5 studies showed no significant difference in total cholesterol levels between the intervention and control groups (standardized MD –0.00, 95% CI –0.06 to 0.06; *P*=.98). No heterogeneity was observed (χ^2_4=18.2, I^2=0%; *P*=.55).

DM Incidence

DM incidence was reported in 3 studies (3515/653, 18.6% participants). Moderate heterogeneity was noted (χ^2_2=4.09, I^2=51%; *P*=.13). Among intervention participants, 307 (17.5%) of 1758 developed diabetes, compared with 346 (19.7%) of 1757 in the control group. The odds ratio for DM incidence was 0.84 (95% CI 0.63 to 1.12; *P*=.23), indicating no statistically significant difference between groups.

Discussion

Principal Findings

This systematic review and meta-analysis synthesized evidence on SMS text message–delivered lifestyle programs for adults with prediabetes, focusing on changes in BMI, weight, waist circumference, HbA_{1c}, total cholesterol, and diabetes incidence.

XSL•FO
RenderX

Overall, the pooled estimates did not demonstrate statistically significant improvements in these metabolic outcomes compared with standard care, although several individual trials showed favorable trends.

mHealth technologies can extend the reach of prevention programs by lowering barriers related to access, workforce capacity, and cost. SMS text messaging is especially attractive because it is simple, low-cost, and highly scalable [18,29]. For adults with prediabetes—a group often characterized by low disease awareness and variable motivation—SMS text messaging may provide timely prompts for early lifestyle change. However, in contrast to prior meta-analyses reporting benefits of SMS text messaging for smoking cessation, weight loss, cardiovascular risk reduction, or glycemic control in type 2 diabetes [30-37], our results showed null effects on anthropometry and cardiometabolic markers in prediabetes. These differences likely reflect population context and mechanism: approaches successful in patients with established chronic disease may not translate directly to prevention in largely asymptomatic prediabetes.

Several design features may explain the limited impact observed. First, interventions varied widely in duration, message frequency, delivery channel, and content design. Frequencies ranged from multiple messages per week to biweekly contact; the literature is mixed on whether a higher cadence improves outcomes or induces message fatigue, suggesting an outcome- and population-specific optimum. Second, most programs used standardized, nontailored content. Evidence from digital behavior change research indicates that dynamic tailoring—linking message content, timing, and cadence to a person's current behavior, preferences, and psychosocial state—improves engagement and maintenance [38]. Third, the predominant communication style was unidirectional. Bidirectional designs that solicit brief replies, troubleshoot barriers, and escalate support after nonresponse may enhance accountability and adherence but were rarely implemented. Finally, several trials combined SMS text messaging with additional components (eg, app access, in-person education, or follow-up calls), which improved ecological validity but reduced the ability to attribute effects specifically to SMS text messaging alone and added heterogeneity in behavioral dose and support intensity [39-41].

Interpreting Null BMI Effects Through Body Composition and Fat Distribution

BMI is an imperfect proxy for metabolic risk because it conflates fat and lean mass and cannot distinguish visceral adipose tissue (VAT) from subcutaneous fat or capture ectopic depots (hepatic or intramuscular fat). Small but meaningful reductions in VAT—or preservation or increases in skeletal muscle mass with modest fat loss—can yield little or no net change in BMI while still improving insulin sensitivity, lipid handling, and inflammatory tone. Early behavior change can also redistribute fat (from visceral to subcutaneous compartments) or prevent sarcopenic weight loss, effects that BMI cannot detect.

In our synthesis, waist circumference similarly showed a precise null effect with relatively narrow CIs; however, centimeter-level changes over short follow-up periods may be below detection thresholds, and meaningful body composition adaptations often require ≥6 to 12 months to manifest. Moreover, adherence decay and metabolic adaptation (reductions in energy expenditure during weight loss) can flatten BMI trajectories when interventions are light touch and largely unidirectional, as seen in most included programs. Therefore, future trials should include body composition outcomes (eg, dual-energy X-ray absorptiometry–derived percent fat and lean mass, VAT area by imaging, and multifrequency bioimpedance) and waist-to-height ratio alongside the BMI.

Regarding publication bias, the small number of studies per outcome precluded formal small-study tests. Notably, several pooled estimates centered closely on the null value with relatively narrow CIs (eg, total cholesterol), suggesting that, at the tested dose and design—generic, 1-way prompts over limited durations—SMS text messaging alone is unlikely to generate the sustained energy deficit and resistance-type stimulus required to materially shift BMI or central adiposity in prediabetes. Thus, the persistence of null results appears plausible even if publication bias might ordinarily favor positive findings.

Clinical and Public Health Implications

SMS text messaging appears best positioned as a reach-and-reinforcement layer rather than a stand-alone metabolic intervention. In clinical pathways, brief messaging can reinforce clinic-initiated goals, prompt self-monitoring (weight, steps, and dietary logs), and support attendance at higher-intensity services (group classes, dietitian visits, or structured exercise). At the service level, programs should incorporate closed-loop features (eg, automated outreach after nonresponse, brief telecoaching, or referral triggers when weight plateaus) and integrate device-captured data to enable tailoring.

Commissioners planning population strategies should pair SMS text messaging with an effective dose (≥12 - 24 weeks), link to evidence-based nutrition and progressive resistance training supports, and evaluate outcomes beyond BMI, including waist-to-height ratio, body fat percentage, VAT surrogates, and glycemic variability. Reporting of engagement analytics (delivery, open, reply, and attrition rates) and behavioral mediators (diet quality, step counts, and resistance training adherence) is essential to clarify mechanisms and optimize deployment.

Limitations

Several limitations of this study should be acknowledged. Moderate to high heterogeneity was identified in outcomes such as HbA_{1c} levels and diabetes incidence, primarily due to the limited number of available studies (n=3 - 4) for these outcomes. Variability in study designs—including differences in intervention duration, SMS text messaging content, and follow-up periods—also posed challenges in synthesizing and comparing results across studies. Due to the small number of studies for certain outcomes, conducting meta-regression analyses and subgroup analyses to adjust for these sources of heterogeneity was not feasible, potentially impacting the reliability of pooled estimates. Assessment of funnel plot asymmetry for publication bias was also precluded due to the limited number of studies.

XSL•FO
RenderX

Furthermore, this meta-analysis did not exclude studies that integrated additional mHealth components, such as mobile apps, alongside SMS text messaging. The inclusion of multicomponent interventions may have introduced bias, limiting the ability to isolate the independent effects of SMS text messaging on clinical outcomes in prediabetes. This review is also limited by its focus on BMI, which may require a longer follow-up duration to detect meaningful changes. Other measures of body composition, such as fat distribution or muscle mass, were not assessed.

Conclusions

In summary, this systematic review found that lifestyle modification programs using SMS text messaging did not produce significant improvements in BMI among adults with prediabetes compared with standard care. The limited effectiveness observed may reflect variations in intervention design, including content, frequency, and delivery mode, highlighting the need for more optimized, theory-driven messaging strategies.

Future research should focus on developing standardized, tailored, and interactive SMS text messaging interventions with larger sample sizes and longer follow-up periods. Isolating SMS text messaging as a primary intervention component will also be critical to better determine its role in prediabetes management and diabetes prevention efforts.

Abstract

Background: Patients with head and neck cancer (HNC) frequently experience functional impairments and psychological distress following surgery or radiotherapy. While mobile health (mHealth) interventions are increasingly integrated into clinical care to support patient self-management and home-based recovery, evidence of their effectiveness in HNC remains inconsistent.

Objective: This study aims to evaluate the effectiveness of mHealth interventions on quality of life (QoL), psychological symptoms, physical symptoms, and functional recovery among HNC survivors.

Methods: This systematic review and meta-analysis followed the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines. Overall, 12 electronic databases were searched for randomized controlled trials published up to December 1, 2025. Two reviewers independently performed study selection, data extraction, and risk of bias assessment using the Cochrane Risk of Bias 2.0 tool. Certainty of evidence was evaluated using the GRADE (Grading of Recommendations, Assessment, Development, and Evaluation) approach. Pooled effects were calculated as standardized mean differences (SMDs) with 95% CIs. The primary outcome was QoL; secondary outcomes included anxiety, depression, fatigue, pain, swallowing function, and maximal interincisal opening (MIO).

Results: A total of 26 randomized controlled trials involving 2385 participants were included. mHealth interventions significantly improved QoL (SMD 0.64, 95% CI 0.41-0.88; *P*<.001), anxiety (SMD −0.75, 95% CI −1.42 to −0.08; *P*=.03), depression (SMD −0.89, 95% CI −1.37 to −0.40; *P*<.001), and fatigue (SMD −0.85, 95% CI −1.19 to −0.51; *P*<.001). Pain showed a small reduction (SMD −0.37, 95% CI −0.49 to −0.24; *P*<.001). However, the improvement in swallowing function reached only borderline significance (SMD 0.66, 95% CI 0.28-1.04; *P*=.04), suggesting that current evidence for this outcome is fragile. No significant effect was found for MIO (*P*=.68). Subgroup analysis revealed that interventions featuring home practice support, self-monitoring, and shorter durations (<3 months) yielded stronger clinical effects. The overall certainty of evidence ranged from low to very low.

Conclusions: mHealth interventions effectively enhance QoL and alleviate psychosocial distress in patients. However, evidence for improving swallowing function and MIO remains insufficient. Future research should prioritize standardized protocols and high-quality trials to validate long-term clinical value.

Introduction

Head and neck cancer (HNC) is an umbrella term for tumors that arise in the oral cavity, oropharynx, larynx, hypopharynx, and paranasal sinuses [1]. As the seventh most common cancer globally, HNC accounted for approximately 4.7% of new cases and 4.9% of cancer-related deaths in 2022 [1-3]. Treatment for HNC typically involves surgery, radiotherapy, and systemic therapies such as chemotherapy, targeted therapy, or immunotherapy [4]. Despite advancements in these modalities, patients frequently experience severe treatment-related adverse

XSL•FO
RenderX

effects. Physical impairments, including dysphagia, trismus, fatigue, and pain, frequently co-occur with psychological distress such as anxiety and depression, severely compromising quality of life (QoL) [5,6]. These symptoms can persist long-term, representing a significant burden to comprehensive rehabilitation. Studies have shown that HNC survivors report lower QoL than survivors of other cancer types [7,8].

In oncology, "rehabilitation" refers to interventions that aim to restore or maintain physical function, manage treatment-related symptoms, and improve psychological well-being during the recovery phase [9]. This stage is essential for enhancing the long-term QoL for survivors. Traditional rehabilitation models mainly rely on face-to-face consultations, which face challenges such as uneven resource distribution, limited accessibility, and low patient adherence [9,10]. Geographical barriers often prevent patients in remote areas from receiving timely, high-quality care, leaving adverse reactions poorly managed. Furthermore, time constraints in clinical settings make it difficult for physicians to capture a comprehensive record of patients' daily symptoms. After discharge, the lack of continuous and personalized support often leads to delayed symptom management and increased complications.

Mobile health (mHealth) offers a promising solution to chronic disease management and cancer rehabilitation [11,12]. It encompasses both hardware, such as smartphones, tablets, and wearable activity tracking or sensor devices, and software, including digital health platforms and mobile apps (eg, WeChat mini-programs) [13]. By using wireless connectivity, these tools support real-time symptom monitoring, personalized rehabilitation exercises, and enhanced information accessibility [14,15]. mHealth technologies streamline patient-provider communication, promote home-based self-management, and enhance overall health outcomes. Furthermore, these applications enable patients to track their health status in real time while fostering social and psychological support through connectivity with peers and health care professionals [13].

Although mHealth shows potential, existing evidence remains inconsistent [13,16-24]. Meta-analyses by Buneviciene et al [17] and Zhang et al [24] support the effectiveness of mHealth in improving QoL and alleviating anxiety or depression in general cancer populations. However, these findings primarily derive from mixed-cancer populations. Some reviews indicate that current mHealth interventions for HNC often involve small samples and nonrandomized designs. For instance, Calver et al [18] found insufficient data to confirm the effectiveness of psychological interventions on QoL. Additionally, high heterogeneity in intervention formats and durations persists, with a notable lack of high-quality randomized controlled trials (RCTs) targeting specific outcomes such as swallowing function [13].

Therefore, based on these inconsistent findings and the recent increase in original research, this meta-analysis aims to assess the effectiveness of mHealth interventions in improving QoL, anxiety, depression, fatigue, pain, swallowing function, and maximal interincisal opening (MIO) in patients with HNC. Furthermore, we explored the effectiveness of different interventions, such as intervention delivery format and intervention durations. This study will provide evidence for the future development and clinical implementation of mHealth-based rehabilitation for patients with HNC.

Methods

Ethical Considerations

This article is a systematic review and meta-analysis. It does not contain any studies with human participants or animals performed by any of the authors.

Design

The review protocol was registered with PROSPERO (CRD42024559825). We followed the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) reporting guidelines (Checklist 1) [25].

Data Sources and Search Strategies

We searched 12 electronic databases from their inception to December 1, 2025. These included PubMed, Embase, Cochrane Central Register of Controlled Trials, Web of Science, PsycInfo, CINAHL, Scopus, Google Scholar, China National Knowledge Infrastructure, Chinese Biomedical Literature Database, Weipu (VIP), and Wanfang Data. Search terms included Medical Subject Headings and keywords such as "head and neck cancer," "mHealth," "digital health," and "RCT." We also manually searched the reference lists of relevant articles and screened gray literature, including ClinicalTrials.gov and the World Health Organization International Clinical Trials Registry Platform. Detailed search strategies for each database are provided in Multimedia Appendix 1.

Eligibility Criteria

We used the PICOS (participants, intervention, comparison, outcome, and study design) framework [26] to define our inclusion criteria: (1) participants: patients diagnosed with HNC of any age or gender after surgery or radiotherapy; (2) interventions: mHealth-based tools, such as smartphone apps, WeChat mini-program, wearable devices, or digital health platforms; (3) comparison: usual care, no intervention, or non-mHealth interventions; (4) outcomes: reported at least one targeted outcome, including pain, anxiety, depression, fatigue, QoL, swallowing function, MIO, adherence, self-efficacy, or perceived stress (mean and SD); (5) study design: RCTs; and (6) language: published in English or Chinese.

The exclusion criteria were as follows: (1) studies focused only on diagnosis, screening, or application development without evaluating clinical or patient-reported outcomes; (2) study types such as case reports, reviews, conference abstracts, or qualitative studies; (3) non-mHealth interventions (eg, telephone-only or face-to-face only); and (4) studies with incomplete data or results that could not be extracted.

To accurately evaluate the effectiveness of these interventions, this study adopts the following definition of key concepts. QoL refers to a multidimensional construct covering physical, psychological, and social functions [27]. Swallowing function is a core survival indicator that is often affected by chemoradiotherapy [28]. MIO serves as the key parameter for

XSL•FO
RenderX

evaluating trismus after treatment [29]. Regarding mHealth functions, self-monitoring refers to patients actively recording their own symptoms [30]. Home practice support involves providing tailored rehabilitation guidance at home through digital media [31]. Telemedical support emphasizes bidirectional interaction or real-time feedback between patients and health care providers rather than the use of a simple tool [32].

Study Selection

We used EndNote X21 (Clarivate) software to manage records and deduplication. Two reviewers (YX and QZ) independently screened titles and abstracts. Then, they evaluated the full text of potentially eligible studies. Any disagreements were resolved by a third reviewer (XY). We used Cohen κ to measure the agreement between reviewers, following standard categories: ≤0 (poor), 0.01 - 0.20 (slight), 0.21 - 0.40 (fair), 0.41 - 0.60 (moderate), 0.61 - 0.80 (substantial), and 0.81 - 1.00 (almost perfect agreement) [33].

Data Extraction

Two independent authors (YX and QZ) extracted data using a standardized Microsoft Excel spreadsheet. Extracted information included first author, year, country, setting, patient characteristics, sample size, mean age, intervention and control details, duration, follow-up, outcomes, and assessment tools. For studies with multiple control groups, we selected the most appropriate comparison, such as usual care. Any discrepancies were resolved through discussion with a third author (XY).

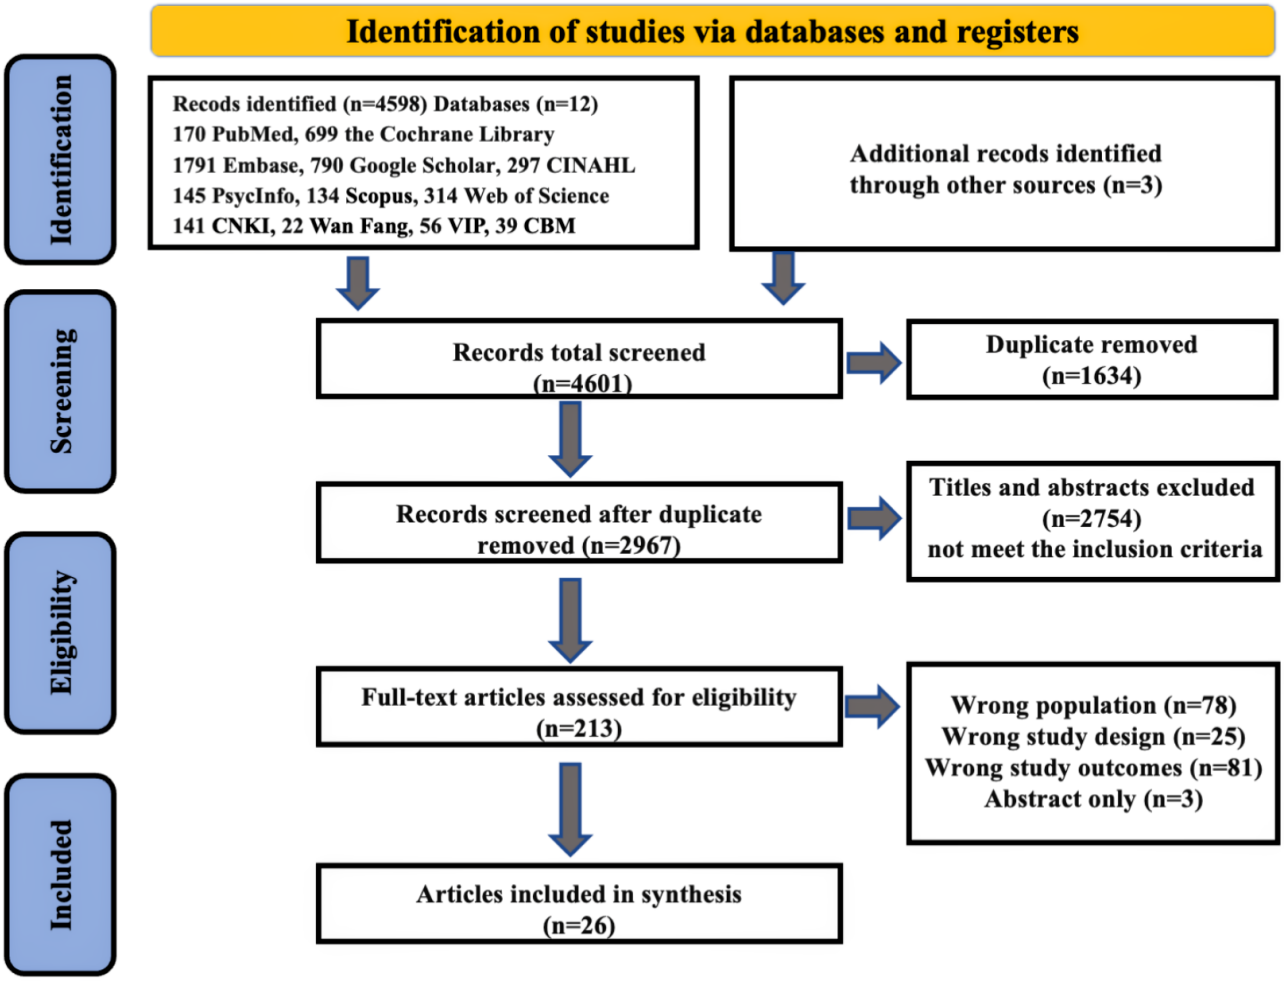
Risk of Bias Assessment and Quality of Evidence

Two researchers (YX and QZ) independently assessed the risk of bias in the included RCTs using the Cochrane Risk of Bias 2.0 (RoB 2.0) tool [34]. Evaluations covered 5 domains: the randomization process, deviations from intended interventions, missing outcome data, measurement of the outcome, and selection of the reported results. Each domain was rated as “low risk,” “some concerns,” or “high risk.”

The certainty of the evidence was evaluated using the GRADE (Grading of Recommendations, Assessment, Development, and Evaluation) approach [35]. Evidence from RCTs was initially classified as “high” certainty and downgraded to “moderate,” “low,” or “very low” based on 5 factors: risk of bias, inconsistency, indirectness, imprecision, and publication bias. Conversely, evidence could be upgraded for a large effect size or dose-response gradient. For both RoB 2.0 and GRADE assessments, the κ coefficient was calculated to determine interrater agreement. Any disagreements were resolved through consensus or by consulting a third author (XY).

Statistical Analysis

Statistical analyses were performed using Review Manager (version 5.4; The Cochrane Collaboration), Stata (version 18.0; StataCorp), and R software (version 4.4.1; R Foundation for Statistical Computing). Continuous outcomes were synthesized using standardized mean differences (SMDs) with 95% CIs. For instruments where scoring directions differed, scores were inverted to ensure a uniform orientation for each outcome. Heterogeneity between studies was assessed using the Cochrane Q test (significance level at $P<.10$) and the I^2 statistic. An I^2 value >50% indicated significant heterogeneity. A fixed-effects model was used when heterogeneity was low; otherwise, a random-effects model was applied [36]. Statistical significance was set at $P<.05$. The magnitude of SMD was classified as small (<0.4), medium (0.4 - 0.7), or large (>0.7) [37]. Additionally, 95% prediction intervals (PIs) were calculated for outcomes with significant heterogeneity [38]. These intervals estimate the range of treatment effects expected in future clinical settings, offering a more robust interpretation of the observed variance. Subgroup and sensitivity analyses were performed to explore sources of heterogeneity. Publication bias was evaluated using funnel plots and the Egger regression test [39].



Results

Search Outcomes

The literature search yielded 4601 records, of which 1634 were removed as duplicates. The remaining 2967 publications were evaluated at the title/abstract phase using predetermined inclusion/exclusion criteria, resulting in 2754 exclusions. Of 213 articles advancing to full-text assessment, 187 were excluded for reasons detailed in the PRISMA flowchart (Figure 1). Ultimately, 26 RCTs were included in the systematic review and meta-analysis [40-65]. The interrater reliability for study selection was substantial at the title and abstract screening stage (Cohen κ=0.85) and reached excellent agreement during the full-text review (κ=0.92).

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart of studies included in the review.

Study Characteristics

A total of 2385 participants were included across the 26 studies. The key characteristics of these studies are summarized in Table 1. The included trials were conducted in various countries, including China, Belgium, Canada, Korea, Germany, the Netherlands, Australia, and the United States, with publication dates ranging from 2015 to 2025. Regarding cancer subtypes, nasopharyngeal carcinoma was the most frequently studied (n=6), followed by oropharyngeal (n=3), laryngeal (n=3), oral (n=3), and thyroid cancer (n=2).

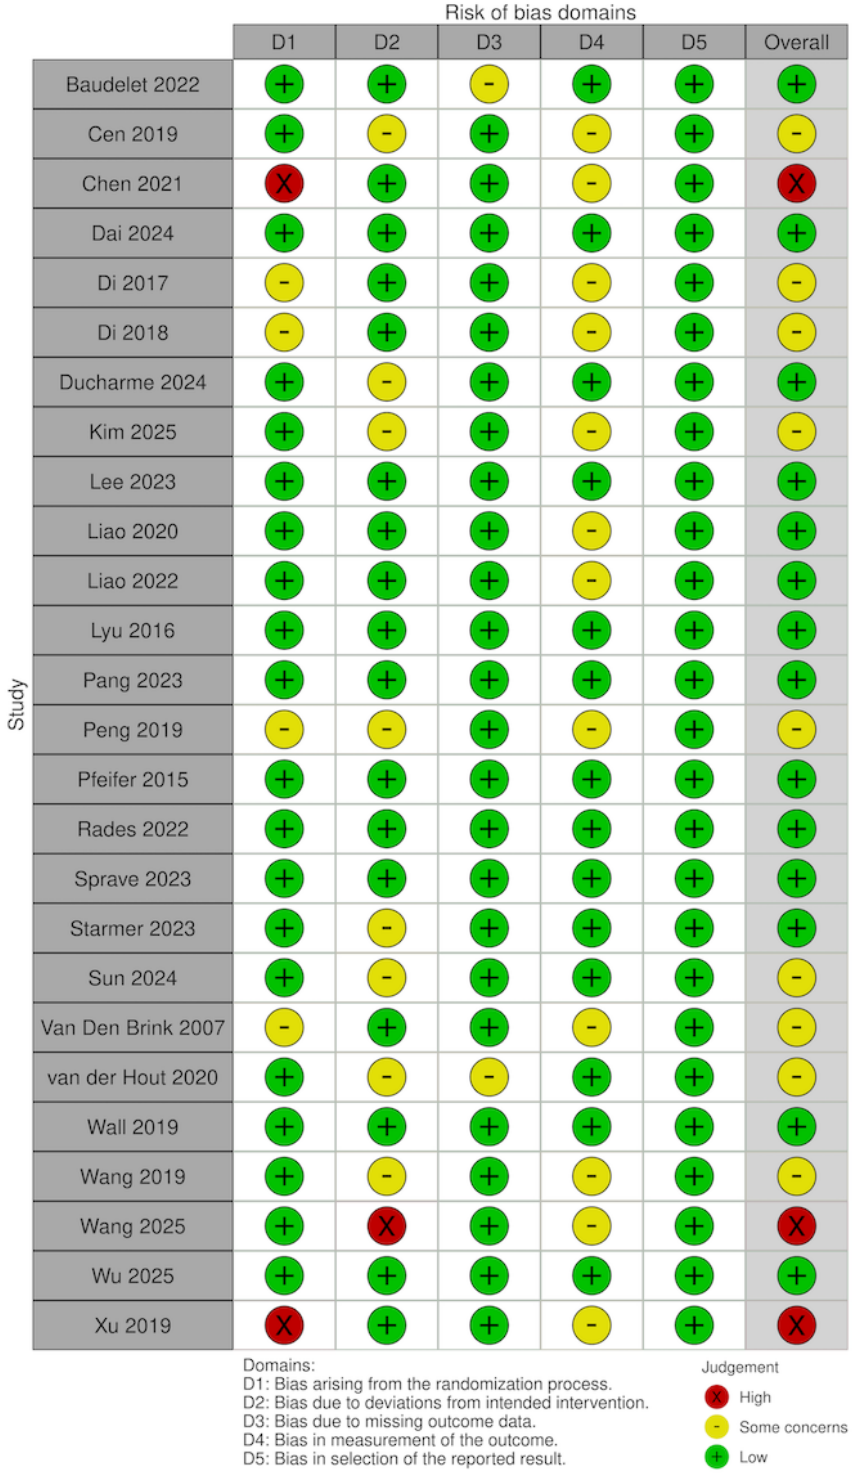
Characteristics of Interventions and Outcome Measures

The mHealth interventions exhibited significant diversity in design and functionality. The most prevalent delivery mode was smartphone apps (n=14), which typically integrated features such as symptom monitoring, educational modules, clinical reminders, and remote follow-up (Multimedia Appendix 1). A notable subset of studies (n=6), primarily conducted in China, used WeChat-based platforms, including mini-programs and

XSL•FO
RenderX

interactive education systems. Other delivery formats included smartwatch-based apps, web-based platforms, and multicomponent telemedicine models. Functional components often focused on symptom self-monitoring, home-based exercise guidance, and bidirectional clinician-patient communication. Several interventions incorporated theoretical frameworks, such as the Health Belief Model, while others used gamification or virtual coaching to improve patient engagement. Intervention durations ranged from 4 weeks to 12 months.



All assessment tools used in the included studies were validated instruments. QoL was most frequently measured using the European Organisation for Research and Treatment of Cancer Quality of Life Questionnaire Core 30 (EORTC QLQ-C30) and its head and neck-specific module (EORTC QLQ-H&N35; 10 studies), followed by the University of Washington Quality of Life questionnaire (n=3) and the Functional Assessment of Cancer Therapy–Head and Neck (n=2). For psychological outcomes, the Hospital Anxiety and Depression Scale was the most common (n=6), followed by the Self-Rating Anxiety/Depression Scale (n=3) and Patient Health Questionnaire-9/Generalized Anxiety Disorder-7 (n=4). Fatigue and pain were primarily assessed through subscales of the EORTC tools. Swallowing function was evaluated using the M. D. Anderson Dysphagia Inventory (n=3) or EORTC QLQ-H&N35 (n=2). Additional outcomes included MIO and self-efficacy (using the Strategies Used by People to Promote Health or the Health Belief Model Questionnaire, and the Mandibular Function Impairment Questionnaire).

Risk of Bias

Methodological quality was evaluated by two reviewers independently using the RoB 2.0 tool. The interrater consistency was high, with κ coefficients ranging from 0.82 to 1.00. Detailed results are presented in Figure 2. While all studies were RCTs, 8 did not specify the method of allocation concealment, resulting in “some concerns” in the randomization process. Due to the nature of mHealth interventions, blinding of participants and personnel was largely unfeasible; thus, most studies were rated as “some concerns” regarding deviations from intended interventions. Three studies were classified as “high risk” for attrition bias due to substantial missing data or high dropout rates. Regarding outcome measurement, only 6 studies reported the use of blinded assessors. Overall, 14 studies were rated as having a “low risk” of bias [40,43,46,48-52,54-57,61,64], 9 as “some concerns” [41,44,45,47,53,58-60,62],” and 3 as “high risk” [42,63,65].” Despite the risk of attrition in certain trials—often due to disease progression or treatment-related mortality—these studies were retained in the analysis to ensure a comprehensive synthesis of the current evidence. GRADE assessment of the 7 outcomes indicated that the overall quality of evidence rating ranged from low to very low (Multimedia Appendix 1). This was primarily due to the high risk of bias in most studies, substantial heterogeneity, and imprecision in certain results.

XSL•FO
RenderX

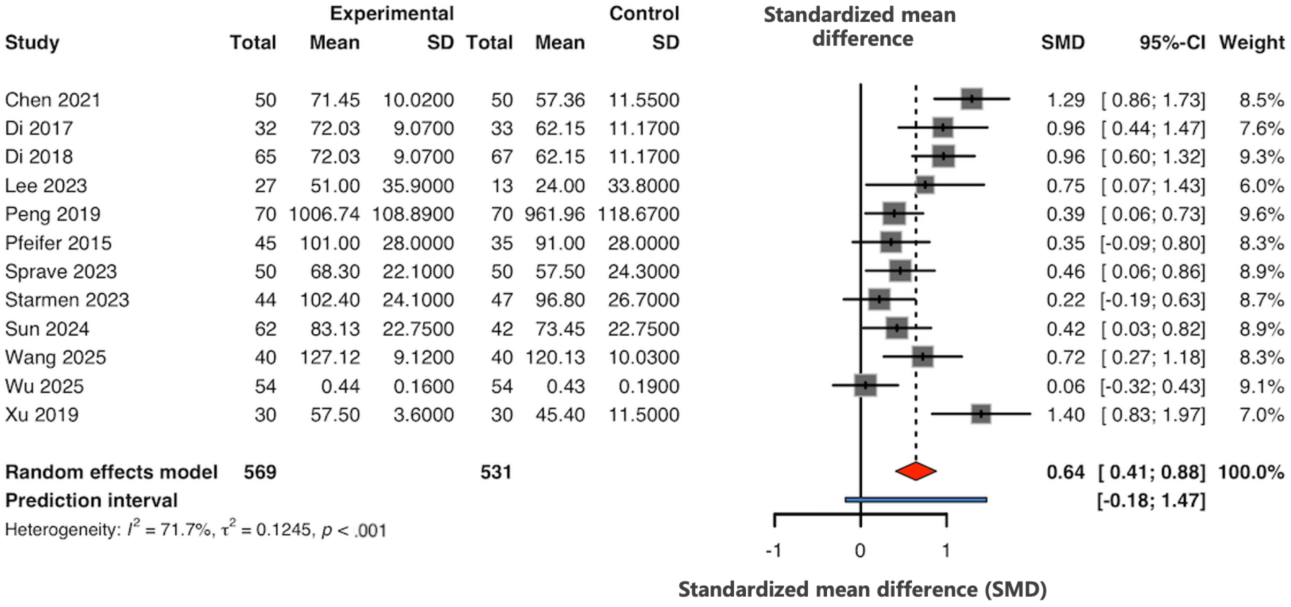
Figure 2. Risk of bias assessment [40-65].

Qualitative Synthesis of Findings

The included studies indicate that mHealth interventions for patients with HNC primarily focus on 4 domains: health education, self-monitoring, psychological support, and remote guidance. Most platforms adopted a multicomponent approach to facilitate self-management. For instance, Ducharme et al [46] used the "PTSD Coach" app, which integrated psychoeducation with coping tools for self-assessment and social support. Kim et al [47] developed "TOP note," a theory-based application that combined goal setting with smartwatch-linked feedback to manage stress and sleep among thyroid cancer survivors. The degree of clinical interaction varied across platforms; for example, Baudelet et al [40] found that while app-based exercise programs provided clear digital instructions and reminders, the absence of real-time clinical feedback potentially attenuated therapeutic efficacy compared to traditional therapist-led modalities.

XSL•FO
RenderX

Regarding psychological outcomes, mHealth interventions showed significant potential. Ducharme et al [46] reported improved anxiety, depression, and QoL scores at the 3-month follow-up. Kim et al [47] observed significant reductions in perceived stress and improvements in both subjective and objective sleep quality. However, the evidence for physical rehabilitation was more heterogeneous. While mHealth tools were generally well-accepted, patient adherence remained a critical challenge, particularly during intensive treatment phases. Baudelet et al [40] noted that adherence to app-based swallowing exercises declined over time and was lower than that of face-to-face therapy.



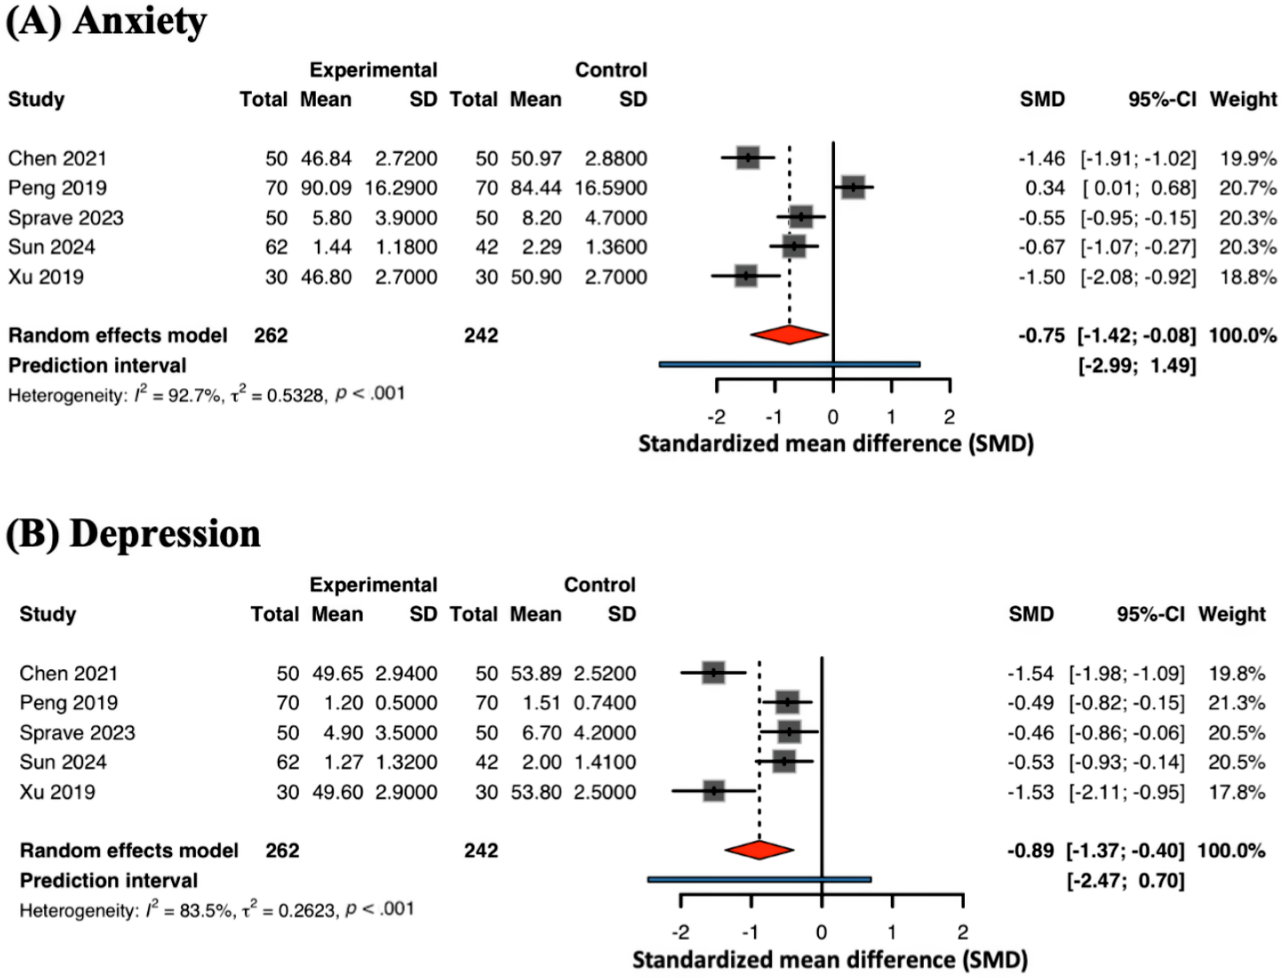
Other studies emphasized different strengths of mHealth. Lyu et al [51] used WeChat for postdischarge follow-up and found it improved patient satisfaction, reduced anxiety, and supported continuity of care. Van Den Brink et al [59] used an early web-based system that helped detect serious complications early and gave patients a strong sense of security. Rades et al [55] tested a simple reminder app for skin and mouth care during radiotherapy; while it did not reach statistical significance, it showed a trend toward fewer severe side effects. Additionally, Wall et al [61] showed that the digital swallowing therapy program "SwallowIT" was clinically equivalent to traditional in-person therapy, suggesting it serves as a viable and practical alternative for HNC rehabilitation.

Meta-Analysis Results

Quality of Life

A total of 12 (46%) studies [42,44,45,48,53,54,56-58,63-65] (46%) provided data on QOL. The pooled results indicated that mHealth interventions had a significant positive impact on the QOL of patients with HNC compared to routine care (SMD 0.64, 95% CI 0.41-0.88; I^2=72%) (Figure 3). However, the 95% PI ranged from −0.18 to 1.47, suggesting that the impact of mHealth on QOL may vary across different clinical settings.

Figure 3. Meta-analysis on quality of life [42,44,45,48,53,54,56-58,63-65].

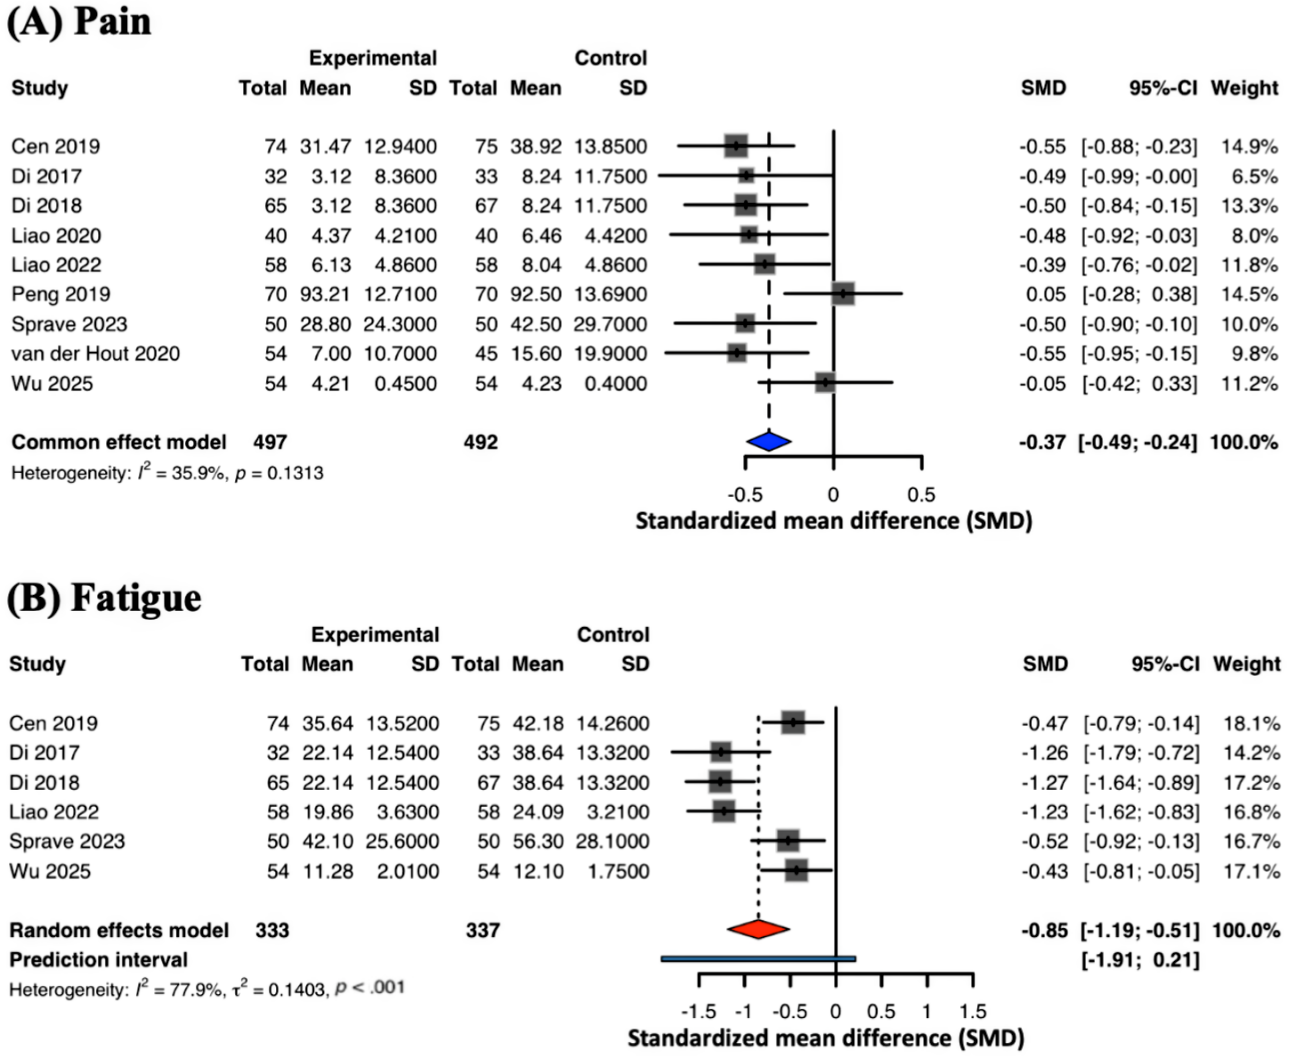


Anxiety and Depression

Five studies [42,53,56,58,65] (19%) evaluated the effect of mHealth on psychological outcomes (Figure 4). The meta-analysis demonstrated that mHealth interventions significantly alleviated anxiety symptoms (SMD −0.75, 95% CI −1.42 to −0.08; I^2=93%). Due to extreme heterogeneity, the 95% PI was wide and encompassed the null value (−2.99 to 1.49), indicating that the intervention's effect on anxiety remains highly variable across different populations. Similarly, 5 studies reported depression outcomes, showing a significant reduction in depressive symptoms (SMD −0.89, 95% CI −1.37 to −0.40; I^2=84%), with a 95% PI of −2.47 to 0.70. These findings suggest that digital platforms are effective on average, though the wide PIs necessitate caution in generalizing these results.

XSL•FO
RenderX

Figure 4. Meta-analysis on (A) anxiety and (B) depression [42,53,56,58,65].



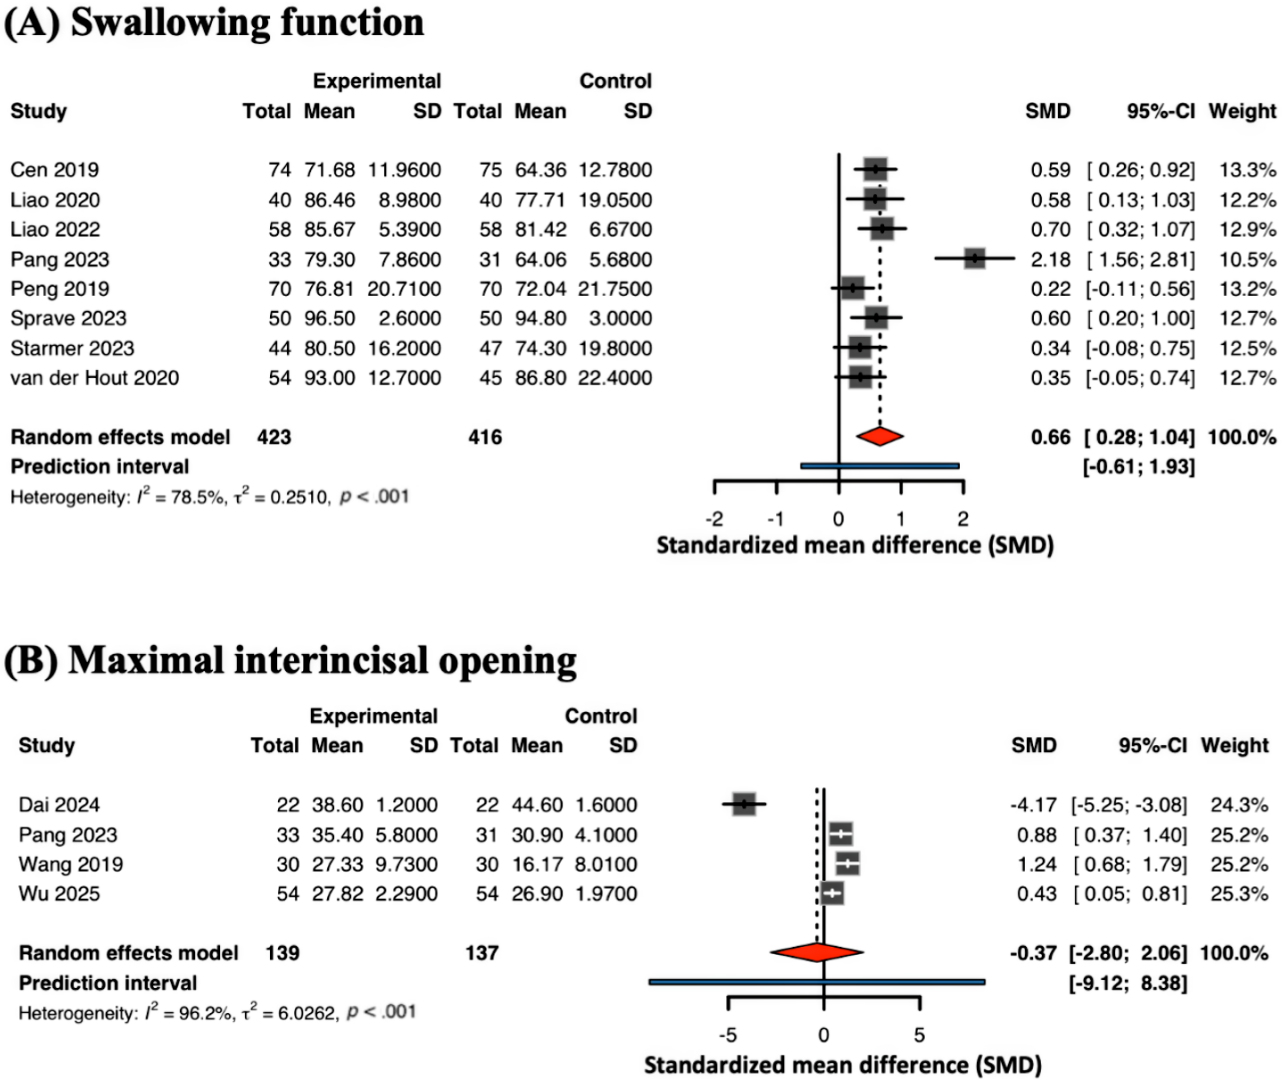
Fatigue and Pain

Fatigue was evaluated in 6 studies [41,44,45,49,56,64] (23%), with the pooled estimate showing a significant beneficial effect of mHealth interventions (SMD −0.85, 95% CI −1.19 to −0.51; I^2=78%) (Figure 5). The 95% PI was −1.91 to 0.21, reflecting considerable variation in expected fatigue reduction.

Nine studies [41,44,45,49,50,53,56,60,64] (35%) assessed pain intensity, and the meta-analysis revealed a small but statistically significant reduction in pain scores (SMD −0.37, 95% CI −0.49 to −0.24; I^2=36%) (Figure 5). The lower heterogeneity in this outcome supports a more consistent effect across studies.

XSL•FO
RenderX

Figure 5. Meta-analysis on (A) pain and (B) fatigue [41,44,45,49,50,53,56,60,64].



Swallowing Function

Eight studies [41,49,50,52,53,56,57,60] (31%) reported on swallowing function. The improvement in swallowing function showed borderline significance (SMD 0.66, 95% CI 0.28-1.04; I^2=91%) (Figure 6), suggesting that the current evidence is fragile and should be interpreted with caution. The 95% PI ranged from −0.61 to 1.93, which indicates that the “average” effect may not be clinically representative for all future patients, and the intervention’s efficacy remains variable.

XSL•FO
RenderX

Figure 6. Meta-analysis on (A) swallowing function and (B) maximal interincisal opening [41,43,49,50,52,53,56,57,60,62,64].

Maximal Interincisal Opening

Four studies [43,52,62,64] (15%) examined MIO as an outcome. The meta-analysis found no statistically significant difference between mHealth and control groups (SMD −0.37, 95% CI −2.80 to 2.06; *P*=.68; I^2=96%) (Figure 6). The wide confidence interval and very high heterogeneity indicate inconsistency across studies, likely due to differences in intervention intensity, follow-up duration, and baseline function. Pooled effect sizes and 95% CIs for all examined outcomes are summarized in Multimedia Appendix 1.

Subgroup Analysis

As shown in Table 2, subgroup analyses were conducted across outcomes, including anxiety, depression, fatigue, pain, swallow function, and QOL. We stratified the data by assessment scale, intervention format, and intervention duration. Additionally, we examined the impact of specific components, including telemedical support, self-monitoring, and home practice support. Detailed results for each outcome are presented in Multimedia Appendix 1.

Home practice support significantly reduced symptoms of anxiety (SMD −1.48, 95% CI −1.83 to −1.12; *P*<.001; I^2=0%) and depression (SMD −1.53, 95% CI −1.88 to −1.18; *P*<.001; I^2=0%), while simultaneously enhancing QoL (SMD 0.72, 95% CI 0.19-1.25; *P*=.008; I^2=86%). Self-monitoring was strongly associated with better swallowing function (SMD 0.50, 95% CI 0.31-0.70; *P*<.001; I^2=0%). The therapeutic impact was found to be moderated by intervention duration. Short-term interventions (<3 months) showed significant effects on both QoL (SMD 0.68, 95% CI 0.38-0.98; *P*<.001; I^2=70%) and swallowing function (SMD 0.59, 95% CI 0.34-0.85; *P*<.001; I^2=0%). Long-term interventions (≥3 months) remained effective for QoL (SMD 0.74, 95% CI 0.44-1.03; *P*<.001; I^2=52%). In contrast, while the pooled effect size for swallowing function appeared positive, it failed to reach statistical significance (SMD 0.42, 95% CI –0.18 to 1.02; *P*=.17; I^2=93%). However, interventions without telemedical support showed stronger effects across all outcomes compared to those with such support (*P*>.05).

[a]SMD: Standardized mean difference.

[b]EORTC: European Organisation for Research and Treatment of Cancer.

Sensitivity Analysis

The sensitivity analyses for the meta-analysis results of anxiety, depression, fatigue, QoL, and pain showed that the pooled estimates remained robust when any single study was excluded. However, swallowing function reached only borderline significance in the random-effects model and was not robust in sensitivity analysis. The results of MIO revealed that after excluding the study by Dai et al [43], the overall pooled result changed from nonstatistically significant (SMD −0.37, 95% CI −2.80 to 2.06; *P*=.68; I^2=96%) to statistically significant (SMD 0.81, 95% CI 0.34-1.28; *P*<.001; I^2=66%). Detailed sensitivity analysis results are presented in Multimedia Appendix 1.

Publication Bias

Publication bias was assessed using funnel plots and Egger tests including QoL, pain, and swallowing function. For other indicators, the number of included studies was insufficient to perform these tests. Visual inspection of the funnel plots showed general symmetry, and Egger tests revealed no evidence of significant publication bias for QoL (*P*=.59), pain (*P*=.78), or swallowing function (*P*=.91) (Multimedia Appendix 1).

Discussion

Principal Findings

HNC survivors often suffer from persistent functional deficits and psychological distress. Compared with other cancers, they require specialized and continuous rehabilitation after discharge.

XSL•FO
RenderX

With the rapid advancement of digital health technologies, mHealth has been an increasingly used approach to support self-management and improve health outcomes in cancer care. This systematic review and meta-analysis provides evidence-based data regarding the efficacy of mHealth in enhancing QoL and alleviating symptoms of anxiety, depression, fatigue, pain, and swallowing function among patients with HNC. Furthermore, we analyzed the influence of various intervention formats and durations on these outcomes, providing evidence for the development of optimized digital health protocols.

Our findings indicate that mHealth interventions significantly enhance QoL and alleviate psychological distress, such as anxiety and depression, aligning with results from previous systematic reviews [17,18,24]. These improvements are primarily attributed to real-time psychological support, peer interaction, and continuous symptom tracking, which help reduce uncertainty about the illness and lower the psychological burden during rehabilitation. Evidence suggests that the mitigation of anxiety and depression is concurrently associated with improved QoL [66]. Despite variations in intervention formats, durations, and target populations, sensitivity analyses confirmed the robustness of these positive psychosocial outcomes. Sun et al [58] used an intervention based on the multitheory model and found significant improvements in anxiety, fear of cancer recurrence, and overall QoL, but no meaningful changes in physical function or somatic symptoms. These results indicate that the primary benefit of such interventions lies in addressing the psychological and emotional challenges faced by cancer survivors. Furthermore, subgroup analyses revealed that “home practice support” is associated with robust improvements in anxiety, depression, and QoL. This indicates that integrating psychological support with specific rehabilitation tasks can enhance self-efficacy and behavioral adherence [58]. The sustained improvement in QoL observed in long-term interventions (≥3 months) further highlights the importance of mHealth in maintaining long-term well-being.

Studies report that pain and fatigue are the most prominent physical symptoms among patients with HNC, particularly in postoperative populations. Our findings indicate that mHealth interventions lead to moderate improvements in both symptoms; specifically, the alleviation of fatigue was relatively pronounced, whereas the reduction in pain was more limited. These findings align with previous systematic reviews [67]. For instance, Hernandez Silva et al [67] reported that self-management-based mHealth interventions effectively improved fatigue in cancer survivors but failed to reach statistical significance for pain symptoms. Among the studies included in this analysis, interventions using self-management applications or WeChat-based platforms showed superior effects in mitigating fatigue and pain [49,56,64]. This efficacy may be attributed to the integration of personalized reminders, symptom tracking, and real-time feedback, which collectively enhance patient self-management capabilities and treatment adherence.

Dysphagia and trismus are common complications following HNC treatment [68]. These impairments can lead to malnutrition, dehydration, weight loss, chronic aspiration, and aspiration pneumonia, significantly affecting patients’ QoL and long-term prognosis. Although this review did not observe an overall significant improvement in MIO through mHealth, the results indicated that self-monitoring significantly enhanced swallowing outcomes. Encouraging patients to actively record and monitor their swallowing status may enhance rehabilitation awareness and behavioral adherence [22]. In addition, the effects on swallowing function were more pronounced in short-term interventions (<3 months), highlighting the importance of early intervention, which aligns with the findings of a recent systematic review [24]. Current evidence on MIO is highly inconsistent and sensitive to individual study inclusion, warranting cautious interpretation. Future research should prioritize large-scale, high-quality trials focused on dysphagia and trismus. Moreover, the long-term benefits of mHealth on these functional outcomes require further validation through rigorous longitudinal studies.

Interestingly, the subgroup analysis showed that interventions without telemedical support appeared to be more effective. This finding is counterintuitive as it challenges the assumption that “human-in-the-loop” interventions are inherently more effective than fully automated systems. For example, some “telemedical” support was limited to low-intensity and noninteractive notifications, which might increase a patient’s cognitive load without providing meaningful clinical feedback. In contrast, simple tools like WeChat may be more successful because they are easier to use in daily life. However, a note of caution is necessary when interpreting this finding. This result may be a statistical artifact specific to the limited number of studies in these subgroups rather than a general rule that “less is more” in mHealth. The better results seen in automated systems likely reflect the high quality of their content and fewer technical difficulties, rather than a disadvantage of human interaction. Future research should focus on identifying which types of human involvement truly contribute to clinical value in HNC rehabilitation.

The extreme heterogeneity observed in outcomes such as anxiety and swallowing function has critical clinical implications. While the pooled SMDs suggest an overall benefit, the 95% PIs for these outcomes encompass the null value. This indicates that the “average” effect may not be clinically representative of every setting, and the results should be interpreted with extreme caution. The observed variance primarily stems from diverse intervention designs (eg, WeChat vs specialized apps), patient population variability (eg, tumor sites and treatment modalities), and inconsistent assessment tools. These findings underscore the need for standardized intervention protocols to better validate the long-term clinical and economic value of mHealth in HNC rehabilitation.

Implications for Clinical Practice

Our findings provide clear guidance for mHealth apps in HNC rehabilitation. Health care professionals should use mHealth to enhance symptom management and QoL, particularly during the first 3 months posttreatment. Effective mHealth tool design should prioritize “home practice support” and “self-monitoring” functions. Using concise mini-programs or lightweight apps is generally more effective and less burdensome than complex

XSL•FO
RenderX

teleconsultation systems. Furthermore, interventions should be based on established behavior change theories and tailored to specific tumor sites and treatment modalities. An ideal care model involves a "hospital-community-home" integrated system, where mHealth platforms facilitate daily tracking and structured training, supported by periodic multidisciplinary feedback. Beyond automated education, platforms should incorporate features for private inquiries and personalized responses. Finally, addressing barriers for older patients and those with low digital literacy through age-appropriate design is essential to ensure equity. Future research requires high-quality, large-scale RCTs to validate functional outcomes, along with systematic evaluations of long-term efficacy and health economic benefits across diverse HNC subtypes and cultural backgrounds.

Strengths and Limitations

This study has several strengths. First, our comprehensive search across multiple databases ensured extensive literature coverage. Second, we exclusively included RCTs, and most of the selected trials had a low risk of bias. In addition, we evaluated both psychosocial and physiological outcomes by detailed subgroup analyses.

Despite these strengths, several limitations must be acknowledged. First, the generalizability of our findings is limited by geographic and platform concentration. Nearly half of the included studies rely on 2 specific platforms: WeChat in China and OncoKompas in the Netherlands. These tools depend on localized digital infrastructures that may not be available elsewhere. Second, most evidence comes from high- or middle-income settings with high smartphone penetration. Consequently, our results may not apply to patients in low-resource settings, rural areas, or low- and middle-income countries. Finally, substantial heterogeneity was observed, and the overall quality of evidence for several outcomes remains low to very low.

Conclusions

mHealth interventions are a promising adjunct for improving QoL and alleviating psychological distress, fatigue, and pain in patients with HNC. Home practice support and self-monitoring are pivotal components for driving efficacy. Future research should prioritize high-quality, large-scale RCTs to further validate the long-term effectiveness and standardized implementation of these digital interventions.

Acknowledgments

The authors would like to express their gratitude to all the researchers whose studies were included in this meta-analysis.

Funding

This work was supported by the Medical Science and Technology Project of Zhejiang Province (grant 2023KY131).

Data Availability

The data that support the findings of this study are available from the original articles included in this systematic review, which are publicly available from the respective journals and databases. Further details can be obtained from the corresponding author upon reasonable request.

Authors' Contributions

YX conceptualized and designed the study, developed the methodology, performed data analysis, validation, and investigation, curated the data, created visualizations, and wrote the initial draft. QZ contributed to data curation and methodology. YL was involved in validation. EL conducted a formal analysis. FH assisted with data curation. XY conceptualized the study and provided supervision. All authors reviewed, edited, and approved the final manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Wearable devices enable the remote collection of health parameters, supporting the outpatient care plans recommended by the World Health Organization to manage chronic diseases. While disease-specific monitoring is accurate, a comprehensive analysis of wearables across various chronic diseases helps to standardize remote patient monitoring systems.

Objective: This review aimed to identify wearables for remote monitoring of chronic diseases, focusing on (1) wearable devices, (2) sensor types, (3) health parameters, (4) body locations, and (5) medical applications.

Methods: We developed a search strategy and conducted searches across three databases: PubMed, Web of Science, and Scopus. After reviewing 1160 articles, we selected 61 that addressed cardiovascular, cancer, neurological, metabolic, respiratory, and other diseases. We created a data analysis method based on our 5 objectives to organize the articles for a comprehensive analysis.

Results: From the 61 articles, 39 (64%) used wearable bands such as smartwatches, wristbands, armbands, and straps to monitor chronic diseases. Wearable devices commonly included various sensor types, such as accelerometers (n=39, 64%), photoplethysmographic sensors (n=18, 30%), biopotential meters (n=17, 28%), pressure meters (n=11, 18%), and thermometers (n=9, 15%). These sensors collected diverse health parameters, including acceleration (n=39, 64%), heart rate (n=24, 39%), body temperature (n=9, 15%), blood pressure (n=8, 13%), and peripheral oxygen saturation (n=7, 11%). Common sensor body locations were the wrist, followed by the upper arm and the chest. The medical applications of wearable devices were neurological (n=21, 34%) and cardiovascular diseases (n=15, 25%). Additionally, researchers applied wearable devices for wellness and lifestyle monitoring (n=39, 64%), mainly for activity (n=39, 100%) and sleep (n=10, 26%).

Conclusions: This review underscores that wearable devices primarily function as bands, commonly worn on the wrist, to monitor chronic diseases. These devices collect data on acceleration, heart rate, body temperature, blood pressure, and peripheral oxygen saturation, with a focus on neurological and cardiovascular diseases. Our findings provide a foundational road map for designing generalized remote patient monitoring systems to manage multimorbidity and support standardized terminology for interoperability across digital health systems. To translate this into practice, we recommend that future research prioritize pragmatic clinical trials with medically certified devices.

KEYWORDS

wearable; sensor; health parameter; vital sign; body location; medical application; standardized terminology

Introduction

Background

According to the World Health Organization (WHO), chronic diseases are long-lasting, noninfectious, and progressively worse over time [1]. These include cardiovascular diseases, neurological disorders, cancer, respiratory diseases, and metabolic disorders, which collectively account for 74% of annual global mortality and make them the leading cause of death worldwide [1,2]. The burden of chronic diseases extends beyond health, severely straining health care resources. The Centers for Disease Control and Prevention reports that 90% of total health care expenditures in the United States address individuals with chronic diseases [3]. This expenditure

XSL•FO
RenderX

encompasses ongoing treatments, regular medical consultations, and other health care–related costs [4].

Owing to their long-lasting nature and the ongoing commitment to curative health services, health care professionals mostly manage chronic diseases on an outpatient basis [5]. However, preventable factors related to these chronic diseases lead to sudden death [6]. The WHO prioritizes individuals with chronic diseases and underscores the need to develop efficient outpatient treatment strategies [7]. Health care providers achieve this by remotely monitoring health parameters [8,9]. Compared to inpatient health care delivery, remote patient monitoring (RPM) systems have become a promising option for managing chronic diseases [10,11]. RPM systems support early detection by real-time monitoring of health and well-being [12] using wearable devices that integrate 1 or more sensors to collect relevant health parameters remotely [13-15]. This reduces clinic visits and conserves time and health care resources [16].

Wearable-based RPM systems rely on custom-built sensors to gather and analyze biometric and physiological data [17]. Contemporary devices such as smartwatches and fitness trackers have several sensors [18] and often pair with mobile apps. Integrating these wearable devices with cloud platforms facilitates efficient data storage and easy access for health care providers. Examples of cloud platforms include Apple HealthKit [19], Google Fit [20], Microsoft Azure Health Data Services [21], Amazon AWS HealthLake [22], and Biofourmis [23]. Such technologies offer substantial potential for clinical trials, fostering research advancements and improving patient care.

Current articles on wearable devices highlight their potential in managing chronic diseases. Various sensors, such as accelerometers, gyroscopes, magnetometers, biopotential meters, photoplethysmographic (PPG) sensors, and thermometers, monitor health parameters remotely. These include activity, electrocardiography (ECG), electroencephalography, electromyography, heartbeats, heart rate, sleep patterns, and body temperature [24-31].

Currently, wearable devices play a key role in monitoring specific chronic diseases, enhancing the effectiveness of RPM by focusing on disease-specific health parameters. For instance, continuous glucose monitors track glucose levels in diabetes management [32], biopotential meters monitor heart rhythms in various conditions [33], and inertial measurement units (IMU) evaluate body movements for diagnosing stroke and neurodegenerative diseases [34,35].

Previous review articles on wearable devices for remote monitoring of chronic diseases often focus on a single condition, a specific population, or a limited clinical setting [36,37]. This narrow focus creates a knowledge gap in understanding their applicability across a broader range of chronic diseases. The increasing variability of wearable devices and stand-alone RPM systems presents substantial challenges for interoperability with digital health systems [38,39], including electronic health record systems [40]. These challenges become even more pressing in the context of rising rates of multimorbidity [41], where patients require integrated monitoring solutions that can simultaneously track multiple conditions. This systematic review addresses these gaps by applying a five-category standardized terminology framework to analyze wearable devices used for remote monitoring of chronic diseases.

Objectives

This systematic review aimed to explore wearable devices and sensor types for remote monitoring of chronic diseases. Specifically, we answered the following research questions:

1. Which wearable devices are used to monitor chronic diseases?
2. Which sensor types are integrated into these wearable devices?
3. Which health parameters do these sensors collect?
4. Where are these sensors located on the human body?
5. Which medical applications are supported by the wearable devices?

Methods

Overview

This systematic review's design and reporting follow the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines (Checklist 1) [42]. We registered the protocol in PROSPERO (CRD42023460873). Although we specified Quality Assessment Tool for Diverse Designs for quality appraisal in the registered protocol, we used the Quality Assessment with Diverse Studies (QuADS) critical appraisal tool instead, as it was better aligned with the design and reporting characteristics of the included articles.

Information Source and Search Strategy

We developed a search strategy and sought full-text articles published in English between January 2019 and December 2023 across three databases: PubMed, Web of Science, and Scopus. Our search strategy incorporated three terms: wearable device, remote monitoring, and chronic disease, as well as relevant synonyms. We used the AND operator between the keywords and the OR operator within the synonyms (Multimedia Appendix 1).

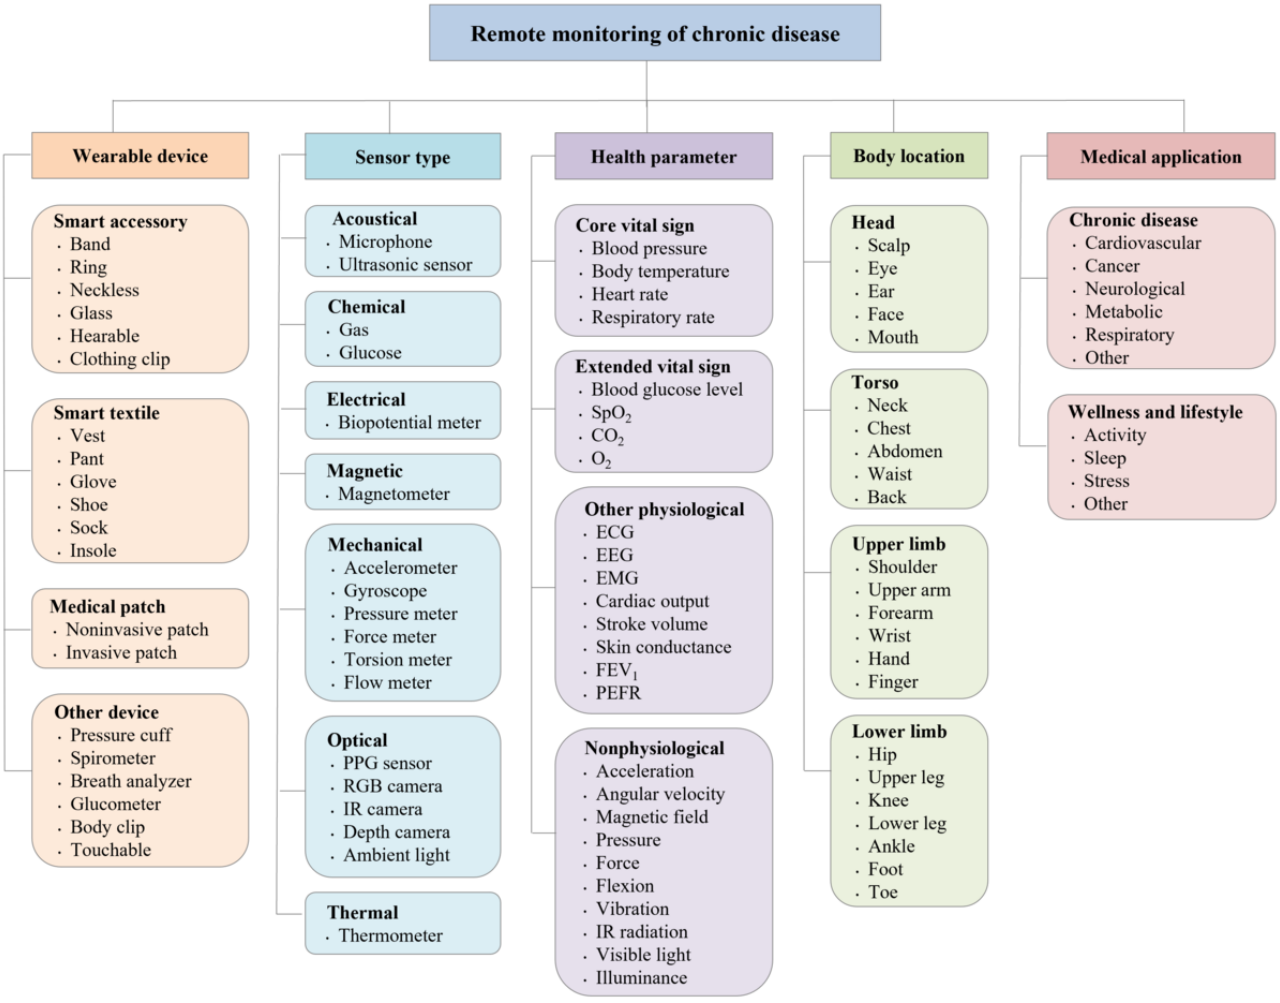
Eligibility Criteria

To ensure a concentrated analysis of wearable devices for remote monitoring of chronic diseases, we established the following eligibility criteria.

- Inclusion criteria:
  - Articles that used wearable devices for the remote monitoring of chronic diseases
  - Articles that used sensors for the remote collection of health parameters
  - Original research articles published in peer-reviewed journals
- Exclusion criteria:
  - Articles that used unobtrusive, implantable, or nonwearable devices or sensor types
  - Articles that did not involve remote monitoring or data collection
  - Nonjournal publications
  - Review articles

XSL•FO
RenderX

Data Management and Extraction



We conducted data extraction through regular team communication while reviewing the articles' titles, abstracts, and full texts. We engaged in thorough interranker discussions to resolve discrepant findings. For data extraction, we used a well-organized spreadsheet (Microsoft Excel) with the following parameters: author names, year of publication, country, study design, study phase, device name, device status, device type, sensor types, health parameters, body locations, and medical applications (Multimedia Appendix 2).

Standardized Terminology

Overview

We developed a standardized terminology based on existing evidence supplemented by insights from our research team. Our terminology encompasses five predefined categories: wearable device, sensor type, health parameter, body location, and medical application (Figure 1). We systematically organized the articles by these categories to facilitate a thorough analysis of the available evidence. The following sections detail the rationale and evidence.

Figure 1. Our standardized terminology framework outlines 5 categories used to guide the systematic analysis of articles on remote monitoring of chronic diseases. CO_2: carbon dioxide; ECG: electrocardiography; EEG: electroencephalography; EMG: electromyography; FEV_1: forced expiratory volume in the first second; IR: infrared; PEFR: peak expiratory flow rate; PPG: photoplethysmographic; O_2: oxygen; RGB: red, green, blue; SpO_2: peripheral oxygen saturation.

Wearable Device

We defined a wearable device as an Internet of Things–enabled electronic device that users wear externally on the body to monitor and collect health parameters, either continuously or sporadically, and to transmit data remotely for health monitoring purposes [43]. Our definition encompasses noninvasive and minimally invasive devices that users wear externally and that do not require surgical implantation [44]. We explicitly excluded fully implantable devices, environmental sensors, and purely handheld devices not designed for body attachment [45]. We categorized wearable devices into four types:

- Smart accessory: a stand-alone electronic device that users wear continuously on the body, including bands (smartwatches, wristbands, armbands, and straps), rings, necklaces, glasses, hearables, and clothing clips
- Smart textile: a device that integrates into everyday clothing items such as vests, pants, gloves, shoes, socks, and insoles
- Medical patch: a device with adhesive skin contact or a minimally invasive needle
- Other device: a device that users wear sporadically for specific measurements, such as pressure cuffs, spirometers,

XSL•FO
RenderX

breath analyzers, glucometers, body clips, and touchable devices, which can remotely transmit data

Sensor Type

Sensor types refer to the categories of sensing technologies that wearable devices use for remote monitoring of chronic diseases, grouped by the physical or chemical properties they measure (ie, acoustical, chemical, electrical, magnetic, mechanical, optical, and thermal) [46].

Health Parameter

Health parameters are measurable indicators that provide insights into an individual's health status, including core vital signs, extended vital signs, other physiological data, and nonphysiological data [14].

Body Location

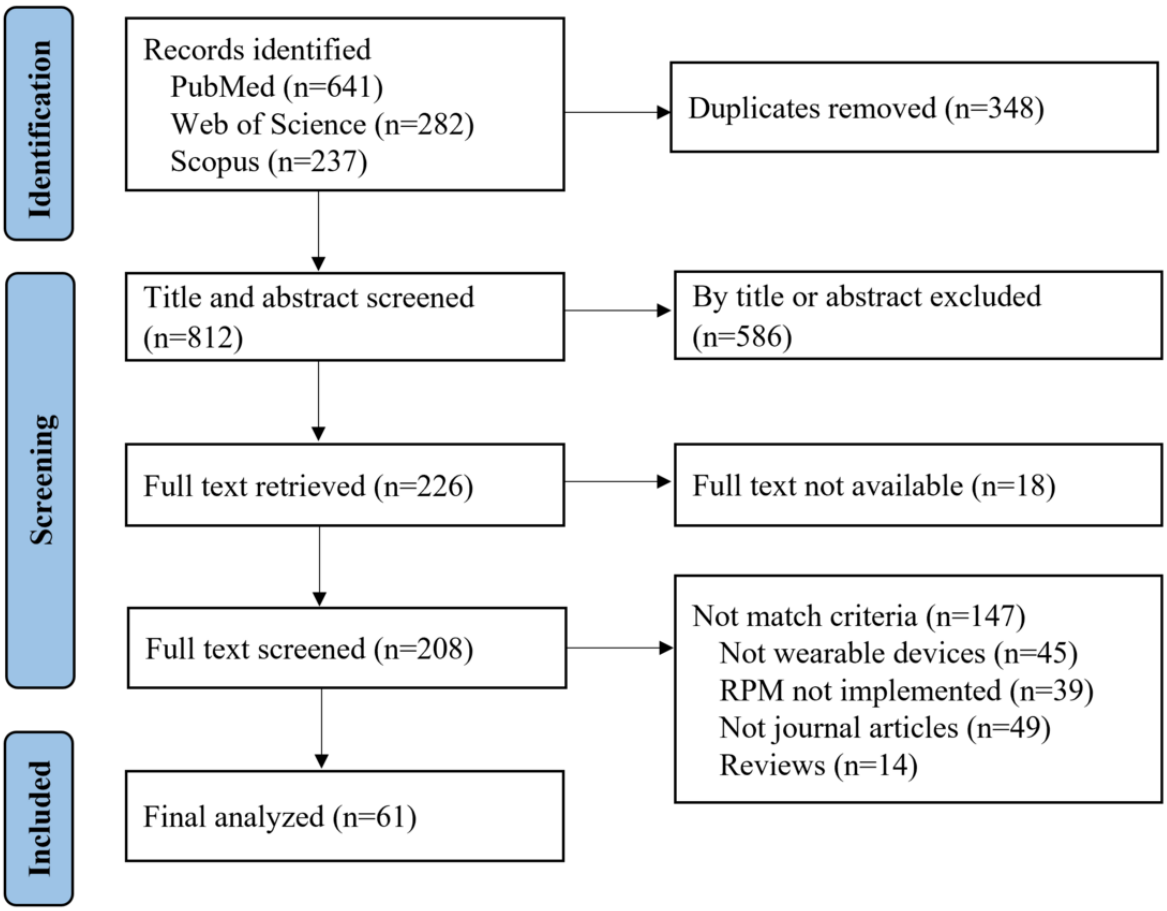
Body location specifies the outer body regions for sensor placement to collect health parameters. On the basis of the classification proposed by Kim et al [47], we grouped these regions into four categories: head, torso, upper limb, and lower limb.

Medical Application

Medical applications refer to the specific uses of wearable devices and sensors designed to monitor, manage, or support health conditions. The primary application of wearable devices focuses on chronic disease management while optionally offering wellness and lifestyle tracking, which can supplement disease monitoring. After identifying more than 10 distinct diseases, we categorized them into five groups based on their physiological systems: cardiovascular (eg, heart diseases and hypertension), cancer, neurological (eg, stroke, epilepsy, neurodegenerative disorders, and peripheral neuropathy), metabolic (eg, diabetes and obesity), respiratory (eg, asthma, chronic obstructive pulmonary disease), and other diseases [48,49]. This allows us to focus on broader applications of wearable devices across various diseases rather than focusing solely on specific conditions.

Quality Appraisal

Our review encompassed various study designs, including user-centered design, observational, experimental, and mixed methods articles. To assess the quality of these diverse articles, we used the QuADS critical appraisal tool [50]. The QuADS includes 13 criteria rated on a scale ranging from 0 to 3 (0=not at all, 1=very slightly, 2=moderately, and 3=complete), with a total quality score ranging from 0 to 39 (Multimedia Appendix 3) [51].



Results

Identified Articles

We identified 1160 articles from the 3 electronic databases. After removing duplicates, we considered 812 articles for title and abstract screening and excluded 586. Of the 226 articles screened, 18 were unavailable in full text. We thoroughly assessed 208 full-text articles for eligibility and excluded 147 that did not meet the inclusion and exclusion criteria. Finally, we included 61 articles (Figure 2).

XSL•FO
RenderX

Figure 2. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart describing the article selection process for this review. RPM: remote patient monitoring.

Characteristics of Included Articles

The included articles span Europe, North America, and the Asia-Pacific region. A total of 29 (48%) articles were conducted in Europe, with Italy contributing the most [25,31,52-55], followed by the United Kingdom [54,56-59]. North America ranks second, with nearly all articles conducted in the United States [26-28,32,34,60-73], except one article conducted in Canada [74].

Researchers used various research methodologies and study designs. Observational designs were the most prevalent (29/61, 48%), followed by 13 (21%) articles using user-centered design paired with experimental validation. Nine (15%) articles relied solely on experimental methods, and 7 (11%) articles focused exclusively on user-centered design. Only 3 (5%) articles adopted a mixed methods approach. In line with these designs, most articles (52/61, 85%) aimed to develop RPM systems and conduct feasibility and usability testing. In contrast, only 9 (15%) articles focused on late-stage validation and clinical efficacy evaluation.

We identified 74 instances of wearable devices used across the included articles. Of these, 28 (38%) instances involved dedicated medical devices approved by regulatory bodies, such as the US Food and Drug Administration (FDA) or the European Conformity Medical Device Regulation (CE-MDR). Most of these (24/28, 86%) collected vital signs and other physiological parameters. Twenty-six (35%) instances were consumer-grade wellness devices lacking medical certification, nearly all (23/26, 88%) designed as bands. Fourteen (19%) instances represented the early-stage development of research prototype devices. Additionally, 6 (8%) used consumer-grade devices with certified medical functions (FDA/CE-MDR/HIPAA [Health Insurance Portability and Accountability Act] approved) [29,34,65,70,75,76] (Table 1).

[a]Percentages may not total 100% due to rounding.

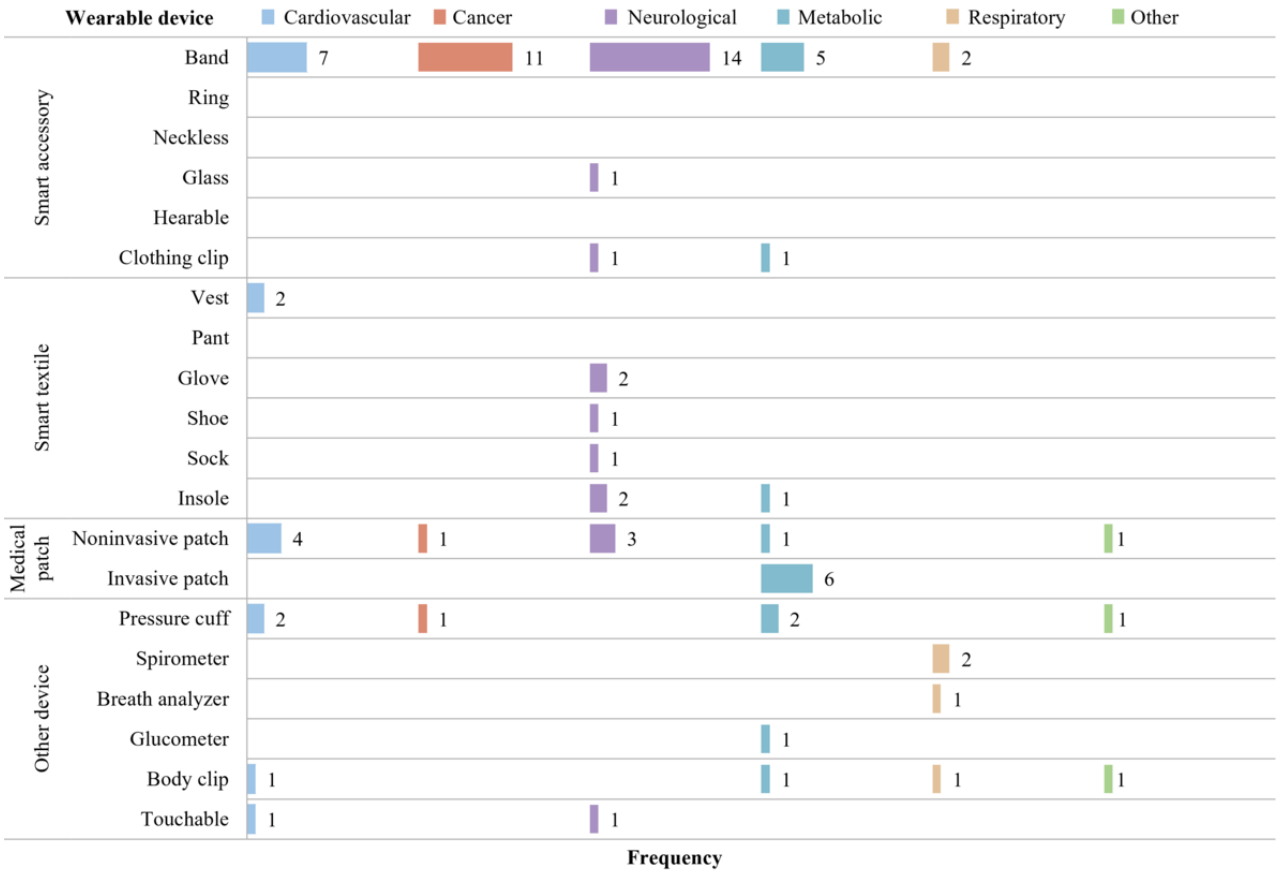
[b]The study design describes the methodological approach used in each article.

[c]The study phase indicates the stage of development or evaluation addressed.

[d]The regulatory status reflects the device's classification at the time of the study, not its current status. Some articles used multiple devices; therefore, device status is reported based on 74 wearable device instances.

[e]FDA: US Food and Drug Administration.

[f]CE-MDR: the European Conformity Medical Device Regulation.



[g]HIPAA: Health Insurance Portability and Accountability Act.

Wearable Device

We identified 16 distinct wearable devices for remote monitoring of chronic diseases (Figure 3). Bands, noninvasive patches, and pressure cuffs emerged as the most frequently used devices across various chronic diseases, appearing in 39 (64%), 10 (16%), and 6 (10%) articles, respectively. Neurological disease monitoring used 9 devices, with bands being the most common [24,25,31,35,54,56,65,72,73,87,89,91,98,101]. Researchers used 8 distinct wearable devices for metabolic diseases, with invasive patches [32,53,55,60,80,83] being exclusive to this category and the most frequently used, followed by bands [29,55,80,95,96]. Cardiovascular monitoring involved 6 wearable devices, primarily bands [67,69,75,76,84,93,94] and noninvasive patches [33,62,71,85]. For cancer monitoring, the articles almost exclusively reported on bands [34,58,63,64,78,81,82,90,97,99,100].

XSL•FO
RenderX

Figure 3. Occurrence of wearable devices by categories summarized in Figure 1. Rows represent the number of articles (N=61) that use each wearable device; colored columns (disease categories) may exceed N because some articles report on multiple devices.

Sensor Type

The wearable devices feature 14 sensor types. Accelerometers, PPG sensors, biopotential meters, pressure meters, and thermometers are most frequently used to monitor chronic conditions, appearing in 39 (64%), 18 (30%), 17 (28%), 11 (18%), and 9 (15%) articles, respectively. The wearable devices typically monitor neurological diseases using a diverse array of 10 sensors, preferring accelerometers [24,25,27,31,35,54,56,65,68,72,73,87,89,91,98,101], gyroscopes [24,25,27,31,35,54,56,65,68,73,91,98,101], and magnetometers [24,25,31,56,65,73,98] being the most common. Researchers used force meters [54,56], torsion meters [27,98], and wearable cameras [70], exclusively for neurological diseases.

We identified sensors such as biopotential meters [33,62,71,75,77,79,85,86], accelerometers [62,67,71,79,84,86,93], PPG sensors [67,69,74,84,93], pressure meters [74,76,77,94], and thermometers [62,71,93] as key sensors for the remote monitoring of cardiovascular diseases, ranked by their usage frequency. Similarly, we identified that these sensors monitor cancer, although their frequency varies. Accelerometers [34,58,63,64,81,82,90,99,100], PPG sensors [78,81,82,97,99], biopotential meters [64,81,82], thermometers [81,82,97], and pressure meters [64] are the most common. Additionally, our analysis showed that the articles used glucose sensors [32,53,55,60,80,83,96] exclusively and frequently for monitoring metabolic diseases (Figure 4).

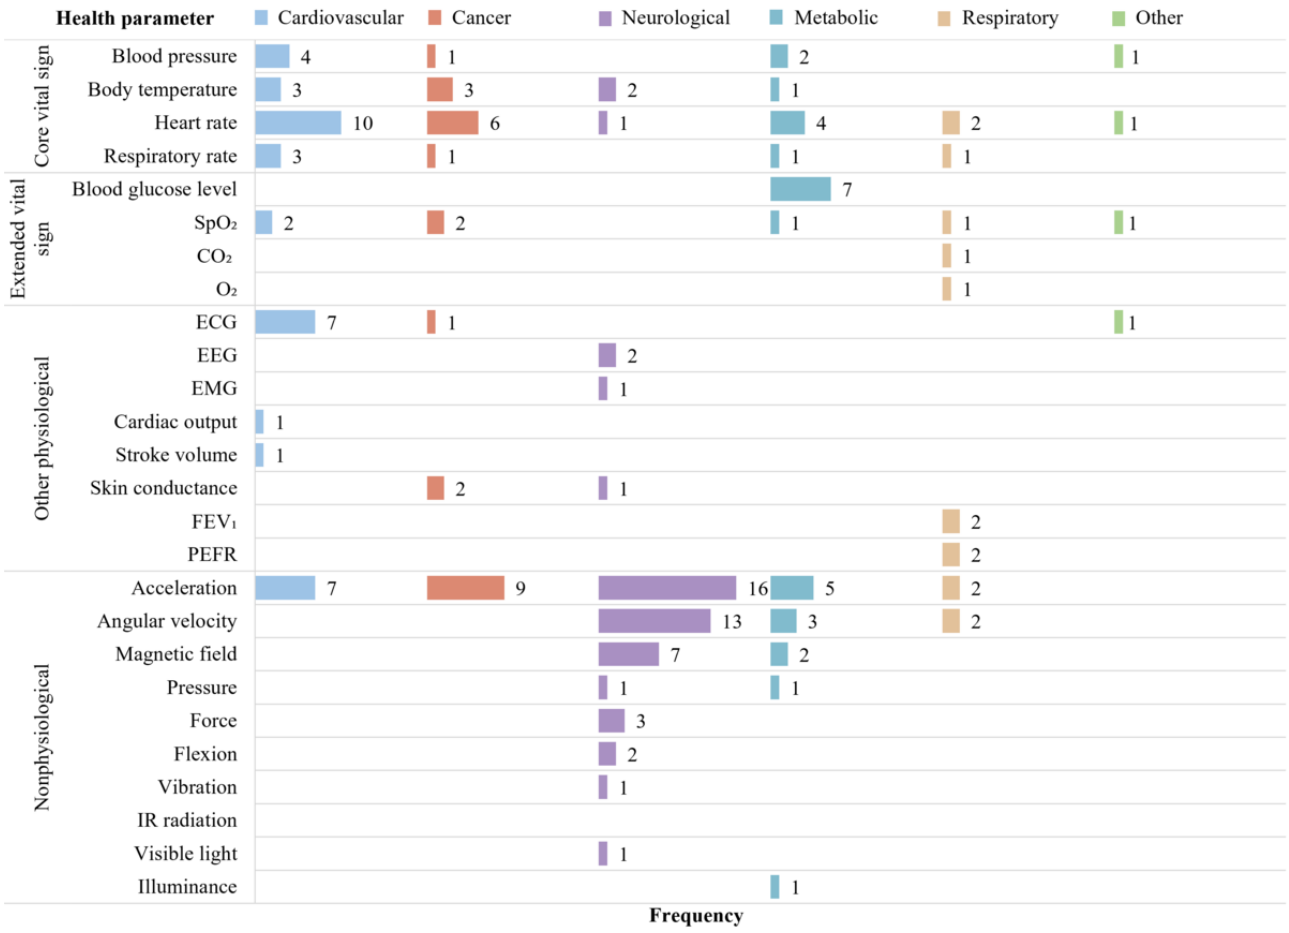
Wearable Device, Sensor Type, and Chronic Disease Mapping

A Sankey diagram visually illustrates the relationships among wearable devices, sensor types, and the corresponding chronic diseases they monitor (Figure 5). Bands have emerged as the most widely used wearable devices, integrating 8 sensor types. They primarily incorporate accelerometers [24,25,31,35,54,56,65,72,73,87,89,91,98,101], gyroscopes [24,25,31,35,54,56,65,73,91,98,101], and magnetometers [24,25,31,56,65,73,98] to facilitate remote monitoring of neurological diseases. They also often feature PPG sensors [29,54,55,57,61,67,69,78,80-82,84,93,96,97,99] and biopotential meters [64,75] to track heart rate and ECG. Moreover, bands are increasingly equipped with other sensor types such as electrodermal activity (EDA) biopotential meters [54,81,82], skin thermometers [54,81,82,93,97], oscillometric blood pressure meters [76,94], barometric altimeters [80], and ambient light sensors [80], enabling remote monitoring of skin conductance, body temperature, blood pressure, atmospheric pressure, and illumination, respectively.

XSL•FO
RenderX

Figure 5. A Sankey diagram illustrating the mapping between wearable devices, sensor types, and the chronic diseases targeted for remote monitoring. Node and link widths reflect match frequency, and node colors correspond to wearable device and sensor types. PPG: photoplethysmographic; RGB: red, green, blue.

Noninvasive medical patches incorporate accelerometers [58,62,71,80] and thermometers [62,71], in addition to common types of biopotential meters such as ECG [33,62,71,80,88], electroencephalography [66,92], electromyography [26], and impedance [85]. Notably, glucose sensors are the only sensor type integrated into minimally invasive devices [32,53,55,60,80,83]. Furthermore, traditional pressure cuffs, such as the blood pressure monitors iHealth (iHealth Labs Inc) [88,96] and Withings (Withings) [29], now transmit their data remotely. Additionally, pulse oximeters such as iHealth [96] and Onyx (Nonin Medical Inc) [88] enhance the functionality of traditional body clips by enabling the remote transmission of peripheral oxygen saturation (SpO_2) and heart rate data.



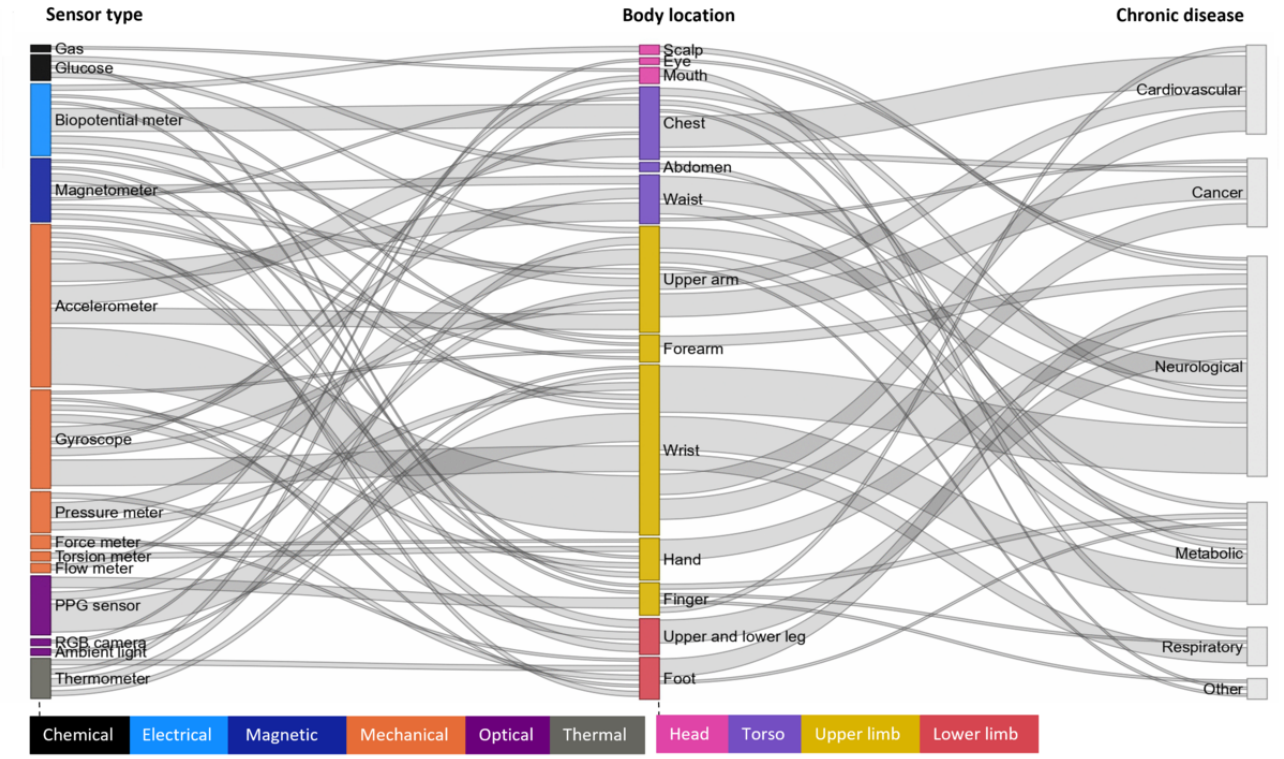
Health Parameter

Sensors gather a total of 25 health parameters for remote monitoring of chronic diseases (Figure 6). Acceleration is a key health parameter for monitoring various chronic diseases, as indicated by 39 (64%) articles. Specifically, it is the most commonly collected health parameter in the remote monitoring of neurological diseases [24,25,27,31,35,54,56,65,68,72,73,87,89,91,98,101] and cancer [34,58,63,64,81,82,90,99,100].

The articles consistently reported on monitoring heart rate, body temperature, blood pressure, and SpO_2, as reported in 24 (39%), 9 (15%), 8 (13%), and 7 (11%) articles, respectively. These core and extended vital signs are essential health parameters for remote monitoring of cardiovascular, cancer, and metabolic diseases. On the other hand, articles primarily monitor neurological diseases using nonphysiological parameters. Furthermore, metabolic monitoring focuses on core and extended vital signs and nonphysiological parameters (Figure 6).

XSL•FO
RenderX

Figure 6. Occurrence of health parameters by categories summarized in Figure 1. Rows represent the number of articles (N=61) that collect each health parameter; colored columns (disease categories) may exceed N because some articles collect multiple health parameters. CO_2: carbon dioxide; ECG: electrocardiography; EEG: electroencephalography; EMG: electromyography; FEV_1: forced expiratory volume in the first second; IR: infrared; PEFR: peak expiratory flow rate; PPG: photoplethysmographic; O_2: oxygen; RGB: red, green, blue; SpO_2: peripheral oxygen saturation.

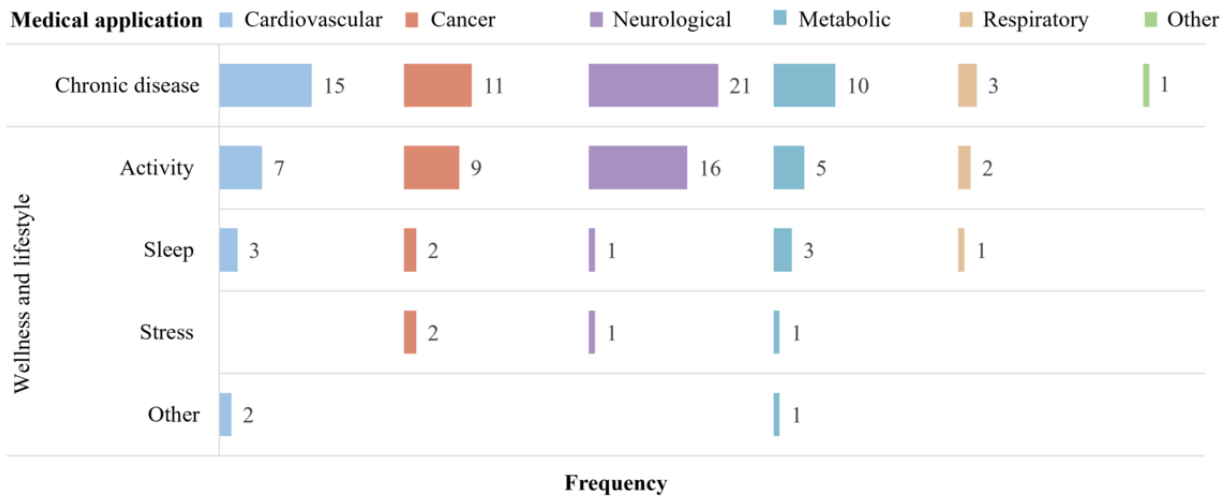


Body Location

The wrist is the most frequent body location for sensor placement, comprising 8 different sensor types. A Sankey diagram illustrates the linkage between accelerometers, PPG sensors, and gyroscopes to the wrist, highlighting that these sensor types are mostly positioned on the wrist (Figure 7). The upper arm is the second-most frequent body location, comprising 8 sensor types, including pressure meters [29,64,74,77,88,96] and accelerometers [35,56,81,82,93,98]. The chest is the third-most common body location, accommodating 5 sensor types. Researchers commonly place biopotential meters [33,62,71,79,80,88] here to monitor cardiovascular diseases. Additionally, the waist is an ideal location for IMU sensors, including accelerometers [64,65,68,72,73,80,95], gyroscopes [65,68,73,80], and magnetometers [65,73,95] for monitoring neurological, metabolic, and cancer diseases. Furthermore, researchers place various sensors on the hand, forearm, upper, and lower legs to monitor neurological diseases [26,27,31,56,73,98].

XSL•FO
RenderX

Figure 7. A Sankey diagram illustrating body locations for sensor placement in the remote monitoring of various chronic diseases. Node and link widths reflect match frequency, and node colors correspond to sensor type and body locations. PPG: photoplethysmographic; RGB: red, green, blue.



Medical Application

The articles primarily highlighted the use of wearable devices for monitoring specific chronic diseases as their primary medical application, with the option to include wellness and lifestyle monitoring. Among chronic diseases, neurological diseases are the primary focus, accounting for more than one-third (21/61, 34%) of the articles. Cardiovascular diseases follow, with 15 (25%) articles, while wearable devices monitored cancer, metabolic diseases, and respiratory diseases in 11 (18%), 10 (16%), and 3 (5%) articles, respectively (Figure 8).

Furthermore, more than half (39/61, 64%) of the articles targeted wellness and lifestyle applications alongside disease-specific metrics. Activity tracking is a fundamental wellness and lifestyle metric collected across 39 (100%) articles. Notably, activity remains essential for monitoring neurological diseases. Furthermore, sleep monitoring is another application widely reported in 10 (26%) articles for various chronic conditions. For cancer, neurological, and metabolic diseases, the articles described remote stress-level monitoring (Figure 8).

Figure 8. Frequency of key medical applications by categories summarized in Figure 1. Rows represent the number of articles (N=61 for chronic disease monitoring and N=39 for wellness and lifestyle applications); colored columns may exceed N because some articles report on multiple wellness or lifestyle applications.

Quality Assessment of Included Articles

More than half of the included articles fully met 11 of the 13 QuADS criteria, receiving the top rating (Complete) on the QuADS scale (Table 2). Specifically, 56 (92%) and 54 (89%) articles clearly described the data collection procedure and stated the research aim, respectively. Fifty-two (85%) articles provided detailed descriptions of the research setting and population, used an appropriate format and content for the data collection tool, and applied proper methods of analysis to address the research aim. In contrast, only 15 (25%) articles thoroughly addressed stakeholder involvement in the design and conduct of the article, while 11 (18%) articles did not report stakeholder involvement at all (Multimedia Appendix 3).

Table . Quality assessment scores for the 13 Quality Assessment with Diverse Studies (QuADS) criteria [50].

QuADS criteria	Rating scale[a], n (%)[b]			
	Not at all	Very slightly	Moderately	Complete
Theoretical or conceptual underpinning to the research	0 (0)	1 (2)	25 (41)	35 (57)
Statement of research aim/s	0 (0)	1 (2)	6 (10)	54 (89)
Clear description of research setting and target population	0 (0)	2 (3)	7 (11)	52 (85)
Study design appropriate to address the stated research aim/s	0 (0)	0 (0)	17 (28)	44 (72)
Appropriate sampling to address the research aim/s	2 (3)	5 (8)	31 (51)	23 (38)
Rationale for choice of data collection tool/s	3 (5)	5 (8)	16 (26)	37 (61)
Format and content of data collection tool appropriate to research aim/s	0 (0)	0 (0)	9 (15)	52 (85)
Description of data collection procedure	0 (0)	0 (0)	5 (8)	56 (92)
Recruitment data provided	4 (7)	5 (8)	14 (23)	38 (62)
Justification for analytic method selected	7 (11)	5 (8)	18 (30)	31 (51)
Method of analysis appropriate to answer the research aim/s	2 (3)	0 (0)	7 (11)	52 (85)
Evidence that stakeholders were considered in design/conduct	11 (18)	12 (20)	23 (38)	15 (25)
Strengths and limitations critically discussed	5 (8)	0 (0)	23 (38)	33 (54)

[a]Each cell indicates the number of articles (N=61) that met the corresponding QuADS criterion at the given rating scale.

Discussion

Principal Findings and Interpretation

We identified the wearable devices, sensor types, health parameters, body locations, and medical applications for remote monitoring of various chronic diseases. We found a clear trend toward wrist-worn bands primarily tracking acceleration, followed by core and extended vital signs. These devices mainly monitor neurological and cardiovascular diseases.

Wearable devices predominantly come in the form of bands, a trend driven by consumer electronics giants such as Fitbit [34,55,67,72,90], Apple [55,69,84,99], Garmin [57,80], Huawei [94,96], Samsung [99], Withings [75], Omron HeartGuide [76], and Misfit [63]. These brands offer a diverse range of wearable devices, including smartwatches, wristbands, armbands, and straps. However, most consumer-grade wellness devices lack medical certification, and 23 of 26 are bands. This finding urges future researchers and clinicians to look beyond wearability and user-friendliness and to consider regulatory status. The emergence of consumer-grade wellness devices with certified medical functions (FDA/CE-MDR approval), although still a minority, represents a significant development for RPM systems by addressing the need for clinical validation.

A wide range of wearable devices integrated accelerometers to track acceleration, which emerged as the most frequently monitored and clinically relevant health parameter across

XSL•FO
RenderX

multiple chronic diseases. This is because acceleration offers valuable insights for designing activity plans that support wellness and slow disease progression [102]. Our findings further highlight its particular prevalence in the remote monitoring of neurological disorders and cancer. This aligns with previous research, demonstrating that tracking acceleration enables researchers to gain a deeper understanding of movement patterns, serving as key indicators of Parkinson disease [103-105], and to assess motor function and recovery following a stroke [106,107]. Acceleration is also a key health parameter for monitoring physical fitness levels and evaluating treatment effectiveness in patients with cancer [108].

Vital sign monitoring remains a cornerstone for the remote management of chronic diseases [109], as it provides critical insights into a patient's overall physiological status [110] and serves as an early warning signal for detecting and preventing patient deterioration [111]. Our findings support this principle in the context of wearable devices, revealing that articles frequently use PPG sensors, biopotential meters, pressure meters, and thermometers to track core and extended vital signs, including heart rate, body temperature, blood pressure, and SpO_2.

The wrist is the dominant body location for sensor placement, primarily due to ongoing technological innovations in bands, which improve comfort and usability [112] while enabling the integration of key sensor types, such as accelerometers and PPG sensors [113,114]. When data quality is essential, researchers often choose the upper arm to minimize motion artifacts that corrupt health parameters, compared to the more dynamic wrist and hand [115]. Sensor placement is specific to the health parameter. The chest remains the major site for placing biopotential meters (ECG tracking), which reflects clinical practice [116]. Conversely, PPG sensors do not perform well when placed on the chest, likely due to factors such as skin type and hair density [117-120]. To quantify motor symptoms in the limbs, researchers monitoring neurological diseases often place IMUs on the extremities (eg, the upper arm, forearm, hand, and leg) [121-123].

Wearable devices primarily target neurological and cardiovascular diseases. A recent report from the Institute for Health Metrics and Evaluation supports our findings, identifying neurological diseases as the leading global cause of disease burden and disability, affecting 3.4 billion people, and surpassing the impact of cardiovascular diseases [124,125]. The effectiveness of wearable-based RPM systems for early prediction and prevention is mainly due to their ability to capture quantifiable biomarkers, such as gait analysis, tremors, speech patterns, and cognitive functions. Alongside this, researchers continue to use wearable devices to monitor cardiovascular diseases, which are the leading cause of death globally [126].

Beyond chronic disease monitoring, there is a significant emphasis on wellness and lifestyle monitoring. Approximately two-thirds of the articles track physical activities, such as counting steps and determining movement. Additionally, movement-related parameters, such as tremors, motor symptom assessment, and muscle vibration, are essential for diagnosing neurological diseases. This aligns with the WHO report, which states that promoting healthy behaviors or responding to warning signs can prevent 80% of chronic diseases [127]. Furthermore, our results align with previous research, demonstrating that regular physical activity is essential for managing chronic diseases [128,129], preventing the onset of new diseases [130-132], reducing medication needs [133,134], and enhancing quality of life [135-138]. This emphasizes the importance of setting physical activity plans as a strategy to prevent the progression of chronic diseases.

Another application of this lifestyle approach is the growing focus on remote sleep monitoring. Evidence from the Centers for Disease Control and Prevention [139] and the Population Reference Bureau [140] supports our findings, highlighting the strong association between poor sleep and various chronic diseases, including cardiovascular and metabolic disorders. As a result, we emphasize the importance of monitoring and addressing sleep problems to prevent deterioration in health and promote healthy behaviors in patients with chronic conditions.

Comparison With Prior Work

Several systematic reviews examined the use of wearable devices for remote monitoring of chronic diseases. Some reviews evaluated the impact of wearable-based RPM systems on patient outcomes [36,41,141]. However, these articles do not specify the wearable devices, sensor types, body locations, or health parameters. Other reviews analyze medical applications of RPM systems [142,143], but they do not provide cross-disease mapping of wearable devices, sensor types, body locations, or monitored health parameters. Some reviews focus on specific applications, such as primary health care [37], rehabilitation [14], or physical activity monitoring [144], but do not compare wearable devices or parameters across health conditions.

In contrast, our systematic review provides a framework for wearable devices, sensor types, body locations, health parameters, and medical applications. We visualize relationships among wearable devices, sensor types, and chronic diseases, as well as between sensor types, body locations, and chronic diseases. Building on the recommendation from Cajamarca et al [145], we argue that managing multiple chronic conditions represents a forward-looking approach to address the global rise in multimorbidity. For instance, data from Watson et al [146] show that 51.4% of US adults live with multiple chronic conditions. By identifying shared components across chronic conditions, our findings provide foundational evidence for designing generalized wearable-based RPM systems. Such multifunctional systems cost-effectively monitor multiple chronic conditions simultaneously, moving beyond disease-specific solutions [147].

Martins et al [148] highlighted the need for common standards to address ongoing interoperability challenges across diverse RPM systems. Identifying shared components across pilot projects, commercial products, and CE/FDA-approved wearable devices represents a critical first step toward the semantic harmonization of clinical data across chronic conditions [149]. Our work fosters a deeper understanding of the increasing diversity of RPM systems, supports the assessment of Fast Healthcare Interoperability Resources requirements, encourages performing concept mapping, and promotes the development

XSL•FO
RenderX

of extensions to medical terminologies, including International Classification of Diseases, 11th Revision [150], Systematized Nomenclature of Medicine—Clinical Terms [151], and Logical Observation Identifiers Names and Codes [152].

Limitations and Future Research Directions

This review has several limitations. First, we limited the scope to wearable devices used for the remote monitoring of chronic diseases, excluding unobtrusive or implantable sensors, as well as articles that do not implement RPM systems. While this allows for a more targeted analysis, it may reduce the generalizability of the results to broader sensor technologies. Second, most of the included articles (52/61, 85%) focused on developing RPM systems and conducting early-stage feasibility and usability assessments. Although the field demonstrates strong innovation, it lacks substantial late-stage validation and evaluation of clinical impact on patient outcomes. Consequently, our findings are primarily based on reported device usage frequencies in early-stage and feasibility studies, rather than on demonstrated clinical outcomes. Therefore, readers should not interpret the frequency of a device's appearance in this review as evidence of its clinical effectiveness. Third, we did not evaluate technical aspects, such as long-term device reliability, low power consumption, or the impact of motion artifacts on sensor accuracy. While these factors significantly affect the long-term monitoring of chronic diseases, they fall outside the predefined objectives of this review and require further investigation in future research.

Given this predominance of early-stage feasibility articles, we strongly recommend a shift in research priorities. Future work should prioritize late-stage clinical trials that use medically certified wearable devices. Such articles are essential for rigorously evaluating the clinical efficacy, data privacy, and system maturity, and the impact of motion artifacts, thereby moving RPM systems beyond proof-of-concept toward evidence-based implementation.

Conclusions

This review confirms that the most frequent devices for remote monitoring of chronic diseases are bands, with the wrist being the preferred body location, followed by the upper arm and the chest. The most common sensor types are accelerometers, PPG sensors, and biopotential meters, which primarily collect health parameters such as acceleration, heart rate, and body temperature. Key applications of wearable devices include monitoring neurological and cardiovascular diseases, tracking activity, and assessing sleep quality. Overall, these findings highlight the need for a foundational road map for designing generalized RPM systems that can manage multimorbidity and support standardized terminology to enhance interoperability across digital health systems.

Abstract

Background: Good motor performance skills (MPS) are relevant in all stages of life. Higher MPS are associated with enhanced cognitive abilities and physical and mental health. The assessment of MPS is important to identify deficits in MPS at an early stage and to implement interventions to address these deficits. One method to assess MPS is through marker-based motion capture in a laboratory setting with multiple cameras. However, this approach is expensive and time-consuming, making it impractical, for example, in large-scale studies for MPS assessment. Recent advancements (eg, artificial intelligence) in technology (eg, smartphone cameras) have opened up innovative solutions for various challenges (eg, testing large sample sizes). A potential solution is using video-based smartphone apps to assess MPS through markerless motion capture with a single camera.

Objective: The objectives of this scoping review were to summarize existing smartphone apps designed to digitally assess MPS through motion capture, identify the target population of the apps, determine whether the apps have been validated, and summarize the specific MPS that were assessed.

Methods: The scoping review was conducted in accordance with the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analysis extension for Scoping Reviews) guidelines. The search was conducted in March 2024 using PubMed, Scopus, SPORTDiscus, Web of Science, Education Resources Information Centre, and SAGE Publications. All included studies investigated video-based motion capture smartphone apps to assess MPS.

Results: A total of 10 studies met the inclusion criteria. Seven different smartphone apps were used within the studies, 6 of which have already been validated. The MPS assessed through the apps were gait, breaststroke, running, countermovement jump, and shoulder mobility, and 1 study assessed a functional movement test battery. The studied populations were healthy adults, older adults, athletes, or individuals with neurological illnesses.

Conclusions: The assessment of MPS through smartphone apps represents a promising tool, which can be used in a variety of fields, such as health and performance monitoring, coaching, and scientific research. In the future, more studies should focus on developing new smartphone apps to assess different MPS and validate these apps.

(JMIR Mhealth Uhealth 2026;14:e65474) doi:10.2196/65474

Introduction

The comprehensive development of motor performance skills (MPS) is critical for healthy human development [1] and remains important throughout all stages of life [2]. Overall, studies have shown that higher MPS are associated with increased physical activity and physical fitness at all ages [3-5], which have both physical and mental health benefits (eg, reduced depressive symptoms) [3,6]. Furthermore, there is an inverse relationship between MPS levels and body weight [5,7,8].

Given the multitude of terms used in motor performance research, it is important to select a definition of the term “motor performance skills” that will be used in this study. In their scoping review, Sortwell et al [9] established a general definition of the MPS term based on existing descriptions in the literature. MPS encompass a range of movements, including those used for space coverage (eg, walking), object manipulation (eg,

XSL•FO
RenderX

throwing), and movements that are needed for overcoming obstacles in vertical, diagonal, or horizontal directions (eg, climbing and jumping). Additionally, they include different kinds of pulling, pushing, and holding. These MPS serve as the foundation for specialized movement and the acquisition of sport-specific competencies [9]. The term MPS is often used interchangeably with the terms "motor skills" and "fundamental movement skills" [9,10].

The use of motor performance test batteries to assess motor performance allows for a precise examination of the current state and development of MPS. The results of these test batteries can be used to target interventions aimed at reducing deficits and improving performance [1,11,12]. However, assessing MPS using test profiles only provides limited or mainly subjective information regarding execution errors or the quality of the movement performed. A quantitative biomechanical measurement of kinematic variables collected via motion tracking systems could serve as an alternative or complementary approach [13,14].

The current gold standard for biomechanical movement assessment is using marker-based 3D motion tracking systems in a laboratory environment [14,15]. However, this method is time-consuming, expensive, and complex to implement, limiting its application in large-scale population studies [15-17]. To address these limitations, some studies have validated markerless 2D motion capture systems by comparing them to the gold standard. For example, a recent study showed a very high agreement between the gold standard and a single smartphone camera in a countermovement jump analysis, where videos were evaluated by Sbsq-pose (Subsequent GmbH), an artificial intelligence (AI)–based motion tracking system using deep learning to predict the 3D positions of 24 skeletal key points from 2D video recordings [18]. Indeed, the use of AI has gained increasing attention in biomechanics [19]. Today, there are pose estimation models that can be used to analyze video recordings of human movement [19]. These pose estimation models are created by deep learning algorithms, which are capable of identifying anatomical landmarks from digital videos [13]. To ensure that the assigned anatomical landmarks are correctly recognized, these human body models are first trained on large datasets [13]. Human annotators manually label the positions of anatomical landmarks in the training images [13,20]. Subsequently, the AI algorithm is able to automatically track human movements within recorded videos [13]. The trained pose estimation models also enable motion capture to be integrated into various everyday apps, such as smartphone apps [13,19]. There are already several smartphone apps that provide biomechanical monitoring, such as gait analysis, which provides information on spatiotemporal parameters (eg, cadence and foot strike), joint kinematics (eg, knee flexion angle) but not joint kinetics [21]. These apps enable automatic kinematic detection of whole-body and partial-body movements, including motion analysis that can be used in the field with minimal effort and even with large sample sizes. The advantage of using smartphone apps to collect MPS is that it is a simple and cost-effective way to perform biomechanical studies on a large population without the need for a lot of equipment or a laboratory environment, as the majority of individuals possess a smartphone [13]. In 2022, 6.4 billion individuals worldwide owned a smartphone, with an estimated 6.9 billion in 2024 and an estimated total of 7.7 billion by 2028 [22]. The widespread ownership of smartphones enables testing of large numbers of individuals, which is not feasible with a laboratory-based approach. The use of smartphone apps may be a particularly beneficial approach for population-based fitness studies, such as the MoMo study [23,24] in Germany or as those using the ALPHA test battery, which includes highly reliable and valid measures of cardiorespiratory fitness, muscular strength, and anthropometry [23-25]. For instance, a large-scale fitness study in European youth successfully collected data from nearly 8 million test results across 34 countries, encompassing a broad age range and using representative national data [25]. By using smartphone apps, a similar number of participants could be assessed on their fitness levels more efficiently. This approach minimizes the need for extensive travel and logistical resources, thereby enabling greater flexibility in test scheduling. By allowing participants to complete assessments remotely from their homes, it eliminates the requirement for in-person appointments or visits to testing facilities, thus streamlining the data collection process and enhancing accessibility for a broader population. However, it is imperative to acknowledge the limitations inherent to such apps, which often exhibit performance deficiencies. A number of factors may contribute to inaccurate movement detection by smartphone cameras. These include, for example, a low sampling rate, the presence of human-like objects in the room, and inaccurate camera positioning. These issues can result in the inability to precisely detect anatomical orientation points, which, in turn, can lead to measurement errors [13]. Furthermore, it should be noted that certain apps are designed to operate within a cloud computing environment, necessitating a stable internet connection for optimal functionality. This aspect should be considered when using such s.

To date, there is one review that gives an overview of video-based motion capture smartphone apps for MPS testing, but it only focuses on healthy adults [26]. Currently, no reviews provide a general overview for all population types.

This gap in the literature hinders the ability of researchers and practitioners to fully understand the capabilities and limitations of these technologies. Therefore, we conducted a scoping review to address this gap by providing a comprehensive overview of the current state of research on existing smartphone apps designed to assess the biomechanics of MPS through markerless motion capture. This review aimed to highlight the advancements, identify potential areas for improvement, and guide future research and development in this field.

We specifically addressed four aims: (1) to summarize existing smartphone apps designed to digitally assess MPS through motion capture, (2) to elucidate the specific MPS that these apps assess, (3) to determine whether these apps have been validated, and (4) to identify the target population of each app.

Methods

This scoping review was performed in accordance with the PRISMA-ScR (Preferred Reporting Items for Systematic

XSL•FO
RenderX

Reviews and Meta-Analysis extension for Scoping Reviews) guidelines (Checklist 1) [27]. A study protocol was designed in advance and then registered on OSF [28].

Eligibility Criteria

Inclusion Criteria

The studies included in the review had to perform motor performance tests that were assessed through video-based motion capture integrated into smartphone apps. The papers were included if they were written in English, published up to February 2024, involved human participants, and assessed motor performance through an AI-based video analysis (without human supervision).

Exclusion Criteria

All articles that used the smartphone's built-in sensors or accelerometers for the assessment of MPS were excluded from the analysis. We also excluded dissertations and conference papers. Meta-analyses, scoping reviews, and systematic reviews were not included in this scoping review but were considered separately in this paper as part of the basis for discussion and can be found in the "Meta-Analyses and Reviews" section.

Search Strategy

To identify potentially relevant articles, the search was conducted on March 5, 2024, in six electronic databases: PubMed, Scopus, SPORTDiscus, Web of Science, Education Resources Information Centre, and SAGE Publications. Before beginning the search, 2 reviewers (CSZ and CN) screened various publications and reviews in the research area, discussed the results, and determined the search term. The search terms included topics related to (1) MPS, (2) motion capture, and (3) smartphone apps, which were combined by Boolean operators. The search terms are shown in the Multimedia Appendix 1. The search was performed on the title and abstract of the papers, and the study type (validation study) was screened manually. There were no preset restrictions on the target population, so all ages were included. Before performing the search, the search strategy was reviewed by an expert (Dr Janis Fiedler) in mobile health technologies. Gray literature was not considered in this scoping review.

Selection of Sources of Evidence

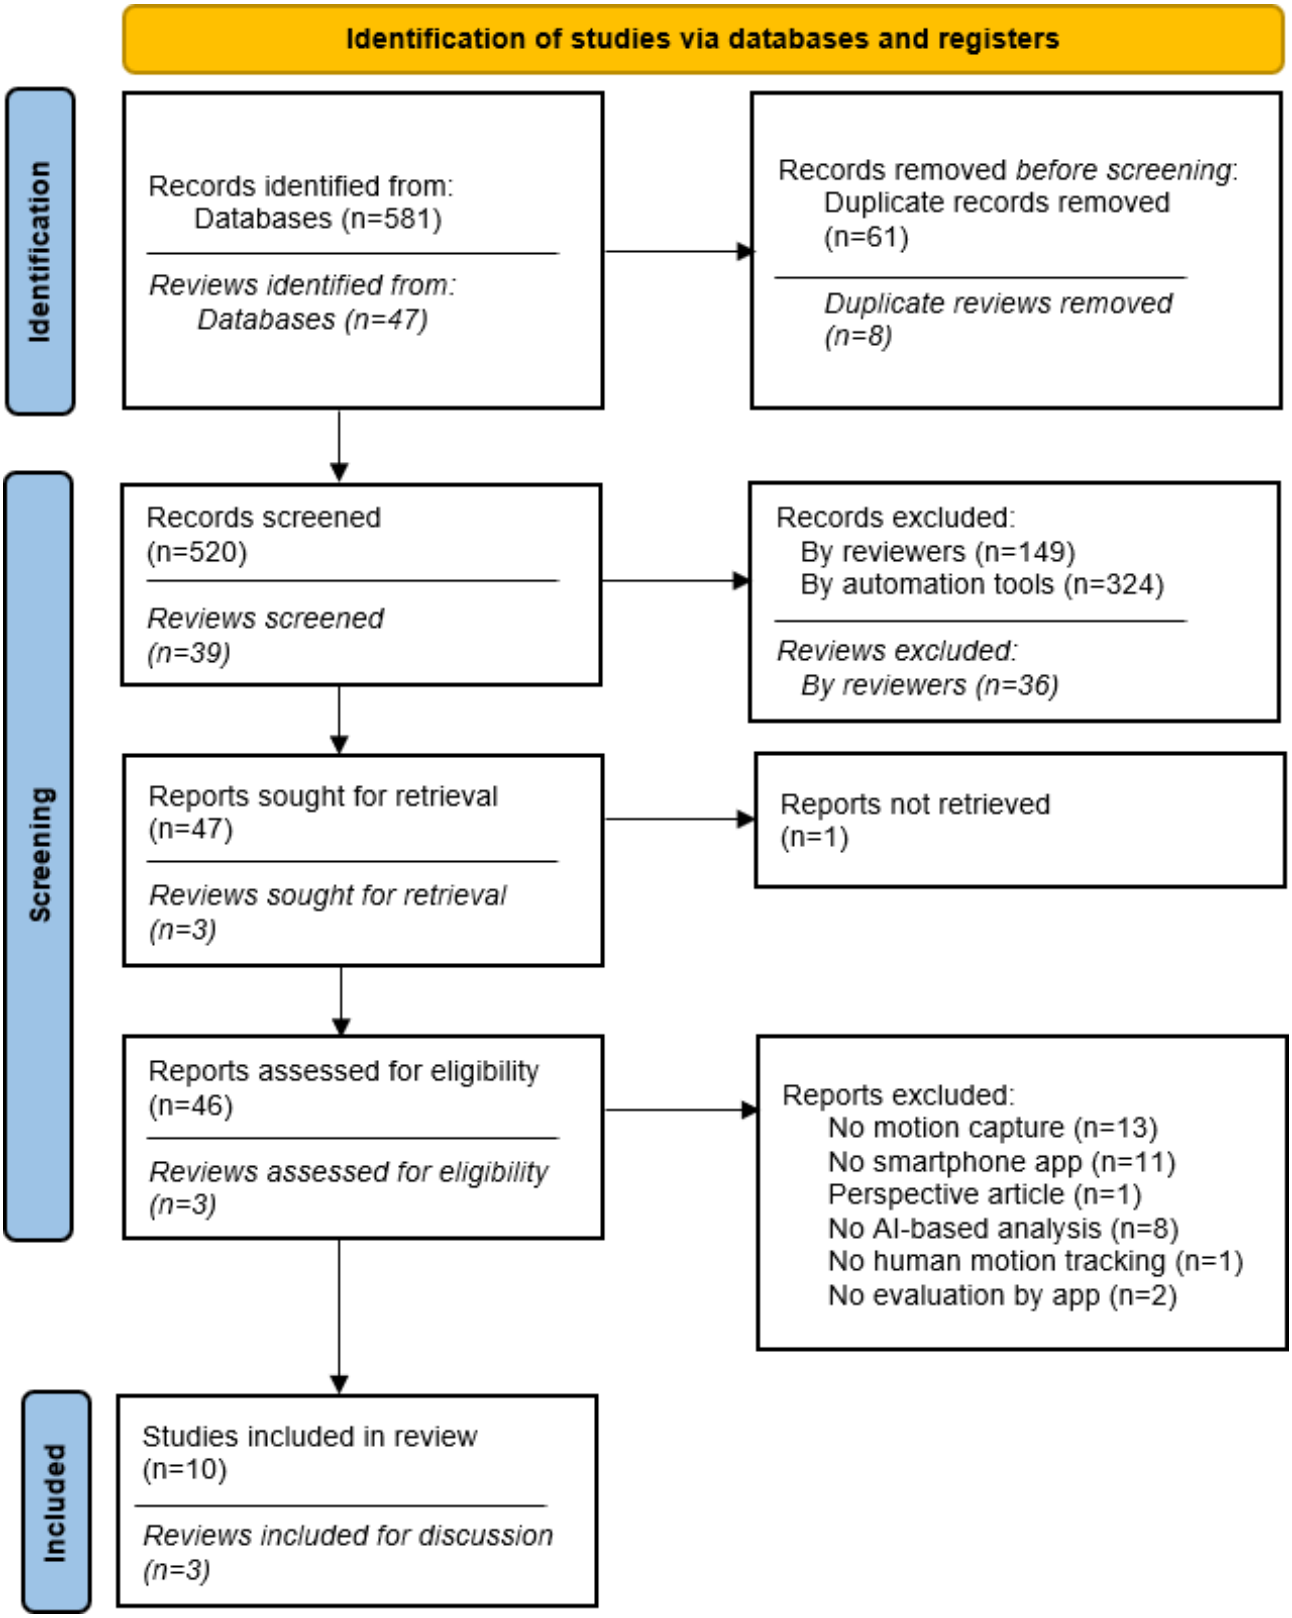
To ensure a consistent and transparent selection process, a standardized screening form was developed by 2 reviewers (CSZ and CN) based on the central research objective: to provide a comprehensive overview of smartphone apps that assess MPS through markerless motion capture. The form was piloted using a small set of studies to calibrate inclusion decisions and refine key criteria such as app type, motion capture method, and degree of automation.

Study Selection

The search results were exported into the citation program Zotero (Corporation for Digital Scholarship). After removing duplicates, the titles and abstracts were screened by one reviewer (CSZ) using the open-source machine learning software "ASReview" (ASReview LAB developers) developed at Utrecht University [29]. To start training the model, 2 studies were initially selected for inclusion, and 2 studies were selected for exclusion [29]. Subsequently, the software presented 1 paper at a time, and the reviewer determined if it should be included or excluded based on its title and abstract. The title and abstract screenings were stopped after 50 consecutive articles were excluded by the reviewer [30,31]. Afterward, the second reviewer (CN) screened the articles excluded by the first reviewer to ensure that no relevant articles were falsely excluded. Following the title and abstract screening, the software provided a list of the included articles, which were then screened manually. If the full text was not available, authors were contacted and asked to provide it. The full-text screening was performed independently by 2 reviewers (CSZ and MF).

Data Charting and Extraction

To chart the data, 2 reviewers created a data charting form in Microsoft Excel to determine which variables should be extracted. Data extraction was then performed by 1 reviewer (CSZ) and verified by another author (TK). During the screening process, we found that information on the validation of the apps was more relevant than initially anticipated. Therefore, a fourth research objective addressing this aspect was added. This refers to whether the app was compared with another measurement instrument, such as a marker-based motion tracking system, regardless of whether the app was validated in the included study or in a previous study. The variables listed in the data chart included information about the authors (first author and year of publication), study design, study aims, population (sample size, age, and gender), name of the smartphone app, assessed MPS, if the app has been validated, and the main findings of the studies. The studies were grouped according to the smartphone app and the MPS studied.



Results

Study Selection

A total of 581 articles were identified by searching the electronic databases. After removing duplicates, 520 (89.4 %) articles were included in the title and abstract screening in ASReview. The number of articles was subsequently reduced to 47 (8.1 %), with 1 article being excluded due to unavailability. Therefore, 46 (7.9 %) articles were included in the full-text screening. On the basis of the full-text screening, a total of 10 (1.7 %) articles were included in this scoping review. A detailed overview of the selection process is shown in Figure 1.

RenderX

Figure 1. Flow diagram of search strategy. Italicized words refer to the selection of separately considered meta-analyses and reviews. AI: artificial intelligence.

Study Characteristics

The included articles were published between 2021 and 2024, with the most articles published in 2022 (n=3) and 2023 (n=4). Four of the studies were conducted in Japan [32-35]. The remaining studies were conducted in Australia [36], Germany [37], Spain [38], the United Kingdom [21], and the United States [39]. One study did not indicate the country in which it was conducted [40]. Research designs of the studies were mainly validation studies (n=5) [21,32,36,37,39], 1 proof-of-concept study [38], 2 cross-sectional studies [34,40], and 2 prospective, observational studies [33,35] (Table 1).

MPS and Smartphone Apps

The following results are presented in accordance with the initial 3 aims of this review and are summarized descriptively to provide an overview of the identified studies (Table 1, Multimedia Appendix 2).

Gait

In the studies included in this review, gait was the most commonly assessed MPS (n=5). Four of the studies used the Three-Dimensional Pose Tracker for Gait Test (TDPT-GT) smartphone app to assess this MPS [32-35]. Aoyagi et al [32] developed the TDPT-GT app to quantitatively assess pathological gait patterns and performed a preliminary validation against a Vicon 3D motion tracking system. The app uses a modified ResNet34 image classification model to detect the coordinates of 24 anatomical key points and calculate the 3D angles of the lumbar, bilateral hip, neck, knee, and ankle joints. To conduct the test, the subjects were instructed to walk in a circle with a diameter of 1 m, both clockwise and counterclockwise [32-35]. The app is capable of reconstructing 3D full-body movements from 2D motion capture data [32].

The other 3 studies examined the gait patterns of idiopathic normal pressure hydrocephalus (iNPH), Parkinson disease, and other neuromuscular diseases, as well as older adults and healthy adults [33-35]. Two studies by Iseki et al [34,35] compared pathological gait patterns with healthy gait patterns.

The final study included in the review used the TDPT-GT app to determine distinct indices for three pathological gait patterns: shuffling gait, wide-based gait, and short-stepped gait [33].

The fifth study developed a new smartphone app for gait assessment and examined the validity and repeatability of the app (the app name was not mentioned) [37]. To test the validity of the smartphone app, a comparison with the GAITRite System was performed. The app includes a series of pose estimation algorithms starting with the Convolutional Pose Machine 25 body joint model, followed by the VNect model and the GASTNet 3D uplifting model, to extract four gait parameters: gait speed, step length, step time, and cadence.

XSL•FO
RenderX

Running

One study developed an unnamed smartphone app that uses the deep learning pose estimation tool BlazePose (MediaPipe framework, Google LLC) to assess running gait in experienced runners [21]. To validate the app, the researchers simultaneously recorded the participants running on a treadmill with an iPhone 13 smartphone camera and a Vicon 3D motion tracking system [21].

Countermovement Jump

The study of Balsalobre-Fernández [38] used the Apple Vision framework (Apple Inc.), integrated into the My Jump Lab app, to assess countermovement jump (CMJ) height. The app was validated by comparing the results from My Jump Lab to those recorded simultaneously using a force plate.

Shoulder Mobility

One study performed shoulder range of motion tests by using the mymobility app, which uses the Apple Vision framework (Apple Inc.) for pose estimation [36]. For validation, participants performed shoulder abduction, adduction, flexion, and extension while being filmed with an iPhone 13s camera, with a sample rate of 30 frames per second, and a marker-based Vicon motion tracking system for comparison.

Functional Movement Test Battery

The study of Fanton et al [39] validated the Amazon Halo Movement app (Amazon Ltd) by comparing it to validated functional movement tests (FMTs) and sensor-collected kinematic variables. The FMT battery of the smartphone app was performed by participants wearing a full-body suit equipped with motion sensors. The app includes 5 FMTs, which are used to assess posture, stability, and mobility (single leg balance, forward lunge, overhead reach, feet together squat, and overhead squat) [39].

Breaststroke

The study of Feng et al [40] used a nonvalidated smartphone app to assess breaststroke technique. The app records the swimmer's movement in the water through a smartphone camera and calculates the angles between the thigh and trunk, thigh and calf, and the trunk and the horizontal plane. The video processing integrated into the app starts with Gaussian filtering, followed by the calculation of gradient amplitude and direction with a Canny operator, double threshold method for edge closure, and, finally, the detection of a straight line by Hough transformation [40].

Population

Most studies used the apps to assess the MPS of healthy adults (n=6) [33,35,36,38,39], 3 studies included athletes (general athletes [39], swimmers [40], and runners [21]), 2 studies included older persons [33,37], and 4 studies included clinical populations, that is, Parkinson disease [34,35], iNPH [33-35], movement impairment [39], and other neuromuscular diseases [34]. One of the studies did not provide any information about their study population [32] (Multimedia Appendix 3).

Synthesis of the Findings

The included studies demonstrate a growing interest in smartphone-based digital assessment tools for MPS, with gait analysis being the most frequently targeted skill, especially in clinical contexts such as Parkinson disease and iNPH (Multimedia Appendix 4). Despite the variety of apps, most tools have been validated through intraclass correlation coefficient or gold standard comparisons such as marker-based 3D motion capture. Deep learning algorithms, particularly modified ResNet34, dominate technical implementation. However, there are clear research gaps: few studies address upper body skills, and most studies focus on adults in controlled settings rather than broader, general-use or preventive contexts. These insights highlight future needs for diversified and validated apps, including those for different target groups (eg, children), and increased attention to real-world usability and accessibility (Table 2).

Meta-Analyses and Reviews

Selection of Meta-Analyses and Reviews

As meta-analyses, scoping reviews, and systematic reviews were not included in the scoping review, they were excluded from the screening process conducted by ASReview and were screened manually (CSZ and CN). A detailed overview of the screening is also found in Figure 1, shown in italics. To gain a more comprehensive understanding of the research field and to provide a basis for discussion, the inclusion criteria were considered more generously here. As a result, reviews were included that consider pose estimation methods without apps or apps that require a human operator to assess MPS.

Findings From Meta-Analyses and Reviews

We did not find any meta-analyses, reviews, or similar studies analyzing video-based motion capture smartphone apps. Using our search terms, we identified 47 meta-analyses and reviews, of which 3 have been included. However, one of the reviews included studies that examined apps that require manual operation, while the others included studies on pose estimation but without the use of smartphone apps. The 3 reviews present the respective findings relevant to specific subareas of video-based motion capture smartphone apps, which justified their inclusion in the evaluation.

The systematic review by Silva et al [41] focused on smartphone apps for capturing strength, power, change of direction, and velocity assessment. The included studies analyzed a total of 11 different smartphone apps, but 10 of them required a human operator to manually perform the assessments. Only the included study by Balsalobre-Fernández et al [42] used a video-based motion capture app (My Lift app). However, the app focused on tracking the barbell used during the snatch motion, rather than on the human movement itself. Nonetheless, this review provides valuable insights for an overview of the research and supports our aim of identifying existing apps, even if most of them require manual operation.

Furthermore, the review by Stenum et al [13] provides a general overview of the research on AI-based human pose estimation and its application in monitoring MPS, but without the use of smartphone apps. This review presents the extensive range of applications for these estimation tools, which are used in monitoring human development, in the motor assessment of neurological diseases, and in performance optimization. The advantages of these tools include a cost-effective and widely accessible alternative to motion capture systems in the laboratory [13].

In light of the growing use of pose estimation software in AI-based smartphone apps, the review by Stenum et al [13] was included to provide a more comprehensive understanding of the field.

Another review examined various technologies for markerless motion capture in combination with pose estimation in clinical surveys [43]. The review included a total of 65 studies, which, in turn, identified 9 different technical devices for markerless motion capture. The 3 most commonly used technologies were the Microsoft Kinect system, cameras such as GoPro, and smartphone video recordings. The review offers a comprehensive overview of the current state of research in this field and highlights the potential of video-based motion capture as a screening tool [43].

Discussion

Principal Findings

Video-based motion capture smartphone apps enable automatic kinematic detection of whole-body and partial-body movements, including motion analysis that can be used in the field with minimal effort and even with large sample sizes. To provide an overview of the current state of research on such smartphone apps, the scoping review had four aims: (1) to summarize existing smartphone apps designed to digitally assess MPS through motion capture, (2) to elucidate the specific MPS that these apps assess, (3) to determine whether these apps have been validated, and (4) to identify the target population of each app.

The findings of this scoping review indicate that there is a variety of smartphone apps that enable the recording and evaluation of MPS through video-based motion capture. Here, “gait” was the most frequently assessed MPS in the included studies, which was mainly recorded using the TDPT-GT app [32-35]. A total of 7 different smartphone apps were used in the aforementioned studies. Six of these apps have already been validated by comparing them with the corresponding gold standard methods. The smartphone apps identified here only include healthy adults, older adults, and individuals with neurological diseases as the target population. Children and adolescents have not yet been the focus of such smartphone apps, but it would be important to develop apps for this target group, for example, to identify motor development disorders in this target group at an early stage to provide appropriate interventions.

As demonstrated by the publication years of the articles, the research field of automatically assessing MPS with the use of video-based smartphone apps is a relatively novel and expanding area. The first publications in this field appeared in 2021 [37].

There are several advantages to assessing MPS through video-based motion capture smartphone apps. One advantage

XSL•FO
RenderX

is that it represents a more cost-effective alternative to laboratory-based systems, such as marker-based 3D motion capture or direct observation by trained professionals and offers the advantage that it can be performed in any location [14,16,17]. Furthermore, the pose estimation software integrated into the app does not require the attachment of markers on the participant, making it less time-consuming than marker-based motion tracking systems [14,17]. Additionally, some groups of people, such as older adults or those with disabilities, may be unable to tolerate the lengthy process of marker attachment and subsequent measurement [35].

These apps offer versatile use in coaching, health and performance monitoring, and scientific research. In scientific research, they can be used to perform testing outside of the laboratory setting and when no expensive motion capture system is available [13]. In the field of health monitoring, these applications would enable the testing of patients at home, as exemplified by the TDPT-GT app [32-35] included in this review. The advantage of testing at home is that patients are not required to visit clinics, physicians' offices, or physiotherapists as frequently [44]. Furthermore, these smartphone apps enable patients to be screened more frequently, which, on the one hand, relieves the burden on physicians and, on the other hand, allows the identification of developmental disorders or other impairments at an earlier stage, thus enabling timely intervention [13]. Additionally, it enables patients to be screened in their everyday environment, which is of great relevance depending on the clinical picture [44]. However, it must be considered that there is a nonnegligible challenge in the use of smartphone apps in epidemiologic health studies, which is the consideration of data sensitivity and privacy issues [45]. These applications often collect and process sensitive health data, which must be protected to ensure participants' privacy. Robust data encryption, secure data storage, and strict access controls are essential to safeguard this information. Furthermore, clear communication with participants about data usage, consent, and their rights is imperative to maintain trust and compliance with data protection regulations. Ensuring these measures are in place will facilitate the ethical and effective use of smartphone apps in health research [45].

In addition to the frequent screening of patients with impairments, the applications can also be used to monitor the athletic performance, as demonstrated in the study of Feng et al [40]. The advantage of the used pose estimation software integrated into the apps is that it enables real-time motion tracking and therefore can provide real-time feedback [13]. This is a valuable addition to the feedback provided by the coach, and it allows for a more frequent performance monitoring, as it enables monitoring during training sessions when the coach is not present. The potential for real-time motion tracking and feedback represents a valuable addition to the field of health monitoring. To ensure these apps deliver reliable and valid results, further development and validation against gold standard methods are essential [13].

Another advantage of using smartphone apps that have integrated AI for pose estimation is that they are less prone to inaccuracies than apps that require an operator to estimate, for example, the start and stop frames of a movement and then set these events manually [41,44].

As the technological revolution progresses, the potential of smartphone apps in scientific research, health monitoring, and athletic performance becomes increasingly evident.

Limitations

Despite the benefits of pose estimation, the following limitations must be considered when using these algorithms. For example, wearing loose clothing, such as dresses, can cause anatomical landmarks to be misidentified or obscured by other parts of the body. Environmental factors, such as lighting conditions, background clutter, or camera positioning, can also significantly affect the accuracy of pose estimation [46]. Variability in these external factors may introduce inconsistencies in results, especially in field-based assessments where standardization is difficult to maintain. It should also be noted that cameras with low sampling rates may not be able to correctly capture fast movements or that the training data used to train the algorithms may be very different from the movements to be analyzed and therefore be prone to error [13]. Another salient problem concerning the training data is that the annotators may lack anatomical knowledge, which can compromise their ability to accurately identify anatomical landmarks. Open-source datasets frequently undergo labeling through the utilization of crowdsourcing methodologies. This method is prone to interindividual variability, as the annotation process is often subjective and may differ between individuals [47,48]. Furthermore, most current pose estimation algorithms are trained on 2D video data, which may introduce inaccuracies when estimating joint angles and body segment orientations in 3D space. While some approaches attempt to reconstruct 3D poses, these are often limited in precision compared to marker-based systems, particularly in complex, multiplanar movements or occluded positions [46]. For these reasons, it is not yet possible to completely replace marker-based 3D motion capture in the laboratory with smartphone apps, but they already enable valid testing and thus facilitate the testing of large sample sizes.

As this scoping review did not aim to evaluate the quality or magnitude of validation outcomes, no conclusions regarding the strength of validity across applications can be drawn.

From a methodological perspective, scoping reviews inherently carry limitations, such as potential selection bias and the lack of critical appraisal. Although we aimed to follow rigorous inclusion criteria, the decision to include or exclude studies may have introduced subjective bias. Furthermore, due to the rapidly evolving nature of pose estimation technologies, it is possible that some recently published or ongoing work was not captured at the time of our review.

Looking forward, we recognize that including articles written in multiple languages could enhance the comprehensiveness of future reviews. By broadening the scope to include non-English studies, we can ensure a more inclusive and thorough understanding of the available research on this topic.

XSL•FO
RenderX

Conclusions

To our knowledge, this is the first scoping review to provide a comprehensive overview of smartphone apps that assess MPS using video-based markerless motion capture. Our findings highlight a growing interest in this cutting-edge field, with a variety of apps already available. These apps demonstrate significant potential across multiple domains, including enhanced monitoring, accurate kinematic measurements, and real-time feedback.

Looking ahead, there is a clear need for the development of more smartphone apps that assess MPS through video-based motion capture. It is crucial that these apps undergo rigorous validation against gold standard systems, such as marker-based 3D motion tracking systems [14,15,49]. Moreover, it is essential to ensure these apps are tested across diverse populations, including children, adolescents, adults, older adults, and individuals with disabilities.

Future research should also explore the integration of these apps with other health monitoring technologies, such as wearable sensors and telehealth platforms, to create comprehensive health management systems. Additionally, leveraging these apps in remote and underserved areas could offer valuable health insights and improve access to medical care. As AI and machine learning continue to advance, the accuracy and functionality of these apps will be further enhanced, solidifying their roles as effective tools for health and performance monitoring.

In summary, video-based markerless motion capture apps on smartphones hold transformative potential for health and performance monitoring. Continued innovation and validation in this field could lead to more accessible, accurate, and comprehensive monitoring systems, thereby facilitating the work of scientists and the development of interventions.

Acknowledgments

The authors would like to thank Dr Janis Fiedler for his assistance in reviewing and refining our search strategy. During the preparation of this work, the authors used DeepL Write to improve the language and readability of the paper. After using this tool or service, the authors reviewed and edited the content as needed and take full responsibility for the content of the publication.

Funding

This work was developed in the research project ”COMO-Study“ (2023-2026). The national study on the impact of the COVID-19 pandemic on the physical and mental health and health behaviors of children and adolescents against the background of socioecological contexts in Germany is funded by the German Federal Ministry of Education and Research (funding reference number: 01UP2222).

Abstract

Background: Effective self-management of type 1 diabetes mellitus (T1DM) by children and adolescents remains challenging despite advances in insulin delivery and glucose monitoring technologies. Mobile health (mHealth) interventions have emerged as promising tools to support pediatric diabetes care. However, their clinical impact and the behavioral mechanisms through which they operate—particularly those grounded in social cognitive theory (SCT)—are not well established.

Objective: This scoping review assesses mHealth apps focused on the management of T1DM in the pediatric population and looks into the underlying behavioral frameworks in accordance with SCT.

Methods: We conducted a scoping review of 5 databases (PubMed, Cochrane Library, EMBASE, CINAHL, and Scopus) for English-language studies published between January 2000 and July 2024. Eligible studies evaluated mHealth apps for children and adolescents with T1DM (≤18 years) and reported outcomes including glycemic control, self-efficacy, adherence, self-management, or quality of life. Data were extracted and synthesized according to clinical outcomes and the presence of SCT constructs, namely self-efficacy, behavioral capability, expectations, reinforcements, and reciprocal determinism.

Results: Of 5607 studies screened, 12 met the inclusion criteria. These comprised 4 randomized controlled trials, 4 pilot studies, 2 pre-post intervention studies, 1 retrospective cohort study, and 1 double crossover trial. App features included glucose logging, insulin tracking, bolus calculators, reminders, gamification, and structured educational content. Hemoglobin A_{1c} (HbA_{1c}) outcomes were reported by 9 studies; 4 demonstrated statistically significant improvements, while the others reported stability or no change. Several studies also reported improvements in treatment adherence and perceived self-efficacy. Of the 12 studies, 11 incorporated at least 1 SCT construct, with most integrating behavioral capability and self-efficacy as core components. Interventions using multiple SCT constructs showed greater promise for supporting sustained behavior change.

Conclusions: mHealth apps for pediatric T1DM are complex behavioral interventions that often leverage key principles of SCT to promote effective self-management. Although the evidence supports modest benefits in glycemic control and behavioral outcomes, heterogeneity in study design and outcome measurement limits broader generalizability. Future research should prioritize the development and evaluation of SCT-informed digital interventions with standardized outcome frameworks to improve pediatric diabetes care.

Introduction

Type 1 diabetes mellitus (T1DM) is a chronic autoimmune condition characterized by the destruction of insulin-producing pancreatic β-cells, leading to insulin deficiency and hyperglycemia. T1DM is among the 5 most common chronic illnesses in children attending school [1]. Findings observed from the SEARCH for Diabetes in Youth study [2] noted the prevalence of T1DM in youth aged 0 years to 19 years increased by 21.1% between 2001 and 2009, with an annual incidence

XSL•FO
RenderX

growth rate of 1.4% reported between 2002 and 2012. This increase was noted across various demographic and ethnic groups.

T1DM management carries a substantial burden—including clinical, cognitive, and psychosocial—for both children and their caregivers, requiring daily insulin administration; frequent blood glucose monitoring; precise dietary management; and ongoing adherence to a structured, health-oriented lifestyle. Advancements in technologies in the treatment of T1DM such as insulin pumps, continuous glucose monitoring (CGM) systems, and intermittently scanned CGM systems have significantly improved patients' metabolic control and, in turn, have helped to mitigate long-term diabetic complications [3].

Despite advances in insulin delivery systems and glucose monitoring technologies, achieving optimal glycemic control continues to rely heavily on effective self-management. Effective management requires strict and sustained discipline in regular glucose monitoring, carbohydrate counting, and adherence to an insulin regimen. This remains a long-term challenge, particularly among children and adolescents as they navigate emerging autonomy in the self-management of their diabetes [4]. With the advent of digital health, patients and health care providers can now leverage digital tools such as video conferencing, mobile health (mHealth) apps, and remote monitoring systems to improve accessibility to consistent health care, revolutionizing the management of T1DM. Recognizing its potential, the American Diabetes Association advocates that telehealth should complement in-person visits to achieve optimal glycemic management [5]. As such, exploring effective and innovative strategies that enhance self-management skills in the pediatric population with T1DM becomes critical. With the rapid advancement of mHealth technologies, mHealth apps have emerged as promising tools to support disease management by children and adolescents with T1DM. These digital interventions integrate features such as real-time reminders, interactive education, gamification, and data sharing to promote treatment adherence and self-management. Although several studies suggest that mHealth apps may improve glycemic control and psychosocial outcomes in pediatric T1DM, the extent and consistency of their clinical and behavioral impact remain unclear.

Social cognitive theory (SCT) [6,7] is a widely applied behavioral framework that explains how individuals acquire and maintain health behaviors through the dynamic interaction of personal factors, behavioral patterns, and environmental influences—a concept known as reciprocal determinism. Key constructs include self-efficacy, behavioral capability, expectations, and reinforcement, all of which are critical to sustaining self-management in chronic conditions such as T1DM. This scoping review aimed to synthesize the current evidence on mHealth interventions for pediatric T1DM, with a focus on their effects on key outcomes including hemoglobin A_{1c} (HbA_{1c}), self-efficacy, treatment adherence, and quality of life. In doing so, we also examined the extent to which SCT constructs are embedded within these interventions to better understand how digital tools are designed to promote behavior change and support sustainable improvements in pediatric diabetes care.

Methods

We conducted our scoping review with reference to the updated Joanna Briggs Institute guidance for scoping reviews. This was also aligned with the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) guidelines for reporting scoping reviews [8]. The review protocol was preregistered on the Open Science Framework.

Data Sources and Search Strategy

We conducted a comprehensive literature search in 5 databases including PubMed, Cochrane Library, EMBASE, CINAHL, and Scopus. A broad search strategy was used and included the following terms as MeSH, EMBASE Subject Headings terms, major headings, or title or abstract keywords: ("diabetes mellitus") AND ("pediatrics" OR "child" OR "adolescent" OR "infant" OR "minor" OR "puberty" OR "schools")) AND ("mobile applications" OR "telemedicine" OR "telehealth" OR "mobile health").

Search results were limited to studies published in English between January 2000 and July 2024. This time frame ensures the inclusion of studies reflecting contemporary technological capabilities and behavioral frameworks relevant to mHealth interventions. The studies were screened and selected by 3 independent reviewers (EB, JL, and GL) and adjudicated by an independent fourth reviewer (DC).

Screening and Data Extraction

We used the web-based software Covidence [9] for title and abstract screening, full-text review, and subsequent data extraction. We extracted the following information about each study: author, year of publication, study design, sample size, type of mHealth intervention, and main outcome findings.

Eligibility Criteria

We included specific study designs such as randomized controlled trials, observational studies, and prospective interventional studies published between January 2000 and July 2024. We focused on studies reporting on the impact of mHealth apps on children and adolescents with T1DM. The definition for a pediatric population in this review was ≤18 years old.

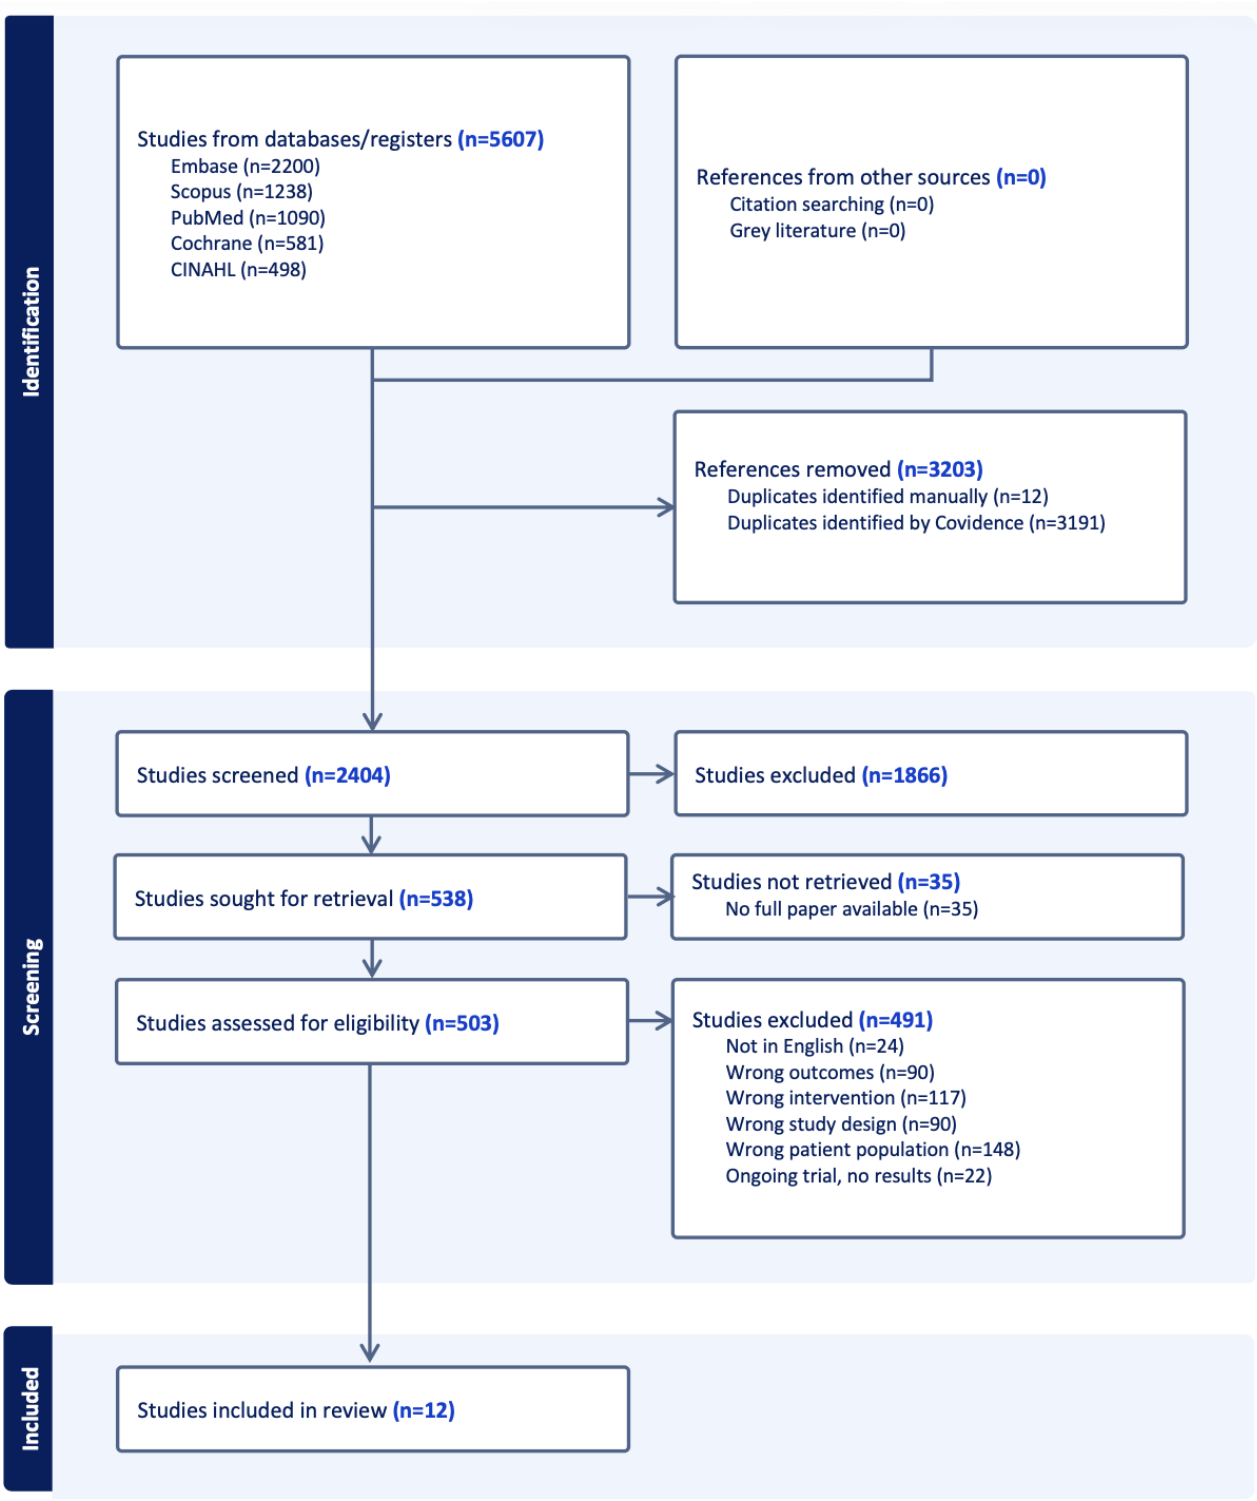
We looked at important outcomes related to T1DM including HbA_{1c}, self-efficacy, adherence to therapy, T1DM self-management skills, and quality of life. T1DM self-management included carbohydrate counting and insulin dosing, treatment of hyperglycemia, and prevention and treatment of hypoglycemia. Quality of life measurements were assessed objectively using validated questionnaires, including items assessing satisfaction with lifestyle, impact on life and relationships, and future concerns.

We excluded feasibility trials, study protocols, design studies, commentaries, case reports, and studies that were not published in English.

XSL•FO
RenderX

Data Synthesis and Analysis

We conducted a thematic analysis using a deductive, semi-iterative approach guided by predefined constructs from SCT. Interventions were categorized and mapped to the 5 core SCT constructs: reciprocal determinism, behavioral capability, reinforcement, expectations, and self-efficacy. This analysis was performed by our team of reviewers independently (EB, JL, GL, PYL, and EJP), with disagreements first discussed and resolved among reviewers followed by further referral for adjudication by DC. We also assessed the reported impact of each intervention on the clinical and behavioral management of pediatric T1DM.



Results

Overview

Our database search, conducted in July 2024, yielded a total of 5607 studies. After removal of duplicates, there were 2404 studies. Through screening of title and abstracts, 1866 papers were excluded. A further 491 studies were excluded after full-text review. The screening and selection process is illustrated in the PRISMA flowchart (Figure 1).

RenderX

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram of study selection for the scoping review on mobile health (mHealth) interventions for pediatric type 1 diabetes mellitus.

We identified a total of 12 suitable studies. Of the 12 papers, 4 were randomized controlled trials, 4 were pilot studies, 2 were pre-post intervention studies, 1 was a retrospective cohort study, and 1 was a randomized double crossover study. Table 1 gives an overview of the included studies. Different diabetes mHealth apps were evaluated across the studies. App features included glucose level recording, insulin dose recording, feedback on glucose measurements, physical activity promotion, daily reminders, educational features, and reward systems. Some apps also combined multiple features on the platform.

[h]QoL quality of life.

[i]Inclusion criterion for the study.

The results for each of the included outcomes are described in the following sections.

HbA_{1c}

HbA_{1c} values as an outcome measure were reported in 9 studies [10,12,14-18,20,21]. In these studies, there were 355 people in the intervention groups and 208 people in the control groups. Significant improvement in HbA_{1c} values (reduced HbA_{1c} values) were reported within the intervention groups in 4 studies (Alfonsi et al [17]: −0.35%, *P*=.03; Klee et al [14]: –0.33%, *P*=.048; Pramanik et al [15]: −0.91%, *P*=.004; Goyal et al [12] −0.58%, *P*=.02). Significant differences were not found in 3 studies [10,16,20]. HbA_{1c} stability in the intervention group (HbA_{1c}: −0.22%, *P*=.26) compared with worsening in the control group (HbA_{1c}:+0.52%, *P*=.02) was reported in 1 study [21].

Holtz et al [18] did not find a significant change in HbA_{1c} levels between the groups; however, a higher use of the mobile app correlated with a greater improvement in HbA_{1c} levels (*P*<.005).

Hypoglycemia

The occurrence of hypoglycemic events as an outcome measure was reported in 3 studies [12,20,21].

Bender et al [20] found a significant difference in the reduction of the time below range between the intervention and control groups at both 6 months (1.2% vs 2.6%, *P*=.02) and 12 months (1% vs 2%, *P*=.05) posttreatment. Klee et al [14] and Goyal et al [12] did not find any significant differences in hypoglycemic events.

Self-Efficacy

Self-efficacy as an outcome measure was reported in 3 studies [13,16,17].

Alfonsi et al [17] reported increased carbohydrate counting accuracy (*P*=.008) and reduced frequency of individual counting errors >10 g (*P*=.047).

Hilliard et al [16] used the Diabetes Strengths and Resilience Measure for Adolescents to assess how often patients engaged in T1DM-related behaviors, but found no significant differences between the groups.

Through a multiple-choice survey designed with a 5-point Likert-type scale, Clifton et al [13] assessed the change in caregivers' knowledge level for T1DM in general, hypoglycemia, hyperglycemia, and diabetic ketoacidosis. They found that 57% (36/63) of the intervention group perceived an increase in diabetes knowledge compared with 39% (16/41) of the control group, though the difference did not reach statistical significance (*P*=.059).

Treatment Adherence

The impact on treatment adherence was evaluated in 4 studies [10,12,18,21].

Holtz et al [18] and Hilliard et al [16] used the Diabetes Behavior Rating Scale, showing significant improvements in diabetes behavior 12 weeks postintervention (*P*=.02 in both studies).

Goyal et al [12] used the Self Care Inventory questionnaire to measure adherence to treatment recommendations but did not find any significant changes in scores. Similarly, Cafazzo et al [10] did not find any significant changes in Self Care Inventory scores but did report a 50% (2.4 to 3.6 per day) increase in the daily average frequency of blood glucose measurements (*P*=.006).

Quality of Life

Quality of life was measured through various questionnaires in 7 studies [10,12,16-19,21]. Alfonsi et al [17], Cafazzo et al [10], and Goyal et al [12] used the Diabetes Quality of Life for Youth questionnaire. Hilliard et al [16] used the Monitoring Individual Needs in Diabetes Youth Questionnaire. Klee et al [14] used the Quality of Life for Youth questionnaire, and Holtz et al [21] used the PedsQl questionnaire. None of the studies found significant differences between the intervention and control groups.

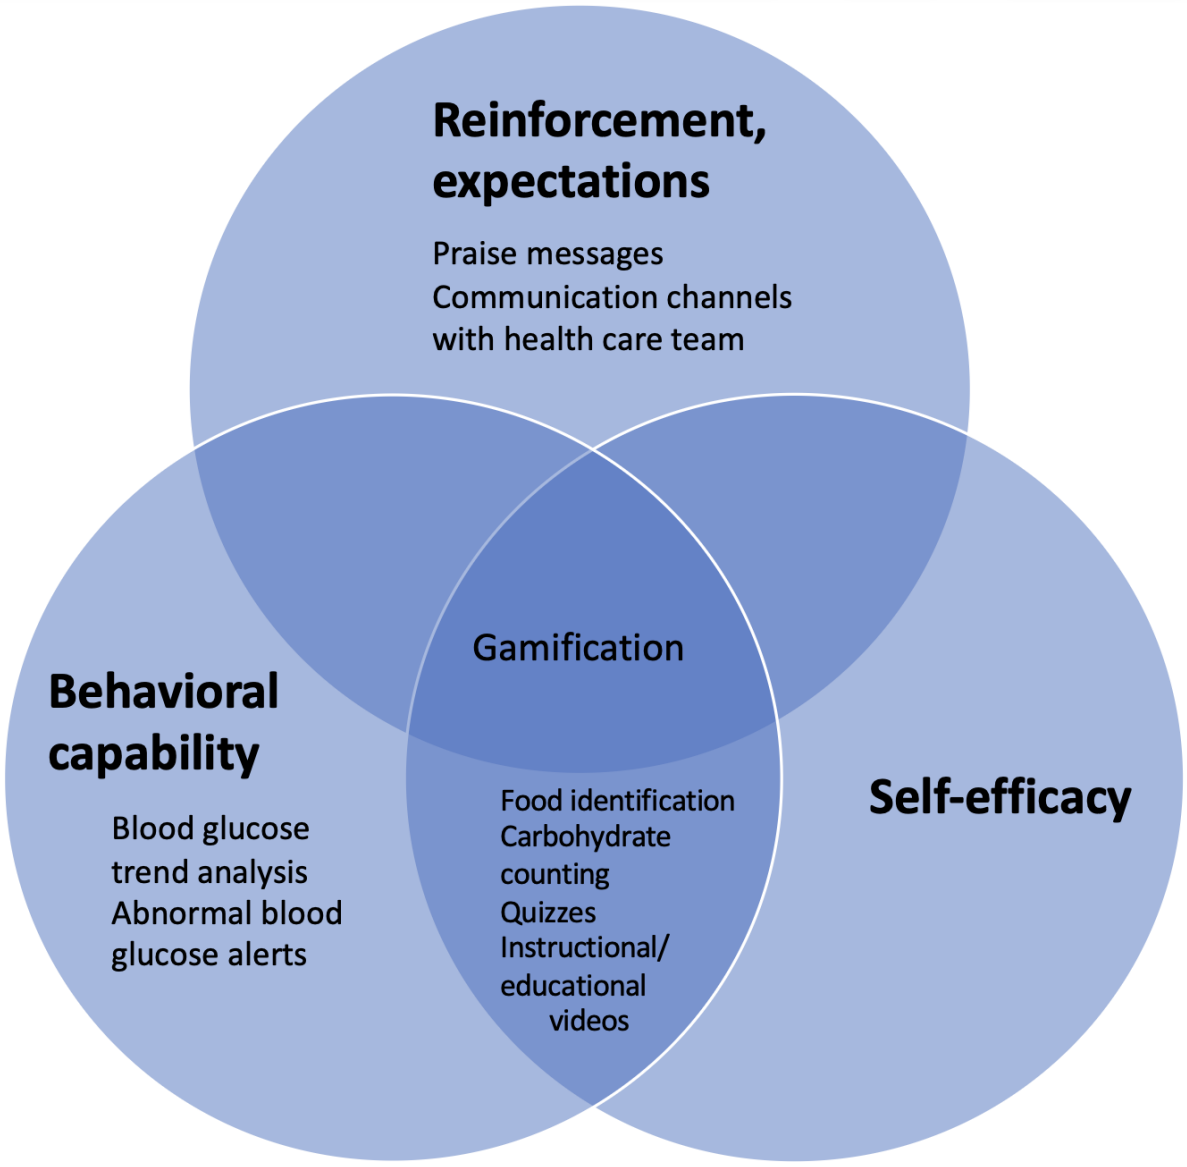
Holtz et al [18] reported significant improvement in quality of life measured via the PedsQoL generic scale (before study:

XSL•FO
RenderX

mean 4.02, SD 0.84; after study: mean 4.27, SD 0.73; t_{24}=2.48, P=.01, d=0.32).

Family Quality of Life and Family Conflict

The impact on quality of life in the family was evaluated in 5 studies [10,12,16,18,21].



Holtz et al [21] used the Impact on Family Scale in their study, showing that parents' perceptions of quality of family life improved significantly for the intervention group (P=.02).

Hilliard et al [16] used the Diabetes Family Impact Scale, Holtz et al [18] used the Revised Diabetes Family Conflict scale, and Cafazzo et al [10] and Goyal et al [12] both used the Diabetes Family Responsibility Questionnaire to examine family conflict and parent-adolescent interaction around diabetes. However, no significant differences between intervention and control groups were found.

SCT Constructs Across the mHealth Apps

All included mHealth apps incorporated at least one SCT construct, with two-thirds of studies using at least 3 constructs within the same app. Among the individual SCT constructs, behavioral capability and self-efficacy were the most frequently used, appearing in 11 of the 12 included mHealth apps. Many of the apps had various tools: DigiBete [19] had the ability to store insulin ratios/doses and pump settings and guidance videos on the administration of injections, while WebDia [14] had a bolus calculator function with a section centered on carbohydrate estimation with pictorial assistance. In the iSpy study [17], the use of a mobile app designed to assist youth with T1DM with counting carbohydrates made food identification through images possible. Figure 2 illustrates the key features of the mHealth apps and their associated SCT construct(s).

Figure 2. Mapping of mobile health (mHealth) app features to core constructs of social cognitive theory in pediatric type 1 diabetes management.

Gamified features were used within the mHealth apps in 5 studies [10,11,18,20,21]. The Bant app [12] in particular was designed with a rewards algorithm that allocated game-like experience points for adherence to blood glucose testing with bonus points and level-ups awarded accordingly. A total of 161 rewards (an average of 8 rewards each) were distributed to

XSL•FO
RenderX

participants based on their frequency of blood glucose measurement, with 50% (10/20) of participants collecting more than 10 awards. The use of gamification and rewards encouraged adherence and reinforced positive health behavior.

The majority of the studies provided educational modules to participants, thereby enhancing their behavioral capability. Alfonsi et al [17] and Klee et al [14] focused on nutrition with food identification and carbohydrate counting, while other studies [11-13,19] included analysis of blood glucose trends and awareness of hypoglycemia and hyperglycemia. Some studies also included educational materials regarding insulin storage, calculation, and administration. The DigiBete [19] and Sten-O Starter [20] apps also made use of quizzes to help users consolidate their learning and understanding of their own condition, with awards for completion that allowed for positive reinforcement.

Intervention Engagement and User Analytics

Hilliard et al [16] reported parental use of the app for an average of 106.1 (SD 37.1) days over the 3-month study period, with parents logging in 1 or more times a day on 80% of the days. Alfonsi et al [17] reported 43% (9/21) of iSpy participants were still engaged (medium to high users) at the end of the study. Both noted high app acceptability ratings among their participants pertaining to usefulness, ease of use, and learning on the app.

Kime et al [19] reported an average of 4.4 videos viewed per app user. Uniquely, their app allowed for communication and interactions with health care professionals. It was noted that more than one-half of health care professionals surveyed (99/178, 55.6%) reported that they frequently or very frequently sent out information and news to support their patients and families via the clinic portal in the app.

Holtz et al [18] reported an average number of 63 (SD 27.7) days of app use, with 84% (21/25) of the participants having use in the medium or high use categories over the 90-day study period. Linear regression analysis demonstrated a significant effect between the overall use of the app and improvement in HbA_{1c} levels ($F_{1,20}$=9.74, P<.005; R^2=0.33).

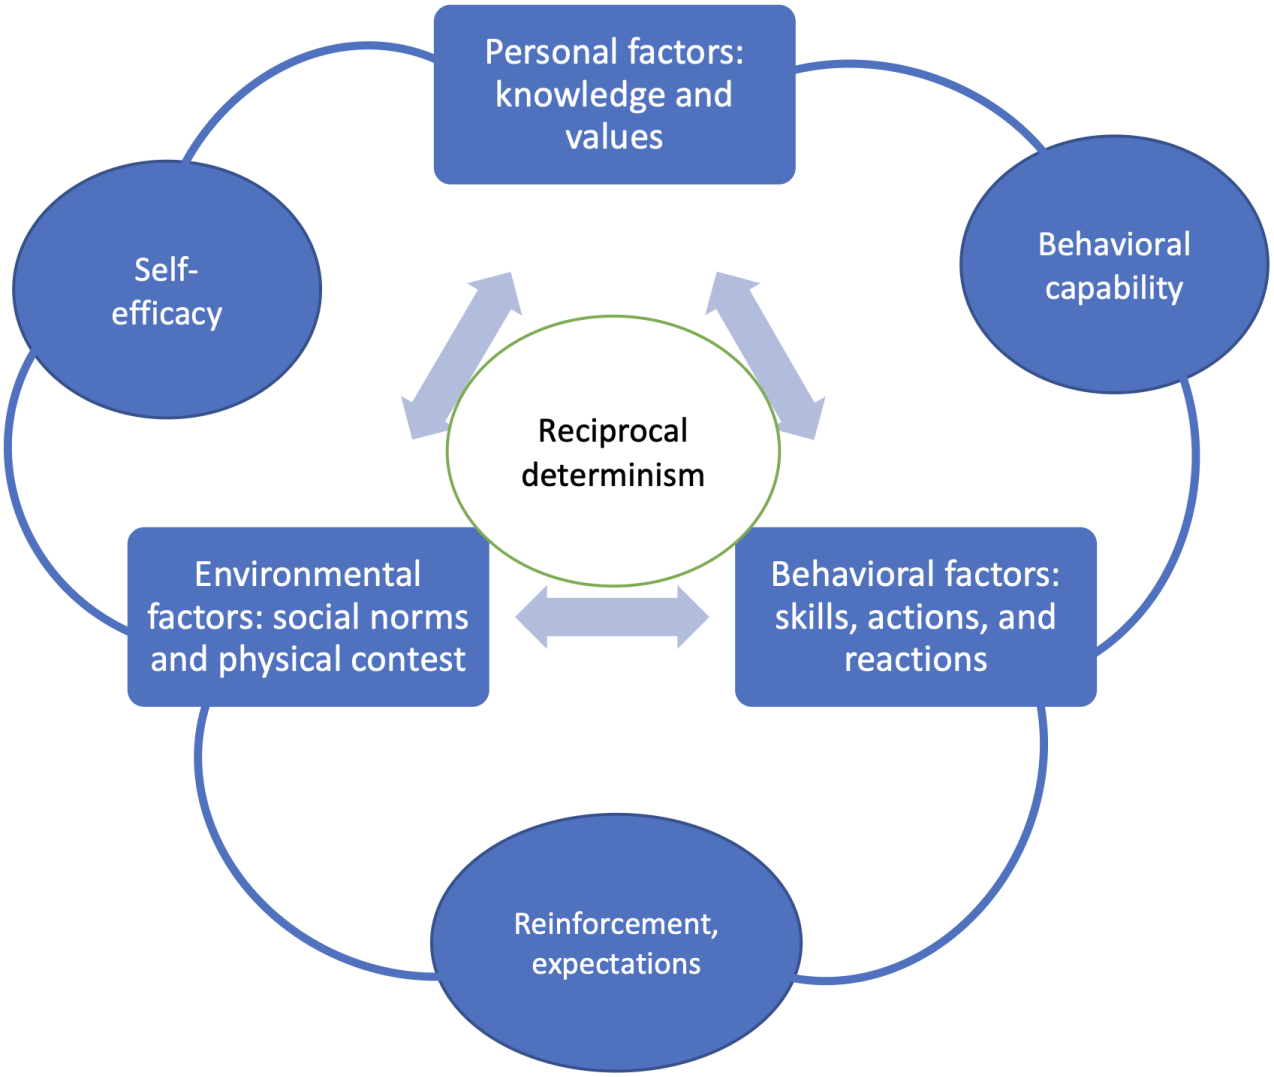
Klee et al [14] shared that 80% (27/33) of participants reported using Webdia daily. However, the subgroup analysis showed that frequency of app use did not influence the effect of intervention, although overall results showed a significant difference in the decrease in HbA_{1c} between intervention and control groups.

Goyal et al [12] reported 35% (16/46) of the participants were moderately or highly engaged users (uploaded self-monitored blood glucose [SMBG] concentrations ≥3 days a week) over the 12-month period. Exploratory regression analysis demonstrated a statistically significant association between increased SMBG and improved HbA_{1c} in the intervention group. For a subgroup of users with SMBG≥5 times daily, there was a significant improvement in HbA_{1c} of 0.58% (P=.02) compared with the parallel control subgroup who did not have a significant HbA_{1c} change.

Holtz et al [21] reported an average of 23.3 (SD 16.44) days of parental app use and 57.72 (SD 25.4) days of adolescent app use over the 12-week study period. However, they did not identify any correlation between adolescents' use days and HbA_{1c} levels.

Of the studies, 4 [11,13,15,20] did not report any usage data, as these were either interventions implemented within the health care setting or they were not included as a studied outcome.

Discussion



Principal Findings

We performed a scoping review to examine mHealth apps focused on the management of T1DM in the pediatric population, looking into their effects on clinical and patient-related outcomes, as well as examining the underlying behavioral frameworks informed by SCT. To our knowledge, no review has been conducted in the past decade to specifically examine pediatric digital health interventions for T1DM, with the most recent being published by Blake et al [22] in 2015. Although recent meta-analyses and umbrella reviews have evaluated mHealth interventions for diabetes [23,24], these reviews have primarily addressed adult populations or mixed-age cohorts, with limited focus on pediatric-specific outcomes. However, children and adolescents with T1DM face distinct developmental and psychosocial challenges that may influence both the design and effectiveness of digital interventions. Although Trnka et al [25] focused on categorizing coaching-based mHealth technologies for pediatric T1DM, our review builds on this by systematically evaluating a broader range of interventions, with specific attention to clinical outcomes such as HbA_{1c} and hypoglycemia, as well as behavioral outcomes including treatment adherence and self-efficacy. Furthermore, we uniquely analyzed the theoretical foundations of these interventions, drawing on constructs from SCT to elucidate the behavioral mechanisms underlying their impact.

The results of our study suggest that mHealth apps for children and adolescents with T1DM are complex interventions grounded in multiple constructs of SCT. A widely used framework in behavioral interventions [26], SCT [27] explains how behaviors are learned within a social context (Figure 3). This process is grounded in the interplay of personal factors, environmental influences, and behavior itself—a concept known as reciprocal determinism. Key constructs of SCT include (1) self-efficacy (belief in one's ability to succeed), (2) behavioral capability (knowledge and skills to perform a behavior), (3) expectations (anticipated outcomes), and (4) reinforcements (responses that influence behavior recurrence) [6].

XSL•FO
RenderX

Figure 3. Triadic reciprocal causation and key elements of social cognitive theory.

For reciprocal determinism, SCT proposes that behavior is influenced by 3 interlocking factors: personal, behavioral, and environmental factors [28]. Behavior is influenced by a continuous interaction between personal factors, environmental factors, and behavior itself.

Behavioral capability refers to an individual's ability to perform a behavior, thus relying on their knowledge and skills [28]. The individual then learns from the consequences of their behavior.

Internal and external responses to a person's behavior then positively or negatively reinforce the behavior. Expectations refer to the anticipated consequences one has of their behavior.

Self-efficacy refers to the level of a person's confidence in their ability to successfully perform a behavior [29]. It is influenced by an individual's own capabilities and environmental factors.

Impact of mHealth on Clinical Outcomes in Pediatric T1DM

Glucose Control

mHealth apps for children and adolescents with T1DM could help improve glycemic control to varying degrees. Among the included studies, some mHealth apps were reported to significantly reduce HbA_{1c} over the course of exposure to the intervention, while others kept HbA_{1c} levels stable as opposed to control groups. This is consistent with observations in previous evidence, with umbrella reviews by Wang et al [24] and Kitsiou et al [23] showing pooled favorable effects of mHealth interventions on HbA_{1c}, at least in the short term. This is a notable observation, as there are unique challenges for maintaining glycemic control in the pediatric population, ranging from hormonal fluctuations, conflicting academic commitments, and struggles with the growing responsibility of diabetes management to the impact of family and peer pressure [30]. Given the pervasiveness of smartphone use even among children and youths today [31], mHealth apps could potentially help by improving self-management ability and health literacy of children and adolescents, which tend to be poorer than that in adults [32], allowing for better treatment adherence and glycemic control. However, one should approach the matter with cautious optimism, as the effectiveness of mHealth apps remains heterogeneous across different studies and its sustained benefits in the long term remain unknown.

XSL•FO
RenderX

Educational Value and Treatment Adherence

mHealth apps can be of educational value by providing structured education that is easily accessible to patients and may facilitate improvement in communication between health care providers and patients, to align treatment steps and goals [33]. Many studies highlighted the usefulness of digital health interventions for improving patients' and their families' knowledge of their disease. From the DigiBete study [19], children and families with T1DM felt that the app was helpful for navigating the large volume of information available on T1DM and allowed them to retrieve information on T1DM readily. Of health care professionals, 83.7% (149/178) believed that the DigiBete app helped patients manage their T1DM better. Our findings corroborate with a previous cross-sectional study that found that educating children with T1DM and their parents regarding major complications of T1DM increased overall adherence to treatment and decreased their HbA_{1c} levels [34].

Family Interaction and Quality of Life

Studies have found that mHealth apps have the potential to improve family interactions as well as patients' and family members' perception of their quality of life. The MyT1DMHero app [18] linked adolescents with T1DM to their parents through two separate interfaces, allowing parents to establish a blood glucose testing schedule on the app so that the child could follow the schedule accordingly and update their blood glucose readings. Parents and children could send each other preprogrammed messages within the app to facilitate positive communication as well. The Type 1 Doing Well app [16], aimed at promoting supportive family diabetes management, allows parents to record positive T1DM-related actions that their child engaged in every day; ratings would be summarized and presented as a strengths summary for each family. There were multiple positive comments from families who felt that the app allowed them to generate a calmer atmosphere at home and helped adolescents feel that their efforts were recognized. Many of these apps, such as Webdia [14] and iSpy [17], received good feedback but did not show statistically significant differences in the quality of life from baseline and at postintervention. T1DM management can be particularly challenging for families, as it requires teamwork between parents and child [35] and conflicts can be common [36,37]. Ineffective communication can lead to youths feeling unsupported. mHealth technology offers a promising avenue to make behavioral interventions for family diabetes management more accessible [38,39]. The extent to which family dynamics and glycemic management are correlated is currently unknown, but the accumulated knowledge within a family has also been shown to have positive effects on glycemic management [40]. These studies show that, although mHealth apps are promising avenues to better improve family interactions and quality of life, more robust evidence is still required.

SCT and its Application to mHealth

The majority of studies used at least 3 SCT constructs within the same app. This underscores the complex interplay between these elements, as they do not function in isolation but could reinforce one another in the design of mHealth apps and driving behavioral change. For instance, building behavioral capability such as equipping children with essential self-care skills could enhance self-efficacy [41], which in turn can strengthen expectations of improved health outcomes [42]. Similarly, reinforcements, such as gamified incentives, have been shown to sustain engagement while bolstering productivity and self-efficacy in pediatric T1DM management through tangible progress [43]. These combinations of constructs align with current taxonomies of the ideal app for people with diabetes [44], including tips and support, rewards, and reminders. Consequently, the dynamic interaction between these constructs also mirror reciprocal determinism, where personal confidence, environmental support (eg, caregiver involvement, app-based reminders), and self-management behaviors continuously influence one another [45].

Among individual SCT constructs, behavioral capability and self-efficacy were the most frequently used. Their prevalence reflects the emphasis of mHealth interventions on fostering self-management, which is in keeping with existing knowledge on the clinical efficacy of self-monitoring as a behavioral change technique in the management of diabetes [46]. This focus on self-management is particularly crucial in the management of diabetes in pediatric populations, where competency in self-care skills (from diet, exercise, and treatment adherence,to monitoring) from early in the life course could go a long way in supporting healthy growth and prevent the development of potentially debilitating complications [47,48]. mHealth interventions could help equip children with the necessary skills and reinforce long-term self-care behaviors while instilling confidence in their ability to manage their condition [49,50]. The spotlight cast on patient self-management also aligns with a broader shift toward patient empowerment, balancing autonomy with structured caregiver and health care provider support.

In this review, studies that used gamification and improved T1DM self-management demonstrated significant differences in clinical outcomes. The use of graphics, aesthetically colorful images, and avatars are important elements in mHealth apps that can make the apps more appealing to use and better engage children and adolescents. Gamification leverages SCT by incorporating its core constructs. For example, completing levels in a game and earning rewards build mastery, provide motivation, and boost self-efficacy. Gamification also works through positive reinforcement using points or social comparisons where users are rewarded for their performance and the relevance of their achievements are recognized on the gaming platform [51].

Intervention Engagement

A key functionality of mHealth in clinical practice is improving clinical outcomes through behavior change and enhancement of patient adherence and treatment compliance. More frequent engagement is generally associated with improved treatment adherence or self-management [33].

Participant engagement and retention continue to be fundamental challenges for mHealth app studies [52]. Similarly, 2 of the included studies [17,18] reported initial high levels of usage followed by decreasing levels over time. This could be attributed to the "novelty effect" [53], whereby participants are more

XSL•FO
RenderX

motivated to good performance when an experience is new to them. Additional feedback given for the mHealth apps included the lack of personalization [16], need for repeated manual entries [12,14], and requiring a secondary mobile or supplementary device [12].

Several studies [12,14,18] that reported data on user engagement noted medium to high usage levels; however, this did not necessarily translate to improved clinical outcomes. To examine the reasons for this gap, we considered research design and participant factors. Regarding the participant factors, the quantity of use might not reflect the quality of use. A user's degree of engagement is influenced by the depth of the individual's investment in the interaction with the digital tool, and this investment may be defined temporally, affectively, and/or cognitively [54]. Hence, current engagement measures are not able to fully detail user characteristics and their interactions with the app platform. For research design factors, there is a lack of standardized classification for user engagement. Studies tended to focus on a limited number of indicators of engagement, leading to obscuration of more complex patterns and posing a challenge for the generalizability of findings [55]. To address these factors, Shani et al [55] proposed an organizing framework to guide the measurement, reporting, and interpretation of engagement in digital intervention research. They suggested the conceptualization of digital interventions as a collection of stimuli (such as notifications and reminders) and tasks (such as opening the mobile app and practicing a relaxation technique) and considering user engagement with digital interventions as a continuous process. Moving forward, the adoption of such a standardized framework would be useful for measuring, reporting, and interpreting user engagement with digital interventions.

mHealth in the Changing Landscape of T1DM Management

There have been transformative advances in technologies to support T1DM management including CGM devices, insulin pumps, and automated insulin delivery systems. There have been significant improvements in both glycemic control and quality of life measures for those who have integrated the use of these technologies into care of their diabetes [56].

Fang et al [57] reported a substantial increase in the use of CGM and insulin pumps among youths. However, the lowest rates of diabetes technology uptake and poorest glycemic control were observed among Hispanic, non-Hispanic Black, and state-insured youths and adults, and these disparities have persisted or even widened over time. Racial, ethnic, and socioeconomic disparities in access to diabetes technology have been identified as common barriers to uptake of diabetes technology in several studies [58-60]. This has also been compounded by individual-level barriers such as physical interferences from the device and body image concerns [61]. Studies [62,63] examining the psychosocial barriers to the uptake of diabetes technology have also highlighted varied user experiences with technical failures, fear of device dependence, and uncertainty of device accuracy. Diabetes care then defers back to SMBG and multiple daily insulin injections. Although CGM and insulin pump technologies are increasingly regarded as the standard of care in contemporary T1DM management, digital health interventions remain as both a valuable and accessible adjunct for individuals who either choose to delay the adoption of these technologies or simply lack access due to psychosocial or socioeconomic barriers. Such tools can still potentially support essential self-management behaviors including carbohydrate counting, insulin logging, and structured education. They could also play a complementary role in addressing educational, behavioral, and psychosocial needs that may not be the primary objective of these technologies.

Proprietary CGM manufacturers feature mobile apps that provide real-time glucose monitoring, trend alerts, and data sharing. Nonetheless, third-party apps such as mySugr and Glucose Buddy remain highly rated apps [64,65] on various mobile operating systems. Zivkovic et al [66] investigated the impact of transitioning from SMBG to CGM alongside the use of a mHealth app, mySugr, on users' glycemic control. They found that this transition significantly improved glycemic control in terms of glucose variability and mean glucose levels. There remains an extensive selection of third-party apps catering to the various needs of those with T1DM, with features supporting data tracking, data analysis, food insights, and motivational support either in the form of online communities or chatbots. mHealth apps offer the potential of an integrated platform for seamless pairing with CGM sensors and devices while providing opportunity for real-time feedback, timely intervention, communication support (with family, health care providers, user community), and education about T1DM.

Strengths and Limitations

This scoping review possesses several methodological and conceptual strengths. First, it represents the most up-to-date synthesis specifically focused on mHealth interventions for pediatric T1DM, addressing a critical evidence gap in the digital health literature. Unlike prior reviews that aggregated data across broader or mixed populations, this review targets children and adolescents—a group with unique behavioral, cognitive, and developmental needs that warrant tailored intervention strategies. The next notable strength lies in our use of deductive thematic analysis guided by an underpinning conceptual framework based on SCT. Intervention components were systematically mapped to key SCT constructs—self-efficacy, behavioral capability, reinforcement, expectations, and reciprocal determinism—allowing for an in-depth exploration of how behavioral change mechanisms are embedded in mHealth design. This theory-driven approach moves beyond descriptive synthesis to offer explanatory insight into how and why mHealth tools may support effective self-management in pediatric T1DM. Finally, by evaluating both clinical outcomes (such as HbA_{1c} and hypoglycemia) and behavioral outcomes (such as treatment adherence, self-efficacy, and quality of life), this review provides a comprehensive and translational understanding of the impact of mHealth interventions. The findings offer valuable guidance for the development and refinement of future digital health strategies that are both evidence-based and behaviorally grounded.

However, we do acknowledge that several limitations should be considered when interpreting the findings of this review.

XSL•FO
RenderX

First, the overall number of eligible studies was limited, and many were studies with small sample sizes and short follow-up durations. This limits the statistical power and generalizability of the reported outcomes, particularly with respect to long-term clinical effectiveness. Next, due to the limited availability of high-quality randomized controlled trials, we included a range of nonrandomized study designs. Although this approach aligns with scoping review methodology and allows for broader coverage of real-world evidence, it introduces inherent risks of bias and limits the ability to draw causal inferences regarding intervention effectiveness. Third, there was substantial heterogeneity in outcome reporting across studies. Clinical and behavioral endpoints—such as HbA_{1c}, adherence, and quality of life—were assessed using a variety of instruments, often with differing definitions, scales, or time points. This lack of standardization hinders direct comparisons across studies and precludes meta-analytic synthesis. Another notable limitation was the lack of inclusion of youths with T1DM as members of our research team to co-design the methodology of our work. Their lived experiences would also have provided deeper insights into contextualizing our findings and direct applicability of digital health. Using the key findings from this paper, our study team aims to involve children and young persons living with diabetes in subsequent qualitative and mixed methods studies examining the role of digital health interventions in both their lives as well as their families.

Conclusion

In conclusion, mHealth apps for children and adolescents with T1DM are complex behavioral interventions that often incorporate multiple constructs from SCT. Current evidence suggests that these interventions may contribute to improved glycemic control, with several studies reporting stability or reductions in HbA_{1c} relative to control groups. Although the evidence base is heterogeneous, mHealth interventions show potential benefits across a range of behavioral and psychosocial outcomes, including self-efficacy, treatment adherence, quality of life, hypoglycemia management, and family dynamics. To strengthen the evidence and guide future implementation, further research is needed, using standardized outcome measures and robust methodological designs to better understand how theory-informed digital tools influence self-management and holistic well-being in pediatric T1DM.

Abstract

Background: College-aged students face persistent academic and social stress that adversely affects their mental and physical health. Digital phenotyping with wearable devices enables real-time stress monitoring from continuous physiological signals, supporting just-in-time therapeutic interventions to improve student well-being. Despite rapid advances in wearables and analytical methods, it remains unclear which devices, physiological signals, and machine learning or deep learning approaches are most commonly used for stress detection in this population.

Objective: This study aimed to systematically review the literature to identify best practices and emerging trends in stress measurement using wearable technology and digital tools among college-aged students. We sought to evaluate commonalities in sensor types, datasets, and machine learning approaches used for stress detection.

Methods: A systematic search was conducted across medical and computer science databases, including Embase, PubMed, IEEE Xplore, and ACM Digital Library, for studies published between January 2020 and December 2025. Studies were included if they examined psychological stress detection using wearable or digital tools among college-aged students and were excluded if they focused on nonpsychological stress, were reviews or prototypes without a defined study population, or lacked clear population information. Two reviewers independently screened studies and extracted data on the wearable sensors, physiological signals, datasets, and modeling approaches to summarize trends in stress prediction.

Results: A total of 134 studies met the inclusion criteria and were included in the review from the original 792 papers. Electrodermal activity was the most frequently used physiological signal, appearing in 57.5% (n=77) of studies, and wrist-worn wearable devices were the predominant sensing modality. Among studies that compared algorithms, support vector machines were identified as the most commonly applied and best-performing model in 33.3% (n=45) of cases. Overall, 62.8% (n=84) of included studies relied on preexisting datasets, and approximately 80% (n=67) of those used the Wearable Stress and Affect Detection dataset, which contains only 15 participants. Demographic reporting was inconsistent, as 27.6% (n=37) of studies did not report sex distribution, and only 4 studies justified the sample size. The use of temporal modeling algorithms was limited, despite their importance for capturing the dynamic, time-varying nature of stress. This review highlights persistent gaps and underscores the need for more diverse datasets and advanced modeling approaches to improve stress detection accuracy.

Conclusions: Our review innovatively synthesizes wearable-based stress detection research focused on college-aged students. Unlike prior reviews that aggregate heterogeneous populations or focus primarily on algorithmic performance, this review focused on wearable sensors, physiological signals, modeling approaches, and methodological quality to identify persistent gaps limiting real-world deployment. These findings inform the development of more generalizable monitoring systems to support early mental health intervention in students.

Introduction

With the widespread adoption of wearable devices, numerous stress monitoring frameworks have been designed specifically for undergraduate students [1-3], given their heightened susceptibility to psychological stress. This need is underscored by findings that over 80% of undergraduate students report experiencing significant stress related to their academic life [4]. University life can be particularly overwhelming, as many students experience independent living for the first time while navigating self-care and decision-making [5]. While positive stress can sometimes enhance academic performance, persistent and long-lasting chronic stress can negatively impact both mental and physical health [6]. By proactively managing stress, individuals can mitigate the risk of stress-related health issues, including cardiovascular problems, gastrointestinal issues, mental health disorders, substance abuse, and chronic diseases such as diabetes or hypertension [7]. Stress also significantly disrupts sleep [8], social interactions [9], and academic performance [10], contributing to insomnia [11], anxiety [12], and a weakened immune system [13]. Digital phenotyping of stress, leveraging wearable and mobile technologies, enables just-in-time stress management solutions that help prevent chronic stress from compromising long-term health.

In recent years, the use of consumer wearables to monitor physical activity [14] and other lifestyle traits [15] has become more prevalent. For example, many commercial consumer wearables are being used to keep track of and improve upon fitness regimens [16]. With this increased availability of wearables comes the possibility for real-time health management using these commercial devices that are more convenient and lightweight [17]. The use of wearables to passively monitor physiological signals and the subsequent analysis using various machine learning and deep learning models brings enormous benefits for health management [18]. By passively tracking heart rate (HR) or heart rate variability (HRV), skin temperature, electrodermal activity (EDA), electroencephalogram, electrocardiogram (ECG), acceleration, and other physiological variables, smartphones and wearable sensors can provide features related to signs indicative of poor mental health [19]. Stress is reflected in the body with increased EDA or HR, reflecting the autonomic nervous system and hypothalamic-pituitary-adrenal axis activity [20]. Many studies have tracked these biosignals with commercial digital tools to build models to measure stress [21]. In this review, we examine the trends in the current use of these digital tools to measure stress.

Stress assessment using wearable and digital technologies has been conducted across both controlled laboratory experiments and real-world, free-living conditions. In laboratory settings, studies commonly use well-established stress elicitation tasks [22] with resting periods used as baselines. Commonly used tasks include the Trier Social Stress Test (TSST), mental arithmetic tasks [23] (eg, the Montreal Imaging Stress Task [24]), the Stroop color-word test, public speaking, startle response tests, cold pressor tests, and stress-inducing video stimuli [25]. Across these studies, researchers used varying combinations of physiological signals and derived diverse feature sets following preprocessing steps such as artifact removal, signal normalization, and feature selection [26]. In contrast, stress monitoring in free-living environments relies on self-reported stress measures alongside passive and unobtrusive sensing approaches that capture daily physiological and behavioral patterns using wearable devices and smartphones [27]. These approaches vary widely in sensor availability, feature extraction methods, and contextual information, leading to substantial heterogeneity in how stress is represented and quantified across wearables and digital tools.

Alongside variability in study design, stress capture methods, and physiological sensing, approaches for stress prediction differ markedly across studies. Both traditional machine learning [28,29] and deep learning [30,31] models have been applied to physiological time-series data to identify stress episodes and enable just-in-time interventions. However, it remains unclear which modeling paradigms are most appropriate for different physiological signals and smartphone-derived active and passive sensing data, how model architectures should be designed to capture temporal stress dynamics, and whether increased model complexity consistently yields performance gains. These methodological challenges hinder the translation of wearable-based stress detection systems into practical tools for continuous monitoring and personalized support in college-aged populations, underscoring the need for systematic evidence synthesis and clearer methodological pathways for future research.

This review aims to identify trends in current research and highlight areas for improvement that future researchers should focus on. There is a need to understand which algorithms perform best, which wearables are most used, and which signals are most informative. The topic of this review is identifying moments of high stress using digital tools and ubiquitous data in college-aged students. We examine both machine learning and deep learning advancements in the field, as well as comparisons of methods, where a scoping review is the most appropriate synthesis method to address the stated objectives. Our population of interest includes college students aged 18 - 24 years. Publication dates of interest include conference and journal papers published between 2020 and 2025, as we focus on advancements in the field, including newer wearable devices and algorithms. We are also narrowing our focus to college students, as university is a particularly stressful place where their health and lifestyle habits are likely to fluctuate [32]. Academic stress is directly linked to health crises such as anxiety and depression, indicating an opportunity to monitor stress and prevent health from deteriorating [33]. In this scoping review, we summarize the wearables used, signals measured, and algorithms performed to measure stress. We then discuss trends in data and practices across papers. We conduct a quality assessment of all included studies. We also provide an overview of the results and a discussion of limitations and future possibilities for stress measurement. As a result, this scoping review aims to synthesize recent research on wearable or digital tool–based stress detection among college-aged students by summarizing the sensing technologies used, the physiological and behavioral signals measured, the machine learning and deep learning models applied, and key methodological practices, to

XSL•FO
RenderX

identify current trends, limitations, and directions for future research.

Methods

Overview

We conducted a scoping review to characterize current research on stress detection using wearable and digital tools among college-aged students. This review synthesizes studies published between January 2020 and December 2025 to summarize commonly used wearable devices, physiological signals, datasets, and machine learning or deep learning approaches for identifying high-stress moments. By organizing existing methods and conducting a quality assessment, this review provides an overview of methodological practices and highlights areas for future research in wearable-based stress measurement. This scoping review adhered to the methodological framework proposed by Arksey and O'Malley [34], which includes identifying the research question, identifying relevant studies, study selection, charting the data, and collating, summarizing, and reporting the results. Finally, this scoping review was conducted and reported in accordance with the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) guidelines to ensure transparency and reproducibility [35].

Protocol and Registration

No formal review protocol was registered for this scoping review, as the objective was to map the scope and characteristics of existing evidence in stress prediction research using wearable technology.

Eligibility Criteria

We defined eligibility criteria to ensure that only relevant and methodologically appropriate studies were included in this review. Studies were included if they measured or classified psychological stress using physiological signals from a tool, wearable, or sensor. Only experimental or observational studies published in English were considered. The target population was college students aged 18 - 24 years. Studies that partially included this age range were eligible if they explicitly mentioned students as a distinct group or if the mean age, along with the SD, fell within the target population. Studies were excluded if they focused on nonpsychological stress (eg, mechanical stress), were review papers, extended abstracts, or prototype descriptions without a defined study population. Papers without clear population details or those identifying participants solely by employment (eg, "office workers" or "hospitalized patients") were also excluded.

Information Sources

We searched IEEE Xplore, ACM Digital Library, PubMed, and Embase for conference and journal papers covering studies published between January 2020 and December 2025, a time frame selected to capture recent developments in wearable sensing technologies and stress detection methodologies.

Search

We used a combination of terms related to the key concepts of psychological stress, wearable devices, and sensors (full search per database is provided in Multimedia Appendix 1). We extracted each database searched and the platform used, including IEEE Xplore, ACM Digital Library, PubMed, and Embase, in accordance with PRISMA-S (PRISMA literature search extension) [36], and all databases were searched independently rather than through a multidatabase platform. No multidatabase searching or study registry searching was conducted. No additional online resources (eg, tables of contents, print conference proceedings, and websites) were browsed. No additional search methods were used, including citation searching, contacting authors or experts, or setting up citation alerts. The full search strategies for each database are provided in Multimedia Appendix 1, including the specification that no filters or limits other than language (English) and publication date (January 2020 to December 2025) were applied. Search strategies were developed with input from 2 academic librarians; however, search strategies from prior reviews were not reused, and no formal peer review of the search strategy was conducted. No additional methods were used to update the search. Therefore, searches were limited to studies published in English within the specified date range. No restrictions were applied based on study design. All retrieved records were initially screened. Following screening, records were imported into Rayyan (Rayyan Systems Inc) [37], where duplicate entries were identified and removed. The deduplicated set of records was then used for abstract and full-text screening.

Selection of Sources of Evidence

Two independent reviewers screened all records using a 2-stage selection process. Studies were checked for eligibility by 2 reviewers independently screening titles and abstracts. This first round of filtering focused on relevance. Abstracts were also screened for population. Some papers did not mention population in the abstract and were thus moved to full-text screening. This resulted in 261 papers for full-text screening. During this second round of filtering, studies were also checked for eligibility by 2 researchers independently reviewing the full text. Disagreements at any stage of eligibility and filtering were resolved by the 2 reviewers discussing their reasons for either inclusion, exclusion, or neither. Full agreement was reached for abstract and full-text screening, leading to the final inclusion of 134 papers.

Data Charting

A standardized data-charting form was jointly developed by 2 reviewers to identify and extract relevant information aligned with the review objectives. The form was pilot-tested on a subset of included studies and refined iteratively to ensure completeness and consistency. Two reviewers independently charted data from all eligible studies, compared their entries, and resolved discrepancies through discussion. All data were extracted directly from the published papers, and no additional information was sought from study authors.

XSL•FO
RenderX

Data Items

To extract consistent information from each paper, we conducted systematic data extraction as outlined in Tables 1-3. Extracted variables included study details (title, authors, publication date, study purpose, and data collection duration), sample characteristics (age, sex, sample size, and demographic information), sensor type, and all available feature categories used in the study (sleep, physiological signals, calorie intake or expenditure, phone use, activity, location, and survey or EMA data). For studies conducting algorithm comparisons, we additionally extracted the types of signals analyzed, devices used, algorithms tested, performance measures, best-performing algorithm, validation strategy, and outcome measures.

Table . Details for studies testing or comparing their own framework or conducting statistical analyses.

Study	Device used	Features used	Algorithm analysis	Performance measure	Results	Validation
Faro and Giordano [39]	ECG[a] wearable and wearable body sensor network	HR[b], activity, time, and location	ANN[c] and SOM[d] for proposed framework	Classification tool	Model successful	Train/test split
Faro et al [40]	ECG wearable and wearable body sensor network	HR	SOFM[e]	—[f]	Defined as accurate enough	Train/test split
Li and Sano [45]	Wrist	SC[g], TEMP[h], and ACC[i]	L2 and 1-norm regularized multitask least squares regression	Mean squared error and MAE[j]	Early fusion better	Train/test split
Cheadle et al [46]	SAM[k] activity wearable, EDA[l] sensor, and Empatica E4	EDA[l]	Linear regression	Statistical correlation	Support prior findings that perceived microaggressive discrimination increases negative emotion	—
Chen et al [47]	Personalized system and surveys	Survey questions	Proposed framework	MAE	—	—
Gupta et al [48]	RespiBAN and Empatica E4	ECG, EMG[m], TEMP, RESP[n], BVP[o], EDA, and ACC	CNN[p] and k-medoid clustering	Accuracy and execution time	Success	4-fold CV[q]
Azgomi et al [51]	Affectiva Q Curve and Nonin Wireless WristOx2 oximeter	SC, TEMP, ACC, HR, and blood oxygenation	Bayesian filtering with an expectation maximization (EM)	*t* test comparison	Success	—
Wu et al [53]	Wrist and smartphone	EDA, PPG[r], TEMP, and ACC	Proposed framework and SVM[s]	Accuracy	Framework proposed	5-fold CV
Jelsma et al [54]	Wrist-worn EDA sensor, Empatica E4, and smartphone	EDA	Econometric fixed-effects with robust SE regression approach	Statistical analyses	—	—
Lai et al [55]	Wearable body sensor network	TEMP and EDA	Proposed framework with Res-TCN[t] classifier	Accuracy	High accuracy	LOOCV[u]
Li and Sano [57]	Wrist	TEMP, SC, and ACC	MTL[v] linear regression model and k-means clustering for the proposed framework	MSE[w] and MAE	The framework can extract features better than feature crafting or static autoencoders, and temporal features demonstrated significantly higher precision than static and crafted features.	4-fold CV
Gil-Martin et al [59]	RespiBAN and Empatica E4	ACC, TEMP, RESP, ECG, EMG, EDA, and BVP	CNN	Accuracy and F_1	—	LOOCV
Han et al [60]	Wrist	EDA, TEMP, ACC, HR, and blood oxygenation	Adversarial networks and transfer learning	Accuracy	Disentangled adversarial transfer learning framework	LOOCV
Momeni et al [62]	Biopac system	ECG, RESP, PPG, and EDA	XGBoost[x] algorithm	Accuracy and F_1	—	Group Shuffle Split CV with 10 iterations.
Rashid et al [63]	Wrist-based PPG sensor	BVP	CNN	Accuracy and F_1	Success	LOOCV

Study	Device used	Features used	Algorithm analysis	Performance measure	Results	Validation
Vos et al [29]	Empatica E4, Mobi, and RespiBAN	EDA, HRV, ECG, ACC, EDA, ST, HR, SPO2[ar], ACC, BVP, IBI[as], EMG, and RESP	RF, SVM, ANN, and XGBoost	Accuracy, precision, recall, and F_1-score	An ensemble ML[at] model trained on a synthesized multidataset to improve the generalization of prediction.	LOSO
Darwish et al [82]	Fitbit Sense 2, Flowtime, Movesense, Prana, and Sentio Solutions Feel Terapeutics	ECG, EDA, and RESP	RF, XGBoost, KNN, LR, DT, AdaBoost, Extra Trees, Bagging classifier, LDA, and QDA[au]	Accuracy, precision, recall, and F_1-score	Validated multimodal wearable data in controlled (WESAD)[av] and real-life (SWEET)[aw] datasets for binary and 5-class stress detection.	CV
Bloomfield et al [3]	Oura Ring	Sleep, surveys, ACC, HR, HRV, and RESP	Mixed-effects regression models	Coefficient and *P* value	Used sleep estimates from wearables in the prediction of perceived stress.	—
Nazeer et al [84]	Customized proposed STRESSCARE and stress detection sensor	ECG, EDA, BVP, EMG, TEMP, and sweat	XGBoost, DT, RF, and SVM	Accuracy and F_1-score	Wrist-worn sensors (2-class and 3-class) prediction model performed worse than chest sensors (2-class).	Exploring various combinations of input sensor data.
Xuanzhi et al [88]	Empatica E4 and RespiBAN	EDA and HRV	Attention mechanism-based XLNet model, BrainNet, Xception, EfficientNetB4, VGG19, ResNet-50, MobileNet, and InceptionV3	Accuracy, recall, precision, and F_1-score	Proposed attention mechanism-based XLNet model for continuous stress monitoring.	Train/test split and CV
Vidal et al [89]	Actigraphy	Sleep duration and self-reports on stress and sleep	Individual-level linear model with a Bayesian framework	Bayesian metrics (pd, UIs, ROPE, ESS, and R-hat)	Negative associations between sleep duration and perceived stress in participants.	Stable estimates of lead-lag associations.
Tazarv et al [91]	Samsung Galaxy Gear Sport	PPG, ACC, GYR[ax], and atmospheric pressure	SVM, XGBoost, and RF with a context-aware Deep Q-Network (DQN)	Recall	A model with a context-aware active learning strategy for fine-grained, personalized stress detection worked with fewer queries.	LOSO
Ganesan et al [97]	Empatica E4	ACC, PPG, ECG, EMG, EDA, RESP, and TEMP	DNN and 1D-CNN	ROC-AUC[ay], F_1-score, accuracy, latency, and memory	An optimized, cost-effective, real-time, and energy-efficient DNN model demonstrated superior performance.	—

[br]RMSE: root mean squared error.

Critical Appraisal of Individual Sources of Evidence

Although critical appraisal is not required for scoping reviews, we conducted an assessment of study quality to better contextualize the strengths and limitations of the included evidence. To address the quality of each paper, we scored every paper across 4 categories on a scale from 0 to 2 as described in Multimedia Appendix 2 and shown in Multimedia Appendix 3. Given the diverse study designs among the extracted papers, we adopted a methodology similar to that used by De Angel et al [155]. This approach integrates the AXIS appraisal tool [156] for cross-sectional studies with the Newcastle-Ottawa Scale [157] for longitudinal studies. Papers were assessed using a 3-point scoring system: 2 points for fully meeting the criteria, 1 point for partial fulfillment, and 0 points for nonfulfillment.

Effect measures extracted from the included studies consisted of accuracy, F_1-score, sensitivity, specificity, precision, recall, and other performance metrics reported for stress detection. These measures were used to compare model performance across studies. For population characteristics, the mean age and corresponding SDs were extracted whenever available.

Synthesis of Results

Due to differences in study designs, methodologies, and outcome reporting, results were synthesized descriptively. Key study characteristics, signals measured, algorithms used, and sensor types were organized into structured tables to enable comparison across studies. Frequencies of the most commonly measured signals, best-performing algorithms, and most-used sensors were calculated and visualized using bar plots. Missing summary statistics were extracted as reported, with no additional transformations applied. No meta-analysis, subgroup analysis, or meta-regression was conducted; instead, the synthesis focused on identifying overarching trends across the included studies. Because the focus of this review was to characterize stress detection methods used among college-aged populations, we extracted data elements that were directly relevant to the review objectives, including participant characteristics, sensor types, physiological signals, analytical methods, and model performance outcomes. Broader intervention-related data items (eg, intervention protocols, adverse event reporting, and clinical outcome metrics) did not apply to the observational and experimental studies included in this review. Therefore, the extraction approach was intentionally streamlined to ensure consistency, interpretability, and comparability across heterogeneous study designs. In addition, we developed an evidence gap map to conceptually organize and summarize the literature across study conditions, methodological enablers, analytical approaches, barriers, and outcomes, highlighting recurring patterns as well as persistent gaps, following a prior standardized method [158].

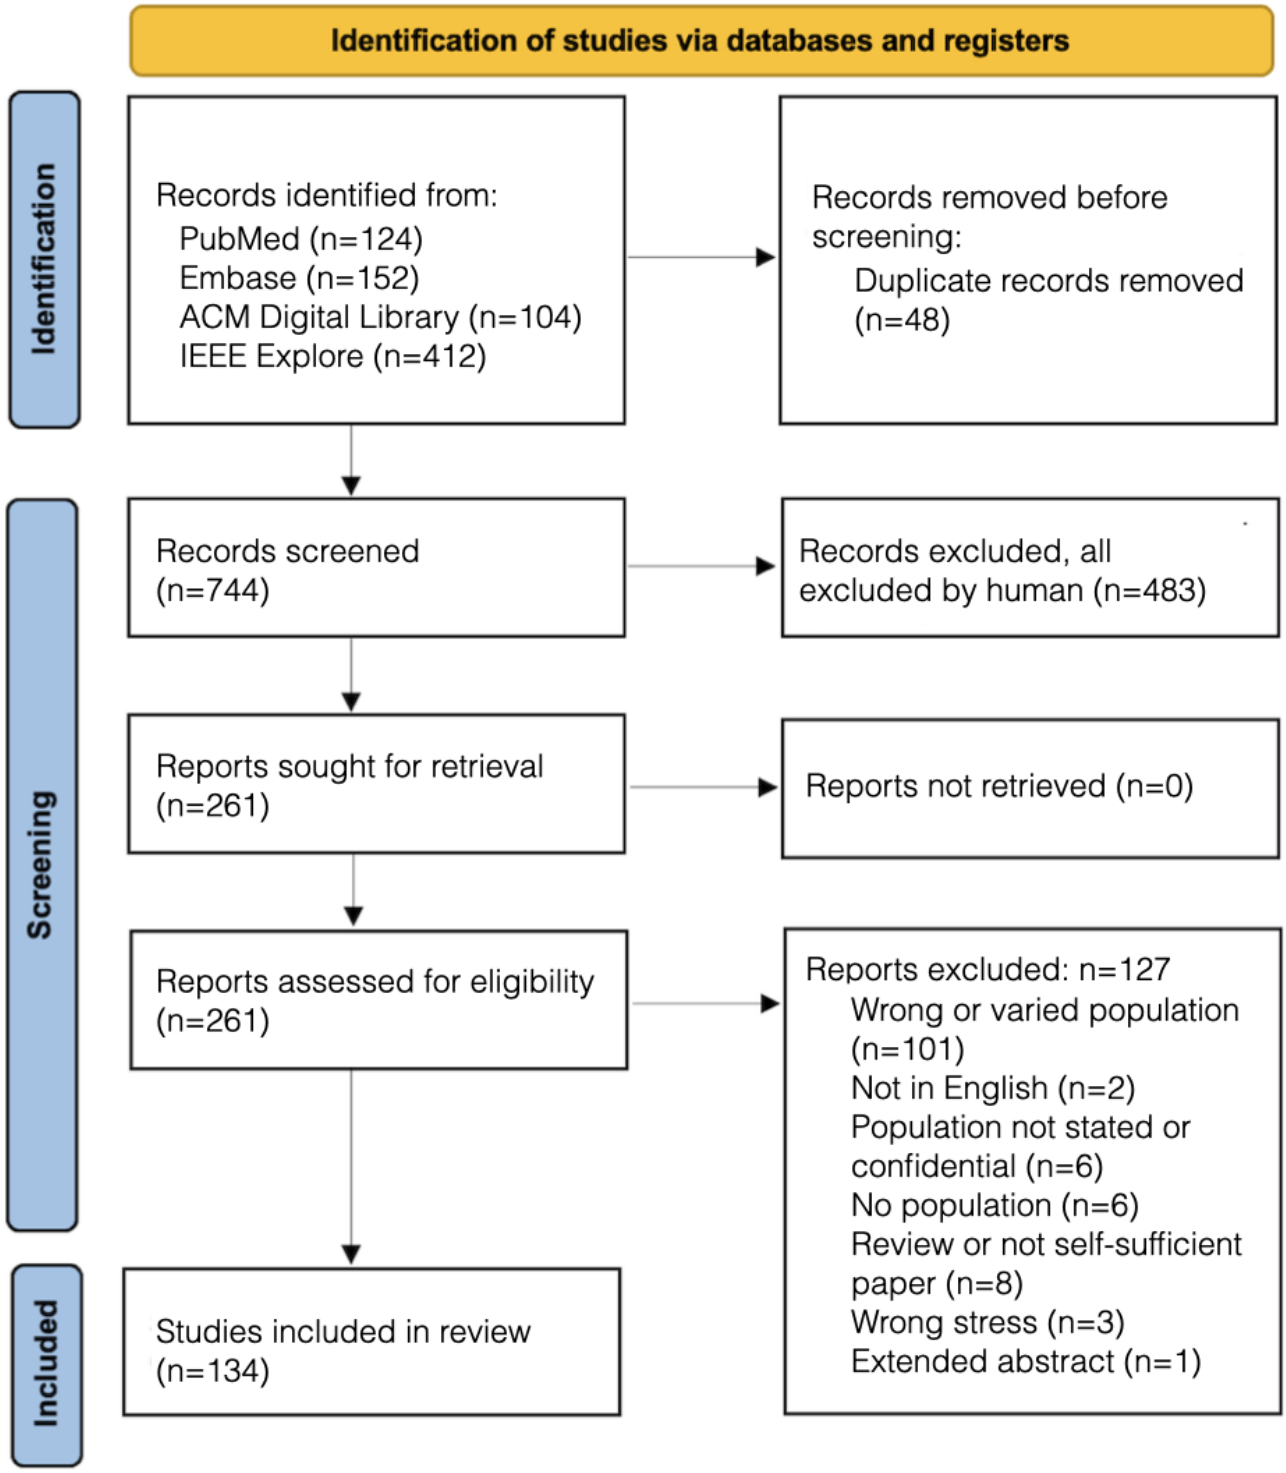
Ethical Considerations

This study is a systematic review of previously published literature and did not involve the collection of primary data from human participants. No new data were generated, and no individuals were directly recruited, observed, or intervened upon as part of this research. Accordingly, a formal review by an Institutional Review Board or Research Ethics Board was not sought. This determination is consistent with standard guidance that systematic reviews relying exclusively on publicly available,

XSL•FO
RenderX

previously published data do not constitute human participant research requiring ethics board oversight.

All included studies were previously published in peer-reviewed journals and were assumed to have undergone appropriate ethical review by their respective authors and institutions before publication. No personally identifiable information was accessed, extracted, or reported at any stage of this review. The conduct of this review adhered to the ethical principles outlined in the World Medical Association Declaration of Helsinki and complied with applicable institutional, regional, and international standards for research integrity.



Results

Selection of Sources of Evidence

Records were screened from IEEE Xplore, ACM Digital Library, Embase, and PubMed, with most records coming from technical journals. A total of 134 studies were included in the review out of the original 792 records, as illustrated in Figure 1 and Multimedia Appendix 4. Forty-eight records were removed after deduplication. Of the remaining records, 483 were excluded after 744 abstracts were screened for relevance. In total, 127 records were excluded after 261 full texts were screened for relevance and correct population. Summary characteristics of the final 134 included studies are provided in Figure 1 and Table 1.

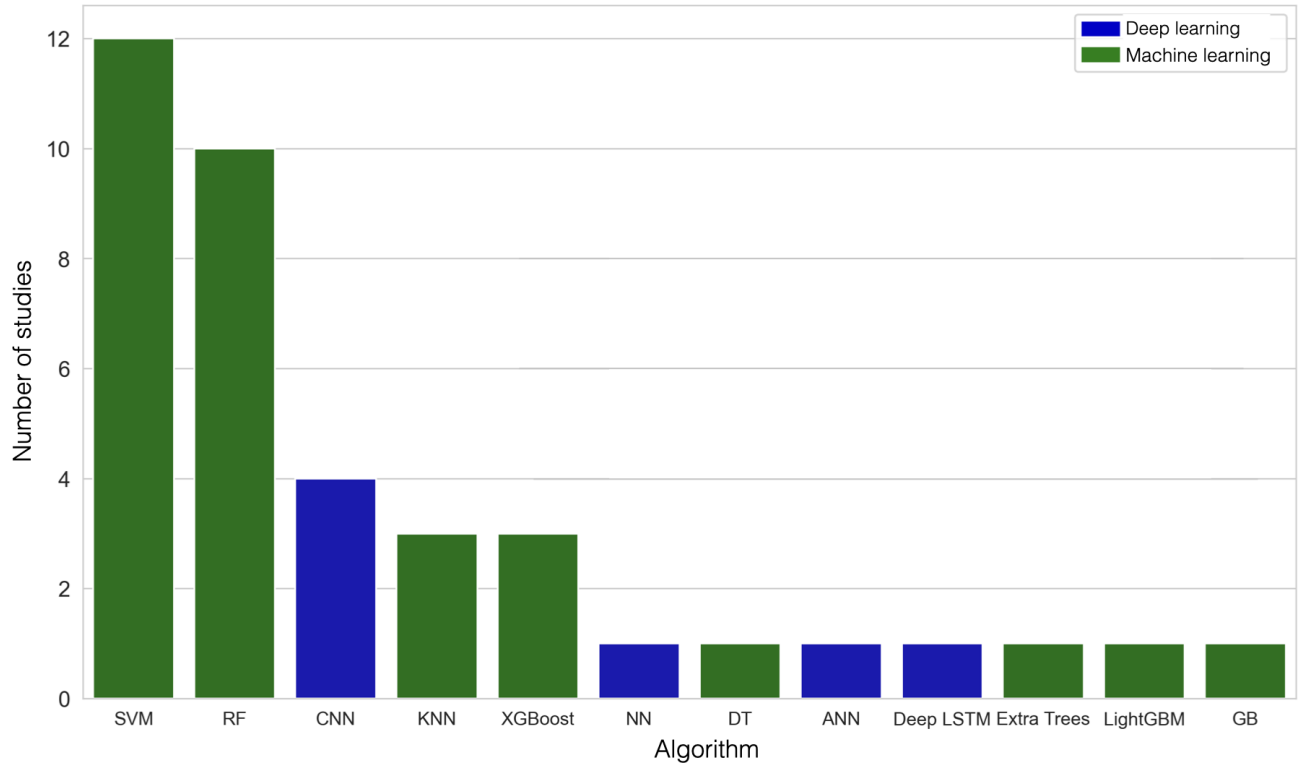
Demographic and Geographic Characteristics of Included Studies

Our population of interest included college-aged students aged 18 - 24 years. In terms of sex demographics, about 72.4% (97/134) of studies specified the number of participants who were male, female, or nonbinary. Among the selected studies, 2 of 134 (1.5%) studies [39,137] failed to mention a sample size. Across the studies that reported sex distribution, most had a higher proportion of male participants than female, indicating a demographic imbalance that may limit the generalizability of findings. In terms of racial demographics, in 42 papers published from 2020 to 2022, about 9.5% (n=13) of papers included race distribution across their sample population, and 21 (50%) studies included other relevant health information, including preexisting conditions, mental health, and underlying illnesses. From papers published from 2020 to 2025, 26 (19.4%) studies were conducted in Europe, 14 (10.4%) studies were conducted in Asia, 2 (1.5%) studies were conducted in the Middle East, 21 (15.7%) studies were conducted in the United States, 3 (2.2%) studies were conducted in South America, and other studies did not explicitly mention where they were conducted. The higher

XSL•FO
RenderX

number of studies conducted in Europe and the United States compared to Asia and other regions suggests regional variations in digital health adoption, research funding, and accessibility of wearable technologies. These differences may influence trends in stress detection research, highlighting the need for region-specific digital health strategies to address varying technological infrastructures, health care priorities, and user needs.



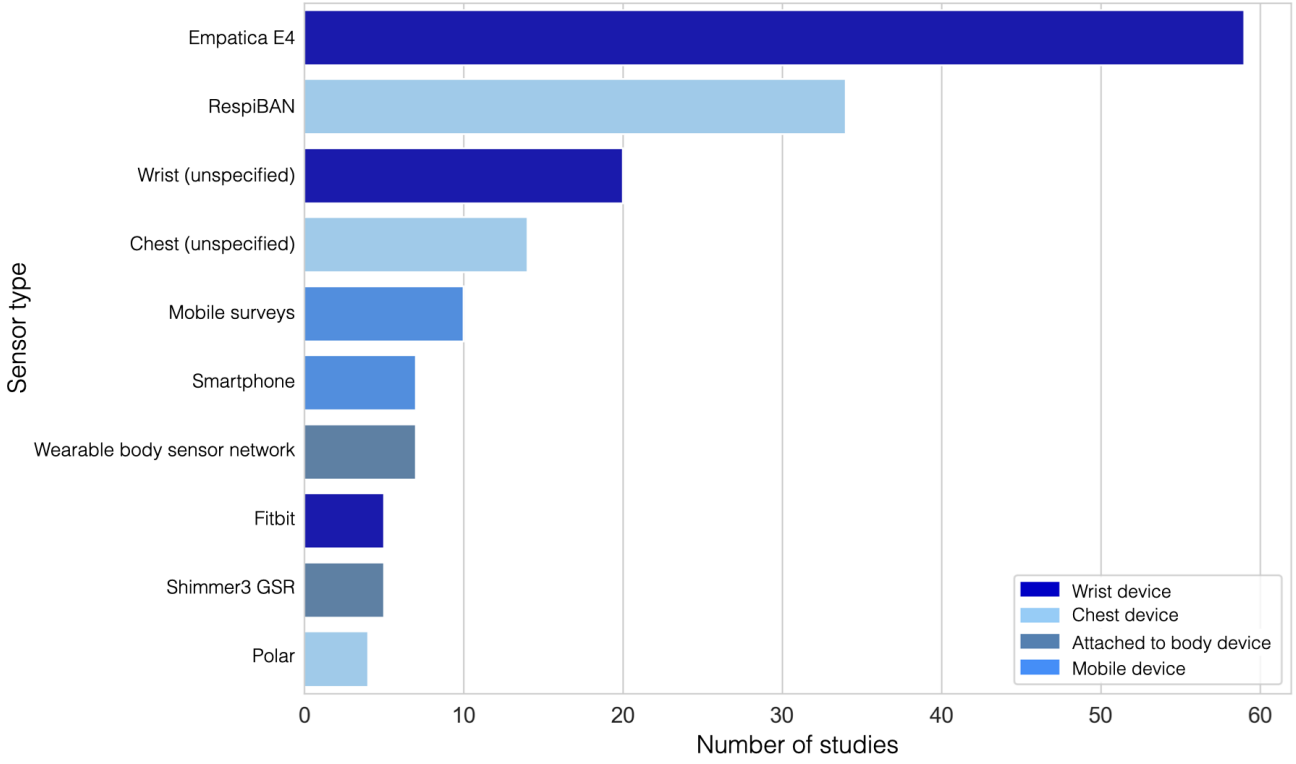
Study Design and Data Collection Characteristics

More than half (62.8%, n=134) of the studies used preexisting datasets to implement their method of stress measurement. The rest of the studies were experimental in nature and carried out "de novo" data collection. Seventeen studies [32,45,46,54,57,61,65,72,73] were longitudinal in nature, published from 2020 to 2022, and 10 studies [3,76,82,89,91,95,99,105,152,154] were longitudinal in nature, published from 2023 to 2025, meaning data were collected for the same study population over a period rather than collected at one time point cross-sectionally. These longitudinal data consist of repeated observations at the individual level rather than data collected at multiple time points across different populations. Individual-level effects are confounded with cohort effects in cross-sectional studies, so being able to isolate and study the effect of time as a repeated measure is critical. Of these longitudinal studies published from 2020 to 2022, 2 were clear in addressing how they handled missing data. These studies either imputed missing values with each person's channel-wise mean values of the day, where days with >25% sensor data missing were discarded [45], or removed missing data [57]. It is difficult to collect comprehensive, complete data from sensors longitudinally, where data are not always complete for each participant. About 6.6% (n=9) of studies included a recruitment method for participants. Two studies used volunteers, and 1 study invited participants to participate.

Approaches in Stress Detection Research

The extracted studies were classified into 3 primary methodological categories: algorithm comparisons (shown in Table 2), the development of custom stress measurement frameworks, and statistical analyses (illustrated in Table 3). Studies focusing on algorithm comparison primarily used 2 approaches: machine learning models, such as support vector machines (SVMs), random forest (RF), k-nearest neighbors, and extreme gradient boosting (XGBoost), which used handcrafted features for stress detection, or deep learning methods, such as convolutional neural networks (CNNs), to automatically extract relevant features [159]. Among the studies reviewed, SVM demonstrated the highest performance, with 33.3% (n=45) of papers identifying it as the best-performing algorithm, as illustrated in Figure 2. In comparison, 11.1% (n=15) of the studies reported CNN as the best-performing model [50,58,67,103]. One study evaluated 3 boosting algorithms—XGBoost, Light Gradient Boosting Machine, and CatBoost—tree-based ensemble methods that iteratively improve weak learners to enhance classification, evaluating the effectiveness of data fusion methods [115].

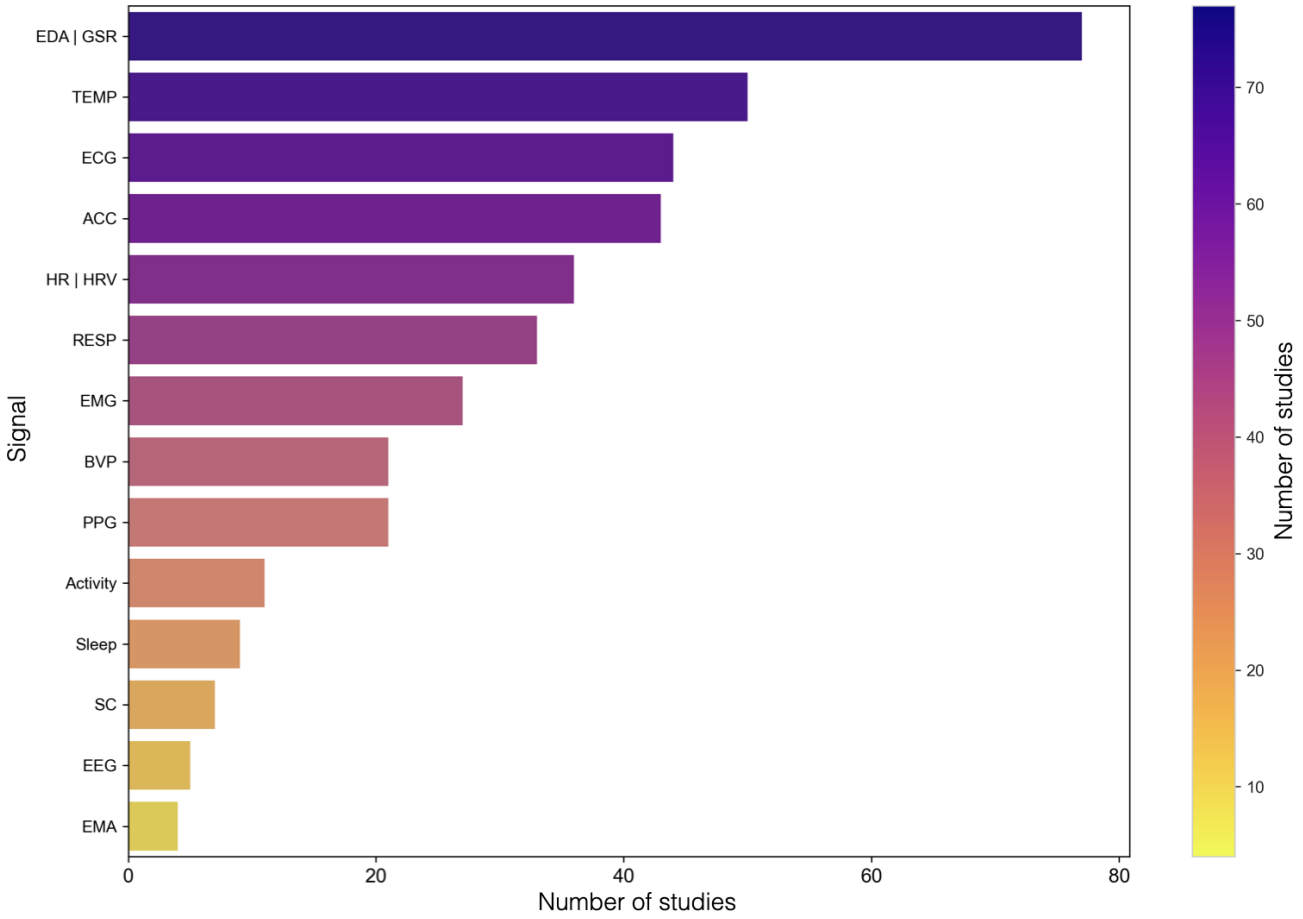
Figure 2. Best-performing algorithms across 36 studies comparing established methods. ANN: artificial neural network, CNN: convolutional neural network, DT: decision trees, Extra Trees: extremely randomized trees, GB: gradient boosting, KNN: k-nearest neighbor, LightGBM: light gradient boosting machine, LSTM: deep long short-term memory, NN: neural network, RF: random forest, SVM: support vector machine, XGBoost: extreme gradient boosting.



One paper [31] focused on comparing long short-term memory (LSTM) and a combination of LSTM and CNN. This study found LSTM alone to perform better. Two studies in Table 3 that focused on a single framework supported the use of a single

XSL•FO
RenderX

modality or a modest set of signals [66,69]. Studies that focused on the comparison of chest and wearable devices found chest devices to perform better [84,109], but chest devices in combination with wrist devices performed the best [71]. Most of these studies focused on time-agnostic algorithms, as shown in Table 2. We also found studies using wrist wearables (eg, Empatica, Microsoft Smartband 2, Fitbit Charge 2, and Samsung Galaxy Gear Sport Watches) and chest-worn devices, with core physiological signals such as EDA, galvanic skin response, HR, photoplethysmography, HRV, respiration, or temperature, evaluated using k-fold cross-validation, leave-one-out cross-validation, or leave-one-subject-out evaluation, and reported performance metrics such as F_1-score, accuracy, precision, and recall. In the "best" column, classic machine learning models were most often SVM, followed by RF, while deep learning wins were fewer (occasional CNN, deep neural network, and a single LSTM). Few studies in Table 2 incorporated nonphysiological or contextual signals [61,72,73]. Recent studies examining the association between sleep and stress have leveraged data from the Oura Ring [3,99]. Two recent studies using Garmin smartwatch–derived stress scores found significant associations with high- and moderate-intensity positive mood in 1 study [154], while another reported a stronger association of HR with self‐reported stress, and the Garmin stress score demonstrated marginal predictive value [24].



Studies mainly aggregated stress on a binary or 3-tier scale, meaning participants were either identified as stressed or not stressed, as opposed to being measured on a continuous scale. Here, a continuous scale captures stress fluctuation over time rather than binary or categorical labels. Sensors or tools used to measure physiological signals included various wrist, chest, and full-body sensors alongside mobile surveys. Figure 3 details the various devices used and shows that wrist sensors, in general, were the most widely used sensor type. About 72.4% (n=97) of the studies used well-validated stress tests or tasks for their models, such as the TSST [160], mental arithmetic tests, video stimuli, the Stroop color word test, startle response tests, cold-pressor tests, or public speaking, to reliably trigger stress responses while incorporating restful periods as a baseline [22]. About 8.3% (n=11) of the studies used self-reported SMS text messaging surveys in their supervised machine learning models. The various physiological features and signals measured are illustrated in Figure 4. The most common signal was EDA, appearing in 57.5% (n=77) of studies. Figure 4 shows the top signals measured per study, including instances where papers used multiple signals together.

Figure 3. Top 10 sensors used across all 134 studies.

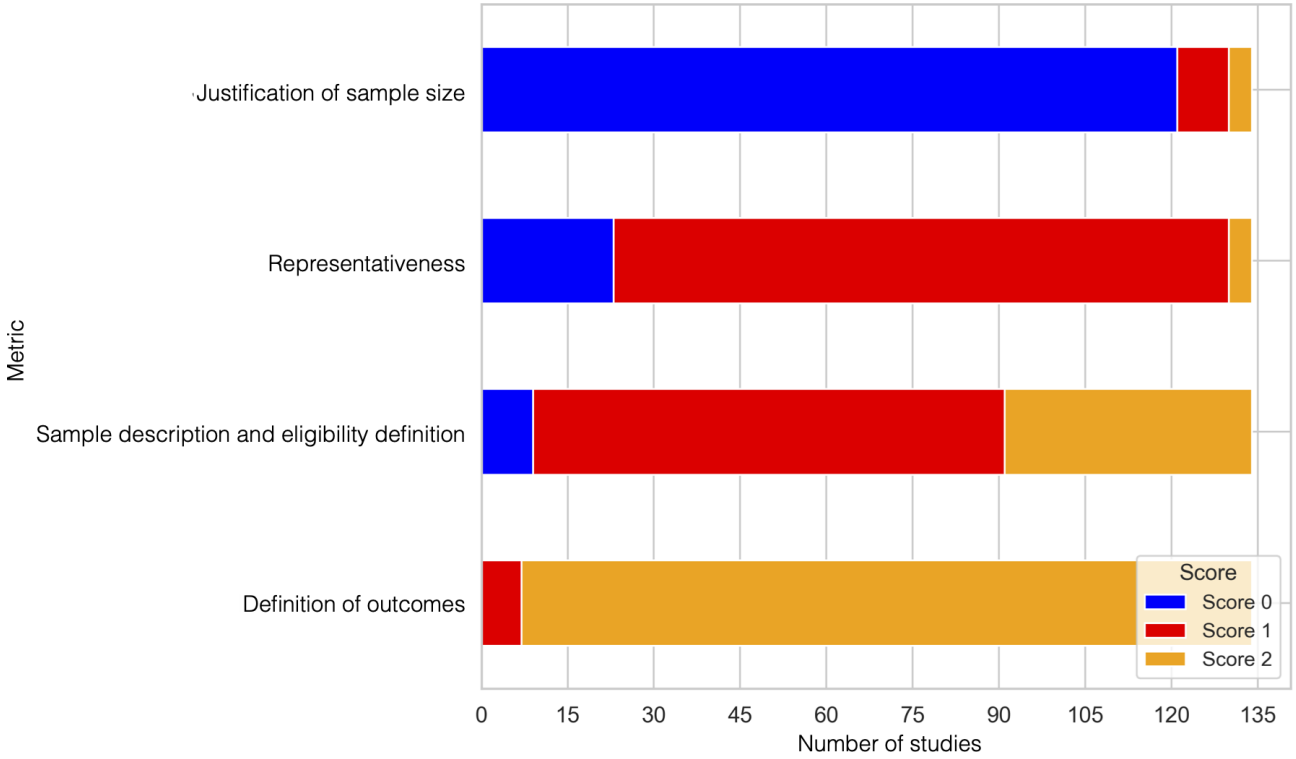
XSL•FO
RenderX

Figure 4. Distribution of top physiological signals used in reviewed studies, including ecological momentary assessment (EMA) as a self-report measure. Many studies used multiple signals, which are counted in the bar plot. ACC: acceleration, BVP: blood volume pulse, ECG: electrocardiography, EDA: electrodermal activity, EEG: electroencephalogram, EMG: electromyography, GSR: galvanic skin response, HR: heart rate, HRV: heart rate variability, PPG: photoplethysmography, RESP: respiration, SC: skin conductance, TEMP: temperature.

Most Commonly Used Wearable Stress and Affect Detection Datasets in Stress Detection

Of the 62.8% of studies that used some preexisting datasets, around 80% (n=67) used the Wearable Stress and Affect Detection (WESAD) dataset, for instance, including papers published from 2020 to 2022 [18,38,42,43,48,55,56,58,59,63,66-71] or a few published from 2023 to 2025 [2,28,75,79,86,94,103,113,122,141]. This dataset was commonly referenced in papers included in this review. This dataset is publicly available and is a widely used dataset for stress and affect detection [161]. The mean age of participants is 27.5 years with a SD of 2.4 years. The sample included 3 females and 12 males for a total of 15 participants. Heavy smokers and pregnant women were excluded, and the participants were composed of graduate students. The signals collected include physiological and motion data from chest-worn and wrist-worn devices. Measurements include blood volume pulse, ECG, EDA, electromyography, respiration, body temperature, and 3-axis acceleration. The protocol used elicits 3 emotional states: baseline, stress, and amusement, followed by a meditation phase. Benchmarks for comparison used the well-studied stress induction method, the TSST, with 0.93 accuracy and 0.91 F_1-score for distinguishing stress, using a linear discriminant analysis classifier, using only chest-based physiological signals.

Although many papers used this same dataset, they experimented with different physiological signals as well as motion data when extracting features for modeling. Modeling and validation methods also varied. The algorithms with the best performance when applied to the WESAD dataset included SVM, RF, XGBoost, k-nearest neighbor, decision tree, deep neural network, self-supervised learning, artificial neural networks, large language models, and CNN. In addition to WESAD, recently published papers used other datasets, including SWELL [29], AffectiveROAD [81], VerBIO [96], S-TEST, or DS-3 [101].



Quality Assessment of Included Studies

Figure 5 shows a breakdown of quality score assessments for all extracted papers, broken down into 4 categories. Papers were scored 0, 1, or 2 for each category. An explanation of each category's scoring is provided in Multimedia Appendix 2, and the individual score breakdown by category for each paper is provided in Multimedia Appendix 3. In general, outcomes and sample descriptions were clearly stated, with most papers having a quality score of 2. However, representativeness and justification of sample size were areas in which many papers did not perform as well. Representativeness was cited as a common issue across many papers, as samples were limited due to recruitment processes for participants or the data that were available. The samples were also limited by age due to the demographic of interest in this review. Around 27.6% (n=37)

XSL•FO
RenderX

of papers failed to give sex demographic information. Most papers analyzed used experimental data from other sources or open-source, publicly accessible datasets such as the WESAD dataset, which did not justify the chosen sample size. From papers published from 2020 to 2022, only 2% of papers failed to give sample size information; however, sample size justification was rarely given, although the papers that did address this issue cited their voluntary recruitment process as a limitation. Almost none of the studies analyzed did a power analysis to determine sample size before running the stress studies, which is a major shortcoming. Across recent papers published from 2023 to 2025, almost all clearly defined outcomes and described their samples, but very few addressed representativeness, and only 3 papers [24,143,154] justified their sample size published, highlighting a major gap in methodological rigor.

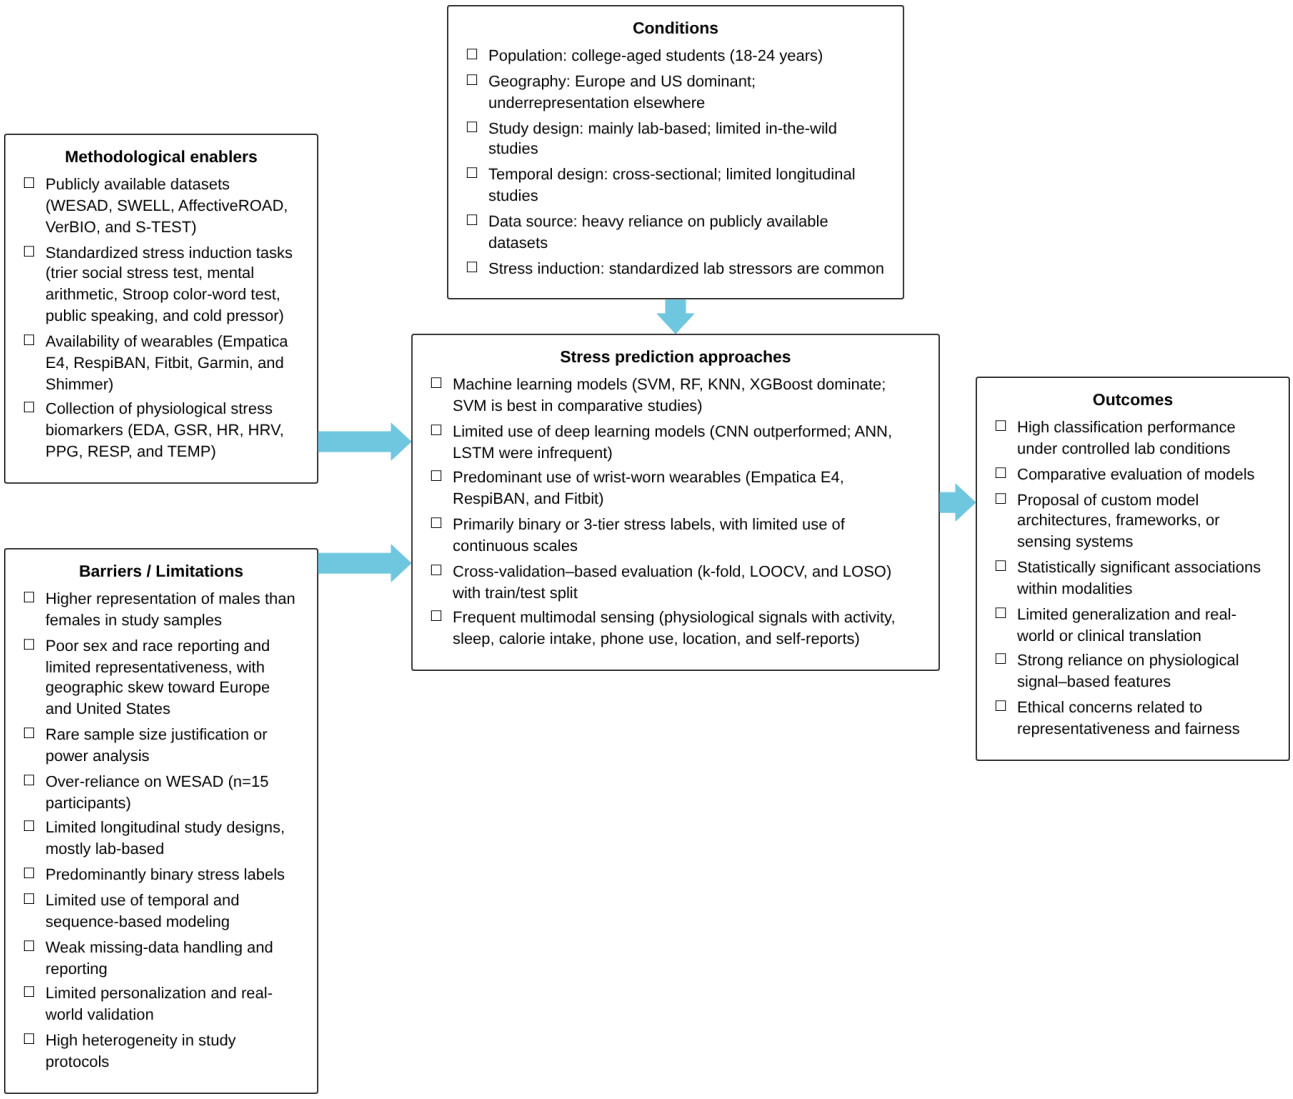


Figure 5. Quality of the literature in each domain. The figure shows the scoring across papers in each category from 0 to 2, with 0 indicating not fulfilled, 1 indicating partially fulfilled, and 2 indicating fulfilled.

Finally, these findings point to substantial heterogeneity and a meaningful risk of bias across the included studies. The wide variation in sample sizes, inconsistent reporting of demographic characteristics, limited disclosure of health information, and strong geographic skew toward Europe and the United States contribute to structural differences that complicate direct comparison of results. This heterogeneity is further shaped by the heavy reliance on the WESAD dataset, a publicly available dataset with only 15 predominantly male participants, with a mean age of 27.5 years, which results in many studies concluding a small and demographically narrow sample. Such repeated use of a single dataset increases the likelihood that reported model performance reflects the characteristics of WESAD participants rather than capturing variability among college-aged students. Accordingly, the synthesized findings should be interpreted with caution, acknowledging that both heterogeneity in study design and risk of bias in sampling and reporting may influence observed performance patterns and limit the extent to which results can be generalized. Using a relational synthesis approach, Figure 6 presents an evidence gap map that synthesizes methodological enablers, study conditions, stress prediction approaches, barriers, and outcomes observed across the included studies. The map illustrates a research landscape shaped by publicly available datasets, standardized in-laboratory stress protocols, and widespread use of wrist-worn physiological sensors. At the same time, it highlights recurring constraints including a predominance of laboratory-based study designs, heavy reliance on publicly available datasets, and limited demographic representativeness. While many studies report strong classification performance using classical machine learning models under controlled conditions, comparatively fewer examine temporal stress dynamics, personalization, or real-world deployment.

Discussion

Overview

In this scoping review, we examined how stress is measured among college-aged students using wearable technologies and machine learning methods between 2020 and 2025, to identify commonly used wearables, the most informative physiological signals, and the best-performing algorithms. Across the literature, we found that SVMs among traditional machine learning models and CNNs among deep learning models were the strongest performers for stress classification. Wrist-worn devices were the predominant sensor platform, and EDA was the most frequently measured and most informative signal. However, most studies relied on small, homogeneous samples, frequently used controlled laboratory datasets such as WESAD, and commonly used binary (stressed vs not stressed) labeling approaches, raising concerns about representativeness and ecological validity. Our quality assessment further revealed inconsistent demographic reporting, insufficient justification of sample sizes, limited attention to social determinants of stress, and substantial variation in how psychological stress was defined, elicited, and validated across studies.

Modeling Approaches for Stress Prediction

Regarding stress prediction model performance, the strong performance of SVMs can be attributed to their robustness in handling high-dimensional physiological data [33,144], their ability to generalize well by maximizing the margin between classes, and their effectiveness in small and imbalanced datasets, which are common in stress detection studies [162]. Additionally, the flexibility of SVM in using different kernel functions [163] allows them to model complex, nonlinear relationships in physiological signals without requiring deep feature extraction. These advantages likely contribute to their superior performance compared with other traditional machine learning models in stress classification. However, SVMs are computationally expensive and may not be practical for real-time applications [164]. More efficient and scalable approaches are needed to enhance practicality in the field. Deep learning models, particularly CNNs, outperformed traditional machine learning approaches in comparative analyses [82,85]. Although

XSL•FO
RenderX

CNNs capture spatial patterns in temporal data, they do not have memory in their architecture, reducing their effectiveness on longitudinal temporal data [165], indicating a need for algorithms that explicitly model temporal patterns, such as RNNs [74]. One study focusing on the comparison of various machine learning and deep learning methods attempted to use a version of an RNN in the form of an LSTM. This paper reported the greatest performance with LSTM alone, as opposed to a combination of LSTM and CNN, indicating some value in noting and using temporal patterns. In addition, emerging evaluations of large language models for stress prediction [135] did not perform well and suggest that parameter count does not consistently correlate with performance. For example, GPT-3.5-Turbo performed comparably to GPT-4 on WESAD [109]. These findings indicate that identifying key biomarkers is essential for improving model efficiency [115]. From 2023 to 2025, published literature emphasized personalization and multitask learning to enhance stress-prediction performance and generalizability [70,79,98,107,112,127]. In addition, 1 study explored stress detection in a virtual reality environment integrated with an Internet of Things system, demonstrating the potential of immersive technologies for stress monitoring [85].

Wearable Technologies and Physiological Signals

Wrist wearables were most commonly considered [166] as they seem less encumbering than full body or chest wearables [22] while attaining better measurement of physiological signals than surveys or smartphones. Other wearable sensors used across studies included chest wearables, full body sensors, or some combination of chest and wrist wearable signals. We saw that EDA was the most frequently measured signal across papers and is important in stress detection [167], since it provides valuable information about a person's sympathetic nervous system activity, which is closely linked to emotional responses, including stress. Most papers used multiple signals in their model building, with EDA most commonly contributing to a more accurate model. For instance, building a stress detection model incorporating both HR and EDA [22,26,81] data might allow for a more comprehensive, accurate, and context-aware assessment of stress and other emotional responses. Ensuring the reliability and reproducibility of physiological measurements is crucial for real-world stress detection [26]. Variability in sensor accuracy, signal quality, and environmental factors can impact consistency [22]. Validating models across diverse settings improves generalizability and practical applicability [168].

Conceptualizing and Measuring Psychological Stress

We saw that most studies used a binary model of stress in which an individual is identified as either stressed or not stressed. A few studies extended beyond binary classification by using multiclass stress prediction (eg, 3-class [62] or 5-class [59,125] models), which allows a somewhat finer-grained view but still treats stress as discrete states. There is a need for a model more in line with how human stress manifests, such as a continuous scale [26,169]. For example, an individual might feel mildly stressed, which is worth noting and which cannot be captured on a binary scale of stress [150]. On a binary scale, mild stress may be interpreted as either diminished or heightened stress. A continuous scale for stress monitoring is valuable for capturing individual differences and for understanding the dynamic nature of stress [150].

We found a lack of detailed explanations on how psychological stress was identified. Accurately distinguishing psychological stress from other physiological responses is complex, as HR alone is insufficient for stress detection [154]. For example, HR alone cannot reliably indicate stress, as an elevated HR may result from various factors [170], such as jogging or facing an unprepared mathematics test. A stress detection model based solely on HR data could misclassify natural variations in HR, such as those caused by excitement or physical activity during social events, as stress, leading to inaccurate assessments [169]. One critical detail to note in studies of stress is the differentiation between physiological and mental stress. This distinction is complicated for wearable devices [154]. To accommodate this, studies need to look at a participant's resting data while they are confirmed to be stressed, as well as their accelerometer data, if necessary, to check movement patterns, and consider these factors while detecting significant stress moments [169]. One's activity must be noted to clearly identify psychological stress. Many studies used some well-validated stress tasks to account for this concern, but could benefit from clearer explanations of how their stress tasks accommodate this issue. These stress tasks mostly used tests such as mental arithmetic, Stroop test, public speaking, or cold-pressor tests, with participants putting their hands in ice water, to benchmark stress [22,26]. By contrast, other datasets (eg, "A Wearable Exam Stress Dataset for Predicting Cognitive Performance in Real-World Settings" [124]) inferred stress levels indirectly from examination grades, raising concerns about the accuracy of stress labeling. Studies that did not incorporate a stress task often used self-report surveys to monitor whether someone is stressed [168,171]. Self-report measures often face challenges with accuracy and completeness [172]. While frequent and timely survey prompts can improve accuracy, they do not fully address issues of completeness. Additionally, repeated survey checks may increase participant burden, potentially leading to survey fatigue and lower response rates [173]. There is also a need for better transparency regarding the wording of questions and the frequency of surveys to ensure consistency and minimize bias [174].

Concerns Related to Study Design and Reporting

When analyzing the quality of research, we saw a need for larger sample sizes [175]. Larger sample sizes help reduce bias, provide a better representation of the target population, and lower the impact of outlier participants [176]. We observed that many studies relied on the WESAD dataset [177], a widely used dataset for stress and affect detection. However, WESAD includes only 15 participants, making it a limited representation of the college student population. Additionally, since WESAD data were collected in a controlled laboratory setting, they do not reflect real-world ("in the wild") stress detection, where external factors and daily life variability play a significant role [171,178,179]. In fact, 1 study that used WESAD achieved strong performance under laboratory conditions but failed to generalize effectively in real-world settings [119], further underscoring the limitations of laboratory-based datasets.

XSL•FO
RenderX

Many studies did not report racial or ethnic demographics or have a representative sample regarding sex. This was a commonly identified issue within papers, as many samples relied on volunteers. Many papers also failed to report on other demographics of their samples besides sex or ethnicity, such as populations for exclusion. This includes excluding populations taking certain medications, populations with certain mental health histories, populations engaging in drug use, or pregnant populations. Knowing the populations for exclusion is crucial for replicability and transparency, as well as for bias detection and interpretation of results [180-182]. Although our population of interest was students, there is a need for more varied student demographics in samples regarding sex, race, and ethnicity, capturing different social determinants [183]. Given that stress is influenced by various social determinants [184,185], future studies should incorporate factors such as socioeconomic status, neighborhood context, physical environment, racial minority representation, and health-lifestyle interactions [186]. Including these elements would provide a more comprehensive understanding of stress in college students. One paper mentioned that its sample may not be representative because participants were recruited from an elite, private university [32]. Along these lines, there is a need for better justification of sample selection as well as sample size. Finally, missing data present a significant challenge in stress studies, affecting both comparability across studies and the reliability of findings [187]. The way missing data is handled, whether through imputation, exclusion, or other techniques, can influence study outcomes and lead to biased conclusions [188]. There is a need for more complete data and more detailed descriptions of how missing data were handled, particularly in longitudinal studies [189].

Relationship to Prior Reviews and Contribution of This Work

Prior literature reviews have explored various aspects of stress detection using wearable technology and machine learning. A meta-analysis examined the effectiveness of wearable AI in diagnosing and predicting stress among students, while emphasizing the need for real-world validation and improvements [190]. Another review categorized stress detection approaches based on different wearable sensor types and environments such as driving, studying, and working [191]. A separate study systematically assessed biosignal responses to psychological stress, analyzing electroencephalogram, ECG, EDA, HRV, respiration, and temperature to evaluate their reliability and consistency [192]. A prior review also examined machine learning techniques used in stress monitoring research, focusing on model generalization when training on public datasets [20]. Another review focused on wearable technologies and smart devices for detecting depression, anxiety, and stress, discussing physiological markers such as HRV, EDA, and electroencephalogram, along with their market availability [193]. Finally, a review analyzed physiological parameters such as HR, temperature, humidity, blood pressure, and speech, exploring various stress detection sensors and machine learning-based classification techniques [194]. Our scoping review extends this literature by specifically focusing on stress measurement in college-aged students, reviewing recent papers published from January 2020 to December 2025, analyzing common datasets, sensor types, and the best-performing machine learning algorithms used in research. We also evaluate weaknesses in current methodologies through a quality assessment while identifying best practices in study design, feature selection, sensor use, and algorithmic approaches.

Taken together, the findings of this scoping review highlight that progress in wearable-based stress detection for college-aged students [3,32,46,73] is constrained primarily by methodological and conceptual design choices rather than sensor availability for digital phenotyping of stress [195] or algorithmic capacity [18,28,30]. While multimodal physiological sensing, particularly EDA combined with cardiac measures, shows consistent promise [22,26], the field remains highly reliant on small, controlled datasets such as WESAD [177] and binary stress formulations that fail to capture the continuous [26,169], context-dependent nature of stress in students' daily lives [171]. Advancing this area will require a shift toward larger [175], more diverse cohorts that reflect different social determinants of health [186], and real-world datasets that support generalizable human behavior modeling [168,196]; along with transparent reporting of participant characteristics, exclusion criteria, and missing data handling [189]; and modeling approaches that explicitly account for temporal patterns [95], personalization [1], and contextual information from students' behavioral patterns [152]. These improvements are not only methodological but also ethical, and without representative samples and robust validation in real-world settings, stress detection systems might risk reinforcing bias [197] and producing misleading inferences when deployed in student populations [183]. By synthesizing recent evidence and identifying persistent gaps, this review provides a foundation for designing more reliable, interpretable, and equitable stress monitoring systems that can support just-in-time interventions and inform institutional strategies to improve student mental health [5].

Limitations

Our focused and systematic approach targeting stress in college students in recent years allows for a more detailed analysis. Recency allows for analysis of the most up-to-date and commonly used sensors as well as the newest algorithms. By systematically categorizing the approach taken by each study, along with the devices used and signals measured, we can synthesize the information, establish trends, and make conclusions about best-performing methods and practices. Many studies relied on commonly used datasets, such as WESAD. Using the same dataset across different research projects enables benchmarking, allowing for direct comparison of methodologies and an understanding of why results may vary across approaches. A common challenge in the reviewed papers was the inclusion of multiple populations or datasets within a single study. While our primary focus was on college students, some papers analyzed mixed populations or multiple datasets. However, as long as college students were included, these studies were still considered in our review. Many papers also used overlapping datasets such as the WESAD dataset, although different papers used different parts of the dataset along with different models. This may lead to some redundancy in findings. The commonly used dataset, WESAD, with only 15 participants, had limited sample sizes, introducing potential bias and reducing

XSL•FO
RenderX

the likelihood of capturing a truly representative population. Additionally, only studies published in English were included, as this was the language accessible to our reviewers, which may have led to the exclusion of relevant research.

Conclusions

This scoping review provides a focused synthesis of wearable- and digital tool–based stress detection research specifically among college-aged students, a population often overlooked or aggregated with broader adult samples in prior reviews. Current research highlights the need for larger and more diverse samples to improve representativeness, as many studies rely on a limited number of existing datasets, potentially leading to overlapping findings. Greater diversity in sex and ethnic demographics, along with clearer justification of sample sizes and improved demographic reporting, is essential for understanding population-level stress patterns. Methodologically, most studies conceptualized stress as a binary state (stressed vs not stressed), failing to capture variations in intensity, such as mild or moderate stress that can be chronic and clinically meaningful. Few studies used algorithms such as RNNs, which can capture temporal patterns, despite the importance of tracking stress progression over time. Greater emphasis on time-dependent modeling could enhance the understanding of how stress evolves. Many studies failed to clearly distinguish between psychological stress and physiological stress responses, despite the critical need for distinct measurement approaches. More precise definitions and methodologies are necessary to differentiate between these 2 aspects of stress effectively. In real-world settings, these limitations constrain the generalizability and clinical usefulness of stress detection systems.

To strengthen the credibility and generalizability of future research, studies should provide clear justifications for their sample sizes and, where possible, aim to recruit larger cohorts that reduce bias and improve statistical reliability. The field would also benefit from the development and use of more varied datasets, which can limit overlap across studies and reduce potential sources of bias. Increasing diversity in participant recruitment is essential; researchers should ensure representation across race, sex, socioeconomic status, and environmental contexts, as well as variation in behavioral and lifestyle factors such as sleep duration and efficiency, physical activity, phone usage, social media engagement, and mobility patterns. Detailed demographic reporting should accompany all studies to enhance transparency and enable meaningful comparisons across research efforts. Future analytical approaches should incorporate algorithms capable of capturing temporal patterns to model fluctuations in stress over time. Rather than relying solely on binary stress categorizations, researchers should develop models that characterize stress as a dynamic and progressive state, allowing for the detection of mild, moderate, and chronic stress levels. Clear explanations of baseline stress measurements are also needed to ensure that resting conditions are consistently defined and comparable across studies. Finally, stress prediction models should increasingly focus on personalization while maintaining robust privacy protections for participants.

Acknowledgments

We would like to thank librarian Alissa Cilfone and Lauri Fennell for their consultation regarding database search strategies and the development of search terms. We used a generative artificial intelligence (AI) tool (ChatGPT-5.2; OpenAI) to polish the initial draft of the manuscript and Microsoft 365 Word built-in tools for spell and grammar checks, solely for language refinement, proofreading, summarization, and reformatting to improve the clarity and readability of the manuscript. No generative AI tools were used to generate any scientific content, figures, results, analyses, or interpretations. All citations were identified, verified, and added manually by the authors, and no AI-generated references were used.

Funding

This study represents independent research funded by Northeastern University’s Project-Based Exploration for the Advancement of Knowledge (PEAK) Experience #2: The Base Camp Award and Northeastern University’s FY23 Transforming Interdisciplinary Experiential Research (Tier) 1 Seed Grant: assessing the scalability and feasibility of digitally phenotyping stress.

Authors' Contributions

AS, OBA, and JA contributed to the literature search and data extraction. AS, OBA, and JO contributed to data analysis and interpretation. All authors contributed to writing the manuscript, and all authors approved the manuscript. All authors guaranteed the integrity of the work. Abstract

Background: Technology-based solutions to support the mental health needs of workers are on the rise, as evidenced by the growing body of research related to e–mental health apps implemented with workers or within the context of workplaces. This expanding landscape of evidence related to mental health apps underscores the necessity of summarizing and consolidating the different ways in which studies are evaluating real-world technology-based interventions in a complex setting such as a workplace.

Objective: The aim of this scoping review is to summarize the growing body of evidence evaluating mental health apps with workers. Specific research questions include "What types of mental health apps are studied?" "With whom are they being evaluated?" and "What outcomes are being tracked with what tools?"

Methods: The scoping review followed 5 stages: specifying the research question, identifying relevant literature, selecting studies, extracting data, and synthesizing the findings. The search strategy was applied across 6 databases (PsycINFO, Embase, MEDLINE, Cochrane Database, OVID Healthstar, and OVID Emcare) to identify relevant studies from January 2000 to August 2023.

Results: From the 288 abstracts screened, 54 studies met the inclusion criteria for this review. Over two-thirds of the studies were randomized controlled trials. The studies included 44 different apps, comprising 23 structured self-guided apps, 15 unstructured self-guided apps, and 6 apps designed as adjuncts to other interventions. Evaluation approaches included examining user engagement and utilization, investigating the impact on users, and evaluating the implementation process. Most studies evaluated the impact on individual mental health–related outcomes as well as workplace-related outcomes.

Conclusions: This scoping review provides a comprehensive overview of the ways in which studies are currently evaluating workplace mental health apps. The review highlights key trends and gaps in the existing research, noting that most studies focus on the effects of mental health apps on individual users, while only a limited number of studies explore how implementing such dynamic interventions within complex real-world settings (eg, workplaces) may influence their overall effectiveness. Future research should explore the implementation process to identify factors that promote and/or hinder the optimal use and impact of mental health apps for workers.

Introduction

Mental health issues have a significant human and financial cost for society and workplaces. Poor mental health and loss of productivity are estimated to cost the global economy approximately US $1 trillion each year [1], and this figure is projected to rise, given the COVID-19 pandemic's impact on workplace mental health. Rapid transitions and changes in workplace demands linked to the pandemic have led to an increase in reports of perceived stress, depression, and anxiety among working adults, particularly for working mothers, people of minority ethnicities, and those working in frontline positions [2-4]. Limited access to traditional mental health services, along with the longstanding stigma associated with seeking support,

XSL•FO
RenderX

has led to a growing need to expand access to a range of mental health supports to address the unmet needs of the workforce and reduce the burden of mental health issues.

In recent years, there has been a growing interest in digital health technologies, including web-based and smartphone-based interventions as tools to address mental health problems. One of the main advantages of digital mental health interventions is their ability to overcome traditional barriers to accessing mental health care by providing on-demand access to quality mental health information and support [5,6]. For example, many people are reluctant to seek help due to the stigma associated with mental illness. Digital interventions, such as mental health apps, offer a private and anonymous way to access support without the fear of being judged. Digital interventions can also help overcome geographical barriers by providing access for people who live in remote or rural areas, where mental health services may be limited or nonexistent [5]. In addition, digital interventions can be accessed at any time and from anywhere, which can help overcome the time constraints that many working adults face when trying to access traditional mental health services. Mental health apps can be used across the full spectrum of mental health care, from prevention to management. For example, there are apps that help people assess and manage stress and anxiety, apps that provide support for people with depression, and apps that help people improve their well-being.

There is a growing body of research that supports the effectiveness of mental health apps in both the general and clinical populations [4,7]. A review of app-based mental health interventions found them to be effective in reducing symptoms of depression and anxiety [4,7], as well as improving mental health literacy and well-being [8] in both clinical and non-clinical populations [4,7-9]. However, a review of publicly available popular mental health apps found that only 2 out of the 6 mental health apps identified were empirically evaluated [10], underscoring the gap between mental health apps available publicly and those that are evaluated in empirical studies. There is an urgent need for high-quality studies in this field to explore mental health apps that are evidence-based, empirically supported, and scalable to broader users.

There is a growing interest in the use of mental health apps across different settings such as clinical, postsecondary, and community settings, and more recently in workplaces. Several reviews provide evidence to support that digital mental health interventions implemented in workplaces have positive effects on improving general mental health and workplace-related outcomes [11-13]. Studies have explored the effects of these interventions in improving well-being, symptoms of stress, and several workplace-related outcomes, such as work effectiveness or productivity and job satisfaction [11-13]. However, the majority of the studies in these reviews consisted of web-based interventions, with only a small percentage of them exploring mental health apps.

As the availability and use of mental health apps in workplace settings become more prevalent, there is a growing need to identify and synthesize the existing evidence related to their systematic evaluation with workers. In this paper, we aim to conduct a scoping review to synthesize and critically reflect on the body of evidence in this emerging field. Specifically, we will summarize and identify trends and gaps in the evaluation of mental health apps in workplace settings.

Methods

Study Design

We followed the 5 steps of scoping review methodology [14]: specifying the research question, identifying relevant literature, selecting studies, extracting data, and synthesizing the findings. The protocol for this review is registered on the Open Science Framework. We also adhered to the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) guidelines (Checklist 1) to ensure consistent and transparent reporting [15]. To examine and summarize the breadth of evidence regarding the evaluation of mental health apps for working adults, we developed the following research questions based on the population, intervention, comparison, and outcome (PICO) framework:

1. How are mental health apps being evaluated with workers and/or in the context of a workplace?
2. What types of mental health apps are studied?
3. With whom are the applications being evaluated (workers or workplace sectors)?
4. What key variables are being assessed, and what tools are being used to track progress and impact?

Inclusion Criteria

Studies were included in this review if they met the following inclusion criteria: (1) the primary study intervention was a mobile mental health app that was tested by employees; (2) the study evaluated the effectiveness, implementation, impact, or use of the mental health app; (3) study participants included workers currently employed in any field and/or implemented in the context of a workplace; (4) the study included any quantitative or qualitative evaluation design; (5) the study was published in a peer-reviewed journal; and (6) the study was available in English. Studies were excluded if: (1) the intervention in the study was primarily a web-based or internet-based intervention (ie, not a mobile app) and (2) the study design only focused on app development (not evaluation) of a mental health app for workers. Conference proceedings and gray literature were not included, as the key focus of this review was to present a summary of published peer-reviewed studies that systematically evaluated mental health apps.

Search Strategy

We searched the following electronic databases: PsycINFO, Embase, MEDLINE, Cochrane Database, OVID Healthstar, and OVID Emcare for peer-reviewed studies from January 2000 to August 2023. A comprehensive search strategy, including search terms, subject headings, and syntax requirements for the databases, was adapted from a previous systematic review of digital mental health interventions for the workplace [11] and was modified in consultation with a health science librarian. Search terms included a combination of constructs such as “Mental Health,” “Workplace,” and “Mobile Application” (Multimedia Appendix 1). The search was conducted from May 2023 to August 2023.

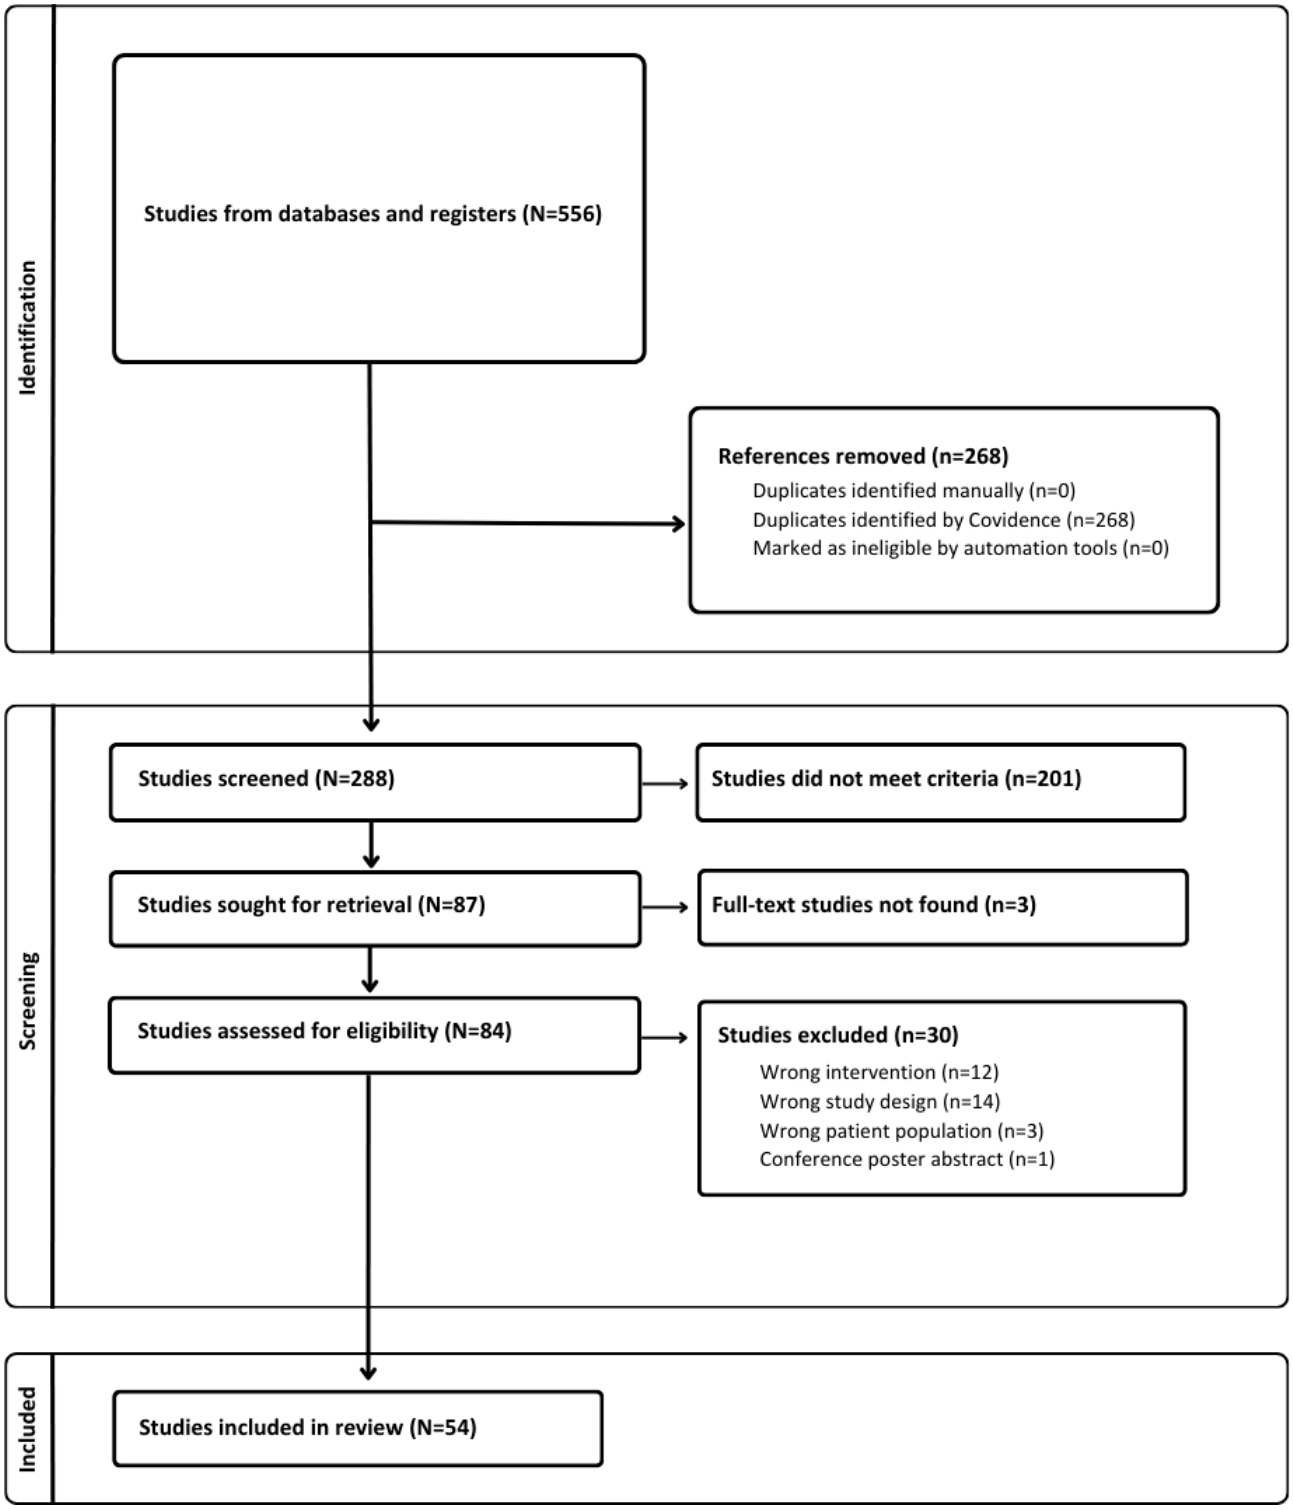
XSL•FO
RenderX

Study Screening

Data screening and extraction were carried out by 2 independent reviewers (SA and ML) using Covidence systematic review software (Veritas Health Innovation), an online tool that supports screening and data extraction for reviews, to facilitate a systematic screening process. All studies were screened independently by 2 reviewers, and any discrepancies in study selection were discussed in a review meeting. A third reviewer, SM, was consulted to resolve any disagreements between the 2 primary reviewers and to improve clarity in decision-making when necessary.

Data Extraction and Analysis

Data extraction was an iterative process designed to develop and refine a data charting sheet in Microsoft Excel to ensure all relevant data were captured comprehensively. The fields of data extracted included study characteristics such as the year, country of publication, study design, workplace context or industry where the study was conducted, intervention characteristics, timeframe, and evaluation approaches including both assessment tools and outcomes explored in the study. The initial extraction chart was piloted with 5 studies and was later revised to capture additional information relevant to our research questions. Analysis of these data included a summary of the study characteristics, types of app interventions, study populations, and approaches to evaluation (variables and evaluation tools). Descriptive summaries of the trends in each category will be outlined.



Results

Overview

We searched 6 electronic databases, identifying 288 studies after the removal of duplicates. After screening titles and abstracts, 85 studies were deemed eligible for full-text screening. Subsequently, 54 studies met our inclusion criteria for being included in this scoping review (Figure 1). Data from these studies were extracted and charted to generate a comprehensive summary of the breadth and trends in the body of evidence of mental health app evaluation in the workplace. Of these 54 studies, 11 were protocols for studies in progress; hence, no results were available for these studies at the time of the review. Upon careful consideration of the protocols and clinical trial registrations, we were able to gather relevant information related to the key outcomes being evaluated and the processes by which the studies were being conducted, which was deemed sufficient to answer our main research question: “How are mental health apps being evaluated with workers and/or in the context of the workplace?” As a result, we decided to report these ongoing studies in our review.

XSL•FO

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart of the study screening process.

Study Characteristics

Among the 54 studies included, approximately two-thirds were randomized controlled trials (RCTs; protocols or trial registrations n=11 [16-26]; completed RCTs n=21 [27-48]; pilot RCTs n=3 [49-51]). A smaller subset of studies adopted nonrandomized methods such as pre-post nonexperimental designs (n=13) [52-63], with even fewer studies using mixed methods (n=5) [64-67] and qualitative designs (n=1) [68]. Over two-thirds of the studies (n=37) were published after the onset of the COVID-19 pandemic, reflecting accelerated remote work and rapid digital transformation in workplaces, with over 26% (n=14) of the studies on this topic published in the year 2022 alone. Table 1 outlines a summary of the key characteristics of all included studies.

Types of Mental Health App Interventions

A total of 44 unique apps were evaluated across the 54 studies included in this review. There was considerable variability across these apps in terms of their therapeutic approach, goals, functionalities, target population, and intervention duration. Over half of the apps (23/44, 52%) included a programmatic structure with predetermined guidelines or prescribed instructions on how to use them, while 34% (15/44) were open-ended and user driven without a fixed guideline for use. Based on these distinctions, we broadly classified these apps as: (1) structured self-guided, (2) unstructured self-guided, and (3) an adjunct to other interventions. See Table 2 for an

XSL•FO
RenderX

overview of the identified apps categorized by type, including proposed purpose and target population noted in the study.

XSL•FO
RenderX

Table . Overview of apps by type and study target population.

Name of app	Overview	Target population
Unstructured self-guided		
e-pD-Work intervention [16]	Self-guided modules to promote physical exercise, improve sleep, expand relationships, solve problems, improve communication, assertiveness, decision-making, and manage work stress.	General practitioners across multiple primary care centers
The Healthy Minds Program [28]	Meditation app focused on awareness, connection, insight, and a model of well-being.	Employees from district school system
Stress management app (no official name found) [31]	Mental health information and mindfulness strategies (eg, music meditation and breathing).	Nurses employed at college hospitals
Lift Intervention [44]	Self-directed mindfulness program with tips and contents for integrating mindfulness into daily life.	Nurses from COVID-19 units at a single hospital
InMind [48]	Mindfulness training, including measurement of heart rate variability with recommended content.	Employees in 3 organizations: legal, construction, and a PR[a] firm
24alife app [49]	Customized activities for relaxation, exercise training, nutritional advice, and physiological responses to stress based on initial assessment of lifestyle habits	Employees from an Information and Communication Technologies company
Jibun kiroku (a self-record app) [52]	CBT[b]-based intervention focuses on self-monitoring and awareness and recording of negative thoughts, daily activities, and daily mood	Employees experiencing mild to moderate psychological distress
The Wellness Hub app [55]	Mental health–related content and resources, and links to local resources.	Employees from a large health system
Listen Leon [56]	Encourages employees to send anonymous strengths-oriented descriptive feedback to colleagues	Employees from 5 industries: retail, consulting, banking, human resources, and education
Stress management app (no official name found) [57]	Mental health and lifestyle assessment, daily lifestyle management, peer support, tools for searching nearby mental health professionals, and relaxation training	Employees from 3 national hospitals and health promotion centers
Healthy Outcomes at Work app [63,64]	Psychoeducation tailored to the needs of the organization (info re: well-being events, access to vocational rehabilitation assistant, option to provide feedback (via app) to management	Child and Family social workers and hospital staff
The Mood Map [65]	Enables daily mood monitoring (happiness, sadness, anxiety, and anger) at regular intervals. Therapeutic strategies include cognitive reappraisal exercises, breathing, and relaxation techniques.	Employees at a large corporation with high stress levels
Oiva (app available in Finnish only) [66]	Promotes stress management and well-being, based on ACT[c], with short skills building sessions (visual or audio).	Employees from 2 information communication and technology organizations
Brightr app [69]	Monitoring of behavior, sleep, physical activity, nutrition, and shift work by providing tailored feedback based on responses to short in-app questionnaires and sleep and physical activity tracking.	Employees from an information and technology company
Structured self-guided		
Unmind App [18,41]	Six to eight 10 - 20 minute self-guided sessions based on principles of CBT and ACT to manage and improve mental health and well-being. Users had 3 weeks to complete their allocated intervention and were sent a weekly intervention reminder message.	Full-time or part-time employees from a research recruitment platform

XSL•FO
RenderX

Name of app	Overview	Target population
SOLAR[d] [20]	Eight modules over 5 weeks focused on behavioral skill development or psychoeducation, delivered in animations, videos, activities, and notifications, that participants can self-complete at their own pace. Developed as an extension of in-person training.	Firefighters experiencing distress (scored between 7 and 18 on the 6-item Kessler Psychological Distress Scale
WorkingWell [22]	Designed for individuals with severe mental health issues to cope on the job. Users are asked to select up to three goals to work towards and on which to reflect in the coming week. Daily reminders of goals upon app opening and new goals can be chosen for each week.	Employees with severe mental illness using supported employment services
EMPOWER [23]	7-week access to intervention: (1) screening tools for stressful psychosocial working conditions, mental distress, and work function; (2) psychoeducational CBT modules to promote mental health and work functioning.	Employees from SME[e] and public agencies
WEDiary[f] [24]	Two-week intervention that facilitates daily self-monitoring of goals and achievements at work.	Employees across different organizations
Holidaily [25]	Daily prompts based on behavioral activation strategies designed to promote recovery behavior and mental detachment from work to extend the beneficial effects of vacation into their daily work life.	Employees who are awaiting to go on vacation
Headspace [26,27,40,68]	Daily guided 10-minute mindfulness practices or techniques including breathing, imagination, and body scan exercises focusing on different bodily sensations.	Staff from 2 emergency departments (NHS[g]), health care workers, and university employees
BetterLife [29]	Guided, 10 weeks (50 min/wk) self-help therapy informed by principles of CBT and problem-solving therapy for addressing stress, depression, anxiety, and sleep disorders.	Employees with elevated perceived stress (score of 14+ on the Perceived Stress Scale)
Well-being mobile app (official name not found) [30]	A 8-week program (4 lessons/wk) with content focused on techniques to reduce stress and promote well-being (breathing techniques, relaxation techniques, and guided meditation).	Female employees at a large private tertiary care hospital
The MoodHacker [32]	A 6-week intervention with sequenced content and prompts to track mood and activities daily. App tracks mood and positive activity planning, promotes cognitive restructuring, mindful self-awareness, gratitude expression, and identifying and using strengths.	Employees from several institutions recruited in partnership with EAP[h]
Smartphone resiliency training (no official name found) [33]	A 6-week intervention for monitoring and awareness for sleep and mood, happiness and positivity, energy, and focus, and productivity. Users were prompted to select a goal (one of the topics) to work on for the next few weeks.	Employees from a large research hospital and medical center
ABC Stress Management app [36]	Six-week (1 module/wk) intervention with two types of stress management apps—Program A, a free-choice multimodule program and Program B, a fixed-sequential order iCBT[i] multimodule program.	Employees from a large public hospital (Vietnam)
ACT-based app [37]	Six weekly modules based on ACT principles to manage stress. Reflections accessible by a therapist who could send encouraging personal messages to the user.	Middle managers from private sector company

XSL•FO
RenderX

Name of app	Overview	Target population
HeadGear [17,38]	30-day therapeutic intervention (1 challenge/day). Content is based on behavioral activation and mindfulness-based therapies. Features include mood monitoring and access to a tech helpline.	Employees from male-dominated industry partner organizations: agriculture, freight, and mining
Anchored app (adapted from HeadGear app) [45,51]	30-day intervention with daily tasks or "challenge" based on evidence-based techniques (behavioral activation, mindfulness, and coping skills training) delivered using videos, exercise, and goal setting to target stress.	Adults experiencing workplace stress from any industry
HeadGear Apprentice app [67]	30-day therapeutic intervention (1 challenge/day). Modifications to HeadGear include gamification, changes to navigation, and customized content for apprentice support.	Trainees enrolled in an apprenticeship program
Kelaa Mental Resilience app [39]	Four weeks of psychoeducational modules designed to reduce stress and promote well-being specifically in the workplace context by providing options for self-monitoring of behaviors, cognitions, and emotions.	Employees from public and private sectors from 3 countries
Foundations app [43]	Daily active use encouraged during first 2 weeks. User chooses one of 6 focus areas during onboarding (relaxation, sleep, anxious thoughts, feeling down, self-esteem, and stress), then relevant programs and activities are presented based on CBT, mindfulness-based CBT, relaxation techniques, and positive psychology.	Health care workers across health system
Mobile-based Stress Management Intervention [46]	Recommended use of 10 minutes twice a week for 6 weeks. Combination of 3 modules that include interventions for relaxation, self-management, and counseling.	White collar workers with elevated symptoms of perceived stress (Perceived Stress Scale-10≥22)
Calm app [47]	Recommend 10 minutes per day over 8 weeks. Incorporates mindfulness, breathing techniques, and body scans.	Employees of a large consumer electronics retailer
P4Well [50]	Three mobile apps: (1) Nokia Wellness Diary, (2) Firstbeat Mobile Coach (fitness training), and (3) SelfRelax (personalized 4-wk relaxation program).	Male working adults (25 - 45 y) with exhaustion, stress symptoms, or sleeping problems
Naluri app [53]	16-week EAP offering personalized programming to promote behavior change (educational modules, health journal, and a habit tracker) and access to a team of professional health coaches via text-based messages and video calls.	Employees from an unspecified company in Malaysia
Shift app [54,60]	30-day intervention based on content and features of HeadGear app, modified to meet the needs of physician population.	Junior medical officers from 2 hospital sites
VA[j] Mindfulness Coach App [61]	12 audio-guided mindfulness exercises on a range of techniques (eg, body or breath awareness, compassion, and mindful eating).	Nurses from psychiatric facility reporting burnout
Smartphone-based meditation app (No official name found) [62]	Ten days of 10-minute audio-recorded mindfulness sessions.	Firefighters from a large metropolitan city
Adjunct to other interventions		
MATESmobile program [21]	Supplements in-person training with a focus on reinforcing face-to-face training messages and enabling links to mental health support as needed.	Construction workers
Spire Stone wearable device and mobile app [34]	Brief modules for mindfulness training with monitoring of respiratory patterns and real-time biofeedback of physiological stress.	Employees from a large technology corporation across seven cities.

XSL•FO
RenderX

Name of app	Overview	Target population
Dayzz [42]	Personalized sleep training app that is an extension to an online SHAW[k] program.	Employees at a large health care organization.
Brain-sensing eyeglasses and a corresponding mobile app [58]	Eyeglasses collected EEG[l] activity during mindfulness, transferring the data to the app. App provided real-time acoustic feedback from data to promote relaxation.	Professionals with top management duties at a public service company
Smartphone-delivered biofeedback training (no official name found) [35]	Self-managed protocol with videos containing guided meditation practices and real-time biofeedback.	Psychiatric ward nurses in 3 hospitals who experienced workplace violence or abuse

[l]EEG: electroencephalogram.

Structured self-guided apps (n=23 apps) had a structured pathway in the form of programs or modules that users needed to complete, often in the form of modules, lessons, exercises, or activities. For instance, the HeadGear app (cited in 8 studies) is a 30-day intervention informed by mindfulness-based techniques that include daily challenges users are instructed to complete [17,38,45,51,54,60,67]. Headspace included daily guided 10-minute mindfulness practices or techniques [26,27,40,68]. Several studies noted that the app content was informed by evidence-based therapies, including behavioral activation and mindfulness [24,38,48,53,62,70], acceptance and commitment therapy [37,42,43,68], and principles of cognitive behavioral therapy [32,59], but varied widely in terms of the extent to which they adhered to evidence-based guidelines.

Unstructured self-guided apps (n=15) were more open-ended and provided users with the choice to select and engage with intervention components on demand. For instance, the Oiva app [66] consisted of information sessions on stress management and well-being based on the principles of acceptance and commitment therapy but had no prescribed guidance for engaging with the app. Many apps included meditation or relaxation exercises [28,31,35,44,48,49], self-monitoring tools (eg, mood, physical activity, and stress) [52,57,65,69], and/or links to resources [55,57].

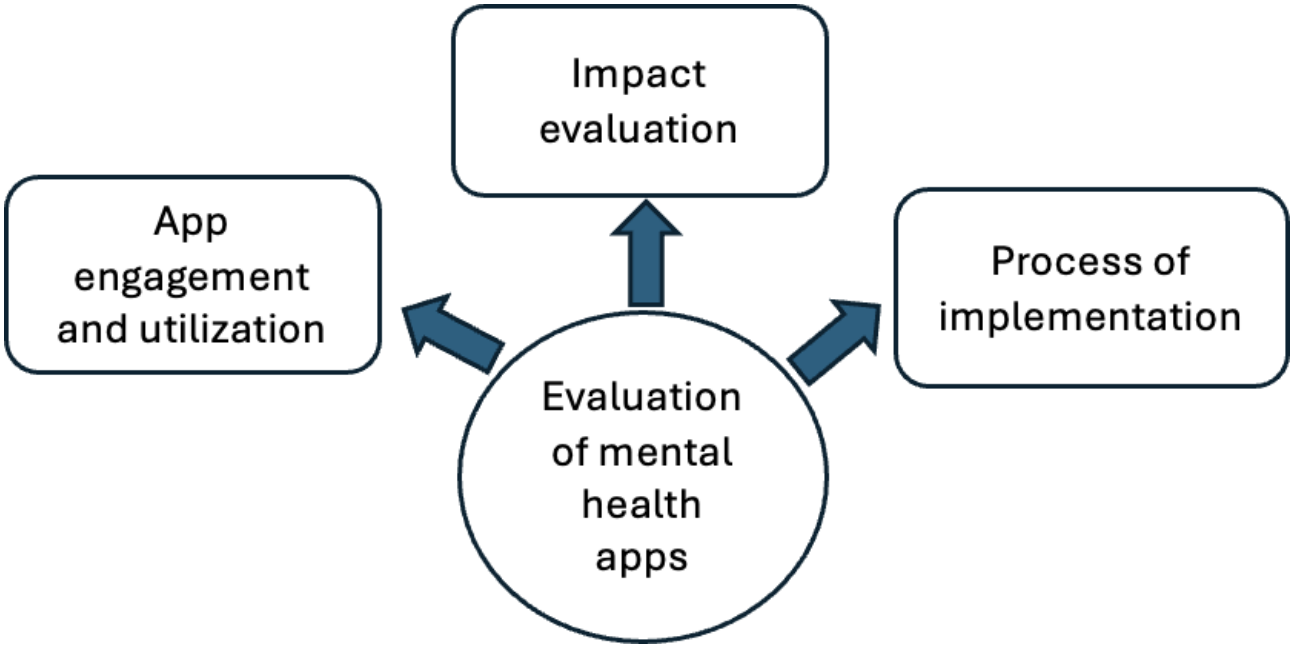
Finally, there were 5 apps that were designed to be implemented in conjunction with other interventions. Three were used to supplement in-person training [21,34,42], and three included wearable devices linked to the mental health app [34,35,58]. One study, for example, combined a brief in-person mindfulness training followed by monitoring of respiratory patterns through a wearable device, with real-time biofeedback received through the app [34].

In terms of intervention duration, most studies (n=38) implemented a fixed intervention period, typically ranging from 2 to 8 weeks, with 4 weeks being the most common. Outcomes were generally assessed at baseline and at the end of the intervention, although some studies included longer follow-up periods, with the longest extending to 12 months [38].

Study Populations

Participant demographics varied significantly across the studies. Some studies targeted the implementation of the intervention with specific gender groups, among individuals with symptoms of mental health issues and/or in specific workplace sectors. For instance, one study targeted male participants experiencing mild to moderate symptoms of stress and/or depression to assess the feasibility of a multicomponent, technology-based (P4Well) intervention [50]. Two other studies specifically recruited individuals from male-dominated industries to evaluate the effectiveness of a therapeutic app (HeadGear) [38,45]. One study focused on evaluating the effectiveness of a well-being and stress management app for working women [30].

Study participants worked in a range of industries, including health and social services (n=23), which largely aimed at implementing therapeutic apps, large corporations or consumer-based industries (n=5), information and technology (n=5), education (n=2), agriculture (n=1), apprenticeships (n=1), and construction (n=1). A subset of studies implemented their interventions across multiple industries (n=7), and a few studies did not explicitly specify the contextual setting (n=10) in which the research was being conducted.



Approach to Evaluation

We identified three primary ways (Figure 2) in which studies evaluated mental health apps with workers: (1) app engagement and utilization; (2) impact evaluation (mental distress, mental

XSL•FO
RenderX

health, and workplace outcomes); and (3) implementation process evaluation. The variables and tools within each approach are summarized in Multimedia Appendix 2.

Figure 2. Three primary approaches to evaluating mental health apps in the workplace.

App Engagement and Utilization

Most of the studies reported on users' engagement with the intervention by tracking app usage patterns. App use ranged from simply tracking the number of downloads or logins to tracking the number of times specific features were used, completion of specific tasks, and tracking the amount of time spent in the app. In the structured interventions, app usage included tracking adherence to the prescribed protocols. The data was typically gathered through built-in analytics that highlighted aggregate usage patterns of the app, although some studies gathered subjective reports of app usage through survey or interview questions. There were at least a dozen studies that did not report app usage data.

User feedback was another common way of tracking engagement, noted in 22 (41%) of the studies. Typically, the follow-up evaluation included exploring perceptions of the app's key features, such as usability, acceptability, quality, motivation to use the app, and overall satisfaction, and/or providing an opportunity to suggest improvements. Standardized measures, such as the Mobile App Rating Scale [70], were used in 5 studies [18,25,41,51,67]; the Systems Usability Scale [71] was used in 2 studies [22,32]; and the eHealth Impact Questionnaire was used in 1 study [16]. Other studies used more informal feedback approaches.

Impact Evaluation

Most of the research on the impact of mental health apps for workers focuses on multiple primary and secondary outcomes, ranging from mental distress to mental health and well-being, as well as specific work-related outcomes for individual app users. Table 3 highlights the most common outcomes that were evaluated, along with an overview of the tools that were used to track impact.

XSL•FO
RenderX

Table . Impact outcomes and measurement tools across studies.

Outcomes and variables	Most frequent measures used
Mental distress	
Symptoms of depression [16-20,23,25,29,31-35,38,40-42,44-47,50-55,57,60,62,67]	• PHQ-9[a] and PHQ-8 (n=16) • DASS-21[b] (n=4) • Center for Epidemiologic Studies Depression Scale (n=3) • Patient Reported Outcomes Measuring Scale (n=3) • Beck Depression Inventory (n=2)
Symptoms of anxiety [16-18,20,23,28,29,31,32,34,38,41,43,45,46,49,51,52,54,55,60,62,65,67]	• GAD-7[c] and GAD-2 (n=16) • STAI[d] (n=2)
Psychological distress [21,37,43,50,52]	• General Health Questionnaire (n=2) • Kessler Psychological Distress Scale (n=2) • General Symptom Index
Perceived stress [25-31,34,37,39,45,46,48,49,57,58,62,63,68]	• PSS[e] (n=16) • Biological markers of stress (n=4)
Psychological trauma [20,55]	• PCL-5[f]
Alcohol use [51,52,55,57]	• AUDIT-C[g] (n=2) • The Daily Drinking Questionnaire (n=1)
Sleep [25,26,33,39,42,47,49]	• Pittsburgh Sleep Quality Index (n=2) • Insomnia Severity Index (n=2) • Fatigue inventory • Sleeping troubles from COPSOQ-II[h]
Mental health	
Well-being [17,18,23,27,28,30,31,33,38-41,43,45,48,51,52,55,56,63,66-68]	• WHO[i]-5 Well-Being Index (n=12) • Warwick-Edinburgh Mental Wellbeing Scale (n=7)
Quality of life [16,23,29,34,50]	• Visual Analog Scale • Euro Quality of Life Questionnaire • World Health Organization Quality of Life • CDC[j] health-related quality of life metrics
Resilience [17,35,38,39,43,45,47,51,55,57]	• Connor-Davidson Resilience Scale (n=3) • Brief Resilience Scale (n=4) • Resilience Scale (n=2) • Korean Resilience Quotient
Self-compassion [28,33,40]	• Self-Compassion Scale (n=2)
Life satisfaction [28,49,50,66]	• 5-item SWLS[k] (n=2) • Meaning in Life Questionnaire–Presence Subscale
Mindfulness [26-28,40,66]	• Five Facets Mindfulness Questionnaire (n=3) • Mindful Attention Awareness Scale
Social connections [28,57]	• Social Readjustment Rating Scale • Social connection (NIH[l] Toolbox Loneliness Questionnaire)
Work-related outcomes	
Work stress [26,31,35,51,57]	• SISQ[m] • Korean Occupational Stress Scale (n=2) • Siegrist Job Strain Scale • Occupational Stress Indicator-2

XSL•FO
RenderX

Outcomes and variables	Most frequent measures used
Burnout [25-27,33,40,44,45,49,50,61,62,68]	• Maslach Burnout Inventory (n=8) • Bergen Burnout Inventory (n=3)
Work engagement [22,24,26,29,36,46,56,63,66]	• Utrecht Work Engagement Scale (9 items; n=7) • Job motivation (job match survey and Multidimensional Work Motivation Scale; n=2)
Job satisfaction [16,22,63]	• Self-report (n=3)
Work performance or productivity [17,23,32,38,39,41-43,45,47,51,56,60,63,67]	• HPQ[n] (n=6) • The Work Productivity and Activity Impairment Questionnaire (n=3) • WLQ[o] • Stanford Presenteeism Scale • Productivity cost (count of absenteeism and presenteeism; n=2)
Working conditions [16,21,31,39,56,63,64]	• MSIT[p] (n=2) • Job Content Questionnaire • Korean-Emotional Labor scale • Psychosocial safety climate • Strengths Use and Deficit Correction scale
Other outcomes	
Mental health knowledge [21,32]	• Author developed 14 multiple-choice scale • GAT[q] suicide awareness questionnaire
Help-seeking or health care utilization [21,23,42,43,47,54,60,72]	• General Help Seeking Questionnaire (n=2) • Intentions of help seeking • Self-report of medical visits or help accessed (n=3)
Healthy behaviors or physical function [23,49,57]	• IPAQ[r] • Fitness test (strength and flexibility) • Exercise and diet patterns
Cognitive function [28,50,58]	• Neurocognitive efficiency tests • Psychological flexibility (Acceptance and Action Questionnaire-2) • Perseverative thinking and Drexel Defusion Scale

[a]PHQ: Patient Health Questionnaire.
[b]DASS-21: Depression, Anxiety, and Stress Scale–21.
[c]GAD: Generalized Anxiety Disorder.
[d]STAI: State-Trait Anxiety Inventory.

[n]HPQ: Health and Work Performance Questionnaire.
[o]WLQ: Work Limitations Questionnaire.
[p]MSIT: Management Standards Indicator Tool.
[q]GAT: General Awareness Training.
[r]IPAQ: International Physical Activity Questionnaire.

Impact on mental distress was the most common outcome, evaluated in 42 of the 54 (78%) studies (Table 3). Symptoms of depression were evaluated in 30 (56%) of the studies, often using standardized tools such as the Patient Health Questionnaire-9 [73]. Symptoms of anxiety were evaluated in 24 (44%) of the studies, many using the Generalized Anxiety

XSL•FO
RenderX

Disorder (GAD-2 or GAD-7) [74]. Perceived stress was another common outcome measure used in 18 of the 54 (33%) studies, with tools such as the Perceived Stress Scale [75]. It is interesting to note that four of the studies incorporated biological indicators of stress [49,58,62]. Other measures of change in mental distress included tools to track symptoms of trauma, alcohol use, and sleep or insomnia.

Impact on mental health and well-being was another common outcome, evaluated across 34 (63%) studies. The primary outcome was the assessment of impact on well-being (n=24, 44%), using standardized tools such as the World Health Organization–5 (WHO-5) Well-Being Index [76] or the 14-item Warwick-Edinburgh Wellbeing Scale [77]. Other well-being outcomes included resilience (n=10), life satisfaction (n=7), quality of life (n=5), mindfulness (n=5), self-compassion (n=3), and social connection (n=2). These measures are congruent with many of the tools that focused on mindfulness and psychoeducation for coping with stress.

Impact on work-related outcomes was examined in 37 (68%) studies. Common work-related outcomes included work productivity and performance, burnout, job satisfaction, work engagement, and subjective perceptions of work stress and working conditions. Work performance outcomes, noted in at least 15 (30%) studies [17,23,32,38,39,41-43,45,47,51,56,60,63,67], included standardized tools such as the Work Limitations Questionnaire, the WHO Health and Work Performance Questionnaire, and the Work Productivity and Activity Impairment Questionnaire. Many of these tools included presenteeism or absenteeism measures, but several studies evaluated these separately [23,40,43,45,63,67], with some noting the productivity cost for organizations [23,47,67]. Burnout was another relatively common outcome noted in 12 (22%) of the studies [25-27,33,40,44,45,49,50,61,62,68], and evaluated using tools such as the Maslach Burnout Inventory or Bergen Burnout Inventory. Positive measures of job satisfaction were noted in four studies, often tracked through self-report [16,19,22,63]. Work engagement was another outcome noted in 9 (17%) studies [22,24,26,29,36,46,56,63,66], typically measured by tools such as the Utrecht Work Engagement Scale. In addition to work outcomes, 14 (26%) studies evaluated whether using a mental health app could change users' perceptions of their working conditions including perceived work stress [25,26,31,35,51,57], job demands or strain [16,31,36], psychosocial climate [21,23], and perceived social support, including support from leaders and co-workers [39,43,63,64].

Other outcomes used to track impact included changes in mental health knowledge [21,32], cognitive function [28,50,58], physical function [49], or engagement in healthy behaviors related to diet and exercise [23,57]. Help-seeking or health care utilization was another outcome noted in 7 (13%) studies [21,23,42,43,47,54,60], particularly with apps that promoted connection to mental health resources. It is interesting to note that very few studies evaluated behavior change.

Process of Implementation

While most studies evaluated the overall effectiveness of the technology on individual or work-related outcomes, only a limited number of studies (n=5) focused on evaluating how the process of implementation affected these outcomes. Protocol studies included in this review proposed examining the relationship between the extent of app usage [19] in terms of its influence on the overall effectiveness of the intervention and understanding strategies needed to initiate and promote the use of the app [22]. Implementation outcomes in 3 other studies involved the evaluation of individual, contextual, and implementation-related barriers and facilitators that influenced the uptake, use, and overall impact of the mental health intervention [66,68,69]. Process measures were incorporated in order to generate recommendations for optimizing the utilization and effectiveness of the mental health technology.

Discussion

Principal Findings

This scoping review identified 54 studies (43 completed RCTs and 11 protocols) evaluating mobile health (mHealth) applications in workplace contexts. The main trends in the research were (1) research on workplace mental health apps has expanded rapidly in recent years, particularly following the pandemic; (2) the majority of studies were conducted in health and social services, with few in male-dominated industries; (3) about half of the 44 distinct apps adopted a structured, self-guided approach with modules or activities for the user to complete, another third were unstructured apps to be used as needed, and 11% of the apps were designed to be used in conjunction with a wearable sensor or web-based program; and (4) commonly evaluated outcomes included mental distress (including perceived stress, anxiety, and depression), mental wellness (well-being and resilience), and workplace-related outcomes (burnout, workplace engagement, work productivity, and performance), with limited studies on the process of implementation. Together, these findings highlight important gaps in both the design and evaluation of workplace mental health apps, underscoring the need for greater use of implementation science frameworks to guide future research.

Study Characteristics

The results of this review profiled 43 completed studies and 11 study protocols that evaluate the impact of mHealth interventions on a working population. A previous systematic review, published in 2019, on e–mental health interventions in the workplace identified 22 studies, but only 3 studies included apps as a primary intervention [78]. The pandemic and post-pandemic era have precipitated a rapid increase in app-related research with workers (41 studies in the past 5 years). This may reflect a shift to mHealth approaches to support the growing mental health needs of workers. The number of completed randomized clinical trials (24/54, 44%) is promising, reflecting high-quality research designs to evaluate impact. Furthermore, this review included 11 trial registrations or published protocols, reflecting that the research is ongoing. The rise of digital technology and associated research on mental health apps for workers speaks to the importance of summarizing current evaluation practices and gaps in the evidence.

XSL•FO
RenderX

Types of Mental Health Applications

The review also highlighted diversity in the nature of mHealth interventions, with 44 different types of unique applications across the mental health spectrum, from promoting wellness to managing illness. In fact, several studies included wearable devices linked to the app, which may reflect a new technology trend. As noted in other review studies of mobile apps in the workplace, many were based on principles of cognitive behavioral therapy or mindfulness, combining information sharing with self-monitoring and self-management activities [11-13,79]. It is interesting to note, however, that even in the structured apps, the mechanisms of action were not consistently explained. There were a few studies that explicitly cited theories such as behavioral activation and cognitive behavioral approaches, but many of the app tools and techniques were not necessarily embedded within a psychotherapeutic protocol. This is a significant gap since explicit links between app design and expected outcomes are important aspects of evidence-based interventions [80].

Over half of the studies featured structured, self-guided apps with specific modules or activities that users were directed to complete, often over a 2 to 8-week period. Outcomes related to engagement, including completion of the activities, were more amenable to tracking "success" than apps that were less structured and available to use "as needed." Given high attrition rates in app use, recommendations for optimizing engagement noted in the literature include providing "challenges" within the technology over short periods to build habits, providing regular "push notifications," and connecting with an online coach or therapist [81]. Additional research is needed, however, to systematically evaluate the effect of these implementation strategies, and longitudinal research is needed to track the impact of these strategies over time [79,81]. Only a few apps (Headspace, Headgear, or Shift) had more than 2 studies examining their effectiveness, reflecting the need for more robust evaluation.

Study Participants

Although studies in this review were conducted across a range of sectors, the highest proportion (23/54, 42%) was in health and social services. Given the mental health crisis noted in health and social services that is leading to significant shortages in staffing [44,68], these studies indicate promising efforts to evaluate innovative strategies to support the mental health of this group of workers. Studies in other sectors were more limited, although there were several in service-based sectors (education and information technology), with comparatively fewer studies in male-dominated industries such as construction. Unfortunately, 10 of the studies did not specify the workplace context where the app was implemented, making it difficult to identify relevant recommendations for specific workplace sectors. Given the importance of the workplace context, future comparative research is needed to explore how mobile apps function differently across industry sectors and organizations. Furthermore, many studies included in this review lacked sufficient reporting details regarding the intervention, research setting, and evaluation plan, making it challenging for future reproducibility, comparability, and dissemination. There are guidelines, such as the 16-item mERA (mHealth Evidence Reporting and Assessment) checklist, that can be used to improve the reporting quality of interventions and support replicability of research [82]. This checklist provides comprehensive recommendations for study authors on adequately describing the content, context, and technology infrastructure to implement the mobile health technology with a specific population group [82].

Key Evaluation Variables and Tools

The review highlights 3 different categories of evaluations conducted by studies exploring mental health apps. User engagement and feedback were important outcomes tracked across many studies, either objectively through app metrics or subjectively through a recall of usage patterns. Feedback about usability, acceptability, and relevance was tracked qualitatively but also through standardized measures such as the Mobile Application Rating Scale [70] and the System Usability Scale [71]. Tracking user perceptions, engagement, and interaction with mental health apps is critical in establishing a relationship between usage (dose) and desired outcomes (response) [79]. Individual studies varied in their operational definitions of these constructs along with how they were measured, ranging from objective measures of usage (frequency and duration of use) that are passively collected from within the app to subjective measures of user ratings of usefulness and satisfaction, making it difficult to conduct cross-study comparisons.

Currently, there is no consensus on what constitutes optimal engagement for a mental health app to produce desired effects [83,84]. One study exploring different types of app use, features, and their effect on outcomes found that the right combination of different features (ie, learning, goal setting, and self-tracking) and their use at a moderate level could lead to desired outcomes, thereby refuting the common belief that higher usage always leads to better outcomes [85]. Collectively, each of the identified measures could be valuable in determining whether users who reported higher levels of usage, found the app useful, and were satisfied were more likely to engage with the intervention optimally, subsequently leading to significant improvements in outcomes. However, only 1 study protocol proposed assessing the link between the dose (the extent to which an app needs to be used) and the response (a significant improvement in outcomes) [19].

In addition to assessing usage and engagement, user experience and feedback were typically assessed only in feasibility studies. Since apps require iterative updates and maintenance, assessing user experience and feedback over time is important when attempting to deploy them in a large-scale, real-world setting [84].

In terms of impact, it is interesting to note that there was a range of approaches to evaluation, ranging from impact on reducing mental distress (78%) to improving mental well-being (63%) or work-related outcomes (68%). Since all of the studies were conducted in the context of the workplace, these workplace-related outcomes may be important for organizational decision-makers who are considering the value of investing in mHealth technology. Although there were 37 studies that considered workplace outcomes, there was a wide range of tools

XSL•FO
RenderX

to evaluate these outcomes, ranging from downstream measures of productivity and burnout to more upstream measures of work engagement, perceived working conditions, and job satisfaction. Although there is a growing body of evidence indicating that digital mental health interventions implemented in workplaces can improve work effectiveness and productivity [13], tracking these outcomes can be complex, considering that studies need to speculate when changes in these workplace performance outcomes will take place and embed appropriate follow-up time points to measure them [86]. Study designs need to clearly outline the components of the intervention and the mechanisms of change to define what constitutes proximal (short-term or immediate) outcomes and distal (long-term) outcomes and determine appropriate time points for the measurement of these outcomes.

Even when apps are designed to be evidence-based, this does not guarantee that the expected outcomes will occur. Evaluating a complex mental health intervention in the context of the workplace requires a multilevel approach, considering the implementation process as well as its impact [81,86]. While several studies in this review acknowledged the complexities of implementing a digital intervention in a workplace setting, very few systematically evaluated the process of implementation, and there appears to be a gap in the application of existing theories to systematically guide this inquiry.

Several implementation science theories and frameworks can be useful to guide further research in understanding and unpacking the complexities of implementing technology across different contexts and achieving large-scale adoption and sustained effects. For example, the Consolidated Framework for Implementation Research (CFIR) provides a summary of evidence-based constructs across 5 domains: the intervention, the individual user, the inner context, the outer context, and the process of implementation [87]. These constructs can help identify and explain the facilitators and barriers to the uptake and impact of the intervention [87]. Another similar framework, called the nonadoption, abandonment, scale-up, spread, and sustainability (NASSS) framework [88], highlights six key domains that can be used to guide researchers in evaluating the success of an mHealth intervention implemented in an organizational context. It considers the characteristics of (1) the condition being addressed (eg, mental health), (2) the technology-based intervention, (3) the adopters of the technology, (4) the value proposition for the users, (5) the organization where the technology is being implemented, and (6) the wider system or society. The NASSS framework also reflects on the complex and dynamic interaction between the 6 domains over time, which can help answer questions related to users' engagement with apps over time [88]. Systematic evaluation of the implementation process can facilitate exploration of key facilitators and barriers that influence the uptake and effectiveness of the intervention. While traditional health care interventions typically emphasize evaluation of their effects on key outcomes, mental health app–based interventions necessitate the examination of the different ways in which users engage with the intervention as well as exploring other implementation-related and contextual factors that influence the uptake and overall impact [79-81,83,86].

Limitations

To our knowledge, this review is one of the first to summarize current research regarding approaches to evaluating mental health apps specifically in the context of the workplace. While a broad objective was established at the onset of the review in order to sufficiently capture all relevant studies, we restricted our search to studies that were published in English to ensure feasibility in terms of timelines and resources. Another limitation was the focus only on descriptions of the evaluation approaches outlined in the studies. There was no formal assessment of the study quality or synthesis of study findings. Future systematic reviews are needed to critically evaluate the current research evidence to identify the impact of mental health apps, and to profile what works for whom and in what context. This is particularly important to assist organizational leaders, policymakers, and stakeholders in deciding how to invest in and optimize the use of mental health apps with frontline workers.

Recommendations

Results from this study informed the following recommendations for future research regarding app-based mental health interventions in the workplace. First, future research should improve transparency and consistency in the reporting of studies by incorporating guidelines such as the CONSORT-EHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and Online Telehealth) [89]. Second, evaluation studies need to identify and measure appropriate outcomes by examining the congruence between intervention goals and outcomes when exploring the effectiveness of mental health apps. Third, there is a need for longitudinal studies to assess the long-term effects of mental health apps, particularly when evaluating their impact on workplace outcomes that may require a longer duration to detect meaningful changes. Fourth, long-term effects of mental health apps, particularly when evaluating their impact on workplace outcomes that may require longer duration to detect meaningful changes. Fifth, there is a need to investigate strategies for integrating mental health apps into existing workplace settings by considering organizational factors and fostering an implementation science lens. Applying implementation theory can generate new insights about what works for whom and in what context. Sixth, there is a need to investigate strategies for integrating mental health apps into existing workplace settings by considering organizational factors and fostering an implementation science lens. Applying implementation theory can generate new insights about what works for whom and in what context. Finally, a future systematic review is needed to synthesize and appraise current evidence regarding the effectiveness of mental health apps for workers.

Conclusions

In conclusion, the past decade has seen tremendous advancements in the field of mHealth innovation, including its application in the context of the workplace. Traditional experimental approaches to evaluating mHealth interventions, however, may not be sufficient to capture the complexities of the facilitators and barriers that shape the adoption of the intervention and the sustainability of its effects within diverse

XSL•FO
RenderX

workplaces. This methodological gap calls for research in this field to embrace new implementation science methodologies to truly capture the nuances of technology adoption and reliably measure its effectiveness over time.

Acknowledgments

The authors thank Meghan Lees, who assisted as a second reviewer in the initial screening process, and Melissa Parker and Ante Cuvalo, who provided assistance with revisions to the final paper.

Funding

The authors would like to acknowledge the support for the article processing fee by the Public Health Agency of Canada.

Data Availability

Data tables generated and analyzed during this study are included in this published study and in multimedia appendices.

Authors' Contributions

SA led the scoping review, including conceptualization, data collection, analysis, and drafting of initial and revised versions of the paper. SM provided supervision throughout the process, from conceptualization to analysis, and actively supported the writing of the initial and revised drafts of the paper. LM and JM provided input into the analysis of the study findings and contributed to the review and editing of the final paper. Generative artificial intelligence was not used in any portion of the manuscript writing.

Abstract

Background: Current methods of cardiorespiratory fitness (CRF) assessment may discriminate against frail individuals who are challenged to perform a maximal cardiopulmonary exercise test. CRF estimations from free-living wearable data, captured over extended time periods, may offer a more representative assessment and increase usability in clinical settings.

Objective: This study aimed to review current evidence behind this novel concept and evaluate the performance and quality of models developed to estimate CRF from free-living, unsupervised data.

Methods: Following the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines, we systematically searched 4 databases (MEDLINE, Embase, Scopus, and arXiv) for studies reporting the development of models to estimate CRF from continuous free-living wearable data. Studies conducted entirely under controlled laboratory conditions were excluded. Performance metrics were combined in a meta-correlation analysis using a random-effects model and Fisher Z transformation.

Results: Of 1848 papers screened, 18 met the eligibility criteria, with a total of 31,072 participants. The weighted mean age was 46.9 (SD 1.46) years. Multiple computational techniques were used, with 8 studies employing more advanced machine learning models. The meta-correlation analysis revealed a pooled overall estimate of 0.83 with a 95% CI 0.77 - 0.88. The I^2 test indicated high heterogeneity at 97%. Risk of bias assessment found most concerns in the data analysis domain, with studies often lacking clarity around the data handling process.

Conclusions: A promising preliminary agreement between CRF predictions and measured values was noted. However, no definite conclusions can be drawn for clinical implementation due to high heterogeneity among the included studies and lack of external validation. Nonetheless, continuous data streams appear to be a valuable resource that could lead to a step change in how we measure and monitor CRF.

KEYWORDS

wearables; cardiorespiratory fitness; free-living data; machine learning; perioperative medicine

Introduction

Cardiorespiratory fitness (CRF) is regarded as a key element of anesthetic preassessment and preoperative decision-making, reflecting an individual's aerobic capacity and ability to withstand and recover from surgery. The most widely recognized measure of CRF is maximal oxygen uptake (VO_2max), a strong indicator of the cardiorespiratory system's ability to capture, transport, and use oxygen during exercise. VO_2max is inversely related to all-cause mortality and linked to several other health outcomes, such as cardiovascular disease (CVD), dementia, and depression [1-3]. In surgery, VO_2max serves as a prognostic marker and is currently the gold standard predictor of early postoperative cardiorespiratory morbidity [4,5].

XSL•FO
RenderX

Cardiopulmonary exercise testing (CPET) is a maximal dynamic test used to assess CRF and global exercise response. CPET is typically performed on a cycle ergometer or a treadmill under conditions of graduated physiological stress, involving computerized gas-exchange analysis of breath-by-breath ventilation. The test is routinely used in cardiorespiratory medicine as a diagnostic tool to distinguish between ventilatory and cardiac exercise intolerance [6]. In the preoperative setting, it is usually used as a risk assessment tool for major surgery to aid clinical decision-making regarding suitability for surgery and to guide perioperative management [7,8].

Despite its proven ability for risk stratification, there remain some drawbacks to this method. VO_2max measurements through maximal exercise can be strenuous and challenging for older or frail adults and those with musculoskeletal conditions who may be limited by pain rather than exertion [9]. Performance-reducing factors, such as peripheral arterial disease, osteoarthritis, and poor effort, have also been associated with inaccurate measurements, which may impact clinical decision-making [10]. In addition, high costs, the requirement for highly trained staff to undertake the test, and reduced hospital availability render regular VO_2max monitoring impractical.

To overcome these limitations, several VO_2max prediction models have been developed: nonexercise models are usually derived from lifestyle and anthropometric data, while submaximal exercise tests rely on prespecified protocols that involve heart rate (HR) monitoring at certain speeds, such as the 20-meter shuttle test or the modified shuttle walking test [9,11,12]. These methods offer an alternative; yet, they are not widely used in routine clinical practice due to some inherent limitations. Submaximal tests rely on the assumption that mechanical efficiency is the same for everyone, often leading to inaccurate VO_2 max estimations, and self-reported physical activity measures are subject to social desirability and recall bias [13]. Equally, lack of protocol standardization has raised concerns about the validity and reliability of submaximal tests [14]. Nonetheless, it seems a great limitation of the above CPET alternatives is their inability to capture and assess unstructured and incidental ambulatory activity accurately [15].

This gap has encouraged the exploration of wearable devices that can collect a substantial amount of information about an individual's activities in daily life, regardless of frequency, duration, or intensity [16]. Wearable technology has experienced a remarkable uptake over the last years, with more users appreciating the potential benefits for health and fitness tracking [17]. Commercially available wearables already offer VO_2max estimations; however, their algorithms are primarily based on short periods of structured exercise data, and their resulting VO_2max estimations have a large degree of error at the individual level [18]. Continuous monitoring of unstructured physical activity, however, shows promise in a variety of settings, enabling constant tracking of physiological data in an unobtrusive manner [16]. Physiological signals captured over longer periods may be more representative of CRF for certain populations. In view of the great potential of these devices, we aimed to explore whether CRF can be accurately predicted leveraging wearable data from unsupervised free-living conditions, outside the controlled laboratory environment. In this paper, we systematically review the research methodology behind the proposed models, the associated challenges and limitations, and discuss the feasibility of applying this concept for CRF estimation in health care settings.

Methods

Search Strategy and Study Selection Process

This study was registered with the international database for systematic reviews PROSPERO (CRD42024593878). We followed the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) statement and recommendations for systematic reviews [19]. Relevant studies were located from a systematic electronic search of 4 databases (MEDLINE, Embase, Scopus, and arXiv), and the last search was performed on July 27, 2024. The full search strategy and key terms are available in Multimedia Appendix 1.

We used online systematic review software to blind reviewers and screen titles and abstracts after removing duplicates [20]. Conflicts were resolved through direct discussion between the 2 reviewers (AD and ABS) after unblinding. The full papers of potentially eligible studies were scrutinized against the eligibility criteria. Citation chaining of references was also completed by AD. Any additional studies identified were subsequently reviewed and assessed for inclusion by a third investigator (MRK; Textbox 1).

XSL•FO
RenderX

Textbox 1. Inclusion and exclusion criteria.

Inclusion criteria:

- All papers reporting the development of a prediction model to estimate maximal oxygen uptake from longitudinal free-living wearable data.
- "Free-living" is defined as data collected in unsupervised, uncontrolled, real-world settings.
- Mixed designs with some simulated activities permitted, provided that at least some unsupervised activity was captured and analyzed.
- Human studies published in English.
- All wearable devices are eligible, including accelerometers, electrocardiogram (ECG) biosensors, commercial smartwatches, and optical heart rate sensors (photoplethysmogram).
- No restriction applied to the clinical setting studied.

Exclusion criteria:

- Studies in which the authors focused solely on physical activity and energy expenditure estimation.
- Monitoring occurring exclusively under controlled laboratory conditions, with no free-living activity studied.
- Wearable data including only exercise activity.
- Studies in which the authors did not report a prediction model but only correlations of wearable metrics with measures of cardiorespiratory fitness.
- Systematic reviews, literature reviews, surveys, conference proceedings, or meeting proceedings.
- Studies focusing on adolescents and young children.

We considered all papers reporting the development of a prediction model to estimate VO_2max from longitudinal free-living wearable data. For this review, "free-living" was defined as data collected in unsupervised, uncontrolled, real-world settings. Mixed designs with some simulated activities were also permitted, provided that at least some unsupervised activity was being captured and analyzed by the authors. A limit was set to human studies published in English. All wearable devices were eligible, including accelerometers, electrocardiogram (ECG) biosensors, commercial smartwatches, and optical HR sensors (photoplethysmogram). No restriction was applied to the clinical setting studied.

Studies were disqualified if (1) the authors focused solely on physical activity and energy expenditure estimation; (2) monitoring occurred exclusively under controlled conditions in a laboratory setting, and no free-living activity was studied; (3) wearable data included only exercise activity; (4) the authors did not report a prediction model, but only correlations of various wearable metrics with measures of CRF; (5) they were systematic or literature reviews, surveys, conference, or meeting proceedings; and (6) studies focusing on adolescents and young children.

Data Extraction and Model Performance Assessment

To ensure consistency, a standardized form was piloted and modified until consensus was reached between 2 authors and the senior investigator for the data extraction tool. Two reviewers (AD and ABS) retrieved all relevant data independently, and a third author (MRK) verified the accuracy of the records, cross-referencing with sources to resolve discrepancies. For each study, the following items were extracted: study details, demographics, setting and sample size, wearable device used for monitoring, and the baseline method used to obtain the ground truth (control). We recorded features derived from wearable data and the preprocessing techniques researchers used for feature extraction. We extracted details on the various machine learning (ML) models that were used, as well as prediction accuracy metrics and the validation process reported.

Quality Assessment

Qualitative appraisal of each included study was independently performed by 2 authors using a modified version of the Prediction model Risk Of Bias Assessment Tool (PROBAST) following the updated TRIPOD-AI (Transparent Reporting of a multivariable or ML prediction model for Individual Prognosis Or Diagnosis–artificial intelligence) guidance [21,22]. In case of disagreements, the opinion of the third author was sought.

Studies received a score of "low," "unclear," or "high" risk of bias on five major domains: (1) predictor choice and definition; (2) participant selection, including source and study setting; (3) outcome measurement; and (4) analysis and methodological quality of the proposed model. Overall judgment was rated as unclear if at least 1 domain was regarded as unclear, and similarly as high if any domain was rated as high. Risk-of-bias plots were created for quality assessment using the "robvis" software package in R (R Foundation for Statistical Computing).

Data Analysis

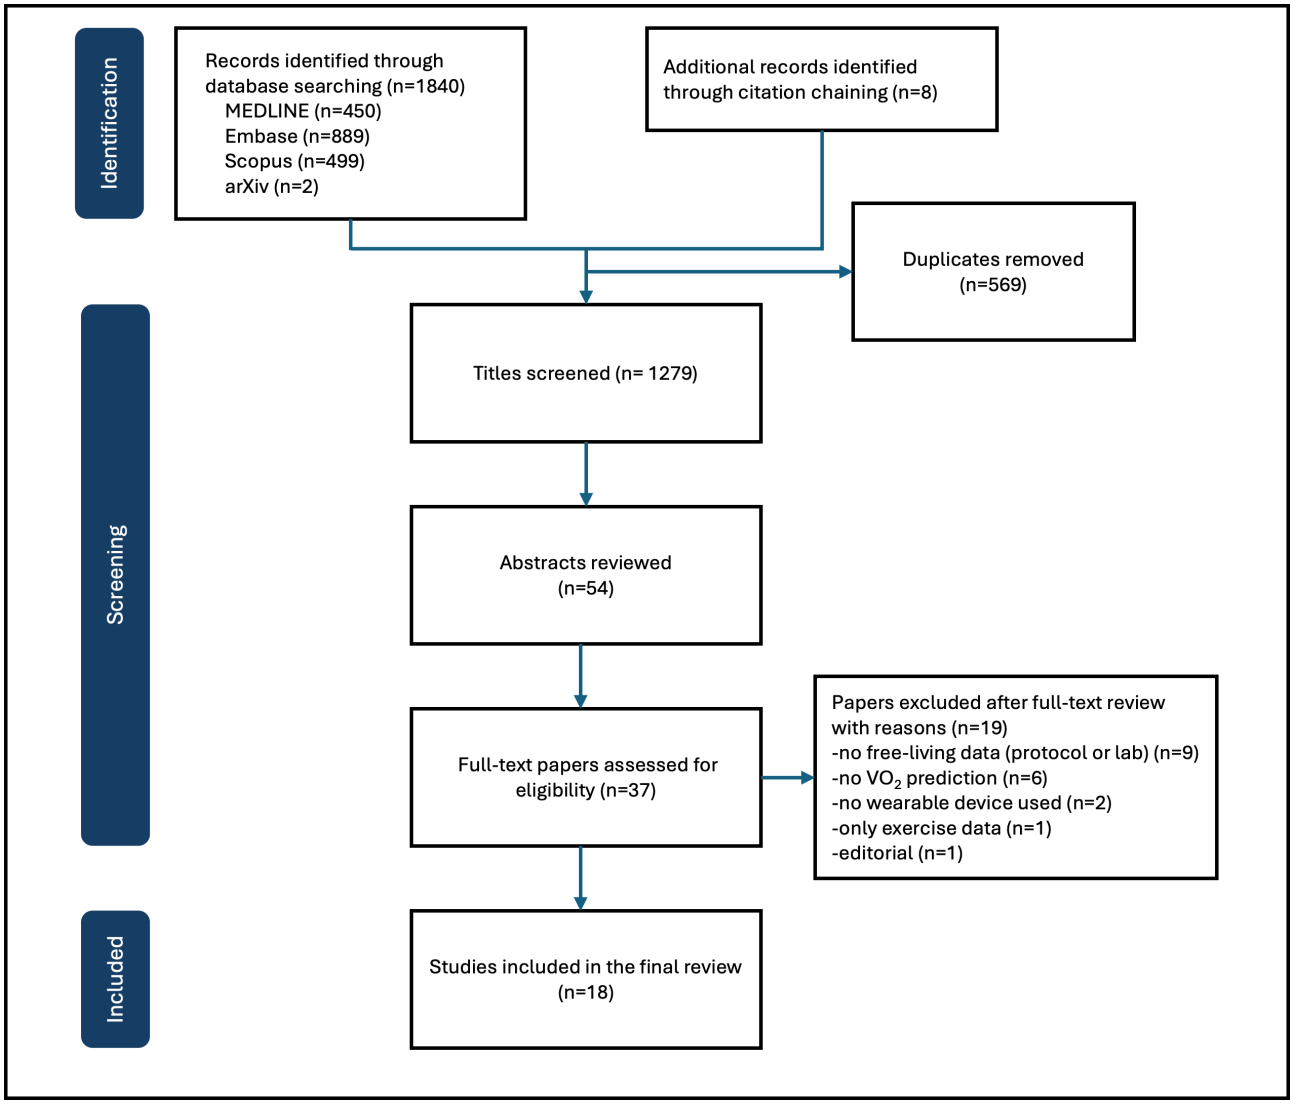
We calculated and reported descriptive statistics to outline each study characteristic. Summary measures are reported as means or medians, including measures of dispersion such as SDs. Key metrics of model accuracy were identified and combined for quantitative analysis.

Frequently reported metrics included the Pearson correlation coefficient (r) and the R^2 values. Other metrics such as the standard error of estimate (SEE) and the root-mean-square error were also reported but less frequently. Although not technically an accuracy metric, where available, the r coefficient was used to indicate how well the model's predictions aligned with the CPET values.

XSL•FO
RenderX

A meta-analysis of correlation estimates was undertaken to integrate measures of performance across the included studies and provide a more objective and systematic assessment. In this instance, reported correlation coefficients (r) were used as the primary effect size, as they represented the most consistently reported metric in this review. When only R^2 values were available, we converted them by taking the square root to obtain the corresponding r values between the predicted and actual VO_2max values and assessing the direction of association in each study. RStudio (version 2024.04.2+764; R Foundation for Statistical Computing) was used for all statistical analyses [23]. Two packages, "metafor" and "robumeta," were installed to perform the meta-analysis. Fisher Z transformation was applied to convert correlation estimates to a more normally distributed metric and obtain standard effect sizes. A restricted maximum likelihood estimation method was used for a standard random-effects model to conduct the meta-analysis [24]. The random-effects model assigns less study weight to larger studies with less variance [24]. Results of the meta-correlation analysis were presented visually using a forest plot. Subgroup analysis was also performed, comparing regression-based models with more advanced ML methodologies.

We assessed heterogeneity using the I^2 and τ^2 statistics. The I^2 statistic quantifies the proportion of total variation in effect sizes that was due to heterogeneity rather than chance. We considered I^2 values of 25%, 50%, and 75% to represent low, moderate, and high heterogeneity, respectively [25]. The τ^2 represents another method to assess the between-study variance, focusing on the absolute variability of true effect size, with higher values indicating greater heterogeneity [26]. The Egger test was used to assess the likelihood of publication bias, which was also presented visually with a funnel plot.



Results

Overview

The combined literature search generated 1848 papers, with 1279 remaining after deduplication. The PRISMA flowchart (Figure 1) shows the paper selection process. Following title and abstract screening, 37 papers qualified for full-text review. Eighteen studies were accepted in the final set with a total sample size of 31,072 participants. Sample sizes varied greatly across studies and ranged from 13 to 12,425. Only 4 studies had a sample size of more than 1000 patients, indicating that most research in this field is based on a relatively small number of participants [27-30].

XSL•FO
RenderX

Figure 1. Flowchart of study selection following the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidance. VO_2: maximal oxygen uptake.

The characteristics of each included study are shown in Table 1 [2,4,5,7,11,12,16,27-37]. Participant-level weighted mean age was 46.9 (SD 1.46) years, with a male participant distribution of 48.9%. Notably, a few studies had exclusively male or female participants, while others had more balanced samples. Most studies included data from volunteers recruited in a prospective manner (n=13, 72%). Smaller studies focused primarily on healthy participants (n=13), in contrast to the larger cohorts (n=5) that used data from population studies involving hundreds of patients (the Fenland and Framingham studies) [38,39]. Overall, there were only 2 research trials that targeted patients scheduled for preoperative assessment [4,7].

[a]M: male.

[b]HR: heart rate.

[c]GXT: graded exercise test.

[d]F: female.

[e]NR: not reported.

[f]ADL: activities of daily living.

[g]PPG: photoplethysmogram.

[h]ECG: electrocardiogram.

A wide variety of wearable devices were used, including triaxial accelerometers, ECG sensors, and smartwatches with optical photoplethysmogram sensors. All studies used accelerometers for motion tracking, while HR monitoring was performed either with ECG (n=9) or optical sensors (n=6). The monitoring durations also differed, with most studies tracking participants over a few days, usually 3 - 7, while others extended up to nearly a year [29]. Measurement of VO_2max as the ground truth was typically obtained through a maximal CPET test, though in 4 trials, a submaximal treadmill test was used. In 1 study, reference VO_2max was not directly measured but estimated using the proprietary algorithm of a smartwatch device [29]. Due to disparities in participant populations, the reference mean VO_2max varied significantly between patient-centered studies (weighted mean VO_2max 19.2 mL/kg/min, SD 1.48) and healthy volunteer studies (40.2 mL/kg/min, SD 6.58; z test, P=.03).

Features

Feature extraction is a crucial first step in signal processing, transforming complex raw data points into meaningful numerical features that can be interpreted and processed in a model [40]. In high-volume continuous wearable data, feature extraction can also help to reduce dimensionality without losing important information. This process makes data handling easier and speeds computation by focusing only on the most relevant aspects of the data [41]. We observed, however, that in 6 studies, researchers adopted features as reported from the internal proprietary algorithm of the manufacturer without further analysis of the raw data. Table 2 summarizes the analytical methods used in the included studies, while Table 3 provides an overview of each feature type with examples in the studies used.

Table . Summary of analytical methods, models, and wearable features used in the included studies.

Study, year	Wearable features	Model used	Preprocessing techniques and analysis	Model performance	Validation	Principal finding
Plasqui and Westerterp [2], 2005	[a]HR/ACM[b] index (ACM: activity counts per minute)	Multiple linear regression	Minute averages for HR and activity counts averaged over the 7 days, ratio of HR/ACM, and missing data removed	SEE[c]=12.4%; r=0.87	NR[d]	Fitness index HR/ACM significantly related to VO_2max[e] corrected for body composition and age
Plasqui and Westerterp [33], 2006	HR/ACM index	Multiple linear regression 2nd equation tested	Same as above and groups combined and sorted for activity counts	r=0.86; SEE=10.7%; Bland-Altman systematic error=5.6%	Cross-validation	A second equation for the fitness index HR/ACM had to be tested to predict VO_2[f]
Cao et al [34], 2009	Daily SC[g]	Hierarchical linear regression	Steps per day provided and handling of missing data not reported	SEE=10.9%; r=0.81	Split test	SC was a significant contributor to the prediction of the measured VO_2max
Cao et al [35], 2010	MVPA[h], VPA[i], and SC	Hierarchical linear regression	As provided (minutes spent in MVPA and VPA) and handling of missing data not reported.	SEE=9.66%; r=0.863	Cross-validation, Subgroup analysis	VPA significantly increased the explained variance in VO_2max, adjusted for age
Novoa et al [4], 2011	Daily SC, Aerobic SC, time spent in aerobic activity, and daily distance in km	Linear regression	As provided and handling of missing data not reported	R^2=0.93	Bootstrapping (1000 iterations)	VO_2max can be significantly predicted by the mean daily walked distance
Altini et al [11], 2016	HR at different walking speeds, stay regions, and activity composites (ie, HR at relative time spent in each activity)	Nonnested hierarchical Bayesian regression, SVM[j] classifier, and HMM[k] for transitions between activities	LDA[l] activity is classified into 6 clusters, accelerometer data was bandpassed between 0.1 and 10 Hz to isolate dynamic components, HR was extracted from R-R intervals and averaged over 15 seconds, and missing data not analyzed	R^2=0.76; RMSE[m]=249.4; SEE=5.79%	Leave-one-participant-out cross-validation	Contextualizing HR by means of activity and speed improved correlation between free-living HR and CRF[n]
Altini et al [5], 1985	HR/min while lying down and while walking at 3.5 and 5.5 km/h	Multiple Linear regression, SVM classifier	HR was extracted from R-R intervals and averaged over 15 seconds windows and unusable ECG[o] was discarded. Acceleration signal was segmented in nonoverlapping intervals of 5s	R^2=0.78; RMSE=284.7	Leave-one-participant-out cross-validation	Submaximal context-specific HR can be used to estimate VO_2max

Study, year	Wearable features	Model used	Preprocessing techniques and analysis	Model performance	Validation	Principal finding
Beltrame et al [37], 2018	Means of HR, VE[p], BF[q], hip acceleration, and SC in the 2 conditions ("active-inactive")	Random forest	HR was averaged every 16 beats, VE and BF average of the last 7 respiration cycles, all features were time-aligned, low-pass filtered at 0.01 Hz. Fast Fourier transformation and frequency domain analysis for hip acceleration, and when hip acceleration was >0.05 g, data were labeled as "active"; otherwise, they were "inactive	r=0.88	Leave-one-participant-out cross-validation	Predicted oxygen uptake data during ADLs[r] were strongly correlated with the temporal characteristics of the VO_2 during a controlled protocol
Ahn et al [31], 2017	aEE[s] (nonlinear model derived from ACM horizontal and ACM vertical signals and HR per minute	Linear regression between HR and aEE	The tri-axial acceleration was band-pass filtered (0.25 to 7 Hz). ECG data were band-pass filtered (5 to 20 Hz), the R-R intervals were averaged for 1 min and converted to a HR, and used only increasing HR periods and excluded data with inaccurate ECG	R^2=0.74; r=0.87; SEE=11.85%	Split test	aEE can be used to estimate VO_2max during daily activities
Kwon et al [12], 2019	HR and daily PA in terms of METs, used slope of HR and PA	Linear regression	Moving average filter was applied, data points at which both HR and physical activity data increased were selected	R^2=0.651; SEE=3.518; 9.6%	PRESS[t] for cross-validation	VO_2max can be estimated using novel features, aEE and the slope between physical activity and HR
Bonomi et al [16], 2020	Acceleration and HR- fitness index named TEE-pulse[u]	Stepwise linear regression	Motion intensity was defined as activity counts per minute, acceleration signal was processed in overlapping windows of 60 seconds, and activity is grouped in (sedentary, or other) based on a set of counts thresholds	RMSE=367 or 12.4%; SEE=13.09%; r=0.89; MAE=10.2%	Leave-one-participant-out cross-validation	The daily average TEE-pulse was highly correlated to the mean TEE-pulse measured in the laboratory without the need for specific exercise protocol
Jones et al [7], 2021	Floors climbed, total number of steps and total distance, average HR and resting HR	Linear regression	Features were used as provided by the device and averaged across the 7-day wear period. Self-reported METs[v] from questionnaires	AIC[w]=181.62; R^2=0.74; r=0.86; AUC[x]=0.93	NR	Using all the wearable variables together in linear regression gave a stronger correlation between the measured CPET[y] values, specifically for peak VO_2

Motion Features

Activity features from the accelerometer data included mainly daily step count (SC), distance covered, time spent in anaerobic or sedentary activity (stay regions), and acceleration or walking speed (Table 3). From these, the most frequently reported feature was the daily SC, which in most instances was precalculated from the accelerometer's proprietary algorithm. We found that some researchers reported steps as an average across several days, removing the temporal context which might be useful in analyzing trends [2,4]. Intensity of movement and walking speed was described as time spent in sedentary or vigorous activity, which can be calculated from the acceleration as activity counts per minute [16]. One study used simulated daily activities to correlate aerobic dynamics of variable intensity [37]. Finally, distance covered was either extracted directly from the device or computed as the total number of steps taken in a day multiplied by the stride length of the participant [4].

Cardiac Features

Features extracted from the ECG and optical sensors included average HR, resting HR, HR per minute, mean HR, and ΔHR (difference between current and previous HR value to capture the magnitude of changes in cardiac activity). ECG signals are generally complex; they are subject to motion artifact, creating noise that affects quality [42]. Various filtering methods were applied to reduce noise. Researchers commonly use a band-pass filter between 5 and 10 Hz to remove artifacts and enhance the detection of the heartbeat from the R-R intervals. The R-R intervals were usually averaged over set-time windows, discarding any inaccurate values [11,31]. Beltrame et al [37] averaged HR every 16 beats, passing HR data through a low-pass filter at 0.01 Hz, removing high frequencies.

Contextualized HR

The combination of HR and activity data, often referred to as contextualized HR, was reported in more recent studies. This contextual dimension of wearable signals can be vital in understanding the physiological cardiac response to exercise. Such features comprised HR at variable-intensity walking speeds, HR and SC per minute, HR/cadence ratio, and HR response to cadence increase (Table 2) [5,27,29]. Kwon et al [12] examined the slope between the concurrent increase in physical activity and HR, while others studied time-series

XSL•FO
RenderX

metadata of HR and movement signals, mining numerous features [27,28]. Advanced signal processing methods, such as principal component analysis and fast Fourier transform, were implemented to tackle noisy heart data, but this was not standardized across the included studies. Authors frequently used resampling techniques (standardizing time intervals between data points) to align HR with movement data, helping to contextualize HR within the corresponding physical activity [30].

Other Features

Less common features included energy expenditure estimates in terms of metabolic equivalents, which were calculated in 3 studies based on daily physical activity and proprietary algorithms [12,16,29]. On 1 occasion, breathing frequency and minute ventilation were extracted as the average of the last 7 respiration cycles, based on respiration bands integrated into the wearable device used for monitoring [37].

Models

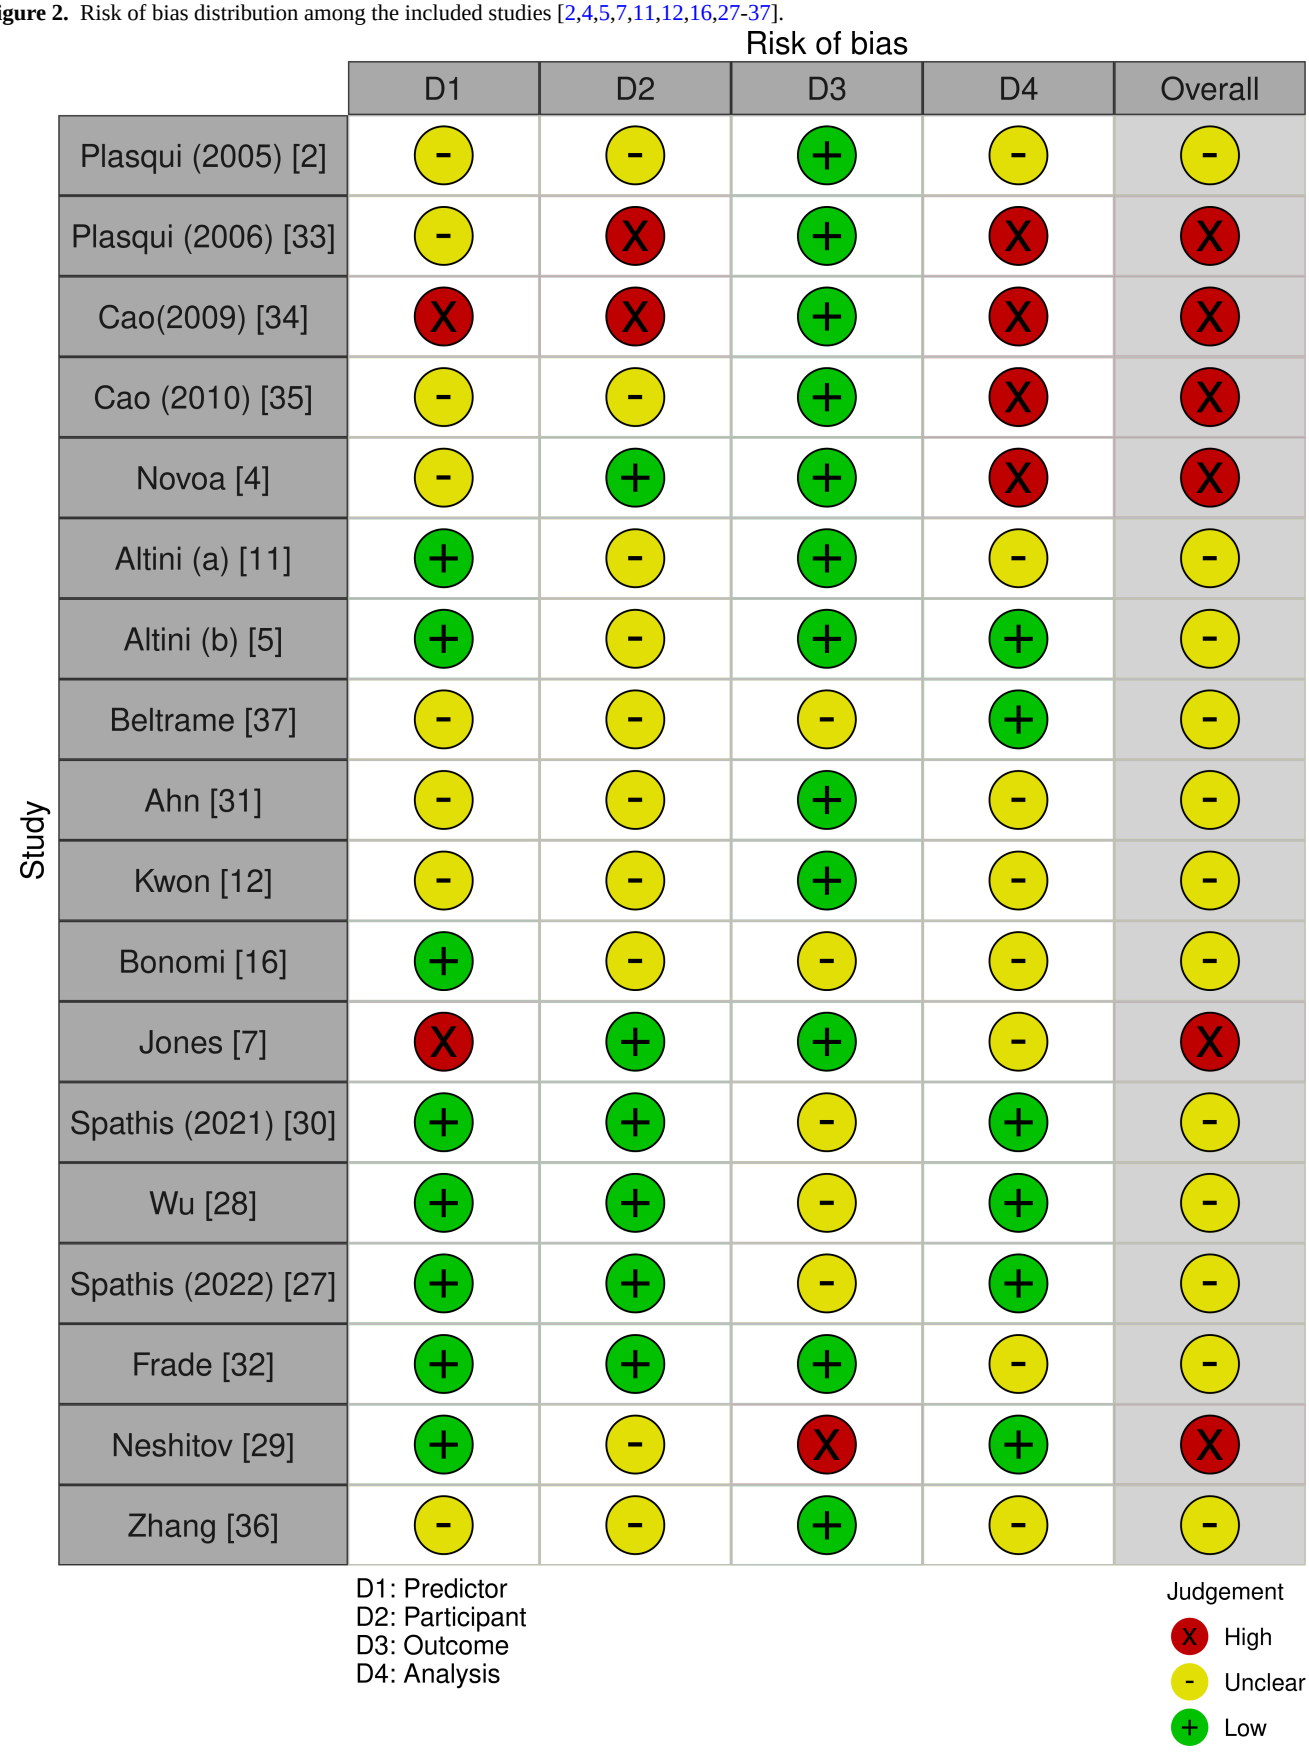
Multiple modeling techniques were used among the included studies, with more advanced ML models such as support vector machines (SVMs) and deep learning gaining interest over regression in recent studies. This trend follows the usage of preprocessing techniques such as fast Fourier transform and frequency domain analysis and represents an effort to mine the raw data and uncover hidden patterns. A detailed breakdown of modeling and preprocessing techniques is provided in Table 2.

Eleven studies used linear models, which allow interpretation of outcomes through reporting of coefficients that give direct insights into how each predictor influences the outcome measured [2,4,7,11,12,16,31,33-36]. The earliest study that examined whether the ratio of HR to activity counts could predict VO_2max was from Plasqui and Westerterp [2]. Two studies used correlation analysis to identify the strongest predictors of VO_2max and built on this using linear regression [4,7]. The rest of the studies outlined combinations of modern ML techniques. Three studies reported SVMs, with Frade et al [32] presenting support vector regression, which is an SVM formulation for regression problems. SVMs are supervised models that identify an optimal decision boundary (hyperplane) to separate data points into distinct classes with the aim of maximizing the margin between observed and predicted values.

Beltrame et al [37] were the only group to consider a random forest model. Random forests aggregate several decision trees together as a group but introduce randomness to prevent overfitting [37]. Another study trained several gradient boosting models and then fitted a quantile regression algorithm to predict the distribution of VO_2max with CIs [29]. In boosting, models are trained sequentially, building on the errors or residuals of the previous model to improve their prediction accuracy.

Finally, 3 studies [27,28,30] leveraged large-scale free-living datasets to predict CRF with variations of neural networks and deep learning. Wu et al [28] introduced a novel 2-stage approach building an adversarial training framework based on unsupervised domain adaptation. The proposed model was pretrained with noisy health-related labels in a fully supervised setting to improve its performance on high-quality, gold-standard data. Coarse- and fine-grained discriminators were used to better handle the distribution shifts between source (silver-standard) and target (gold-standard) datasets. Spathis et al [27] applied principal component analysis to denoise the raw data and developed deep neural network models able to capture nonlinear relationships between numerous wearable features and VO_2 max.

Length of Available Data Required for Prediction



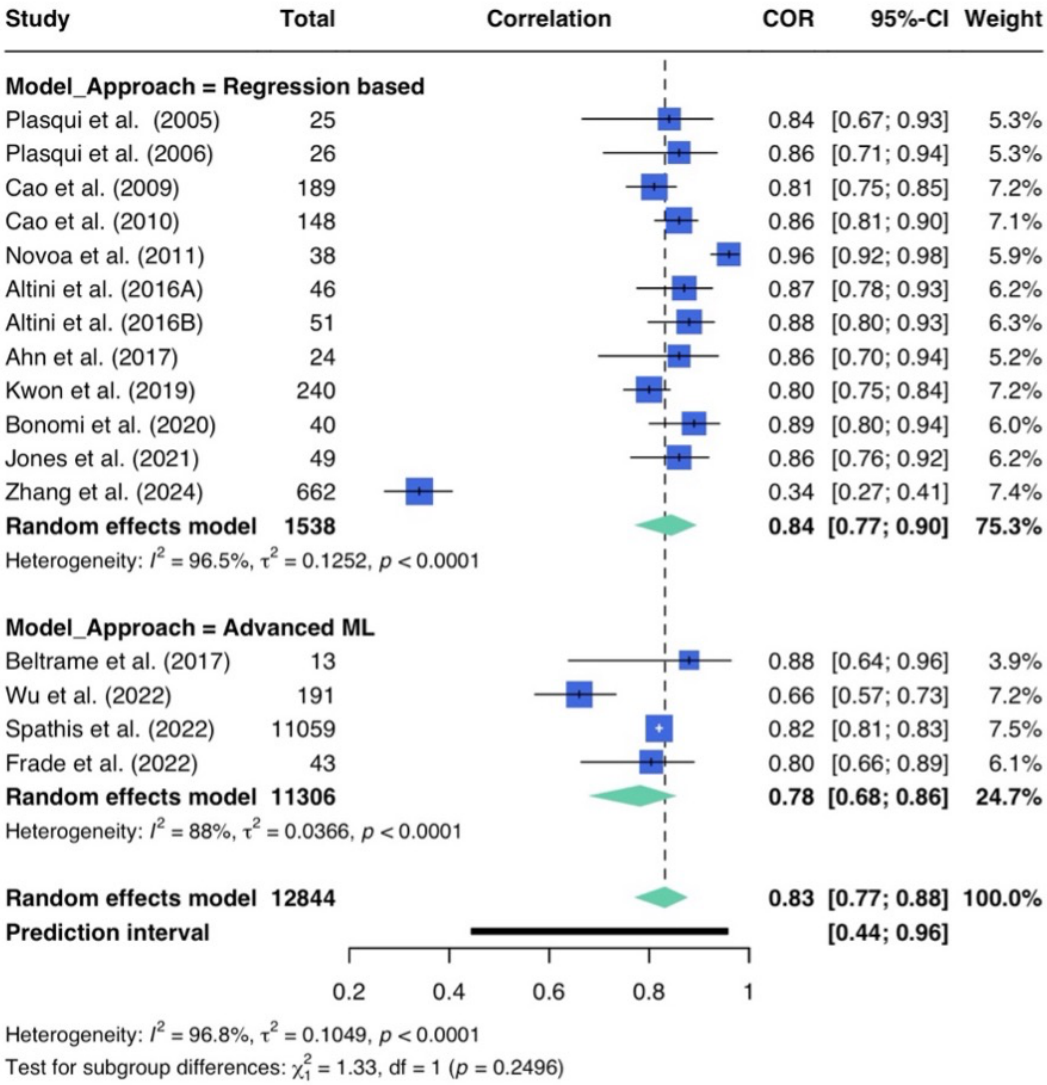
Some studies examined the minimum length of free-living wearable data that would be required to reach reliable conclusions regarding VO_2max estimations, but no agreement was observed. The most thorough assessment was provided by Neshitov et al [29], who tested the degree of certainty for 5 different models using various amounts of available data. They advocated that a minimum of 200 minutes is required for an error estimation range of 4.5 mL/kg/min, but more than 1000 minutes is needed to improve this to under 4 mL/kg/min. Ahn et al [31] plotted the correlation coefficient values with the included measurement time and found no drastic improvements between VO_2 max and estimated values past the 900-minute mark, which yielded an r value of 0.81. On the contrary, other researchers reported that even 10 minutes per day of good-quality data might be sufficient to predict VO_2max. Beltrame et al [37] determined the 10-minute window from the frequency domain analysis as the ideal size for data extraction based on iterative testing of different window lengths (200-1000 seconds, incrementing by 100 seconds). A window length of 600 seconds (10 minutes) was found to provide the best balance between maximizing frequency resolution and ensuring enough reliable samples for analysis across participants. Altini [5,11] proposed this on a theoretical basis, as many submaximal protocols are of a 10-minute duration (eg, 6-minute walking test). Other studies did not account for a minimum length but excluded patients with <72 hours of data from the analysis [27]. Ultimately, this large disparity in the length of data required for feature engineering reflects the exploratory nature of some of the included studies.

Quality of Studies

Risk of bias distribution for each domain is provided in Figure 2 [2,4,5,7,11,12,16,27-37]. Critical appraisal of the included papers showed that only 1 study was classified as “low risk of bias” for all domains. CRF was aptly measured as the outcome of interest in 12 (67%) studies using data from maximal exercise tests (also provided in Multimedia Appendix 2). Appropriate selection of participants and predictors was documented in 6 and 8 studies, respectively. Higher degrees of bias were observed in the analysis domain with robust reporting of analytical methods noted only in 6 (33%) studies. Handling of missing data was not reported adequately in 5 studies [4,5,11,34,35], while others excluded data from analysis arbitrarily, without fully justifying their decisions [12].

XSL•FO
RenderX

Figure 2. Risk of bias distribution among the included studies [2,4,5,7,11,12,16,27-37].



Most studies (n=13) reported internal validation methods for their predictive model, such as split-test or leave-one-participant-out cross-validation (Table 2). Model validation was not considered in 3 studies, and only 2 papers tested their algorithm externally on unseen data [27,28].

XSL•FO
RenderX

Model Performance

Various model performance metrics were reported (Table 2). The weighted average SEE was 9.03%, indicating that models overall predict VO_2max with an error of approximately 9%. In total, 16 studies were included in the meta-correlation analysis, which is provided in Figure 3 [2,4,5,7,11,12,16,27,28,31-37]. The pooled overall estimate of r=0.83 with a 95% CI of 0.77-0.88 from the random-effects model indicates a positive agreement between predicted and observed VO_2 max values. Heterogeneity among the included studies was high, with I^2=97% and a Q test of statistical significance (P<.01). Furthermore, moderate variance was observed (τ^2=0.1049), suggesting underlying differences in how well VO_2 max is predicted across studies. Subgroup analysis comparing regression-based methods with more advanced ML methodologies favored regression, but the difference was not statistically significant (P<.24; Figure 3 [2,4,5,7,11,12,16,27,28,31-37]).

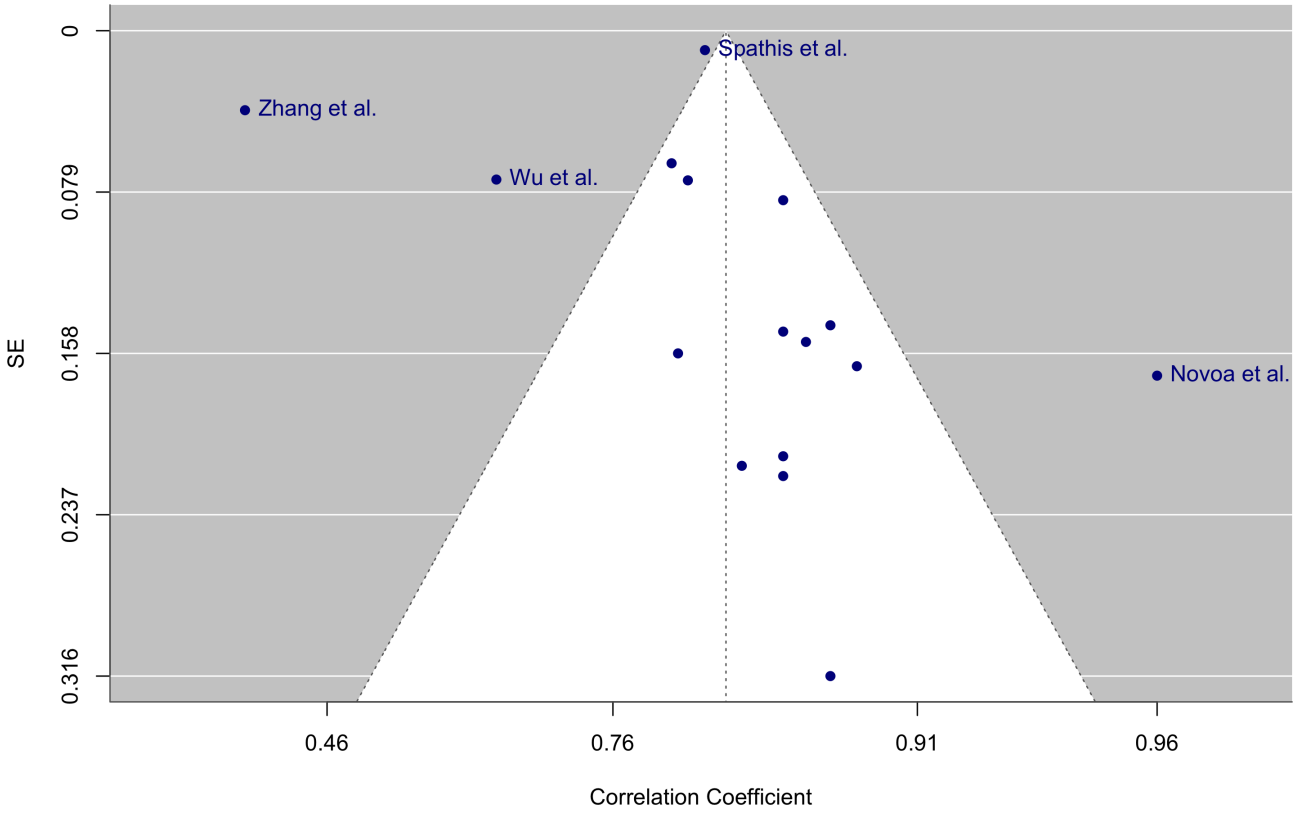


Figure 3. Forest plot of the meta-correlation analysis between maximal oxygen uptake estimates and reference values. Random-effects study weighting was calculated as the inverse sum of the in-study variance and the between-study variance (τ^2). Subgroup analysis comparing modeling approaches is also presented [2,4,5,7,11,12,16,27,28,31-37].

In studies reporting high correlations, there are several common features. While most research indicated the use of validation methods with unseen data (train-test split and cross-validation) to test model performance, several studies reported the R^2 values from the linear regression model [4,7]. Another common factor among the highest-performing models was the incorporation of data collected from laboratory protocols, either to contextualize or interpret free-living data, into feature extraction and modeling processes [5,11,16]. In addition, the funnel plot provided in Figure 4 [4,27,28,36] revealed asymmetry with 4 outliers, which was also confirmed with an Egger test (z=2.29; P=.02). This suggests the presence of small-study effects and publication bias. Notably, the overoptimistic, smaller-sized study by Novoa et al [4] is likely overrepresented in the pooled estimate, and results need to be interpreted with caution.

XSL•FO
RenderX

Figure 4. A funnel plot illustrating the distribution of study effect sizes to assess potential publication bias. Four studies fall outside the expected range, suggesting potential publication bias [4,27,28,36].

Discussion

Principal Findings

This systematic review identified research using real-world, unsupervised wearable data to develop predictive models for CRF estimation, focusing on VO_2 max as the measure of interest. Our study adds to the literature as the first to appraise evidence in this field and showcase the ability of advanced ML algorithms to harness the power of unstructured physical activity outside controlled laboratory settings. The included meta-correlation analysis revealed a pooled overall estimate of 0.83 with a 95% CI of 0.77-0.88, and a mean SEE of 9.06%, demonstrating a promising overall agreement between predicted VO_2max and ground truth. Authors experimented with a range of sensor modalities and various population groups, but models were predominantly designed based on small-sized, healthy volunteer data. Several features were extracted from the free-living information, including SC and distance covered, resting and mean HR, and cardiac response to cadence increase. Quality control of the eligible studies showed that authors were consistent in predictor and outcome reporting, but analytical methods were often ambiguous and included some arbitrary decisions regarding data manipulation.

Advantages

The concept of CRF estimation based on free-living activity holds considerable potential, and results from this study suggest that this could be a pragmatic alternative to CPET. Leveraging longitudinal wearable data can aid preoperative risk assessment for frail patients or those with musculoskeletal conditions that underperform during CPET (indicated usually by a respiratory exchange ratio of <1.10) [8]. Researchers have argued that physiological signals captured over longer time periods may even be more representative of cardiac health in these populations [5,37] compared to a snapshot laboratory measurement. In addition, at-home monitoring offers a convenient and unintrusive assessment without the need for specific protocols, improving patient experience and reducing the psychological stress related to the hospital environment [43]. Considering decreasing costs and increasing accessibility [44], continuous monitoring could represent a complementary, more cost-effective, efficient method that can be scaled to accommodate all patients [7]. Serial measurements of VO_2max can not only help patients track progress and meet targets set during prehabilitation and rehabilitation programs but also guide clinician decision-making [45].

CRF is a well-established marker of CVD and all-cause mortality [3]. Considering that low levels of CRF may precede the clinical detection of CVD, early recognition and intervention are of patient benefit [37]. Wearable-driven evaluation of the aerobic response during unsupervised activities of daily living holds prognostic value in tracking changes in fitness over time, as demonstrated by Spathis et al [27]. Arguably, models that predict future CRF levels could help identify early-stage CVD before general symptom manifestation [37]. Finally, scrutinizing free-living data with advanced ML presents a rare opportunity to study patient behavior and activity habits, shedding light on individual CRF levels [37]. But above all, tailored interventions can be implemented promptly to improve patient fitness and outcomes [46].

XSL•FO
RenderX

Contextualizing HR

The advent of wearables is undoubtedly transforming the landscape of health monitoring, providing clinical teams with a substantial amount of user-generated time-series data [27]. Although some earlier published studies used aggregates over several days as features (average steps or HR data), potentially losing information on trends and variability [2,33-36], most researchers in this review worked on extracting features from the raw signals, with seven studies aligning cardiac and activity points to contextualize HR and gain insights into the participants' physiological response to workload. Based on this principle, Plasqui and Westerterp [2] were the first to publish a fitness index as a ratio between acceleration and HR. Studies of more advanced modeling included other multimodal features such as HR at certain speeds or activities and the HR response to acceleration and recovery [5,29,37]. As physical activity encompasses both body movement and an associated cardiovascular response, leveraging these signals concurrently allows for a better evaluation of the temporal dynamics of CRF and enhances the understanding of the individual's physiology [27,37,47]. It should be emphasized, though, that contextualizing HR in unlabelled data requires navigating many intricacies, as investigators need to account for external factors that can influence HR, such as emotional stress, illness, heat, or medications that can potentially lead to invalid results.

In addition, a key observation arising from studying the multimodal features is the inverse relationship between VO_2max and HR at a given physical activity, which conforms to what is seen during the submaximal tests [5,29,33]. This observation reinforces the concept of estimating fitness from free-living activity, as even in the absence of controlled settings, behaviors approximating submaximal laboratory conditions will spontaneously occur [47]. Neshitov et al [29] demonstrated this inverse relationship, with the slope of the HR-over-cadence regression line being lower for participants with high than those with low VO_2max, and it was mainly noticeable between the 60 - 100 steps per minute exercise effort. Interestingly, Bonomi et al [16] highlighted the need for activity-specific prediction equations, showcasing models that combined energy expenditure and HR based on different activity types. Ultimately, tailoring predictive models to account for specific activity patterns and physiological responses enhances the accuracy of CRF predictions.

Challenges

Despite their potential, free-living data present some intrinsic statistical and computational challenges [48]. Using wearables in out-of-hospital, free-living settings often results in lower-quality, noisy data that require heavy filtering and preprocessing to become usable. Vigorous human motion can disturb on-body sensors and easily corrupt cardiac and accelerometer signals [40]. Aside from noise, missing data can also prevent meaningful features from being extracted. As reported in the "Results" section, preprocessing techniques are an essential step in the data-mining process to ensure that only reliable data points contribute to predictions. Another challenge lies in the precise physical activity detection in unlabeled data. Owing to the diverse nature of daily living, activity patterns overlap, and assumptions are occasionally made on how certain patterns in the data correlate with physical activities [5,49]. Furthermore, the abundance of sedentary data often leads to a data imbalance bias when low-intensity activities are overrepresented, leading to inaccurate estimations [5,16]. Consequently, due to the novelty of the task and the challenges outlined, there is currently no consensus on a specific approach and model that is most suited for free-living data.

Regression and ML Approaches

Interestingly, in the subgroup analysis, regression-based models appeared to perform slightly better than ML approaches. Much research examining the 2 approaches has repeatedly demonstrated comparable performance between regression-based and ML approaches, but this is not universal [38,39]. Nonetheless, this finding from our review warrants attention, as it likely stems from issues such as reporting bias and overfitting rather than genuine superiority. Results are influenced by the notable disparity in sample sizes, with 1 study driving the pooled estimate in ML modeling studies [27]. Finally, the limited external validation in ML suggests that the robustness and interpretability of simpler models can, in some cases, outweigh the complexity when appropriate validation has not been considered.

Limitations

This systematic review showed that free-living data can be valuable for CRF prediction and may prove a useful alternative in a variety of clinical settings. However, some limitations merit attention. First, although we observed promising preliminary agreement between VO_2max estimates and predictions, we need to acknowledge that, although we chose the correlation coefficient as the primary effect size for the meta-correlation analysis for its availability, it is not an accuracy metric and therefore does not imply that predictions are close in absolute terms. Further, as in certain instances, conversion of the R^2 was applied, this may have artificially inflated perceived predictive ability and, as such, influenced the overall result. Error-based metrics such as root-mean-square error or SEE would better capture accuracy, which is particularly relevant in clinical settings, but these measures were not consistently reported.

Second, there was significant heterogeneity and variance among the included studies, which varied in trial design, sample size, wearable device used, and modeling approach. Understandably, this limits the generalizability of our results, and the pooled estimate needs to be interpreted cautiously. However, in contrast to the synthesis of randomized trials, heterogeneity is frequently noted in meta-analyses of predictive modeling studies, mainly due to the disparity of eligible study designs or models [50].

Some studies used resting HR as a feature in their models, limiting monitoring to daytime periods only, excluding nocturnal HR data [31,32,36,37]. Research, however, demonstrates that using nighttime data can yield closer estimations to true testing values when it comes to resting HR [51]. As such, using daytime-derived resting HR may have implications for model performance and potentially lead to erroneous results. Godkin et al [51] underline the lack of standardization and considerable shortcomings among the criteria and methods used to estimate

XSL•FO
RenderX

resting HR. Since daytime HR can be affected by numerous behavioral, psychological, and environmental factors, we advocate for continuous monitoring of free-living data that captures both activity and rest phases for a more stable profile of HR distributions.

Considerations should also be made when interpreting the outputs of the presented models, as the papers reporting the highest correlations between predicted and actual measurements share several common features. Notably, several studies presented outputs from regression models without using unseen data for validation. Directly comparing these outputs against models validated on unseen data likely overestimates the model's true predictive ability. In such cases, high performance may reflect only how well the data fit the model, not its ability to generalize. Therefore, the lack of external validation may contribute to inflation in the aggregated meta-correlation analysis. Under such conditions, a single pooled correlation does not necessarily reflect a uniform level of accuracy and should certainly not be viewed as evidence of clinical readiness. Instead, it demonstrates the potential for future research that a strong association may be achieved.

Another limitation concerning the applicability and validation of the reported models is the selection bias, as most trials recruited young, healthy volunteers, making models less applicable to patient populations. We found that models predict VO_2max with an average 9%, which, arguably, may be clinically relevant in borderline cases—for instance, during preoperative risk assessment of frail individuals. Consequently, no direct conclusions can be drawn for clinical decision-making, and future research should focus more on medical settings to assess the effect of patient-specific factors, such as regular medication and comorbidities, in model training. Interestingly, although there were several different devices used in the included trials, no study explored the practicalities of monitoring patients remotely to collect the free-living data, which could explain the quality issues of noise and missingness that these datasets exhibit.

Implications for Real-World Use

The absence of a shared methodological framework across studies remains a major barrier to translation. As stated previously in the "Limitations" subheading, heterogeneity in this review was high, with studies using distinct device types, signal processing strategies, and validation tactics, often with insufficient external testing. Consequently, this limits confidence in generalizability and reproducibility, making direct comparisons difficult. From a clinical perspective, a model optimized for one setting may fail to transfer effectively in different patient groups, sensors, or wear patterns [52].

For clinical adoption to become feasible, several credibility issues need to be addressed. Pitfalls such as model overfitting, lack of standardized analytical pipelines, and limited evidence that performance is stable under real-world conditions (device updates, medication effects on HR) present significant challenges. Similar challenges have been identified in studies of prediction modeling for CVDs, highlighting the need for independent tools to assess replicability and external validation [52]. Therefore, until uniform data handling and transparent external validation become routine, results from research in this field should be considered promising but not ready for clinical application.

Future Considerations

Despite the challenges and limitations identified in this review, several models reported here should not be overlooked in this expanding research field. Future research should aim to streamline the deployment of wearable devices in out-of-hospital settings and educate and support patients and clinical teams. Furthermore, given the increasing influence of the wearable industry in health care, it is essential for such predictive models to undergo rigorous validation before being fully integrated into clinical practice. Establishing consensus on feature extraction, validation, and reporting guided by frameworks such as TRIPOD-AI and recent calls for transparency in wearable research (INTERLIVE) are recommended for future research to yield reproducible and clinically useful results [21,53].

For public health systems, regulatory frameworks regarding the digital storage, privacy, and security of the vast amount of patient-generated data should be considered early. With the myriad of wearables available, it is important that feasibility work is undertaken to set standards for a reliable and accurate technology, helping avoid a repetitive cycle of temporary models being developed that cannot be extrapolated to clinical contexts or used in clinical practice. Finally, a cost-effective analysis will determine the viability of these remote monitoring systems, ensuring they offer a sustainable solution for patients and health care systems.

Conclusion

This work explores a novel concept for CRF estimation from unsupervised free-living patient data. Contrary to the current gold-standard CPET, which is a snapshot of the individual's functional capacity, wearable health monitoring in free-living conditions generates rich datasets that can be exploited to train models for fitness estimation. Several models are discussed in this paper, with studies applying ML to mine raw data and enhance accuracy.

The combined results from this review show promise, with good preliminary agreement between predictions and measured values. However, no firm conclusions can be drawn for clinical implementation due to the heterogeneity of the studies and the lack of external validation. Nonetheless, continuous data streams appear to be a valuable resource for ML methods to shed light on human behavior and health, leading to a step change in how we measure and monitor CRF, ultimately aiming to improve health outcomes.

Abstract

Background: Health interventions delivered by digital platforms are gaining popularity and are evolving to address the needs of patients with chronic diseases. The heterogeneity of chronic diseases requires that digital health platforms vary in their approaches to chronic disease management.

Objective: This review aimed to explore the characteristics of digital health platforms and the corresponding digital interventions developed to support patients with chronic diseases. This includes those platforms' design, development, and the metrics by which any incremental benefits they provide are assessed.

Methods: We searched electronic databases including Scopus, Web of Science, PsycINFO, IEEE Xplore, MEDLINE, and Embase. Relevant articles published from January 2013 to November 2024 were extracted. Extracted data were then synthesized using qualitative content analysis and presented in narrative form with relevant tables.

Results: In total, we identified 69 digital health platforms supporting the management of 20 chronic diseases. Most platforms were mobile apps (n=22) or a combination of web and mobile apps (n=15). Most of the platforms (n=44) were tailored to support self-management of chronic diseases. These platforms also provided a web-based portal where health care providers could review and manage the information recorded by patients. In 77% (53/69) of the studies, patients reported that the digital interventions delivered by the platform improved their quality of life, their health, and their ability to self-manage their chronic diseases. In addition, health care providers reported positive outcomes, including improved clinical utility and patient communication. While short-term health outcomes of the digital health interventions were largely positive, long-term health outcomes remain unknown. This was because most of the studies were short-term pilots and often formative in nature (n=42). Many had limited sample sizes, limited participant uptake of the digital platforms, and technical issues. In many cases, further personalization of platforms was required to meet patients' self-management needs.

Conclusions: Digital health interventions can be beneficial in the management of chronic disease. The adoption of digital interventions in combination with regular clinical care can improve health outcomes, support self-management, and enhance communication between patients and health care providers. However, long-term user engagement is the major barrier to their long-term success. High dropout rates, often resulting from a lack of motivation or technical issues, testify to the need for adaptive, low-burden interventions that function seamlessly in users' daily lives. Adopting user-centered and co-design approaches that engage both clinicians and patients in designing digital health platforms may enhance the usability and uptake of such platforms.

Introduction

Background

Chronic diseases are defined as long-lasting conditions (ie, 1 y or more) and require ongoing care and account for 41 million (74%) deaths worldwide [1-3]. They can cause disability that affects the quality of life and reduces life expectancy. Patients with chronic diseases may face several challenges when managing their condition, such as (1) conflicting knowledge about the disease or how to manage it, (2) access to care, and (3) communication with health care providers [4]. Chronic diseases pose a significant burden on health care systems, families, and caregivers [5]. Therefore, the prevention and management of chronic diseases has become a global priority, as the prevalence of those diseases can undermine social and economic development.

Digital health interventions use technology to deliver health care services or treatments and facilitate knowledge exchange [6]. These interventions are designed to enhance the quality of patient care by capturing and conveying information in a digital format. Digital health interventions may involve electronic medical records (EMRs), mobile apps or web applications, and wearable sensors such as Fitbit (Google). Technologies such as digital health platforms are gaining increased use in managing chronic diseases [7]. The proliferation of mobile apps and the ubiquitous nature of information technology have fueled the development of platforms that support the management of chronic disease [8,9]. The digital health technologies discussed in this study include mobile apps, web applications, electronic health records (EHRs), EMRs, wearable devices, and telehealth services [10]. We have used digital platforms as an umbrella term throughout the paper to denote these technologies.

With the rapid growth of digital platforms for chronic disease management, a systematic synthesis of these platforms is needed to inform effective and efficient care. Recent studies have investigated the framework for managing chronic diseases [11] and the potential of technology adoption [12]. To our knowledge, no studies have examined how digital platforms support the management of chronic diseases. Due to the heterogeneity of digital platforms, it is vital to investigate the types of digital platforms that are available and the usability and acceptability of these platforms. In addition, it is important to investigate the processes that led to their design and development, as well as the metrics used to assess their benefits. In this study, digital platforms are characterized as assortments of web-based and mobile applications and related technologies that are used to deliver health care services [13].

Aims

This review aims to explore the characteristics of digital health platforms and corresponding digital health interventions that support patients with chronic disease. This exploration will include those technologies' design, their development processes, and the metrics by which their incremental and long-term benefits have been assessed.

Methods

Overview

This review adopts the scoping review methodology proposed by Arksey and O'Malley [14] because we are interested in identifying and mapping emerging evidence [15]. PRISMA-ScR (Preferred Reporting Items for Systematic reviews and Meta-Analyses extension for Scoping Reviews) checklist [16] was used throughout the review to ensure adherence (Checklist 1). However, there are some differences between the registered protocol and this paper regarding database searching. Furthermore, 2 additional databases (Medline and Embase) have been searched, and the search period has been extended to November 2024 for all the databases.

Step 1: Identifying the Research Questions

First, what are the characteristics of digital platforms that support the management of chronic diseases, including self-management and provider-led management?

Second, what principles and theoretical frameworks have been used to design or co-design these platforms?

Third, how were these platforms evaluated for clinical utility?

Finally, what is the effectiveness of those platforms?

Step 2: Search Strategy

The search terms used for the literature search are "chronic disease" OR "chronic illness," OR "long-term conditions," OR "chronic conditions" AND "Digital" OR "mHealth" OR "App" AND "management."

We did not include the exact term "self-management" in our search, nor the standard indexing terms that databases use for that idea (eg, PubMed's MeSH heading Self Care and Embase's Emtree term self-management). To reduce the chance of missing papers, we implemented citation chasing, that is, for each included study, we checked its reference list and looked up newer papers that cite it.

Initially, databases such as Scopus, Web of Science, PsycINFO, and IEEE Xplore were searched from January 2013 to 30 November 2022. Later, an additional search was conducted on these databases from November 2022 to November 2024. Furthermore, 2 additional databases, MEDLINE and Embase, were searched from January 2013 to November 2024 (Refer to Multimedia Appendix 1 for the search outcomes). Articles retrieved were imported into Covidence software (Veritas Health Innovation Ltd) [17], and duplicated items were automatically removed.

XSL•FO
RenderX

Step 3: Study Selection

The following inclusion and exclusion criteria were used.

Inclusion criteria

First, the study must be a peer-reviewed journal article and present primary data. Second, it should be published within the last 12 years (January 2013 to November 2024). We chose 2013 as the starting year to reflect a critical turning point in the evolution of digital health technologies. Around this time, the widespread use of smartphones and mobile apps, breakthroughs in wearable sensors, and more prevalent usage of EHRs began to transform chronic disease management [18,19]. Third, it should be available in English. Finally, it should involve digital applications in the context of chronic disease management.

Exclusion criteria

The study was excluded if (1) it was a review article or opinion piece, or (2) hypothetical use of digital technology was found in it.

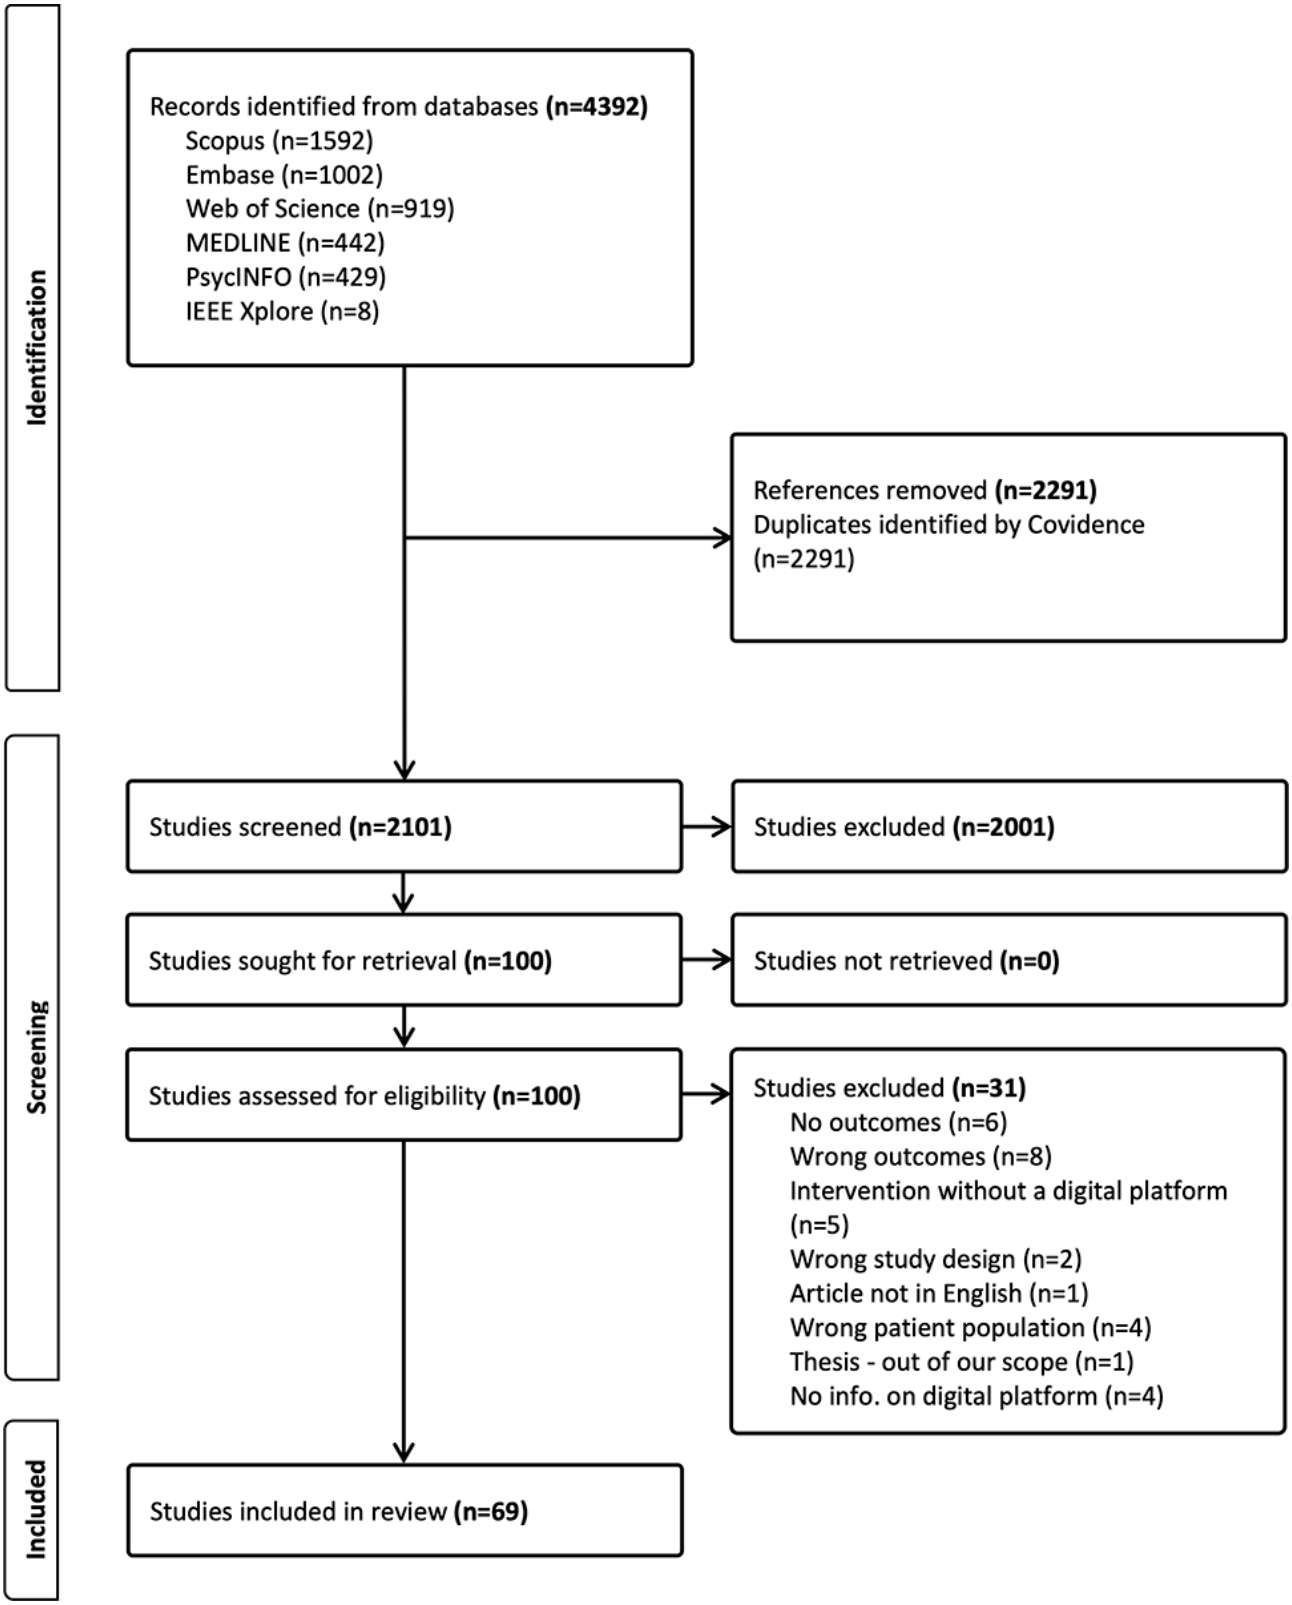
Initially, titles and abstracts were reviewed against the selection criteria and were marked as "include," "exclude," or "uncertain." Two reviewers (AAM and MS) conducted the screening independently, and regular discussions with the research team were undertaken to resolve any discrepancies and to fine-tune selection criteria. This screening and discussion process continued until we reached a consensus. Subsequently, for the included studies, a full-text review was carried out (AAM and MS) against the selection criteria following the same screening procedure.

Step 4: Data Extraction and Charting the Data

Two authors (AAM and MS) developed a data charting form to identify relevant information to extract from the included studies. Using this form, the following data were extracted: study citation, publication type, authors, study location, study year, user acceptability of the digital interventions or digital platforms, and outcome of the study (quantitative results, qualitative themes, recommendations, key learnings, and limitations). AAM and MS charted the extracted information.

Step 5: Collating, Summarizing, and Reporting the Results

First, the extracted data were analyzed using descriptive statistics (eg, frequencies). This provided numerical summaries of (1) digital platforms and their characteristics, (2) chronic diseases, (3) platform design principles, and (4) outcomes. These details were presented using tables, charts, and graphs, followed by a summary. Second, 2 authors (AAM and CL) independently analyzed the extracted data thematically to identify themes. Results from the 2 reviewers' thematic analysis were combined to select the final collection of themes.



Results

Overview

A total of 4392 studies were identified from the 4 databases. Of these, 2291 were duplicates, leaving 2101 to be screened. In total, 2001 studies were excluded during the title and abstract screening process, and 100 were assessed for eligibility. Of these, 69 studies [20-88] met our eligibility criteria and were included for review. Refer to Figure 1 for the article selection process.

XSL•FO
RenderX

Figure 1. PRISMA diagram showing the article selection process.

Characteristics of the Included Studies

In total, 69 studies were conducted in 26 countries. Of the total, 15 studies (22%) were conducted in the United States [22,25-27,30,31,37,38,49,50,52,55,61,66,85]. Canada had 5 studies (7%) [38,49,50,76,84], and China had 10 studies (15%) [24,32,41,43,58,63,65,69,79,81], while 4 studies (5%) [28,59,67,83] were conducted in Spain. The most common chronic disease reported was type 2 diabetes (n=17, 20%), followed by heart failure (n=11, 13%), chronic obstructive pulmonary disease (COPD; n=9, 11%), and hypertension (n=9, 11%) (Multimedia Appendix 2). In total, 27 studies (39%) [21,22,24,27-29,31,33,34,37,41,42,45,49,50,52,54,55,59,60-68,69] are reported as randomized controlled trials (RCTs), and the

XSL•FO
RenderX

remaining 42 studies (61%) are formative studies [20,23,25,26,30,32,35,36,38-40,43,44,46-48,51,53,56-58,61,62,70-88]. Table 1 summarizes the aims of the digital platforms, the platform types, and the study settings.

Table . Summary of the platforms.

Platform characteristics	Total, n (%)
Aim of the digital platform (n=77)	
Self-management[a]	44 (57)
Behavior changes	17 (22)
Communication with health care providers	16 (20)
Types of digital platforms (n=69)	
Web-based application	15 (22)
Mobile app	33 (48)
Combination of web-based application and mobile app (ie, multimodal)	14 (20)
Other[b] (SMS text messaging)	7 (10)
Wearable device (in combination with web app, smartphone app, or both)	16 (23)
Study setting (n=78)	
Hospital or primary care setting	34 (44)
Home	36 (46)
Online Community	8 (10)

[a]Includes self-monitoring of symptoms, medication, physical activity, etc.

[b]One intervention used telehealth and SMS text messaging.

Characteristics of the Study Participants

All the included studies had adult participants (aged >18 y). Participants from various age groups were included in the studies (30 - 35 y: n=2, 40 - 45 y: n=1, 45 - 50 y: n=1, 60 y or older: n=19, and 75 - 80 y: n=1). Several studies (n=15) did not specify the mean age or age range. Most of the studies are dominated by female participants, especially studies related to the management of chronic diseases such as asthma (eg, 80 women vs 26 men [20]), hypertension (eg, 49/67, 73% female [21]), diabetes, and rheumatoid arthritis. Some studies target specific gender groups to address health disparities or disease prevalence, such as Black women with hypertension [22]. Most chronic conditions are higher in females, which may be a reason for overrepresentation. Some studies, like those dealing with heart failure (eg, N=25, 100% male participants [23]), atrial fibrillation (eg, 59/96, 61.5% male [24]), and other cardiovascular disorders (eg, 48/79, 61% male [54]), might have a greater proportion of males. In some instances, these conditions may be more prevalent in men within specific age groups. Most male-dominated studies occur in areas such as cardiovascular health, where men are more prone to certain conditions.

In total, 6 studies [40,54,57,58,71,89] mentioned the literacy levels of participants in the participant eligibility criteria. Only 1 study [26] mentioned digital literacy (ie, technical and cognitive abilities to use information and communication technologies [89]), defined as "acceptable literacy level to read and write with a smartphone," in the inclusion criteria. None of the studies measured the participants' digital literacy level as part of the intervention. Most studies (n=19; 61%) had predominantly male participants (66%). Where literacies were mentioned, the most reported literacy was linguistic (English language literacy, n=2 out of 6), followed by health literacy [90], defined as the capability to process and understand health information (n=2 out of 6).

Characteristics of the Digital Interventions

The digital interventions identified in the literature targeted a range of chronic diseases and thus had a variety of operational aims. Multimedia Appendix 3 provides a summary of the digital intervention strategies used in the studies. The definition of each digital intervention is extracted from the National Institute for Health and Care Excellence (NICE) Framework [91]. An analysis of the digital intervention strategies based on the NICE Evidence Standards Framework for digital health [1] found self-management to be the most prevalent strategy, appearing in 68 studies (99%) [20-46,49-86,88]. Collaborative care (ie, self-management plus provider-led management) followed with 43 occurrences (39%) [20-25,27,28,32-37,39-42,44,51-53,56,57,60-63,65,67,69,70,72,74,77-83,85,87], while information and education were present in 27 studies (39%) [20-24,26,33,37,40,45,46,57,59,63,64,66,72-79,81,84,85]. Personal health record systems were identified in 25 papers (62%), digital therapeutics in 15 papers (22%) [22,23,25,28,35,44,45,51,59,60,63,66,72,73,77], clinical decision support systems in 8 papers (12%) [26,28,44,48,59,65,70,72], and active monitoring in 1 paper (2%) [30].

XSL•FO
RenderX

Self-management frequently co-occurs with collaborative care (47 times), reflecting strong integration between patient-driven health management interventions and the need for clinical support (ie, provider-led management). Information and education (31 times) and personal health record systems (25 times) also frequently co-occur with self-management, underscoring the importance of providing users with relevant knowledge and real-time data to make informed health decisions. This, in turn, enhances self-care practices and promotes better health outcomes. Additionally, digital therapeutics (15 times) and clinical decision support systems (8 times) demonstrate strong associations, emphasizing their role in remote treatment guidance and data-driven clinical decision-making. These findings highlight how personalized digital interventions, combined with real-time insights, can enhance both patient engagement and clinical oversight.

Features of the Digital Platforms and Behavior Change Techniques Offered

Overview

The most common features by far are self-monitoring and tracking (65/69 studies, 94%), showing the trend of users' empowerment for active management (Table 2) of chronic diseases with support from health care providers. Medication reminders (59/69 studies, 86%) and behavioral support features (48/69 sources, 70%) are essential in helping patients stay committed to their treatment plans, with alerts (59/69 studies, 86%) and gamification using points, badges, or levels (8/69 studies, 12%) playing key roles in engagement. Most of the platforms are also targeted at improving user awareness and engagement by educating the users about better health practices (55/69 sources, 80%) and communicating with health care providers (45/69 studies, 72%). Such features ensure that patients are supported not only through technology but also by and through human contact.

XSL•FO

Symptom reporting	4
Daily check-ins or reports	3

[a]SpO2: peripheral oxygen saturation.

Table 2 provides a summary of the features and their frequencies by category. Routine input of health data was facilitated through surveys and questionnaires, using free-text or drop-down menu functionalities. Some apps facilitated image uploads, allowing patients to supply photos of wounds, rashes, or other relevant aspects of their conditions to be assessed by health care providers [27,28]. To support the self-management and tracking of health data, many platforms use tools for self-measurement and reporting of key health indicators, such as blood pressure (BP), glucose levels, and heart rate. Furthermore, 2 platforms embedded these functionalities in motion sensors [29,30]. However, the majority of platforms incorporating self-reporting functionalities did so through Bluetooth-enabled technology, such as smart watches, BP monitors, and scales [31-36]. These either fed data directly to the platforms or provided data for participants to input manually. Refer to Table 3 for the overview of the wearable devices used in the included studies.

XSL•FO
RenderX

Table . Wearable devices used in the included studies (n=16).

Wearable device	Type of wearable	Purpose	Study
Fitbit	Activity tracker or fitness band	General health monitoring, physical activity, and heart rate tracking	Oh et al [34]
Apple Watch	Smartwatch	ECG[a], heart rate monitoring, activity tracking, and general health monitoring	Guo et al [32]
Omron BP Cuff	Blood pressure monitor	Blood pressure tracking and monitoring for hypertension	Evans et al [30]
Dexcom CGM	Continuous glucose monitor	Continuous glucose monitoring for diabetes	Schnall et al [37]
iHealth Pulse Oximeter	Pulse oximeter	Monitoring oxygen levels (SpO2[b]) for respiratory conditions	Guo et al [32]

[a]ECG: electrocardiogram.

[b]SpO2: peripheral oxygen saturation.

Only 5 studies [29,44-47] explicitly mentioned the use of artificial intelligence (AI) in the digital platforms. In these, AI was used to aggregate and analyze patient data across multimodal platforms. This was achieved through machine learning algorithms or recommender systems on platforms that use conversation agents. For example, the Snapcare app (Snapcare Technologies Pvt Ltd) gathered daily activity data over 12 weeks to address chronic back pain, including walking distance and workouts [29]. Notifications were sent to patients based on app usage and physical activity data collected by built-in phone sensors. This information was automatically transferred to a secure server, where machine learning algorithms examined the daily data on physical activity and produced suggestions for the session the following day. Similarly, the ProACT digital platform helps older patients manage their multimorbidity, including diabetes, congestive heart failure, COPD, and chronic heart disease [44]. Health information, including BP, heart rate, blood glucose, pulse oximetry, weight, activity, and sleep readings, is collected using off-the-shelf technologies. ProACT's AI algorithms can gain knowledge from the data to provide more accurate personalized recommendations and highlight a condition that needs attention. Likewise, using an embodied conversational agent named Laura, My Diabetes Coach (The University of Melbourne) provides patients with individualized support, monitoring, and motivational coaching [45]. The algorithms and conversational scripts that direct each person's progress were developed using behavior change theories, and they can accommodate recommendations by a general practitioner. Natural language processing and automated speech recognition are used to enhance the capability of a voice-enabled chatbot in user interactions in French [46]. The Medly voice app (University

XSL•FO
RenderX

Health Network) for heart failure management leverages various AI technologies, including machine learning, natural language processing, and automated speech recognition, which process the speech of users and formulate responses [47].

In total, 14 of the platforms included in the review were multimodal. For example, a platform might function as a combination of web-based and smartphone-based applications or work in combination with a wearable Bluetooth device, such as a smartwatch or BP monitor. Of the total, 8 interventions included some form of wearable technology or measurement device. These ranged from smartwatches and activity trackers [30-32,40,44] to BP monitors [33,34,36,44], glucose monitors [34,44], scales [31], and sleep monitoring devices [44]. Additionally, 15 interventions [26-28,35,37,39,44,47,48,50,53,58,61,62,71] were designed to work in conjunction with in-person consultations. These included functionalities that were integrated with routine clinical visits to monitor appointments, provide technical support, and review progress. Digital platforms in 10 studies supported multimorbidity [27,34,35,38,44,48-52].

Behavior change was broadly reported to be a multistep process requiring numerous complementary features. Tailoring features to the specific needs of participants based on both demographics and disease type was shown to be important in achieving behavior change [32,48,53]. Although not all of the studies explicitly used theoretical frameworks for behavioral change, many of the platforms are underpinned by theories intended to enable behavior change. Theories applied include social cognitive theory, which is detailed in the work of Dale et al [54], and the transtheoretical model, which is elaborated upon by Salari et al [53]. Furthermore, Sittig et al [55] explore the Fogg Behavior Model, and both cognitive theory and self-efficacy theory are examined by Park et al [60].

A range of methods was used to deliver tailored behavior change features to facilitate user engagement and improved health outcomes. Reminders, goal-setting, and motivational messages were widely used in 5 studies [38,39,44,56,88]. Those features aimed to motivate patients to engage with their health interventions and help them stay on track with their treatment plans. Behavioral trigger messaging was used to promote engagement, motivation, and self-belief. It was also used to provide reinforcement to participants based on behavior change theories [55]. Similarly, theory-based approaches specific to tailored SMS text messaging were used to improve personalization and increase the acceptability of the health interventions [32,53].

Gamification and learning material were incorporated in some studies for the optimization of motivation and to increase users' knowledge of managing their conditions. Gamification, either through rewards or challenges, stimulated usage of the app, while educational information [26,33,40,57] provided valuable information to allow patients to better understand their conditions and make informed decisions on their treatment. Furthermore, 5 platforms used gamification techniques to enhance user experience while embedding learning principles [29,42,45,58,59]. In-app conversation agents supported by AI [45] were used in a platform to change behavior too.

Furthermore, self-monitoring, tailored feedback, and social support were key features of some platforms [26,35,40,60]. These features fostered engagement and behavior change. Self-monitoring permitted users to monitor their health measurements (ie, BP or blood glucose), while personalized feedback assisted in matching interventions to individual needs and encouraging ownership of one's health. Social support, either through peer interaction or direct contact with health care providers, also facilitated long-term engagement by providing users with emotional encouragement and accountability.

Chronic Disease Management: Patient Self-Management and Provider-Led Care

In analyzing digital platform features, we distinguish 2 complementary approaches: patient self-management and provider-led management. Provider-led management refers to the coordinated, proactive activities delivered by health care services and clinicians to support people living with chronic conditions, typically including comprehensive care planning, risk stratification, guideline-concordant treatment, continuity, between-visit care coordination, and use of clinical information systems for monitoring and quality improvement across settings and providers [92]. In contrast, patient-led self-management encompasses the day-to-day work undertaken by people living with chronic conditions, including symptom monitoring, medication adherence, lifestyle and behavioral changes, decision-making, help-seeking, and the usage of tools and supports, including digital platforms [93].

The vast majority of digital platforms (n=36) were designed to be used at home by patients, and this was usually done in conjunction with their ongoing health care plans. To support at-home interventions, some platforms incorporated automated SMS text messaging, including conversational agents and trigger SMS text messaging [45,55]. The key focus of platforms that were exclusively home-based was self-management through input and self-monitoring of health data. Of the 36 interventions, 13 designed to be used in the home were also implemented in primary care settings, including hospitals. The digital platforms, which contained a patient-facing mobile health (mHealth) app, primarily focused on self-management of the symptoms of a chronic condition. The data collected by an mHealth app is usually passed to a practitioner-facing portal, where the practitioner can view patient data and adjust care plans. In some cases, these digital platforms supported bidirectional communication, allowing the practitioner to directly communicate with patients through the platform [32,35,45,53,60,61]. A few platforms also supported the booking of appointments with relevant health care providers [33,48,49] or sent reminders about upcoming appointments [43].

Because a high number of digital platforms are tailored to support self-management (n=44), the majority of platforms were primarily managed by the patients themselves. However, where the digital platforms were multimodal, consisting of a smartphone app and a web-based application, the smartphone apps tended to be managed by the patients, while the web-based applications were used by health care providers to review and manage patient information through an online portal.

XSL•FO
RenderX

Principles Used in the Design and Development of the Digital Platforms

In total, 25 studies (36%) used some form of co-design, consultative, or user-centered approach to developing the digital platforms. Furthermore, 11 studies focused on platforms that either had already existed or were adapted from existing models. Co-design approaches varied and included expert consultation with health care providers and user-centered iterative approaches, which sought feedback from patients throughout an intervention period.

Most of the platforms were developed by using surveys or focus groups to gather information and determine requirements. Often, these surveys and focus groups lacked the full participation of end users. In some studies, the iterative development approach also included gaining input from caregivers, patients, and related stakeholders. For example, the iMHere 2.0 [35] system was iteratively designed, developed, and evaluated with patients involved at all stages. Other studies that discussed the development of digital platforms did not follow or report on the iterative development process. One platform [62] was not accepted as it failed to meet the needs of the patients. Studies adopting an iterative approach tended to make changes to the digital intervention throughout the testing period in response to feedback, whereas those using professional consultations at the beginning and end of the process did not make changes during the testing period. Platforms primarily seeking to influence behavior change tended to be developed using more theoretically based approaches, such as behavior change models and social cognitive theory [54,55].

Outcomes of Studies Assessing the Digital Platforms

Outcomes of the digital platform assessments reported in the studies are grouped into 2 categories: outcomes of randomized controlled studies and other formative studies.

Outcomes of RCTs

The majority of the included studies demonstrated significant benefits and health outcomes, such as symptom reduction, better disease control, and improved quality of life. A smaller proportion of studies showed no significant effect on the primary outcomes, with improvements in only secondary measures that did not significantly impact the main health indicators. Some trials did not have the expected results, sometimes due to high dropout rates, lack of long-term effects, or problems with patient engagement (Table 4).

XSL•FO
RenderX

Table . Summary of the randomized controlled trial studies (n=27).

Study	Favorable outcomes	No effects	Name of the platform and target disease
Li et al [63]	Significant improvement in disease control at 6 months (*P*=.001).	At 12 months, no significant difference between groups (*P*=.90).	A smart system of disease management; rheumatoid arthritis
Goulding et al [64]	Decreased relapse risk in the low-risk group (*P*=.02), improved depressive symptoms (*P*=.02), and relational quality of life (*P*=.02).	There was no significant improvement in relapse risk for the high-risk group (*P*=.62).	A smartphone-based self-management intervention (LiveWell) app and website; bipolar disorder
Goodman and Locke [21]	Significant improvements in blood pressure were found, with systolic BP[a] decreasing from 140 to 134 mm Hg (*P*=.001) and diastolic BP decreasing from 78 to 74 mm Hg (*P*=.007)	No effect on the usual care group for HbA1c[b] (*P*=.19).	A mobile phone-delivered diabetes intervention; diabetes
Zhang et al [65]	Significant improvements in HbA1c (*P*<.05), diastolic BP (*P*<.05), and fasting plasma glucose (*P*<.05).	No effect on BMI.	A digital health technology to provide shared decision-making–informed dietary intervention; diabetes
Buis et al [66]	Both groups showed significant reductions in systolic BP (*P*<.001).	No significant differences between groups for BP or other outcomes (*P*=.99).	MI-BP, a culturally tailored multibehavior mobile health intervention; hypertension
Zhang et al [41]	Significant improvement in HbA1c (*P*<.001) and ABC[c] control rate (*P*=.025). ABC goals are HbA1c <7%, systolic BP/diastolic BP <140/80 mm Hg, and LDL-C[d] <2.6 mmol/L.	No changes in LDL-C or blood pressure (*P*=.95).	SMARTDiabetes app; diabetes
Tabernero et al [67]	Significant improvement in emotional well-being and self-efficacy for chronic disease management (*P*<.05).	No effect on anxiety and depression levels.	Psychological interventions delivered via mHealth[e] technology; chronic cardiac diseases
Hartch et al [52]	Significant improvements in medication adherence (Cohen *d*=−0.52, *P*=.014) and medication self-efficacy (Cohen *d*=0.43, *P*=.035).	No significant effect on medication knowledge or social support (*P*=.15).	Medisafe app; hypertension, diabetes, and asthma
Xu et al [24]	Significant improvement in anticoagulation knowledge, medication compliance, and patient satisfaction (*P*<.05).	No effect on bleeding or thrombotic events.	Alfalfa app; atrial fibrillation
Abel et al [22]	Significant reduction in systolic BP (*P*<.001), weight (*P*<.001), and physical activity (*P*=.018).	No significant difference in BP control between the treatment and control groups (*P*=.99). No sustained effect on BP control after 6 months.	Chronic disease self-management program; hypertension
Oh et al [34]	Significant reduction in body fat mass (*P*=.04) and HbA1c (*P*=.03) in the integrative mHealth group.	No significant changes in body weight, BMI, blood pressure, or HbA1c.	Integrative mHealth platform; hypertension and diabetes
Sittig et al [55]	Statistically significant improvements in self-efficacy (*P*=.008) and exercise (*P*=.01) in high and mid-users.	No significant differences across groups in overall health measures (ANOVA).	“capABILITY” app; diabetes
Patnaik et al [68]	Significant improvements in weight, BMI, waist circumference, and systolic blood pressure (*P*<.05).	No significant difference in metabolic equivalent (MET) levels (*P*=.54).	A mobile interactive platform: an Android-based application; diabetes
Jia et al [69]	Significant improvement in HbA1c (*P*<.001) and ABC control (*P*=.025).	No effect on hypoglycemia or weight gain (*P*=.95).	Graded the ROADMAP app and a website; diabetes

XSL•FO
RenderX

Study	Favorable outcomes	No effects	Name of the platform and target disease
Lear et al [49]	Fewer hospitalizations and in-hospital days (*P*<.05).	No significant reduction in hospitalization rates (*P*=.12).	An internet-based self-management and symptom monitoring program for diabetes, heart failure, ischemic heart disease, chronic kidney disease, or chronic obstructive pulmonary disease
Gray et al [50]	Participants set meaningful self-management goals.	No significant improvement in quality of life (*P*=.24).	Electronic patient-reported outcome mobile app and portal system; multiple chronic diseases such as arthritis, asthma, and hypertension
Kryger et al [27]	Significant reduction in urinary tract infections (*P*=.03).	No significant change in psychosocial outcomes.	iMHere mHealth system; spinal cord injury
Gong et al [45]	Significant improvement in quality of life (*P*=.04).	No significant change in HbA1c (*P*=.83).	My Diabetes Coach program, an app-based interactive embodied conversational agent; diabetes
Chhabra et al [29]	Significant improvement in disability (*P*<.001).	No significant change in pain.	Snapcare app; low back pain
Puig et al [28]	High patient satisfaction (85.2% find it useful, 91.4% would recommend it).	No significant change in quality of life or clinical outcomes.	+Approp app; HIV
Dale et al [54]	Significant improvements in medication adherence (*P*=.004).	No long-term effects on lifestyle changes (*P*=.13).	An mHealth-delivered comprehensive cardiac rehabilitation program called Text4Heart for coronary heart disease
Dorsch et al [31]	Improvement in Minnesota Living with Heart Failure Questionnaire at 6 weeks (*P*=.04).	No effect on self-reported HF management (*P*=.78).	ManageHF4Life app; heart failure
Velardo et al [33]	High compliance with self-monitoring (96% of symptom diaries completed).	No significant impact on patient outcomes or disease progression.	"Self-management and support programme (EDGE);" COPD[f]
Poppe et al [42]	Improvement in physical activity in some groups (*P*<.05).	Limited improvements in sitting time and moderate physical activity (*P*=.09 to *P*=.07).	MyPlan 2.0 comprises a website and an optional mobile app for diabetes
Schnall et al [37]	Significant improvement in 5 symptoms (anxiety, depression, neuropathy, fever or chills, and weight loss) (*P*<.05).	No effect on other symptoms.	mobile video information provider app; HIV
Morcillo-Muñoz et al [59]	Improvement in catastrophizing, rumination, and quality of life (*P*<.05).	No effect on magnification or satisfaction with health.	NO+Dolor (NO+ Pain) app; chronic pain
Park et al [60]	Improved self-care behavior (*P*=.01) and physical activity.	No improvement in self-efficacy for managing dyspnea. The number of steps per day did not significantly differ at 6 months.	Smartphone app-based self-management program; COPD

[a]BP: blood pressure.

[b]HbA1c: hemoglobin A1c.

[c]ABC: the "ABC" goals for type 2 diabetes management and stands for A1C (a measure of blood sugar), blood pressure, and cholesterol (specifically low-density lipoprotein cholesterol).

[d]LDL-C: low-density lipoprotein cholesterol.

[e]mHealth: mobile health.

[f]COPD: chronic obstructive pulmonary disease.

mHealth technologies are emerging as a promising solution in managing chronic conditions, offering patients a convenient and efficient way to monitor and improve their health. These randomized controlled studies (n=26) that reported favorable outcomes indicate that the impact of the mHealth intervention is evident in chronic disease management [21,22,24,27-29,31,33,34,37,41,42,45,49,50,52,54,55,59,63-69]. The clinical improvements were the more consistent outcome

XSL•FO
RenderX

across many of the included studies. Out of 26 RCTs, 30.8% (n=8) reported favorable improvements in key clinical health metrics, including BP [22,65,66,68], hemoglobin A1c (HbA1c) levels [21,34,41,65,69], weight [22,68], and blood glucose levels [65]. For example, the SMARTDiabetes trial [41] demonstrated better glycemic control in the intervention arm, improving HbA1c, BP, and low-density lipoprotein cholesterol control. These improvements were particularly notable in chronic diseases like diabetes and hypertension, suggesting that mHealth interventions can be effective in helping patients manage these conditions over time.

Beyond symptoms and clinical improvements, many studies found that these mHealth apps could create better self-management; 12 out of 26 studies (46%) demonstrated that patients became more involved in managing their health by tracking symptoms, medication adherence, and healthier behavior changes, such as increased physical activity [22,24,31,33,37,41,42,45,52,55,67,68]. For example, in the bipolar disorder study [64], participants using the smartphone-based self-management intervention showed reduced depressive symptoms and improved relational quality of life. This underlines the fact that mHealth tools are instrumental in improving clinical outcomes and empowering patients to take greater control of their conditions.

A common theme from these studies is increased patient engagement, which is favorable in 14 (54%) of these studies [22,24,31,33,37,41,42,45,52,54,55,63,67,68]. Most participants shared that engaging in mobile apps to track symptoms and remind themselves about their medication and educational content increased patients' interest in their health. In the study conducted on rheumatoid arthritis, it was observed that patients who were exposed to the mobile app had better control of their disease, while the smart system of disease management group [63] had a higher rate of patients with controlled disease than the control group, at 71% versus 64.5%.

Besides engagement, user satisfaction also appeared consistently high across the positive-outcome studies. Specifically, participants expressed appreciation for the ease of use in navigating the interfaces, personalized feedback, and easy access to health care information in studies by Xu et al [24] and Puig et al [28]. For example, in the study on the Alfalfa App [24], there was improved medication adherence among patients, $P<.001$, and a very high satisfaction regarding the app's utility in managing anticoagulation therapy.

Another important insight from the positive studies is the reduction in disease symptoms, reported in 5 of the 26 RCTs (19.2%) [27,31,37,63,64]. Indeed, many studies reported significant improvements in specific symptoms such as pain, depression, anxiety, and fatigue. This was especially true in conditions like HIV, where the mobile video information provider app [37] helped alleviate symptoms, such as neuropathy, anxiety, and depression, while also increasing medication adherence.

mHealth interventions also helped most patients improve their overall quality of life. Many studies have shown evidence for the above fact as the common resultant factor in the case of chronic diseases. Statistical improvements in scores over health-related quality of life were noticed to be significantly higher among app users than control subjects in the "My Diabetes Coach" study [45]; thus, providing evidence that such tools are effective in managing not only the clinical symptom improvement but also in emotional function and life satisfaction improvement.

In addition to clinical outcomes and user satisfaction, these mHealth interventions brought positive behavioral changes. Many studies reported that participants became more physically active, followed exercise routines more consistently, and had healthier dietary habits (11/26, 42%). For example, in a diabetes study [68], systolic BP, body fat, and BMI decreased significantly ($P<.001$) among the intervention group, thus indicating the effectiveness of mobile apps in bringing about healthier lifestyle changes.

Finally, 1 study [59] examined the cost-effectiveness of mHealth interventions. It noted that these tools are effective and economically viable, presenting affordable solutions for managing chronic diseases, especially in resource-constrained settings. For example, the chronic pain therapy study [59] established that app-based mobile treatments for pain management were effective and cost-effective, incorporating them into existing treatment plans.

Outcomes of the Formative Studies

The following sections present the findings of the formative studies (n=42) [20,23,25,26,30,32,35,36,38-40,43,44,46-48,51,53,56-58,61,62,70-88]. The most frequent outcomes are patient engagement and satisfaction, but also clinical improvements and self-management behavior are the focus of many studies. There are some usability issues and challenges reported in the studies (Table 5).

XSL•FO
RenderX

Table . Summary of the outcomes and challenges mentioned in the formative studies (n=42).

Outcomes (favorable, no effect, and challenges)	Explanation	Frequency
Favorable outcomes		
Patient engagement and satisfaction (eg, ease of use and positive feedback) [30,32,38-40,44,46,51,58,61,70-78,88]	Most of the studies reported a high level of patient engagement and satisfaction, naming ease of use and personalized feedback as major advantages. Many studies have shown that user-friendly digital health tools improved adherence to health regimens and helped patients manage their diseases more effectively.	22
Clinical improvements (eg, pain reduction, improved blood pressure, and LDL-C[a] levels) [25,32,39,40,43,71,79,80]	These studies reported various clinical improvements, including pain reduction, blood pressure control, improvement in LDL-C level, and overall disease management. Key results included highlighting digital health tools' potential to enhance self-management, support patients to achieve clinical goals, and improve overall health.	8
Self-management behavior (eg, adherence to medication and lifestyle changes) [32,38-40,43,44,46,51,53,56,61,70-73,75,78,81,82]	Overall, digital health tools across these studies helped improve self-management behaviors in medication adherence, lifestyle changes, and engagement in physical activity. The most significant improvements were seen in the management of chronic diseases like COPD[b], diabetes, hypertension, and heart failure.	19
Remote monitoring and resource usage (eg, reduction in hospital visits and health care costs) [25,32,43,51,71,83]	These studies highlight how remote monitoring systems can avert hospital admissions and reduce health costs by helping patients manage their conditions at home and, in real-time, provide the clinician with timely interventions. These findings were seen in heart failure, asthma, COPD management, hypertension, and ankylosing spondylitis, showing how digital health tools could improve clinical outcomes and optimize the use of resources within health care systems.	6
No effect		
No effect on disease management (eg, no improvement in symptom control or disease management) [30,38,48,70,79,84]	Some studies did not find any significant improvement in disease management, especially when the digital health tools did not sufficiently help engage patients or when the patients had barriers such as a lack of interest or limited use of digital health tools. In some cases, the personalization or customization of the tools was insufficient, leading to low effectiveness in managing the conditions.	6
Challenges encountered		
Usability issues (eg, technical issues and user disengagement) [32,35,38,39,61,72,88]	The most common usability issues reported across studies included technical problems, such as device inaccuracies, data syncing issues, and interface complexity. User disengagement was also another common challenge in many instances due to a lack of motivation, the tediousness of the process, and issues relating to poor integration into existing healthcare workflows.	7

XSL•FO
RenderX

Outcomes (favorable, no effect, and challenges)	Explanation	Frequency
Challenges in provider integration (eg, issues with workflows and data sharing) [32,38,43,44,61,71,77,78,81,83]	Provider integration challenges were highly reported in many studies, especially on integrating digital health tools with clinical workflows and the sharing of data between patients and providers. In most cases, the difficulty in adopting digital health tools in routine clinical care was cited as a barrier to clinical decision-making, with issues such as data synchronization and interoperability, assuring that providers can use the data collected remotely efficiently.	10
Privacy and data security concerns (eg, data interoperability and concerns about privacy) [32,38,43,44,61,71,76,81,85]	Privacy and data security issues were consistently identified in the reviews, particularly regarding transmission, storage, and interoperability with other healthcare information systems. There were issues of patient consent, data sharing, and following regulatory policies such as the Health Insurance Portability and Accountability Act (HIPAA). A concern was raised about protecting sensitive health information from unauthorized access.	9
Lack of participation (eg, limited use due to lack of time, motivation, or technical issues) [32,38,43,44,46,51,56,61,70-75,78,81,82]	Several of these studies repeatedly mentioned problems of non-participation for which technical issues, such as malfunction of a device and connectivity problems, together with a lack of motivation, were major reasons for dropouts and inconsistent use of digital health tools. Time constraints were also a significant factor in disengagement, as the patients struggled to integrate such tools into daily life. Personalization and support appeared very pivotal for long-term engagement.	17

[a]LDL-C: low-density lipoprotein cholesterol.

[b]COPD: chronic obstructive pulmonary disease.

One of the significant trends observed across the formative studies is the potential of digital health tools to improve the management of chronic conditions such as COPD, hypertension, diabetes, and heart failure. A significant percentage of studies (17/42, 40%) reported favorable clinical and self-management outcomes, including improved BP control, weight management, and self-efficacy. For example, HbA1c was reduced by approximately 0.79% [57], and patients suffering from COPD on the Wellinks mHealth platform showed improved symptoms and quality of life [71]. Similarly, 1 study [36] demonstrated that digital management tools for hypertension reduced systolic BP/diastolic BP by 14/5 mm Hg. These results suggest that digital tools can offer tangible improvements in managing chronic diseases, particularly when integrated with traditional care methods.

The second trend to emerge from these studies is the centrality of user-centered design in the overall success of digital health interventions. A substantial proportion of studies (13/42, 31%) indicated that designing the digital tool for patient preferences and needs enhances engagement and satisfaction. For example, the iMHere 2.0 system, which offers personalized app modules to support various self-management tasks, was praised for its customizability and ability to keep patients engaged [61]. Similarly, the Wellinks mHealth platform for COPD was well-received due to its ease of use and support in daily disease management [71]. The above findings point out the importance of developing digital tools that are not only functional but can also be tailored according to the needs of the patients in improving usability and increasing engagement.

Whereas the initial engagement and clinical outcomes from the studies were generally good, the longer-term health outcomes tend to be more mixed. The main challenges with the long-term maintenance of digital interventions were mentioned in 12% (5/42) of the selected studies, where initially engaged patients stopped using the tools due to various barriers, such as motivational issues, technical problems, or difficulties in maintaining regular use. For example, some patients in the studies of COPD management dropped off after an initial burst of engagement due to difficulties in integrating the technology into their daily routines [71]. This points to the need for continuous engagement strategies and more user-friendly designs to maintain patient involvement over the long term [26].

The studies also indicate an increased awareness that, in treating chronic conditions of a complex nature, it is more often than not challenging to rely on one-size-fits-all approaches. Some studies with generalized tools showed positive outcomes; others (5/42, 12%) indicated that tools must be customized to meet individual patient needs. For instance, a digital health tool for diabetes showed promising results in improving medication adherence but struggled with user engagement in the long term, particularly among patients who required more personalized support [39]. Many studies emphasized the need for adaptive technologies that can adjust to the changing needs of patients

XSL•FO
RenderX

and those that can integrate seamlessly into existing health care systems.

Despite promising results, the need for further research and development is a constant note in several studies, as shown by 9.52% (4/42). These studies have shown that while the performance of digital tools has a promising side, there are serious gaps in personalization, scalability, and integration into health systems [60,62]. Issues of provider workflow problems [38], data interoperability [38], and assurance about patient privacy concerns were considered the most important to resolve to make them more acceptable.

Discussion

Principal Findings

This review highlights the growing potential of digital platforms in enabling both self-management (patient-facing monitoring, decision support, and behavior change) and provider-led management (remote monitoring dashboards, care coordination, and clinical decision support). The digital platforms were primarily designed for use at home and complement patients' routine health care practices seamlessly, giving major importance to self-monitoring, personalization, and motivational aspects such as rewards. While self-management is valued, our findings suggest that platforms without embedded communication facilities with health care professionals or social support may limit user interaction and effectiveness. The fact that collaborative care and self-management co-occurred in the included studies underscores the value of hybrid interventions that combine patient autonomy with professional oversight.

A significant proportion of the studies reported the usage of co-design or user-centered design approaches as the best practice when developing health interventions. The lack of methodological details and theoretical underpinnings in some studies hinders clear conclusions regarding their effectiveness. While the review found a range of features, there was limited evidence on which features are most effective at facilitating long-term engagement. Most studies were feasibility or pilot studies with brief follow-up periods and small or nonrandomized samples. As such, large-scale assessments of the effectiveness of platforms, particularly for long-term health outcomes, are lacking. Platforms addressing single chronic diseases were more likely to exhibit improved outcomes, whereas those addressing multimorbidity encountered more usability and implementation issues, underscoring the need for more personalized designs to meet complex health needs.

One of the significant barriers to the long-term adoption of digital health solutions was user disengagement. Several longitudinal studies reported high dropout rates due to a lack of motivation or technical issues, highlighting the importance of adaptive and personalized engagement strategies that are unobtrusive and seamlessly integrate digital health platforms into everyday life.

In the following sections, we elaborate on the principal findings and compare and contrast them with relevant literature.

Characteristics of Digital Platforms Supporting the Management of Chronic Diseases

Our findings show that most of the interventions focused on self-management of chronic diseases. We also found that the vast majority of interventions were designed to be used at home by participants, usually in conjunction with their ongoing health care plans. Self-management is critical in managing chronic disease [94,95], and new digital platforms heavily target this aim. According to the literature, chronic disease can be managed well by balancing traditional medical care with self-management [96]. Effective self-management requires optimal communication with health care teams [97]. Although self-management requires support from health care providers and caregivers, this review discovers that not all identified platforms offer such options. Similarly, it is necessary that digital platforms provide options for social support to maintain long-term engagement in self-managing disease [98]. Only a few platforms in our review had options for social support. Our findings suggest that features like self-tracking, customization, and rewards support users' engagement with digital platforms [12]. Although we have identified a range of features in the studied platforms, there is still a lack of evidence in the included studies as to which features are best for supporting long-term engagement. Therefore, more research is needed to investigate which features of digital platforms will best support long-term user engagement and motivation.

The findings from applying the NICE Evidence Standards Framework emphasize the necessity of a multifaceted and integrated approach to delivering effective digital health interventions. The significance of self-management reflects the growing emphasis on patient empowerment, enabling individuals to actively monitor, track, and manage their health. However, self-management alone is not always sufficient, as structured support systems improve engagement and adherence. The frequent co-occurrence of self-management with collaborative care (47 times) highlights the effectiveness of a hybrid model that combines patient autonomy with a form of clinical oversight. This integration ensures that while patients take a leading role in their health management, they are still supported by health care professionals who provide guidance and add to the rigor of the digital intervention. However, as noted earlier, some platforms lack direct communication with health care providers, which could reflect as a limiting factor in their effectiveness as a digital intervention. This comprehensive analysis highlights the interdependencies among digital intervention strategies, advocating for a cohesive, patient-centered approach. Self-management is most effective when complemented by collaborative care, education, and evidence-based tools, ensuring engagement, clinical effectiveness, and long-term sustainability in chronic disease management.

Principles and Frameworks Used in Designing and Developing the Platforms

We have observed that more than half of the studies reported some form of co-design, consultative, or user-centered approach to the development of digital platforms. This is a positive indication that health care interventions are co-developed to

XSL•FO
RenderX

meet the needs of the stakeholders, as suggested in the literature [99,100]. Overall, adopting a co-design approach might have contributed to positive outcomes. However, due to the lack of relevant data in those studies, we could not determine if there was any relationship between the co-design of the digital platforms and their effectiveness in managing chronic disease. A lack of theoretical basis in some of the included studies limits their reliability. Therefore, it is suggested that the future development of digital platforms needs solid theoretical support, and such support may well improve effectiveness and user engagement.

A range of behavior-change techniques was used in the included studies, generally informed by behavior-change models and social cognitive theory [101]. However, future studies should focus on measuring the effects of these design principles, determining the extent to which they contribute to the efficacy and continued use of the platforms. In addition, we identified 5 platforms that used gamification techniques to enhance user experience and embed learning principles. This suggests that platform designers considered the notion that gamification improves health behaviors, as reported in the literature [102].

Effectiveness and Efficacy of the Platforms

Most of the included studies were pilot in nature, focusing either on design, development, usability, uptake, or clinical utility. In many of these studies, not all features of the platforms were tested for effectiveness. One key reason for not testing all the features of a digital platform during the trial period (for example, study by Doyle et al [44]) was that the development was based on the initial success of the trial, and this was the focus of the majority of the included studies. This suggests that future work should identify those studies where the full potential of digital platforms is evaluated, so that more complete conclusions can be drawn about the platforms' effectiveness.

It is important to note that the majority of studies reporting improved health outcomes focused on a single or localized chronic disease. Conversely, those reporting no effects on health outcomes largely focused on multiple chronic diseases. This suggests that focused digital platforms have a higher likelihood of positive health outcomes than those targeting multiple chronic health issues. Further research is needed to investigate how digital platforms could successfully be designed and evaluated to manage multimorbidity (ie, the presence of 2 or more long-term health conditions). Furthermore, it is worth noting that the testing duration of the digital platforms was generally short in most studies. In some cases, the formal sample size was not calculated since the studies were feasibility or pilot studies. This highlights the importance of meticulously evaluating digital platforms with appropriate sample sizes in future studies to ensure the validity and reliability of the research.

Uptake of the Digital Health Interventions

A few of the included studies, which were conducted over a longer period (ie, 6 months or more), explicitly mentioned dropout rates and the causes of disengagement, including lack of motivation, technical issues, or health problems. For example, a study [86] aimed to understand the effects of long-term (eg, 12 months) smartphone-based self-monitoring in patients with lipid metabolism disorders reported that 43% (43/100) of patients never started using the app due to a lack of time, health problems, lack of motivation, and technical problems. Dropout due to technical issues (eg, poor wireless connection) was also reported in another study, where an mHealth system was developed for managing chronic conditions [61], where 1 patient dropped out of the study after the initial engagement. Another included study [39] mentioned that approximately 80% (400/500) of users used Mobiab (ForaCare Suisse AG) for managing diabetes for less than 1 week. Such a dropout may imply that the daily use requirements of the app were challenging for individuals to maintain. User fatigue is a likely issue where daily data entry or constant interaction with digital tools is required. As digital health interventions often require continuous self-monitoring and engagement—whether through tracking symptoms, inputting data, or responding to feedback—users may experience burnout, leading to disengagement. A high dropout rate (95/162, 58.6%) was mentioned in a study [66] where the effect of an mHealth self-monitoring intervention among black individuals with uncontrolled hypertension was tested for 1 year. While digital health tools show promise in improving short-term health outcomes, dropout rates, user fatigue, and sustainability remain substantial challenges. For digital health interventions to be successful in the long run, continuous engagement strategies and adaptive features must be prioritized to ensure users remain motivated and that interventions can be integrated smoothly into everyday life. However, further investigation is required to understand the dropout and disengagement with digital health interventions.

Digital literacies play a key role in the uptake of digital health interventions [103]. Researchers found that even though patients with low literacy may have access to technology, they may not be able to use it without any help [104]. Some studies were conducted with adults aged between early (20 - 39 y) [27,35,43,61] and middle adulthood (40 - 59 y) [30,34,40,55]. Chronic diseases are more common among older adults, who may have poor digital literacy and difficulty adopting new information technologies. In the included studies, no information was collected regarding the digital literacy levels of the participants. However, some of the included studies had information about income and education level that are linked to the participants' digital skills and health literacy. Low digital literacy may be a barrier to the adoption and engagement of digital platforms. Another limitation of the included studies is that not all studies reported parameters such as participants' skills, experience, or level of education, and these might have contributed to the infrequent use of the platform [28] or withdrawal from the study [42]. Some of the studies excluded patients who were unwilling to participate or could not meet the study requirements. Such nonparticipants may provide insights for the design of more user-centered platforms. Therefore, future studies should account for the varying digital literacies of different cohorts of platform users, as this may impact the overall feasibility of digital health interventions.

Participant confidentiality, including data security, was not widely discussed in the papers included in this review. Only 1 paper provided a detailed overview of the data security measures

XSL•FO
RenderX

of their platform [39]. Researchers have reported that health and fitness apps often violate users' privacy by not following existing guidelines and regulations [105,106]. Therefore, it is of the utmost importance to protect the health data that digital platforms gather. Ensuring the privacy and security of health data may contribute to the long-term uptake of digital health interventions.

Implications and Real-World Adoption

While most studies focus on the efficacy of digital health interventions in pilot settings, large-scale integration within already prevailing health care systems was not reported in any studies. However, some studies have promising steps toward integration within the current health care system. As an example, a mobile app called Mobiab [39] for diabetes management integrated with health care systems was partially successful, particularly where patient data could be automatically transmitted to clinicians through platforms like mobile apps. The study reported that the use of different software was an additional complication for the clinicians, as they already used some commercial software. Also, the researchers did not implement data into hospital information systems due to the lack of communication interface specifications. A hypertension management platform was developed that can be integrated into EHRs to facilitate real-time patient data analysis and effective decision-making [85]. However, the efficacy of the system is yet to be tested. Another application called "electronic patient-reported outcome mobile app and portal system" was developed for people with complex care needs. During the trial, the electronic patient-reported outcome system was not interfaced with other existing technology systems, that is, EMRs or other available platforms, but the system was designed in such a way that interoperability could be a possibility [50].

None of the studies explicitly discusses interoperability, clinician workload, or regulatory constraints, although these could hinder the implementation of digital health solutions in real-world health care settings [107,108]. These barriers are implicit in the included studies and require investigation in future studies. For example, one of our included studies [39] refers to the long-term involvement of clinicians in managing diabetes but does not discuss the potential impact it would have on clinician workload. Clinicians would be required to review the data generated by the app, resulting in an increased workload if the app is not providing actionable insights or is not well-integrated into clinical workflows. Research shows that the lack of seamless integration of digital health platforms into health care systems poses obstacles to broader adoption and implementation [109,110] and may hinder sustainability and scalability. In addition, regulatory restrictions on patient data protection (eg, General Data Protection Regulation and Health Insurance Portability and Accountability Act) are not discussed in the included studies, but these would be necessary to make the platform health care regulation compliant and legally viable for real-world adoption and implementation. Such concerns were echoed in a recent study, where authors highlighted the need for transparent data government policies to be implemented in order to meet regulatory requirements and address security concerns [107].

Many of the papers included in this review suggested that further research into the interventions was needed. Reasons for this included limited sample sizes, limited participant uptake, technical issues, and the need for further personalization of the platforms. Furthermore, while short-term health outcomes of the digital interventions were largely positive, long-term outcomes remain generally unknown. Thus, it was frequently suggested that strategies to maintain long-term use were required, along with further analysis of platform use. Additionally, it was noted in some instances that future studies should account for the varying digital literacies of different cohorts of users, as this may impact the overall feasibility of digital health interventions. Finally, where studies focused on a single or localized chronic health issue, it was broadly concluded that platform design could easily be replicated to address other health issues. However, interventions that sought to address multiple chronic diseases had a higher incidence of technical issues or problems with usability and feasibility. This could be because those studies have methodological challenges, such as higher sample sizes and complex sampling frames to measure the required outcomes. However, such challenges were not reported in those studies, and this suggests that further research is needed to enable digital health interventions to effectively address multiple chronic health conditions.

Limitations

There are several limitations to our study. Our objective was to explore the broader perspective of chronic diseases rather than focusing on individual chronic diseases. Therefore, the search strategy used was general terms related to chronic disease management rather than specific conditions such as diabetes, hypertension, cardiovascular disease, or COPD. While this approach allowed us to draw on a wide range of interventions, it may have inadvertently omitted condition-specific intervention studies using narrowly defined keywords. This could have affected the completeness of the review in 2 ways. First, we might have missed highly specialized interventions tailored to the unique management needs of particular chronic diseases. Second, excluding disease-specific search terms could have led to underrepresenting certain populations or technologies in specific disease domains. Nonetheless, studies in this review constitute an important and representative sample of the current digital intervention landscape for chronic disease management. These studies encompass a diverse range of technologies, user groups, and interventions to identify trends, design issues, and gaps in digital interventions for chronic disease management. We acknowledge that a more targeted search strategy, perhaps in a future scoping or systematic review, would offer more information about condition-specific digital health innovations and their impact.

Our search strategy did not include the exact keyword "self-management" or corresponding controlled-vocabulary terms. Although the broader "management" concept and citation chasing were used to capture patient-led self-management studies indirectly, records that exclusively use "self-management" terminology may have been missed. A future update should incorporate a self-management term cluster (eg, "self-management," "self care," and "self-monitor") and mapped controlled vocabulary to improve sensitivity.

RenderX

In this review, we only included articles that were published in English. For the included studies, we have primarily reported the results qualitatively. Where available, we reported the frequency of outcomes but were unable to capture the effect size due to the variability of the studies. Furthermore, not all studies measured the impact of digital platforms; several of them instead measured the usability and acceptability of those platforms. Therefore, we could not compare all the outcomes, and in some cases, the outcomes were inconclusive due to the preliminary nature of the studies. Finally, the digital platforms included in the studies were designed for diverse users with varying degrees of digital literacy. However, we could not analyze how the digital literacies of the participants contributed to outcomes because such data were not reported in the studies.

Conclusions

This study provides a comprehensive overview of digital platforms for managing chronic diseases, delineating features for self-management versus provider-led management. Overall, the vast majority of papers in this review concluded that digital health interventions can be beneficial in managing chronic health issues. They also indicated that the adoption of such methods in combination with regular clinical care has the potential to improve health outcomes, support self-management, and support communication between patients and health care providers. However, challenges remain in long-term engagement, overcoming technological barriers, and integrating these tools into existing workflows in health care. The effectiveness and acceptance of digital health interventions vary based on patient characteristics, such as age, health literacy, and the capacity for intervention tailoring. Success will be contingent on interventions that can fulfill specific patient needs through user-centered, tailored engagement while being effortless to use and integrated seamlessly within the health care ecosystem. These tools, therefore, require further research for their full development so that they are adaptable, scalable, and meet the diverse needs of patients with chronic conditions. More research is needed to further develop these tools for wider acceptance and improving engagement.

Abstract

Background: Recently, mobile health and mobile apps have been proposed as a potential tool to improve different outcomes (eg, daily steps, blood glucose) in both people with and without chronic conditions. In particular, healthy people could benefit from these tools by improving health variables and for prevention. Previous evidence investigated different types of health interventions adopting apps in various settings and populations, but evidence of their effectiveness is still unclear.

Objective: The aim was to assess the effectiveness of mobile apps in improving health variables (eg, daily steps, maximal aerobic capacity) in healthy adults, involving an intervention regarding physical activity, diet, or their combination thereof. Evidence would suggest if apps could be effectively adopted in health interventions aiming toward prevention.

Methods: A systematic review was performed using Medline via PubMed, Cochrane Library—CENTRAL, and Embase. Only randomized controlled trials comparing the same intervention provided with and without a mobile app or a treatment and a mobile app compared with the treatment only were included in this systematic review. The Risk of Bias tool 2.0 was used to assess the risk of bias, and the GRADE (Grading of Recommendations, Assessment, Development and Evaluation) was adopted for rating the certainty of evidence.

Results: Considering studies up to June 2025, only 2 studies were included in the review of mobile apps for physical activity, and none were included for mobile apps for diet and none for mobile apps for physical activity and diet combined. The quality of evidence of the 2 studies included was low due to a high risk of bias, several missing data, and deviation from the original interventions, suggesting a scarce rigor in the methodology adopted. Therefore, mobile apps' effectiveness in improving diet, physical activity, or their combination cannot be assessed.

Conclusions: Despite the widespread use of mobile apps for health and the large number of relative publications, the results of this systematic review did not allow us to ascertain the effectiveness of mobile apps for health, but they provided fundamental insights for future research. Hence, it is not possible to state if apps for health might be used as supporting tools for health interventions aiming toward prevention and health improvements in healthy people. There is an urgent need to develop stronger evidence of apps' effectiveness in addressing different populations and types of interventions for different health domains.

KEYWORDS

active aging; diet; exercise; healthy ageing; health apps; mobile apps; physical activity

Introduction

Promoting active aging [1] requires new strategies to reach different populations in a feasible and effective way to help people improve their health status [2,3]. For this reason, the use of technology interventions is getting paramount attention to help people improve their health variables [4], identified as both clinical (eg, blood pressure, weight) and nonclinical outcomes (eg, daily activity or sleep) [5,6]. The attention to the use of technology-supported health interventions is due to the ease of

XSL•FO
RenderX

the use of mobile devices, their portability, their quality-price ratio [7], and the quantity of information they can provide with good data storage and live data analysis [8].

The World Health Organization describes this type of app as mobile health app (mHealth), defining it as "medical and public health practices supported by mobile devices, such as mobile phones, patient monitoring devices, personal digital assistants, and other wireless devices" [9]. Wireless devices can be fitness trackers, smartwatches, and smartphones, which makes it easy to collect several types of data (ie, number of daily steps, macronutrients, sleep, and stress level) from different health-related spheres, such as physical activity and diet [10,11], automatically (ie, using a wearable device [12]), through user's action or both. In particular, to do so, smartphones allow for downloading different types of apps, including health ones. These apps can be focused on just 1 health-related sphere [13,14] or a combination thereof [15].

Due to their easy use and versatility, people with and without diseases can benefit from mHealth apps to prevent or treat different conditions [16,17]. In line with that, different studies have been carried out in the last few years to test the effectiveness of apps for health on people with [18] and without diseases [19]. Unfortunately, the quality of the studies is low, and the results are often controversial [20], thus not allowing for definitive results on this topic. Moreover, to understand the effect of apps for health, one should compare the effectiveness of an intervention provided with and without the adoption of an app, while most of these studies adopt apps as baseline treatment with different interventions as adjunctive therapy, therefore testing the effectiveness of the adjunctive therapy rather than the app one [21,22]. Furthermore, mobile apps were chosen as mHealth to be investigated, as they are one of the most adopted technologies worldwide in health contexts [23], and those targeting fitness, nutrition, and healthy living are widely diffused [24].

Hence, the main purpose of this systematic review is to analyze the effectiveness of mobile apps in improving healthy adults' (ie, >18 years old) health variables, analyzing only randomized controlled trials (RCTs) that compare the same intervention with and without this technology in physical activity, diet, and a combination thereof.

Methods

The protocol of this systematic review was created and submitted to PROSPERO [25] (CRD42023485803). Furthermore, PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses; Checklist 1) [26] guidelines and PRISMA-S (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Literature Search Extension; Checklist 2) [27] were followed to report this review.

Deviations from the Protocol

The protocol initially restricted inclusion to English-language studies. During screening, it became clear that this would underrepresent available evidence and introduce potential language bias. We therefore expanded the criteria to include studies in other languages when reliable translation or accurate data extraction was possible. This deviation was made to enhance the review's completeness and international representativeness, while maintaining all other methodological criteria.

Study Objective

The main objective of this systematic review was to analyze the effectiveness of mobile apps for physical activity and diet to improve healthy adults' health variables. The research question was as follows: are mobile apps effective in improving health-related variables in healthy adults? To address this topic, three different options were investigated: (1) mobile apps for physical activity, (2) mobile apps for diet, and (3) mobile apps for physical activity and diet. The main outcomes listed hereafter correspond to each of the abovementioned points: (1) physical activity variables (eg, daily steps, moderate-to-vigorous physical activity), (2) diet variables (eg, weight, BMI), and (3) physical activity and diet variables as mentioned above.

Eligibility Criteria

For this systematic review, studies were considered eligible if they were published RCTs. No limitations on publication time were set, and RCTs published online until June 3, 2025, were included. Systematic reviews, reviews, meta-analyses, single-case studies, case series, observational studies, books, documents, guidelines, reports, and conference abstracts were excluded. Gray literature, systematic reviews, and meta-analyses were consulted, but not considered eligible, to find useful studies.

We included all those studies that involved healthy adult participants (>18 years old), with no cognitive impairments, musculoskeletal or neuromotor diseases, chronic conditions (eg, diabetes, hypertension), obese (ie, BMI≥30), or pregnant women. Interventions were considered eligible if a mobile app was used as an intervention to improve variables related to physical activity, diet, or their combination or only as a supportive technology to a specific intervention. No limitations on time or sessions of interventions were set. Mobile apps, including automatic or self-reported data collection and the use of a wearable device, were taken into account. Conversely, we excluded interventions with non-standalone apps, using high-cost sensors, exergames, nonmobile monitoring systems, robotics systems, or just clinician's telemedicine. Moreover, studies that did not precisely describe the health conditions of their population were excluded.

Search Strategy

Three scientific databases were sought for the study research: Medline via PubMed, Cochrane Library—CENTRAL, and Embase. They were chosen as they are reported as mandatory by the *Cochrane Handbook for Systematic Reviews of Interventions* [28].

The literature search was performed on the databases up to June 3, 2025, and the results were later merged into a single file to be subsequently uploaded onto Covidence [29], where the automatic duplicate detection was conducted. Specific search strings were created for the 3 databases, mixing Boolean

XSL•FO
RenderX

operators (ie, AND, OR), MeSH terms, and keywords. The research strategy is reported below.

- Mobile apps and physical activity and RCT: ((mHealth) OR (m-health) OR ("mobile health") OR ("mobile application") OR ("mobile app") OR ("smartphone application") OR ("smartphone app") OR (apps) OR (smartphone) OR ("Mobile Applications"[Mesh]) OR ("Smartphone"[Mesh])) AND ((fitness) OR ("physical exercise") OR ("physical fitness") OR ("fitness behavior") OR ("Physical Fitness"[Mesh]) OR ("Exercise"[Mesh]) OR (pedometer) OR (steps) OR (exercise) OR ("training exercise") OR ("heart rate variability") OR ("Heart rate") OR ("Heart Rate"[Mesh])) AND ((single blind) OR (double blind) OR (trial) OR (random*) OR (randomized) OR (randomized controlled))
- Mobile apps and diet and RCT: ((mHealth) OR (m-health) OR ("mobile health") OR ("mobile application") OR ("mobile app") OR ("smartphone application") OR ("smartphone app") OR (apps) OR (smartphone) OR ("Mobile Applications"[Mesh]) OR ("Smartphone"[Mesh])) AND ((diet) OR ("calorie counter") OR ("calorie counting") OR (calorie) OR ("calorie intake") OR (diet) OR ("Diet"[Mesh]) OR (dieting) OR ("weight loss") OR ("weight loss"[Mesh]) OR ("Weight Reduction Programs"[Mesh])) AND ((single blind) OR (double blind) OR (trial) OR (random*) OR (randomized) OR (randomized controlled))

Selection Process

Regarding the first research question, 2 researchers (GL and MJ) manually and independently screened titles and abstracts of the retrieved papers and evaluated them against the inclusion criteria. At the same time, for the second research question, 2 researchers (GL and RT) followed the same procedure. For the third research question, studies were identified among the papers selected by the above-described screening. The eligibility of the studies was then agreed upon through a consensus meeting between the 2 authors of each review and, in case of disagreement, a third researcher (CC) was consulted to reach a final decision. Afterward, the full texts of the selected papers were further screened against the inclusion criteria following the same process.

Data Collection

Two researchers (GL and MJ and GL and RT) proceeded blindly and independently to extract specific data from each study such as authors, year of publication, country, intervention setting, study design, total number of participants, number of participants for each experimental group, mean age of the participants and standard deviation (if available), number of female and male participants, type and timing of intervention sessions for both experimental groups, number and timing of follow-ups, outcomes, key conclusions, and eventually even a researcher's comment on each study. Moreover, all data available in each study were extracted and reported, such as mean, median, IQR, SD, number of follow-ups, and data registered at each follow-up. In case of missing data, authors were contacted.

Data Items

The most relevant characteristics of the selected studies are summarized in Table 1. According to our research questions, the outcomes of this systematic review are grouped as follows: (1) physical activity outcomes, (2) diet outcomes, and (3) physical activity and diet outcomes. No limits were identified for the reporting of any outcome. In case of missing data, authors were contacted.

Table . Study characteristics.

Study characteristics	Zongpa et al [30] (2020)	Muntaner-Mas et al [31] (2021)
Total number of participants	47	66
App name	Take a Walk	Vidahora
Type of intervention	App+diet indications	App
Type of control	No app+diet indications	No app
Primary outcome	VO_2 max[a] + HRV[b] + FBG[c] + adherence	Weigh + waist and hip circumference + 20-m shuttle run test + handgrip + standing long jump test + 4 × 10 m shuttle run test + sit and reach + IFIS[d]
Follow-ups	Week 4	Week 9
Intervention sessions and duration	6 reminders/day, 1 for every working hour	Free

[a]VO_2 max: maximal aerobic capacity.

[b]HRV: heart rate variability.

[c]FBG: fasting blood glucose.

[d]IFIS: International Fitness Scale.

Risk of Bias Assessment

The risk of bias (RoB) assessment was performed, independently and blindly, by 2 researchers for each study (GL and MJ or GL and RT, respectively) following the Revised Cochrane Risk of Bias tool 2.0 (RoB 2.0) [32] for RCTs or the Rob 2 CRT for cluster-randomized controlled trials [33]. This tool aims at assessing the RoB specifically for 5 domains: "Risk of bias arising from the randomization process," "Risk of bias due to

XSL•FO
RenderX

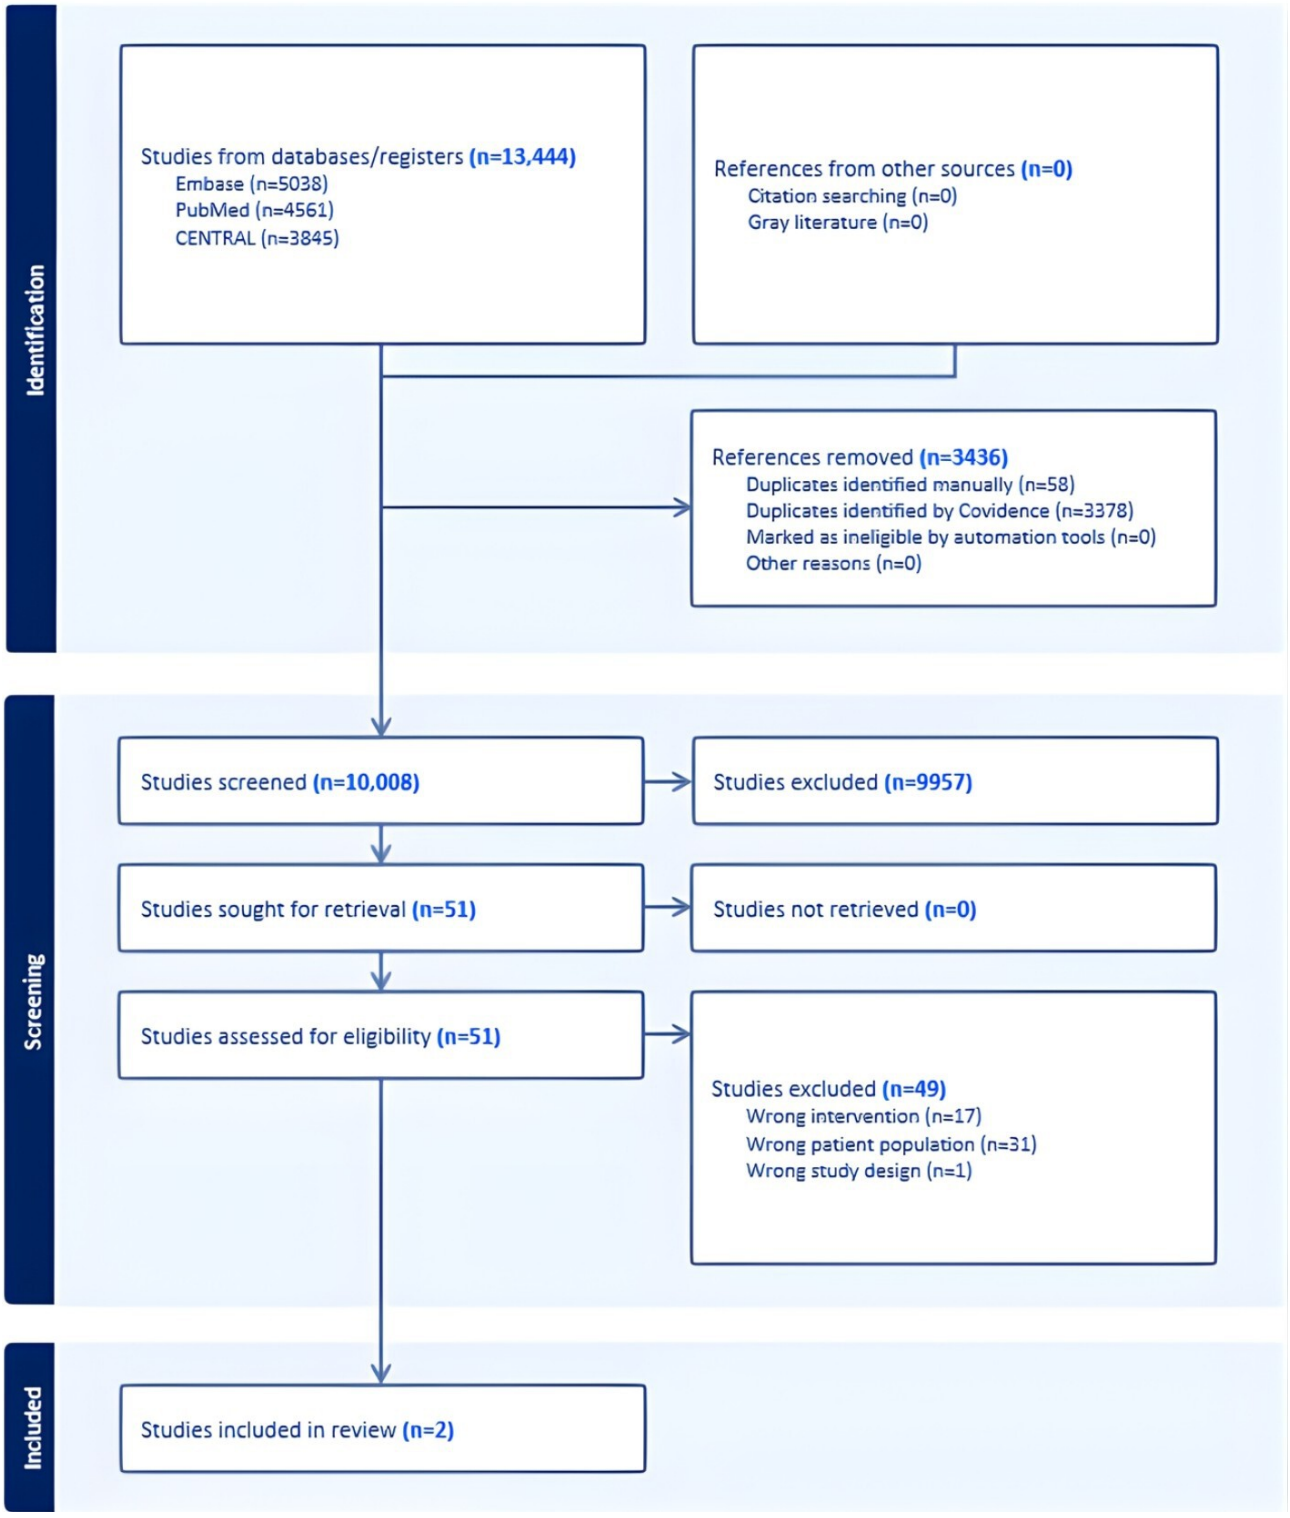
deviations from the intended interventions," "Risk of bias due to missing outcome data," "Risk of bias in measurement of outcome," and "Risk of bias in selection of the reported results." Consequently, an overall RoB for the study is provided. Domains and studies can be classified at low, moderate, or high RoB. The tool also allows one to indicate "no information" as an answer for each item of every domain and, in this case, it would often be considered at high RoB. A third researcher (CC) was contacted in case of disagreement to reach a consensus.

Statistical Analysis

Data from each study were extracted and reported, and a descriptive statistic was performed. For intergroup comparisons, the mean, SD, and/or mean differences for pre- and posttreatment conditions were reported. Additionally, the 1- or 2-tailed *t* tests for normally distributed data and the Mann-Whitney *U* test for nonnormally distributed data were also reported if performed in the studies. All statistical analyses were performed using the Jamovi statistical software [34].

Quality of Evidence

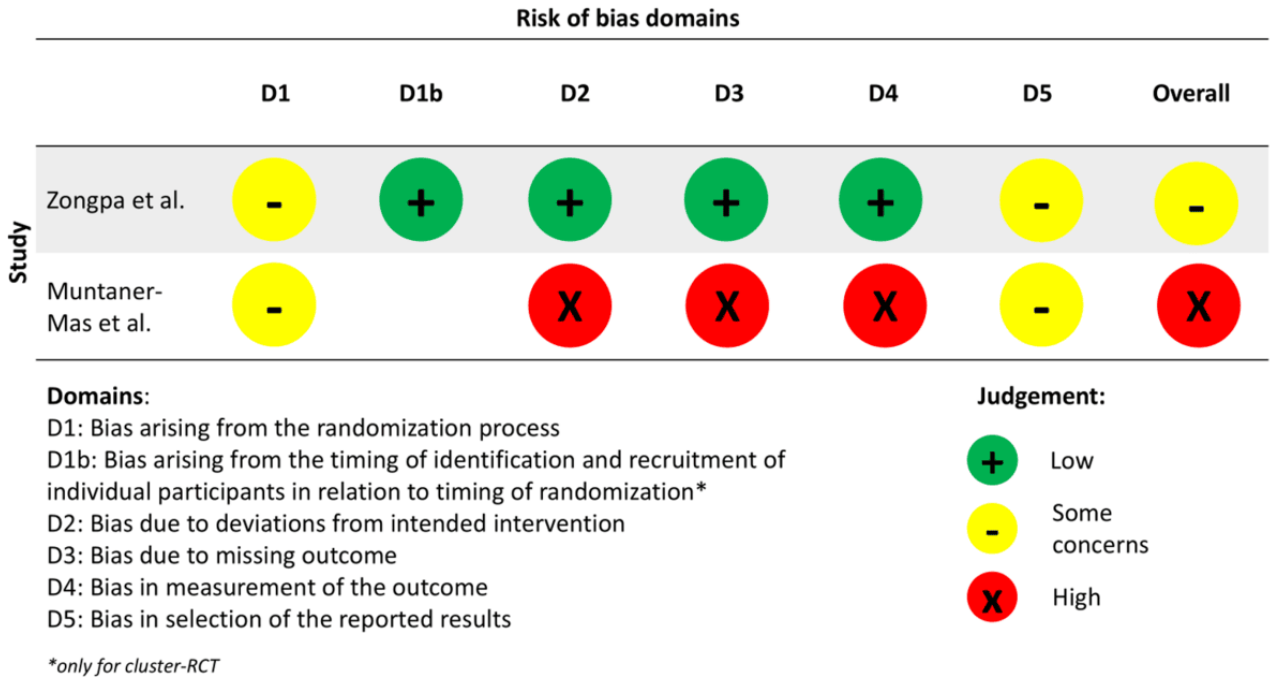
To perform the quality of evidence assessment, the GRADE (Grading of Recommendations, Assessment, Development and Evaluation) [35] approach was used via the GRADEpro GTD tool. This tool helps assess both the certainty of evidence and the strength of recommendations. The evaluation process took into account 5 different domains: risk of bias, imprecision (eg, sample size, confidence intervals), inconsistency (eg, heterogeneity), indirectness (eg, eligibility criteria against actual studies included), and publication bias (eg, bias in results publication).



Results

Study Selection

The literary search process for the first review identified a total of 13,444 studies. Duplicate removal eliminated 3436 studies, leaving a total of 10,008 studies to screen. After applying the inclusion and exclusion criteria to titles and abstracts, 51 studies were left [19,30,31,36-82]. Full-text studies were read independently by 2 researchers (GL and MJ), and in due course, another 49 papers were excluded [19,36-82], resulting in the final inclusion of 2 studies for further analysis [30,31]. The complete research process is graphically displayed in Figure 1, and the reasons for exclusions are reported in Multimedia Appendix 1. Multimedia Appendix 2 reports the complete research processes of the other 2 research questions.



XSL•FO
RenderX

Figure 2. Risk of bias (RoB) assessment for randomized controlled trial (RCT) and cluster-RCT [30,31].

Regarding the second and third questions (ie, mobile app for diet, and physical activity and diet), unfortunately, no studies were included. The selection processes are shown in Multimedia Appendix 2.

Study Characteristics

Among the 2 studies included in the final analysis, the first was a cluster RCT published in 2020 [30], and the second one was an RCT published in 2021 [31]. Both had only 1 intervention group and 1 control group [30,31]. The time of the intervention ranged from 4 to 9 weeks. The countries of study development were India [30] and Spain [31]. The studies' characteristics are indicated in Table 1. The first study [30] involved 47 participants, and the intervention consisted of giving a smartphone app (Take a Walk) to remind them to perform a few minutes of walking at regular intervals. The intervention group received "walk breaks" reminders each hour of work for a total of 6 reminders a day. The intervention lasted 4 weeks. Both intervention and control groups received an indication to follow a standard diet of 2300 Kcal/day. Physical activity–related variables were evaluated using different tests or variables, such as the fasting blood glucose, VO_2 max (maximal aerobic capacity), heart-rate variability, and adherence to walking breaks.

In the second study [31], involving 66 participants, the intervention group was provided with an app (Vidahora) to be used for 9 weeks. Participants were free to use the app whenever they wanted and were only advised to perform at least 10 minutes of physical activity 3 times a day. The second study assessed physical activity–related variables using several performance tests, anthropometric tests, and a questionnaire. Anthropometric tests were weight, hips, and waist circumferences. Performance tests were 20-m shuttle run test, handgrip test, standing long jump test, 4×10 m shuttle run test, and sit and reach test. The questionnaire used was the International Fitness Scale [83].

The characteristics of both studies are reported in Table 1, while the studies' outcomes are reported in Table 2.

[a]VO_2 max: maximal aerobic capacity.

[b]HRV: heart rate variability.

[c]SDNN interval: standard deviation of NN intervals.

[d]RMSSD: root mean square of successive RR interval differences.

[e]NN50: successive RR intervals that differ by more than 50 ms.

[f]pNN50: percentage of successive RR intervals that differ by more than 50 ms.

[g]VLF: very low frequency of power.

[h]LF: absolute power of the low-frequency band (0.04-0.15 Hz).

[i]HF: absolute power of the high-frequency band (0.15-0.4 Hz).

[j]LF/HF: ratio of LF-HF power.

[k]SD1 and SD2: Poincaré plots perpendicular to line of identity.

[l]FBG: fasting blood glucose.

[m]NA: not available but requested to authors.

App's Characteristics

Information about the Take a Walk app was limited; it was described as a simple Java–based Android app that allowed participants to set personalized reminders for walking, including customizable times and data. Participants were only required to manually set when to receive the reminders to walk.

The Vidahora app was made of 4 different sections: the first section dedicated to a quiz about healthy habits, the second section dedicated to the challenges for improving different physical activities' components via suggested video exercises (eg, strength, aerobic exercise, yoga), the third section hosted an artificial intelligence–assisted chatbot that could ask the participant about progress in a friendly way, and the last section was for setting the user data (eg, username, personal data). Badges for achievements were also present, as well as individual and community challenges with daily or weekly aims. Participants in the intervention groups were invited to use the app as they wished, with the only suggestion of recording at least 3 sessions of a minimum of 10 minutes per week of physical education.

Risk of Bias in Studies

The RoB assessment for the included RCT studies is graphically reported in Figure 2 using the Robvis tool [84]. The first study presents some concerns in the overall RoB, due to the randomization process since it is not clear how the experimenters performed it. Moreover, the study reports the registration of a protocol with a registration number, but in the mentioned database, it is not possible to find the protocol. In this case, it cannot be excluded that the results were not analyzed by a prespecified analysis plan that was finalized before unblinded outcome data were available for analysis. Indeed, the authors reported having several missing data but without any reasonable explanation.

The same 2 domains (D1 and D5) influence the overall RoB of the second study as well. The second study has the overall RoB indicated as "high risk." Domains 2, 3, and 4 are at high RoB, and those are influencing the overall RoB. The corresponding authors of the studies were contacted, but no answer was ever received.

GRADE Assessment

The assessment of the quality of evidence adopting the GRADE approach could not be performed due to the high heterogeneity of the outcomes considered in the studies included. First, the 2 studies did not consider the same outcome. Moreover, even involving the same sphere of interest (ie, physical activity) did not consider the same outcomes. Specifically, the first study [30] mainly considered physiological outcomes (ie, VO_2 max, blood glucose), while the second study [31] investigated performance outcomes (eg, 20-m shuttle run test, handgrip). Therefore, it is not possible to assess the quality of this evidence.

Discussion

Principal Findings

The included studies were overall characterized by a high RoB due to many missing values, high dropout, small sample sizes, and poor data reporting. In particular, the randomization processes were evaluated with the RoB 2.0 tool with "some concerns" as this tool requires this scoring if the paper does not describe the randomization procedures adopted in detail but just mention their adoption. Additionally, for 1 study, a protocol was not available. Moreover, the RoB of the second study was influenced by the decision of not including in the data analysis the participants who had missing data in 1 of the evaluations or were outliers. Thus, it might not be excluded that the results were influenced.

XSL•FO
RenderX

Furthermore, their study designs were significantly different, and it was not possible to make a direct comparison between their results. Our findings highlight the urgent need for standardized outcome measures to enable the generation of stronger, comparable evidence in this field. For each health domain examined, a validated set of standardized outcomes should be developed, allowing for their consistent use across diverse study designs and settings, including RCTs. Such standardization would facilitate more accurate assessments of mobile app effectiveness on health outcomes in healthy adults. Due to the heterogeneity of outcome measures among the included studies, it remains difficult to draw definitive conclusions regarding the efficacy of health-related mobile apps in this population. Therefore, future studies should aim to include larger sample sizes to enhance statistical power and improve the reliability of findings. Additionally, greater participant numbers may also help mitigate issues related to dropout and incomplete data during interventions. Moreover, intervention times should also be standardized to be able to compare results from different studies. Another problem that emerges from our results is the lack of standardized apps or guidelines to develop them for different health domains, and this might be seen from the different outcomes considered in each study included in our review. A standardized version of the health app could allow for having a set of common health data across different apps, with the possibility of adding other health variables specific to each app based on its characteristics and aims. In this way, studies could compare the use of different health apps for the same domain and consider a minimum set of common health variables.

Other systematic reviews were carried out on mHealth in the last years [85-89] and were also characterized by a very limited number of selected studies with high heterogeneity, and therefore they could not assess mHealth effectiveness. Indeed, many of the studies they included presented mixed results of the delivered interventions and the way of delivering them [64,87,90,91]. Hence, those studies did not assess the effectiveness of the same intervention delivered with and without mHealth, as we conversely did in our work. Considering the available literature, it is fundamental to emphasize the need to evaluate the effectiveness of specific mHealth interventions. However, the intrinsic variability in the designs and the scarce quality of the currently available studies do not allow us to state if mobile apps can be effective to improve health variables.

To overcome this problem, we decided to include in our work the studies that compared the same intervention provided with and without the mobile app, and additionally also the studies considering the same treatment provided via mobile app against the treatment. By applying these severe criteria, many studies were excluded from this systematic review for improper control, leaving only 2 studies to analyze. Consistent with our findings, other works reported the need for more studies with clearer designs to test the effectiveness of mHealth technology in different settings [92-95].

Studies Included

Digging into the included studies, Zongpa et al reported that physical activity–related variables improved over a 4-week period, specifically VO_2 max, heart rate variability, and fasting blood glucose. It should be noted that dropouts were 11.32%, and VO_2 max improvements may be questioned because the validity of a submaximal test in healthy people is questionable. Moreover, the VO_2 max improvement reported by this study was only 1.33%, while the minimal clinically important difference for VO_2 max should be higher than 6% [96]. Finally, the results should be taken carefully, as the results included in the analysis considered only an intervention adherence of at least 70%, thus imposing a possible bias in the selection of the results.

In the second study, Muntaner-Mas et al reported that many physical activity–related variables evaluated in the study improved, and the authors decided to split them into 3 categories: fatness indicators, physical fitness components, and self-reported fitness.

Starting from fatness indicators (ie, weight, waist, and hip circumference), no changes were obtained that could be attributable to the app. Physical fitness components (ie, 20-m shuttle run laps, handgrip strength, standing broad jump, 4×10 m shuttle run, and sit-and-reach) were improved, but even though few changes are indicated as statistically significant, the actual improvements are minimal and might not even be clinically relevant [97]. Second, improvements of a few units of centimeters or seconds obtained in 9 weeks and from a healthy and young population could be considered scarce. The category “self-reported physical fitness” explored 5 domains, and all the components were evaluated via Likert-type questions and reported the results obtained from the International Fitness Scale. The results improved for the intervention group and decreased for the control group, but considering the possible bias emerging from the self-evaluation, improvements should be carefully addressed since changes were minimal. Even in this category, the results on mobile app effectiveness could not be considered conclusive.

Despite the study considering the mobile app effective in improving physical activity–related variables, there were many missing data (ie, about 30%), and the sample size is limited. Summarizing, the effectiveness of the Vidahora app cannot be assessed. Although the selected studies highlighted that diet and physical activity levels can be improved by mHealth apps, their weak methodological design raises some concerns about their conclusions.

Limitation

A limitation of this work must be acknowledged: this systematic review included only studies involving healthy participants. Therefore, it is not possible to report anything about people with chronic conditions or pathologies. Additionally, a librarian was not consulted to develop the research strings, as people with expertise in conducting systematic reviews, and in their methodology, were consulted.

Conclusions

Despite the studies we included seeming to support the effectiveness of mobile apps to improve physical activity, diet-related variables, or their combination in healthy adults,

XSL•FO
RenderX

their poor methodological quality as well as the high variability in literature does not allow any definitive conclusion on this topic. Besides, the long-term effects of mobile apps interventions on different outcomes are scarce [92,95], and further research is needed. In addition, the interventions' (eg, activity, diet) effectiveness should be tested a priori and then provided via mHealth. Some urgent needs emerge from the literature analyzed and from this study. Specifically, for future studies, there is a need for high-quality RCT designs with large sample sizes to better assess the possible effects of health apps and the generalizability of results. Moreover, there is a need for clearer and consistent methodology that could provide stronger evidence of effectiveness, more transparent reporting of results that would prevent any bias and would additionally allow for acknowledging what is not working with apps for health and why, and addressing healthy people to test the mobile apps' effectiveness in preventing diseases and improving health conditions. Furthermore, standardized outcomes for each health domain of interest (eg, physical activity, diet) should be adopted, allowing for comparing the results of different studies and populations. Additionally, different studies could include, in the same health domain of interest, the chosen standardized outcomes as well as new ones, to try to expand possible results. Moreover, mHealth should be tested and validated by both patients and users before using them to deliver an intervention. Further research should test mobile apps as a tool supporting preventive approaches for health and well-being in young people and healthy participants as well. Finally, clear guidelines should be created on how to build up different types of mHealth, specifically for mobile apps, to standardize this process among health apps and to further try to ensure better use of this technology in the active aging and well-being fields.

Acknowledgments

We would like to sincerely express our gratitude to Dr Simone Battista for his support in carrying out this work. In all parts of this manuscript, generative artificial intelligence was used solely to ensure clarity and correct syntax. It was not used to create or contribute any insights into the research itself or any of its components.

Funding

No funding was received for this study.

Data Availability

All the relevant details and information are presented in the manuscript. Nonetheless, the data are available on reasonable request from the authors.

Authors' Contributions

GL, CC, MJ, and MT performed study conceptualization. GL and CC performed methodology. GL, RT, and MJ conducted the analysis, investigation, and data extraction. GL wrote the original draft preparation. GL, MJ, CC, RT, AS, and MT reviewed and edited it. All authors read and approved the final manuscript.

Abstract

Background: Wearable sensor technologies such as inertial measurement units, smartwatches, and multisensor systems have emerged as valuable tools in clinical and real-world health monitoring. These devices enable continuous, noninvasive tracking of gait, mobility, and functional health across diverse populations. However, challenges remain in sensor placement standardization, data processing consistency, and real-world validation.

Objective: This systematic review aimed to evaluate recent literature on the clinical and research applications of wearable sensors. Specifically, it investigated how these technologies are used to assess mobility, predict disease risk, and support rehabilitation. It also identified limitations and proposed future research directions.

Methods: This review was conducted according to the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines. We searched the PubMed, Scopus, and Web of Science databases up to March 9, 2025. Inclusion criteria focused on studies using wearable sensors in clinical or real-world environments. A total of 30 eligible studies were identified for qualitative synthesis. Data extracted included study design, population characteristics, sensor type and placement, machine learning algorithms, and clinical outcomes.

Results: Of the included studies, 43% (13/30) were observational, 27% (8/30) were experimental, and 10% (3/30) were randomized controlled trials. Inertial measurement unit–based sensors were used in 67% (20/30) of the studies, with wrist-worn devices being the most common (13/20, 65%). Machine learning techniques were frequently applied, with random forest (6/30, 20%) and deep learning (5/30, 17%) models predominating. Clinical applications spanned Parkinson disease, stroke, multiple sclerosis, and frailty, with several studies (4/30, 13%) reporting high predictive accuracy for fall risk and mobility decline (area under the receiver operating characteristic curve up to 0.97).

Conclusions: Wearable sensors show strong potential for mobility monitoring, disease risk assessment, and rehabilitation tracking in clinical and real-world settings. However, challenges remain in standardizing sensor protocols and data analysis. Future research should focus on large-scale, longitudinal studies; harmonized machine learning pipelines; and integration with cloud-based health systems to improve scalability and clinical translation.

Introduction

Throughout this paper, we use standardized terminology to ensure clarity and consistency. The term "wearable sensor" refers to any body-worn device capable of measuring physiological or biomechanical parameters, including inertial measurement unit (IMU)–based sensors, smartwatches, smart insoles, and multisensor systems. "IMU" refers specifically to devices incorporating accelerometers, gyroscopes, and magnetometers for motion tracking. When referring to specific device types (eg, smartwatches and smart insoles), we use the precise terminology to distinguish their unique features and applications.

Wearable sensors have gained significant attention in clinical research and health care for their ability to provide continuous, real-world assessments of mobility and physiological health. These devices, including IMU-based sensors, smartwatches, and multisensor systems, have transformed traditional gait and activity monitoring by enabling remote, noninvasive tracking of movement patterns and health status [1]. The integration of advanced analytics, particularly machine learning (ML), has further enhanced their diagnostic and predictive capabilities, positioning wearable sensors as key tools in digital health and precision medicine [2].

Gait analysis and mobility tracking have been central to wearable sensor applications, particularly in neurological, musculoskeletal, and age-related conditions. In Parkinson disease (PD), wearable sensors have been used to detect subtle changes in gait speed, stance and swing phase durations, and postural instability, aiding in early disease detection and progression monitoring. In stroke rehabilitation, these sensors enable remote motor recovery assessment and provide continuous mobility data outside traditional clinical settings [3]. Wearable sensors also demonstrate high efficacy in frailty assessment and fall risk prediction, offering objective, real-time alternatives to conventional tools such as the Performance-Oriented Mobility Assessment (POMA) and Timed Up and Go (TUG) tests.

Despite their growing clinical adoption, several challenges hinder the widespread implementation of wearable sensor technology. Variability in sensor placement, study methodologies, and data processing techniques limits cross-study comparability and reproducibility [3]. Additionally, while controlled laboratory studies have validated their accuracy, real-world validation remains insufficient, necessitating further large-scale, longitudinal studies to assess their usability and reliability across diverse populations [4]. Furthermore, standardization of ML frameworks and data interpretation methodologies is essential to ensure consistent clinical application [5].

This systematic review aimed to provide a comprehensive evaluation of wearable sensor research, analyzing their clinical applications, technological advancements, and methodological challenges. By synthesizing evidence from recent studies, we highlight key trends in wearable sensor use, discuss their implications for health care, and propose future directions to enhance their impact in mobility monitoring and rehabilitation.

Methods

Study Design

The protocol of this review was not registered in PROSPERO due to its exploratory nature and inclusion of emerging sensor studies. However, the review process followed the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 guidance to ensure methodological transparency. The study selection process followed PRISMA 2020 guidelines, including identification, screening, eligibility assessment, and final inclusion. This review focused on studies published in the last 10 years that investigated the applications and effectiveness of wearable sensors, including smartwatches, in remote health monitoring, rehabilitation, and disease assessment. Full-text articles were included to ensure a comprehensive analysis. We aimed to synthesize evidence on clinical and research applications of wearable sensors, particularly for gait analysis, fall risk assessment, and disease monitoring. Given study heterogeneity, we categorized and synthesized the findings narratively, emphasizing disease-specific insights and sensor use trends.

Search Strategy

A comprehensive database search was conducted across PubMed, Scopus, and Web of Science.

The search strategy combined terms related to wearable technologies, inertial sensors, digital biomarkers, and rehabilitation. Representative Boolean operators were used as follows:

> *("smartwatch" OR "smart watch" OR "wearable sensor" OR "wearable sensor") AND ("accelerometer" OR "acceleration sensor" OR "inertial sensor" OR "IMU") AND ("remote monitoring" OR "digital biomarkers" OR "telemedicine" OR "wearable health tracking") AND (aging OR older adults OR elderly OR Parkinson OR stroke OR "gait disorders" OR "neurological disorders" OR "movement disorders" OR "fall risk" OR rehabilitation OR "functional mobility" OR sarcopenia OR osteoarthritis OR dementia) NOT review.*

The initial search yielded 4226 records. Of these 4226 records, after removing duplicates and studies unrelated to clinical applications (n=3664, 86.7%), 562 (13.3%) remained for screening. Of these 562 studies, those focusing solely on technical performance comparisons (n=501, 89.1%) were excluded, leaving 61 (10.9%) for eligibility assessment. Of these 61 studies, an additional 31 (51%) were excluded due to limited relevance to disease-related applications, resulting in 30 (49%) studies included in the final review. The search was finalized on March 9, 2025. In total, 30 studies met the inclusion criteria and were included in the final synthesis. Additional references cited throughout the manuscript (n=43) were used for background, context, and methodological justification.

XSL•FO
RenderX

Study Selection Process

A single researcher conducted study selection and data extraction following a predefined protocol to minimize bias. The eligibility criteria were clearly defined and consistently applied. Studies published from March 9, 2015, to March 9, 2025, were considered, reflecting a 10-year search window. Eligible study designs included randomized controlled trials (RCTs), observational studies, and experimental validation studies conducted in either clinical or real-world settings. Both research-grade and commercial wearable sensors were included provided that they reported measurable health or functional outcomes. Only English-language, peer-reviewed articles were included, and conference abstracts, reviews, and purely technical feasibility reports without human participants were excluded. Quality appraisal using the Newcastle-Ottawa Scale (NOS), Joanna Briggs Institute (JBI) appraisal tools, or version 2 of the Cochrane risk-of-bias tool for randomized trials (RoB 2) was conducted to describe study rigor but did not influence inclusion decisions.

Any uncertainties during the selection process were resolved by re-evaluating studies against the predefined inclusion criteria. Data extraction was conducted manually using a standardized form. No independent reviewers cross-checked the extracted data, which is acknowledged as a limitation. Missing or unclear data were clarified when possible, by contacting the corresponding authors. No automation tools were used for data collection.

Participant Selection in the Included Studies

The included studies targeted diverse populations, including healthy adults; older individuals; and patients diagnosed with neurological disorders (eg, stroke and PD), musculoskeletal disorders (eg, sarcopenia and osteoarthritis), or metabolic conditions (eg, diabetes). Participants could walk independently and provided informed consent. We excluded studies lacking clear participant definitions or standard gait analysis metrics to maintain consistency. Pediatric studies were excluded except for those including toddler cohorts (aged <3 years) and specifically designed for developmental gait analysis. To ensure data quality, studies were required to report a minimum wear time of 30 minutes of valid sensor data per session.

Wearable Sensor Technology

The wearable sensors reviewed featured advanced components such as high-precision accelerometers, gyroscopes, and pressure sensors. These sensors accurately captured key gait and mobility parameters: step length, stance and swing phase durations, plantar pressure distribution, and center of pressure. Smartwatches were primarily used for activity tracking and remote monitoring, whereas wearable sensors and foot-mounted sensors specialized in gait and postural assessments. The wearable sensors integrated seamlessly into daily life, ensuring high usability and real-world applicability.

Data Acquisition and Analysis

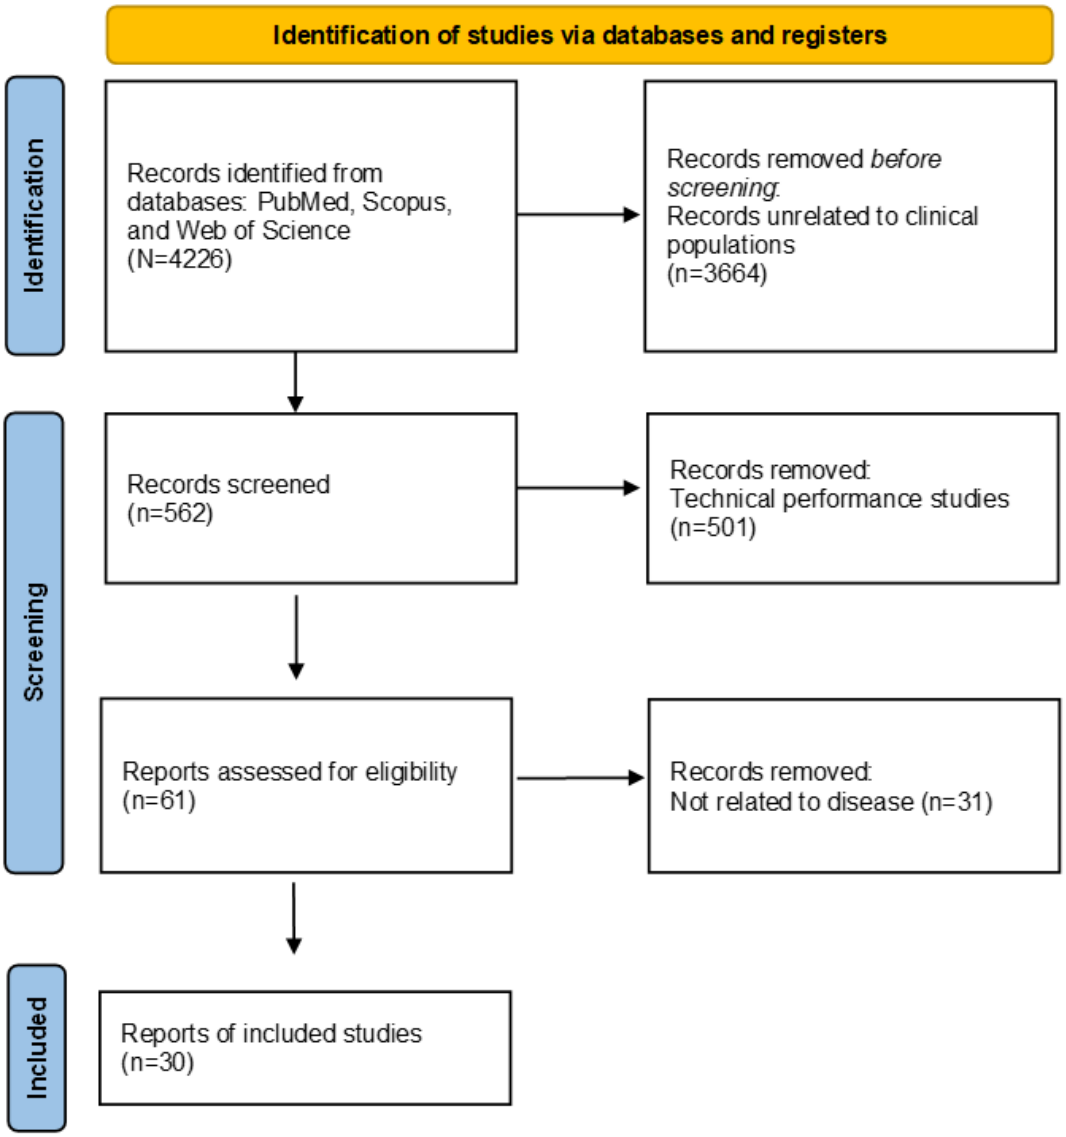
Data were collected using a variety of wearable sensor systems, including IMUs, smart insoles, smartwatches, and pressure-sensing devices. Sensor placement varied by study objective and included the wrist, waist, ankle, thigh, lumbar spine, and foot. The IMU sensors incorporated accelerometers, gyroscopes, and magnetometers with sampling rates ranging from 10 to 1149 Hz depending on the device and measurement context. Pressure-sensitive insoles provided additional biomechanical insights through plantar pressure distribution and force-time characteristics.

Wireless data transmission via Bluetooth or cloud platforms enabled real-time monitoring and digital biomarker extraction. Embedded preprocessing algorithms were applied to reduce noise, improve signal quality, and enhance feature extraction accuracy. Studies used various ML techniques, including random forest (6/30, 20%), deep learning (5/30, 17%), elastic net regression (4/30, 13%), and principal component analysis (PCA; 2/30, 7%), for pattern recognition, mobility classification, and disease risk prediction. All reported quantitative values (eg, area under the receiver operating characteristic curve [AUROC], accuracy, and improvement rate) were extracted from individual studies and are presented descriptively, not as pooled estimates.

The methodological quality of the included studies was systematically evaluated using appropriate assessment tools based on the study design. The NOS was applied to prospective cohort studies, whereas the JBI critical appraisal checklist was used for observational, cross-sectional, and experimental studies. For RCTs, the RoB 2 tool was used to ensure a robust evaluation of study quality. The results of the quality assessment guided the interpretation of the reliability and clinical applicability of the findings. Studies were categorized as low (JBI or NOS score of ≥8), moderate (JBI or NOS score of 6-7), or high (JBI or NOS score of ≤5) risk of bias according to established thresholds.

Ethical Considerations

All studies included adhered to ethical standards for human research, following the Declaration of Helsinki. As this study is a systematic review of published literature and did not involve human participants, interventions, or identifiable private data, ethics approval was not required. Data privacy and participant well-being were prioritized across the studies.



Results

Study Design and Population Characteristics

A total of 4226 records were identified through database searching. After removing duplicates and screening titles and abstracts, 562 articles remained for full-text assessment. Of these, 30 studies met the inclusion criteria and were included in the final review. The full screening process is summarized in Figure 1 (PRISMA 2020 flow diagram). Among the analyzed studies, the most frequently used research design was prospective observational studies, accounting for 43% (13/30) of the total. Experimental studies comprised 27% (8/30), whereas RCTs were limited to 10% (3/30). Cross-sectional studies and cohort studies accounted for 13% (4/30) and 7% (2/30), respectively. Observational studies were most common due to their feasibility, whereas experimental studies validated sensor-based assessments. RCTs were scarce, indicating limited rigorous intervention-based evaluations. Cohort studies were included in long-term monitoring applications.

Figure 1. PRISMA flow diagram illustrating the screening process of papers for study selection.

The studies focused on various populations, with healthy adults being the most common participant group, as summarized in Table 1. Studies involving neurodegenerative diseases such as PD, stroke, Huntington disease, and multiple sclerosis (MS) were also prevalent. Healthy adults were often included for sensor validation and reliability assessment, whereas studies on neurodegenerative diseases primarily aimed at mobility and functional monitoring. Research on frailty in older adults (4/30, 13%) focused on mobility assessment, balance, and fall risk analysis. The reviewed studies covered a wide range of age groups and health conditions. Studies involving healthy adults typically included participants from early adulthood to middle age, with some extending to adolescent and pediatric populations. Research on neurodegenerative diseases such as PD and Huntington disease focused primarily on older adults, whereas cardiovascular disease– and frailty-related studies involved older participants as well. Certain studies (12/30, 40%) targeted specific conditions such as osteoarthritis, rheumatoid arthritis, MS, cystic fibrosis, stroke, and spinal cord injury, highlighting the diverse application of wearable sensors, particularly smartwatches, in different clinical populations. The distribution of male and female participants varied across studies, with some (1/30, 3%) focusing specifically on age-based differences in sensor performance and health monitoring.

Sensor Use and Data Analysis in Wearable Research

Studies relied heavily on IMU sensors (20/30, 67%) and smartwatches (8/30, 27%). Shoe-mounted sensors and multisensor systems incorporating electrocardiograms were less frequently used. Wrist-worn sensors (13/30, 43%) were the most common due to ease of wear and practical data collection. Smartwatches, as a subset of wrist-worn devices, were frequently used for continuous activity tracking and health monitoring. Additionally, ankle and thigh placements (7/30, 23%) were primarily used for gait analysis, whereas foot and insole sensors (2/30, 7%) were implemented for more specialized balance and gait assessments.

The predominant activity type studied was gait analysis, which appeared in 60% (18/30) of the studies, followed by activities of daily living (12/30, 40%), balance assessments (8/30, 27%), energy expenditure evaluations (6/30, 20%), and rehabilitation exercises (6/30, 20%). Gait analysis was especially relevant in research focused on neurodegenerative diseases and mobility impairments, where smartwatches were often used for free-living gait monitoring. Studies on activities of daily living leveraged smartwatches for continuous data collection in real-world settings. Balance assessments were primarily conducted for frailty and fall risk evaluations, with some smartwatch-based apps integrating accelerometry for postural control analysis.

Data processing in wearable sensor research used a range of ML techniques. Random forest was the most commonly applied method (6/30, 20%), followed by deep learning models (5/30, 17%), elastic net regression and support vector machines (SVMs; 4/30, 13%), and PCA (2/30, 7%). Random forest was frequently used in gait analysis and activity recognition, whereas deep learning models were applied for long-term movement pattern analysis, particularly in smartwatch-based apps. Elastic net and SVM were commonly used for classification tasks, and PCA was used for dimensionality reduction, optimizing the performance of wearable sensor data processing.

Clinical Applications of Wearable Sensors

Overview

The diverse clinical applications of wearable sensors, categorized into 5 main areas—healthy individuals, age-related conditions, neurological conditions, musculoskeletal disorders, and metabolic conditions—are summarized in Table 2.

XSL•FO
RenderX

Table 2. Summary of clinical results for wearable sensors across populations.

Category and condition	Key findings	Clinical significance and utility
Rehabilitation assessment and functional recovery		
Knee arthroplasty (TKA[a] and UKA[b])	Bone stimulus: +52%; impact load: +371%; OKS[c]: +52%; EQ-5D: +32%	IMU[d]-based wearables support accurate postoperative monitoring and personalized recovery for knee arthroplasty.
CR[e]	6MWD[f] prediction error: 42.8 m; R^2=0.661	CR progress can be reliably tracked remotely, improving long-term care.
Stroke—upper-limb rehabilitation	Movement quality classification accuracy: 92%; F_1-score: 0.95	IMUs enable remote monitoring of home-based rehabilitation, enhancing adherence and personalization.
Rotator cuff injury rehabilitation	Exercise classification accuracy: 99.99%	Smartwatches improve rehabilitation compliance and exercise tracking at home.
Lumbar mobility assessment	Significant ROM[g] differences between wrist and lumbar sensors (up to 8, *P*=.003)	Wrist-worn sensors allow for remote lumbar mobility assessment for rehabilitation use.
Disease state prediction and risk assessment		
PD[h]—tremor and fall risk	Tremor detection accuracy: 83%; sensitivity: 86%; specificity: 86%; fall risk prediction RMSE[i]: 0.42	Wearables objectively monitor PD symptoms and fall risk for early intervention.
HD[j]	Sensitivity: 85%; specificity: 72%; accuracy: 81%; AUROC[k]: 0.82	HD motor decline can be tracked remotely for personalized care.
Frailty assessment in older adults	QTUG[l] accuracy: 75.8%; ScanWatch-enhanced model: 79.3%	Wearables detect frailty early, enabling preventive intervention in older adults.
OHCA[m] detection	Optimized balance between sensitivity and specificity	OHCA can be detected in real time via wearables for rapid emergency response.
Activity and behavior tracking		
Arthritis—pain and function monitoring	5-STS[n] performance significantly correlated with morning pain scores (*P*<.05)	IMUs enable noninvasive, remote tracking of arthritis pain and function.
CF[o]—activity monitoring	Fitbit and iOS smartphone showed strong agreement with SWA[p]	Consumer wearables offer scalable, affordable physical activity monitoring.
Consumer vs research-grade wearables (activity monitoring)	Z-Track sedentary behavior detection: AUC[q]=0.95; MVPA[r] detection: AUC=0.93	Fitbit-level devices reliably track sedentary behavior and activity levels.
Medication adherence monitoring	Medication intake detection accuracy: 93.6%; sensitivity: 92%	Wearables automate medication tracking, improving adherence in chronic care.
Gait analysis and balance assessment		
Gait symmetry analysis (head-worn sensor)	Gait event detection accuracy: 99.35%	Head-worn sensors support gait symmetry analysis for neurological rehabilitation.
Balance assessment (smartwatch based)	Strong correlation between smartwatch and research-grade sensors (*r*=0.861-0.970)	Smartwatches enable balance monitoring at home to prevent falls.
MS[s]—balance and mobility	AUROC=0.97	Wearables track long-term mobility and balance in MS, supporting personalized rehabilitation.

[q]AUC: area under the curve.

[r]MVPA: moderate to vigorous physical activity.

[s]MS: multiple sclerosis.

Rehabilitation Assessment and Functional Recovery

Wearable sensors were used to analyze gait metrics in both young and older adults. Studies on young adults focused on plantar pressure distribution, step length, swing time, and ground reaction force, achieving high accuracy in real-time gait analysis, such as 95% using the FreeWalker system with a 1000-Hz sampling frequency. Advanced ML techniques further enhanced center of pressure prediction accuracy by over 30%. Among older adults, wearable sensors were effective in assessing fall risk and mobility. Improvements were observed in swing time (+6.45%) and slip and trip classification accuracy, which exceeded 98% (P<.05).

Disease State Prediction and Risk Assessment

Studies addressed frailty and fall history using wearable sensors to measure load distribution, gait phases, and stance and swing time. Load distribution assessments demonstrated high reliability, with intraclass correlation coefficient values reaching 0.91 and strong correlations for the left (r=0.7171) and right (r=0.7502) foot. Fall risk indexes provided significant predictive accuracy, with AUROC values of 0.919 (P<.05), making them comparable to traditional tools such as the POMA and TUG tests. These findings emphasize the potential of wearable sensors for early identification of frailty and fall risk in older adults.

Activity and Behavior Tracking

Wearable sensors were used to evaluate gait characteristics in individuals with stroke, MS, and PD. Among stroke survivors, significant reductions in gait speed and step length were observed compared to controls, with strong correlations between Fugl-Meyer Assessment lower-limb scores and stance time differences (R^2=0.71). In MS, high agreement was reported between the FeetMe and GAITRite systems (intraclass correlation coefficient>0.8), validating the utility of wearable sensors for mobility monitoring. For individuals with PD, significant differences were detected in gait speed, stride length, and swing and stance time compared to healthy controls (P<.05), demonstrating the role of wearable sensors in tracking disease progression.

Gait Analysis and Balance Assessment

Wearable sensors were effective in managing diabetes and other metabolic disorders. For diabetes, total contact casts reduced forefoot contact area by 5% and peak pressure by 8% (P<.05), effectively offloading pressure and reducing the risk of complications. These devices provide actionable data that support better management of metabolic health and reduce disease-related complications.

Quality Assessment Results

The quality assessment results are summarized in Table 3, with the studies rated using the JBI critical appraisal tools scoring between 5 and 8 out of 10, NOS-rated cohort studies scoring between 6 and 7 out of 9, and RoB 2–rated RCTs scoring 8 out of 10. Of the 30 included studies, 6 (20%) were rated as low risk, and 24 (80%) were rated as having a moderate risk of bias. Studies investigating wearable sensor–based mobility assessments, gait analysis, and rehabilitation applications showed high feasibility and reliability, particularly those incorporating real-time monitoring and signal processing techniques. However, several studies (26/30, 87%) exhibited limitations such as small sample sizes, lack of validation in real-world settings, and limited applicability to diverse patient populations. Additionally, some studies (12/30, 40%) faced technical challenges, including sensor displacement errors, signal-to-noise ratio issues, and data synchronization difficulties.

Discussion

Expanding the Role of Wearable Sensors in Health Monitoring

Wearable sensor technology, including IMU-based smartwatches, smart insoles, and multisensor systems, has significantly transformed health monitoring, rehabilitation tracking, and disease risk assessment [36]. These devices enable continuous, real-world tracking of mobility and functional health, addressing key limitations of traditional clinical assessments [37]. The reviewed studies highlight these devices' diverse applications in neurological, musculoskeletal, cardiovascular, and metabolic conditions, supporting early disease detection, remote therapy adherence, and precision rehabilitation [38].

Observational studies accounted for 43% (13/30) of the reviewed studies, reflecting the feasibility of longitudinal monitoring, whereas experimental studies made up 27% (8/30), playing a crucial role in validating sensor-based assessments. However,

XSL•FO
RenderX

the limited number of RCTs, representing only 10% (3/10) of the studies, underscores the need for rigorous intervention-based research to establish causal relationships between wearable sensor use and patient outcomes. The study populations were diverse, with healthy individuals comprising 33.3% of the participants, often included for sensor validation and reliability testing. Clinical populations, including individuals with PD, stroke, frailty, and cardiovascular conditions, were the primary focus of applied research, demonstrating the potential for wearable sensors to support patient management in real-world health care settings.

Evolution of Wearable Sensor Applications

In our review, 30% (9/30) of the included studies conducted validation in healthy adults, indicating that early wearable-sensor research primarily focused on device feasibility and performance testing before expanding into clinical populations. These devices have revolutionized mobility monitoring, particularly in neurodegenerative conditions such as PD, MS, and stroke, where continuous tracking of gait parameters enables early detection of motor impairments and disease progression. They also play a significant role in frailty assessment (4/30, 13%) and fall risk prediction. Smart insoles demonstrate high predictive accuracy (AUROC=0.919; P<.05) as noninvasive, real-world mobility assessment tools.

Technological Integration and Advances in Data Processing

The studies primarily used IMU-based systems (20/30, 67%) and smartwatches (8/30, 27%). Wrist-worn sensors were the most common, representing 43% (13/30) of the devices used, as they offer practicality, ease of wear, and convenience for everyday use. Ankle- and thigh-mounted sensors accounted for 23% (7/30) of applications and were primarily used for gait and posture assessments, whereas multisensor systems integrating electrocardiograms and pressure sensors provided additional biomechanical and cardiovascular insights, although they were less frequently studied.

Advances in ML have significantly enhanced data interpretation and predictive capabilities in wearable sensor applications [2]. Random forest models, applied in 20% (6/30) of the studies, were widely used for gait classification and activity recognition, whereas deep learning techniques were applied in 17% (5/30) of the studies and demonstrated high accuracy in long-term movement analysis. Elastic net regression and SVMs were used in 13% (4/30) of cases for classification tasks, whereas PCA was used in 7% (2/30) of the studies to reduce dimensionality and optimize data processing. However, variability in feature extraction methods remains a challenge. Standardized approaches are needed to improve reproducibility and clinical translation.

Clinical Applications of Wearable Sensors

Wearable sensors demonstrated strong feasibility across multiple health care applications, including rehabilitation monitoring, disease risk assessment, activity tracking, and gait analysis. For rehabilitation assessment, wearable sensors improved postsurgical monitoring in patients who underwent knee arthroplasty, showing 52% better bone stimulus and 371% better impact load tracking. Wearable sensors for cardiac rehabilitation demonstrated reliable 6-minute walk distance prediction, with an error of 42.8 m and an R^2 value of 0.661, facilitating remote patient monitoring. In stroke rehabilitation, IMU-based movement quality assessments achieved 92% accuracy (F_1-score=0.95), supporting their use for personalized therapy and remote monitoring.

Recent studies have also extended the application of IMU-based wearable sensors to shoulder rehabilitation. Tranquilli et al [39] demonstrated that a single IMU could simultaneously capture joint mobility and muscle strength dynamics during postinjury recovery. Ajčević et al [40] applied IMU sensors to quantify shoulder kinematics and evaluate therapeutic response in adhesive capsulitis, whereas Parel et al [41] introduced a kinematic biofeedback program integrating inertial sensors for patients after rotator cuff repair. These studies highlight the versatility of IMU technology for upper-limb functional assessment and real-time feedback during rehabilitation.

Wearable sensors also played a key role in disease prediction and risk assessment. In PD monitoring, wearable technology achieved an accuracy of 83% in tremor detection and both a sensitivity and specificity of 86% in fall risk prediction, supporting the feasibility of early intervention strategies. Fall risk assessments using wearable sensors reached an AUROC value of 0.919, demonstrating their ability to provide noninvasive, real-world alternatives to clinical assessments such as the TUG and POMA tests.

Activity and behavior tracking applications showed high accuracy, particularly in arthritis-related pain and function monitoring, where significant correlations were observed between morning pain scores and 5-time sit-to-stand performance, with P values of less than .05. Consumer wearables such as Fitbit and iOS-integrated smartwatches achieved a strong agreement with research-grade sensors, with an AUROC of 0.93, demonstrating their feasibility for large-scale, real-world activity tracking. In medication adherence monitoring, smartwatch-based tracking achieved an accuracy of 93.6%, highlighting its potential for improving adherence in chronic disease management.

Gait and balance assessments using wearable sensors provided highly accurate insights into functional mobility. Head-worn IMU–based gait symmetry analysis reached an accuracy of 99.35%, indicating its effectiveness in neuromuscular rehabilitation and postural correction. Wearable sensor–based assessments of balance and mobility for patients with MS achieved an AUROC of 0.97, reinforcing their potential to support personalized rehabilitation planning and disease progression monitoring.

The included studies encompassed diverse populations, including healthy adults, neurological patients (eg, PD), individuals with musculoskeletal disorders, and pediatric or rehabilitation cohorts. This diversity introduces biomechanical and physiological variability in gait patterns, movement strategies, and sensor placement feasibility. Differences in muscle coordination, assistive device use, and experimental environments further contribute to heterogeneity. Given these

XSL•FO
RenderX

variations, direct quantitative comparisons between studies were avoided. Instead, a narrative synthesis was used to identify overarching technological and methodological trends across populations. This approach emphasizes generalizable insights—such as the importance of standardized placement, calibration, and cross-population validation—while acknowledging disease-specific distinctions in biomechanics and sensor performance.

Many of the included studies (19/30, 63%) used ML algorithms such as random forest, deep learning, elastic net regression, and PCA for signal interpretation and disease classification. However, reporting transparency and methodological rigor varied substantially. Several studies (26/30, 87%) were limited by small sample sizes and internal validation only, increasing the risk of model overfitting. In addition, few studies (4/30, 13%) provided sufficient details regarding cross-validation protocols, feature selection strategies, or hyperparameter optimization.

Adherence to standardized ML reporting frameworks—such as the Transparent Reporting of a Multivariable Model for Individual Prognosis or Diagnosis–Artificial Intelligence and Prediction of Model Risk of Bias Assessment Tool–Artificial Intelligence—was rarely observed, which may affect reproducibility and generalizability.

Future research should emphasize external validation, open-source code sharing, and adherence to established ML reporting standards to ensure reliability and transparency in sensor-based clinical modeling.

Challenges in Wearable Sensor Research

Despite the promising applications of wearable sensors, several challenges remain that must be addressed to ensure widespread clinical adoption and real-world impact.

First, small sample sizes (26/30, 87% of the studies) and limited real-world validation (12/30, 40% of the studies) reduced finding generalizability. Short study durations (8/30, 27%) also hindered long-term effectiveness assessment. Beyond these methodological limitations, the scope of this review was restricted to English-language, peer-reviewed publications, excluding gray literature such as conference abstracts and theses. This language restriction and publication bias may have favored studies reporting positive or statistically significant outcomes, potentially overestimating the clinical impact of wearable sensor technologies. Furthermore, although some studies (3/30, 10%) discussed the potential cost-effectiveness of sensor-based systems, no direct economic evaluations were identified, limiting the ability to substantiate financial feasibility claims.

Technical challenges also persist. Variability in signal-to-noise ratios, sensor displacement errors, and inconsistencies in data collection protocols underscore the need for improved hardware design and standardized preprocessing algorithms. Differences in feature extraction and model architectures limit cross-study comparisons and reproducibility.

Finally, the field urgently requires greater standardization. Variability in sensor placement, protocols, and data interpretation hinders reproducibility and large-scale comparison. Establishing consensus-driven guidelines for wearable sensor research—including standardized task protocols, data reporting frameworks, and model transparency criteria—will be essential to enable scalability, reproducibility, and eventual clinical translation.

Future Directions

To fully realize the potential of wearable sensors in health care, future research should focus on several key areas. Expanding RCTs is essential to establish causal relationships between wearable sensor use and health outcomes beyond feasibility studies. Standardized data analysis frameworks will improve comparability and reproducibility, enabling integration into multicenter trials and large-scale studies. Long-term, multicenter studies will enhance real-world validation and assess sensor accuracy, usability, and adoption across health care settings.

Integration with cloud-based platforms and telemedicine will enhance scalability and enable real-time remote monitoring across diverse populations [42]. Cost-effectiveness analyses will determine financial feasibility and accessibility, supporting broader health care adoption and effective use in resource-limited settings [43].

Conclusions

This systematic review highlights the growing clinical relevance of wearable sensors for rehabilitation monitoring, disease risk assessment, and personalized health care. IMU-based smartwatches, multisensor systems, and gait-monitoring devices demonstrate high accuracy in mobility assessment, fall risk prediction, and chronic disease management for digital health and precision medicine.

Despite their utility, the following challenges remain: small sample sizes, real-world validation gaps, and inconsistent ML methodologies. Future research should standardize protocols, expand clinical trials, and integrate sensors into telemedicine and cloud-based analytics platforms.

Overcoming these challenges will enable wearable sensors to revolutionize health care through real-time, noninvasive monitoring that bridges traditional clinical assessments and continuous real-world health tracking.

Abstract

Background: Psychological stress during pregnancy is common and has been associated with adverse maternal and neonatal outcomes. Digital health interventions (DHIs) have emerged as a scalable approach to support stress management during pregnancy, yet evidence remains fragmented, and prior reviews have largely focused on broad perinatal mental health outcomes or delivery platforms rather than stress-specific effects and targeted intervention components.

Objective: This systematic review and meta-analysis aimed to evaluate the effectiveness of DHIs specifically designed to reduce stress during pregnancy and to examine how intervention strategies and delivery methods are associated with stress outcomes.

Methods: We conducted a systematic review and meta-analysis following PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 guidelines. Randomized controlled trials and quasi-experimental studies involving pregnant women were eligible if they evaluated any digitally delivered intervention—such as mobile apps, web-based programs, or telemedicine—intended to reduce stress, and reported validated stress outcomes. We searched CINAHL, the Cochrane Library, Embase, and PubMed from database inception through November 2025. Risk of bias was assessed using the Cochrane risk of bias 2 tool for randomized trials and the risk of bias in nonrandomized studies of interventions tool for nonrandomized studies. Where appropriate, effect sizes were pooled using random-effects meta-analysis with the Hartung–Knapp–Sidik–Jonkman method and reported as standardized mean differences.

Results: A total of 19 studies were included. Overall, DHIs were associated with a significant reduction in stress compared with control conditions (standardized mean difference –0.45, 95% CI –0.59 to –0.32; 95% prediction interval –0.78 to –0.13), with low to moderate heterogeneity. Strategy-based subgroup analyses indicated that mindfulness- and education-focused interventions showed favorable effects, but formal tests for between-subgroup differences were not statistically significant. Evidence certainty was rated as moderate, primarily due to risk-of-bias concerns in some trials.

Conclusions: This review provides stress-focused evidence that DHIs can support stress reduction during pregnancy and extends existing literature by systematically disaggregating interventions according to delivery methods, functional features, and content strategies. This study offers a component-oriented synthesis that informs the design and selection of digital stress-management interventions for pregnant women. In real-world antenatal care, these tools may complement clinician-delivered services by expanding access to low-intensity, scalable support, particularly when interventions integrate skills-based content with supportive digital functions. Future research should directly compare single versus combined strategies and evaluate implementation across diverse populations and care settings.

Introduction

Overview

Pregnancy represents a major life transition that is frequently accompanied by heightened psychological stress, including pregnancy-specific stress related to concerns about maternal health, fetal well-being, and childbirth. Recent evidence indicates that pregnancy-specific stress is prevalent even among low-risk populations and tends to increase with perceived pregnancy risk and advancing gestational age [1]. Elevated stress during pregnancy has been consistently associated with adverse maternal mental health outcomes as well as negative neonatal and child health outcomes, underscoring the importance of timely and effective stress management during the antenatal period [2-4].

A range of nonpharmacological interventions has been developed to address stress during pregnancy, and their effectiveness has been demonstrated across multiple studies. These include psychoeducational programs, structured psychotherapies such as cognitive behavioral therapy and interpersonal psychotherapy, and mind–body approaches including mindfulness and yoga [5-8]. Traditionally, such interventions have been delivered through face-to-face sessions. While effective, in-person delivery can be constrained by barriers related to access, cost, time, geographic distance, and the availability of trained professionals—limitations that may be particularly salient during pregnancy.

Digital health interventions (DHIs) have emerged as a scalable and low-threshold approach for delivering stress-management strategies, with growing evidence supporting their effectiveness in the general population. Meta-analytic evidence indicates that app-based stress-management interventions yield small but statistically significant improvements across self-reported, physiological, and neuroendocrine stress outcomes [9], and similar modest reductions in perceived stress have been reported in randomized trials of mental health smartphone apps [10]. These findings suggest that digitally delivered interventions can effectively support stress reduction when designed and implemented appropriately.

However, evidence specific to pregnancy remains more limited and less conclusive. Much of the existing literature on DHIs during pregnancy has focused on broader perinatal mental health outcomes—particularly depression and anxiety—rather than stress as a primary target. For example, reviews of digital mindfulness and nurse-led eHealth interventions have reported consistent benefits for depressive and anxiety symptoms but mixed or inconclusive effects on stress [11,12], while telemedicine-based psychological interventions often combine antenatal and postpartum populations and rarely prioritize stress outcomes [13]. An umbrella review of DHIs for perinatal women suggested overall benefits for psychological outcomes, including stress; however, its findings were pooled across heterogeneous populations, intervention types, outcomes (stress, depression, and anxiety), and perinatal stages, with only a small subset of reviews specifically addressing stress during pregnancy [14]. Collectively, these syntheses highlight that stress-focused evidence in pregnant populations remains fragmented and underdeveloped.

At the same time, DHIs offer distinct methodological and practical advantages that warrant more nuanced evaluation. Digital interventions are inherently multicomponent, comprising combinations of delivery methods (eg, mobile apps, web-based platforms, and telemedicine), functional features (eg, self-monitoring, automated feedback, and reminders), and intervention contents (eg, psychoeducation, mindfulness, relaxation, and cognitive behavioral skills). Behavioral science frameworks emphasize that technology functions primarily as a delivery vehicle rather than the therapeutic agent itself [15], and empirical assessments of stress-management apps similarly distinguish delivery modalities, functional features, and therapeutic content as separable but interacting components [16]. Despite this, prior reviews of digital mental health interventions during pregnancy have rarely synthesized evidence across these dimensions, limiting understanding of which combinations of delivery methods, functions, and contents are most relevant for stress reduction in pregnant women.

Rationale

Taken together, the existing literature highlights a persistent gap in evidence regarding digital interventions specifically designed to reduce stress during pregnancy. Although DHIs for perinatal mental health have received growing attention, most prior reviews have focused primarily on depression and anxiety or have pooled multiple psychological outcomes, with stress often insufficiently examined as a primary outcome. As a result, the effectiveness of digital interventions targeting stress during pregnancy remains unclear.

Moreover, previous syntheses have largely categorized digital interventions by delivery platform, providing limited insight into how specific intervention components contribute to stress reduction. DHIs are inherently multicomponent, integrating delivery methods, functional features, and therapeutic content; however, the relative importance of these components for managing pregnancy-related stress has not been systematically examined.

To address these gaps, the present systematic review and meta-analysis provide an updated and focused synthesis of digital stress-management interventions during pregnancy. By centering stress reduction as the primary outcome and examining intervention effectiveness through the lens of delivery methods and intervention content, this review aims to clarify how digital interventions can be optimally designed and implemented to support stress management in real-world antenatal care settings.

Objectives

Following PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 guidance [17] and PRISMA-S [18], this systematic review aimed to (1) identify and describe digital stress-management interventions for

XSL•FO
RenderX

pregnant women (Population), including delivery platforms and key components (Intervention); (2) evaluate the effectiveness of these interventions compared with usual care, wait-list, or active comparators (Comparator) on validated stress outcomes (Outcome); and (3) summarize intervention strategies and delivery methods associated with engagement and stress reduction.

Methods

Overview

We conducted a systematic review and meta-analysis to evaluate digitally delivered interventions for reducing stress in pregnant women. The review adhered to the PRISMA guidelines [17] and PRISMA-S (PRISMA literature search extension) [18] (Multimedia Appendix 1).

Eligibility Criteria

Eligibility criteria were predefined using the PICOS (population, intervention, comparison, outcome, and study design) framework. Participants were pregnant women. Interventions included any digitally delivered program primarily aimed at reducing or managing stress during pregnancy (antenatal period), delivered via mobile apps, web-based platforms, telemedicine, or other technology-enabled modalities. Studies in which the intervention was initiated postpartum were excluded. Comparators included usual care, waitlist/no intervention, or nondigital interventions. Outcomes included stress assessed using validated instruments; when the Depression Anxiety Stress Scales (DASS) was used, only the stress subscale was extracted. Study designs included RCTs and quasi-experimental/nonrandomized intervention studies with extractable pre-post outcome data.

Exclusion criteria included (1) postpartum-only interventions (interventions initiated after delivery), (2) interventions not primarily targeting stress management (eg, programs targeting depression, weight control, smoking cessation, or other conditions in which stress was only a secondary outcome without a stress-focused rationale), (3) insufficient outcome data to estimate effects (no extractable pre-post data or between-group comparisons), and (4) conference abstracts or trial registry entries without sufficient methodological detail or outcome data for extraction and risk-of-bias assessment.

Information Sources

The initial systematic search was conducted across 4 databases (CINAHL, Cochrane Library, Embase, and PubMed) from database inception to September 2023. In response to reviewer comments and to ensure the currency of the evidence base, the search was updated by re-running the same search strategy in all databases for records published from September 2023 through November 30, 2025. The updated search was executed on December 10, 2025, by JYL and SHP, and all newly retrieved records were screened and incorporated into the final synthesis as appropriate. Searches were conducted with the assistance of 2 medical librarians, and the final search strategies for each database are reported in Multimedia Appendix 2. Each database was searched independently using its native platform (PubMed, Embase.com, CINAHL via EBSCOhost, and the Cochrane Library). Databases were not searched simultaneously on a single platform. In addition to database searching, reference lists of included studies were manually screened to identify potentially relevant articles using citation searching methods. We did not contact study authors, experts, or intervention developers to obtain additional data, nor were other information sources such as trial registries or gray literature repositories searched.

Search Strategy

Electronic search strategies were developed in consultation with 2 medical librarians, who proposed candidate keywords and controlled vocabulary; the research team reviewed and refined the strategies, and final searches were executed by the study team with librarian support. All search strategies were newly developed for this review and were not adapted from or reused based on search strategies reported in previous literature reviews. The strategy combined controlled vocabulary (MeSH [Medical Subject Headings], Emtree, and CINAHL Subject Headings) and keywords related to pregnancy, digital health, and stress. Pregnancy-related terms included “pregnan*,” “pregnancy,” “antenatal,” and “prenatal” (and related indexing terms). Digital health terms included “digital health,” “mHealth,” “eHealth,” “telemedicine,” “mobile app,” and “smartphone.” Stress-related terms included “stress” and relevant intervention terms (eg, relaxation, mindfulness, cognitive behavioral). Animal studies were excluded, and results were limited to English-language publications. Full search strategies for each database are provided in Multimedia Appendix 2.

Selection Process

All records were imported into EndNote and deduplicated. Three reviewers (JIK, JYL, and SHP) independently screened titles and abstracts to identify potentially eligible studies. Full texts were retrieved for records deemed relevant or uncertain; when full-text articles were difficult to obtain, a medical librarian assisted with document retrieval. Two reviewers (JIK and SHP) independently assessed full-text eligibility and cross-checked decisions, with disagreements resolved through discussion (and adjudication by a third reviewer when necessary). For the updated search, a second screening pass was completed on December 12, 2025, and all newly retrieved articles were screened and assessed for eligibility using the same procedures as the initial review, with eligible studies incorporated into the final synthesis.

Data Collection Process and Data Items

Data was extracted using a piloted structured form capturing intervention purpose, participant characteristics, timing and duration, intervention strategies/components and digital functions, delivery mode, comparator, sample size, stress measures, and outcome values. When outcomes were measured repeatedly, the assessment closest to intervention completion was extracted; follow-up outcomes were extracted separately where available. Two reviewers independently entered data into an Excel file and verified consistency. Discrepancies were resolved by consensus among 3 reviewers to ensure accuracy and consistent terminology.

XSL•FO
RenderX

Study Risk of Bias Assessment

Risk of bias was assessed using RoB 2 (a revised Cochrane risk-of-bias tool for randomized trials) for randomized trials [19] and ROBINS-I (risk of bias in nonrandomized studies of interventions) for quasi-experimental/nonrandomized studies [20]. Two reviewers (JIK and SHP) independently rated each study, and disagreements were resolved through discussion with adjudication by a third reviewer [JYL] when needed. RoB 2 judgments were made across 5 domains and summarized as low risk, some concerns, or high risk. ROBINS-I judgments were made across 7 domains and summarized as low, moderate, serious, or critical risk of bias. Risk-of-bias assessments informed sensitivity analyses and the certainty of evidence (GRADE [Grading of Recommendations, Assessment, Development and Evaluation]).

Effect Measures

The primary outcome was the change in stress from baseline to postintervention (closest to intervention completion). When DASS was used, only the stress subscale was extracted. Continuous outcomes were synthesized as standardized mean differences (SMDs; Hedges *g*) and reported with 95% CIs [21], with negative values indicating lower stress in the intervention group. When studies did not report means and SDs directly, effect estimates were derived from available statistics (eg, *F* values, odds ratios, chi-square values) using standard conversion methods.

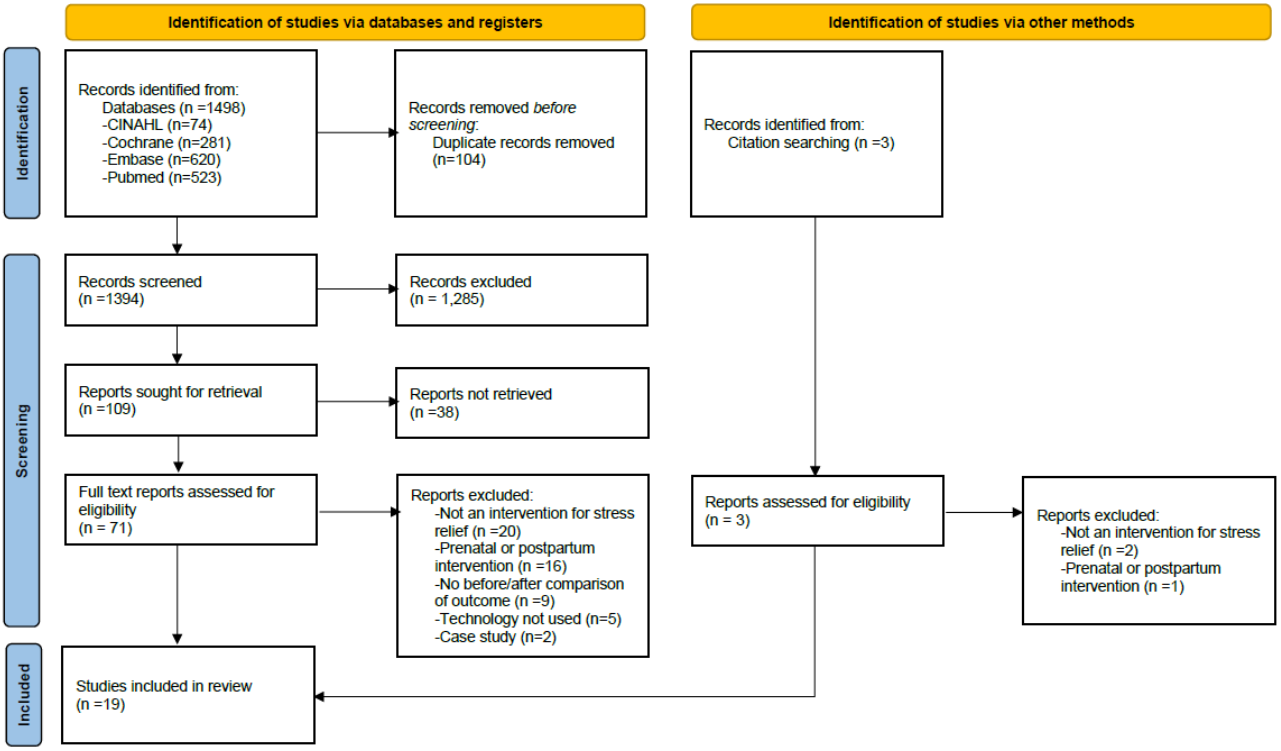
Synthesis Methods

Study characteristics (population, intervention components and digital functions, delivery mode, stress measures, and effects) were summarized narratively. For quantitative synthesis, meta-analyses were conducted using random-effects models to reflect expected between-study variability in true effects. Analyses were performed in in R (version 4.5.2; R Foundation for Statistical Computing, Vienna, Austria) using the Hartung–Knapp–Sidik–Jonkman method [22]. Heterogeneity was quantified using τ^2 and I^2, with the Cochran Q test reported where appropriate. To distinguish the average pooled effect from the expected distribution of effects across settings, we reported 95% prediction intervals for the main meta-analyses (but not for subgroup analyses). CIs describe uncertainty around the pooled mean effect, whereas prediction intervals indicate the plausible range of effects in a new setting. Prespecified subgroup analyses (eg, intervention strategies/components and delivery modes) and, when sufficient studies were available, meta-regression were used to explore potential sources of heterogeneity. Sensitivity analyses excluded studies at high or serious risk of bias and tested alternative assumptions for imputed parameters where applicable. Small-study effects were assessed using funnel plots and Egger's regression test when ≥10 studies were available for a given main analysis.

Certainty Assessment

Two reviewers (JIK and SHP) independently assessed certainty of evidence using GRADE, with disagreements resolved through consensus and third-reviewer adjudication. Certainty was evaluated across risk of bias, inconsistency, indirectness, imprecision, and publication bias. Downgrading decisions were documented in the Summary of Findings table and were informed by RoB 2/ROBINS-I judgments, heterogeneity (including the extent to which prediction intervals indicated variability across settings), imprecision (width of CIs and information size), and evidence of small-study effects (funnel/Egger).

Results



Study Selection

The study selection process is summarized in Figure 1. Studies were excluded if they targeted health conditions other than stress (eg, depression or anxiety, weight control, or smoking cessation) without a stress-focused intervention rationale, or if stress was measured only as a secondary outcome. Studies describing intervention development without reporting evaluable effectiveness outcomes were also excluded. Citation searching identified additional records, which were assessed at the full-text level but ultimately did not meet the inclusion criteria. Reasons for exclusion at each stage were documented and are presented in the PRISMA flow diagram.

Following the updated search and eligibility assessment of newly retrieved records, 4 additional studies were included. In total, 19 studies (15 from the initial search and 4 from the updated search) were included in the final review.

XSL•FO
RenderX

Figure 1. Study selection process based on the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 flow diagram.

Study Characteristics

Included studies were published between 2016 and 2025 [23-41]. Among them, 7 studies [24,26,28,31,33,34,38] were conducted in the United States (37%), followed by studies from Iran (n=2) [29,37], China (n=2) [25,34], Korea (n=2) [24,32], and other countries. Overall, there were 12 RCTs (63%) and 7 quasi-experimental studies (37%; Table 1).

Barber and Masters-Awatere [41]	New Zealand (2022)	Pregnant women recruited from midwifery clinics, through antenatal educators, and via social media	<24 weeks	12 weeks	Mobile	Education and relaxation	• Four types of modules: (1) interactive self-assessments with associated feedback, (2) activities for relaxation, stress management and planning for parenthood, (3) information about psychological and social changes in pregnancy, and (4) discussions with a partner or support person to build social support and interactive reflection and problem-solving

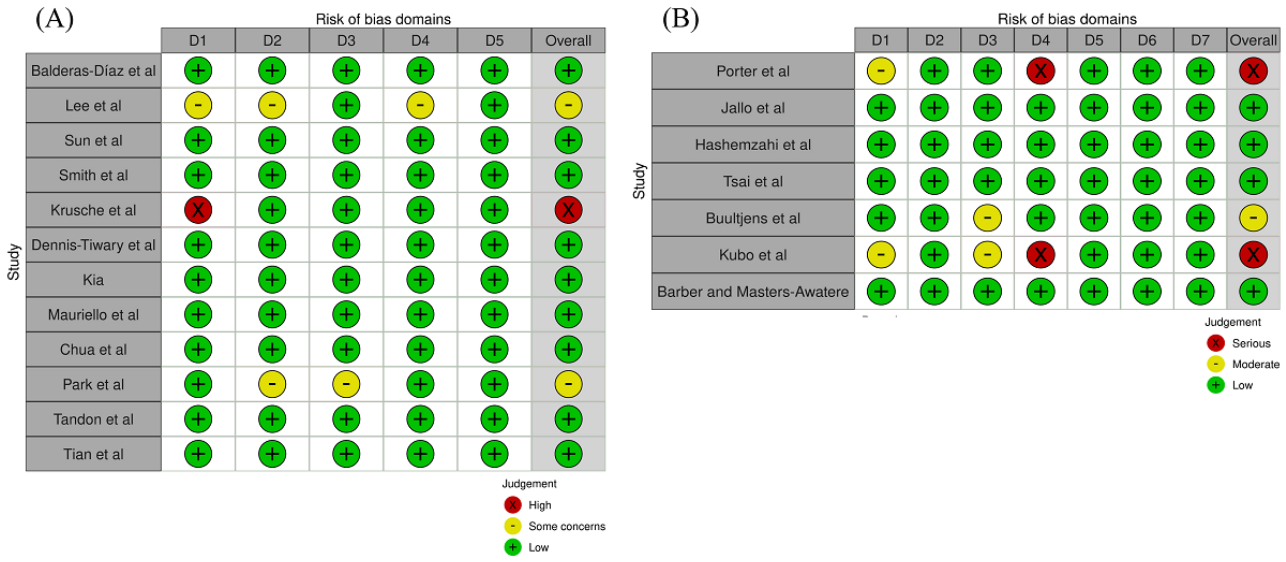
[a]SGA: small for gestational age.

[b]EPDS: Edinburgh Postnatal Depression Scale.

[c]PHQ: patient health questionnaire.

[d]CBT: cognitive behavioral therapy.

[e]PSS: Perceived Stress Scale.



[f]CDAS: Corona Disease Anxiety Scale.

[g]PHQ-8: Patient Health Questionnaire-8.

Risk of Bias in Studies

The results of the risk of bias assessment are presented in Figure 2 [23-41]. Among the 12 RCTs assessed with RoB 2, one study was judged at high risk of bias overall, driven by concerns in the randomization process (Domain 1). Two additional RCTs were rated as having some concerns overall, reflecting incomplete reporting or concerns in specific domains, while the remaining RCTs were judged at low risk of bias across domains.

Figure 2. Risk of bias assessments. (A) Risk of bias for randomized controlled trials assessed using the revised Cochrane risk-of-bias tool. Domains: D1 (randomization process), D2 (deviations from intended interventions), D3 (missing outcome data), D4 (measurement of the outcome), and D5 (selection of the reported result). (B) Risk of bias for nonrandomized studies assessed using the risk of bias in nonrandomized studies of interventions. Domains: D1 (confounding), D2 (selection of participants), D3 (classification of interventions), D4 (deviations from intended interventions), D5 (missing data), D6 (measurement of outcomes), and D7 (selection of the reported result) [23-41].

Among the 7 nonrandomized studies assessed with ROBINS-I, 2 studies were judged at serious risk of bias overall, primarily due to deviations from intended interventions (Domain 4). One study was judged at moderate risk of bias, and the remaining studies were judged at low risk across ROBINS-I domains. No study was judged at critical risk of bias.

Results of Individual Studies

Study Population

All studies targeted pregnant women, with 12 studies focusing on low-risk pregnancies (63%), while the remaining studies targeted pregnant women with specific issues or risk factors. Two studies focused on women at risk of perinatal depression, while one study each targeted women with perceived stress,

XSL•FO
RenderX

stress induced by the COVID-19 pandemic, small for gestational age fetuses, and those hospitalized due to preterm labor. Additionally, one study focused on stress management in working pregnant women. Among the 12 studies, 9 studies in the low-risk group primarily started in the second trimester and often continued into the third trimester. Interventions targeting pregnant women with depression or stress and those carrying small for gestational age fetuses started in the second trimester. Interventions for preterm labor were initiated between 22 and 33 weeks of gestation. Meanwhile, interventions for working pregnant women could be initiated at any time before 34 weeks of gestation.

Intervention Strategies

When categorizing the intervention strategies, 4 studies provided only education and information (21%), while 7 studies incorporated additional strategies (37%). Specifically, 2 studies included professional support, and 2 studies incorporated peer support, which we classified as the strategy of "seeking support." Three studies included relaxation content, such as guided imagery audio files or activities for relaxation, such as watching humorous YouTube videos. One of these studies also included peer support. Furthermore, 7 studies primarily focused on mindfulness, and one study offered an intervention in the form of a game (Table 2).

Table 2. Intervention strategies and functions included in the stress management intervention.

Reminder	
Notifications and reminders to prompt use	Barber and Masters-Awatere [41], Sun (WeChat) et al [25], Krusche (e-mail) et al [27], Kubo et al [40], Tian et al [34]

In the process of content extraction, some elements were classified as functions according to the categorization by Paganini et al [16]. For instance, monitoring (recording) included studies where participants regularly assessed stress or fetal development through health logs, diaries, or self-assessment tools. Automated feedback involved the delivery of tailored guidance and feedback messages through programmed communication. There was an intervention incorporated with

XSL•FO
RenderX

interactive chatbot functions that responded to users' questions in real time, providing guidance related to stress management and pregnancy. Additionally, 4 studies included a reminder function, which prompted participants to re-engage with the digital intervention if they had not participated for a certain period.

Intervention Delivery Mode

The digital interventions, which were the focus of the studies, were delivered via mobile app in 15 (79%) studies, via the web in 2 (10.5%) studies, and via telemedicine in 2 studies, using video conferencing and WhatsApp Messenger.

Measure of Stress

Stress was measured using various tools. Ten (53%) studies used the Perceived Stress Scale, making it the most frequently used measure. Four (21%) studies used DASS, with one of these also measuring salivary cortisol. Other measures used in the studies included the COVID-19 stress score, prenatal distress questionnaire, Pregnancy Stress Rating Scale-36, Visual Analog Stress Scale, and the Stage of Change in Stress Management, each being used in one study.

Intervention Outcomes

Among the studies, significant changes in intervention outcomes were observed in 10 cases, while in 8 studies, stress levels decreased but were not statistically significant (Table 3). In the study that used a game for stress reduction [28], the DASS results did not exhibit a significant difference, whereas the salivary cortisol results did.

Results of Syntheses

The meta-analysis results of these studies were as follows.

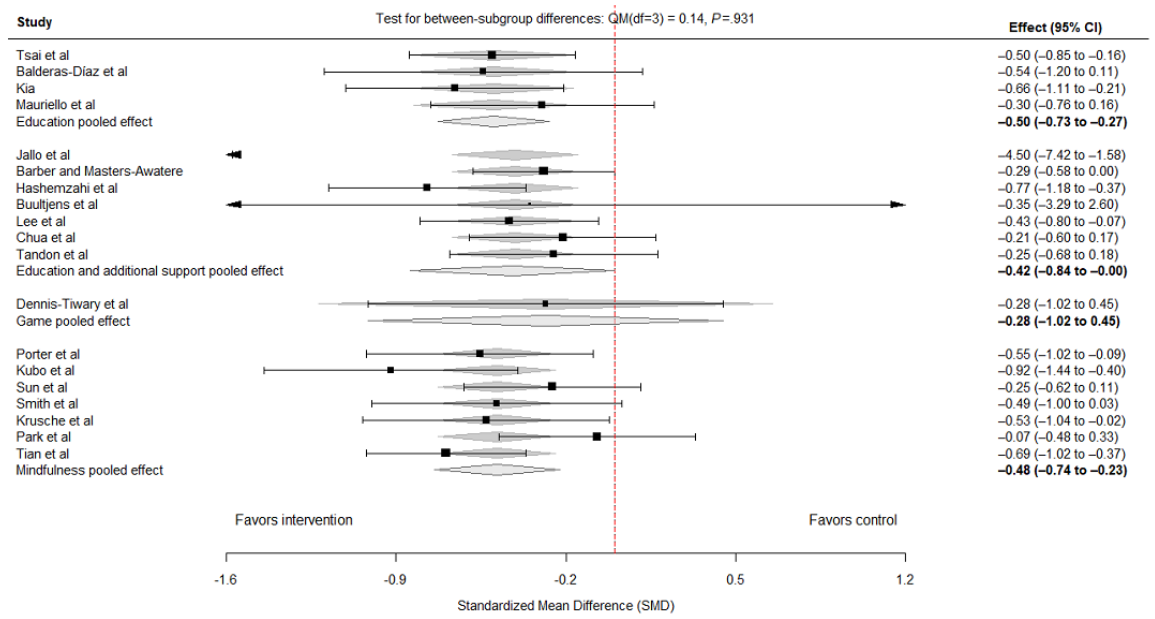
Overall

Across 19 studies, effect sizes were calculated and synthesized. A random-effects meta-analysis using the Hartung–Knapp–Sidik–Jonkman method yielded a pooled average effect of SMD –0.45 (95% CI –0.59 to –0.32), indicating a statistically significant reduction in stress (t_{18}= –6.97, P<.001). Between-study heterogeneity was low to moderate (τ^2=0.0195, τ=0.1395, I^2=27.62%, Q (18)=24.87, P=.13). The 95% PI ranged from –0.78 to –0.13, indicating that the true effects in new settings are expected to remain beneficial overall, although the magnitude of benefit may vary across implementations (Figure 3 [23-41]).

Figure 3. Forest plot of the overall effect of digital interventions on stress reduction [23-41]. DASS: Depression Anxiety Stress Scale; PDQ: prenatal distress questionnaire; PSRS-36: Pregnancy Stress Rating Scale-36; PSS: Perceived Stress Scale; VASS: Visual Analog Stress Scale.

By Strategies

When the intervention effects were categorized by strategies, the pooled estimates were directionally beneficial across subgroups, but statistical certainty varied:



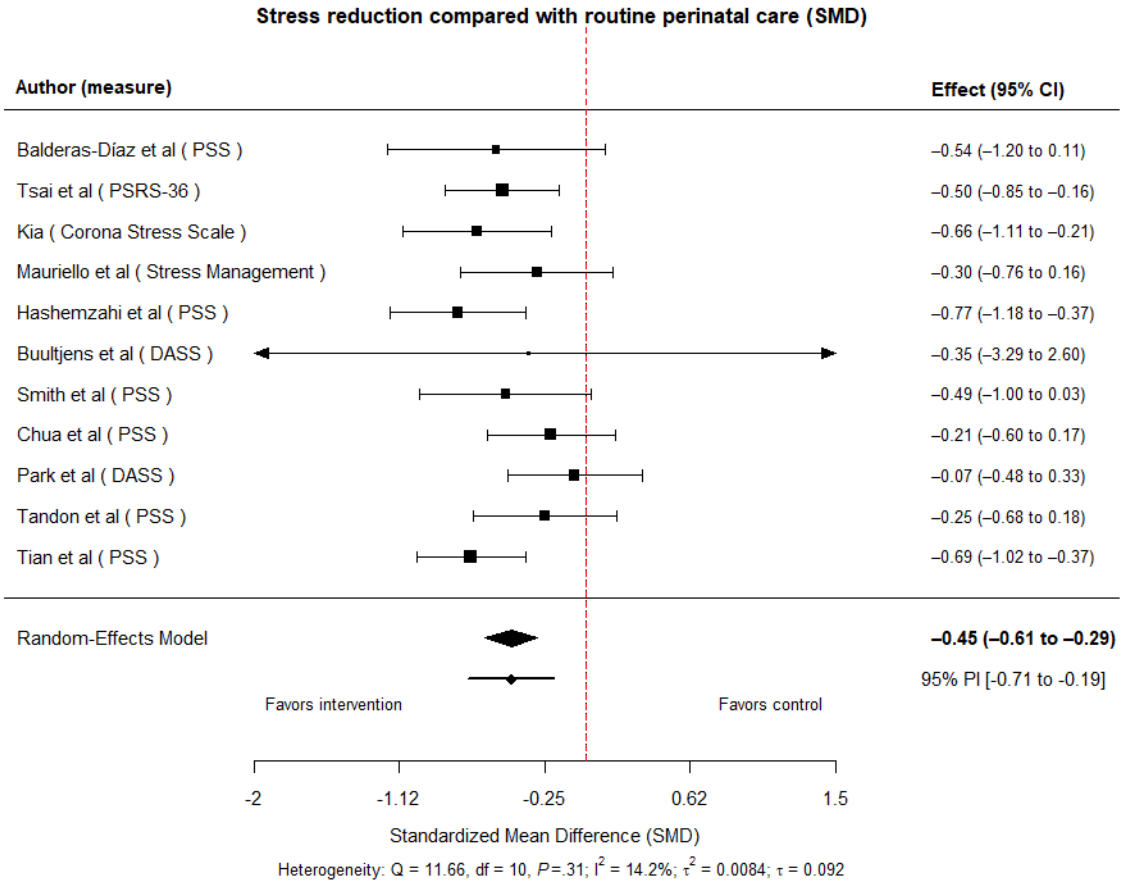
- Education only (k=4): SMD –0.50, 95% CI (–0.73 to –0.27), I^2=0%, τ^2=0
- Education with additional support (k=7): SMD –0.42, 95% CI (–0.84 to 0.00),I^2=52.8%, τ^2=0.059
- Game-based interventions (k=1): SMD –0.28, 95% CI (–1.02 to 0.45),I^2=0%, τ^2=0

XSL•FO
RenderX

- Mindfulness (k=7): SMD –0.48, 95% CI (–0.74 to –0.23),I^2=39.4%, τ^2=0.031

These findings suggest that while several strategies (education-only and mindfulness) show statistically significant average effects, estimates for strategies supported by fewer studies (game-based) or with greater heterogeneity (education with additional support) are less precise and should be interpreted cautiously (Figure 4 [23-41]). A test for between-subgroup differences based on meta-regression showed no statistically significant differences in effect sizes across intervention strategies (Q statistic for moderators: QM_3=0.14; P=.93).

Figure 4. Forest plot for the effects of the intervention by strategies [23-41].



Comparison With Routine Antenatal Care

Studies comparing DHIs with routine antenatal care/usual care showed a significant reduction in stress (pooled average effect SMD −0.45, 95% CI −0.61 to −0.29, t_{10}=−6.27, P<.001). Heterogeneity was low (Q (10)=11.66, P=.31; I^2=14.24%, τ^2=0.0084; Figure 5 [23,26,29-34,37-39]).

XSL•FO
RenderX

Figure 5. Forest plot for the effects compared with routine perinatal care [23,26,29-34,37-39].

Certainty of Evidence

Twelve of the 19 included effect sizes were derived from RCTs. Using the GRADE, the certainty of evidence for stress reduction was rated as moderate, downgraded by one level for risk of bias (1/12 RCTs rated overall high risk, and 2/12 rated some concerns in RoB 2), with no serious concerns identified for inconsistency, indirectness, imprecision, or publication bias.

The certainty of evidence was rated as moderate, downgraded by one level for risk of bias. The pooled effect estimate for RCTs was SMD −0.39 (95% CI −0.52 to −0.26), reflecting a moderate level of certainty in the stress-reducing effect of digital interventions (Multimedia Appendix 3).

Discussion

Principal Findings

Guided by our objectives to characterize antenatal DHIs for stress management, evaluate their effectiveness, and summarize intervention strategies associated with engagement, this systematic review and meta-analysis found that digitally delivered stress-management interventions are generally effective in reducing stress among pregnant women compared with routine care or control conditions. These findings support the growing role of DHIs as a feasible and scalable approach for addressing pregnancy-related stress. Consistent with an umbrella review of digital interventions for perinatal psychological outcomes, digital approaches appear capable of reducing stress symptoms overall, although prior syntheses often pooled stress with other mental health outcomes [14]. They are partially aligned with a recent systematic review and meta-analysis of digitally delivered mindfulness interventions in pregnant women, which reported clear benefits for depression and anxiety and more variable effects for stress [11]. Our findings extend this evidence by focusing specifically on stress as a primary outcome during pregnancy.

When interventions were classified by dominant strategy, mindfulness-based approaches tended to show the most consistent signals of stress reduction. This pattern aligns with earlier reviews of perinatal mindfulness interventions and with emerging trials of digital mindfulness programs tailored to pregnancy [13,42]. Recent randomized trials suggest that mobile-delivered mindfulness programs can reduce depression, underscoring the potential value of skills-based, self-directed content when engagement is maintained [43]. Education-focused programs were also beneficial, particularly when paired with supportive elements such as coaching, peer interaction, or structured follow-up, suggesting that informational content alone may be insufficient for sustained stress reduction. In contrast, gamified interventions were evaluated in only one

XSL•FO
RenderX

study and showed mixed results, with improvements detected in a biological stress indicator but not in self-reported stress, underscoring the need for further research using multiple outcome measures. Importantly, although subgroup-specific point estimates varied across strategies, the formal test for between-subgroup differences was not statistically significant. This indicates insufficient meta-analytic evidence to conclude that any single strategy is superior for stress reduction during pregnancy. Given the limited number of studies within some subgroups and the resulting low statistical power to detect moderator effects, these subgroup patterns should be interpreted cautiously and viewed as exploratory rather than confirmatory.

Beyond intervention strategy, how these programs were delivered also appeared to shape feasibility and engagement. Across studies, most interventions were delivered via mobile apps, with fewer web-based platforms and telemedicine approaches, reflecting contemporary trends in digital health delivery for pregnant populations. The predominance of mobile app–based interventions observed in this review mirrors widespread smartphone use among pregnant women and supports the feasibility of delivering brief, scalable stress-management content within routine antenatal care [16,44]. The increasing dominance of mobile-delivered interventions in more recent studies highlights a shift toward app-based platforms that can leverage a wider range of interactive functions—such as continuous monitoring, automated feedback, and reminders—which may enhance engagement and responsiveness compared with more static web-based programs. While earlier meta-analyses of internet-delivered psychological interventions primarily emphasized benefits for depression and anxiety outcomes [45], our findings suggest that web-based interventions can also contribute to stress reduction during pregnancy, albeit based on a smaller number of trials.

Beyond delivery mode alone, consistent patterns emerged in how interventions were constructed. Most DHIs combined mobile or web-based delivery with self-guided use, supported by functional features such as self-monitoring, automated feedback, reminders, or asynchronous communication, and delivered therapeutic content including psychoeducation, mindfulness practices, relaxation techniques, or cognitive behavioral therapy–based skills. Multi-component designs were the norm rather than the exception, indicating that digital stress-management interventions during pregnancy rarely rely on a single active ingredient. Compared with earlier reviews that grouped interventions primarily by delivery methods or broad perinatal mental health outcomes [13,46], the present review adopts a strategy-oriented perspective that provides a more clinically meaningful framework for understanding how digital interventions may be designed to reduce stress during pregnancy. These findings highlight the need for future research that directly compares single-strategy interventions (such as mindfulness alone or psychoeducation alone) with multi-component interventions, in order to clarify whether additive or synergistic effects contribute to stress reduction in this population.

Interpretation of these findings should consider both between-study variability and study quality. Although between-study variability did not indicate extreme inconsistency, the prediction interval suggests that beneficial effects are likely across future settings, albeit with meaningful variation in magnitude. Reporting prediction intervals alongside CIs helps distinguish the average effect from the distribution of effects expected in real-world implementations [19]. Subgroup findings should therefore be interpreted in the context of overall consistency rather than as definitive evidence of differential effectiveness across strategies [47]. Finally, assessments of small-study effects should be interpreted cautiously, as funnel plot asymmetry may reflect mechanisms beyond publication bias, including true heterogeneity or methodological differences across studies [48].

Clinical Implications

These results suggest that DHIs can serve as a practical adjunct to routine antenatal care by extending access to evidence-based stress-management skills, particularly for women who face barriers to in-person services. Interventions that combine structured mindfulness practice or targeted education with functional support (eg, reminders, progress feedback, brief coaching, or moderated peer support) may be especially useful for maintaining adherence and reinforcing skills [16]. Implementation may be facilitated by integrating these tools into prenatal education pathways and ensuring appropriate guidance for women with elevated distress who may need stepped-up care. Recent trials suggest that mobile-delivered mindfulness may improve depressive symptoms during pregnancy, but sustained engagement and equitable access remain key implementation challenges [43]. From a design perspective, the most promising programs provided clear goals, brief and repeatable programs, and opportunities for personalization. Future DHIs could also explore safe integration of passive sensing or wearable-enabled feedback to tailor content in real time, while ensuring data privacy and minimizing user burden [47,48]. Recent trials also highlight the practical importance of reporting engagement metrics (eg, module completion, frequency of practice, and prompt response) so that implementation decisions can be based not only on efficacy but also on real-world use patterns [43].

Limitations

Several limitations should be noted. The number of trials within some strategy subgroups was small, limiting precision and the ability to detect differential effects. Our restriction to English-language publications and the use of only 4 databases may have missed relevant studies, and most included trials were conducted in high-income countries, which may limit generalizability to low- and middle-income contexts. Outcomes were primarily self-reported, raising the possibility of reporting bias. In addition, incomplete reporting of intervention details and adherence in some trials constrained the interpretation of which components drove benefit. Because the review was not prospectively registered, transparency may be lower than in preregistered reviews; however, we sought to mitigate this limitation by adhering to PRISMA guidance and applying the GRADE approach to characterize certainty of evidence. Moreover, given the rapid evolution of digital perinatal interventions, studies published after our search window may

XSL•FO
RenderX

influence future pooled estimates; ongoing evidence surveillance or living-review approaches may therefore be warranted [14,43].

Conclusions

Overall, this systematic review and meta-analysis provide novel evidence that digitally delivered stress-management interventions can meaningfully reduce stress during pregnancy, highlighting the potential of digital health approaches as a complementary component of antenatal care. Unlike previous reviews that primarily categorized interventions by delivery platform or aggregated stress with other psychological outcomes, this study offers an innovative strategy-based synthesis that disentangles how specific intervention contents and supportive features contribute to stress reduction in pregnant women. By distinguishing intervention strategies rather than technologies alone, the findings advance understanding of what works within digital stress-management programs during pregnancy.

Across studies, the most consistent benefits were observed for mindfulness-based approaches and for educational interventions combined with supportive features such as coaching or peer interaction, underscoring the importance of active skill-building and engagement rather than information provision alone. Importantly, while digital tools are not intended to replace clinician-delivered care, the results indicate that they can extend access to evidence-based coping strategies and provide scalable, low-intensity support that fits within real-world antenatal workflows. As mobile app–based interventions continue to expand, their ability to integrate multiple functions—such as self-monitoring, feedback, and reminders—positions them as particularly feasible and adaptable tools for routine maternity care.

By clarifying the effectiveness of digital stress-management interventions specifically during pregnancy and by framing interventions according to their strategic components, this review contributes actionable insights for clinicians, researchers, and health system planners. The findings support the integration of digital stress-management programs as an adjunct to standard antenatal services, with the potential to improve reach, equity, and continuity of psychosocial support for pregnant women in diverse care settings.

Acknowledgments

We are grateful to Sangkeun Hyon, Dong-Hwan Shin, and Saeam Kim, medical librarians at the Soonchunhyang University Seoul Hospital, for their contributions to database searches and the collection of full text articles for this study. Generative artificial intelligence was used to support English translation and language editing. The authors carefully reviewed and revised all artificial intelligence–assisted text and remain fully responsible for the content of the manuscript.

Data Availability

The data that support the findings of this study are available from the corresponding author upon reasonable request.

Funding

This work was supported by the National Research Foundation of Korea (NRF) grant funded by the Korea government (MSIT) (number 2023R1A2C1003355 and RS-2023-00239536) as well as by Soonchunhyang University.

Authors' Contributions

JIK contributed to the conceptualization, data curation, and formal analysis, and was involved in writing the original draft, reviewing and editing the manuscript, and providing supervision. JYL contributed to conceptualization and methodology, conducted data curation and formal analysis, and participated in writing the original draft and reviewing and editing the manuscript. SHP contributed to data curation and formal analysis and participated in writing the original draft.

Abstract

Background: Overweight and obesity, as defined by the World Health Organization, correspond to BMI values of 25-29.9 kg/m² for overweight and ≥30 kg/m² for obesity. Both conditions remain major public health challenges worldwide due to their strong link with type 2 diabetes, cardiovascular disease, and hypertension, which place a heavy clinical and economic burden on health care systems. In Canada, obesity rates are notably high, with vulnerable populations disproportionately affected due to socioeconomic barriers, limited access to preventive care, and higher comorbidity rates. Calorie-counting Mobile health (mHealth) apps support dietary self-monitoring and weight control; however, varied designs and evidence complicate assessment of feasibility and effectiveness.

Objective: This study aimed to systematically evaluate the structure and content of 46 calorie-counting apps, identify factors related to their acceptability and feasibility among adults living with obesity or weight-related chronic diseases, and formulate evidence-based recommendations for app developers, clinicians, and researchers.

Methods: We conducted a scoping review of papers on calorie-counting apps published between January 2013 and March 2024. We identified 771 records and applied the PRISMA-ScR (Preferred Reporting Items for Systematic reviews and Meta-Analyses extension for Scoping Reviews) eligibility criteria. Data on app functions, features, user engagement, and acceptability and feasibility among adults with overweight or related chronic conditions were synthesized to generate practical recommendations for designing and clinically implementing calorie-counting apps.

Results: A total of 68 studies met the inclusion criteria. Randomized controlled trials (23/68, 34%) and cohort studies (16/68, 24%) were the most common designs. Most studies targeted adults with overweight or obesity (53/68, 78%), while diabetes and hypertension were less frequently represented. In total, 46 distinct calorie-counting apps were identified, with MyFitnessPal and Lose It! being the most frequently studied. Nearly all apps (45/46, 98%) offered calorie logging, often through manual entry supported by food databases, and about half included goal-setting features. The most cited acceptability factors were personalization, automation, user-friendly design, and data sharing with health care professionals; barriers included technical issues, limited food databases, and manual entry. Adherence declined over time. For example, self-monitoring with MyFitnessPal decreased from 5.4 to 1.4 days per week from weeks 4 to 12, while use of Lose It! dropped to 4 days per week by the end of 12 weeks. Twelve recommendations were developed to enhance the feasibility and acceptability of calorie-counting apps for people living with weight-related chronic diseases.

XSL•FO
RenderX

Conclusions: Calorie-counting apps hold potential as tools for supporting individuals living with obesity and weight-related chronic diseases. To improve clinical usability, app developers should enhance engagement via personalization and automation, ensuring food database comprehensiveness, and minimizing tracking effort. Further research should validate effectiveness and strategies for sustaining adherence, thereby informing development of user-friendly mHealth interventions.

calorie counting; clinical feasibility; mHealth; obesity management; weight-related chronic diseases

Introduction

One of the major challenges that health care systems around the world are currently facing is the prevalence of weight-related chronic diseases [1]. According to the World Health Organization, an estimated 2.5 billion adults aged 18 years and older were living with overweight, and 890 million were living with obesity in 2022. This corresponds to 43% and 16% of the adult population being overweight or obese, respectively. In Canada, the prevalence of obesity is even higher, with just over 26% of Canadians having a BMI of 30 or above in 2016 [2]. These Canadian statistics vary greatly within the country, with Atlantic provinces showing the highest figures. Notably, New Brunswick currently has the highest rates of obesity at 34.1%. While there can be many contributing factors, low income (42% of households earning less than CAD $60,000 [US $43,842] a year), low education rates (40% of the population having not completed postsecondary studies), and poor health behaviors account for the most significantly lacking determinants of health [3]. These figures are worrisome not only because of their drastic increase within the past 30 years [2], but also due to the well-established link between obesity and several health conditions, notably type 2 diabetes, cardiovascular diseases, and hypertension [4-6]. These weight-related chronic illnesses all lead to significant costs for society [7].

Tackling the epidemic of obesity and weight-related chronic diseases can be complex, especially when considering the impact of socioeconomic factors linked to obesity [2]. In general, the therapeutic approach includes interventions aiming to create a negative calorie balance, which can notably be achieved by dietary self-monitoring [8]. Current dietary self-monitoring methods include the traditional paper food diaries, wearable devices, websites, personal digital assistants, and mobile phone apps [9]. With the current smartphone ownership rates at 90% in certain countries, such as the United States [10], and the COVID-19 pandemic, which encouraged the use of telemedicine [11], mobile health (mHealth) apps in the form of calorie-counting apps show a promising field for calorie intake control. Such apps represent novel approaches that should be included in dieticians' and health care professionals' toolkit to help patients manage weight and weight-related chronic illnesses [12].

The increase in popularity of calorie-counting apps has prompted many studies to attempt to establish their efficacy in achieving weight loss [13,14]. A systematic review and meta-analysis of 12 randomized controlled trials demonstrated that mobile phone apps help achieve significant weight loss and BMI reduction in comparison with control groups, thus demonstrating the potential for mobile phone apps in weight management [15]. Calorie-counting apps are very heterogeneous in terms of functionalities, features, and objectives, making it difficult to compare them and provide evidence [16]. This, combined with the fact that calorie-counting apps often see a drop in adherence after only 3 to 5 weeks of use in most cases [17], contributes to difficulties with establishing clinical feasibility. Therefore, before implementing these apps as weight management options in a clinical setting, there is a clear need for studies to analyze key design elements and to identify the factors increasing the acceptability and feasibility of these calorie-counting apps. Some studies have already begun tackling this topic, but have either not evaluated calorie-counting apps specifically or have only studied such questions in healthy adult populations, and not in patients living with weight-related chronic illnesses.

As illustrated, it is urgent to establish the state of knowledge on existing apps and thereby identify knowledge gaps for future direction of research on calorie-counting apps in an adult population living with obesity and weight-related chronic disease. Accordingly, this paper explores the structure and content of calorie-counting apps and examines the factors influencing their acceptability and feasibility among adults living with obesity or weight-related chronic disease. The findings also inform evidence-based recommendations for app developers, clinicians, and researchers.

Methods

Overview

Scoping reviews are conducted to map existing theoretical and empirical research on a given topic. The main aims of a scoping review are to identify gaps in knowledge and theories and propose directions for future research. Thus, considering the aims of our study, a scoping review is the most appropriate and structured approach to map the literature. This scoping review was guided by the methodological guidance for scoping reviews as initially proposed by Arksey and O'Malley [18] and updated by Levac et al [19]. The manuscript was drafted according to the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) checklist [20]. The study protocol was not registered and was not published.

Search Strategy

The search strategy was built through team discussion. The research team consisted of 4 medical students and 1 postdoctoral fellow in data science, working under the supervision of a public health physician holding a PhD in community health, with recognized expertise in health care management and

XSL•FO
RenderX

implementation science. Literature search was conducted on May 17, 2024, in PubMed for papers published from January 2013 to March 2024. A period of 10 years was considered sufficient, given the large number of studies published and the rapid advancement of knowledge on the topic. Our search strategy included the following five main concepts: (1) calorie-counting apps, (2) weight-related chronic diseases, (3) calorie intake or weight, (4) acceptability and feasibility, and (5) structure, features, and functionalities. For each concept, we used a list of keywords presented in Textbox 1. These terms were either formatted as free-text words or as controlled vocabulary (Medical Subject Headings; MeSH) in PubMed and IEEE. Asterisks were used at the root of certain words when relevant to extend the scope of the Boolean search. The search was restricted to titles and abstracts. Selected papers were handled by the bibliographic reference manager, Zotero [21], then exported in Microsoft Excel form for paper screening and data extraction.

Textbox 1. List of keywords used in PubMed and IEEE.

Calorie-counting apps

- App to count calories
- Apps for tracking calories
- Apps for tracking food
- Calorie counting app
- Calorie smart phone app
- Calorie tracking app
- Food logging app
- Diet app
- Diet tracker
- Diet tracking app
- Diet-tracking app
- Dietary mobile app
- Food imaging app
- Food monitoring app
- Food intake monitoring app
- Food intake tracking app
- Food picture app
- Food recognition
- Food recognition app
- Food balance estimation
- Food scan
- Food-scan
- Foodscan
- Nutrition app
- Nutrition tracking app
- Weight app
- Weight management app

Weight-related chronic diseases

- Cardiovascular disease
- Cardiovascular Diseases (MeSH)
- Chronic disease
- Chronic Disease (MeSH)
- Chronic health condition
- Chronic illness
- Diabetes
- Type 2 diabetes
- Diabetic patients
- Diabetes Mellitus (MeSH)
- Heart disease
- Hypertension
- Hypertension (MeSH)

XSL•FO

- Feasibility
- System Usability Scale
- Usability
- Usefulness

Structure, features, and functionalities

- Content
- Design
- Feature
- Function
- Structure

To identify factors related to acceptability, each publication was independently reviewed by 4 authors to extract narrative descriptions of users' and health care professionals' perceptions of the apps, including aspects such as usability, usefulness, satisfaction, and perceived barriers. Discrepancies between reviewers were resolved through discussion with the principal investigator.

Study Selection

The initial search strategy led to 771 records. After removing duplicates, 639 studies were retrieved for screening. We applied a preset list of inclusion and exclusion criteria to identify relevant papers (Table 1). A total of 4 team members discussed the screening strategy and completed a calibration using 4.5% (29/639) papers to ensure interrater reliability. Disagreements regarding inclusion were resolved through team discussion, with the principal investigator serving as referee. Following the PRISMA flowchart (see Results section), we retained 68 papers for data extraction. The principal investigator then reviewed the full list of papers for data synthesis.

XSL•FO
RenderX

Table 1. Criteria for inclusion and exclusion of papers.

Criteria	Inclusion	Exclusion
Population	• Participants living with weight-related chronic disease (including overweight or obesity, prediabetes or diabetes, prehypertension or hypertension, cardiovascular disease, and metabolic syndrome) • Adult population (aged 18 years and older) • Human participants	• Papers targeting participants with mental illnesses or eating disorders • Papers targeting pediatric participants exclusively
Intervention	• Use of a calorie-counting app • English or French app	• Use of health apps that do not include calorie-counting features (eg, exercise tracker, heart rate tracker) • Intervention limited to using text messages only • Use of app for data collection only (eg, phone-based questionnaires)
Comparison	• Not restricted	—[a]
Outcome	• Not restricted	—
Study design	• Quantitative design • Qualitative design	• Systematic review, narrative review, scoping review, and case reports
Type of documents	• Peer-reviewed papers	• Conference abstracts, conference proceedings, book chapters, letters to editors, opinion papers, governmental reports, theses, policy reports, and papers unavailable through institutional access
Dates	• Published between January 1, 2013, and March 31, 2024	—
Language	• Full text available in English or French	• Abstract in English or French, but full text in another language • All other languages

[a]Not applicable.

Although specific keywords related to the outcome of interest in our study were used in the search strategy, the outcomes did not represent the inclusion criteria that needed to be present in papers. In fact, the final set of papers needed to include papers describing the app structure and functionalities. It was not an inclusion criterion whether these papers aimed to address the effects of calorie-counting apps on weight management, monitoring, and control, or on healthy eating, or to evaluate the acceptability and feasibility of these apps.

Data Extraction

Data were extracted using a standardized form developed in Excel and approved by all authors. The variables extracted are described in Table S1 in Multimedia Appendix 1. We systematically collected information on the following:

- Study characteristics: geographic location, research protocol, and type of weight-related chronic disease in the study population.
- App characteristics: names and objectives of the calorie-counting apps, logging-in features and functionalities, calorie-counting functionalities, goal-setting functionalities, user interaction features, and aspects related to validity, accuracy, and reliability.
- Determinants of acceptability: user and health care professional perspectives, including information on user-friendliness, usability, usefulness, satisfaction, and barriers limiting acceptability.
- Determinants of feasibility: user and health care professional perspectives, including the lack of certain functionalities, accuracy of calorie-counting features, socioeconomic barriers, and data privacy concerns.

Data on adherence were also extracted inductively during the data extraction process, as adherence emerged as a recurring theme across the included studies.

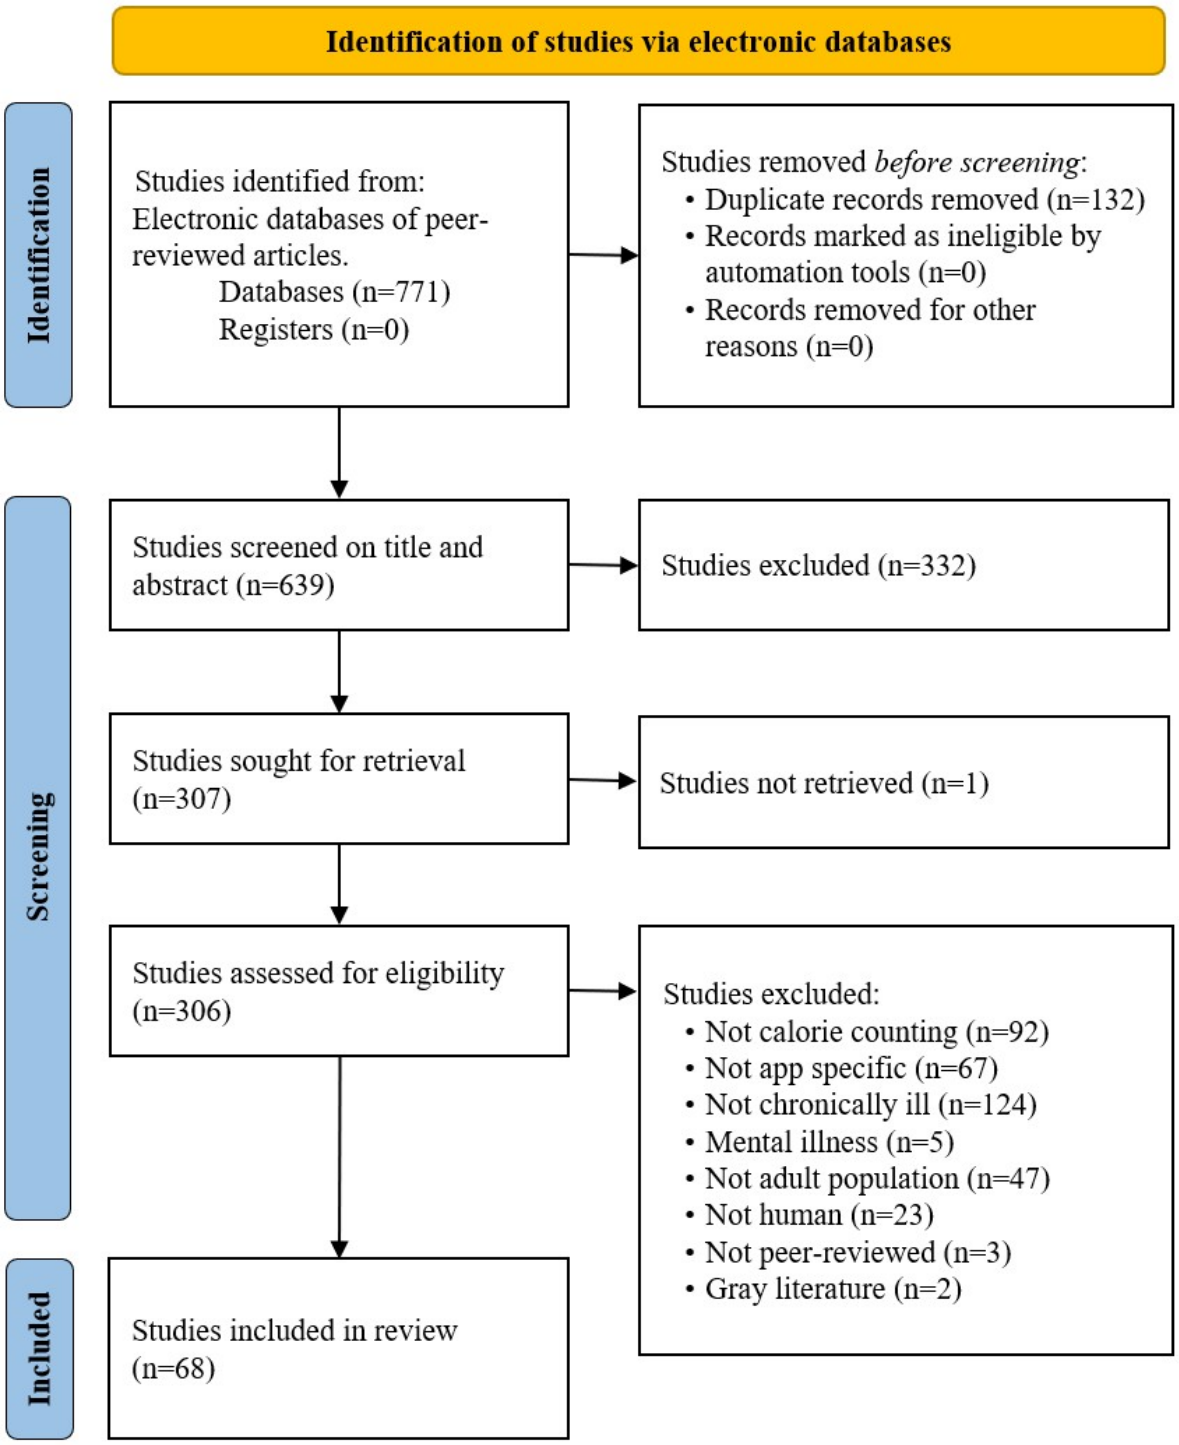
To ensure intercoder reliability, daily team meetings were organized, and a calibration exercise consisting of data extraction from 5 papers (7%) was performed. The principal investigator acted as referee in cases of disagreement.

Notably, information on intervention duration was extracted when available from the included studies; however, this variable was not reported in all sources.

Data Analysis and Synthesis

After extracting information from the included papers, we performed descriptive statistics (eg, count and proportions) to present an overview of the main characteristics of the retrieved studies (including geographic location, type of design, and weight-related chronic diseases). The results were summarized using a qualitative approach, built upon thematic content analysis, to synthesize, organize, and conceptualize findings. Whenever a dimension or an aspect could not be sorted into an existing category of concepts, we invited a meeting to discuss the possibilities of classification or the creation of a new

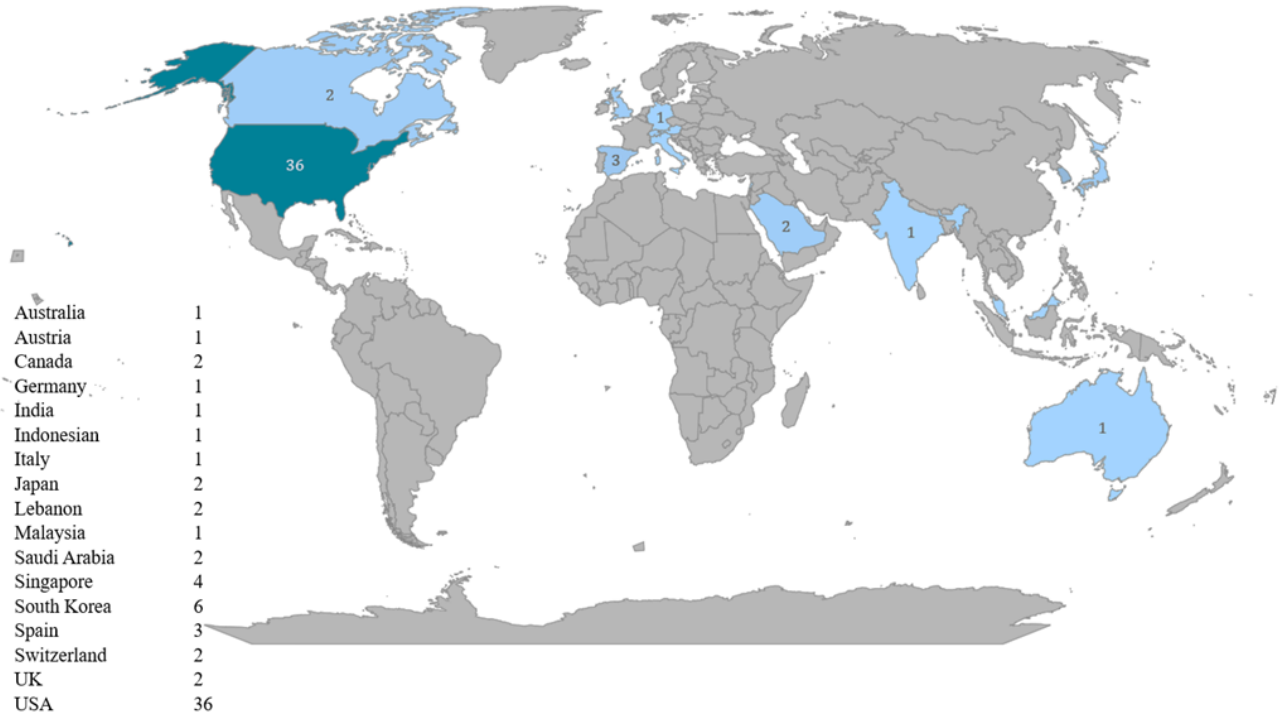
XSL•FO
RenderX



conceptual category. The final conceptual categorization first included features and functionalities of logging in, calorie-counting, goal setting, app interactions with users, other key features, and validity. It then included factors contributing to acceptability, feasibility, and adherence (see full list in results).

Results

Description of Included Papers



Of the 68 retrieved papers [13-17,22-85], (Figure 1), most studies were conducted in the United States (36/68, 52.9%), followed by South Korea (6/68, 8.8%) and Singapore (4/68, 5.9%; Figure 2).

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram. Note that excluded papers can fall under multiple exclusion criteria.

RenderX

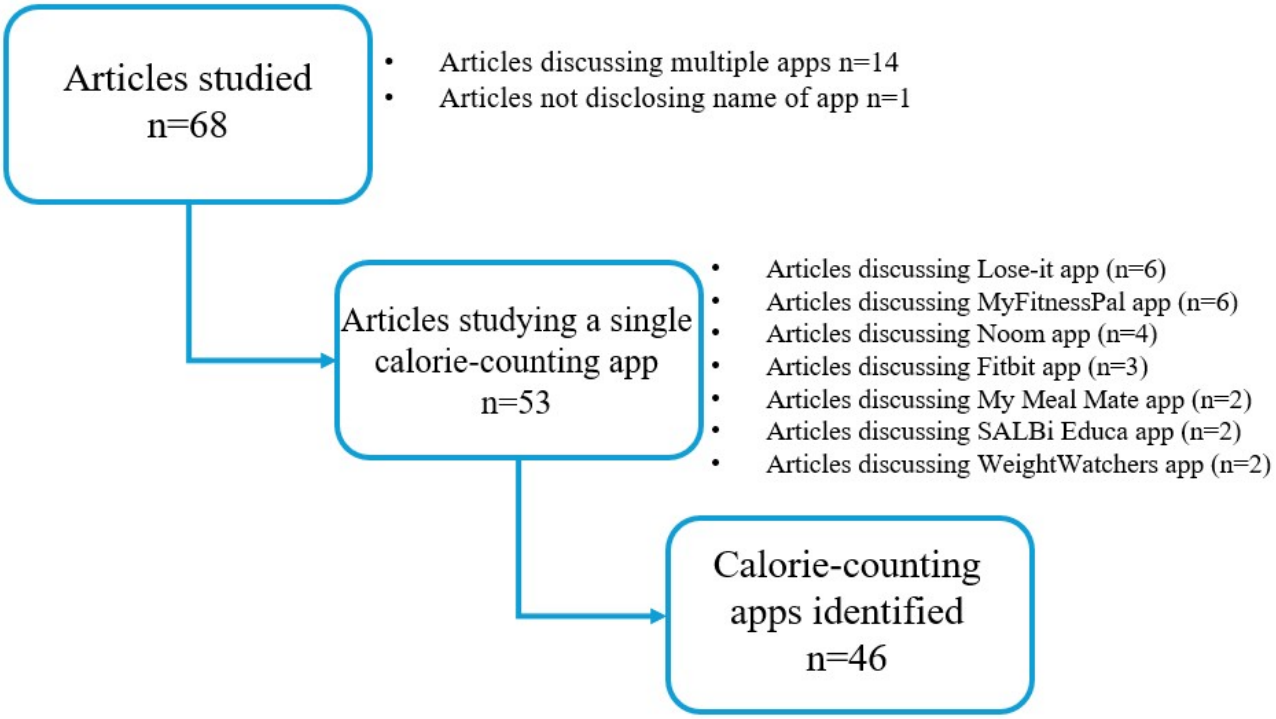
Figure 2. Distribution of included articles by geographic location.

Randomized controlled trial (23/68, 34%) and cohort study (16/68, 24%) represented the main research designs used, followed by cross-sectional study (9/68, 13%), mixed methods design (5/68, 7%), qualitative study (5/68, 7%), and quasi-experimental study (10/68, 15%; Table 2).

Table 2. Distribution of included papers by study design.

Study design	Papers, n (%)
Randomized controlled trial	23 (34)
Cohort study	16 (24)
Cross-sectional study	9 (13)
Mixed method design (qualitative-quantitative)	5 (7)
Qualitative study	5 (7)
Quasi-experimental study	10 (15)

Among the 68 retrieved papers [13-17,22-85], 53 (78%) studies included participants living with obesity [13-17,22-31,36,37,40,42-44,49-53]. Participants with prediabetes or diabetes (type I or II) and prehypertension or hypertension were included in 18 of 68 (26.5%) [27-30,36,37,40,42-44,50,51,53,55,58,59,75,78] and 10 of 68 (14.7%) papers [28,30,40,43,52,64-66,69,81], respectively. Multimorbidity, or the presence of more than one weight-related chronic disease within a study population, was identified in 18 of 68 (26.5%) papers [22,27-30,36,37,40,42-44,50-53,59,69,81]. For the other weight-related chronic diseases included in this scoping review, cardiovascular disease was only found in 1 (1.5%) paper [81], and metabolic syndrome was not identified in any paper.



Out of the papers reviewed, only 19 of 68 (27.9%) provided detailed or brief descriptions of the theoretical or conceptual foundations of calorie-counting apps [22,26,29,32-36,39,41,45-48,50,54-56,72]. Among these, the social cognitive theory appeared in 8 of 68 (11.8%) studies [22,27-29,37,43,72,82]. Self-management education and chronic disease self-management frameworks were each used in 4 of 68 (5.9%) studies [25,27,51,82]. Additionally, the self-regulation theory and behavioral theory were each referenced in 3 of 68 (4.4%) papers. The goal setting theory was mentioned in 2 of 68 (2.9%) papers [68,69], while the information–motivation–behavioral skills model and behavioral economics theory were each used in a single paper.

Among the 68 papers identified through our search, 14 (20.6%) examined more than one calorie-counting app [23,24,26,28,49,50,60,65,66,73,77,78,80,85]. Within this subset, 7 papers did not provide a detailed evaluation or noted commonalities and differences among the apps [23,24,26,50,65,73,80], while the other 7 conducted detailed comparisons and evaluations [28,49,60,66,77,78,85]. One paper (1.5%) did not disclose the name of the app studied [69]. The remaining 53 papers (78%) focused on evaluating or discussing a single app [13-17,22,25,27,29-48,51-59,61-64,67-72,74-76,79,81-84]. In sum of all papers, MyFitnessPal was the most frequently studied app (20/68, 29.4%)

XSL•FO
RenderX

[15,16,23,24,28,46,48,49,52,54,57,60,63,67,76,79-81,84,85], followed by Lose It! (14/68, 20.6%) [15,16,23,24,31,44,49,54,61,62,68,71,75,80], the Fitbit app (9/68, 13.2%) [16,31,37,40,67,75,77,80,84], and Noom (9/68, 13.2%) [16,28,31,52,67-70,73]. The process used to extract individual apps is illustrated in Figure 3, while Table 3 presents the 46 apps along with their available establishment year, country, and a brief description.

RenderX

Table 3. Description of the 46 single apps included in the retrieved studies.

App name: study	Established year	Country	Short description
Akser Waznk; Alturki and Gay [22]	__[a]	Saudi Arabia	The app was developed in Saudi Arabia and assists users with obesity in adopting a healthy lifestyle through motivation and dietary tracking.
Argus; Ferrara et al [23]	2012	United States	The app tracks activity, dietary intake, and sleep to support weight management.
Bitesnap; Gioia et al [24]	2017	United States	The app helps users track food intake and manage their diet through a visual approach.
Cronometer; Gioia et al [24]	2005	Canada	The app provides detailed nutrition tracking and calorie-counting to support weight management.
DialBetics Lite; Kondo et al [25]	—	Japan	The app records diet, physical exercise, and diabetes self-management data.
DietLens; Tahir and Loo [26]	2018	Singapore	The app uses AI[b] to identify foods and estimate nutritional composition from images.
Doctor Diary; Kim et al [27]	—	India	The app tracks calories and diabetes-related data and enables monitoring by health care professionals.
Easy Diet Diary; Chen and Allman-Farinelli [28]	2012	Australia	The Australian app provides calorie-counting and dietary tracking with physical activity monitoring.
EatsUp; Agustina et al [29]	—	Indonesian	The Indonesian app records dietary data and recommends menus based on caloric targets.
ENGAGED; Pellegrini et al [30]	2012	United States	The app was developed as part of the ENGAGED trial, allowing for dietary self-monitoring and calorie counting, as well as physical activity tracking.
FatSecret; Ferrera et al [23]	2007	Australia	A free food diary app that allows users to log the amounts and types of foods and beverages consumed, providing nutritional information, including calorie estimates.
FDDB extender app [86]	—	Germany	The app assists users in tracking calories for weight reduction or maintenance.
Fitbit; Burke et al [31]	2007	United States	The app tracks calories, diet, and other health-related metrics.
Food Tracker; Tahir and Loo [26]	2019	Canada	The app logs food intake and monitors nutritional consumption for health management.
FoodCam; Raju and Sazonov [32]	2015	United Kingdom	The app uses image recognition to identify foods and provide nutritional information.
FoodLog; Lemacks et al and Aizawa et al [33,34]	2013	Japan	The app tracks meals and monitors nutritional intake.
Fooducate; Chaudhry [35]	2010	Israel	The app helps users make healthier food choices by providing nutritional insights.
GoCarb; Anthimopoulos et al [36]	2016	Switzerland	The app estimates the carbohydrate content of meals from food images for diabetes management.
Good Measures; Olfert et al [37]	—	United States	The app is designed to support healthy food choices and behavior change related to eating and exercise via food entry and nutritional balance evaluation.
iDAT [38]	—	Singapore	The app is designed for the Singapore population. Functions as a calorie counter, helping users to balance calories consumed with calories burned daily.
Im2Calories; Myers et al [39]	2015	Japan	The app uses deep learning to estimate calorie content from food photographs.
January AI; Zahedani et al [40]	2023	United States	The app integrates CGM[c] and HR[d] data with user-entered diet and activity data.
Keenoa; Moyen et al [41]	2020	Canada	The app uses image-assisted food diaries with AI-based food recognition.
KIT-Nutrition app; Schusterbauer et al [42]	—	United States	The app combines dietary self-monitoring with diabetes management features.

XSL•FO
RenderX

App name: study	Established year	Country	Short description
LIBIT; Oh et al [43]	—	Korea	The app records diet and exercise, connects to home devices, and provides feedback.
Lifesum; Ferrara et al [23]	2013	Switzerland	The app combines calorie counting with healthy lifestyle recommendations.
Lose It!; Burke et al [44]	2008	United States	The app allows users to record daily food intake and physical activity for weight loss.
Menu-Match; Beijbom et al [45]	2015	United States	The app helps users with dietary restrictions find suitable restaurant meals.
Mobile food record (mFR); Ahmad et al [46]	2021	United Kingdom	The app captures before-and-after meal photos to assess dietary intake and patterns.
MyDietCam, Tahir and Loo [26] and Chui et al [47]	2020	Malaysia	The app analyzes meal photos to provide nutritional information and personalized diet advice.
MyFitnessPal; Tosi et al [48]	2005	United States	The app tracks foods and beverages to provide nutritional information and calorie analysis.
MyMacros+; Gioia et al [24]	2014	United States	The app tracks macronutrients for weight management.
MyMealMate; Carter et al [49]	2012	Australia	The app facilitates weight loss with an electronic food diary for dietary self-monitoring.
MyNetDiary; Fu et al [50]	2007	United States	The app provides personalized weight loss advice and tracks food intake.
MyPlate by Livestrong; Ferrara et al [23]	2004	United States	The app tracks calories and nutrients and supports diabetic users.
nBuddy Diabetes (Nutrition Buddy Diabetes); Lim et al [51]	2017	Singapore	The app supports diabetes self-management through meal logging and activity tracking.
Noom; Jin et al [52]	2008	United States	The app combines calorie tracking with behavioral coaching for weight management.
Nutritionix; Kay et al [53]	—	United States	The app enables self-monitoring of dietary intake for daily nutrition tracking.
PlateMate; Zhou et al [54]	2011	United States	The app estimates the nutritional content of foods from photos using crowdsourcing.
SAlBi (Salud, Alimentación, Bienestar, and educación); Gonzalez-Ramirez et al [55]	2022	Spain	The app provides self-monitoring and tailored dietary advice based on the Mediterranean diet.
Snap-n-Eat; Zhang et al [56]	2015	United States	The app automatically recognizes food and estimates calorie and nutrient content.
SparkPeople; Bardus et al [57]	2001	United States	The app tracks diet, exercise, and weight changes over time.
T1DEXI; Riddell et al [58]	2020	United States	The app tracks food intake and exercise for diabetes management.
Unnamed prototype app	—	United States	The prototype app provides real-time feedback on diet quality and heart disease risk.
WeightWatchers (WW); O'Neil [59]	1963	United States	The app uses a point system to promote healthy eating and weight loss.
Yazio; Puigdomènech et al [60]	2013	Germany	The app assists with calorie counting and diet planning for weight loss.

[a]Not available.

[b]AI: artificial intelligence.

[c]CGM: continuous glucose monitoring.

[d]HR: heart rate.

Synthesis of Results

The data extracted from the 68 papers were categorized into four dimensions: (1) features and functionalities of calorie-counting apps, (2) acceptability, (3) feasibility, and (4) adherence. These dimensions are presented below in more detail.

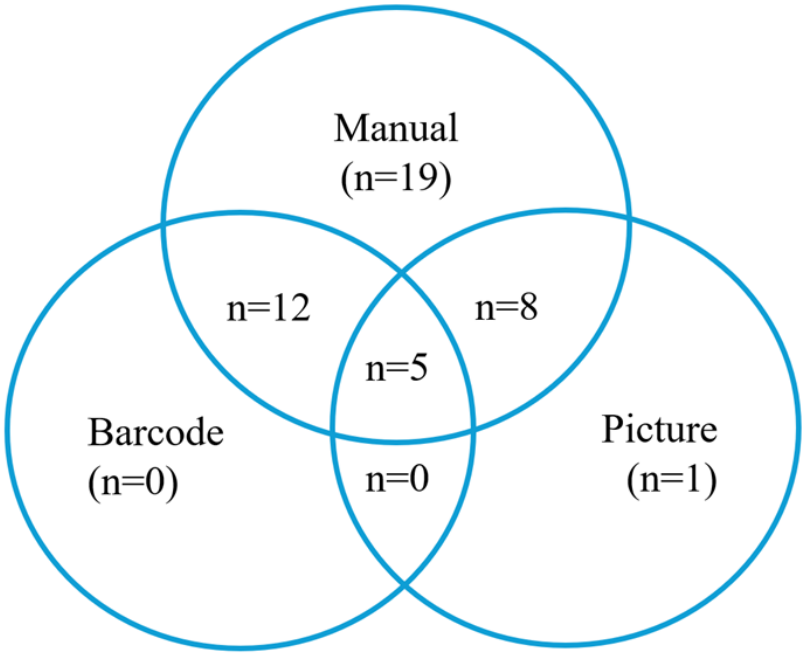
XSL•FO
RenderX

Features and Functionalities

Logging-In

When beginning to use an app, it may ask the user to provide personal information, such as an email, to allow the user to sign up and create an account to use the app. This allows for information on the mobile device to be saved as the user uses the app, linking the user's information to their account. The review of papers underlined two methods for the storage of information on an app: the creation of a new account on the app's software itself or signing in by linking to an already existing social media account. Of the 46 total apps discussed, 16 (35%) were said to have a login feature. One additional paper discussing this feature was asked not to specify the app portrayed. Doctor Diary [27], Akser Waznk [22], and Lose It! [61] were apps that were mentioned to use email addresses as a means of signing up to the platform. Akser Waznk was also described as offering the option of linking to a Facebook, Instagram, or X (formerly known as Twitter) account for users to sign up to the app [22].

Additionally, papers also described the process of entering personal and health information in order to accurately customize goals and recommendations. Akser Waznk [22], Lose It! [62], and Noom [52] were reported to ask users to enter their gender, age, height, and weight at the time of sign-up. Additionally, Akser Waznk had an optional step of adding health information, such as the user's medications and chronic diseases [22]. Doctor Diary [27], MyFitnessPal [63], and FDDB extender [64] had mentions of a login feature requiring user information, but no further description was provided. The 18 other apps had no mention of the logging-in process, according to this study, although it is possible that this feature is present in these apps and has yet to be described.



Calorie-Counting Features

When determining the acceptability of an app, the way that the process of calorie counting is done is crucial [65]. On that same note, an app that allowed for fast analysis of calorie content (meaning that the user needed to spend as little time as possible to log their calorie intake, as well as the ease of use of the said feature) was generally viewed as favorable [66]. Among the 68 papers, 17 (25%) included more than one app or did not mention the availability of calorie-counting functionality. The remaining 51 papers described 3 main methods of calorie counting: manual entry, picture-based entry, and barcode scanning.

Manual entry was generally described as the ability of the user to enter food products to get an estimation of total calories (ie, diary data entry). A total of 44 out of the 46 (95.6%) apps used calorie manual entry. Although the general concept of manual entry is well described, there is one significant difference when it comes to the functionality of calorie estimation: the integration of a food database. These databases, which could include up to 6 million foods within the app [67], provided a base of caloric information to be retrieved when users logged their consumption and removed the need for users to enter the calorie counting themselves. The databases could also be tailored to match certain population demographics (17/46, 37% apps had country-specific food databases). Once a food item was found, the user quantified the amount consumed. Of the 44 manual entry method apps, 26 (56.5%) had the use of a food database mentioned within their respective paper. Finally, it is worth noting that LIBIT had a voice recognition feature for logging meals [43].

Picture-based entry was described as the process of taking a picture of a food before consumption to get a calorie count estimation by the app. This was usually done through an integrated software that recognizes food items [62]. A total of 14 (30.4%) of the 46 apps mentioned this method of calorie counting (Figure 4).

Figure 4. Venn diagram shows overlap of calorie-counting methods used by apps.

XSL•FO
RenderX

The last method of calorie counting was through barcode scanning. This method relied on scanning barcodes of store-bought food items, which allowed the app to identify food items, and the user then logged the quantity consumed to get a calorie intake estimate [64]. A total of 17 (36.9%) of the 46 apps were mentioned to have this feature.

It is important to mention that certain apps include multiple methods for calorie counting. A total of 17 apps had both manual entry and barcode entry, while 5 apps had a combination of all 3 methods. These relationships are portrayed in Figure 4.

Goal Setting

Another feature that was often described within the calorie-counting apps designed for individuals living with chronic health conditions was the ability for users to set goals within the app. Indeed, among the 46 individual apps discussed in papers, 24 (52.2%) had a form of goal setting. While the specific type of goal could vary in composition, the most commonly described is one that calculates a calorie budget or allotment via the input of a weight loss goal determined by the user, as well as the input of certain characteristics such as current weight, height, and physical activity level (usually done when going through the account setup). One method by which this caloric budget calculation was made was through the Harris-Benedict equation [29]. Goal setting in the form of a weight loss target and a caloric budget was clearly described by Wharton et al [68] and was found to be the most common type of goal setting since it is used by 17 of the 24 apps (70.8%) that have a goal setting functionality.

Of the remaining 7 apps, 6 had goal settings mentioned without specifying the way it was integrated, and 1 was mentioned to have goal setting in the form of nutritional balance, which consisted of encouraging users to preset a goal of servings per food category, such as fruits and vegetables [69].

App Interaction With User

Some mobile apps could interact with the user to encourage use of the app and its functionalities (ie, tracking). These interactions could be done while the user was actively using the app (synchronous) or when the app was not in current use (asynchronous), such as providing reminders to the user. Of the 46 total apps, 30 (65.2%) mentioned in the papers interacting with the user by using reminders or by providing intake recommendations and feedback. Notably, MyFitnessPal [67], Akser Waznk [22], Noom [70], EatsUp [29], nBuddy Diabetes [51], Lose It! [44], January AI [40], Keenoa [41], WeightWatchers (WW) [59], FatSecret, Cronometer [24], Yazio [60], MyPlate by Livestrong, Lifesum, SparkPeople, Argus, and MyMealMate [49] used reminder messages to log intake or to increase adherence to recommendations. Eisenhauer et al [71] found that text messages, such as Lose It!, would improve self-monitoring in users at 3 and 6 months. While the presence of reminder functionalities was extracted, the frequency or timing of these reminders was not consistently reported across studies and, therefore, was not included in the data synthesis.

Interactions also consisted of providing feedback and health information to the users. Doctor Diary [27], MyFitnessPal [67], DialBetics Lite [25], SAlBi educa [55,72], Nutritionix [53], January AI [40], LIBIT [43], EatsUp [29], MyMealMate [49], and Good Measures [37] provided feedback on nutrition. This consisted of proposition suggestions on energy intake and food recommendations. Gonzalez-Ramirez et al [55] stated that users found the tailored feedback messages to be one of the most useful features used in the SAlBi educa app and that 86.1% of users believed this feedback would have a positive effect on user diet, while Kay et al [53] stated that only 55% of users believed this feedback was useful in the Nutritionix app. Nutrition feedback was also conducted in different manners other than live in-app messages, such as providing health-related papers in Noom [73] or educational videos on nBuddy Diabetes [74]. Some apps also displayed the logging of calories in visual feedback for the users, which allowed a more comprehensive way of showcasing their data. Easy Diet Diary [28], MyFitnessPal [67], Lose It! [75], Fitbit [31], ENGAGED [30], SAlBi educa [55], and MyMealMate [49] were apps that mentioned presenting the user's intake data in graphs or charts, according to the select papers.

Other Functionalities

Most of the apps studied in the selected papers had multiple functions other than calorie counting, for example, weight or blood glucose monitoring. Other key features described in the literature were related to the ways users can log health information. These key features included remote patient monitoring by health care providers, graphical or visual data, and sharing progress with other users. Some apps included information on recipes and color schemes, as well as the possibility to upgrade to a premium version (with more features and functionalities). Out of the 46 total apps, 34 (74%) were mentioned to have some of these features. Doctor Diary [27], EatsUp [29], LIBIT [43], Good Measures [37], MyFitnessPal [76], Lose It! [71], SAlBi educa [55], January AI [40], MyMacros+, Lifesum, SparkPeople, Argus, and WeightWatchers (WW) [13] had features other than calorie counting for users to track, such as weight tracking or glucose monitoring, according to the literature retrieved.

Sharing the user's progress with health care providers could be done in real-time tracking or later, providing insight into the user's tracking habits. A total of 15 (32.6%) out of the 46 total apps included this feature. Doctor Diary [27], Noom [70], EatsUp [29], Easy Diet Diary [28], nBuddy Diabetes [51], FDDB extender [64], LIBIT [43], Nutrinaut [42], Good Measures [37], Cronometer, MyNetDiary, WeightWatchers, Lifesum, MyPlate by Livestrong, and SparkPeople were described as apps that allowed health care providers to access the user's tracking data. Where specified, health care providers involved were physicians and registered dieticians.

An additional key feature discussed for 15 (32.6%) of the 46 apps was the ability for users to have real-time chats with other users or to share their progress on the app for others to see. Lose It! offered discussion boards that would have benefited the users more if they were done in a synchronous manner, which would have increased the feeling of support, according to participants [71]. Akser Wankz and WeightWatchers also provided features for users to chat with others about their progress [22]. Other apps like iDAT, Yazio, Lifesum, SparkPeople, Argus,

XSL•FO
RenderX

WeightWatchers, and Fooducate allowed users to share their progress directly to a social media platform, Facebook [78]. MyFitnessPal's networking feature was assessed, and 80% of participants reported having "no friends" on the app, which highlighted the minimal use of this feature [79].

Color schemes were also discussed in select papers, providing an insight into the importance of aesthetics in applications. Out of the 46 total apps, 13 (28.3%) had discussions on the aesthetics used. Both EatsUp [29] and Akser Waznk [22] were discussed in terms of their use of color schemes. The use of colors allowed for an increase in appeal and encouraged the use of apps. According to Alshathri et al [80], MyFitnessPal, Fitbit, and Lose It! were also some of the highest-ranked apps in engagement and aesthetics.

Some apps also had the option of premium access, allowing the user to pay for more advanced features not included in the free version of the app, such as Noom [73], MyFitnessPal [81], and Lose It! [62]. In general, 13 (28.3%) of the 24 apps mentioned have a premium option, which offers exclusive functions with enhanced support and patient monitoring. Although premium features were available, most participants expressed a preference for free apps, with cost emerging as one of the primary factors influencing their app selection [64].

Overall, free, of charge, and self-explanatory apps were most preferred by users. Sharing their progress with others or through a platform were features deemed to be less important by users [66].

Validity, Accuracy, and Reliability

Calorie-counting apps that were available to the public used different methods to log calories and could provide recommendations to users for healthier options. For reliability, these apps could rely on evidence-based theories, use known food databases, or be developed by a team of health care professionals. Of the total 46 apps, 22 (47.8%) were mentioned in papers to use at least one of these methods. EatsUp [29], Nutritionix [53], Kit-Nutrition [42], and SAlBi educa [55] were apps mentioned in the retrieved literature to have been developed or maintained by health care professionals, such as dieticians or physicians.

As discussed previously, food databases were sometimes used by the apps to correctly estimate calorie counting for the user. This thereby provided reliable, accurate information to the users. Easy Diet Diary was described to use the Australian Food and Nutrient Database 2011-2012 [28] while FDDB extender used the FoodData Central of the US Department of Agriculture and the Souci-Fachmann-Kraut databases [64]. Additionally, SAlBi educa used the BEDCA database for reference during food logging [55]. January AI was also said to use known databases, but this was not further detailed in the chosen literature [40]. On the other hand, Nutritionix itself was highlighted as the largest verified database for nutrition information by [53].

In terms of evidence-based theories, these apps were mainly developed to manage chronic diseases, such as obesity or diabetes. They could thereby rely on chronic disease management or behavioral theories to develop an effective calorie-counting app, like the social cognitive theory. Akser Waznk [22], EatsUp [29], MyMealMate [82], SAlBi educa [72], and Good Measures [37] were apps that were described to have relied on evidence-based theories on nutrition or chronic disease management. Lee et al [73] rated Noom the highest score of information accuracy, but the paper did not provide additional information on the theories used to develop the app. Keenoa was evaluated to have moderate to strong relative validity compared to an Automated Self-Administered Dietary Assessment Tool, but more validity establishment was needed [41]. Table 4 summarizes the main identified features and functionalities, along with the number of papers where they were presented and a short description.

XSL•FO
RenderX

Table 4. Description of the identified features and functionalities.

Feature	Apps with the feature mentioned (N=46), n (%)	Description
Logging in	• 16 (35)	Logging in to the app allows users to save information. The sign-up process may require personal or health information.
Calorie counting	• 45 (98)	There are 3 general ways by which apps count calories: manual entry, barcode scanning, and picture-based entry. Almost all apps have some form of manual entry, which is facilitated by the integration of a food database in most cases. A total of 5 apps offer a combination of methods.
Goal setting	• 24 (52)	Goal setting is generally available in the form of a weight loss goal, which allows the app to calculate a caloric budget. One app offers the setting of nutritional balance goals.
App interaction with the user	• 30 (65)	Interactions consisted of reminders to increase app use or the provision of feedback and recommendations on nutrition.
Other	• Other functions of the app: 34 (74) • Monitoring by health care providers • 15 (33) • Premium subscription: 13 (28) • Data sharing: 13 (28) • Visual aesthetics: 13 (28)	Most apps have a combination of calorie counting and other functionalities, including information exchange with health care professionals or other patients, data visualization, and an upgrade to a premium version.
Validity, accuracy, and reliability	• 22 (48)	To be reliable, some apps were developed according to evidence-based theories, such as behavioral theories. Other ways of ensuring reliability include health care professionals in the development of apps or using known food databases for accurate nutritional information.

Acceptability

From the scoping review database, we extracted the factors that favor or limit the acceptability of calorie-counting apps from the perspective of users and of health care professionals. When identifying factors contributing to acceptability, we used the following definition as provided by Garizábalo-Dávila et al [83]: “Acceptability is the perception of patients and health professionals versus determining whether the intervention is appropriate to address the problem, in a reasonable, adequate, and convenient manner for its application in daily life.” We summarized below the key findings according to the various structural, cultural, socioeconomic, behavioral, quality standards, and ethical factors identified.

Structural Factors

Various characteristics of the apps’ format, features, functionalities, and content influenced their acceptability from the users’ perspective (Textbox 2). The scoping review showed that features or functionalities personalized according to users’ preferences and characteristics increased the acceptability of calorie-counting apps. For instance, users were very satisfied with the possibility to choose color schema and app themes through a variety of options [22]. Users also liked the feature of allowing them to highlight the nutrients of most importance to them in the app when tracking their dietary intake [28]. The personalization of reminders or feedback generated by the app improved acceptability. Receiving app recommendations based on previous successes or failures to meet dietary goals [65] or getting a personalized progress report each week [84] are examples of functionalities that increased users’ satisfaction.

XSL•FO
RenderX

Textbox 2. Facilitators of acceptability of calorie-counting apps.

Format (structural)

- Esthetically pleasing design
- Streamlined interface
- Ease of carrying a smartphone
- Paperless food record

Features (structural)

- Personalized features
- Self-monitoring features
- User-friendly screen features
- Food image
- Technical support from the app provider (data derived from both users and health care professionals)

Functionalities (structural)

- Augmented reality
- Automatic calorie or nutrient estimation
- Automatic food recording
- Integration with other apps or platforms
- Sharing information with a health care professional, family, or on social networks
- Ability to monitor goals
- Useful and personalized reminders or feedback

Content (structural)

- Availability of varied food items
- Appropriate and clear terminology
- Appropriate translation
- No need for training
- Availability of support or training

Cultural

- Health awareness (data reported exclusively by health care professionals)

Socioeconomic

- e-literacy
- App free of charge
- Gender
- Rurality

Behavioral

- Sense of accountability
- Motivation
- Performance expectancy
- Habit
- Anxiety risk

Quality standards

- Validation

XSL•FO
RenderX

- Certification

In Textbox 2, all items represent data reported by participants, unless indicated.

Automated functionalities and the possibility to share app data through well-integrated platforms increased app usability or usefulness and increased users' acceptability (Textbox 2). For instance, users enjoyed an app including automatic calorie or nutrient estimation [66] and automatic food recording through barcode readers, meal image analysis, or artificial intelligence-based food detection [65,66,69]. On the contrary, manual entry of food consumption represented a major deterrent to using a calorie-counting app [85]. Users were satisfied with the possibility to share data recorded on the app with health care professionals, family members, or on social media. Because saving and sharing dietary record history was not available on all calorie-counting apps, the absence of this functionality was also a factor hampering acceptability. Users also noted that the functionalities of some apps were limited by bugs, crashes, and insufficient updates, and these factors all reduced acceptability.

The self-monitoring features were considered by users to be useful components of an app. Being able to daily track food intake [84], to easily log dietary intake with copy-paste functionalities [28], or to easily input beverage count [29] was appreciated. Users were also motivated by the ability to monitor goals or to fill out an action plan weekly [84]. Being able to visualize a weight chart showing the initial, current, and goal weight on a progress screen on some apps represented a great source of satisfaction for users [22]. These self-monitoring features, being available as paperless food records on an easy-to-carry device such as a smartphone, were also noted by users as a strength in terms of usability [29].

In terms of interface and content, user-friendliness was highlighted as an important characteristic of a calorie-counting app. Users' satisfaction increased with the presence of self-explanatory features that did not require training [66] or when users could easily find all subscreens on the main screen [22]. With respect to recording food consumption, the availability of a variety of food items represented a clear strength for an app [37]. This was especially true when app designers chose to use food images over text as an option to select dietary items [29]. On the contrary, the acceptability of an app decreased when users were unable to find specific food items on the app, either because they were unavailable or difficult to find. More specifically, many papers highlighted that an app's usefulness decreased when lacking multiethnic, local, and home-cooked foods as well as take-out meals and restaurant options [28,37,65,79,81]. In addition, confusion on the app with respect to portion size was another barrier to acceptability. Finally, users noted the importance of clear terminology [72] and appropriate translation [81] in calorie-counting apps. Nutritional messages that were easily understood by users with a lower level of education were also identified as a positive factor of acceptability [72]. Finally, users' satisfaction was higher when the app design was aesthetically pleasing, for instance, when it used attractive color schemes, an appropriate font size, and a streamlined interface [79].

Other Factors

Among cultural factors, health awareness was recognized by both users [37,74,78,81] and health care professionals [22] as a factor that increased the acceptability of an app. In parallel, some users identified that they were not comfortable sharing their electronic dietary record with a health care professional, and this limited the usefulness of the app [28].

The scoping review identified many socioeconomic factors contributing to the acceptability of calorie-counting apps. The most frequently cited factor was e-literacy. In fact, some apps were considered user-friendly, but only for users familiar with smartphone apps [28]. One study identified that this could be especially true for older patients [75]. The influence of the level of e-literacy on the acceptability of calorie-counting apps was not restricted to users, as one study reported that health care professionals with low levels of e-literacy could also lack the skills to efficiently use or counsel patients using calorie-counting apps [28]. Financial aspects were also addressed as factors influencing acceptability. Free apps had a higher level of acceptability [66], but not being able to afford a smartphone was a major barrier to app usability [37]. In addition, the usefulness of certain recommendations generated by apps varied with the type of work schedules. For instance, shift workers reported that, depending on their shift schedule during a given week, they were not always able to meet fixed weekly goals included in recommendations automatically generated by the app [65]. Sex affected adherence to app use, as females were more consistent users compared to males [78]. Finally, participants living in rural areas compared to those in urban areas shared more favorable views of calorie-counting apps [37].

Behavioral characteristics of users could affect the acceptability of calorie-counting apps. For users who mentioned the importance of being kept accountable, the usefulness of using a calorie-counting app increased when combined with the oversight from a dietician [28]. In 2024, Chew et al [74] showed that the intention to use AI-assisted weight management apps is influenced by factors such as age, anxiety risk, and the desire to maintain a healthy diet. These factors together explain a significant portion of why people might choose to use these apps. However, self-regulation, depression risk, BMI, and waist circumference do not seem to affect the decision to use AI-assisted weight management apps.

In terms of quality standards, validation and certification of an app represented criteria for selecting a nutrition and diet app by users [66]. Although automated functionalities in an app increased its acceptability level as addressed above, the lack of accuracy of automated functionalities led to user frustration [69]. Finally, for dieticians, a key barrier to using calorie-counting apps was the lack of confidence associated with the reliability of sharing patients' personal information [28].

In Textbox 3, all items represent data reported by participants, unless indicated.

XSL•FO
RenderX

Textbox 3. Barriers to the acceptability of calorie-counting apps.

Functionalities (structural)

- Saving and sharing history and favorite not supported
- Bugs, crashes, or server connectivity
- Insufficient app updates
- Manual entry of food consumption
- Impossibility to edit and delete entered values
- Reliability of data sharing unknown (data reported exclusively by health care professionals)

Content (structural)

- Demotivating reminders
- Unavailability or difficulty in finding food items
- Confusion with portion sizes

Cultural

- Discomfort with sharing app data with a health care professional

Socioeconomic

- Internet unavailability
- Low level of e-literacy (data derived from both users and health care professionals)
- Older age
- Smartphone availability
- Work schedule

Quality standards

- Automated techniques not accurate
- App not validated (data derived from both users and health care professionals)
- App not certified (data derived from both users and health care professionals)
- Confidentiality of data sharing is unknown (data reported exclusively by health care professionals)

Feasibility

Barriers that affected the feasibility of the apps in a clinical context were classified into 5 categories: structural, cultural, socioeconomic, behavioral, and accuracy (Textbox 4).

XSL•FO
RenderX

Textbox 4. Barriers to feasibility from the patient (or health care professional) perspective.

Structural

- App crashes
- Server connectivity
- Technical problems
- Calorie logging difficulties
- Limited smartphone platform
- No barcode scanning option
- Time consuming

Cultural

- Limited food database

Socioeconomic

- Web version of the mobile app
- No compatible smartphone

Behavioral

- Food recommendation
- Portion estimation by the user

Accuracy

- App underestimating calories
- App overestimating calories

Structural

It was not unusual for the users to experience app crashes, technical problems, and difficulty with server or internet connectivity [42,79,85].

Some apps did not contain the barcode scanning feature or needed the internet for the entry of food items, which then caused loss of motivation [22]. Logging food and beverage intake in an app could be effortful and time-consuming, taking an average of 15 to 20 minutes per day, and behavioral fatigue sometimes resulted [42,87]. On a similar note, one study found that dieticians thought the Easy Diet Diary was time-consuming to monitor and made it difficult to review patient records in a timely manner. The issues created a loss in motivation to keep using the app [28].

Socioeconomic

Some participants did not have a smartphone, or the smartphone was not compatible with the app [22,42]. Lose It! had a smartphone and web-based version, although the web version could be limiting since it did not contain the same features. For example, the photo feature of the app was not available through the web version [62].

Behavioral and Cultural

Users did not always accurately estimate food portions and nutritional contents [69]. Food databases were available to help users, but the databases could be quite large for the calorie-counting apps, and could be missing certain food products or recipes, especially when it came to more regional food items and homemade meals [41,42,64,72]. Capacity and accuracy of the search engine and the variety of meals and food terminology are key aspects to consider when food databases are created.

Accuracy

In a prospective controlled trial that assessed the quality and effectiveness of popular calorie-counting apps in weight management and behavior change, calorie and activity recommendations were compared with standards, and over 65% of apps over- or underestimated calorie intake [85]. Recent evidence further emphasizes that incorporating structured behavior change strategies within mobile app interventions can significantly enhance their effectiveness in improving weight-related outcomes [88].

Adherence

All calorie-counting apps saw a decline in adherence over time, although both the definition and level of adherence differed from one study to another. Definitions ranged from logging total daily dietary intake to simply using the app at least once a day, with some studies requiring a minimum number of calories to be recorded. Despite varying definitions of adherence, studies consistently showed that adherence declined over time, with several reporting a sharp drop, in some cases to nearly zero, after the intervention period. Adherence levels were typically measured by collecting the app data, which tracked how frequently and how much information participants entered.

XSL•FO
RenderX

However, recent findings suggest that strong early app engagement may predict better long-term adherence and greater weight loss outcomes [89].

Notably, some apps had good adherence in the first few months before decreasing. One study reported that participants self-monitored with MyFitnessPal an average of 5.4 days/week during the first 4 weeks, declining to 1.4 days/week during weeks 5-12, and to 0 days/week after the 12-week intervention [67]. Another study in Doctor Diary found that 14/32 participants (43.8%) failed to record three daily meals throughout the 8-week period, meaning only 18/32 participants (56.2%) were considered adherent based on the study's criteria [21].

Comparingly, a study on "Lose it!" found that in the first 6 weeks, participants used the app daily but decreased to 4 days per week at the end of the 12-week study [75]. Multiple studies showed that Lose It! had high adherence compared to a food journal group or an electronic diary group [31,61,68]. In one study that evaluated the adherence of MyMealMate, calorie counting declined over time so that by 6 months, 7 of the participants (16%) in the smartphone group had managed to record their dietary intake every day, but no participants in the food journal and web group had achieved this [49]. The following section outlines 4 factors found to enhance adherence, also summarized in Textbox 5.

Textbox 5. Factors that facilitate adherence are divided into 4 categories: structural, user-related, financial, and environmental.

Structural

- Photo feature
- Paired with a structured program
- Paired with a Facebook group
- Simplified monitoring

User-related

- Health awareness
- High motivation by the participant
- Higher education

Financial

- Monetary incentive
- Access to the premium version

Environmental

- Internet access

Socioeconomic Factors

In a study comparing premium versions of apps to free versions, they found that premium versions had a higher adherence rate, defined as logging of 800 daily calories or more [71]. Although another study with MyFitnessPal Premium also confirmed that the adherence to logging all meals 4 or more days a week still decreased over time, from 39% to 8% to 0% at week 1, 12, and 24, respectively [81].

One study examined the effectiveness of a monetary incentive with a deposit system with the goal of motivating participants using Noom. With this in place, more than half of the participants completed the 16-week program by logging three or more times a day [73].

User-Related Factors

Adherence to daily app use was found to be associated with good comprehension of the impact associated with their health condition and the desire for weight loss [85]. Similarly, low motivation for habit change was associated with low daily adherence [78,85].

In terms of specific user demographics, a study on Good Measures noted that adherence to daily meal-logging in the app did not vary between peri-urban and rural sites [37]. In another study, participants with a higher level of education had a higher general adherence to the app [53].

Structural Factors

Some features were found to have increased participants' adherence to the app. For example, a retrospective cohort study evaluating Lose It! showed that the group who used the photo feature by taking a snapshot of their food items and selecting the right items from a list of suggestions to display calories had 6.1 more total logged days than those who did not use this feature [62]. This remained significant after adjusting for user demographics such as age, gender, and BMI.

One way to increase adherence was to pair the app with a structured program or a Facebook group [31,81], but another documented way is to simplify calorie counting. For example, monitoring only the high-calorie foods consumed that have limited nutritional value. In a study comparing detailed counting of calories on Fitbit to simplified calorie counting, the group with the simplified option had better adherence throughout the

XSL•FO
RenderX

study, with a median day of self-monitoring of 97% compared to 49% for the detailed group [84].

Environmental Factors

The need for an internet connection to manually enter food intake in the app was negatively associated with daily food logging adherence [85].

Discussion

Recommendations

Based on the results of our scoping review, we provided a list of recommendations to improve acceptability and feasibility associated with the use of calorie-counting apps to monitor and manage weight in adult populations living with obesity and weight-related chronic disease. We present below our recommendations for developers, clinicians, and researchers (Table 5), based on potential improvements associated with behavioral, structural, socioeconomic, and research and development components of the use of calorie-counting apps. These recommendations are a result of collecting information on the functionalities, features, and user engagement metrics that factored into the acceptability and feasibility of the apps.

Table 5. Recommendations to improve the acceptability and feasibility of implementing the use of calorie-counting apps in clinical practice in populations living with weight-related chronic disease.

Category and subcategory	Recommendations
Behavioral	
Motivation	• Ensure a thoughtful frequency of reminders, feedback, and progress reports to help users stay on track without inducing fatigue or discouragement • Allow users to opt out of notifications to avoid discouragement in certain users • Include game features in apps, deliver app-based interventions in a context of group competition, and/or provide financial incentives associated with app use to increase motivation
Guidance	• Provide more guidance on how to make healthy food choices and how to deal with diet slips to help users progress toward their goals
Structural	
App function	• Ensure regular app updates to stop the frequent app crashes and decrease frustration from app users • Allow offline functioning to improve consistency of calorie logging • Offer users simplified calorie logging options, such as only keeping track of high-calorie and low-nutrition food, to reduce the workload associated with calorie tracking
Content	• Include a variety of multiethnic, local, and home-cooked foods as well as take-out meals and restaurant options for users to choose from when logging dietary intake • Include features adapted for users with low vision, such as simplified terminology and screen organization, as well as clearly defined tabs • Include a tutorial with the app to make sure users understand all functionalities
Socioeconomic	
Costs	• Offer a free or very affordable app when implementing an app used in clinical interventions to avoid reduced accessibility for populations with low income
Research and development	
Engagement	• Involve future users and health care professionals in all stages of app development and clinical interventions, as well as in associated research projects, to foster co-construction of technological and clinical approaches

Behavioral Recommendations

Motivation

To develop a calorie-counting app that is well-suited for clinical implementation, it is important to consider some factors that keep users engaged. Motivation is one of the major factors fostering long-term app use and thus promoting adherence. Our scoping review showed that reminders, feedback, encouragement, and progress reports were well received by users (see the Acceptability section). For the best results, they should be thoughtfully spaced out so that they help users to stay on track without being too frequent to avoid fatigue or discouragement. This is especially true for the progress reports, where too frequent reports can lead to stagnant results and loss of motivation. In addition, allowing users to opt out of notifications to avoid feeling discouraged represents another associated recommendation. To increase motivation to use calorie-counting apps, other behavioral recommendations have been suggested, such as including game features in apps, delivering app-based interventions in a context of group competition, and providing financial incentives associated with app use [79].

XSL•FO
RenderX

Guidance

Our scoping review suggested that greater user understanding of calorie intake and its health implications may be linked to better engagement with calorie-counting apps [85]. Accordingly, providing structured guidance on healthy food choices and strategies to address dietary lapses could support user adherence and long-term behavior change.

Structural Recommendations

App Function

We formulated various recommendations related to the app function. First, ensuring regular app updates to stop the frequent app crashes would decrease frustration from app users. In addition, having an offline option would enable users to be more consistent by tracking calories when they do not have internet access. To reduce the workload and time spent tracking calories, we recommend offering users simplified calorie-counting options, such as only keeping track of high-calorie and low-nutrition food, for instance. Another recommendation to improve function while reducing workload for users would be to rely on artificial intelligence to perform automatic estimation of the calorie content of food items shown in pictures. This could significantly simplify the task of calorie logging for users and hence increase motivation and adherence.

Content

The content of calorie-counting apps could also be improved. To reduce workload for users and increase app usefulness, we recommend including a variety of multiethnic, local, and home-cooked foods, as well as take-out meals and restaurant options for users to choose from when logging into dietary intake. Moreover, app content should reflect diverse cultural and racial backgrounds to ensure inclusivity and relevance across populations with different dietary habits and nutritional needs. In addition, to tailor the app for users with low vision, we recommend the use of simplified terminology and screen organization with clearly defined tabs that can be easily seen. Finally, including in the app content a tutorial for users to understand all the functions the apps have to offer also represents a key recommended improvement for calorie-counting apps.

Socioeconomic Recommendations

Our scoping review identified that the cost of a calorie-counting app could represent a barrier limiting its acceptability and, consequently, the adherence to the app. We recommend offering a free or very affordable app to improve accessibility for users with lower income, thus making it easily recommendable by health care professionals to all patients.

Research and Development Recommendation

Successful implementation of calorie-counting apps in clinical interventions targeting patients living with weight-related chronic diseases relies on reaching high enough acceptability, feasibility, and adherence levels for both users and health care professionals. For that purpose, we provide a general recommendation to foster engagement of these stakeholders in all stages required to develop an app, but also to implement app use in clinical practice. Co-construction of the technological and clinical approaches together with users and health care professionals would be instrumental to strengthening acceptability, feasibility, and adherence.

Limitations

Given our search strategy, which required papers to include populations living with chronic conditions, studies that only described apps without targeting these populations were not necessarily included. This may have limited the depth of our features and functionalities of calorie-counting apps analysis. Even when combining app descriptions from the included studies, it is possible that some features were missed if the primary objective of certain papers was not to describe the app in detail. We acknowledge that this may have led to the omission of specific app features. Nevertheless, we believe that our study still achieved its objective of providing an overview of the most common design features of calorie-counting apps for adults living with chronic conditions. Another limitation of this review is the lack of consistent reporting on reminder frequency within the primary studies, which prevented analysis of how reminder timing or intensity might influence user engagement.

Implications for Future Research

Building an app with these recommendations in mind will be a crucial step toward developing an application that meets the needs of adults living with chronic conditions in clinical settings. Another essential step in the development of these applications is the need for future research. As is the case with any intervention destined for a clinical setting, the validity of these apps, as well as an evaluation of their effectiveness, should be documented through future research. Many of these applications have a goal of promoting weight loss and healthy eating behaviors, and the effectiveness with which they can achieve those goals should be studied. As was done throughout the development of many studied apps in the papers selected by this study, future research should also evaluate the acceptability and the feasibility of the app throughout every stage of development to allow for necessary adjustments to be made. These future research initiatives should involve users and health care professionals in every stage, from app design to implementation in clinical practice. This will allow them to better meet the needs of the various stakeholders through fostering their engagement.

Throughout this paper, it was also possible to highlight several elements of acceptability and feasibility for calorie-counting apps, with more general information for app structure and content. While this was partly due to the nature of our scoping review, which was to provide an overview, we still noticed that the literature was somewhat limited when it came to detailed explanations of features and functionalities, especially for commercially available apps. Therefore, future research exploring specific features and functionalities of apps and their relationship with acceptance among adults living with chronic conditions is needed.

Conclusion

Calorie-counting apps can support management of obesity and related chronic diseases provided they reduce logging friction, personalize guidance, integrate with clinical workflows, and

XSL•FO
RenderX

leverage comprehensive, culturally inclusive food databases. Persistent barriers, technical instability, incomplete databases, and the time cost of manual entry contribute to erosion of adherence over time. Future development should emphasize automation (barcode- and image-based capture, offline use), privacy-preserving clinician data sharing, and simplified monitoring paradigms that maintain engagement. Rigorous evaluations are needed to verify automated calorie estimation, benchmark database quality, and assess equity and accessibility.

Acknowledgments

We would like to thank Marc Harper, bibliometric expert at Université de Moncton, for his valuable contributions to the development of the search strategy, including the formulation of keyword chains and Boolean syntax, conducting comprehensive searches across electronic databases, eliminating duplicates, performing initial data cleaning, and organizing the literature retrieved in Zotero.

Funding

This study was supported through grant programs from the Université de Moncton and the Centre de formation médicale du Nouveau-Brunswick. This study was supported by a postdoctoral grant from the Université de Moncton (PLEIADE grant) awarded to AR under the supervision of JJ and GR. JJ also received funding from ResearchNB (grant PM_2025_017) to conduct this study and cover publication fees. Additional support for data analysis was provided through a funding award from the McKenna Institute on behalf of Shoppers Drug Mart. We extend our sincere thanks to the Centre de formation médicale du Nouveau-Brunswick for their administrative assistance.

Authors' Contributions

Conceptualization: JJ
Methodology: JJ
Validation: JJ
Data extraction: KD, MAG, AG, JL, AR
Data synthesis: KD, MAG, AG, JL, AR
Writing – original draft: KD, MAG, AG, JL, AR
Writing – review & editing: KD, AR, GR, JJ
Supervision: JJ
Project administration: GR, JJ

Conflicts of Interest

None declared.

Abstract

Background: Nutrition apps offer scalable opportunities to support dietary behavior change and prevent chronic diseases. Their success depends on sustained user engagement, which is essential yet challenging to achieve and, consequently impacts the long-term effectiveness of these digital tools. Engagement strategies have been widely explored in digital health, but a comprehensive synthesis focusing on nutrition apps for adults is lacking.

Objective: This scoping review aimed to map the current engagement approaches and metrics implemented in nutrition apps targeting adults and to identify how user engagement is defined across studies.

Methods: We conducted a search of the PubMed, Scopus, Cochrane, and Web of Science databases for relevant studies published from January 1, 2013, to June 30, 2024. The inclusion criteria included original adult interventional or observational studies that evaluated nutrition apps and reported user-engagement strategies or metrics. Two reviewers independently screened records in Covidence, with discrepancies resolved by a third reviewer. Data were charted across study characteristics, engagement strategies, and engagement metrics and then synthesized narratively.

Results: A total of 59 studies that used apps to improve dietary behaviors were included in our analysis, including randomized controlled trials, observational trials, and mixed methods studies. Most of these apps were designed for adults who were overweight and obese. The studies were primarily conducted in North America and Europe and were randomized controlled trials or nonrandomized intervention studies, with varying durations and sample sizes. Engagement strategies varied widely, and engagement was typically measured by frequency of specific function use and frequency of app use, followed by retention rate. The most common engagement strategies reported in studies were push notifications (n=29, 49%), behavioral theory integration (n=24, 41%), personalization and customization (n=19, 32%), and goal-setting features (n=18, 31%). Only 31% (n=18) of studies provided an explicit definition of "user engagement," and definitions were highly heterogeneous. Engagement measurement was dominated by quantitative system-recorded metrics, including time and frequency of using specific functions (n=38, 64%), app use frequency (n=34, 58%), and retention (n=17, 29%). Few studies assessed qualitative or long-term engagement dimensions, and long-duration studies rarely integrated adaptive or contextualized engagement mechanisms. Research apps more frequently used theory-driven strategies compared with commercial apps, which tended to emphasize streamlined user experience.

Conclusions: Although several engagement strategies are commonly used, their implementation is inconsistent and often lacks grounding in conceptual frameworks. Research in the future needs to prioritize the use of common definitions for user engagement and measurement criteria while implementing user-centered design methods and using multiple research approaches to study the

XSL•FO
RenderX

complex patterns of user engagement. The evidence base for engagement strategies needs strengthening because it will support the development of sustainable nutrition mobile health interventions.

Introduction

Background

Noncommunicable diseases, including cardiovascular disease, cancer, respiratory conditions, and diabetes, are the leading causes of death globally, accounting for more than 70% of deaths worldwide [1]. Overweight and obesity significantly increase the risk of these noncommunicable diseases, impacting morbidity and mortality rates [1]. The global obesity epidemic is worsening, with significant implications for physical and economic health [2].

Digital health tools for diet monitoring, planning, and precision nutrition have the potential to provide scalable tools to support health care professionals in managing nutrition-related diseases and obesity [3]. Despite the potential benefits, the integration of digital health tools into large, complex health systems remains limited. Challenges such as the need for user-centered, context-dependent, and customizable designs hinder widespread adoption, particularly in low-income countries with limited financial resources [4].

Mobile health (mHealth) apps, specifically those targeting nutrition, have proliferated over the past decade, aiding users in tracking food intake, providing personalized dietary advice, and promoting healthier lifestyles. There were more than 330,000 digital health apps available, with a substantial proportion focusing on nutrition [5]. These apps are increasingly being recognized for their potential to improve poor dietary habits and diet-related chronic diseases. The scalability and wide reach of mHealth apps, combined with their capacity to deliver personalized dietary guidance at a low cost, position them as a valuable approach to promote healthier diets and thereby support public health efforts to reduce the burden of chronic disease [6]. Two primary categories can be identified based on the developers' affiliations and goals: academic apps are created by nutrition or dietetics experts to offer a dependable, scientifically validated tool, primarily for research purposes. Conversely, consumer apps are usually developed by private companies specializing in digital development, aimed at the general public, with a primary focus on commercial objectives [7].

Although there is modest evidence that nutrition apps can be effective in promoting healthier dietary behaviors [6], a significant challenge lies in maintaining long-term user engagement with the app ("Little e"), which is necessary to ensure sufficient exposure to relevant behavior change techniques [8] and ultimately engagement in the behavior change process and outcomes ("Big E") [9].

Although there is modest evidence that nutrition apps can be effective in promoting healthier dietary behaviors [6], a significant challenge lies in maintaining long-term user engagement, which is necessary to ensure sufficient exposure to relevant behavior change techniques [8]. User engagement is a multifaceted concept and includes both the extent of app use, such as frequency, duration, and depth of access, as well as the quality of the user experience, including attention, interest, and emotional involvement. Despite the growing popularity of mHealth apps, many nutrition apps struggle to retain user engagement over time [10-12]. For example, users of the commercial weight loss app Lose It! engaged for an average of only 29 days [13]. Similarly, in a short-term intervention, participants recorded vegetable intake on just 11 out of 28 days, with engagement declining as the study progressed [14]. Low engagement is a common challenge in app-based interventions, with approximately 71% of users discontinuing within the first 90 days. Since this significantly undermines effectiveness [15-17], it is crucial to understand the factors that support sustained user engagement [18].

In an effort to understand user engagement in mHealth apps, several systematic reviews have been conducted to synthesize the different approaches in digital health interventions, particularly in mental health [19-23], physical activity, and chronic disease prevention and management [18,24,25]. In addition to these focused reviews, broader systematic reviews have also been performed, encompassing digital health interventions through multiple modes of delivery beyond mHealth apps, combining a variety of lifestyle behaviors [26,27]. Furthermore, specific reviews have examined digital health interventions for population groups, such as children [28] or older adults [29]. These studies provide an overview of useful engagement strategies in mHealth more broadly and for specific applications (ie, physical activity, mental health, and chronic disease).

To address the challenge of sustaining engagement in nutrition apps, various strategies have been implemented to enhance motivation and user experience, including gamification, personalization [30], and the integration of social features [31]. However, to the best of our knowledge, no review has yet provided a comprehensive overview of the full range of strategies used to promote user engagement in nutrition apps for the general adult population.

Objectives

This scoping review aims to provide an overview of the current landscape of predefined strategies implemented in apps used for nutrition interventions to enhance user engagement, identify gaps in the literature, and guide future research and app

XSL•FO
RenderX

development. Another goal is to map and synthesize the definitions of user engagement used in the studies, creating a comprehensive and unified definition.

Methods

Overview

We chose a scoping review to explore how user engagement is defined, measured, and promoted in nutrition apps due to the broad and heterogeneous nature of the literature across disciplines such as nutrition, behavioral science, and digital health. This approach enables a comprehensive overview of existing evidence without limiting study design or outcomes. This review is guided by the methodological framework originally proposed by Arksey and O'Malley [32], which outlines 5 key stages: identifying the research question, identifying relevant studies, study selection, charting the data, and summarizing and reporting the results. This scoping review was conducted in accordance with the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) checklist, which can be found in Multimedia Appendix 1.

Search Strategy and Selection Criteria

We searched 4 databases, namely PubMed, Scopus, Cochrane, and Web of Science, for relevant studies published between January 1, 2013, and June 30, 2024. The detailed search strategy can be found in Multimedia Appendix 1.

Eligibility Criteria

Our inclusion and exclusion criteria followed the population, intervention, comparison, outcome, and study design framework (Multimedia Appendix 1). This scoping review included studies that examined engagement strategies within nutrition apps used by adults aged above 18 years, across a range of health conditions. The review focused on interventions that incorporate elements such as gamification, personalized content, social integration, and behavior change techniques aimed at enhancing user engagement. Excluded were studies involving children and adolescents below 18 years, and those focusing on non–nutrition-related apps (eg, fitness-only or medication adherence apps without a primary nutrition component). Furthermore, studies that assessed engagement without reporting specific metrics such as daily active users, time spent in the app, or adherence rates were excluded. Only original interventional and observational studies were considered, excluding any type of review (eg, umbrella reviews, scoping reviews, or narrative reviews); conference abstracts; case reports; expert opinions without empirical data; and editorials, as well as quality and content analyses of apps found in app stores.

Screening and Data Extraction

Covidence software was used to manage the screening flow, beginning with the removal of duplicate records, followed by title and abstract screening conducted by pairs of reviewers (MFV, EAS, EB-B, TB, ACF, FR, SL, NvD, and ZvdH). All potentially eligible abstracts underwent full-text assessment by pairs of reviewers (MFV, EAS, SL, ACF, EB-B, FR, ZvdH, NdV, and DAL). Data extraction of eligible papers was performed by a single investigator and then verified by a second investigator (MFV or ZvdH). Any discrepancies were resolved through discussion with a third reviewer (EB-B).

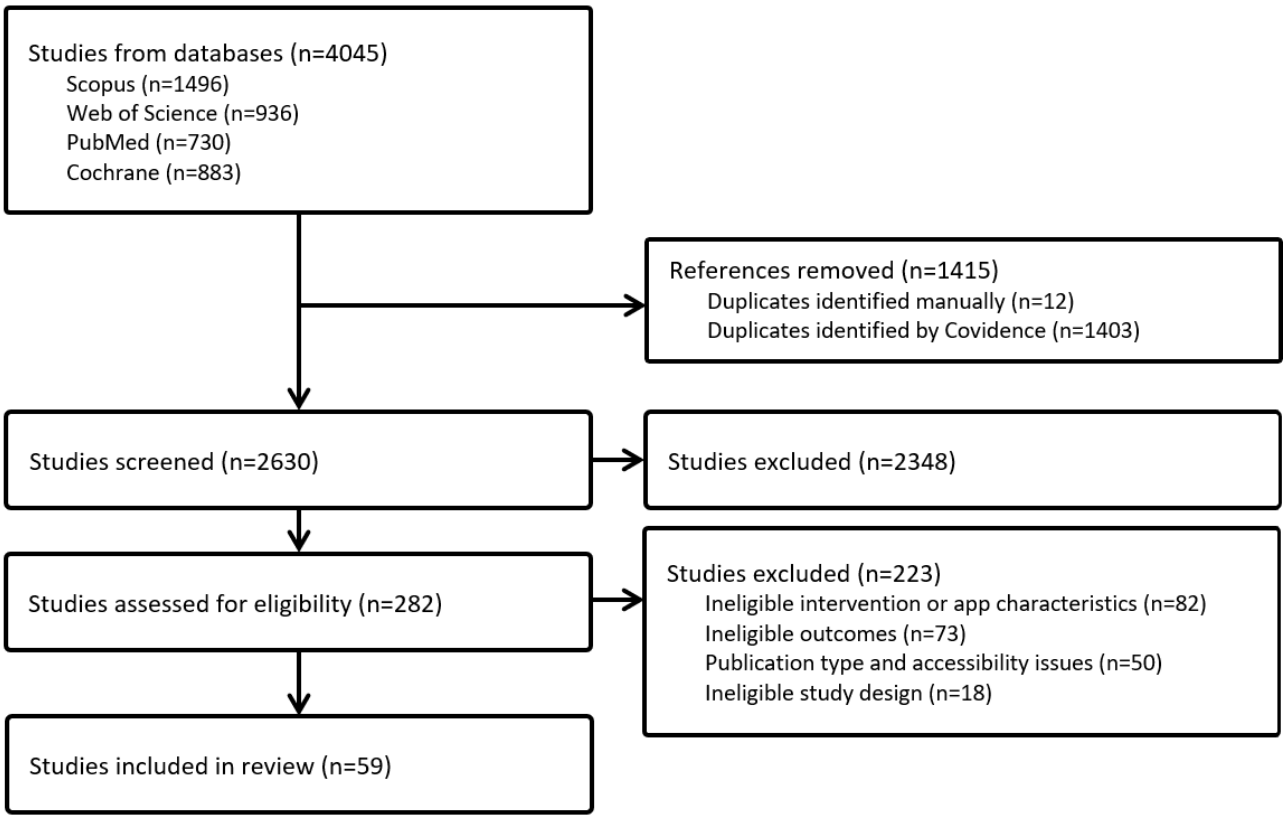
An Excel (Microsoft Corp) data extraction spreadsheet was developed to systematically compile the following study-level information: author, year, aim, study design, location, total number of participants, female or male, intervention group, control group, duration, age, BMI, condition or disease, type of app, commercial or research, app features, intervention description, incentive, user-engagement strategies, description of those strategies, engagement definition, app evaluation criteria, specification of metrics, description of metrics, relationship between user engagement with smartphone apps and main outcome, app evaluation results, and strengths and limitations. Extracted data on engagement strategies were classified into the following categories: push notifications, personalization, goal setting, game-like features, multimedia formats, monitoring (real time or passive), peer-to-peer communication, access to professionals, content reliability, quality of feedback, behavioral theory, or none or insufficiently specified. User metrics (ie, engagement metric or indicators as specified in the protocol) were categorized into average session length, daily app use, drop-offs, most visited or active screens, overall time used, retention rate, time and frequency of using specific functions, frequency of app use, and others.

The effect on health outcomes were extracted from the included studies and were first categorized as follows: (1) *positive outcomes*—significant improvements ($P<.05$) or positive trends ($P<.10$), (2) *negative outcomes*—significant deterioration ($P<.05$) or negative trends ($P<.10$), (3) *neutral or no outcomes*—no significant changes ($P\geq.10$), or (4) not reported—no or insufficient data on health outcomes. Subsequently, the number of studies reporting positive, neutral, or neutral or no outcomes was counted for each category of user metrics to describe how frequently each metric appeared in studies with different types of outcomes. This counting procedure was purely descriptive and was not intended to infer causality, comparative effectiveness, or the predictive value of specific engagement metrics.

Finally, the duration of the studies was defined as short when it lasted less than a month, medium when it lasted 1 to 3 months, and long when it lasted more than 3 months. These classifications were developed specifically for this study by the authors.

Results

In the following section, the outcomes from the screening and analysis process are presented, including the characteristics of the included studies, the engagement strategies, and the metrics identified.



Search Results

Our searches retrieved 4045 records, and after the exclusion of duplications, 2630 (65%) records underwent abstract screening, of which 282 (7%) underwent full-text review (Figure 1). On the basis of the established inclusion and exclusion criteria, 59

XSL•FO
RenderX

studies were included in our scoping review (Multimedia Appendix 1).

Figure 1. PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) flowchart.

Characteristics of Included Studies

Population

The scoping review included a total of 59 studies examining nutrition apps. The most common study design was a randomized controlled trial (RCT), accounting for 41% (24/59) of the studies. The remaining study designs were nonrandomized intervention studies (11/59, 19%), mixed methods studies (10/59, 17%), observational studies (8/59, 14%), and secondary analyses (6/59, 9%). Most studies (26/59, 44%) were conducted in North America, followed by Europe (14/59, 24%), Australia (9/59, 15%), Asia (7/59, 12%), and New Zealand (2/59, 3%); 1 (N=59, 2%) study did not specify a location. Sample sizes varied across studies from 12 to 1,011,008. Most of the participants (50/59, 85%) were adults (aged 18-55 years). In 24% (14/59) of the studies, women made up 75% to 90% of the participants, and in 39% (23/59) of the studies, women constituted 50% to 75% of the study population.

The duration of studies also varied widely. Most studies (22/59, 37%) had a medium duration of 1 to 3 months. A smaller proportion (10/59, 17%) had a short duration of less than 1 month, including 2 (N=59, 3%) studies that lasted 1 week or less. Studies with a long duration of more than 3 months accounted for 32% (19/59), spanning from over 3 months to over a year. A notable portion did not specify the study duration or left it unreported (8/59, 14%). Most studies (24/59, 41%) focused on weight management. Diabetes (type 1, type 2, and gestational) was the focus in 10% (6/59) of the studies, while pregnancy was the target in 7% (4/59) of the studies. Table 1 provides detailed information about the studies and their populations.

In our analysis, the distribution between commercial and research-based nutrition apps was assessed. Research apps constituted the majority, comprising 75% (44/59) of the studies included in our review. In contrast, commercial apps were represented in 25% (15/59) of the studies. Detailed characteristics of the included studies can be found in Multimedia Appendix 1.

Mental health conditions	3 (5)
Older adults	2 (3)
Suboptimal lifestyle habits	2 (3)
Others	7 (14)
Not reported	12 (20)

Features

A variety of user-engagement strategies were used across the included nutrition apps (refer to Figure S1 in Multimedia Appendix 1). The most frequently applied strategies were push notifications or prompts (29/59, 49%), behavioral theory (24/59, 41%), personalization and customization (19/59, 32%), and goal setting (18/59, 31%). Less commonly reported were features such as peer-to-peer communication (9/59, 15%), game-like features (8/59, 14%), and multimedia formats (5/59, 8%). A total of 4 (N=59, 7%) studies did not report on user-engagement strategies applied or described them insufficiently.

To better understand how these strategies were operationalized, data were extracted on the specific app features used. The most common feature was self-monitoring or tracking (44/59, 75%), followed by prompts or notifications (25/59, 41%). Personalized feedback (22/59, 37%), goal-setting tools (15/59, 27%), and outcome tracking or progress summaries (13/59, 22%) were also frequently included. Less commonly used features included multimedia materials and social features (both 11/59, 19%),

XSL•FO
RenderX

data sharing or professional access (9/59, 15%), and more advanced technologies such as artificial intelligence chatbots or image recognition (2/59, 3%). A small number of studies reported features such as rewards (4/59, 7%), reflective logging tools (7/59, 12%), or photo-based modules (6/59, 10%).

User-Engagement Metrics Included

To evaluate how users interacted with these features, most of the studies (38/59, 64%) included metrics of functions related to time and frequency of specific functions. Many of them also included frequency of app use (34/59, 58%). Moreover, some of the studies (17/59, 29%) included retention rate and others included the number of drop-offs (15/59, 25%). Fewer studies (n=11, 19%) included metrics such as the overall time that an app was used, the daily app use time (9/59, 15%), the most visited or the most active screens (8/59, 14%), and the average session length (3/59, 5%; Figure S2 in Multimedia Appendix 1).

Table 2 presents the health outcomes reported in studies that included a given engagement metric. For each metric, we examined only the subset of studies that reported that specific metric and assessed whether they described improvements, no changes, or insufficient detail regarding effects on health outcomes. Most metrics were included in studies reporting positive effects. There were no studies that reported a negative association of a metric with health outcomes or components.

Table 2. Frequency of engagement metrics applied, used, and corresponding health outcomes reported in studies that included the specific metric (N=59).

Engagement metric	Improvements or positive changes, n	No changes, n	Not reported or insufficient detail, n	Studies, n (%)
Time or frequency of using specific functions	14	5	19	38 (64)
Frequency of app use	12	6	16	34 (58)
Retention	6	2	9	17 (29)
Drop-offs	2	3	10	15 (25)
Overall time used	4	3	4	11 (19)
Retention	3	0	7	10 (17)
Daily app use	4	1	4	9 (15)
Most visited or active screens	2	1	5	8 (14)

Commercial Versus Research Apps

A total of 15 (N=59, 25%) commercial apps and 44 (75%) research apps were analyzed to compare user-engagement strategies. Push notifications or prompts were used in 33% (5/15) of commercial apps and in 55% (24/44) of research apps, suggesting that research apps may more frequently incorporate reminder-based engagement. Personalization and customization features were equally present in commercial and research apps, each used by 33% (5/15) and 32% (14/44) of the apps, respectively. Goal setting was more common in research apps (15/44, 34%) compared to commercial apps (3/15, 20%). Game-like features were used by 13% (2/15) of commercial apps and 14% (6/44) of research apps.

App Evaluation Results Among Apps That Included Evaluation

In our review, 32 (54%) of the 59 included studies reported various dimensions of app evaluation. The most frequently assessed aspect was user satisfaction, noted in 50% (16/32) of the studies that included evaluations. This was followed by ease of use, reported in 25% (8/32) of the studies. App functionalities were evaluated in 28% (9/32) of the studies. Aesthetics, intention to use, and attitude toward the app were each evaluated in 9 (n=32, 28%) studies. Attitude toward one's own health was assessed in only 3% (1/32) of the studies. Suggestions for improvement were noted in 19% (6/32) of the studies. Additionally, 19% (6/32) of the studies did not report specific categories of user feedback.

App Evaluation Criteria

Feasibility was the most frequently assessed criterion, reported in 13 of 59 (22%) studies. This was closely followed by user satisfaction, which was evaluated in 12 of 59 (20%) studies. Usability and acceptability were each assessed in 10 of 59 (17%) studies. Finally, 26 of 59 (44%) studies did not report any specific evaluation criteria.

Key Engagement Strategies Among Adult Populations With Specific Needs

Key approaches varied across the 30 studies analyzing engagement strategies in apps targeting specific populations of adults. Among the 24 studies on apps for individuals with overweight and obesity, push notifications and prompts (n=12, 50%), behavioral theory (n=12, 50%), goal setting (n=8, 33%), peer-to-peer communication (n=5, 21%), and access to professionals (n=5, 21%) appeared as key engagement strategies. Engagement tracking focused on assessing the time and frequency of using specific functions (15/24, 63%), app use frequency (15/24, 63%), and the retention rate (11/24, 46%). Similarly, the 6 studies on apps for individuals living with diabetes prioritized behavioral theory (n=5, 83%), with half (n=3, 50%) of them incorporating push notifications, professional support, and real-time monitoring features, while

XSL•FO
RenderX

goal setting (n=1, 17%) and passive data monitoring (n=2, 33%) were less common.

Variation in Engagement Strategies Across Study Durations

In studies with different durations, distinct patterns emerged. Of the 10 (17%) short-duration studies (<1 month), 8 (80%) studies used push notifications or prompts extensively. The 22 (N=59, 37%) medium-duration studies (1-3 months) highlighted the importance of behavioral theory, with 11 (50%) of them incorporating it. The 19 (N=59, 32%) long-duration studies (>3 months) also favored behavioral theory and push notifications equally, each used in 42% (8/19) of the cases.

Short-duration studies prioritized tracking the time and frequency of using specific functions (7/10, 70%) and the frequency of app use (6/10, 60%). In medium-duration studies, 73% (16/22) focused on the time and frequency of using specific functions, and 55% (12/22) focused on the frequency of app use. Long-duration studies showed a significant measurement of time and frequency of using specific functions (9/19, 47%) and retention rates (6/19, 32%).

The presence of defined engagement strategies was examined across 59 studies. Of these, 18 (31%) studies provided an explicit definition of user engagement, while 9 (15%) studies presented an implicit conceptual definition. However, most of the studies (32/59, 55%) did not define user engagement at all. Among the 27 studies that contained either explicit or implicit definitions, various dimensions were highlighted. The most referenced criterion was use patterns, mentioned in 21 (n=27, 78%) studies. Feature interaction was the second most common, appearing in 8 (n=27, 30%) studies, followed by behavioral indicators in 6 (n=27, 22%) studies and user feedback and responses in 5 (n=27, 19%) studies. Outcome-based definitions, linking engagement to specific user achievements or health outcomes, were noted in 3 (n=27, 11%) studies. The least common approach was game-like features, mentioned in just 1 (n=27, 4%) study.

To summarize how user engagement was operationalized across the included studies, we derived a working description based on those studies that provided an explicit definition of user engagement (18/59, 31%). This description is intended as a synthesis of observed operationalizations rather than a novel or normative definition:

> *User engagement is operationalized as the extent, frequency, and persistence of users' interactions with the app over time. It's typically quantified using system-recorded metrics, such as the number of active or logged-in days, total time spent in the app, frequency of accessing app modules, and the number or intensity of recorded actions (e.g., logging meals or viewing content). In some cases, these indicators are combined into composite scores, points totals, or weekly usage summaries, while other studies operationalize express engagement as the proportion of days with recorded activity. A small number of studies additionally incorporate the user's reflections on factors that support or hinder continued app usage.*

Discussion

Principal Findings

This scoping review provides a comprehensive overview of 59 mHealth nutrition studies, focusing on user-engagement strategies and metrics. Most apps targeted adults with overweight and/or obesity and were tested in RCTs and nonrandomized intervention studies. The included study samples comprised a predominantly female population. Study durations and sample sizes varied. Engagement was typically measured by the time and frequency of using specific functions and overall app use frequency. Push notifications and behavioral theory elements were the most frequently reported engagement strategies.

Push notifications and behavioral theory (elements) were commonly used to enhance engagement, aligning with findings from other digital health interventions, including mental and social well-being [33], diabetes management [34], weight loss interventions [35], or physical activity promotion [36]. While their widespread use suggests versatility across health contexts and adult populations, poorly timed or excessive push notifications can lead to user fatigue or disengagement, emphasizing the need to optimize the implementation of the engagement strategies. Notably, user engagement is known to be influenced by individual factors, including an individual's digital literacy and technology acceptance [37,38], health and demographic characteristics [39], or behavioral and psychological factors [40]. In addition, contextual factors also affect user engagement. For instance, sending notifications at specific times during weekends may yield better engagement rates [41,42]. Therefore, a standardized approach may not engage all users effectively, highlighting the need for adaptive frameworks that tailor engagement strategies to individual user characteristics and contextual factors.

Looking into the differences between commercial and research apps, the latter often used structured engagement tools such as push notifications and goal setting, likely reflecting a focus on behavioral theory and evidence-based practices. In contrast, commercial apps tended to emphasize user experience and simplicity since they are designed for broader appeal, with minimal features to reduce user burden. Both app types similarly adopted personalization and game-like elements, suggesting their broad value. For future studies and development, commercial apps could adopt more evidence-based strategies, while research apps might benefit from commercial design strengths.

The adoption of evidence-based strategies in mHealth apps is essential to ensure their effectiveness, equity, and sustainability in real-world settings. Evidence-based approaches integrate the best available scientific evidence with professional expertise and contextual considerations, thereby reducing reliance on ad hoc or intuition-driven decision-making [43]. In this review, engagement was primarily assessed using quantitative metrics, often referred to as "Little e" engagement, such as time spent on specific functions and overall app use, aligning with existing literature [25]. While standardized quantitative metrics aid comparability and benchmarking, they provide only a limited

XSL•FO
RenderX

view on user engagement, which also involves emotional, cognitive, and behavioral dimensions [44]. Most studies focused on short-term metrics, limiting insights into sustained engagement. Therefore, longitudinal assessments are needed to better understand long-term user interaction, while qualitative measures, such as interviews and in-app feedback, could provide deeper insights into user experience motivations, satisfaction, perceived usability, and barriers, and for explaining why certain engagement strategies succeed or fail [44-46]. Therefore, a mixed methods approach may better capture engagement dynamics and may help optimize future mHealth nutrition tools to better meet user needs and preferences. This variation between research and commercial apps underscores the need for standardized guidelines to ensure consistent quality and effectiveness in behavior change apps, an aim already addressed by several ongoing initiatives [47].

This review highlights gaps in how user engagement is conceptualized, defined, and measured. Only 31% (n=18) of studies explicitly defined engagement, limiting comparability and generalizability, an issue noted in multiple previous reviews on the topic [48,49]. Despite existing conceptual frameworks [44,45], their adoption remains limited, leading to high heterogeneity in engagement metrics [50]. This inconsistency hinders the understanding of real-world challenges, such as low uptake of nutrition apps, and impedes the development of standardized measures. These measures are crucial for comparability, establishing benchmarks, and deriving robust conclusions on effective engagement strategies. Future research should prioritize implementing established frameworks and developing standardized metrics to enhance cross-study synthesis and support evidence-based best practices for mHealth nutrition tools.

Limitations

Despite the broad scope of this review, several limitations must be acknowledged. The diversity of the included studies, both in design and in the involved engagement strategies, made direct comparisons of effectiveness challenging. Additionally, the findings highlight the need for further investigation into how engagement strategies can be tailored to individual user characteristics and contextual factors. The included studies use a wide range of methodologies, including RCTs, pilot RCTs, secondary analyses of RCTs, observational cohort studies, and mixed methods research, such as feasibility and acceptability studies. There is also significant variability in sample sizes, ranging from as few as 12 participants in the study by Robinson et al [51] to more than a million (1,011,008) in the study by Serrano et al [13]. Moreover, while this review analyses engagement among users who accessed the included interventions, it is crucial to acknowledge that nonuse may reflect structural and contextual barriers rather than a lack of interest. Several barriers, including limited access to digital infrastructure, low digital literacy, and socioeconomic constraints, may prevent certain populations from engaging with nutrition apps. The latter could affect both the extent and quality of recorded engagement, potentially leading to underestimation or misrepresentation of true user behavior. Thus, it is important to note that our findings represent the experiences of the included active users.

A significant limitation observed across the reviewed studies is the lack of clear, standardized definitions for essential terms such as “engagement,” which is often undefined, as well as broad concepts such as “acceptability” and “feasibility.” Furthermore, few studies include reflective discussions on how to improve user engagement, despite its critical role in the success of interventions [44]. The absence of standardized reporting metrics further complicates the synthesis of findings, limiting the ability to draw meaningful comparisons across studies. It should be noted that the counting of studies reporting positive, negative, or neutral findings across engagement-metric categories was purely descriptive. This approach does not allow any causal, comparative, or predictive inferences regarding the effectiveness of specific engagement metrics, and the observed distribution reflects reporting patterns in the included studies rather than true differences in impact.

Finally, another limitation of this study was the uneven distribution between commercial and research-based nutrition apps across the reviewed articles, with the latter constituting a majority (n=44, 75%). Whereas commercial apps typically prioritize consumer design principles and advanced user interface aesthetics, research apps may focus more on evidence - based content, and, in some cases, compensate users to sustain use. Therefore, the insights gained from this review can be further explored in future studies that incorporate a broader range of commercial apps.

Future Directions

Future research should focus on more rigorous evaluations, potentially through RCTs or long-term observational studies, to establish clearer insights into the efficacy of these strategies.

Co-design approaches in the development of nutrition and health apps have been shown to enhance user engagement and improve intervention effectiveness. Many studies have used participatory methods, involving stakeholders in the design process to ensure that the app aligns with user needs and preferences. Some commonly used co-design techniques include participatory research approaches, stakeholder engagement, and iterative design workshops. According to Davis et al [52] and Jackson et al [53], the benefits of co-design include higher user satisfaction, improved app usability, and a greater likelihood of meeting users’ needs, particularly by addressing cultural considerations. While co-design in mHealth is still an emerging field, it has demonstrated effectiveness across various health domains, including disease management and health promotion. Further research is needed to fully implement co-design processes and evaluate their impact on nutrition interventions.

Although many studies report use patterns, such as log in frequency and session duration, few provide insights into how users engage with specific behavioral components of nutrition apps. This lack of detail makes it difficult to identify which features drive engagement and behavior change. Additionally, engagement metrics vary widely across studies, making comparisons and synthesis challenging. For example, “active use” may be defined as a single session in one study but as daily interactions in another, complicating efforts to draw meaningful conclusions.

XSL•FO
RenderX

Moreover, most studies rely on static, one-size-fits-all engagement metrics that do not account for changes in user behavior over time. Without adaptive metrics, where use patterns dynamically inform engagement strategies, apps risk missing opportunities for personalization and sustained engagement. This static approach limits the potential for iterative improvements and real-time feedback loops that could optimize user experience and long-term outcomes. A recent methodological framework has been developed to analyze and model the dynamic processes involved in participant engagement with mHealth apps and identify factors that foster or undermine engagement in an individual's respective context [54,55]. However, the uptake of this type of approach is still very limited. Future research on user engagement may find this type of approach particularly valuable to understand how different contextual factors impact engagement as a dynamic process.

Conclusions

This review provides a broad overview of the various strategies used to enhance user engagement in nutrition apps. mHealth nutrition apps predominantly target adults with overweight or obesity and are often evaluated through controlled trials with female-majority samples. Despite variability in study design, engagement is commonly tracked via use patterns, with push notifications and behavioral theory–based strategies emerging as key tools to enhance user involvement. By understanding and implementing these strategies, we can design more engaging and effective digital tools to promote healthy dietary behaviors and ultimately contribute to improved public health outcomes.

Funding

The authors declared that no financial support was received for this work.

Data Availability

The datasets generated or analyzed during this study are available from the corresponding author on reasonable request.

Authors' Contributions

MFV, TB, and EB-B designed, conceptualized, and defined the methods in this study. All the authors contributed to the screening of the studies. MFV drafted the manuscript, and all the authors reviewed the final manuscript. All authors contributed to screening abstracts and full texts. MFV and ZvdH conducted the data extraction.

Conflicts of Interest

At the time of publication, MFV, ACF, EAS, and FR were employees of Nestlé Research, which is part of the Société des Produits Nestlé S.A.

Abstract

Background: Virtual care technologies have rapidly expanded in emergency medicine, particularly following the COVID-19 pandemic. However, comprehensive economic evaluations of their cost-effectiveness remain fragmented across different clinical applications and health care settings, creating uncertainty for policymakers and health care administrators considering implementation.

Objective: This study aimed to systematically review and synthesize evidence on the cost-effectiveness of virtual emergency care models compared to traditional in-person emergency care across diverse clinical conditions, populations, and health care settings.

Methods: We conducted a systematic review following PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines, searching 8 electronic databases (PubMed, Embase, Scopus, Web of Science, CINAHL, Cochrane Library, MEDLINE, and PsycINFO) from inception to February 2025. We included full economic evaluations comparing virtual emergency care interventions with usual care. Two reviewers independently screened studies, extracted data, and assessed quality using the Drummond checklist and Consensus Health Economic Criteria (CHEC) list. Evidence certainty was evaluated using Grading of Recommendations Assessment, Development, and Evaluation (GRADE) methodology. Given heterogeneity in interventions and methods, we conducted a narrative synthesis by virtual care modality and clinical application.

Results: From 5817 identified references, 13 studies met inclusion criteria, representing diverse virtual care modalities across 6 countries (United States, Australia, Italy, Canada, Haiti, and Belgium). All included studies reported favorable economic outcomes for virtual emergency care. Video consultation was the most common modality (11/13 studies), achieving 31% to 73% reduction in patient transfers and cost savings of US $73 (AUD $105) to US $5118 per encounter. A total of 6 (46%) studies found virtual care to be dominant (both less costly and more effective). Incremental cost-effectiveness ratios ranged from US $1273 (€990) to US $108,363 per quality-adjusted life year, with most below accepted willingness-to-pay thresholds. Transfer avoidance was the primary economic driver, particularly in rural settings. Quality assessment revealed high methodological rigor (mean Drummond score 92.3%, SD 6.0%; mean CHEC score 95%, SD 4.2%). Using GRADE, evidence certainty was rated high for cost-effectiveness, moderate for transfer reduction and quality of life improvements, and low for emergency department length of stay and mortality benefits.

Conclusions: Virtual emergency care demonstrates strong and consistent cost-effectiveness across diverse clinical conditions, populations, and health care settings. The evidence particularly supports implementation for stroke care, pediatric emergencies,

XSL•FO
RenderX

and rural/remote populations where transfer avoidance drives substantial economic benefits. All evaluated modalities achieved favorable economic outcomes, suggesting technology should match context rather than maximize sophistication. These findings provide robust economic justification for expanding virtual emergency care access and removing regulatory barriers. As health care systems face mounting pressures from aging populations, workforce shortages, and budget constraints, virtual emergency care offers a proven strategy for improving access and quality while reducing costs.

KEYWORDS

cost-effectiveness; economic evaluation; emergency care; telemedicine; virtual care

Introduction

The Challenge of Emergency Department Pressures

Emergency departments (EDs) worldwide face unprecedented challenges, including overcrowding, workforce shortages, and geographic disparities in access to specialist care [1,2]. These pressures have intensified following the COVID-19 pandemic, which accelerated the adoption of virtual care technologies while highlighting systemic vulnerabilities in emergency care delivery [3]. These issues not only hinder operational efficiency but also lead to delays in care, reduced patient and staff satisfaction, and increased adverse clinical outcomes [4,5].

Virtual Emergency Care Models

For the purposes of this review, we define "virtual emergency care" as any technology-mediated health care interaction that replaces or augments in-person emergency care delivery, encompassing synchronous telemedicine (real-time video or audio consultations), asynchronous telemedicine (store-and-forward transmission of clinical data), remote monitoring, and digital triage tools. We use "virtual emergency care" as the overarching term, with specific modalities (eg, telestroke, telepsychiatry, and telephone consultation) specified where relevant.

Virtual emergency care models have emerged as a promising approach for addressing these challenges by potentially expanding access, improving efficiency, and containing costs [4-6]. However, these technologies also raise concerns, including the risk of diagnostic error without physical examination, potential mistriage, technology dependence and failure modes, patient safety considerations, and the possibility of exacerbating health disparities for populations with limited digital access or literacy [6-8]. Patient-to-provider telemedicine enables individuals to engage with emergency clinicians via synchronous (eg, video) or asynchronous (eg, text) methods for clinical assessment without the need for physical ED visits [9,10]. Provider-to-provider teleconsultations, such as telestroke or teletrauma, extend specialist expertise to individuals in underserved rural and remote areas where access to specialized emergency medical services is often limited or nonexistent [11]. Digital triage tools include symptom checkers, decision support algorithms, and chatbot-based platforms that guide disposition and urgency based on self-reported symptoms [12]. Remote monitoring systems, such as wearables or sensor-based technologies, enable continuous physiologic surveillance and timely escalation for conditions such as sepsis or acute decompensated heart failure [13,14].

Economic Implications of Virtual Emergency Care

The economic implications of virtual emergency care are particularly significant given that emergency services account for a substantial proportion of health care expenditures. In the United States alone, ED visits generate over US $150 billion in annual costs, with rural and underserved populations facing additional burdens from unnecessary transfers and delayed care [15]. While the clinical benefits of virtual emergency care have been increasingly documented, the economic case for implementation remains a critical consideration for health care decision-makers. Economic evaluation provides a framework for comparing the costs and outcomes of virtual care models against traditional approaches, informing resource allocation decisions in resource-constrained health care systems. While virtual care technologies have demonstrated clinical efficacy in various emergency applications, their economic value proposition remains incompletely understood, with cost-effectiveness evidence scattered across different clinical domains and implementation contexts.

Gaps in Existing Evidence

Previous systematic reviews have predominantly emphasized clinical effectiveness, patient satisfaction, or implementation feasibility [16,17]. Some other reviews have examined telemedicine applications in specific emergency conditions or settings [7,9,18-20], but none have comprehensively synthesized the economic evidence across the full spectrum of virtual emergency care modalities. This gap is problematic for health care decision-makers who must justify infrastructure investments and policy changes based on robust economic evidence. Furthermore, the heterogeneity of virtual care interventions, from simple telephone consultations to sophisticated hub-and-spoke telestroke networks, necessitates a nuanced analysis of which modalities provide optimal value in different contexts.

The urgency of understanding virtual emergency care economics has intensified as health care systems globally face budget constraints while demanding improved access and quality. Policymakers require evidence not only of clinical effectiveness but also of economic sustainability and return on investment (ROI). Additionally, the rapid evolution of virtual care technologies and payment models necessitates a current synthesis of available evidence to guide implementation decisions.

XSL•FO
RenderX

Study Aim

This systematic review addresses these knowledge gaps by comprehensively evaluating the cost-effectiveness of virtual emergency care models compared to traditional in-person care. We examine economic outcomes across different virtual care modalities, clinical applications, and implementation settings while identifying factors that influence cost-effectiveness. Our analysis aims to provide actionable evidence for health care administrators, policymakers, and clinicians considering virtual emergency care implementation.

Specifically, we sought to answer the following research question: "In patients requiring emergency medical care (population), is virtual care technology including telemedicine, remote monitoring, and digital triage (intervention) cost-effective compared to traditional in-person emergency care (comparator), as measured by incremental cost-effectiveness ratios (ICERs), cost savings, and quality-adjusted life years (QALYs; outcomes), across various health care settings and time horizons (setting/time)?"

Methods

Study Design and Protocol

We conducted this systematic review following the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines (Multimedia Appendix 1) [21]. The review protocol was registered prospectively in PROSPERO (International Prospective Register of Systematic Reviews; registration number CRD42025648218). No ethical approval was required as this study involved analysis of published literature only.

Search Strategy

A comprehensive search strategy was developed to identify all relevant economic evaluations of virtual emergency care. We searched 8 electronic databases from inception to February 2025: PubMed (n=2084), Embase (n=1827), Scopus (n=916), Web of Science (n=645), CINAHL (n=199), The Cochrane Library (n=82), MEDLINE (n=30), and PsycINFO (n=3).

The search strategy combined 3 concept blocks using Boolean operators: (1) virtual care terms ("telemedicine," "telehealth," "virtual care," "remote consultation," "digital health," "eHealth," and "mHealth"); (2) emergency care terms ("emergency," "urgent care," "acute care," "emergency department," "emergency room," "trauma," and "critical care"); and (3) economic evaluation terms ("cost-effectiveness," "cost-benefit," "cost-utility," "economic evaluation," "cost analysis," "ROI," "ICER," "QALY," and "cost-minimization"). The search strategy was refined iteratively with input from an information specialist. While we primarily used free-text terms to maximize sensitivity across databases with varying indexing systems, we acknowledge that the absence of MeSH terms for economic evaluation concepts (eg, "cost-benefit analysis" [MeSH]) and emergency-specific controlled vocabulary may have reduced search precision. During the screening process, one eligible study was initially misclassified during automated deduplication in Covidence due to similar authorship and title to another included study [22,23]. This study was subsequently identified through manual verification, retrieved, and included in the final analysis. Our broad digital health terms were designed to capture the rapidly evolving terminology in this field, though this approach may have introduced some irrelevant results during initial screening. We recognize that certain virtual care terms (eg, "teleconsultation," "teleurgency," and "store-and-forward") may not have been captured by our search terms. No language or date restrictions were applied. The full search strategy for each database is available in Multimedia Appendix 2.

Additionally, we performed citation searching of included studies (n=14) and searched gray literature sources (n=17) to identify unpublished economic evaluations, government reports, and health technology assessments.

Eligibility Criteria

Studies were included if they met all predefined eligibility criteria. Eligible studies focused on patients of any age presenting to EDs or requiring emergency medical care. The intervention of interest was any form of virtual care technology applied to emergency care delivery, encompassing synchronous or asynchronous telemedicine, remote monitoring, digital triage tools, or mobile health apps. Prehospital emergency care interventions, including ambulance-based telemedicine, were eligible for inclusion provided they met all other criteria for full economic evaluation. Stand-alone digital triage tools without clinician involvement (eg, automated symptom checkers used independently by patients without subsequent clinician assessment) were excluded, as these represent a distinct category of intervention with different economic evaluation considerations. This distinction was made a priori to maintain a focus on clinician-mediated virtual care models. Studies were required to include a comparator group involving traditional in-person emergency care or usual care practices. Only full economic evaluations were considered, specifically those that incorporated both cost and outcome data through cost-effectiveness, cost-utility, cost-benefit, or cost-minimization analyses. Relevant outcomes included economic measures such as cost-effectiveness ratios and other forms of comparative economic analysis.

Studies were excluded if they reported only costs or only outcomes without integrating both into an economic evaluation. Abstracts without accessible full texts, even after attempts to contact authors, were not considered. Additional exclusions applied to studies with unsuitable designs such as reviews, editorials, commentaries, or protocols; studies focusing on nonemergency settings or conditions (such as routine outpatient care or scheduled procedures); those lacking a clear economic evaluation framework; and those not involving direct patient care, such as research limited to provider education or administrative systems.

Study Selection

All identified references were imported into Covidence systematic review software for deduplication and screening. Two reviewers independently screened the titles and abstracts based on predefined eligibility criteria. Full texts of studies deemed potentially eligible were then retrieved and assessed independently by the same reviewers. Any disagreements were

XSL•FO
RenderX

resolved through discussion and, if needed, with input from a third reviewer. Interrater agreement was found to be strong across both stages of screening. The entire screening process, including reasons for exclusion, was documented in accordance with PRISMA guidelines. During quality checks, 1 study that had been inadvertently excluded during automated deduplication was identified. This study, which shared the same lead author and similar title as another included study, was manually retrieved, assessed for eligibility, and subsequently included in the final synthesis.

Data Extraction

A standardized data extraction form was developed and pilot-tested to ensure consistency, with initial testing conducted on a small sample of studies. Two reviewers independently extracted data from all included studies across several key domains. Study characteristics were recorded, including the first author, publication year, country, study design, and funding source. Population details such as sample size, age, sex distribution, emergency conditions, triage acuity levels, and comorbidities were documented. Information on intervention characteristics included the type of virtual care model, technology platform used, provider types involved, frequency and duration of interventions, and how the virtual model related to in-person care. Comparator details focused on usual care practices and the associated providers and resources. Economic evaluation methods were captured, including the type of analysis, analytic perspective, time horizon, discount rate, currency, and price year. Outcome measures covered effectiveness indicators such as QALYs, disability-adjusted life years (DALYs), and clinical outcomes, as well as cost-related metrics including direct, indirect, and societal costs, and ICERs. Data on the types of sensitivity analyses conducted and key results were also extracted. Finally, implementation factors, including any barriers and facilitators identified, were noted. Any discrepancies in data extraction were resolved through discussion and careful reexamination of the original source materials.

Quality Assessment

Methodological quality of included studies was assessed using 2 validated checklists: the Drummond checklist for economic evaluations [24] and the Consensus Health Economic Criteria (CHEC) list [25]. The combined use of both checklists is recommended by the Cochrane Handbook for Systematic Reviews of Interventions for appraising the methodological quality of full economic evaluations [26], as each tool addresses complementary quality domains. The Drummond checklist (10 items) focuses on the completeness and rigor of reporting in economic evaluations, including research question clarity, study design appropriateness, cost identification, incremental analysis, and uncertainty assessment [27]. The CHEC list (19 items) emphasizes methodological quality and reporting transparency, covering domains such as appropriate study population, time horizon, discount rate, outcomes measurement, and generalizability discussion [25]. This dual-checklist approach has been used in previous systematic reviews of economic evaluations to provide a more comprehensive quality assessment, as noted by Watts and Li [28] in their meta-review of checklist use in 346 systematic reviews of economic evaluations. Where the 2 tools assessed overlapping domains (eg, research question clarity and cost identification), we prioritized the more detailed tool's assessment for that domain.

Two reviewers independently rated each study, with disagreements resolved through consensus. We acknowledge that presenting quality scores as percentages has limitations, as these checklists were not originally designed to produce aggregate numerical scores, and individual checklist items may vary in importance [29]. The percentage scores should therefore be interpreted as broad indicators of methodological quality rather than precise quantitative measures. Item-level quality assessment results are presented in Multimedia Appendix 3 to allow readers to evaluate specific methodological strengths and weaknesses across studies.

Evidence Synthesis

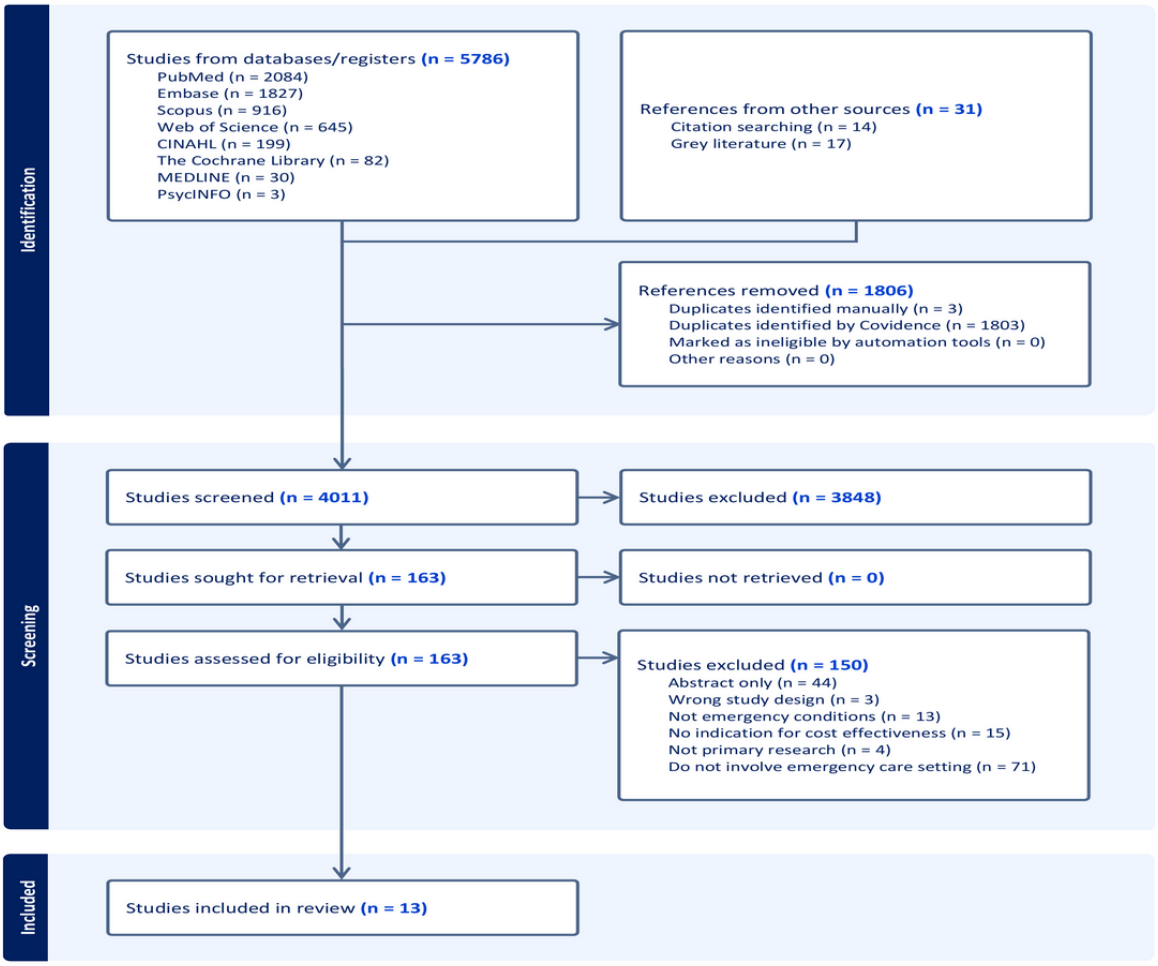
We adapted the Grading of Recommendations Assessment, Development, and Evaluation (GRADE) approach to assess the certainty of evidence for key outcomes [30], recognizing that GRADE was originally developed for clinical interventions rather than economic evaluations. Our adaptation followed the framework described by Brunetti et al [31], which provides guidance on considering resource use and rating the quality of economic evidence within the GRADE system. We additionally drew on the conceptual GRADE approach for assessing the certainty of modeled evidence outlined by Brozek et al [32], which confirmed that the standard GRADE domains apply to evidence from modeling studies, including those used in health economic evaluations.

Specifically, we assessed risk of bias (considering study design, model assumptions, and potential conflicts of interest), inconsistency (direction and magnitude of findings across studies), indirectness (applicability of study populations and settings to the review question), imprecision (confidence in effect estimates), and publication bias. For upgrading considerations, we evaluated the magnitude of effects and the consistency of the direction of findings across studies. The reference to dose-response relationships that appeared in the original protocol has been removed, as this criterion is not directly applicable to economic evaluations in this context [31]. Given the heterogeneity in interventions, populations, and economic evaluation methods, we conducted a narrative synthesis organized by virtual care modality and clinical application.

Subgroup and Sensitivity Analyses

We planned a priori subgroup analyses to explore potential sources of heterogeneity across included studies. Subgroup analyses examined variations by clinical condition, virtual care modality, geographic setting, patient age group, and economic perspective. These subgroup analyses are distinct from the sensitivity analyses conducted within individual included studies, which tested the robustness of each study's findings to variations in key parameters and assumptions. We report the results of within-study sensitivity analyses as part of our data extraction and discuss their implications for the certainty of findings.

XSL•FO
RenderX



Costs were reported in the original currencies and price years as presented in the included studies. We did not convert costs to a common currency or adjust for inflation, as the primary objective was to assess the direction and magnitude of cost-effectiveness findings within each study's context rather than to pool absolute cost figures. This approach is consistent with narrative synthesis methodology for heterogeneous economic evaluations. However, we acknowledge that this limits direct cross-study cost comparisons. Where available, we report the original publication year for each study to facilitate reader interpretation.

Results

Study Selection

The systematic search identified 5786 references from electronic databases. After removal of 1806 duplicates (3 identified manually and 1803 by Covidence), 3980 unique database references remained. Combined with 31 references from citation searching (n=14) and gray literature (n=17), a total of 4011 references were screened at the title and abstract level. Title and abstract screening excluded 3848 studies, leaving 163 for full-text review. Exclusion categories at the full-text stage were abstract only without accessible full text (n=44), unsuitable study design (n=3), focused on nonemergency clinical conditions such as routine outpatient management (n=13), no formal cost-effectiveness analysis (n=15), not primary research (n=4), and did not involve an emergency care delivery setting despite addressing acute conditions (n=71). The distinction between "nonemergency conditions" and "did not involve emergency care settings" reflects studies where the clinical condition was nonacute (eg, chronic disease management) vs studies where the condition was acute but the care setting was not an ED or emergency care pathway (eg, postdischarge follow-up and scheduled urgent care). A total of 13 studies met all inclusion criteria and were included in the review (Figure 1).

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram.

Study Characteristics

The 13 included studies were published between 2011 and 2024, with over half (n=7, 54%) published after 2015, reflecting recent growth in virtual emergency care evaluation. Studies originated from 6 countries: the United States (n=6), Australia (n=2), Italy (n=2), Canada (n=1), Haiti (n=1), and Belgium (n=1), representing diverse health care systems and economic contexts (Table 1).

XSL•FO

Study designs varied, with model-based economic evaluations being most common (n=7, 54%) [22,23,34,35,39,42,43], followed by observational cost-effectiveness analyses (n=4, 31%) [8,36,37,40] and 2 (15%) within-trial analyses [22,38]. Sample sizes ranged from 108 to 109,750 patients, with a median of 1068 (IQR 706-4358) patients (Table 1). The largest study [8] evaluated a prehospital electrocardiogram triage program in Italy serving a population of 4 million.

Clinical conditions addressed included stroke/cerebrovascular emergencies (n=7, 54%), pediatric emergencies (n=4, 31%), general neuroemergencies (n=2, 15%), psychiatric emergencies (n=1, 8%), and cardiac emergencies (n=1, 8%). One study [41] examined general ED presentations without condition-specific focus (Table 1).

Economic Outcomes

Economic evaluation methods varied across studies, with cost-effectiveness analysis being most common (n=8), followed by cost-utility analysis (n=3), cost-minimization (n=1), and cost-consequence analysis (n=1). A total of 8 (62%) studies adopted a health care system perspective, while 4 (31%) used a broader societal perspective incorporating patient and family costs (Table 2).

[h]NIHSS: National Institutes of Health Stroke Scale.

[i]YLL: years of life lost.

[j]ED: emergency department.

[k]LOS: length of stay.

[l]ROI: return on investment.

Cost-Effectiveness Results

Virtual emergency care was associated with favorable economic outcomes across all included studies, though the strength and mechanisms of cost-effectiveness varied by clinical domain. Stroke-related applications (n=6) demonstrated the most consistent evidence of dominance, driven by increased thrombolysis rates and transfer avoidance. Pediatric applications (n=4) achieved cost-effectiveness primarily through reduced transfers and averted hospitalizations, while psychiatric and

XSL•FO
RenderX

general emergency applications were each supported by single studies, limiting the certainty of subgroup-specific conclusions. A total of 6 (46%) studies found virtual care to be dominant, that is, both less costly and more effective than usual care. These included telestroke networks [34,42], pediatric telemedicine [43], neuroemergency consultation [37], and rural generalist services [41].

Among studies reporting ICERs, the time horizon significantly influenced results: Nelson et al [23] reported an ICER of US $108,363/QALY at 90 days, which improved to US $2449/QALY over a lifetime horizon. Nelson et al [22] demonstrated that from the spoke hospital perspective, ICERs ranged substantially depending on the proportion of implementation costs borne by the spoke facility: US $1322/QALY when the spoke bore 0% of implementation costs, US $25,991/QALY at 50%, and US$50,687/QALY at 100%. From the hub perspective, the overall ICER ranged from US $22,363/QALY to US $71,703/QALY. Cost-effectiveness was most pronounced for patients with severe stroke (National Institutes of Health Stroke Scale [NIHSS] score ≥15), with spoke ICERs ranging from US $7794/QALY to US $40,071/QALY, while mild strokes (NIHSS <5) were not cost-effective from the spoke perspective when spokes bore ≥50% of implementation costs. Most reported ICERs fell below commonly accepted willingness-to-pay thresholds of US $50,000-$100,000 per QALY [44].

Cost savings varied by setting and intervention type. Per-encounter savings ranged from US $73 (AUD $105) [41] to US $5118 [40]. The primary driver of cost savings was a reduction in patient transfers, which decreased by 31%-73% across studies [37,43]. Transfer avoidance alone generated savings of US $3729 per patient in [42]. The prehospital model demonstrated different economics: Espinoza et al [35] found in-ambulance telemedicine to be dominant with time gains of 12 minutes or more, saving US $30 per patient while gaining 0.00456 QALYs. Notably, this intervention became cost-effective with time gains as small as 6 minutes, demonstrating that time gains influenced cost-effectiveness thresholds.

Clinical Effectiveness

Virtual care interventions consistently improved clinical outcomes alongside economic benefits. QALY gains ranged from 0.02 [34] to 0.20 [42] per patient (over a lifetime), with stroke and neuroemergency applications showing the largest improvements. Nelson et al [22] reported an incremental effectiveness of 0.039 QALYs per patient for telestroke compared to nontelestroke assisted care, with telestroke implementation leading to a more than threefold increase in tissue plasminogen activator (tPA) treatment rates (from 9.2% to 31.7%). This treatment effect was most dramatic in moderate-severity strokes (NIHSS 5-14), where a nearly seven-fold increase in tPA treatment was observed (6.9% to 47.7%). The Haiti pediatric service [36] averted 199.76 DALYs annually at a cost of US $1288 per DALY averted, which is well below the country's GDP-based cost-effectiveness threshold.

ED length of stay decreased by 2.8 hours with virtual consultations in Thomas et al [40]. This study documented a median ED length of stay of 5.5 hours for telepsychiatry vs 8.3 hours for usual care (P<.001). Hospital admission rates fell significantly: Thomas et al [40] reported a reduction from 56% to 42% for pediatric psychiatric emergencies. Importantly, these efficiency gains occurred without compromising quality or safety, with patient satisfaction exceeding 90% in all studies reporting this outcome.

Quality Assessment

Methodological quality was independently assessed using the Drummond checklist (10 items focused on analytical rigor) and the CHEC list (19 items emphasizing reporting standards). The included studies demonstrated consistently high quality, with mean scores of 9.29 (SD 0.60) out of 10 criteria met for the Drummond checklist and 18.04 (SD 0.79) out of 19 criteria met for the CHEC list. While we present these aggregate figures for descriptive purposes, we note that these checklists were designed as qualitative assessment tools rather than quantitative scoring instruments, and individual items are not equally weighted. Item-level quality assessment results are presented in Multimedia Appendix 3 to allow readers to evaluate specific methodological strengths and weaknesses. The term "overall mean quality score" has been removed to avoid implying a validated composite metric. All 13 (100%) studies achieved an "Excellent" quality rating (≥85%), with Kim et al [38] scoring the highest at 100% (Table 3). All studies clearly stated research questions, appropriately selected the type of economic evaluation, comprehensively identified costs, and explicitly reported perspectives and time horizons. Sensitivity analyses were conducted in the majority of studies (12/13, 92%), often using multiple approaches. The most common limitations were inadequate discussion of generalizability (observed in 5/12, 42% of studies) and incomplete conflict of interest reporting (7/12, 58%). Notably, no study scored below 83% on either checklist, indicating that the economic evaluations of virtual emergency care consistently meet high methodological standards. This uniform methodological rigor, paired with consistently favorable economic findings.

Using GRADE methodology, we assessed the certainty of evidence as high for cost-effectiveness outcomes based on 10 studies with consistent positive findings. Evidence certainty was moderate for transfer rate reduction and quality of life improvements, and low for ED length of stay and mortality benefits due to study design limitations and imprecision (Table 4).

The evidence generally supports virtual emergency care implementation, with 6/10 economic evaluations demonstrating dominance (cost-saving with better outcomes). However, one study showed unfavorable short-term cost-effectiveness, and effectiveness measures varied across studies. Large reductions were observed primarily in transfer rates (31%-90%), with cost impacts varying by setting and condition.

Subgroup Analyses

By Clinical Condition

Stroke care showed the most robust evidence, with 5/6 studies demonstrating dominance [22,23,34,37,42]. The consistent mechanism was increased thrombolysis rates through rapid specialist consultation, generating both clinical benefits and cost savings through avoided transfers and improved outcomes. Nelson et al [22] extended this evidence by demonstrating that the cost-effectiveness of telestroke varied significantly by stroke severity: severe strokes (NIHSS ≥15) showed the most favorable ICERs (US $7794/QALY to US $40,071/QALY from the spoke perspective), while mild strokes (NIHSS <5) were dominated when spokes bore ≥50% of implementation costs. This severity-stratified analysis, the first of its kind in the telestroke cost-effectiveness literature, provides critical nuance for implementation planning. Demaerschalk et al [34] documented US $1436 lower costs and 0.02 QALY gains over patient lifetimes in their hub-and-spoke telestroke network evaluation. The prehospital stroke model [35] achieved cost-effectiveness through a different mechanism, through time savings enabling earlier treatment rather than transfer avoidance. Their model showed that every minute saved translated into measurable economic and clinical benefits.

Pediatric emergency applications [36,39,43] achieved favorable economics through different mechanisms. Critical care consultations avoided unnecessary transfers (31% reduction) [43], while the Haiti model prevented hospitalizations through early intervention. Yang et al [43] reported ROI ranging from 1.28 to 1.96 across pediatric studies, with annual cost savings of US $46,620 per ED treating 10 children with telemedicine.

By Geographic Setting

Rural and remote implementations [22,23,34,36,41-43] consistently showed superior cost-effectiveness compared to urban applications, driven primarily by high transfer costs and distances. Rural settings achieved 6 of 7 dominant outcomes, with savings amplified by avoided air medical transports and family travel costs. Whetten et al [42] demonstrated that transfer rates from rural hospitals to urban medical facilities decreased from 85% to 5% (no tPA) and from 90% to 23% (tPA) with their Access to Critical Cerebral Emergency Support Services (ACCESS) telestroke program. Nelson et al [22] provided additional evidence from the Pacific Northwest, where 17 spoke facilities in the Providence Oregon Telestroke Network (POTN) served rural communities. Their analysis uniquely demonstrated how cost-sharing arrangements between hub and spoke facilities influence cost-effectiveness, with the spoke perspective yielding ICERs as low as US $1322/QALY when implementation costs were fully subsidized by the hub.

Urban network implementations [23,34] achieved cost-effectiveness through operational efficiency and care standardization rather than transfer reduction. The Italian regional networks [8,37] demonstrated how high-volume centralized systems can achieve economies of scale.

By Technology Type

Video consultation technology's [22,23,34,35,37-43] versatility across clinical conditions and ability to support visual assessment appeared critical for both clinical and economic success (Table 5). These implementations typically featured 2-way, high-definition audiovisual systems connecting EDs to remote specialists. Hub-and-spoke models were common, with specialist coverage ratios of 1:7-8 peripheral sites as documented by Demaerschalk et al [34] and Nelson et al [23]. Nelson et al [22] used a similar hub-and-spoke model with 2 hub facilities (1 primary stroke center and 1 comprehensive stroke center) supporting 17 spoke facilities, demonstrating scalability of this approach.

Other virtual modalities included mobile electrocardiogram transmission [8], telephone consultation with medication delivery [36], and a hybrid model combining 75% virtual with 25% in-person coverage [41]. Technology sophistication varied considerably, from basic telephone systems in resource-limited Haiti to advanced platforms with peripheral examination devices and rapid imaging transfer capabilities. Lower-technology solutions proved viable in resource-constrained settings. The Haiti telephone-based model [36] achieved cost-effectiveness despite, or perhaps because of, its simplicity, suggesting technology should match context rather than maximize sophistication. The in-ambulance telemedicine model [35] represents an intermediate technology approach, combining real-time consultation with automated data transmission. This prehospital intervention uniquely demonstrated that time gains as small as 6 minutes could achieve cost-effectiveness, with dominance achieved at 12 minutes.

By Provider Type

Provider types delivering virtual care included neurologists and stroke specialists [23,34,35,37,38,42], pediatric critical care physicians and psychiatrists [36,39,40,43], rural generalist physicians [41], cardiologists [8], and nurses with physician oversight [36]. Most programs operated 24/7, though the Haiti service functioned only during nighttime hours when traditional care was unavailable. A unique prehospital model was evaluated by Espinoza et al [35], featuring in-ambulance telemedicine with live bidirectional audio-video communication, automated vital signs transmission, and 24/7 neurologist consultation. This system served 150 patients per ambulance annually, with 39% of eligible patients receiving telemedicine consultation.

Sensitivity analyses were conducted in 12/13 (92%) studies. The most common approaches were 1-way deterministic sensitivity analysis (n=9), probabilistic sensitivity analysis using Monte Carlo simulation (n=7, with iterations ranging from 1000 to 10,000), 2-way sensitivity analysis (n=4), and scenario analysis (n=2). Kadel et al [37] were the only study that did not perform a sensitivity analysis. Key findings from sensitivity analyses included results were robust to parameter variation in 10/12 studies; Nelson et al [23] found that the ICER was most sensitive to the time horizon assumption, shifting from US $108,363/QALY at 90 days to US $2449/QALY over a lifetime; Nelson et al [22] demonstrated through probabilistic sensitivity analysis (10,000 iterations) that telestroke was the most cost-effective strategy in at least half of simulation runs when willingness-to-pay thresholds exceeded US $5000/QALY (spoke bearing 0% costs), US $30,000/QALY (50% costs), or US $52,000/QALY (100% costs); Espinoza et al [35] identified the minimum time gain threshold (6 minutes) needed for cost-effectiveness; and Yang et al [43] reported that ROI estimates remained favorable (range 1.28-1.96) across probabilistic iterations. Key uncertainty drivers across studies included time horizon, transfer rates, intervention use rates, cost-sharing arrangements, and discount rates. No study identified scenarios under which virtual care became definitively cost-ineffective in their primary sensitivity analyses, though shorter time horizons and lower use rates reduced the magnitude of economic benefits.

Cost Components Analysis

Direct medical costs consistently favored virtual care, with per-consultation costs ranging from €16.70 (US $21) for electrocardiogram telemedicine [8] to US $600 per consultation for neurological telemedicine [42]. While initial infrastructure investment was substantial, break-even typically occurred within 1-3 years based on operational savings. The Victorian Stroke Telemedicine program showed cost savings of US $142 (AUD $190) per patient (control: US $61,631 [AUD $82,449]; intervention: US $61,489 [AUD $82,259]) at 12 months [38]. Direct medical costs consistently favored virtual care across multiple studies. Brunetti et al [8] reported telemedicine electrocardiogram consultation costs of €16.70 (US $21) per encounter compared to €24.80-€55.20 (US $32-71) for conventional ED visits in Italy. Similarly, Von Huben et al [41] documented cost savings of US $73 (AUD $105) per ED encounter for their Virtual Rural Generalist Service (US $93 vs US $167 [AUD $134 vs AUD $240] for usual care). Nelson et al [22] provided detailed cost breakdowns from POTN: spoke facility fixed costs included monthly camera fees (US $1980/month), 1-time equipment setup (US $11,000), and yearly training (US $768), while hub facility costs included 1-time equipment (US $26,300), annual wireless connectivity (US $4500), a full-time telestroke coordinator (US $89,679), and yearly training (US $900). These real-world cost data, derived from encounter-level financial records rather than literature estimates, represent a significant contribution to understanding the true infrastructure investment required for telestroke implementation.

Infrastructure investment varied considerably by program scope and technology. While initial setup costs could be substantial, rapid ROI was consistently demonstrated. Yang et al [43] calculated an ROI of 1.28 in their base case, rising to 1.96 in probabilistic analyses for pediatric telemedicine consultations.

Transfer and transportation represented the largest cost differential, particularly in rural settings. Virtual care programs achieved dramatic reductions in transfer rates—from 85%-90% to 5%-23% in patients with stroke [42] and a 73% reduction in neurosurgical transfers [37]. Nelson et al [22] reported a slight decline in transfer probability for tPA-treated patients (55.6% to 51.9%) but an increase among untreated patients (11.2% to 16.8%), the latter likely reflecting improved identification of patients requiring higher-level care. Beyond direct ambulance costs, virtual care eliminated family travel costs and productivity losses. The Canadian pediatric teleresuscitation program documented mean costs of US $1563 (CAD $2032.73) for telemedicine cases vs US $244 (CAD $317.45) for controls [39]. Transfer and transportation costs represented the largest area of savings. Whetten et al [42] reported cost savings of US $3729 per patient, primarily from reduced unnecessary transfers (85% to 5% for non-tPA patients and 90% to 23% for tPA patients). Kadel et al [37] documented a 73% reduction in transfer rates for neurosurgical emergencies, saving 139,916 km in travel distance and €3,095,863 (US $4,303,250) over 4 years. Beyond direct ambulance costs, virtual care eliminated associated family expenses and productivity losses.

Staffing efficiencies emerged as a significant economic driver. Hub-and-spoke models achieved specialist coverage ratios of 1:7-8 sites compared to traditional 1:1 models [23,34]. The POTN model [22] demonstrated a similar approach with 2 hub facilities supporting 17 spoke facilities, with an average of 14.4 patients with acute ischemic stroke per spoke per year. Von Huben et al [41] documented substantial reductions in expensive locum physician shifts (from 1456 to 609 days), with the Virtual Rural Generalist Service achieving a price per activity unit of

XSL•FO
RenderX

AUD $1047 compared to AUD $1753 for usual care. Staffing efficiencies emerged as a critical economic driver. They reported a 60% reduction in expensive locum physician shifts from 1456 to 609 days annually, with the price per activity unit lower for virtual care (AUD $1047) compared to usual care (AUD $1753). Hub-and-spoke models achieved efficient specialist coverage, as demonstrated by Demaerschalk et al [34] with 1 hub hospital supporting 7 spoke hospitals.

The Haiti pediatric telemedicine program demonstrated unique cost-effectiveness at US $1288 per DALY averted, well below the World Health Organization cost-effectiveness threshold of 3 times per capita GDP (US $3531) [36]. This program included medication delivery, representing an innovative model combining consultation and pharmaceutical services.

Implementation Factors

Studies consistently identified high initial technology costs as the primary implementation barrier, though rapid ROI mitigated this concern. Yang et al [43] demonstrated an ROI of 1.28 in base case analysis, with pediatric telemedicine generating annual cost-savings of US $46,620 per ED treating 10 children. Rural connectivity challenges were addressed through tiered technology approaches—the Haiti study successfully operated using basic telephone systems [36], while other programs required high-definition videoconferencing [41]. Technology infrastructure costs emerged as the primary implementation barrier across studies. However, flexibility in technology requirements facilitated adoption. Flaherty et al [36] successfully implemented a nighttime pediatric telemedicine service in Haiti using basic telephone technology, while Von Huben et al [41] used high-definition videoconferencing in Australian rural hospitals.

Facilitators of successful implementation included strong clinical champions, executive support, and phased rollout strategies targeting high-need populations. Programs focusing on time-critical conditions like stroke demonstrated early wins that facilitated expansion. The Victorian Stroke Telemedicine program strategically excluded 4 large hospitals with existing stroke protocols, focusing implementation where impact would be greatest [38]. Programs targeting high-need populations demonstrated early wins—stroke programs consistently showed increased tPA administration rates and improved outcomes [23,34].

Integration with existing workflows proved critical for success. Kadel et al [37] demonstrated efficiency with 75% of teleconsultations completed within 15 minutes and 90% within 30 minutes. The ACCESS program achieved consultation completion rates with neurologists available for rural EDs, resulting in cost savings of US $4241 per patient and QALY gains of 0.20 per patient [42]. Clinical workflow integration proved critical for success. Kadel et al [37] reported that 75% of teleneurosurgery consultations were completed within 15 minutes and 90% within 30 minutes, demonstrating efficiency that encouraged provider adoption. Similarly, Brunetti et al [8] achieved rapid electrocardiogram interpretation with remote cardiologists available 24/7.

Volume and case mix significantly influenced economic outcomes. The Brunetti et al study processed 109,750 electrocardiograms from 274,198 total emergency calls in 2012, achieving economies of scale with a cost per electrocardiogram/consultation of €16.70 (US $21) [8]. Programs with lower volumes, such as the Belgian in-ambulance telemedicine study with 39% use rates, still achieved cost-effectiveness when time gains exceeded 6-12 minutes [35].

Provider acceptance was enhanced by demonstrable benefits to work-life balance and patient outcomes. Thomas et al [40] reported reduced ED length of stay (5.5 vs 8.3 hours) and lower charges (US $3493 vs US $8611) for telepsychiatry compared to usual care. Pace et al [39] documented an ICER of US $50 (CAD $64.61) per year of life lost averted for pediatric teleresuscitation, demonstrating clear value.

Funding models and reimbursement structures varied by country and health care system. In the United States, several studies noted consultation fees ranging from US $600 per consult [42] to operational costs of US $222,800 annually for telepsychiatry services [40]. The dominant finding across studies was that virtual emergency care programs generated net savings despite initial investments.

Discussion

Principal Findings

This systematic review found that virtual emergency care was associated with favorable economic outcomes across diverse clinical applications and health care settings. While these findings suggest economic viability, the predominance of model-based evaluations (7/13, 54% of included studies) and the absence of empirical negative findings warrant cautious interpretation. Model-based analyses rely on assumptions about clinical pathways, costs, and transition probabilities that may not fully capture real-world complexities. Multiple mechanisms underlie these favorable outcomes, including avoiding patient transfers and improving operational efficiency. Our results present a supportive economic case beyond direct cost savings, highlighting workforce sustainability benefits as well. For instance, one study documented a 60% reduction in the use of costly locum physicians [41].

It is important to recognize that the clinical heterogeneity across included studies spanning telestroke, pediatric telemedicine, psychiatric emergencies, cardiac triage, and rural generalist services limits the generalizability of aggregate conclusions. Each clinical domain involves distinct patient populations, care pathways, cost structures, and outcome measures (QALYs, DALYs, transfers avoided, and length of stay). While the overall direction of findings was consistently positive, the evidence base is strongest for stroke care (supported by multiple studies with concordant findings) and more preliminary for psychiatric and general emergency applications (each supported by single studies).

Comparison With Prior Work

Our findings extend earlier domain-specific reviews in several important ways. Previous systematic reviews of telestroke cost-effectiveness [7] have demonstrated favorable outcomes

XSL•FO
RenderX

in stroke-specific applications, while reviews of telemedicine in emergency settings [7,17,18] have primarily focused on clinical effectiveness rather than economic outcomes. Our review is the first to synthesize economic evidence across the full spectrum of virtual emergency care modalities, demonstrating that the favorable economics observed in telestroke extend to pediatric, psychiatric, and general emergency applications. This broader scope strengthens the evidence base for policy decisions that span multiple clinical domains.

Unlike the mixed results reported for telemedicine cost-effectiveness in nonemergency settings by Whitten et al [45], our findings were uniformly positive—a discrepancy that may reflect emergency care's unique characteristics (high baseline costs, time-sensitive decisions, and clear outcome metrics) rather than a true absence of unfavorable results. Furthermore, the success of simpler technologies in resource-constrained settings challenges the assumption that high technological sophistication is necessary for cost-effectiveness. For example, a telephone-based consultation model in Haiti was found to be cost-effective [36], suggesting that matching the technology to the context can be more important than using the most advanced tools. Our review also highlights the prehospital telemedicine model as an important middle ground: ambulance-based systems can achieve cost-effectiveness without a full hospital infrastructure.

Moreover, by including full economic evaluations rather than cost-only studies, our review provides more robust evidence than prior reviews that examined only cost data without health outcome integration.

Interpretation of Cost-Effectiveness Findings

The cost-effectiveness of virtual emergency care was driven by distinct mechanisms across clinical domains. In stroke care, the primary value proposition was enabling time-sensitive thrombolysis through rapid specialist consultation, where even modest improvements in treatment times translated into substantial QALY gains and reduced long-term disability costs. The strong lifetime cost-effectiveness (ICER of US $2449/QALY) despite unfavorable short-term economics (US $108,363/QALY at 90 days) underscores the importance of capturing downstream benefits in economic evaluations of acute interventions.

In pediatric applications, cost-effectiveness was primarily driven by transfer avoidance and reduced unnecessary hospitalizations, reflecting the high baseline costs of pediatric emergency transfers and the ability of specialist teleconsultation to safely manage patients locally. The variability in ICERs across studies—ranging from US $1273 (€990)/QALY to US $108,363/QALY—reflects differences in time horizons, health care system costs, comparator practices, and the specific clinical conditions studied. These contextual factors mean that the transferability of specific ICER values to new settings requires careful consideration of local cost structures, existing care pathways, and patient populations.

Policy and Clinical Implications

The evidence supports consideration of expanding virtual emergency care programs, particularly in settings where the economic case is strongest, while acknowledging that implementation decisions should account for local contextual factors not fully captured in economic models. The rapid uptake of virtual care during temporary COVID-19 policy relaxations demonstrated the feasibility of swift implementation. Health care administrators should prioritize high-impact virtual applications (eg, telestroke and pediatric critical care) in underserved areas to maximize early ROI and build organizational support; documented break-even periods of 12-24 months can reassure budget-conscious decision-makers.

Moreover, the fact that all economic perspectives examined showed positive results further strengthens the investment case: even analyses using a narrow health care system perspective demonstrated cost savings, while broader societal perspective analyses revealed added benefits such as reduced costs for families and productivity gains. For clinicians, it is significant that the economic benefits of virtual emergency care were accompanied by quality improvements (maintained or improved patient outcomes, >90% patient satisfaction, and reduced ED length of stay). This finding suggests that virtual care can enhance care quality rather than compromise it, while also reducing clinicians' workload through improved patient flow.

Methodological Considerations

Although the included studies used diverse economic evaluation methods reflecting real-world variability, this heterogeneity complicates direct comparisons and underscores the need for more standardized reporting of cost-effectiveness outcomes (eg, consistent use of ICER calculations, uniform costing methods, and common time horizons). The development of a core set of economic outcome measures for virtual emergency care could significantly improve comparability across studies.

While 54% (7/13) of the studies were model-based analyses, thereby raising some questions about generalizability, the consistency of findings between these models and the observational studies is reassuring. However, the reliance on modeling introduces inherent uncertainty, as results depend on assumptions about clinical pathways, transition probabilities, and cost structures that may not hold across all settings.

Overall, the quality of the economic evidence was generally high: on average, studies met over 90% of criteria on validated quality assessment checklists, though we note that these percentage scores should be interpreted as descriptive indicators rather than precise quality metrics, as these checklists were not designed for numerical aggregation. However, future evaluations should strengthen their reporting of generalizability and better disclose any conflicts of interest. Encouragingly, 92% (12/13) of the studies included sensitivity analyses, indicating that uncertainty was appropriately handled—which is an important practice for decision-maker confidence.

Sensitivity Analysis and Uncertainty

While 92% (12/13) of included studies conducted sensitivity analyses, several important sources of uncertainty merit

XSL•FO
RenderX

discussion. Key parameters driving variation in cost-effectiveness estimates included the time horizon of analysis, with shorter horizons (eg, 90 days) producing less favorable ICERs than lifetime models; patient volume and use rates, which influenced the spread of fixed infrastructure costs; transfer rates and distances, which were the dominant cost drivers in rural settings; and discount rates applied to future health benefits.

Notably, no study systematically explored scenarios in which virtual care would not be cost-effective, such as settings with very low patient volume, high existing specialist availability, or unreliable technology infrastructure. Future evaluations should explicitly model conditions under which virtual emergency care may not represent good value for money, to provide decision-makers with a more complete picture of when implementation is and is not warranted.

Equity and Global Generalizability

The evidence base is dominated by high-income countries (the United States, Australia, Canada, Italy, and Belgium), with only one study conducted in a low-income setting (Haiti). This geographic concentration significantly limits the generalizability of findings to low- and middle-income countries (LMIC), where health care infrastructure, digital connectivity, workforce composition, and cost structures differ substantially. While the Haiti study demonstrated that simpler technologies can achieve cost-effectiveness in resource-constrained environments, this single study cannot address the diverse challenges faced across LMIC. Claims about global scalability should therefore be interpreted with caution.

Future research should prioritize economic evaluations in LMIC, where the potential impact of virtual emergency care may be greatest but where implementation barriers—including limited broadband access, electricity reliability, and trained workforce availability—are also most pronounced. Equity considerations, including whether virtual emergency care reduces or exacerbates disparities related to digital literacy, language, age, or socioeconomic status, also require dedicated investigation.

Strengths and Limitations

This review implemented several measures to minimize bias. We conducted a comprehensive search across multiple databases, including gray literature and non-English studies, and applied rigorous quality assessments using validated tools alongside the GRADE approach. Furthermore, by focusing exclusively on full economic evaluations, we ensured that our conclusions reflect true value generation rather than cost shifting between settings.

Despite these strengths, the study has several limitations. The interventions evaluated were heterogeneous, which precluded a meaningful meta-analysis. In addition, most included studies adopted a health care system (rather than societal) perspective, potentially underestimating the full benefits of virtual care.

Publication bias represents a significant concern in this review. Despite our comprehensive search across 8 databases and gray literature sources, all 13 included studies reported favorable economic outcomes for virtual emergency care. The complete absence of negative or neutral findings is noteworthy and may reflect selective publication of studies with positive results, selective reporting of favorable outcomes within studies, or genuine cost-effectiveness of virtual emergency care across all evaluated contexts. The possibility that unfavorable economic evaluations remain unpublished or were not identified by our search cannot be excluded. This limitation should temper the certainty with which the overall positive conclusions are interpreted.

Several important cost dimensions are underrepresented in the included studies. Ongoing technology maintenance and upgrade costs, which can be substantial as hardware ages and software requires updates, were rarely incorporated. Staff training costs—both initial and recurrent—were inconsistently reported, yet represent a significant and recurring investment. Workflow integration costs, including the time and resources required to redesign clinical processes, develop protocols, and manage change, were largely absent from economic evaluations. Additionally, the included studies did not systematically account for potential downstream costs such as follow-up care resulting from remote diagnostic limitations, liability and malpractice considerations, or the costs of addressing technology failures and downtime.

The long-term sustainability of cost savings remains uncertain, as initial efficiencies may diminish as programs scale, technology costs evolve, or reimbursement structures change. While early evidence indicates that the benefits are sustained or even amplified over time, longer-term studies will be important to confirm this durability.

While this review adhered to PRISMA 2020 guidelines, certain recommended items—including formal assessment of reporting bias across studies and provision of underlying extracted data—were not fully addressed. The complete dataset of extracted study characteristics and economic outcomes is available from the corresponding author upon request.

Future Research Directions

Looking ahead, further research is needed in several key areas. First, economic evaluation methods should be standardized to facilitate cross-study comparisons and enable future meta-analyses. Second, researchers should evaluate emerging virtual care modalities such as AI-driven triage algorithms and integrated digital emergency systems to determine which features truly drive cost-effectiveness and which simply add expense. Third, dedicated studies should assess the equity impacts of virtual emergency care to determine whether it reduces or exacerbates health care disparities, with particular attention to the digital divide. Fourth, implementation science approaches are needed to optimize how virtual emergency care is delivered. Comparative studies of different care models, training methods, and change management strategies could offer practical guidance for health systems, given that current variation in program success suggests significant room for improvement. Finally, long-term evaluations are crucial to assess how the benefits of virtual emergency care evolve over time, how quality of care is maintained as programs scale up, and how these models adapt to changing technology landscapes.

XSL•FO
RenderX

Future evaluations should also adopt longer time horizons and incorporate comprehensive implementation cost frameworks—including technology maintenance, staff training, workflow redesign, and opportunity costs—to provide a more complete economic picture. Studies should explicitly model conditions under which virtual emergency care may not be cost-effective to help decision-makers identify appropriate implementation contexts.

Despite these research needs, the existing evidence supports broader implementation of virtual emergency care, particularly for high-need populations and time-sensitive emergency conditions where its benefits are most pronounced.

Conclusion

This systematic review found consistent evidence of favorable economic outcomes for virtual emergency care across diverse clinical conditions, settings, and modalities. The evidence is strongest for stroke care and rural/remote implementations, where transfer avoidance drives substantial savings. While all included studies reported cost-effectiveness or cost savings, the predominance of model-based analyses, the absence of evidence from LMIC, and the possibility of publication bias warrant cautious interpretation. These findings support the continued expansion of virtual emergency care, particularly for high-need populations and time-sensitive conditions, while highlighting the need for standardized economic evaluation methods, long-term sustainability assessments, and equity-focused research to guide future implementation decisions.

Funding

This research received no specific grant from any funding agency in the public, commercial, or not-for-profit sectors.

Data Availability

All data generated or analyzed during this study are included in this published article and its supplementary information files. The complete search strategy, data extraction forms, and quality assessment ratings are available in Multimedia Appendices 2 and 3. The dataset of extracted study characteristics and economic outcomes is available from the corresponding author upon reasonable request.

Abstract

Background: Unintentional childhood injuries represent a major public health issue affecting the lives and health of children worldwide, with the risk and injury type dynamically changing with age and developmental stage. To effectively prevent unintentional injuries, intervention measures must be adjusted based on actual circumstances and kept up to date in real time. Mobile health (mHealth) technologies can meet this need, but their specific functions and intervention methods remain unclear at present.

Objective: This study aimed to conduct a scoping review of research on the application of mHealth technologies in the prevention and emergency management of unintentional injuries among children, with a focus on identifying the types of mHealth technologies used, intervention contents, and outcome measures, thereby providing a reference for related studies.

Methods: We systematically searched 5 databases—PubMed, Web of Science, Embase, Cochrane Library, and CINAHL—from their inception to December 31, 2025. Data extraction and synthesis were performed on the included studies.

Results: Of 1085 articles, 15 (1.3%) met the inclusion criteria, and 1 additional reference was added during full-text review. Thus, 16 studies were included. The included studies comprised 9 (56.2%) randomized controlled trials, 2 (12.5%) quasi-experimental studies, 3 (18.8%) mixed methods studies, 1 (6.2%) qualitative study, and 1 (6.2%) descriptive study. mHealth technologies included apps, WeChat, mobile-based e-learning programs, and virtual reality combined with wearable devices. Their functions included health education, interactive communication, monitoring and reminders, behavioral training, questionnaires and record-keeping, and emergency response. Outcome measures included the incidence of unintentional injuries among children; knowledge, attitudes, and behaviors regarding injuries; other psychological and social indicators; and usability of mHealth technology.

Conclusions: mHealth technologies have shown some progress in reducing unintentional injuries among children. Content based on this technology has demonstrated positive effects in reducing injury incidence, enhancing caregivers' awareness, and improving related attitudes and behavioral capabilities. However, only 2 mobile apps are currently available to the public. Future research should optimize the functional design of mHealth, strengthen sustainability, explore long-term implementation methods, and conduct large-scale, long-term studies to further evaluate its impact on the incidence of unintentional injuries among children.

KEYWORDS

child; mobile health; scoping review; technologies; unintentional injuries

Introduction

Background

Unintentional injuries are bodily harm caused by sudden events, including accidental falls, drowning, burns, suffocation, and poisoning [1]. It is estimated that unintentional injuries are the leading cause of death among children aged 1 to 19 years globally and the fifth leading cause of death among infants aged <1 year [2,3]. The 2019 Global Burden of Disease Study reveals that 205,000 children and adolescents aged 5 to 24 years died from unintentional injuries, with children aged 5 to 9 years facing the highest risk of death. According to China's Under-5 Child Mortality Surveillance System reports, between 2010 and 2020, a total of 7925 children died from unintentional injuries, and the proportion of deaths among injuries rose from 15.2% in 2010 to 23.8% in 2020 [4]. It not only poses a severe threat to children's lives and health but also imposes heavy economic burdens and psychological stress on families and society. The occurrence of unintentional injuries involves multiple factors, including the child's age and developmental stage, the guardians' educational and supervisory levels, and the safety conditions of the surrounding environment [5-7]. Among all the risk factors, age and developmental stage are important predictors, indicating that injury types and risk factors vary dynamically with the child's age and developmental stage. For example, young children are more prone to unintentional injuries, and infants aged <1 year are commonly more prone to choking or suffocation; while children over 1 year of age are more likely to experience accidental falls or burns [6]. It is this characteristic that requires interventions for unintentional injuries to be timely adjusted and updated to the child's age and developmental stage.

The World Health Organization published the World Report on Child Injury Prevention (2008), which outlines key interventions across multiple areas, including legislation, product safety, environmental modification, education, and first aid [8]. However, the strategies, both domestically and internationally, primarily rely on offline approaches that have limited coverage, target smaller populations, and yield short-term effects, wasting time and money and lacking sustainability. With the rapid development of IT, mobile health (mHealth) offers a new perspective and platform for preventing and controlling unintentional childhood injuries. mHealth refers to the use of smartphones, wearable devices, mobile apps, and other technologies to deliver health promotion, disease prevention, and public health management services to the public [9]. This technology offers convenience, real-time access, personalization, and intelligence, enabling dynamic updates to intervention content and long-term tracking, thereby addressing the shortcomings of traditional approaches and aligning with the requirements of unintentional injuries [10]. Currently, mHealth technologies are widely used in areas such as chronic disease management, rehabilitation, cancer care, and perinatal care, and show great promise [11-14].

In the field of child injury prevention, some studies have also attempted to develop mHealth interventions to prevent unintentional injuries in children. For example, Feng et al [15] used WeChat to regularly send information on the prevention of unintentional injuries and emergency strategies to parents. Cooray et al [16] used a mobile app to help parents of children aged <1 year improve their ability to prevent infant falls. Wong et al [17] used serious games to help children learn traffic safety signs and understand potential safety hazards in different areas. Because researchers use different mHealth technologies, the target populations, functional focuses, and intervention outcomes vary. A review is needed to clarify the format, advantages, effectiveness, and potential limitations of each technology. Currently, there are few systematic reviews in this field. Schulze et al [18] conducted a review of mobile apps for unintentional injuries in children aged <7 years, detailing the user groups, specific needs, and evaluation metrics of these apps. However, this study included only 5 papers published before 2021, resulting in limited evidence that does not comprehensively reflect the full scope of the field. Shetty et al [19] reviewed studies on interventions for unintentional injuries in children from 2013 to 2023, including 9 eHealth-based studies; however, they similarly failed to provide detailed descriptions of the technologies' features. Overall, there remains a lack of systematic reviews that comprehensively describe the current status of mHealth technology applications, the types of technologies, and the effectiveness of interventions for preventing unintentional injuries among children.

Objectives

This study aims to provide a systematic review of the current status of mHealth technology applications in interventions for unintentional injuries in children. The primary objectives are to (1) summarize the types of mHealth technologies used for unintentional injuries in children through a systematic review of the existing literature and (2) examine how these technologies are used in interventions for unintentional injuries in children, what the outcome measures of these interventions are, and how effective these interventions are.

Methods

The study followed the Joanna Briggs Institute Manual for Scoping Reviews Framework and the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews; Multimedia Appendix 1) [20]. The protocol was registered in Open Science Framework.

Defining Research Questions

The review was guided by the following research questions:

1. What mHealth technologies are used in interventions for unintentional injuries among children? Which technologies are currently available?
2. What are the target populations and intervention content of studies on mHealth technology-based interventions?
3. What are the outcome measures for mHealth technologies?

XSL•FO
RenderX

4. How effective are mHealth technologies in preventing unintentional injuries among children?

Definition of mHealth Technology

The concept of mHealth originates from eHealth, which refers to the use of information and communication technology to support health care services and information dissemination [21]. With the widespread adoption of smartphones and tablets, eHealth services—which previously relied on fixed devices or locations—are gradually shifting toward mobile devices as their primary platform. This study follows the World Health Organization's definition, which defines mHealth as health care and public health practices supported by mobile devices [9]. Whether a technology falls under the category of mHealth is primarily determined by whether it is accessed via mobile devices such as smartphones and tablets. Accordingly, in addition to common apps and wearable devices, this study includes within the scope of mHealth any technology accessed or operated through mobile portable devices, such as internet platforms, serious games, and virtual reality (VR) technology.

Search Strategy

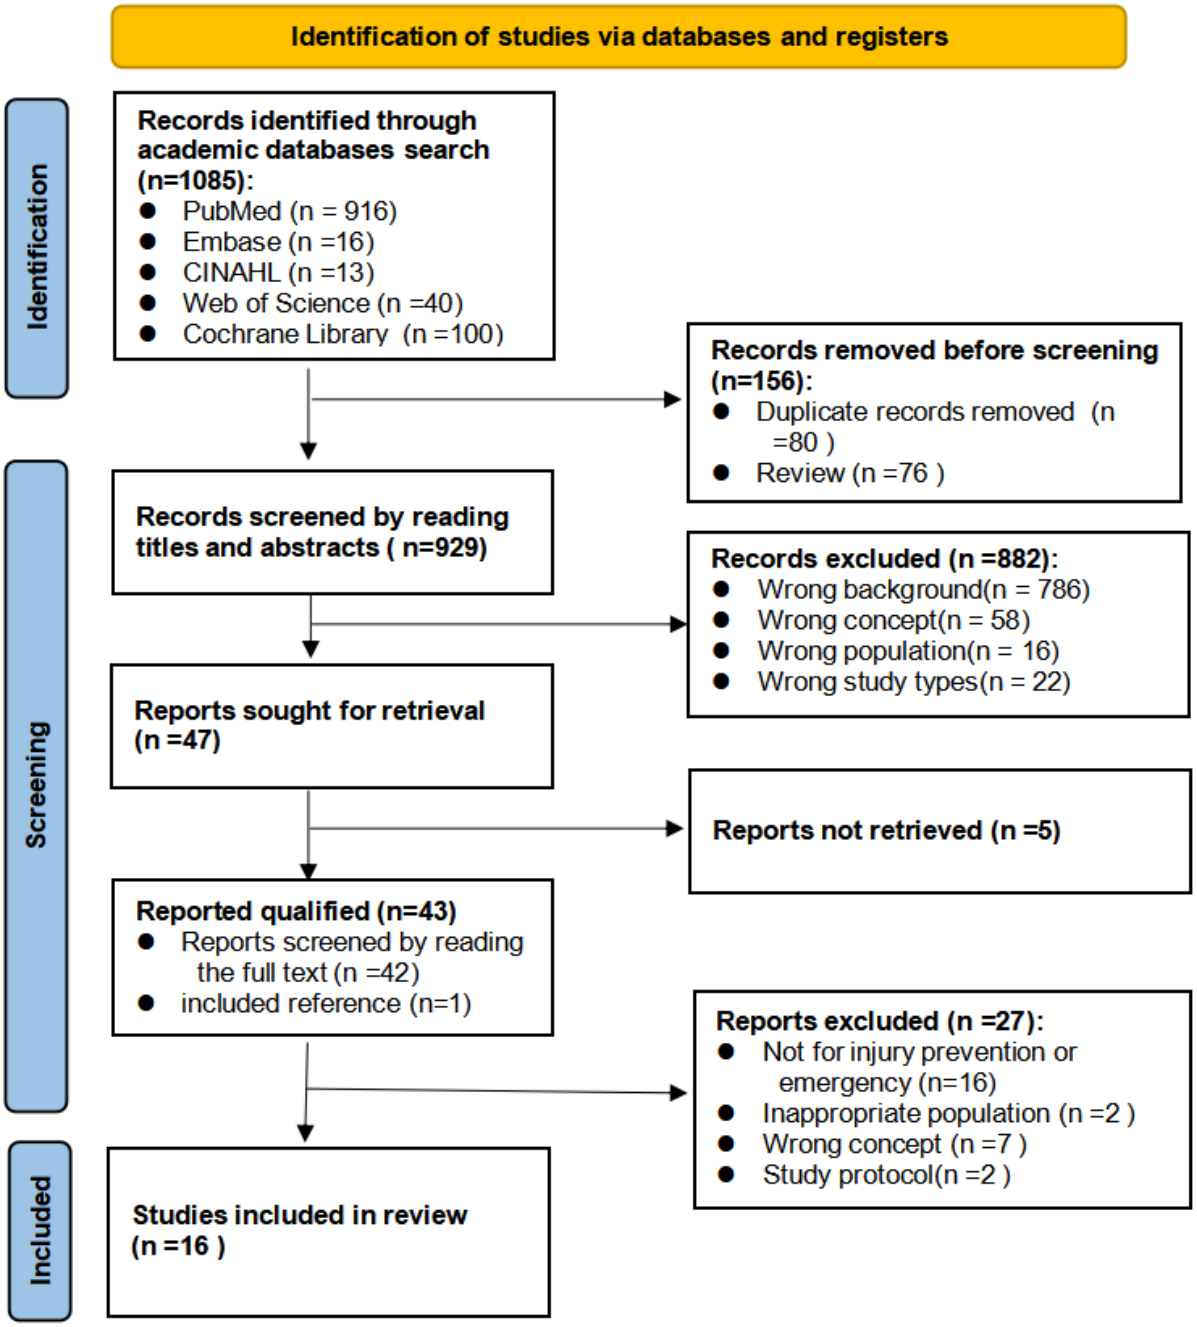
A systematic search was conducted across 5 databases: PubMed, Web of Science, Embase, Cochrane Library, and CINAHL. A combination of subject headings and free-text terms was used, with additional reference tracing. The search covers each database from its inception to December 31, 2025. Search terms included "children," "child," "infant," "child, preschool," "accidental injuries," "unintentional injuries," "accidental," "injuries," "mobile applications," "app," "mobile phone," "social media," "digital health," "digital media," "telemedicine," "internet," "text messaging," "virtual," "digital technology," "artificial intelligence," "Web," "WeChat," "online social network," "message," and "smartphone." The search terms and strategy used are presented in Multimedia Appendix 2.

Literature Inclusion and Exclusion Criteria

Literature inclusion criteria were established based on population, concept, and context principles: (1) the study population comprised children, child caregivers, or child educators; (2) the study concept involved mHealth technology research; (3) the context pertained to studies related to unintentional injuries among children. The study types included original research such as randomized controlled trials, quasi-experimental studies, mixed method studies, and observational studies. Exclusion criteria were as follows: (1) duplicate publications; (2) if there are multiple papers reporting on the same study, only the one reporting the final results will be included; (3) study protocols; (4) publications for which the full text is unavailable; and (5) publications not in Chinese or English.

Literature Screening and Data Extraction

Literature screening was conducted using NoteExpress software (version 4.1.0.10030; Beijing Aegean Software), with 2 researchers independently performing initial and duplicate screening. Disagreements were resolved through discussion with a third researcher. Extracted data included authors, publication year, country, study type, study subjects, sample size, app type, study duration, specific implementation methods, control group measures, and outcome measures.



Results

Literature Search Results

The initial search yielded 1085 articles. After removing duplicates and reviews, 929 articles remained. Following a review of titles and abstracts, 882 articles were excluded. After reviewing the full texts, 25 articles were excluded for irrelevant research topics, 2 were excluded as protocols, and 5 could not be retrieved. There were 15 remaining articles, and 1 article was included through reference tracing. Finally, a total of 16 articles were ultimately included. The literature screening process is illustrated in Figure 1.

XSL•FO
RenderX

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analysis) flow diagram.

Basic Characteristics of Included Literature

All included studies were in English. The collection comprised 9 randomized controlled trials [15,17,22-28], 2 quasi-experimental studies [29,30], 3 mixed method studies [16,31,32], 1 qualitative study [33], and 1 descriptive study [34]. Geographically, 6 studies were from China [15,17,25,26,28,30], 3 from the United States [23,24,32], 1 from South Korea [22,29,34], 2 from Australia [16,27], and 1 each from the United Kingdom [33] and Germany [31]. Specific characteristics are shown in Multimedia Appendix 3.

Types of mHealth Technologies

Mobile Apps

Twelve studies [16,17,23-25,27-29,31-34] used apps as their delivery platform. Among these, 6 apps [16,17,23,25,27,28,33,34] were specifically developed by the research teams to meet their own research needs. Ning et al [25] and He et al [28] used the same app (Bao Hu San, Protective Umbrella), which was developed by Ning et al [25] for injury prevention education among urban child caregivers; He et al [28] adapted and improved it based on that study to address rural conditions. The game app Safe City, developed by Wong et al [17], is designed to help children develop proper traffic safety behaviors. This app is currently available for download via a web browser, but users must provide a mobile phone

XSL•FO
RenderX

number to register. The apps developed by Kang et al [34] and Jones et al [33] provide education on the prevention of unintentional injuries to schoolteachers and mothers, respectively; however, all of them are currently in the development and usability testing phases. A total of 4 apps [24,27,29,31,32] have been developed by relevant organizations in advance. The app used by McKenzie et al [24] and Roberts et al [32] (Make Safe Happen) was developed by the US Centers for Injury Prevention and Control and is specifically designed for parents of children aged 0 to 12 years. Its features include age-appropriate safety information, room safety checklists, links to purchase safety products, the ability to create shopping lists and set calendar reminders, and the option to add a poison control hotline to phone contacts with a single tap. However, this app is no longer being updated and is unavailable for download. The app used in the study by Kim and Cho [29] was developed by the South Korean Ministry of Education to help children handle emergencies they might encounter at school or in daily life; the download link was provided in the literature but is currently unavailable. Müller et al [31] conducted an evaluation of the Vergiftungsunfalle bei Kindern ("child poisoning accidents") app, developed by the German Federal Institute for Risk Assessment in 2013. This app is designed for caregivers and primarily provides information on toxic substances, prevention advice, and emergency call functions. This app is currently available for download on the Google Play Store and the App Store. The Cool Runnings app, used in the study by Burgess et al [27], was developed by a research team at the University of Queensland's Center for Pediatric Burns and Trauma to raise mothers' awareness of scald injuries from hot beverages and improve their emergency response capabilities; however, the app is no longer being updated and is unavailable for download.

WeChat

Two studies [15,26] used WeChat to provide relevant resources for child caregivers. Feng et al [15] established WeChat groups and an official account to provide caregivers with resources on injury prevention; the WeChat official account registered for this study is currently searchable but is no longer being updated. In the other study, Yan et al [26] provided on-site training to child caregivers at schools and subsequently used WeChat groups to regularly distribute learning materials on child restraint systems.

Mobile-Based e-Learning Program

Choi and Ahn [22] developed an e-learning program using Storyline 360 e-learning software and generated a course link. The course includes videos, audio, and slides, and parents can access the link via computers, tablets, and smartphones to study at their convenience. In addition, the course supports repeat viewing and progress tracking, allowing caregivers to review the material whenever needed. This program is not available to the public.

Mobile-based VR technology and wearable devices: Schwebel et al [30] developed a VR pedestrian safety training system. This system uses a smartphone as both the platform for running VR content and the display device; the smartphone is inserted into a Viewmaster VR stereoscopic display equipped with goggles and a joystick to run a virtual crosswalk environment. Children undergo 12 days of repeated crossing training in the classroom. The system provides immediate feedback based on their crossing performance and automatically records behavioral data such as collisions and unsafe crossings. This technology is currently still in the experimental stage and has not yet been made available to the public.

Study Duration and Follow-Up Periods

The duration of the included studies varied. Specifically, for studies assessing mHealth interventions, the intervention periods ranged from 1 week to 12 months. In contrast, among studies adopting observational or cross-sectional designs, only 2 reported the study duration: 7-10 days [32] and 3 months [16], respectively.

Target Population

Eleven studies [15,16,22,24-28,31-33] focused on caregivers of children, covering those caring for children aged 0 to 12 years; 4 studies [17,23,29,30] targeted children directly, with participants ranging in age from 5 to 13 years; and 1 study [34] was conducted with schoolteachers.

Injury Type Addressed

Nine studies [15,22,24,25,28,29,32-34] addressed unintentional injuries as a whole, including common types such as choking, aspiration, falls, poisoning, drowning, and burns. The remaining 7 studies focused on specific types of injuries, including 2 on traffic accidents [17,26], 1 on burns and scalds [27], 1 on accidental falls among infants [16], 1 on accidental poisoning [31], and 1 on the prevention of bicycle injuries and animal bites [23].

Theoretical Framework

The included studies drew upon behavior change theory [16,23], Orem's self-care theory [29], and the Haddon model [15] to guide the design of learning content; Choi and Ahn [22] designed their learning program based on the analysis, design, development, implementation, and evaluation (ADDIE) model; Wong et al [17] developed a game app by integrating social cognitive theory with an experiential game model; Ning et al [25] designed an app by combining behavior change theory, the Haddon model, and the rational analysis framework for mobile education; Müller et al [31] evaluated the app's perceived usefulness, perceived ease of use, trust, and intention to use based on the technology acceptance model.

Intervention Content

Health Education

A total of 15 studies [15-17,22-29,31-34] used mHealth technologies to deliver health education on unintentional injuries to children and caregivers via text, images, audio, video, and games. The interventions included raising awareness of injuries, changing attitudes or beliefs regarding injury supervision, providing home environment checklists and hazard-identification tools, disseminating knowledge and skills on prevention, and teaching emergency response methods following an incident. The curriculum designed by Choi and Ahn [22] covered 6 scenarios: the bedroom, living room, bathroom, kitchen,

XSL•FO
RenderX

outdoors, and inside a vehicle. Each scenario included prevention knowledge for injury types such as choking, aspiration, falls, poisoning, physical injuries, drowning, and burns. The program also provided information on safety products but did not include purchase links. Ning et al [25] and He et al [28] used the same app to provide education on unintentional injuries to caregivers of urban and rural children, respectively. The Make Safe Happen program used by McKenzie et al [24] and Roberts et al [32] categorizes children by age into 5 groups: 0 to 11 months, 12 to 23 months, 2 to 4 years, 5 to 9 years, and 10 to 12 years. It develops personalized safety information tailored to the types of injuries most common in each age group and provides home environment checklists to help caregivers identify potential hazards. Feng et al [15] conducted a study that used WeChat groups and official accounts to regularly send weekly updates to parents regarding the prevention of common childhood accidents, aiming to enhance their awareness of such injuries. Wong et al [17], Burgess et al [27], and Dixon et al [23] incorporated game-based simulations of relevant scenarios to improve caregivers' or children's awareness of and ability to prevent unintentional injuries. Furthermore, Cooray et al [16] focused on the differences in fall risks between infants and children over 1 year of age. They provided caregivers with customized safety information centered on four themes—safe feeding, furniture use, infant product safety, and the environment—demonstrating a personalized educational strategy tailored to population characteristics, which further highlights the refinement and personalization of health education.

Interactive Communication

Five studies [15,16,23,25,28] provided communication support channels via mHealth technology for caregivers of children. Through these platforms, caregivers can raise questions encountered while implementing accident prevention measures in user forums, discussion areas, or expert consultation channels, and receive insights from experienced caregivers or targeted guidance and answers from health care professionals and researchers. Ning et al [25] focused on facilitating mutual communication among users and between users and researchers. Building on this, He et al [28] optimized expert consultation and customer service functions, added online forums and themed activities, and strengthened interactions among researchers, experts, and caregivers. Feng et al [15] collected caregivers' questions via WeChat groups, with community doctors providing responses within 48 hours to ensure timely guidance. Cooray et al [16] focused on collaborative communication, with researchers and caregivers jointly developing emergency response plans to enable rapid and effective action in the event of an infant fall. Dixon et al [23] encouraged increased communication between children and their caregivers regarding the prevention of bicycle injuries and pet bites.

Behavioral Training

Five studies [17,23,26,27,30] used mHealth technologies—such as WeChat, smartphone-based VR systems, and gaming apps—to deliver injury prevention training to children and caregivers. The content included safe road-crossing skills for children, proper child safety seat installation methods for caregivers, and the identification and management of household safety hazards. Schwebel et al [30] used a smartphone-based VR system to train children's road-crossing behavior, enabling their performance to meet adult standards. Wong et al [17] used a game to simulate road-crossing scenarios and train children's safety behaviors; to prevent game addiction, the study implemented an energy-point mechanism that required a 2-hour wait before restarting once energy was depleted. Dixon et al [23] combined an app with a game to simulate street environments, indoor and outdoor residential settings, animal shelters, and parks, requiring children to learn and practice safe cycling skills and how to interact with animals while responding to various risk scenarios. Burgess et al [27] used gamification techniques to help caregivers master measures to prevent accidental poisoning and burns in children.

Monitoring and Reminders

Six studies [16,24,27,29,32,34] used mobile apps or WeChat to monitor and provide reminders about the safety behaviors or learning progress of children and their caregivers. McKenzie et al [24] and Roberts et al [32] guided caregivers to set up reminders in the app for testing and replacing safety equipment and monitored their implementation. Kim and Cho [29] established a classroom log system within the app, requiring students to record their completion of the previous day's learning tasks daily. Cooray et al [16] used task tracking lists and progress dashboards to show parents the completion status of safety tasks and sent regular SMS text message reminders prompting users to read relevant articles. Burgess et al [27] required caregivers to upload photos of home equipment between push notifications to assess the safety status of the equipment, and to complete pop-up quizzes to reinforce injury prevention knowledge. Kang et al [34] designed a child safety checklist for teachers to use for self-assessment of safety behaviors, with the system providing feedback through colors or markers.

Other Intervention Components

In terms of data collection and user settings, 2 studies [25,28] used mobile platforms to collect data on childhood accidents, survey responses, and user feedback online. Among these, Bao Hu San [25,28] also allowed users to customize the app interface to suit their personal preferences, thereby enhancing user satisfaction. Regarding emergency features, Make Safe Happen [24,32] included a poison control hotline that could be added to a user's phone contacts with a single tap; Jones et al [33] provided emergency phone numbers for caregivers to look up; and Müller et al [31] included a 1-tap button to call a poison control center and provided guidelines for pediatric care to help caregivers seek immediate medical assistance.

Outcome Measures and App Effectiveness

Overview

The studies included in this review used various methods to evaluate the effectiveness of mHealth technology interventions, including researcher-designed questionnaires, participant self-reports, and individual or focus group interviews. Consequently, there were significant variations in the naming and measurement of outcome measures. For ease of presentation, this study categorized these measures into 5 groups.

XSL•FO
RenderX

Incidence of unintentional injuries among children

Three studies [15,25,28] measured the incidence of unintentional injuries in children as the primary outcome, using caregivers' self-reported data for statistical analysis. Among these, He et al [28] and Feng et al [15] both found that the incidence of unintentional injuries in the intervention group was lower than that in the control group after the intervention was completed; however, the incidence of falls in the intervention group led by He et al [28] was slightly higher than that in the control group (adjusted risk ratio 1.17, 95% CI 1.06-1.30); whereas in the 6-month follow-up period reported by Ning et al [25], although the incidence in the intervention group decreased from 8.76% to 8.11%, the difference was not statistically significant (P=.59).

Knowledge, Attitudes, and Behaviors

Knowledge Level

Eight studies [15,17,22-24,26,27,29] measured knowledge level as one of the outcome indicators, primarily including awareness of unintentional injuries [22], knowledge of prevention and safety [17,23,24], knowledge of child restraint system use [26], and first aid knowledge in the event of an accident [15,27,29]. All were assessed using questionnaires designed by the researchers. Among these, the studies by Choi and Ahn [22], Feng et al [15], and Wong et al [17] did not observe any significant statistical differences.

Attitudes

Three studies [25,26,28] used attitude levels as outcome measures, including caregivers' attitudes toward accident prevention [25,28] and the use of child restraint systems [26]. Among these 3 studies, only the study by Ning et al [25] did not show statistically significant differences.

Behavior

Eleven studies [15-17,22-26,28,30,32] used behavioral competence of children and their caregivers as one of the outcome measures, including injury prevention and safety behaviors [17,22-25,32], caregiver supervision behaviors [15,28], traffic safety behaviors [30], use of child restraint systems [26], and behaviors with the potential to reduce the risk of infant falls [16]. Regarding the measurement of this outcome indicator, with the exception of Wong et al [17], who observed no significant differences, all other studies reported statistically significant differences.

Psychosocial Outcomes

Wong et al [17] used the Strengths and Difficulties Questionnaire to assess psychosocial problems in children. While the study did not observe statistically significant changes in these outcomes following the intervention, an analysis of the dose-response relationship revealed that cumulative game scores were associated with improvements in internalizing problems at the 3-month mark of the intervention, suggesting that serious games can enhance children's psychosocial functioning. Feng et al [15] assessed improvements in caregivers' beliefs regarding the prevention of unintentional injuries following the intervention. This indicator was divided into 3 components based on relevant literature: injury attribution beliefs, preventability beliefs, and responsibility beliefs. The results showed that mHealth technology can improve caregivers' beliefs regarding the preventability of unintentional injuries (β=.344, 95% CI 0.152-0.537; P<.001). Schwebel et al [30] measured children's self-efficacy when crossing the street using both questionnaires and behavioral observations. The study showed that the proportion of children able to safely cross busy streets increased from 3.6% to 19.6% (odds ratio [OR] 4.7; P=.002).

Other Indicators

Other indicators included home environment safety (β=3.38, 95% CI 2.51-4.16; P<.001) [28], the use rate of child restraint systems (OR 0.29, 95% CI 0.11-0.79; P=.016) [26], and caregivers' awareness of injury prevention (which increased significantly from 63% before the intervention to 81%, P<.01) [32]. Additionally, 2 studies [16,32] identified barriers and facilitators to caregivers' adoption of unintentional injury prevention measures through focus group interviews. Both studies indicated that simplifying tasks and increasing app reminders and feedback features could promote the implementation of injury prevention measures; conversely, incomplete functional content, impractical recommendations, time constraints, high costs, cumbersome tasks, and a lack of family support hindered their implementation.

Usability of mHealth Technologies

Eleven studies [15-17,22-26,28,30,32] reported metrics related to mHealth technologies, primarily including user satisfaction [22,26,34], user engagement [16,23,27,32,33], user experience [30-33], user acceptance [16,23], the educational effectiveness of smartphones (frequency, practicality, interest, and ease of understanding) [29], economic losses resulting from childhood accidents [25], and the economic costs of the apps [15,25], as well as the identification of facilitators and barriers affecting user acceptance through targeted individual interviews [31]. The specific results are presented in Multimedia Appendix 3.

Discussion

Overview of mHealth Technologies for Unintentional Childhood Injuries

The results of this study indicate that mHealth technologies currently used in the field of unintentional childhood injuries include mobile apps, WeChat, mobile-based e-learning programs, VR technology, and wearable devices. Apps and WeChat are primarily targeted at child caregivers, as their busy daily schedules make it difficult to set aside time for in-person training. Apps and WeChat platforms offer convenience and quick access to health information, helping caregivers learn in spare moments or obtain necessary information promptly when needed. Among the mobile apps included in this study, with the exception of the 3 apps cited by Wong et al [17], Dixon et al [23], and Kim and Cho [29], all others were designed for child caregivers, with one specifically targeting teachers. In terms of functional design, health education or regular learning content is primarily delivered through audio, video, text, images, and gamified formats; user forums or comment sections facilitate interaction between users and researchers or health care professionals; check-in features and progress bars are used to monitor users' learning progress and adherence to safety

XSL•FO
RenderX

measures; additionally, some apps include emergency contact information or links to purchase safety products. The results of this study indicate that participants demonstrated high levels of engagement, acceptance, satisfaction, and positive user experience with the apps they used. For children, games and VR technology are currently widely adopted. This study included 2 gaming apps, one VR app combined with wearable devices, and one health education-focused app. Key features included simulations of real-world environments such as streets, residential areas, dog shelters, and parks, designed to help children develop appropriate safety behaviors and prevent traffic accidents and pet bites. The health education-focused app provides children with emergency response knowledge for various situations, covering 8 categories of emergency scenarios: school safety, off-campus safety, responding to violent incidents, traffic accidents, accidental poisoning, basic first aid skills, natural disasters, and evacuation drills—totaling 48 specific emergencies. Each scenario includes a brief description and response recommendations, with some supplemented by instructional videos. Compared with traditional lecture-style education, children demonstrate greater acceptance of this engaging, interactive learning method.

Positive Effects and Development Requirements

This study describes the effectiveness of mHealth-based interventions in preventing unintentional injuries among children. The results indicate that such interventions have a positive impact on reducing the incidence of unintentional injuries among children, enhancing the safety knowledge of children and caregivers, and improving their safety attitudes and behaviors. However, among the mHealth technologies currently used for interventions targeting unintentional injuries in children, only the Vergiftungsunfälle bei Kindern and Safe City apps are available for download and use via app stores or web browsers. The remaining technologies are either not publicly released or have ceased to be updated and maintained. The development and long-term maintenance of mHealth apps require significant investments of time, effort, and funding, while the actual social and health benefits are relatively limited, making it difficult for many projects to sustain operations [35]. Furthermore, mHealth technologies can overcome spatial and temporal constraints and address the shortfall of caregivers who are unable to participate in in-person training due to time constraints through online interventions. The online intervention model itself may experience low user adherence, with some users potentially losing motivation to continue participating after initial use [36]. Although this study did not assess user adherence, based on the dropout rates reported by Feng et al (24.38%) [15], Ning et al (32.19%) [25], and Burgess et al (51%) [27], long-term user adherence may be relatively low, which could be one of the reasons why mHealth programs fail to operate sustainably over the long term. The World Health Organization advocates that countries incorporate mHealth into their national public health strategies [37]. The “Action Plan for Injury Prevention and Control (2026-2030)” issued by China’s National Center for Disease Control and Prevention also emphasizes exploring and promoting appropriate technologies and strengthening education on child injury prevention and control skills, providing clear policy guidance for mHealth interventions. Therefore, it is recommended that future research leverage national public health programs to conduct long-term, large-scale studies on mHealth technologies. Relying on the public health system to overcome cost and adherence barriers can promote the sustainable application of mHealth interventions.

Outcome Measures and Assessment Tools

Regarding the evaluation of the effectiveness of mHealth technologies, most studies have focused on caregivers’ knowledge, attitudes, and behaviors as primary outcome measures, while only 3 studies have primarily examined the incidence of unintentional injuries in children. The occurrence of unintentional injuries in children is influenced by multiple factors, including the home environment, the level of supervision, and the child’s developmental stage. To detect statistically significant differences, large sample sizes and long-term follow-up may be required, resulting in high research costs and significant implementation challenges [38,39]. Most of the studies included in this review had sample sizes ranging from 100 to 200 participants, with intervention durations of approximately 1 week to 3 months, which may not meet the basic requirements for conducting effective statistical tests for this outcome. Furthermore, regarding the selection of assessment tools, the studies included in this review all used self-developed or adapted questionnaires. Since the data rely on self-reports from caregivers, there is potential for bias and subjectivity, which may lead to a lack of comparability across study results [35,40]. Regarding the assessment of mHealth technology usability metrics, the literature included in this study generally reported favorable evaluations of these metrics by children and their caregivers across multiple dimensions, including user acceptance, engagement, user experience, and satisfaction. However, these evaluations were also largely based on assessment tools and criteria developed by the researchers themselves, lacking uniformity and comparability. Only the studies by Kang et al [34] and Müller et al [31] conducted standardized assessments of app usability and user satisfaction using the validated User Interaction Satisfaction Scale and the System Usability Scale, respectively. Currently, the academic community has developed a variety of assessment tools with good reliability and validity for the systematic evaluation of the usability of mHealth technologies. Therefore, it is recommended that future studies adopt these standardized, validated assessment questionnaires wherever possible to enhance the scientific rigor and comparability of research findings [41].

Limitations

This study is a scoping review, so the quality of the included literature was not assessed. Additionally, the literature search was limited to English-language publications, which may have led to incomplete coverage of studies from certain regions or specific populations. Finally, this study focused on research that has been officially published and contains complete methodological information; gray literature, which often exists in the form of preliminary abstracts or unpublished data, usually does not meet the inclusion criteria for this review, so it was not systematically searched.

RenderX

Conclusions

This study provides a scoping review of the current use of mHealth technologies for the prevention and control of unintentional injuries among children. The findings indicate that mHealth technologies play a positive role in improving the knowledge, attitudes, and behaviors of children and their caregivers regarding unintentional injuries. However, only 2 mobile apps are currently available to the public. It is recommended that future efforts continue to optimize the functional design of mHealth, strengthen the technology's sustainability, explore methods that can be implemented over the long term, and conduct large-scale, long-term studies to further evaluate the impact of mHealth on the incidence of unintentional injuries among children.

Funding

This study is jointly supported by 3 research projects, 2 of which are funded by the Mianyang Municipal Federation of Social Sciences: the Special Research Project on Vocational Education, named Job Content Analysis of Infection Prevention and Control Nurses in Northwestern Sichuan and Development of a Competency-Based Training Program (grant MY2025ZX686), and the General Project, named A Survey on the Current Status of Family First-Aid Competence for Infant Unintentional Injuries in Mianyang and a Progressive Intervention Strategy Based on Social Cognitive Theory (grant MY2026YB151). The third project is funded by the Chuanbei Health Humanities Research Program under the Nanchong Municipal Social Science Planning Project (grant NC26CB16).

Abstract

Background: Cardiovascular diseases remain a major global health burden, highlighting the need for long-term physiological monitoring. Photoplethysmography (PPG) is widely used in wearable devices for noninvasive monitoring of heart rate (HR), rhythm, and oxygen saturation in mobile health (mHealth) apps. However, the reliability of wearable reflectance PPG depends on sensing conditions, including sensor-skin contact force and pressure.

Objective: This scoping review maps how contact force and contact pressure have been defined, controlled, measured, represented, and reported in wearable or wearable-relevant reflectance PPG studies; characterizes the reported signal-, waveform-, feature-, and task-level responses under different contact conditions; and identifies methodological and evidence gaps.

Methods: A comprehensive literature search was conducted in PubMed, IEEE Xplore, Scopus (Elsevier), and Web of Science Core Collection (Clarivate) from database inception to June 1, 2026. Studies were eligible if they addressed contact force or contact pressure in wearable or wearable-relevant reflectance PPG and reported measurement approaches, measurement sites and device configurations, force or pressure representation, or PPG responses across signal quality, waveform and feature characteristics, and downstream physiological estimation. Database filters were applied, where available, to restrict results to English-language publications. Search results were imported into EndNote for deduplication. Database searches were supplemented by reference-list screening. After screening, 53 reports were sought for retrieval; 1 was not retrieved, 52 were assessed at full text, and 21 studies met the inclusion criteria.

Results: The 21 included studies showed substantial heterogeneity, with sample sizes ranging from single-participant experiments to a wrist PPG dataset including 1142 participants. Most human studies recruited healthy volunteers, whereas some used public datasets or tissue-vessel phantoms, and 1 combined theoretical modeling with human-participant validation. The mapped evidence identified contact force and contact pressure as important measurement conditions in wearable reflectance PPG. Across the included studies, different contact conditions were associated with changes in alternating current/direct current components, amplitude- and morphology-related features, derivative-based indices, wavelength-dependent responses, and fiducial-point detection. Several studies also examined downstream physiological tasks, including HR, oxygen saturation, pulse transit or arrival time, blood pressure–related estimates, and HR variability.

Conclusions: The evidence mapped in this scoping review supports a multilevel conceptual pathway in wearable reflectance PPG, in which mechanical conditions at the sensor-skin interface are associated with changes in PPG signal characteristics, derived features, and, in a smaller body of studies, downstream physiological estimation. Evidence remains limited by small samples, short-term controlled protocols, and inconsistent reporting of mechanical parameters, including units, contact area, and probe geometry. Insufficient population diversity and limited free-living validation further restrict generalizability. Future research should standardize reporting of contact conditions and device geometry, incorporate real-world validation, and develop force-aware signal-quality assessment algorithms, adaptive attachment designs, and context-aware models to improve mHealth and cardiovascular monitoring.

KEYWORDS

contact force; contact pressure; wearable photoplethysmography; reflectance photoplethysmography; signal quality; waveform morphology; artifact susceptibility; temporal stability; physiological parameter estimation

Introduction

Background

Cardiovascular diseases remain a major cause of morbidity, mortality, and health care burden worldwide [1,2]. As many cardiovascular conditions may remain asymptomatic in their early stages, timely risk identification and intervention are critical for improving outcomes and preventing disease progression [3,4]. However, current screening and diagnostic approaches still largely depend on professional medical settings and centralized equipment, limiting their accessibility for long-term follow-up and routine management. Therefore, scalable and low-cost digital health technologies for continuous monitoring are increasingly important in cardiovascular disease prevention and management [5]. In this context, photoplethysmography (PPG) has become one of the most widely used sensing modalities in digital health and mobile health (mHealth) apps because of its noninvasive nature, convenience, and suitability for long-term use.

By optically detecting pulsatile blood volume changes, PPG can support the assessment of heart rate (HR), oxygen saturation, blood perfusion, and certain vascular function–related indices [6]. With advances in sensors, wearable devices, and artificial intelligence [7], PPG has expanded from traditional pulse and oxygen saturation monitoring to broader applications such as HR monitoring [8], blood pressure (BP) assessment, oxygen saturation estimation [9], and cardiovascular health monitoring. With the rapid development of wearable technologies, PPG has been widely integrated into smartwatches, wristbands, patches, and other devices for continuous and noninvasive health monitoring [10-12]. In homes, communities, and other nonclinical settings, these wearable PPG systems offer practical advantages for remote monitoring and proactive health management, highlighting their strong potential for large-scale cardiovascular health assessment [5].

At the same time, the effectiveness of PPG in wearable applications is fundamentally constrained by signal quality, which in turn is highly dependent on specific sensing conditions, including sensor geometry, the skin-sensor interface, ambient light, contact force, and measurement-site characteristics [13,14]. Previous studies have identified contact force and contact pressure as relevant interface conditions associated with differences in sensor-skin coupling, local vascular loading, waveform quality, and downstream interpretability [13,15]. However, contact force has often been treated as a secondary issue. In practice, sensor-skin pressure is not constant and changes with wearing conditions. Too little contact force weakens mechanical coupling, facilitates relative motion, and increases susceptibility to ambient light and random noise. Excessive contact force can compress superficial vessels and capillary beds, alter local microcirculation, suppress pulsatile blood-volume changes, and distort the waveform [16]. Across analytical levels, contact conditions have been reported in relation to differences in alternating current/direct current (AC/DC) components, waveform morphology, signal-quality indices, and feature stability [16,17]. In wearable settings, these differences have also been examined alongside posture, motion, tissue deformation, strap fit, and downstream tasks, including peripheral oxygen saturation (SpO_2) estimation [15,18,19], heart-rate monitoring, heart rate variability (HRV) analysis, pulse arrival time (PAT)/pulse transit time (PTT) extraction, blood pressure modeling, and other PPG-driven applications [15,20,21].

Related Reviews

To position this scoping review within the existing literature, we reviewed representative PPG-related reviews published over the past decade. Existing reviews have addressed PPG from several perspectives, including its physiological basis, waveform characteristics, signal processing methods, and applications in HR, BP, oxygen saturation, and arrhythmia detection [7-10,22-29]. Other reviews have focused on wearable PPG devices, summarizing sensor structures, measurement sites, device forms, system architectures, and application scenarios [30-34]. In addition, some reviews have discussed PPG signal analysis from the perspectives of signal quality, artifact sources, dataset resources, and algorithmic tools [7,29,35-37]. Overall, these reviews have mainly approached PPG from the perspectives of signal technology, wearable implementation, signal quality, or downstream physiological applications. Existing reviews have acknowledged contact pressure, wearing tightness, and sensor-skin interface stability as factors related to PPG measurement quality [29-32], but these issues have generally been treated as secondary acquisition considerations within broader discussions of wearable devices, signal quality, or physiological applications. As a result, limited attention has been given to how contact force and contact pressure are defined, measured, controlled, represented, and reported across wearable reflectance PPG studies. This scoping review addresses this gap by using contact force and contact pressure as the central organizing concepts and mapping measurement and control approaches, anatomical sites, device configurations, reporting practices, and corresponding PPG responses across signal quality, waveform characteristics, derived features, and downstream physiological estimation. It further examines the distribution of evidence across populations, experimental contexts, and protocol durations to clarify the methodological structure of the field and identify areas in which evidence remains limited.

Objectives

This scoping review aimed to map and characterize the existing literature on contact force and contact pressure in wearable reflectance PPG. The review was guided by the following research questions: (1) How have contact force and contact

XSL•FO
RenderX

pressure been defined, applied, controlled, measured, estimated, and reported in wearable reflectance PPG studies? (2) Which signal-level, waveform-level, feature-level, signal-quality, and task-level outcomes have been investigated under different contact conditions? (3) How is the available evidence distributed across measurement sites, sensor configurations, study populations, experimental settings, and outcome categories? In addition, this review aimed to identify current evidence gaps and methodological challenges to inform future force-aware wearable PPG acquisition, sensor-skin interface design, algorithm development, and standardization in wearable cardiovascular monitoring.

Methods

Protocol and Registration

No review protocol was registered or publicly published for this scoping review. The eligibility criteria, information sources, search strategy, study-selection procedures, and initial data-charting framework were established before full-text screening. The data-charting categories were subsequently refined iteratively during data extraction as familiarity with the terminology, methodological diversity, and outcome categories of the included studies increased. The final review methods are reported in this section and Multimedia Appendices 1-3.

Study Design

This study used a scoping review methodology to address the breadth and heterogeneity of the available evidence on contact force and contact pressure in wearable reflectance PPG. The review mapped how these contact conditions were defined, measured, and reported, together with the associated PPG outcomes and evidence gaps. The review was conducted following the framework proposed by Arksey and O'Malley [38] and was reported in accordance with the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) checklist (Multimedia Appendix 1) [39]. In addition, the literature search was reported according to the PRISMA-S (Preferred Reporting Items for Systematic Reviews and Meta-Analyses literature search extension; Multimedia Appendix 2) [40] checklist to strengthen the transparency and reproducibility of the search process.

Eligibility Criteria

Inclusion Criteria

Peer-reviewed journal articles and conference proceedings published in English were considered for inclusion. Eligible studies were required to examine or report contact force, contact pressure, or related sensor-skin interface conditions in wearable or wearable-relevant reflectance PPG and to provide relevant evidence on methodological characteristics, including measurement sites and device configurations, and PPG outcomes across signal-quality, waveform, feature, artifact-susceptibility, and downstream-task domains. Specifically, studies were required to meet all 3 core criteria: (1) the study must involve contact force, contact pressure, or sensor-skin interface conditions (including direct measurement, controlled application, or qualitative description); (2) the study must use wearable or wearable-relevant reflectance-mode PPG systems; and (3) the study must report at least one PPG-related methodological characteristic or outcome that was observed under, compared across, or interpreted in relation to the contact condition. In this review, contact force refers to the total mechanical load applied at the sensor-skin interface, whereas contact pressure refers to the distribution of that load over the effective contact area. Terms and units were retained as reported by the source studies and were not treated as interchangeable unless sufficient contact-area or geometric information was available.

Exclusion Criteria

Non–peer-reviewed publications, non-English articles, and studies without accessible full text were excluded. Studies were further excluded if they met 1 or more of the following criteria: (1) did not address contact force, contact pressure, or sensor-skin interface–related factors in the context of PPG signal acquisition or analysis; (2) focused solely on transmission-mode PPG systems without clear relevance to wearable or wearable-relevant applications; or (3) were review articles, editorials, commentaries, conference abstracts, or other nonoriginal research publications.

Information Sources and Search

To identify relevant studies, a comprehensive literature search strategy was designed by the review authors and further refined through iterative discussion. The search strategy was developed with reference to PRISMA-S reporting principles and methodological recommendations from Cochrane and Joanna Briggs Institute, emphasizing the combined use of controlled vocabulary terms, free-text terms, field modifiers, and a broad range of synonyms. The search strategy was built around 3 concepts: PPG and wearable reflectance PPG; contact force/contact pressure and the sensor-skin interface; and signal quality, waveform morphology, feature extraction, and downstream physiological estimation. The strategy combined controlled vocabulary terms, where available, with free-text keywords and was first developed for PubMed before being translated to the other databases with syntax-specific adaptations. The search was conducted in PubMed, IEEE Xplore, Scopus (Elsevier), and Web of Science Core Collection (Clarivate), accessed through the university library, covering records from database inception to June 1, 2026. Search terms included concepts related to PPG, wearable-device applications, contact conditions, and relevant signal- and task-level outcomes. Database filters were applied, where available, to restrict results to English-language publications. Review articles, editorials, commentaries, conference abstracts, and other nonoriginal publications were excluded during screening because this scoping review aimed to map original research evidence. The complete database-specific search strategies are reported in Multimedia Appendix 3. All search results were exported as RIS files and imported into EndNote (Clarivate Analytics) for reference management and deduplication. Duplicate records were first identified using EndNote's automated duplicate-detection function and then checked manually. The database searches were supplemented by backward citation searching of the reference lists of included studies. Potentially relevant reports were cross-checked against the original database

XSL•FO
RenderX

exports using DOI and title information. No formal peer review of the search strategy by an information specialist or librarian was performed; however, the search strategy was iteratively reviewed by the author team and checked against PRISMA-S reporting items.

Selection of Sources of Evidence

All retrieved records were imported into EndNote for reference management, and duplicate records were removed before screening. Title and abstract screening was independently conducted by 2 reviewers (JX and ZH) to identify potentially relevant studies. Each record was assessed by both reviewers, and studies deemed relevant were subsequently subjected to full-text review. Full-text articles were independently evaluated by the same 2 reviewers according to the predefined inclusion and exclusion criteria. Any disagreements arising during the title and abstract screening or full-text review stages were resolved through discussion; if consensus could not be reached, a third reviewer (CY) was consulted for final adjudication. The reference-list entries identified through citation searching were screened by the same reviewers, and potentially relevant reports were assessed using the same inclusion and exclusion criteria applied to reports identified through the database searches. Reports were assigned to the citation-searching pathway only after confirming that they were not represented in the original database exports. Given the scoping nature of this review, the selection process aimed to map the available evidence broadly and transparently according to the predefined eligibility criteria.

Data Charting Process and Data Items

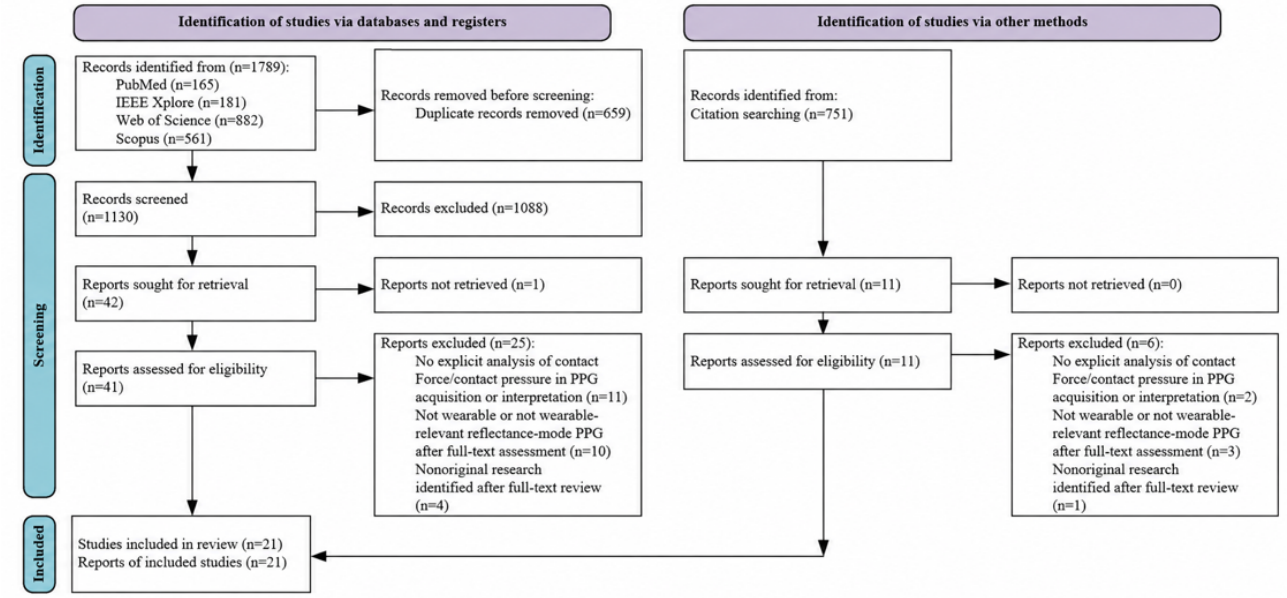
Relevant data were extracted from the included studies using a standardized data-charting approach. Extracted items covered study and publication characteristics; participant or experimental-platform characteristics; measurement sites and device configurations; contact-condition terminology, measurement or control approaches, and force or pressure representation; experimental protocols; key methodological reporting details; and reported PPG outcomes and main findings across signal and signal-quality, waveform, feature, artifact-susceptibility, and downstream-task domains. The data-charting process was iterative, allowing refinement of categories as familiarity with the literature increased. Information unavailable in the source articles was recorded as not reported.

Critical Appraisal of Individual Sources of Evidence

A formal critical appraisal of individual sources of evidence was not conducted because this scoping review aimed to map the breadth, characteristics, and methodological heterogeneity of the available evidence rather than to assess the certainty of the evidence or generate pooled effect estimates.

Synthesis of Results

To address the review questions, the charted data were first summarized using descriptive numerical analysis. Frequencies and percentages were calculated for key study, methodological, and outcome characteristics, with categories treated as nonmutually exclusive where appropriate. The individual sources of evidence were subsequently analyzed and synthesized narratively to compare methodological approaches, study contexts, and reported PPG outcomes across contact conditions. Finally, cross-study synthesis was conducted using evidence mapping, study-level linkage analysis, and study-level methodological and analytical coverage mapping to characterize the distribution, connections, and breadth of the available evidence. Owing to substantial heterogeneity in study designs, contact-condition definitions, measurement protocols, and outcome measures, a meta-analysis was not conducted.



Results

Selection of Sources of Evidence

Figure 1 presents the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram illustrating the identification, screening, eligibility assessment, and final inclusion of studies. Database searches identified 1789 records, of which 1130 remained after deduplication and were screened; 16 reports were included through the database pathway. In addition, 751 reference-list entries were screened through citation searching, resulting in 5 additional included reports. Overall, 21 studies were included in the review.

Characteristics of Sources of Evidence

Characteristics of Publication and Baseline

Multimedia Appendix 4 summarizes the baseline characteristics of the 21 included studies, including publication year, publication type, country or region, and primary study focus [15,16,18,20,21,41-56]. The included studies were published between 2006 and 2026. Of these 21 studies, 15 (71%) [15,16,20,21,42-52] were published from 2020 onward, showing that most of the included evidence was published in recent years; besides, 16 (76%) [15,16,21,41-44,46-51,53-55] were journal articles and 5 (23.8%) [18,20,45,52,56] were peer-reviewed conference papers. In terms of country or region, the included studies were mainly from the United States (6/21, 29%) [18,42,47,48,52,56], China, including Hong Kong (3/21, 14%) [15,43,54], the United Kingdom (2/21, 10%) [16,46], Finland (2/21, 10%) [20,51], and Italy (2/21, 10%) [21,49], with 1 study each from South Korea [41], Slovakia [44], Canada [45], Spain [50], Latvia [53], and Israel [55]. Country or region was summarized according to the reported study location when available; when the study location was not explicitly stated, it was assigned according to the first or corresponding author's institutional affiliation.

Characteristics of Study Designs and Research Focus

The study-level characteristics of all included sources are summarized in Multimedia Appendix 4, with additional methodological and outcome details provided in Tables 1-3 and Multimedia Appendix 5. The included studies contributed to 3 broad and nonmutually exclusive research domains: contact-condition measurement, control, sensing, or estimation; directly measured signal-, waveform-, or feature-level responses; and directly evaluated downstream wearable monitoring tasks. Of the 21 included studies, 4 (19%) [41,43-45] had a primary methodological focus, 16 (76%) [15,16,18,20,41-45,47,49-51,53,55,56] reported at least 1 directly measured signal-, waveform-, or feature-level response, and 10 (48%) [15,18,21,42,47,49,51,52,54,56] directly evaluated at least 1 downstream task under different contact conditions. As these domains were nonmutually exclusive, individual studies could contribute to more than 1 domain.

Table 1. Summary of contact-force control and sensing methods.

Study	Study population and sample size	Measurement site/experimental condition	Method type	How force is controlled	How force is sensed	Force/pressure reporting and convertibility	Key hardware/implementation	Main information provided
Sim et al [41]	• Healthy human-participant validation • Main posture-change experiment: 1 healthy participant • Additional contact-force–dependency experiment: 4 participants. • Male/female distribution: not reported	Radial artery at the wrist	Active closed-loop control	Probe displacement is actively adjusted with a thermo-pneumatic actuator to maintain constant contact force in real time.	A FlexiForce A201 flexible force sensor measures force through force-dependent conductance changes.	• Contact force • Unit: Newton; target force: 0.6 N; measurable range: 0.2-4.0 N • Effective contact area: not reported • Contact-force–related signal • Unit/range: not reported	• Wrist platform comprising a force regulator, main body, force sensor, and reflectance PPG[a] probe.	Demonstrates a closed-loop contact-force regulation strategy for improving wrist PPG stability under posture-related contact changes.
Liu et al [43]	• Sample size and participant health status: not reported	Wrist; elastic wristband positioned over the radial and ulnar artery regions.	Multipoint synchronous monitoring	More of a force-sensing/regulation platform than a strict actuator-based closed loop; emphasis is on synchronous spatial monitoring.	Four ceramic piezoelectric sensors track changes in mechanical stress/contact force.	• Geometry/contact area: wrist-contact PPG and piezoelectric sensors; sensor diameter reported as 12 mm, but the effective skin-contact area for pressure conversion was not reported. • Contact force; authors used the term contact pressure force. • Unit/range: Newton; 5 force levels	• Wearable platform integrating 9 PPG sensors and 4 piezoelectric sensors. • The PPG sensors form a 3 × 3 array embedded in an elastic wristband, enabling simultaneous acquisition of 9 PPG channels and 4 contact force channels.	Provides a multipoint view of how local contact-force variation and spatial sensor position affect wrist PPG waveform behavior.
Přibil et al [44]	• 6 healthy volunteers: 4 males and 2 females • Mean age 56 (SD 8) years • All healthy volunteers	Left and right index fingers; five force levels	Direct contact force	No active control is emphasized; the main goal is direct quantification of probe-skin force.	A force-sensitive resistor directly measures probe-skin contact force.	• Male: 0.147-1.078 N; female: 0.147-0.753 N • Geometry/area: The force-sensitive resistor active sensing region had a diameter of 4 mm, but the effective skin-contact area was not reported; pressure in mm Hg (millimeters of mercury)/kPa (kilopascals) was not reported.	• PPG probe integrated with humidity, temperature, and force-sensitive resistor sensing.	Provides direct sensor-level documentation of finger PPG changes under different applied contact-pressure-force levels.

XSL•FO
RenderX

Study	Study population and sample size	Measurement site/experimental condition	Method type	How force is controlled	How force is sensed	Force/pressure reporting and convertibility	Key hardware/implementation	Main information provided
Fortin et al [45]	• 1 participant: male (28 years old), right-handed, pale White skin tone; self-administered protocol because of COVID-19 self-isolation restrictions.	Wrist and index fingertip	Indirect force estimation	No active force-control device is added; force is changed experimentally using a clamp and adjustment screw.	A miniature load cell provides the ground-truth force during development; the long-term aim is to estimate force from raw PPG alone.	• Contact force • Unit/range: Newton; 0-2.6 N in 0.2 N increments • Effective contact area: not reported	• 3D-printed clamp, 500 g load cell, HX711 module, and Arduino. • Force sampled from 0 to 2.6 N in 0.2 N steps. • 55 features extracted from raw PPG and modeled with a bagged-tree approach.	Shows the feasibility of estimating contact force from raw PPG features without adding a dedicated force sensor to the final wearable system.

[a]PPG: photoplethysmography.

Table 2. Measurement sites and wearable configurations in representative studies.

Study	Study design	Sample size and participant characteristics	Main measurement site	Wearable configuration/device form	Reference/auxiliary channel	Main findings
Charlton et al [46]	Measurements in different postures and sensor heights to examine effects of posture and sensor position relative to the heart on wrist PPG[a] signal quality.	1142 participants from the Aurora-BP dataset with varying ages and health statuses.	Wrist	Wrist-worn reflectance PPG	Posture and sensor height considered	Wrist PPG signal quality was strongly shaped by body posture and sensor height relative to the heart, indicating that wrist-site performance depends on acquisition geometry rather than anatomical site alone.
Ho et al [47]	A wrist-finger dual-channel dataset study for contact-pressure effects on wrist PPG morphology.	27 healthy young participants (16 males and 11 females)	Wrist	Force-adjustable wrist module	High-perfusion fingertip reference	Wrist posture changed sensor-skin contact pressure and produced different wrist PPG morphologies; the wrist setup supports analysis of wrist-site distortion in smartwatch-like monitoring
Dresher and Mendelson [18]	A forehead reflectance pulse-oximetry walking study under different contact pressures; involved an oxygen-saturation monitoring context	10 healthy volunteers; male/female distribution: not reported	Forehead above the eye	Elastic-headband–based forehead reflectance pulse oximeter with custom housing	Fingertip reference	The forehead above the eye was evaluated as a motion-tolerant reflectance pulse-oximetry site, but its performance depended on headband fixation and appropriate sensor-skin pressure during walking.
Chan et al [48]	A wearable reflectance pulse-oximetry study at the sternum; involved a continuous SpO_2[b] monitoring context	Total sample size, sex distribution, and participant characteristics: not reported	Mid-sternum	Chest/central reflectance PPG	Continuous SpO_2 task	The mid-sternum was assessed as a central wearable reflectance PPG site using a chest patch; this configuration enabled continuous SpO_2 monitoring but required attention to weak local perfusion and respiratory artifacts.

Table 3. Static and dynamic study protocols in representative contact-force research.

Study	Study design/protocol characteristics	Sample size and participant characteristics/platform	Measurement site	Protocol design	Force/pressure reporting	Main observation and finding
Scardulla et al [49]	A dynamic in vivo step-exercise wrist PPG[a] study evaluating how preset wristband contact pressure affects PPG-derived heart-rate accuracy under different stepping intensities.	17 participants (12 males and 5 females), with a mean age of 36 (SD 11) years; health status was not explicitly reported.	Wrist reflectance PPG with electrocardiogram chest-strap reference.	• Participants stepped on a 22.5 cm platform at 90, 120, and 140 bpm for 60 seconds, preceded by 10 seconds of rest. • Three contact pressures were randomized across 3 activity intensities, yielding 9 tests per participant.	• Contact pressure • Unit/range: mm Hg (millimeters of mercury); 12, 33, and 54 mm Hg. • Geometry/contact area: contact area = 473 mm2	Dynamic step-exercise protocol: PPG-derived heart rate was compared with electrocardiogram-derived heart rate under 3 contact pressures and 3 stepping intensities. Contact pressure affected heart rate agreement during movement, showing that pressure optimization remains important in dynamic wrist PPG recordings.
Sirkiä et al [20]	A quasi-static in vivo finger multiwavelength PPG pressure-ramp study examining how controlled external finger pressure affects wavelength-dependent PPG waveforms, vascular occlusion/opening behavior, and pulse-foot timing.	3 volunteers (1 female); health status and age were not reported	Index finger of the right hand; 5-wavelength multiwavelength PPG with controlled external pressure.	• External pressure was continuously increased by lowering a bar with a stepper motor until the maximum allowed pressure was above systolic blood pressure and then released. • Multiwavelength PPG and pressure signals were recorded synchronously, with 3 measurements per volunteer and reference blood pressure after each measurement.	• External pressure/contact pressure. • Unit/range: mm Hg; pressure was increased above systolic blood pressure and then released. • Geometry/contact area: multiwavelength PPG sensor printed circuit board diameter of approximately 9.6 mm; effective skin-contact area not reported.	Quasi-static finger pressure-ramp protocol: multiwavelength PPG was observed during external pressure increase and release. Pressure produced wavelength-dependent blockage/opening behavior and pulse-timing changes, indicating that external pressure alters vascular responses differently across optical wavelengths.
Scardulla et al [21]	A standardized dynamic in vivo treadmill wrist PPG study evaluating heart-rate accuracy, precision, and uncertainty under different strap pressures and exercise speeds.	25 healthy volunteers; male/female distribution was not reported.	Wrist PPG prototype with electrocardiogram chest-strap reference.	• For each pressure condition, blood pressure was measured first. • Participants then performed treadmill trials at 3, 6, and 8 km/h for 90 seconds each with 60-second rest intervals, followed by a 5-minute seated PPG recording and another blood pressure measurement. • The full sequence was repeated at 20, 60, and 75 mm Hg.	• Contact pressure. • Unit/range: mm Hg; 20, 60, and 75 mm Hg. • Effective contact area: not reported.	Dynamic treadmill protocol: heart rate accuracy, precision, and uncertainty were evaluated under 3 strap pressures and 3 treadmill speeds. Intermediate pressure, especially around 60 mm Hg, generally provided better PPG-heart rate performance than lower or higher pressures.

XSL•FO
RenderX

Study	Study design/protocol characteristics	Sample size and participant characteristics/platform	Measurement site	Protocol design	Force/pressure reporting	Main observation and finding
May et al [16]	A static in vitro tissue-vessel phantom study examining how progressively increased sensor contact pressure affects reflectance PPG signal quality and morphological features under simulated blood pressure states.	In vitro tissue-vessel phantom; no human participants; sex distribution not applicable.	Above the embedded vessel in the phantom.	• Under pulsatile flow fixed at 60 bpm, 4 hemodynamic states were simulated: hypotension, normotension, stage 1 hypertension, and stage 2 hypertension. • A linear actuator progressively increased sensor pressure until complete vessel occlusion.	• Contact pressure. • Unit/range: mm Hg; continuously increased until complete vessel occlusion; optimal range was reported as 35.1-48.1 mm Hg. • Effective contact area: not reported.	Static phantom protocol: signal-to-noise ratio and 17 morphological features were observed as contact pressure increased until vessel occlusion. PPG signal quality and morphology changed nonlinearly with pressure, with an optimal pressure range before complete occlusion.
Ho et al [47]	A static/quasi-static seated wrist-finger dual-channel PPG dataset study examining how wrist contact-pressure variation affects wrist PPG morphology, with fingertip PPG recorded simultaneously as a reference.	27 healthy young participants (16 males and 11 females); mean age 24.3 (SD 2.74) years	Wrist PPG with fingertip PPG reference	• Each participant completed 6 sessions. • Each session included blood pressure measurement, contact-pressure adjustment, and 4 minutes of seated recording, with a 2-minute rest between sessions. • Wrist PPG, fingertip PPG, load cell, electrocardiogram, blood pressure, and SpO_2[2] were synchronized.	• Contact pressure. • Unit/range: load-cell reading; gradually increased across 6 sessions. • Geometry/contact area: load cell placed between the wrist PPG sensor and movable jaw; effective skin-contact area was not reported.	Static/quasi-static seated wrist-finger protocol: wrist PPG morphology was observed across 6 contact-pressure sessions with fingertip PPG as a reference. Wrist contact-pressure variation systematically changed wrist PPG morphology, supporting dual-site recordings to characterize pressure-related wrist-site distortion.

[a]PPG: photoplethysmography.

[b]SpO_2: peripheral oxygen saturation.

Characteristics of Participants and Data Sources

The included sources of evidence varied substantially in terms of participant characteristics and data sources. Most human-participant studies involved healthy volunteers [18,20,21,41,42,44,45,47,49-53,56], whereas some studies used larger datasets or study populations with broader participant characteristics [46,52]. Sample sizes ranged from single-case feasibility studies [41,45] to large-scale wrist PPG datasets [46]. Several studies did not fully report participant age, sex distribution, or health status [18,43,48,50,55], limiting characterization of population diversity across the evidence base. In addition to the in vivo human studies, the evidence base included an in vitro tissue-vessel phantom study [16] and a study combining theoretical modeling with human-participant experimental validation [54].

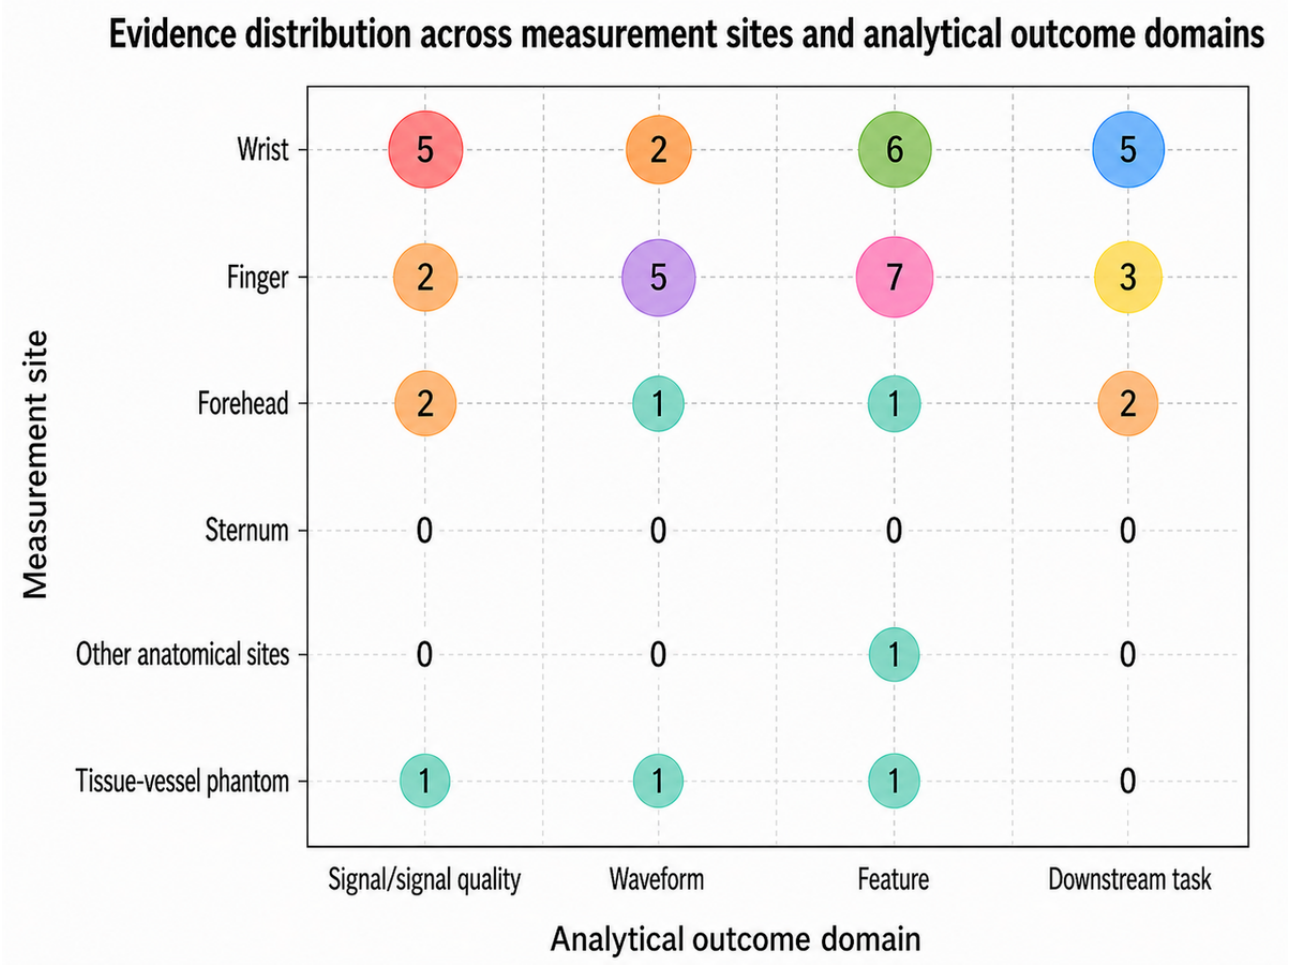
Characteristics of Measurement Sites and Wearable Reflectance PPG Configurations

Measurement-site categories were nonmutually exclusive because some studies included more than 1 PPG acquisition site or used a secondary PPG site as a reference channel. Of the 21 included studies, 10 (48%) [15,21,41,43,45-47,49,52,55] involved wrist-based configurations, 9 (43%) [20,42,44,45,47,50,51,54,55] involved finger-based measurements, and 3 (14%) [18,55,56] involved forehead-based configurations. One study (5%) [48] examined a sternum-based configuration, 1 (5%) [53] examined other anatomical sites, and 1 (5%) [16] used an in vitro tissue-vessel phantom rather than a human anatomical measurement site. As several studies involved more than 1 measurement site, the summed percentages exceeded 100%. Primary device or experimental configurations were coded into mutually exclusive categories according to the principal PPG setup used in each study. Of the 21 included studies, 7 (33%) [15,21,41,43,46,49,52] used single-site

XSL•FO
RenderX

wrist-based systems, 6 (29%) [20,42,44,50,51,54] used single-site finger-based systems, and 3 (14%) [45,47,55] used multisite configurations involving more than 1 PPG acquisition site; 2 (10%) [18,56] studies used forehead-based reflectance pulse-oximetry systems, 1 (5%) [48] used a sternum-based reflectance PPG system, 1 (5%) [53] used a probe at other anatomical sites, and 1 (5%) [16] used an in vitro tissue-vessel phantom rather than an in vivo wearable configuration. Several secondary design features were identified across these primary categories. Three studies (14%) [15,41,47] used force-adjustable or force-regulated platforms, 3 (14%) [43,47,55] used multichannel or multisite PPG acquisition, and 3 (14%) [20,51,55] used multiwavelength reflectance PPG configurations. These secondary categories were nonmutually exclusive because individual systems could incorporate more than 1 design feature. Detailed study-level configurations, fixation strategies, optical settings, and reference measurements are presented in Table 2.

Characteristics of Contact-Force and Contact-Pressure Reporting



The representation of contact conditions differed substantially across the included studies. Based on the principal mechanical quantity or descriptor reported in each study, the 21 studies were classified into 4 mutually exclusive categories. As many as 5 (24%) studies [15,41,44,45,54] used force-based representations. Of these, all 5 [15,41,44,45,54] explicitly reported contact force in Newtons. Among them, Teng and Zhang [54] examined discrete applied contact-force levels through theoretical modeling and validation involving human participants. Ten studies (48%) [16,18,20,21,42,49,51,53,55,56] used pressure-based representations reported in physical pressure units, including mm Hg (millimeters of mercury), kPa (kilopascal), or torr. These representations included externally applied or cuff-derived pressure values [20,42,51], preset wristband or strap-pressure levels [21,49], and locally applied probe-skin, sensor-skin, or device-housing pressure [16,18,53,55,56]. Four studies (19%) [43,47,50,52] used nonstandardized sensor-output, normalized, indirect, or categorical representations. These included contact-force–related piezoelectric sensor output without a reported physical unit [43], sequential load-cell readings without conversion to a standardized force or pressure value [47], normalized force divided into predefined ranges [50], and pressure-related waveform-morphology labels [52]. Two studies (10%) [46,48] described sensor-skin contact qualitatively or contextually without directly quantifying the applied force or pressure. One study [49] explicitly reported the sensor-skin contact area. Four studies [20,43,44,47] provided partial sensor, probe, printed circuit board, or device-geometry information but did not report the effective skin-contact area. For the remaining studies, contact-area or probe-geometry information was insufficient or unavailable. Sensor or device dimensions were not assumed to represent effective skin-contact area unless this relationship was explicitly established. Consequently, reported force values could not always be converted into contact pressure or directly compared with pressure values across devices. Although contact force and contact pressure are mechanically related, they were not treated as interchangeable when sufficient contact-area information was unavailable.

Characteristics of Multilevel PPG Responses Under Different Contact Force/Pressure

The reported outcomes spanned signal or signal-quality, waveform, feature, and downstream-task domains. Sixteen studies [15,16,18,20,41-45,47,49-51,53,55,56] contributed direct signal-, waveform-, or feature-level evidence, whereas 10 studies [15,18,21,42,47,49,51,52,54,56] evaluated at least 1 downstream task under different contact conditions. These categories were nonmutually exclusive. Detailed study-level findings are presented below and synthesized across measurement sites, protocol contexts, and analytical domains in Figures 2-4 and Table 4. The studies considered in the empirical linkages in Figure 3 are [15,18,42,47,49,51,52,56].

XSL•FO
RenderX

Figure 2. Evidence distribution across measurement sites and analytical outcome domains. Bubble size represents the number of unique studies contributing direct empirical response evidence to each site-outcome combination. Studies could contribute to more than 1 cell. Empty cells indicate that no direct empirical evidence of a response to the contact condition was mapped to that combination.

Results of Individual Sources of Evidence

Overview

To avoid duplicating the detailed study-level tables, the following narrative highlights key findings from individual sources.

Contact-Force Control and Sensing Methods

As outlined in Table 1, the included studies can be broadly categorized into 4 methodological groups according to their approaches to contact force and contact pressure in wearable reflectance PPG: active closed-loop force control, direct contact force/pressure measurement, multipoint contact-force monitoring, and indirect contact-force estimation based on PPG signals. These approaches reflect 4 distinct methodological priorities, namely, stabilizing contact conditions, quantifying contact state, characterizing spatial variations in contact, and reducing reliance on additional hardware. Sim et al [41] represented the first direction by developing an active closed-loop force-control platform, through which the analysis could be performed under constant contact conditions, thereby emphasizing signal stability and experimental repeatability. By contrast, Liu et al [43] extended the problem from single-point force regulation to multipoint synchronous sensing, enabling the investigation of relationships between spatial variations in contact state and PPG waveform behavior. Přibil et al [44] further highlighted the direct measurement and quantitative characterization of probe-skin contact force by integrating force-sensitive sensing into the optical probe, which improved the physical interpretability of experimental conditions and facilitated comparison across studies. Fortin et al [45], in turn, explored a different direction by attempting to estimate contact force indirectly from raw PPG signals, thereby reducing dependence on dedicated force-sensing hardware.

Measurement Sites and Wearable Configurations

As shown in Table 2, from the perspective of measurement site and device configuration, current reflectance PPG research has moved beyond the simple question of where a sensor should be placed. Instead, it increasingly treats measurement site, wearing form, reference channel, and target task as a coupled system-level design problem. Charlton et al [46] reported that wrist PPG signal quality varied across body postures and sensor heights relative to the heart. Ho et al [47] further showed that this systemic issue also involves contact-force control and reference-channel configuration; by combining a force-adjustable wrist module with a high-perfusion fingertip reference, they more clearly revealed the coupling among measurement site, wearing structure, and reference design. The study by Dresher and Mendelson [18] likewise indicated that the effectiveness of the forehead as a measurement site cannot

XSL•FO
RenderX

be understood independently of the specific wearing configuration. Using a forehead reflectance pulse oximetry device consisting of an elastic headband and a custom housing, they systematically evaluated the performance of PPG signals measured from the supraorbital forehead region under different contact pressures and showed that forehead signal quality and measurement reliability during motion are shaped not only by the measurement site itself but also by the combined effects of fixation structure and contact-pressure conditions. Chan et al [48] extended the measurement site from the periphery to the mid-sternum, further indicating that although more central reflectance PPG holds promise for continuous oxygen saturation monitoring, its performance remains constrained by multiple factors, including local perfusion, optical path design, and wearing strategy.

Static and Dynamic Study Protocols

As summarized in Table 3, existing protocols can be broadly categorized into static/quasi-static designs and dynamic in vivo designs. Static and quasi-static protocols primarily examined contact-condition–related changes in waveform morphology, signal-to-noise ratio (SNR), and derived features while minimizing motion-related variation. Dynamic protocols examined whether similar response patterns were observed during stepping, walking, running, or other wearable-use conditions. In the dynamic category, Scardulla et al [49] investigated wrist PPG during step exercise at 3 preset contact pressures and showed that contact pressure had a greater impact on heart-rate measurement quality than exercise intensity itself. Scardulla et al [21] later extended this line of work using a more standardized treadmill protocol across 20, 60, and 75 mm Hg and found that 60 mm Hg offered the best overall balance of accuracy and precision, although the optimal pressure still varied across individuals. By contrast, quasi-static and static studies have been more focused on mechanism. Sirkiä et al [20], using a controlled pressure ramp on the fingertip with multiwavelength PPG, showed that externally applied pressure changes not only oscillation amplitudes but also pressure-dependent occlusion behavior and interchannel timing differences, indicating depth-dependent vascular responses. May et al [16], in an in vitro tissue-vessel phantom study with continuously increasing pressure under multiple simulated blood pressure states, demonstrated the existence of an optimal contact-pressure range and further showed that temporal features are relatively robust, whereas amplitude- and geometry-related features are substantially more pressure-sensitive. Ho et al [47] further contributed a quasi-static wrist-finger dual-channel dataset collected under sedentary conditions, in which wrist pressure was gradually adjusted while a fingertip channel was maintained as a high-quality reference; their results showed systematic pressure-dependent transitions in wrist PPG morphology and corresponding degradation in downstream HR and HRV estimation under suboptimal pressure.

Contact-Condition–Related Findings in Reflectance PPG

Signal and Signal-Quality Responses

As outlined in Table S1 in Multimedia Appendix 5, the included signal-quality studies reported contact-condition–related differences across several PPG dimensions, including signal amplitude, perfusion-related measures, noise, baseline stability, motion artifacts, and morphology-based quality indices. Lambert Cause et al [50] evaluated normalized fingertip force across 5 bins using skewness, kurtosis, relative power, entropy, zero-crossing rate, and perfusion index and found that different signal-quality indices favored different force ranges. May et al [16] demonstrated in vitro that the SNR first increased and then decreased as contact pressure rose, with a clear optimum before full occlusion. He et al [15] quantified the force dependence of high-frequency noise, baseline drift, and motion artifacts, showing that higher force could reduce some motion-related degradation, although not uniformly across all indices. Charlton et al [46] further emphasized that contact pressure should be interpreted jointly with posture, sensor height, and skin contact state when signal quality is assessed at the wrist.

Waveform and Feature Responses

As outlined in Table S2 in Multimedia Appendix 5, the included studies reported contact-condition–related differences not only in signal amplitude but also in waveform morphology and derived feature behavior. May et al [16] showed that PPG amplitude and SNR followed an inverted-U pattern as pressure increased. Ho et al [47] revealed that low-force wrist PPG often appeared single-peaked or noise-dominated, whereas moderate force revealed a more canonical 2-peak morphology with a clearer systolic peak, dicrotic notch, and diastolic peak; at still higher force, the waveform could collapse back toward a distorted single-peak shape. Sirkiä et al [20,51] further demonstrated that contact pressure affects both AC and DC components and that wavelength channels respond differently. Grabovskis et al [53] investigated the effect of probe contact pressure on PPG-based conduit artery stiffness assessment and showed that variable probe pressure affected the AC PPG second-derivative peak ratio b/a, a morphology-derived parameter associated with arterial stiffness. Fine and Kaminsky [55] showed that, in reflection pulse oximetry, gamma, a dual-wavelength PPG-derived ratio parameter used in arterial oxygen saturation calculation, increased with increasing applied pressure.

Findings on Artifact Susceptibility and Temporal Stability

As outlined in Table S3 in Multimedia Appendix 5, several included studies examined contact conditions in relation to artifact susceptibility and the temporal stability of PPG-derived measurements. At the wavelength level, Sirkiä et al [20,51] found that shorter wavelengths were more pressure-sensitive than red and infrared channels, with earlier onset of occlusion-like behavior and waveform distortion as pressure increased. At the feature level, Sim et al [41] showed that amplitude-dominated indices were more force-sensitive than interval-dominated indices. At the task level, Scardulla et al [49] found that excessively low pressure promoted poor contact and motion artifacts during exercise, whereas excessively high pressure could reduce precision by compressing local microcirculation.

Findings for SpO2 and Other Downstream Estimation Tasks

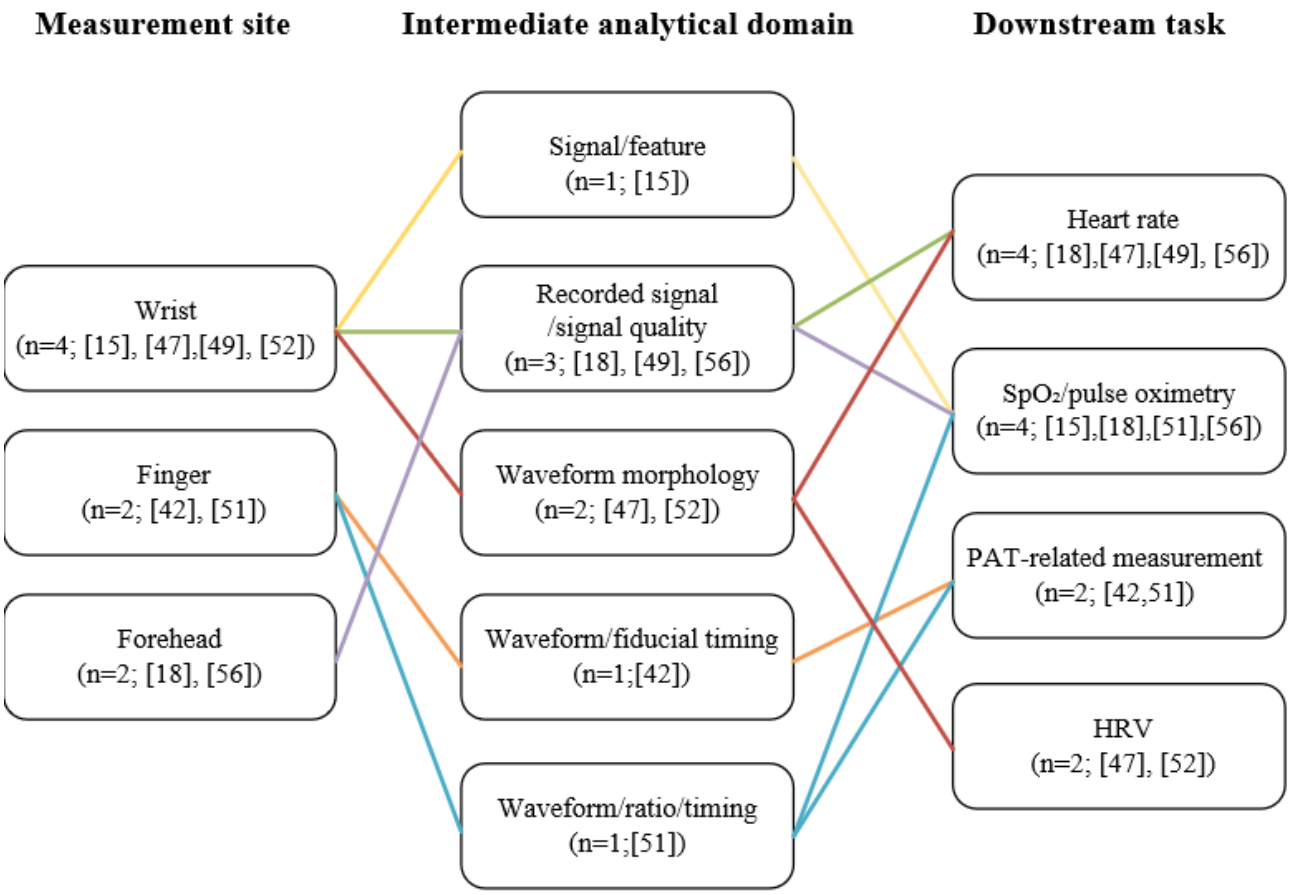
As outlined in Table S4 in Multimedia Appendix 5, a smaller body of evidence examined contact force and contact pressure in relation to downstream physiological estimation tasks beyond

XSL•FO
RenderX

signal- and waveform-level outcomes. For SpO_2 estimation, He et al [15], in a study of wrist reflectance PPG-based oxygen saturation prediction, showed that explicitly incorporating force-related features into an SpO_2 prediction model improved estimation accuracy, reducing the mean absolute error to 0.8811%. For BP estimation, Chandrasekhar et al [42], in a study using PPG-derived PAT for potential cuffless BP measurement, found that contact-pressure–induced changes in waveform morphology and fiducial-point location shifted PAT_{foot} and PAT_{peak} by 22 (SD 2) ms and 40 (SD 7) ms, respectively. Here, PAT_{foot} refers to PAT estimated from the foot of the PPG waveform, whereas PAT_{peak} refers to PAT estimated from the systolic peak. These timing shifts corresponded to approximately 11 and 20 mm Hg of BP estimation error, respectively, indicating that pressure-induced waveform distortion can directly propagate into BP estimation. For heart-rate estimation, Dresher and Mendelson [56] designed a reflectance pulse oximeter housing with contact-pressure measurement and showed that excessive sensor-skin pressure can impair local blood flow, attenuate or even eliminate PPG signals, and thereby affect pulse-oximetry measurement accuracy. Their dual-housing design improved HR accuracy under large contact-pressure variations. Their findings linked contact-pressure variation with differences in pulse-oximetry and heart-rate performance. Scardulla et al [21,49], in studies evaluating PPG signal performance under different contact-pressure conditions, showed that heart-rate estimation is strongly pressure-dependent, with intermediate pressures generally providing the best group-level performance, whereas both loose and excessively tight configurations degrade accuracy through different mechanisms. Hu et al [52], in wrist-PPG–based HRV estimation under sedentary conditions, demonstrated that even subtle waveform morphology distortions can degrade HRV estimation performance. They showed that morphology-aware modeling reduced the gap between wrist PPG and reference measurements, indicating that pressure-related morphology changes may impair HRV estimation by disturbing beat-to-beat timing and waveform-feature extraction.

Nonlinear Force Dependence and Moderate-Force Behavior

Several included studies reported nonlinear or task-dependent response patterns under their respective experimental conditions. As outlined in Table S5 in Multimedia Appendix 5, for example, May et al [16] found that both waveform amplitude and SNR first increased and then decreased as pressure rose. Lambert Cause et al [50] reported that the perfusion index, which is strongly amplitude-dependent, was also highest in lower-to-moderate force ranges before declining at higher force. Their signal-quality indices likewise showed that both low and high extremes were suboptimal, whereas moderate force better preserved waveform detail. Sirkiä et al [20,51] further showed that SpO_2 estimates remained relatively stable at low pressure but began to rise as pressure approached diastolic and mean arterial pressure, indicating that pressure-induced changes in AC/DC relationships and feature points can bias downstream metrics. Teng and Zhang [54] investigated the effect of sensor contact force on PPG-derived PTT using theoretical modeling and validation involving human participants. By considering the nonlinear pressure-volume relationship of the finger arterial wall, they showed that PTT increased with contact force under positive transmural pressure, reached a maximum near zero transmural pressure, and then remained nearly constant under negative transmural pressure. This finding indicates that sensor contact force can nonlinearly alter PPG-derived timing parameters through changes in local transmural pressure and arterial wall mechanics. Across these studies, nonlinear or inverted-U-like response patterns were reported under the respective experimental conditions. Intermediate contact levels were frequently associated with better signal quality, waveform clarity, or task performance than the lowest or highest tested levels. Importantly, the location and shape of this optimum are not fixed but vary with the physiological target, wavelength, measurement site, and feature type.



Synthesis of Results

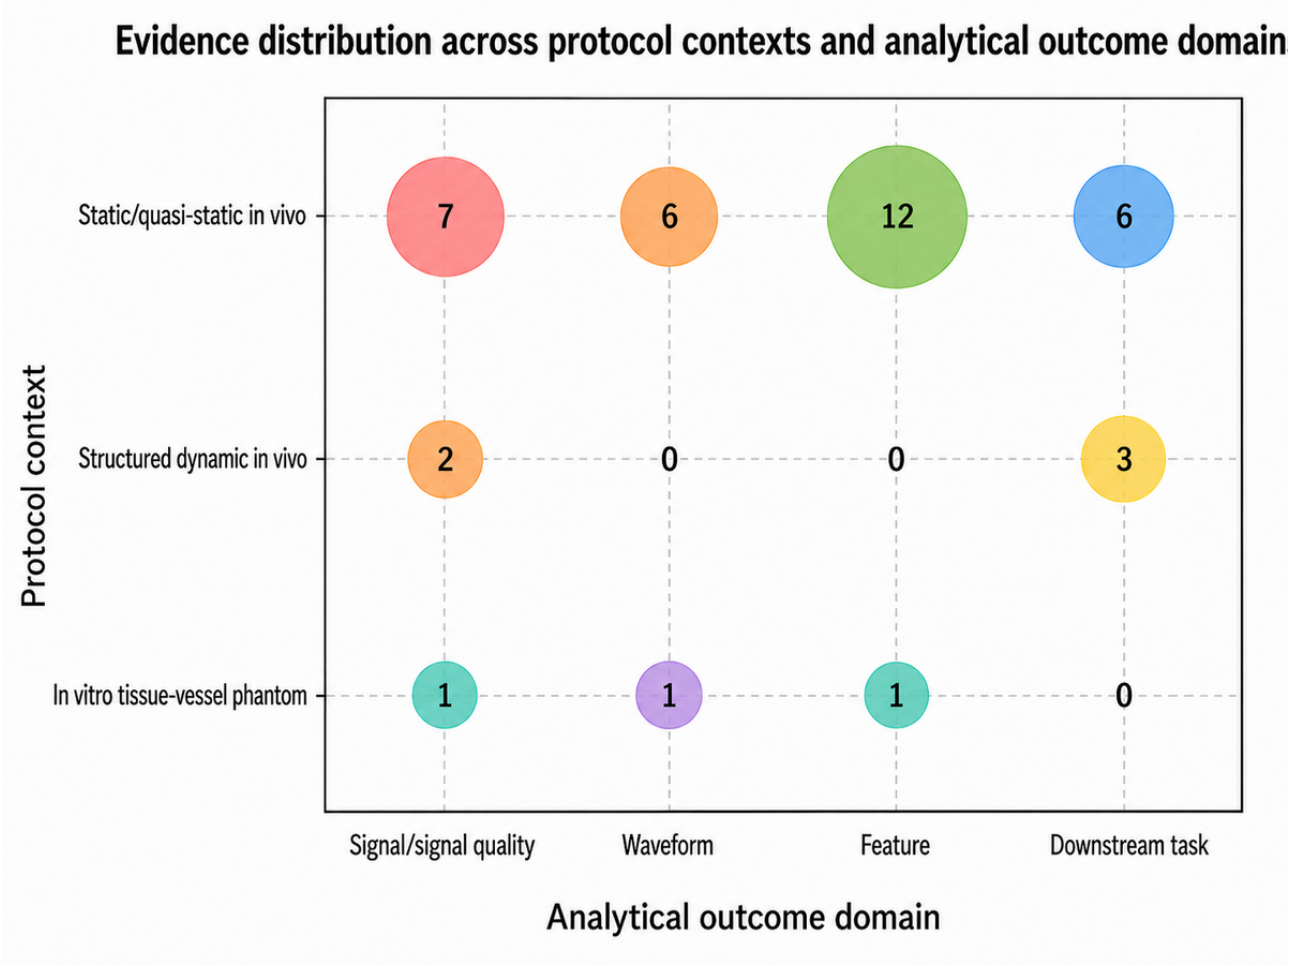
Evidence Distribution Across Measurement Sites and Analytical Outcome Domains

Figure 2 maps direct empirical response evidence across measurement sites and analytical outcome domains. At the wrist, direct empirical evidence included 5 signal- or signal-quality-level studies [15,21,41,43,49], 2 waveform-level studies [43,47], 6 feature-level studies [15,43,45,47,52,55], and 5 downstream-task studies evaluating SpO_2, HR, or HRV [15,21,47,49,52]. At the finger, 2 studies reported signal-level responses [44,50], 5 examined AC/DC behavior, pulse shape, or waveform fiducial points [20,42,44,51,55], 7 evaluated timing-, morphology-, perfusion-, or ratio-based features [20,42,44,45,50,51,55], and 3 assessed SpO_2, PAT, or PTT as downstream tasks [42,51,54]. At the forehead, 2 studies reported signal- or signal-quality-level responses [18,56], 1 examined waveform-level responses [56], 1 evaluated feature-level responses [55], and 2 assessed HR or pulse-oximetry performance [18,56]. Evidence from other sites was limited: 1 study [53] at other anatomical sites reported morphology- and derivative-based feature responses, whereas the tissue-vessel phantom study [16] contributed signal-, waveform-, and feature-level evidence across progressively increased pressure conditions. No direct empirical contact-condition response was mapped for the sternum study [48]. As individual studies could contribute to more than 1 measurement-site or analytical-domain category, the categories were nonmutually exclusive. The figure summarizes the distribution of evidence but does not determine whether intermediate PPG responses and downstream tasks were connected within the same study; these complete within-study linkages are presented in Figure 3.

XSL•FO
RenderX

Figure 3. Complete within-study empirical linkages from measurement sites through intermediate photoplethysmography domains to downstream tasks. Each colored pathway represents a single study; branches indicate that a study contributed evidence linking the same pathway to multiple downstream tasks. HRV: heart rate variability; PAT: pulse arrival time; SpO_2: peripheral oxygen saturation.

Evidence Linkages Across Measurement Sites, Intermediate Analytical Domains, and Downstream Tasks



At the wrist, He et al [15] linked contact-force–responsive signal-quality indices, including high-frequency noise, baseline drift, and motion artifact, together with contact-force information, to PPG-based SpO_2 prediction. Ho et al [47] linked pressure-related changes in waveform morphology, including the systolic peak, dicrotic notch, and diastolic peak, to HR and HRV estimation. Scardulla et al [49] linked contact stability and motion-artifact susceptibility during exercise to PPG-derived HR evaluation. Hu et al [52] used raw wrist PPG waveforms and pressure-related morphology labels to estimate NN intervals and beat count for HRV computation. At the finger, Chandrasekhar et al [42] linked changes in waveform-foot and systolic-peak timing to PAT_{foot} and PAT_{peak}. Sirkiä et al [51] linked AC/DC components, wavelength-dependent waveform responses, amplitude- and perfusion-related characteristics, and pulse-foot and pulse-peak timing to SpO_2, PAT_{foot}, and PAT_{peak}. At the forehead, Dresher and Mendelson [18] linked contact-pressure–related PPG signal quality and measurement reliability during walking to HR and SpO_2 performance. In a related housing study, Dresher and Mendelson [56] linked pressure-related differences in forehead PPG amplitude and signal quality to SpO_2 and HR measurement performance. Overall, the complete within-study linkages involved signal-quality indices and contact-force information for SpO_2 prediction [15], waveform morphology for HR and HRV estimation [47,52], dynamic signal stability for HR evaluation [49], fiducial-point timing for PAT measurement [42], AC/DC and wavelength-dependent responses for SpO_2 and PAT calculation [51], and forehead PPG signal quality and amplitude for HR and pulse-oximetry performance [18,56].

Evidence Distribution Across Protocol Contexts and Outcome Domains

Under static or quasi-static in vivo conditions, direct empirical evidence included 7 studies [15,41,43-45,50,56] reporting signal- or signal-quality-level responses, 6 [20,42,44,47,51,55] examining waveform-level changes, 12 [15,20,42-45,47,50-53,55] evaluating feature-level responses, and 7 [15,42,47,51,52,54,56] assessing downstream tasks. Under structured dynamic conditions, 2 studies [18,49] reported signal- or signal-quality-level responses, whereas 3 [18,21,49] evaluated downstream tasks, primarily HR-related performance. In the in vitro tissue-vessel phantom protocol, 1 study [16] provided signal-, waveform-, and feature-level evidence across controlled pressure conditions. Overall, Figure 4 maps directly measured or calculated PPG responses across principal protocol contexts and analytical outcome domains. The mapped distribution indicates that waveform- and feature-level evidence was concentrated in static or quasi-static in vivo protocols, whereas structured dynamic protocols mainly addressed signal behavior and downstream HR performance.

Study-Level Coverage Across Methodological and Analytical Domains

Table 4 provides a study-level overview of the methodological and analytical domains covered by the 21 included studies. Measurement site and principal protocol context were identifiable for all studies. Participant characteristics and contact-condition representation were more consistently documented than effective contact area or probe geometry. Sensor, printed circuit board, load-cell, or device dimensions without sufficient information on the effective skin-contact interface were classified as partial rather than sufficient reporting. Analytical coverage varied across studies, with some studies addressing multiple signal-, waveform-, feature-, and downstream-task domains. Overall, the matrix highlights variation in methodological reporting and analytical breadth rather than differences in study quality.

Discussion

Principal Findings

This scoping review identified 21 studies that examined how contact force or contact pressure was controlled, measured, estimated, or characterized in wearable or wearable-relevant reflectance PPG, together with the reported signal-, waveform-, feature-, and task-level outcomes under different contact conditions [15,16,18,20,21,41-56]. Previous reviews have synthesized the physiological basis of PPG, waveform analysis, signal-processing methods, and downstream applications such as HR, BP, oxygen saturation, and arrhythmia detection [7-10,22-29]; wearable-device architectures and configurations [30-34]; and signal-quality challenges, datasets, and analytical tools [7,29,35-37]. Within these broader reviews, contact pressure, wearing tightness, and sensor-skin interface stability have generally been discussed as acquisition or signal-quality considerations rather than as the central framework for organizing the evidence [29-32]. Building on this literature, our review places contact force and contact pressure at the center of the synthesis, distinguishes these 2 mechanical quantities, and integrates evidence on their measurement, control, representation, and reporting with outcomes across multiple levels of PPG analysis. It also maps the distribution of evidence across anatomical sites, device configurations, populations, experimental settings, and protocol durations.

The mapped evidence indicates that contact force and contact pressure are important measurement conditions associated with variability in wearable reflectance PPG observations and should not be treated solely as minor wearing-related factors. Across the included studies, different contact conditions were reported in relation to differences in signal amplitude, signal quality, motion susceptibility, waveform morphology, feature stability, and downstream physiological estimation [15,16,18,20,21,41,42,46-56]. However, these responses were not uniform across feature categories or experimental settings. Amplitude-, morphology-, and derivative-based parameters generally varied more across contact conditions than some timing-related features, suggesting that feature stability may depend on the type of parameter examined [16,41,53]. The reviewed studies further indicated that contact-condition–related responses varied across measurement sites, wavelengths, fixation strategies, postures, and motion conditions, rather than following a single relationship that could be generalized across devices or settings [18,20,21,46-48,51]. Their practical relevance also appeared to differ by task: applications that rely on waveform morphology, amplitude relationships, or precise fiducial-point localization may require more task-specific evaluation than applications based primarily on preserved periodicity [15,20,21,42,49,51,52]. Compared with previous broad reviews of wearable PPG, this review therefore provides a focused methodological and conceptual map of the sensor-skin mechanical interface. It also identifies incomplete mechanical reporting, limited real-world validation, restricted population and measurement-site diversity, and incomplete linkage between intermediate signal characteristics and downstream estimation as important priorities for future research.

Limitations

Inconsistent Reporting of Contact Force and Contact Pressure

Despite growing interest, the mapped evidence remains methodologically heterogeneous [15,16,18,20,21,41-56]. A major limitation is the lack of a standardized framework for representing, measuring, and reporting contact force and contact pressure [15,16,18,20,21,41-56]. Importantly, contact force and contact pressure are mechanically related but not interchangeable: contact force describes the total load applied to the sensor-skin interface, whereas contact pressure depends on how that load is distributed over the effective contact area [15,16,20,21,41-47,50-56]. Across studies, contact conditions were described using different units or concepts, including Newtons, mm Hg, normalized force units, cuff pressure, preset strap levels, inferred tightness, or qualitative descriptions of skin contact [15,16,18,20,21,41-56]. This heterogeneity limits direct comparison and the development of quantitative design guidance [15,16,20,21,41-47,49-56]. It also limits the transferability of terms such as “moderate force” or “optimal pressure” across wearable configurations [16,20,21,47,49-51,54]. In particular, when studies report only force without specifying the effective contact area, probe geometry, or active sensing area, the corresponding contact pressure cannot be reliably derived [15,41,43-45,47,50,52]. Even when similar terms are used, the underlying physical meaning may differ because reported pressure can depend on probe geometry, active sensing area, tissue compliance, or the way force is converted into pressure [16,20,21,47,49-51,53,54].

XSL•FO
RenderX

A more standardized reporting convention would therefore be an important step toward improving comparability and reproducibility [57,58]. Future studies should report the effective sensor-skin contact area or probe geometry when reporting contact force, or directly report contact pressure in standardized units such as mm Hg or kPa [57,58]. This would improve reproducibility, cross-study comparability, and practical translation for wearable PPG device design.

Limited Real-World and Longitudinal Validation

A major evidence gap is the limited validation of contact conditions during prolonged and unsupervised wearable use. Most included studies used small samples, short recordings, highly structured protocols, static or quasi-static tasks, or predefined pressure conditions [16,18,20,21,41,42,44,45,47,49-51,53-56]. These designs are informative for characterizing responses under controlled conditions, but they provide limited evidence about the variability encountered during everyday wear. During free-living use, the sensor-skin interface may vary with posture transitions, arm movement, sweating, changes in skin hydration, tissue deformation, strap displacement, repeated device removal and reattachment, and prolonged wear [14,18,21,46,48,49]. Accordingly, the available laboratory evidence may not capture the full range or temporal instability of contact conditions in natural settings [14,18,21,46,49]. Current evidence does not establish whether a contact condition measured at the start of a recording remains stable over several hours, whether users reproduce similar conditions after repeated donning, or whether contact-related variability is consistent across days. Short supervised walking, stepping, or treadmill protocols should therefore be distinguished from longitudinal or free-living validation. Future studies should jointly document contact force or pressure, motion, posture, wear duration, and contextual factors rather than evaluating contact conditions only under isolated, idealized protocols [14,21,46,47,49,58]. Recent benchmarking efforts, including the QUMPHY D4 report [58], also indicate the value of standardized benchmark datasets in addition to algorithm development. For wearable reflectance PPG, future public datasets should document acquisition context more systematically, including site, device configuration, fixation strategy, wear duration, and other factors that may be associated with signal quality and estimation performance [46,47,58]. Repeated-measures studies should report within-session drift, between-day reproducibility, reattachment procedures, strap or fastening settings, and the frequency of contact-related signal-quality failures.

Gap Between Signal-Level Changes and Task-Level Estimation Bias

As shown in Figure 3, complete within-study pathways connecting measurement site, an intermediate signal-, waveform-, or feature-level domain, and a downstream task were identified in 8 studies [15,18,42,47,49,51,52,56]. The remaining studies did not report a complete site-intermediate-domain-downstream-task pathway [16,20,21,41,43-46,48,50,53-55]. This distinction is important because signal or feature differences observed under varying contact conditions do not necessarily correspond to clinically or algorithmically meaningful estimation differences. Their practical relevance is likely to depend on the target task, the signal properties used by the algorithm, and the selected reference method. Conversely, task-level differences should not be attributed solely to contact conditions without also considering motion, wavelength, device configuration, reference-measurement uncertainty, and participant characteristics. Future studies should therefore evaluate contact conditions, intermediate signal or feature behavior, and task-level estimation error within the same experimental protocol and against an appropriate reference standard. Stratified analyses across contact conditions, together with sensitivity or feature-ablation analyses, may help identify which signal properties are most closely associated with task-specific performance differences [15,21,42,49,52,57,58].

Limited Population and Measurement-Site Diversity

A further evidence gap concerns population and measurement-site diversity. The evidence was concentrated at the wrist and finger: 10 [15,21,41,43,45-47,49,52,55] of the 21 included studies involved wrist-based configurations, and 9 [20,42,44,45,47,50,51,54,55] involved finger measurements, whereas only 3 [18,55,56] examined the forehead, 1 [48] examined the sternum, and 1 [53] examined another anatomical site; these categories were nonmutually exclusive. Given differences in anatomical structure, device geometry, fixation strategy, and optical measurement configuration across sites, numerical pressure ranges reported at the wrist or finger should not be assumed to apply directly to the forehead, sternum, ear, or other anatomical locations [18,46-48,55,59,60]. Most human studies recruited healthy volunteers [18,20,21,41,42,44,45,47,49-54,56], leaving limited direct evidence for older adults, children, patients with cardiovascular or peripheral vascular conditions, and individuals with edema or impaired perfusion. Previous studies and systematic reviews have reported differences in pulse-oximetry accuracy across skin-pigmentation groups, particularly under lower oxygen-saturation conditions [61-64]. However, the included contact-condition literature did not adequately characterize whether skin pigmentation modifies the relationships between contact conditions and wearable reflectance PPG outcomes. More broadly, the reported specificity of reflectance PPG and SpO_2 estimation to participant and measurement-site characteristics suggests that population and site characteristics should be considered when interpreting contact-condition–related findings [59,60]. Future studies should report participant age, sex distribution, health status, the method used to characterize skin tone or pigmentation, and relevant vascular or tissue characteristics more consistently. Harmonized multisite protocols are needed to determine whether reported contact-condition responses are site-specific or reproducible across anatomical locations. Findings derived mainly from healthy adults and common peripheral sites should therefore be generalized cautiously to broader populations and other anatomical locations [46,59-64].

Scope Boundaries for Transmission-Mode and Hybrid PPG Systems

The focus on wearable or wearable-relevant reflectance PPG represents a deliberate scope boundary of this review. Accordingly, the mapped findings should be applied cautiously to transmission-mode and hybrid reflection-transmission PPG systems. Transmission-mode PPG remains important in wearable pulse oximetry, particularly in finger-clip, ring-type, earlobe, and in-ear devices, in which the light source and photodetector are positioned on opposite sides of relatively thin tissue [30,65-67]. These configurations may provide strong pulsatile signals for SpO_2 monitoring, but they involve different anatomical constraints and fixation mechanisms, including clips, rings, and in-ear fittings. Differences in optical path, contact area, tissue compression, and fixation mean that reported contact-condition responses may not be directly comparable across optical modes. Numerical force or pressure ranges and response patterns mapped in reflectance studies should therefore not be transferred directly to transmission-mode or hybrid devices. Several methodological principles remain relevant across optical modes, including distinguishing force from pressure and documenting geometry, effective contact area, fixation, and calibration. For hybrid systems, the reflectance and transmission interfaces should be described separately rather than summarized using a single wearing-tightness descriptor. For each sensing interface, studies should report the measurement site, optical mode, wavelength, emitter-detector geometry, fixation method, effective contact area, and contact force or pressure. Direct comparative studies, and potentially a separate evidence synthesis focused on transmission-mode and hybrid systems, are needed before cross-mode recommendations can be established.

Methodological Limitations and Scope of the Review

This review also has methodological limitations related to its scope and review process. Although the review followed a scoping review framework and was reported with reference to PRISMA-ScR and PRISMA-S [38-40], the protocol was not formally registered or publicly available. The search strategy was developed by the review authors and refined iteratively, but it did not undergo formal peer review by an information specialist or librarian. In addition, only English-language peer-reviewed journal articles and conference proceedings with accessible full texts were included, whereas non-English studies, non-peer-reviewed sources, conference abstracts, preprints, technical reports, theses, and other gray literature were excluded. Although 4 major databases were searched, publication bias and incomplete database coverage cannot be fully ruled out. Finally, because this was a scoping review, no formal risk-of-bias assessment, critical appraisal, or quantitative meta-analysis was performed; therefore, the findings should be interpreted as a structured mapping and qualitative synthesis of the available evidence rather than as a quantitative estimate of effect size or certainty of evidence.

Conclusions

Wearable reflectance PPG has become an important sensing technology for mHealth. As wearable PPG moves from controlled settings to real-world use, measurement quality varies with anatomical site, skin and tissue characteristics, motion, and the sensor-skin interface. This scoping review identified a multilevel relationship between contact conditions at the sensor-skin interface and wearable PPG outcomes. Differences in contact conditions were associated with changes in signal characteristics and derived features and, in a smaller body of studies, with differences in downstream physiological estimates such as HR, oxygen saturation, PTT or PAT, blood pressure–related indicators, and HRV. Therefore, contact force should not be treated as a minor wearing-related factor because contact-condition–related differences may extend from PPG signal acquisition to derived features and, in some studies, to downstream physiological estimation. Current evidence remains limited by short-term controlled study designs, inconsistent reporting of force or pressure conditions, insufficient description of contact area and probe geometry, and limited validation in long-term, unsupervised, or free-living settings. Only a few studies have directly linked contact-condition–related signal or feature differences with the robustness of downstream estimation models. Future research should therefore adopt standardized reporting of contact force or pressure, probe geometry, contact area, body site, wavelength, and fixation strategy. Long-term real-world validation, force-aware signal-quality assessment, robustness testing, adaptive attachment design, and context-aware modeling will be essential for improving the reliability and comparability of wearable PPG systems.

Acknowledgments

The authors thank all individuals who provided feedback and support during the development of this review. The authors also declare the use of generative AI (GAI) in the research and writing process. According to the GAIDeT (Generative AI Delegation Taxonomy) (2025) framework, the following tasks were delegated to GAI tools under full human supervision: text generation, proofreading and editing, translation, and reformatting. The GAI tool used was: ChatGPT 5.5/5.6 (OpenAI). Responsibility for the final manuscript lies entirely with the authors. GAI tools are not listed as authors and do not bear responsibility for the final outcomes.

Data Availability

All data extracted and charted in this scoping review are provided in Multimedia Appendices 4 and 5. No additional datasets were generated.

Abstract

Background: Infections are a major health concern in hospitalized patients. Fever is an early sign of infection, making temperature monitoring essential for infection surveillance. Wearable devices are increasingly being explored for continuous temperature monitoring in acute care hospitals, but how temperature data from wearables are monitored, presented, and used to support fever or infection management in clinical practice remains poorly understood.

Objective: This study aims to map existing evidence on the use of temperature data from wearables for fever or infection management in acute care hospitals, focusing on wearables' characteristics; data transmission, storage, and presentation strategies; data preprocessing and analytic approaches; and the maturity of wearables' clinical integration.

Methods: We searched MEDLINE, Embase, Web of Science, CINAHL, and IEEE Xplore for publications from January 2013 to July 2026 using the population, concept, context (PCC) framework. Primary research studies using wearables to monitor patients' body temperature in acute care hospitals for fever or infection management, published in English or Chinese, were eligible. Temperature data analyses were classified according to the descriptive, diagnostic, predictive, and prescriptive analytics framework. The clinical integration of wearables was assessed using a tailored maturity framework modified from the World Health Organization's stages of maturity for digital health interventions.

Results: We included 29 publications from 26 studies, published between 2018 and 2026. Eighteen wearable devices were identified, monitoring temperature at the axilla, chest, wrist, or upper arm. Continuous data streams were predominantly transmitted in real time, while 5 studies used non–real-time batch uploads, periodic synchronization, or device-memory downloads. Only 7 studies presented wearable temperature data in clinical settings, displaying data on mobile devices and/or centralized monitoring stations; only 1 study reported enabling alerts through electronic health records (EHRs). Invalid sensor data filtering methods varied across studies, such as physiological thresholds, firmware quality scores, and statistical outlier detection. Temperature data were most frequently analyzed by descriptive analytics (n=19) to depict the frequency, timing, and duration of fever episodes, followed by diagnostic analytics (n=6) to identify risk factors or distinguish causes of fever, and predictive analytics (n=9) to forecast impending fever or infections. None of the included studies used prescriptive analytics. For clinical integration, most studies were at the clinical validation stage (n=9) or clinical research stage (n=17), corresponding to an early stage of maturity; 3 studies reached the routine clinical practice stage, and none progressed to multicenter implementation or full integration stages.

Conclusions: While promising, the clinical integration of wearables remains at an early stage of maturity. Critical gaps exist in translating temperature data into actionable clinical insights, with limited data presentation, poor EHR interoperability, and

XSL•FO
RenderX

underdeveloped analytic approaches. Future research should prioritize standardized data cleaning frameworks, workflow integration, and clinical interpretation to facilitate the active use of wearable data in clinical decision-making.

Introduction

Infections are a major health burden in hospitalized patients, particularly those acquired within health care settings, posing a significant threat to global patient safety [1]. An estimated 5.4% to 7.8% of patients in acute care hospitals across Europe [2] and 12% to 18% in the Eastern Mediterranean Region [3] are affected by health care–associated infections. Timely recognition and earlier treatment of infections are crucial for reducing morbidity and mortality [4]. As one of the earliest and most apparent symptoms, fever is a vital diagnostic and monitoring indicator that reflects the clinical course of many infectious diseases [5]. Therefore, temperature monitoring serves as a fundamental component of infection surveillance and management, supporting clinical decisions on whether to initiate a fever workup or prescribe antibiotics.

Traditional temperature measurement mainly relies on intermittent manual recording by nurses. However, the intervals between observations cannot fully capture temperature changes and may miss febrile events or delay the detection of infections [6]. In recent years, wearable technologies have enabled continuous temperature monitoring in acute care hospitals [7]. Wearable devices are electronic sensors designed to be directly worn on the body to perceive and record various physiological parameters [8], encompassing a range of sensor-based devices such as patches, rings, wristbands, and smartwatches. Featuring wireless connectivity, real-time data collection, and remote monitoring capabilities, wearables have attracted growing interest for clinical applications. Recent studies have explored the accuracy and feasibility of wearables for temperature monitoring in diverse clinical settings, such as surgical wards, emergency departments, oncology wards, and intensive care units (ICUs) [9].

The high-frequency temperature data generated by wearables contain rich physiological information, which holds the potential to transform infection care by providing data-driven insights into inflammatory responses and infection trajectories [10]. With advanced analytical approaches, these data can be used to derive temperature features that capture temporal dynamics such as trends, patterns, and circadian rhythms. These features could serve as digital biomarkers to support early detection of febrile events, personalized alerts, and timely interventions [11]. For instance, a fever detection algorithm using a chest patch captured fever episodes 4.3 hours earlier than clinical assessments in patients at high risk of febrile neutropenia [12]. Vargas et al [13] demonstrated that entropy analysis of continuous body temperature could distinguish bacterial infections from other causes of fever, potentially enabling earlier antibiotic cessation. More broadly, wearable data are increasingly integrated into AI predictive models of infectious disease within real-time surveillance and clinical decision support ecosystems [14].

However, translating this potential into practice remains hindered by considerable hurdles when deploying wearables within the complex, high-noise environments of acute care hospitals. Wearable data collected in such environments typically contain various anomalies, such as missing values, outliers, motion artifacts, random noise, recording errors, and redundant data [15]. Without effective filtering, these anomalies may trigger false alerts and contribute to alert fatigue. Although wearables technically streamline routine temperature measurement and reduce time and effort [16], they may counterproductively increase nurses' workload without proper clinical integration [17]. Moreover, while continuous monitoring captures subtle physiological fluctuations, difficulties in interpreting the sheer volume of temperature data often prevent these data from being translated into actionable clinical insights [18], resulting in a paradoxical situation where cognitive overload and data waste coexist. Given these limitations, wearables may simply be used as tools for passive data collection rather than active clinical decision support [19], with their potential remaining largely underexplored.

To better integrate wearables into clinical practice, there is a need to incorporate wearable data into existing clinical workflows and facilitate data interpretation to support clinical decision-making. However, most current studies remain focused on evaluating the accuracy and feasibility of wearables in clinical care [20]. While existing literature reviews have summarized available wearables and their clinical validation findings [9,21], there is a lack of synthesized evidence on how temperature data from wearables are processed, presented, and interpreted in clinical practice. For the next step, it is essential to shift the research focus from device performance assessment toward proactive data usage in clinical contexts. Therefore, to bridge the gap between technical feasibility and clinical utility, this study aims to review evidence on the use of wearables for continuous temperature monitoring in acute care hospitals to support fever or infection management, focusing on strategies for data transmission, presentation, and use, and the overall maturity of these wearables' clinical integration.

Methods

Overview

We chose a scoping review because it provides the flexibility to synthesize heterogeneous evidence across different wearable device types, clinical contexts, and data analytical methods in this rapidly evolving field. We conducted the review following the Joanna Briggs Institute (JBI) manual for scoping reviews [22] and reported it in alignment with the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) guidelines [23]. The protocol was registered on the Open Science Framework (OSF) [24] and published [25] ahead of this review. The PRISMA-ScR checklist is provided in Multimedia Appendix 1.

Research Question

Our review addressed the following questions:

- Question 1: what types of wearable devices have been used in acute care hospitals to monitor body temperature for fever or infection management?
- Question 2: how are the temperature data from wearable devices monitored, transmitted, and presented in acute care hospitals?
- Question 3: what analytical approaches have been used to process temperature data from wearable devices to support the management of fever or infections?
- Question 4: to what extent have these wearable devices been integrated into clinical practice?

Selection of Studies

We adopted the Population, Concept, Context (PCC) framework to guide the development of search strategies and eligibility criteria.

- Population: hospitalized patients who are confirmed, suspected, or at risk of developing fever or infections.
- Concept: wearable devices that are capable of wireless, continuous, noninvasive body temperature monitoring by being worn on the external body surface [8]; fever was defined as a pathological elevation in the body's set-point temperature [26,27]; infections refer to the invasion and multiplication of microorganisms, including bacteria, viruses, fungi, or parasites, in body tissues. We define continuous monitoring as automated time-series data acquisition at a predefined sampling frequency in real time or near real time (eg, every 1 minute or 5 minutes) [28], without manual initiation of each measurement.
- Context: acute care hospitals, which provide short-term, hospital-based care for patients with acute illness or injury. All inpatient wards and emergency departments were eligible.

The MEDLINE, Embase, Web of Science, CINAHL, and IEEE Xplore databases were searched from January 2013 to July 2026, as bibliometric analysis indicates a rapid increase in research on wearable technologies for health monitoring since 2013 [29,30]. The search was initially conducted in February 2025 and updated in July 2026 (both by reviewer YL). Search terms were organized into categories, including "wearable*," "body temperature," "fever," "infecti*," "patient*," and "hospital." Specific brands of wearables were identified from previous reviews and added to search strings [7,9]. Gray literature, including conference proceedings, preprints, and dissertations, was also searched. The detailed search strategies for databases and websites for gray literature are provided in Multimedia Appendix 2. The full search strategy was reviewed by a professional medical librarian using the PRESS (Peer Review of Electronic Search Strategies) checklist [31].

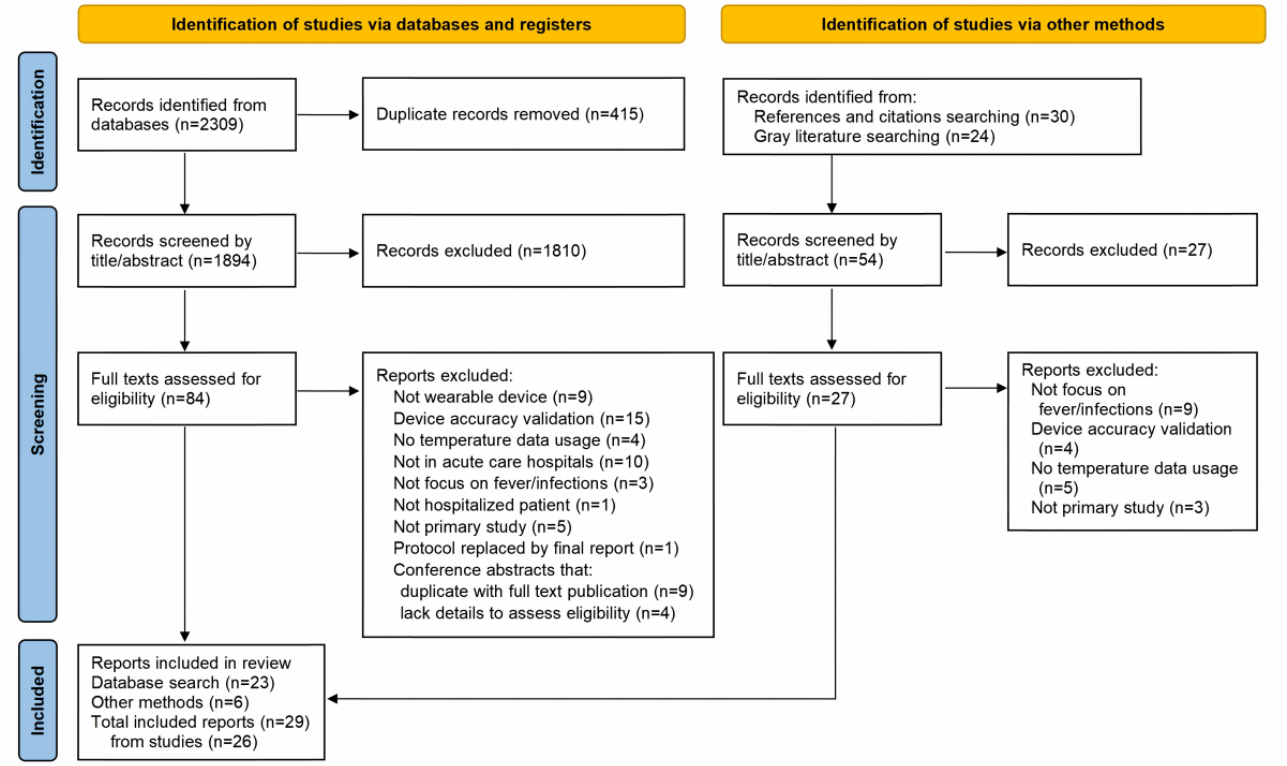
We uploaded the search results to Rayyan [32] to remove duplicates and conduct online screening. During the pilot screening, we compiled a preliminary list of potential temperature monitoring devices, discussed which qualified as wearables, and reached consensus on the eligible boundaries before formal screening. Then, a 2-step process, including title and abstract screening and full-text screening, was used. One reviewer (YL) screened all literature, with 20% randomly selected and independently screened by a second reviewer (QZ) to assess screening consistency. The interrater agreement using Cohen κ coefficients was 0.778 and 0.746 for each screening step, indicating substantial agreement. Disagreements were resolved through discussion with a third reviewer (DD). For multiple records derived from the same study, such as conference abstracts and research protocols, the formally published article was retained. The reference lists and citation lists of eligible articles and relevant literature reviews were manually searched to identify additional publications.

Studies were included if they used wearables to monitor patients' body temperature in acute care hospitals for the purpose of fever or infection management, including but not limited to detection, diagnosis, prediction, treatment, or prognostic assessment. Primary research studies published in English or Chinese were eligible regardless of study design or publication type. Studies were excluded if they focused on monitoring local tissue temperature (eg, wound or foot), reported the technical design or development of wearables, assessed device accuracy exclusively without clinical interpretation of temperature data, or focused on the prevalence of epidemic infectious diseases rather than clinical care.

Data Extraction and Analysis

Data were extracted from the main text and supplementary materials using a predefined data extraction form (Multimedia Appendix 3), including bibliographic and contextual attributes, wearable device characteristics, and strategies for data transmission, storage, and presentation. We also extracted temperature data analysis strategies, including data preprocessing, derived temperature features, and analytic methods. We classified temperature data analyses according to the descriptive, diagnostic, predictive, and prescriptive analytics framework [33,34], and further assessed the maturity stage of wearables' integration in clinical practice with reference to the World Health Organization's (WHO) manual, "*Monitoring and Evaluating Digital Health Interventions*" [35]. We also identified the role of nurses by reviewing the main text, author lists, and affiliations. We did not assess the methodological quality of the included publications in an attempt to map all

XSL•FO
RenderX



available evidence, and quality appraisal is not mandatory in a scoping review according to JBI methodology [36]. Data extraction was performed by one reviewer (YL). A second reviewer (QZ) independently extracted data from a random 20% of the included publications to evaluate the reliability of the data extraction process. Discrepancies were discussed to reach a resolution, and a third researcher (DD) was consulted for unresolved discrepancies. A descriptive synthesis of the findings was presented in tables and figures.

Results

Study Selection

A total of 2309 records were identified through database searches. After duplicate removal (n=415), 1948 records (1894 from database searches and 54 from manual identification) were screened by title and abstract. Subsequently, 111 records (84 from database search screening and 27 from other methods) underwent full-text screening. We included 29 publications (from 26 studies) in this review. Figure 1 presents the study selection process. Three publications [6,37,38] reported data derived from the same patient cohort in one study, while 2 publications [39,40] analyzed data from another study.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram.

Study Characteristics

The 29 included publications (from 26 studies) comprised 25 journal articles (including 1 research letter with original data) and 4 conference abstracts, published in English (28/29, 97%) and Chinese (1/29, 3%) between 2018 and 2026. The included studies were conducted in Asia (9/26, 35%), Europe (8/26, 31%), North America (6/26, 23%), and Oceania (3/26, 12%). The majority were prospective observational studies (20/26, 77%), while 3 were retrospective observational studies, 1 was a randomized controlled trial, and 2 observational studies did not specify whether they were prospective or retrospective. Most studies were single-center (24/26, 92%), with only 2 studies being multicenter. Study populations were adult patients (17/26, 65%), pediatric patients (5/26, 19%), women in labor or pregnancy (3/26, 12%), and older adult patients (1/26, 4%). Clinical settings comprised oncology wards (9/26, 35%), surgical wards (6/26, 23%), medical wards (6/26, 23%), prenatal or delivery rooms (3/26, 12%), and ICUs (2/26, 8%). The primary events of interest were febrile events (15/26, 58%; including fever, febrile neutropenia, cytokine release syndrome [CRS], and intrapartum fever) and infections (11/26, 42%; including sepsis, pneumonia, intraamniotic infection, postoperative infectious complications, and COVID-19).

Wearable Device Characteristics and Monitoring Parameters

A total of 18 wearable devices were identified (Table 1), including 4 chest patches, 6 axillary patches, 2 smartwatches, 2 wristbands, 3 upper arm or leg bands, and 1 neck patch. Most devices (11/18, 61%) monitored multiple physiological parameters, while 7 devices were dedicated temperature sensors. Seven devices measured axillary temperature, while 11 devices measured skin temperature at various sites, including the chest (n=3), wrist (n=4), upper arm or leg (n=3), and neck (n=1). Five devices provided estimated core temperature (VitalPatch, CORE, Everion, Moni-Patch, and iThermonitor), with measurements derived from axillary or skin temperature readings. Axillary

XSL•FO
RenderX

patches were the most frequently used device, with the highest number of studies reported in oncology wards (Figure 2).

Among the 18 identified wearables, 78% (14/18) were medical-grade and 11% (2/18) were consumer-grade, while the grade was not specified for 2 devices. Ten wearables were approved by the US Food and Drug Administration (FDA), with the majority (8/10) approved as class II devices for use by health care professionals on general patients in health care settings, while 2 were approved for home use or ovulation tracking (Multimedia Appendix 3). However, reporting on the regulatory status and clinical validation of wearables showed gaps. Among the included publications, only 41% (12/29) reported the device grade, and just 35% (10/29) confirmed FDA approval or Conformité Européenne (CE) marking. Only 35% (10/29) of publications validated the wearables by comparing the temperature data with standard clinical measurements as part of their results, and 17% (5/29) cited previously published validation findings. One article noted that the wearable device used in their study had not yet been clinically validated [41], and 2 articles mentioned manufacturer preclinical validation [42,43]. The remaining publications (11/29, 38%) did not mention clinical validation.

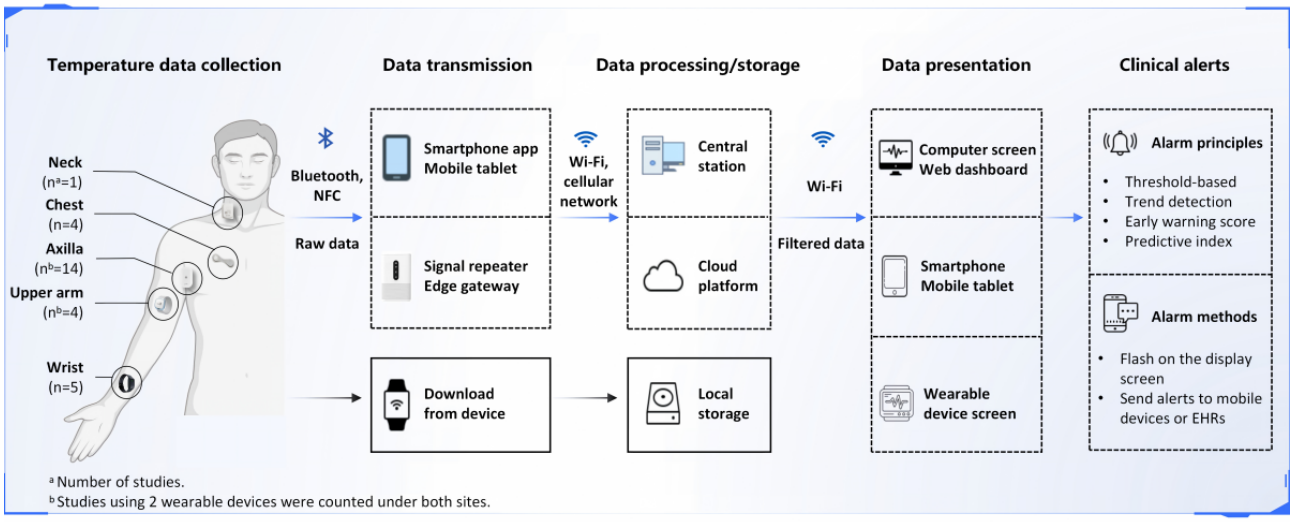
Figure 2. Number of included studies by clinical setting and wearable device type. Bubble size and color intensity represent study count for each combination. Studies using 2 wearable devices were counted under both types. ICU: intensive care unit.

There was variation in monitoring frequency and duration across studies. Body temperature was monitored at varying intervals, including every 1, 2, 4, 10, or 30 seconds; every 1, 2, 5, or 15 minutes; or at sampling frequencies of 4 Hz or 25 Hz. The median duration of temperature monitoring per patient ranged from 3 hours to 20 days across studies. Battery life across the included wearables ranged from 1 to 30 days. Holt et al [44] reported that, despite a theoretical maximum battery life of 3 days, the device recorded data only up to 44 hours in practice. To meet the requirements of clinical monitoring durations, different strategies were used depending on the device, such as daily charging [41,45,46], battery replacement [47], or regular device change every 24 hours [39,42,48], 3 days [49,50], or 6 days [51].



Temperature Data Transmission, Storage, and Presentation

Data Transmission

Figure 3 illustrates the data transmission strategies. Wearable data were predominantly transmitted through a wireless pipeline (20/26, 77%), initially from sensors via Bluetooth to nearby mobile devices (smartphones, tablets, or iPads), engineered bridges, signal repeaters, or transportable gateways. Subsequently, 16 studies described the further transmission of data from mobile devices or bridges to cloud service platforms (n=11) or central computers in the wards (n=5). These data were typically transmitted in real time or as continuous streams. Data latency was quantitatively reported in only 1 feasibility study [46], where data arrived at the dashboard with a median delay of 5 minutes for Everion and 2 minutes for CORE. After addressing transmission bottlenecks caused by 2 wearables competing on a single gateway, the median delay for both devices decreased to 0 minutes (range 0-2 minutes). Kim et al [52] used a dual-gateway wireless architecture that allowed the patch to communicate simultaneously with 2 nearby gateways, thereby ensuring uninterrupted transmission with minimal data latency or signal loss.

XSL•FO
RenderX

Figure 3. Data transmission, storage, and presentation in clinical practice.

In contrast, 19% (5/26) of studies used non–real-time data transmission methods, which included a batch upload strategy with 10-minute intervals [48], synchronizing temperature data each morning via a smartphone app following overnight monitoring [43], reading out patch data via near-field communication (NFC) every 24 to 72 hours using a smartphone app [53], or downloading data from the devices' internal memory after regular removal [44,45]. The remaining 1 study did not specify data transmission strategies or frequency.

Data Storage and Protection

Four studies reported that data could be stored temporarily on the device for 18 hours [54], 90 hours [45], or up to 6 days [55] with time stamps [47]. This feature supported local data retention during periods without network coverage, with buffered data automatically synchronizing upon connection restoration. Eight of the studies [41,46,50,54,56-59] reported that wearable data were stored on cloud platforms, with 2 studies [41,46] irreversibly deleting data from the cloud dashboard after they were transferred to a local research database. Four studies [47,52,55,60] stored wearable data on local central workstations or hospital computer systems. One study [45] reported that data were stored on the device, downloaded via a stationary Bluetooth interface for local storage, without using a web application due to regulatory requirements. Reporting on data security remains poor: only 38% (10/26) of studies described privacy protection strategies, including access restrictions [17,50,55,56], data anonymization [39], encryption for data in transit and data stored [41,46], local data storage [45], and the use of a secure wireless network and secure communication protocols [52]. Among these, 2 studies [45,49] reported alignment with the European Union (EU) General Data Protection Regulations.

Data Presentation in Clinical Practice

Only 27% (7/26) of studies presented temperature data from wearables in clinical settings, displaying data on mobile devices (n=5) and/or centralized monitoring interfaces (n=6). Among these, 4 studies [17,51,54,61] used multiple interfaces, displaying data both on mobile devices carried by nurses and on ward computer screens [17,61] or web-browser–based dashboards enabling remote access [51,54]. In contrast, 3 studies used a single interface, visualizing temperature curves either on a central computer screen in the nurse station [47,60] or on a paired bedside tablet [62]. Two studies reported that the wearable systems could send digital alerts to health care professionals via smartphones [17,61] or electronic health records (EHRs) [17]. Apart from the single study allowing alerts through EHRs [17], no other studies reported integration with EHR systems.

Conversely, 42% (11/26) of studies did not present wearable data in clinical settings, using the devices solely for research data collection. Among these, 9 studies explicitly stated that wearable data were blinded to clinical staff [41,45,48,50-53,58,59] to avoid influencing clinical decisions [46], while 2 studies [44,45] directly downloaded data from the device without dashboards. In 1 study [49], although heart rate, respiratory rate, and peripheral oxygen saturation (SpO_2) were available in real time for caregivers to support care, skin temperature was not directly available because its clinical relevance was considered uncertain. The remaining studies (8/26, 30.8%) lacked sufficient information to determine whether data were displayed or provided to clinical staff.

The Use of Temperature Data

Data Quality Assessment and Preprocessing

The reporting of missing sensor data varied across the studies. Only 62% (16/26) of studies reported the reasons and proportions of missing temperature data, while 2 studies indicated that no missing data were observed [47,60]. In the remaining 31% (8/26) of studies, missing data were not mentioned. The reported causes for missing data were grouped into 4 main categories: patient factors (eg, discomfort, nonadherence to the wearing protocol, and improper handling), device factors (eg, device malfunction and battery issues), wearing quality (eg, device detachment, poor skin contact, and sweating), and signal factors (eg, synchronization failure, motion artifacts, and patients moving out of signal coverage). The metrics used to quantify missing data also varied. Five studies described the hours with low-quality or missing data (ranging from 3.6% to 11.7%), 5 studies reported the hours with valid

XSL•FO
RenderX

data (ranging from 67% to 99%), while 6 studies reported the cases with missing values (ranging from 2% to 31.4%).

Several methodologies to detect invalid data were identified from the included studies, including heuristic filtering based on physiological plausibility thresholds, firmware-integrated quality indexing, and statistical outlier detection frameworks. Six studies used thresholds to filter out implausible values (eg, below 35.5 °C or 35 °C for axillary temperature [39,40,50,52] or 31 °C for skin temperature [44]), with one of them involving patients with terminal illness using a lower threshold of 25 °C for skin temperature [49]. Four studies [41,45,46,51] reported that wearables' firmware generated a quality score for temperature data per minute, though the use of the quality score differed. In the study by Garbern et al [54], a quality score was calculated based on signal quality each minute; windows with quality scores below 75% were labeled as low quality and excluded from analysis. In contrast, Jacobsen et al [45] did not use the quality score to select data; instead, they retained only periods with at least 3000 data points per hour for analysis. Eisenkraft et al [51] picked outliers with a difference from the mean exceeding the Q3 + 3 × IQR threshold. Additionally, the initial 5 minutes of data were often excluded due to device warm-up and stabilization periods [49].

Strategies for handling invalid or missing sensor data were heterogeneous across studies, spanning data filtering, smoothing, imputation, and native algorithmic handling. Some studies excluded entire cases [43,44,50,52,53,56] when extensive missingness occurred (eg, patch fell off over 6 hours), or targeted removal of data points identified as anomalies [17,44,50,51,53,54]. For smoothing, van Goor et al [49] computed 15-minute median values to reduce the impact of short-lasting outliers and missing data. For imputation, Rajeeve et al [59] applied forward-fill methods to address missing sensor data, whereas Debnath et al [40] retained the dropped data without imputation, considering the imputation process may introduce potential bias. Finally, 2 studies embedded missing-data handling directly within their modeling pipeline. Chen et al [56] used extreme gradient boosting (XGBoost), which handles missing values during training by automatically learning the optimal split direction; Jacobsen et al [45] used end-to-end deep learning algorithms that could handle artifacts and data gaps without extra preprocessing.

Temperature Features Derived From Wearable Data

Three major categories of temperature features were derived from raw continuous readings, including basic descriptive statistics, threshold-based features, and temporal features. Basic descriptive statistics were the most commonly used features, including the mean (n=14), median (n=3), maximum body temperature (n=5), SD (n=5), variance, and coefficient of variation (n=1). These features were used to characterize the temperature dataset and to compare temperature measurements across different monitoring methods, patient cohorts, and anatomical sites. For example, Liu et al [47] compared the peak temperature monitored by continuous monitoring and intermittent monitoring, finding that continuous monitoring captured 0.29 °C higher peak values.

The second major category was threshold-based temperature features, which were identified in 21 publications. These studies used various predefined cutoffs (eg, 37.2 °C, 37.8 °C, 38 °C, and 38.5 °C) to identify fever, subsequently using continuous temperature data to quantify the features of fever episodes, including frequencies, the cumulative duration [62] or percentage of time spent above the threshold [54], and severity (quantified by calculating the area under the time-temperature curve [62]). Notably, Rajeeve et al [59] reported that individualized axillary temperature thresholds (baseline mean + 2 SD) combined with a fixed threshold (36.4 °C) enabled earlier detection of temperature elevation before clinical recognition of CRS episodes than a simpler fixed 38.0 °C threshold did. Four studies [17,51,54,61] relied on thresholds set by early warning score (EWS) systems to trigger alerts when body temperature deviated from the preset physiological range. Eight studies focused on the timing of fever detection [6,39,42,47,50,52,58,60]. For instance, Sampson et al [42] compared the differences in the timing of fever detection, showing that continuous temperature monitoring detected fever events 12 hours earlier than standard monitoring. Wang et al [60] used 24-hour continuous recordings and a brute-force strategy to simulate different intermittent monitoring schedules, identifying the combination with the highest fever detection rate.

Ten publications further incorporated temporal features of body temperature, including trends, trajectory patterns, and circadian rhythmicity. Five studies explored visual trends and patterns: 3 studies observed rising temperature trends associated with infections [6,51,62]; 2 studies tried visual inspection of temperature curves in the 48 hours preceding fever episodes, although they did not yield clinically significant predictive information [41,46]. A more computational pattern recognition technique was used by Ren et al [37], who used dynamic time-warping to characterize temporal trajectory patterns to differentiate between fever etiologies. Another 3 studies focused on circadian rhythmicity, either by modeling the rhythm with cosinor models to detect a loss of circadian variation in skin temperature among patients who were critically ill with COVID-19 [49], or by using residual deviations from the patient's individual circadian rhythm pattern to predict febrile adverse events [6,45]. Two studies developed machine learning models using temperature data as inputs, with time-series features generated by aggregating temperature data into rolling windows of 6 to 14 hours in one study [59], while the other used a fixed 12-hour window [63].

Classification of Temperature Data Analytics

An established data analytics framework categorizes 4 analytic approaches by the questions they address: "What happened?" (descriptive), "Why did this happen?" (diagnostic), "What might happen in the future?" (predictive), and "What should be done next?" (prescriptive) [34]. Using this framework, we classified the temperature data analyses in the included publications as descriptive (used in 19/29, 65% of studies), diagnostic (used in 6/29, 21% of studies), and predictive (used in 9/29, 31% of studies); none used prescriptive analytics (Table 2). Five publications used multiple analytic approaches.

XSL•FO
RenderX

Table 2. Classification of data analytics for wearable-generated temperature data.

Types of analytics and description of the included studies	Temperature features	Analysis techniques
Descriptive analytics (n=19)		
Compared differences in temperatures recorded across monitoring methods, patient cohorts, or anatomical sites [43,44,47]	Mean, SD, median, and maximum	Student *t* test and ANOVA
Counted the numbers and frequencies of febrile events and compared the time difference between fever episodes detected by continuous and intermittent monitoring [17,38,39,42,47,48,50,52,58,61]	Timing of fever	Student *t* test
Developed a heuristic scoring system to quantify the clinical relevance of fever detection, incorporating fever duration (short spike <60 minutes; prolonged episode ≥60 minutes) and clinical actions triggered [53]	Thresholds and fever duration	Descriptive comparison
Hourly points from the continuous temperature data were used to simulate 1 to 24 intermittent daily measurements to identify the optimal timing and frequency achieving the highest fever detection rate [60]	Counts and frequencies	Brute-force strategy
Compared the performance of fixed, individualized (baseline mean + 2SD), and combined thresholds for axillary temperature in detecting cytokine release syndrome [59]	Thresholds	Grid search
Detected abnormal values or temperature deviations from preset thresholds to trigger alerts [17,61]	Thresholds	Described the counts and frequencies
Visualized patterns of temperature, such as rising trends or fluctuations in temperature curves [41,46,51]	Visual patterns	Line plots
Described the disappearance of the circadian rhythm of skin temperature in patients with critical illness, in comparison with recovered patients [49]	Circadian rhythmicity	Cosinor models
Diagnostic analytics (n=6)		
Classified fevers of infectious or non-infectious causes using temperature trajectory patterns within 4 hours around fever start time [37]	Trajectory patterns	Dynamic time warping and k-means clustering
Quantified fever intensity and evaluated its association with epidural analgesia duration and dosage to identify risk factors for fever [62]	Area under time-temperature curve	Logistic regression and ROC[a] curve analysis
Examined the correlation between skin temperature and oral/ear canal temperature and identified a diagnostic cut-off value of skin temperature for detecting fever or infections [44,48,57]	Correlations	ROC curve analysis
Analyzed the correlation between standard deviation and peak temperature to reveal an increased temperature variability before and after the spike [39]	Correlations	Pearson correlation and linear regression
Predictive analytics (n=9)		
Predicted SCC[b] by inputting temperature data into a deep neural network to calculate an SCC score reflecting dissimilarity from normal patterns [45]	Cosine similarity	Deep neural network
Used aggregated temperature features (median, variance, coefficient of variation) as inputs for pulmonary infection prediction models [56]	Median, variance, coefficient of variation	XGBoost[c]
Extracted residual deviations of temperature from the patient's individual circadian rhythm pattern as early signs of febrile adverse events [6]	Circadian residuals	Circadian modeling and genetic algorithm
Used continuous temperature data as inputs for machine learning models to predict the risk of advanced sepsis [54], cytokine release syndrome [59], or COVID-19 deterioration within the next 24 hours [63]	Mean, SD, extreme value, and percentage of time spent over thresholds	Machine learning models
Used skin temperature features (eg, mean and maximum) within various time windows before fever onset as early predictive signals for impending fever episodes [40,55,57]	Correlations	Logistic regression and generalized estimating equation

[a]ROC: receiver operating characteristic.

[b]SCC: serious clinical complications.

[c]XGBoost: extreme gradient boosting.

Descriptive analytics were used in 18 publications. Descriptive analytics describe the temperature data using basic descriptive statistics such as means, frequency, and variation, and present the data through histograms, box plots, scatter plots, and line charts. These studies reported that continuous temperature monitoring via wearables enabled earlier fever detection [17,38,39,42,47,48,50,58,61], captured higher temperatures [43,44,47], detected more febrile events [38,42], and yielded

XSL•FO
RenderX

higher fever detection rates [52,60] than conventional intermittent monitoring, suggesting the potential of wearables to improve fever or infection detection.

Diagnostic analytics were used in 6 publications. Diagnostic analytics involve comparing coexisting trends, uncovering correlations between variables, and determining causal relationships where possible to identify the risk factors or causes of fever. Pearson correlation, linear regression, and logistic regression were used to explore associations between temperature variables [39,57] and identify risk factors for fever [62]; receiver operating characteristic (ROC) analysis was used to derive diagnostic cutoff values for fever based on wearable skin temperature [44,48]; and k-means clustering was used to classify fevers of infectious or noninfectious causes [37]. These studies highlighted the potential of wearable data to support clinical diagnosis related to fever or infections.

Predictive analytics were identified in 9 publications. By using historical data and statistical modeling, predictive analytics identify patterns and predictors of future events and forecast the probability of fever or infections. Methods included logistic regression, machine learning models, and circadian modeling, with temperature features serving as predictive inputs. Six studies developed predictive models to estimate the risk of pulmonary infection [56], febrile adverse events [6,45], CRS [59], deterioration [63], and advanced sepsis [54]. Another 3 studies [40,55,57] focused on identifying skin temperature features within various time windows before fever onset as early predictive signals for impending fever episodes. These findings suggested the potential of wearables to enhance personalized fever or infection risk prediction.

Prescriptive analytics uses algorithms with “if” and “else” rules to analyze data and recommend optimal next steps or actions. In health care, this approach can be operationalized through clinical decision support systems that provide therapeutic recommendations, for example, whether medication or physical examinations are required. However, none of the included studies used prescriptive analytics.

Maturity Stages of Wearable Device Integration in Clinical Practice

Table 3 maps the original WHO stage of maturity for digital health interventions and our modified maturity framework tailored to wearables, outlining 6 phases in a continuum. As specified in the eligibility criteria, studies focused on prototype design, preclinical testing, or only on validating the accuracy of wearables were excluded. Among the 29 included publications, most were classified as being at the clinical validation stage (stage 3a: 9/29, 31%) or clinical research stage (stage 3b: 17/29, 59%). The primary objectives of these studies were to evaluate the performance of wearables for monitoring body temperature in clinical settings or to collect research data, corresponding to the pilot stage in the WHO framework. In 3 studies, wearables were applied in routine clinical practice (stage 4: 3/29, 10%) as a supplement to standard temperature monitoring by nurses, aligning with the demonstration stage. None of the studies in this review had progressed to multicenter implementation or full integration.

RenderX

Table 3. Maturity stages of wearable devices' integration in clinical practice, modified from WHO[a] "Monitoring and Evaluating Digital Health Interventions."

WHO stage of maturity and modified stage of maturity	Publications	Focus on wearable devices at each stage
Early		
Preprototype		
Stage 1: proof of concept	Not included	Hypothesis building, clinical needs/context assessment, preliminary solution modeling, and initial technical feasibility testing
Prototype		
Stage 2: preclinical test	Not included	Technical design, functionality assessment, and testing of technical stability (eg, device compatibility, data transmission range, and system robustness) in simulated or controlled environments
Pilot		
Stage 3a: clinical validation	n=9	Validation of accuracy, precision, and feasibility in real clinical settings, typically via field tests and clinical trials using gold standards for comparison [39,41,42,46,47,50,52,58,61]
Stage 3b: clinical research	n=17	Wearables are used exclusively for data collection in research, with the data collected not being provided to support clinical practice [6,17,37,38,40,43-45,48,53-57,59,62,63]
Mid		
Demonstration		
Stage 4: routine clinical application	n=3	Wearables are integrated into routine clinical workflows as a supplement to standard care; wearable system operating independently from the hospital's EHR[b] [49,51,60]
Advanced		
Scale-up		
Stage 5: multicenter implementation	n=0	Wearables are adopted as part of routine clinical practice across multiple centers or scaled up to subnational, national, or population levels.
Integrated and sustained program		
Stage 6: full integration	n=0	Full integration into clinical practice, with EHR interoperability, use in decision support systems, and supportive policies and financing enabling broader health system incorporation.

[a]WHO: World Health Organization.

[b]EHR: electronic health record.

Nurses' Roles

The findings show that nurses were engaged in both research and clinical practice related to wearable devices. As researchers (identified in 7 studies), nurses acted as principal investigators who led and conducted the research [47,48,50,55,57,61] or served as clinical research nurses responsible for patient recruitment, device maintenance, and data collection [54,61]. In clinical practice, 12 studies described nurses as direct users of wearable devices for temperature monitoring, evaluating temperature data generated by the devices, and responding to device alerts.

Discussion

Principal Findings

This scoping review assessed 29 publications from 26 studies using wearables to monitor body temperature in acute care hospitals for fever or infection management. We identified a variety of wearables used across diverse patient populations and clinical settings since 2018, indicating growing interest in this emerging technology despite its recent introduction to clinical practice. By mapping the current evidence on wearable temperature data pipelines from sampling through transmission and presentation to clinical use, we also identified overall limited clinical integration and critical gaps at each stage. These findings may serve as a practical reference for the design and implementation of wearable-based monitoring systems within clinical workflows and highlight barriers to be addressed to move toward more sustainable clinical adoption.

Different Types of Wearables and Clinical Utility of Their Temperature Data

This review identified a preference for medical-grade devices in clinical settings, while consumer-grade devices predominated in home-based remote monitoring in oncology [20] or cardiovascular care [64]. This preference reflects the need for accurate temperature data in clinical practice, which influences

XSL•FO
RenderX

the selection of wearables and how the data can be used. Wearables generally provide temperature readings by monitoring thermal activity at the skin surface, which is susceptible to ambient conditions and skin perfusion [65]. In order to meet clinical and regulatory standards, medical-grade wearables adopted several strategies to deliver accurate temperature data, including monitoring at more reliable anatomical sites such as the axilla, which closely approximates core temperature when properly acquired [66], and developing algorithms to estimate core temperature from raw sensor signals. Accordingly, the average readings of estimated core temperatures and axillary temperatures were around 36.3 °C to 37.2 °C [40,62], which were mainly considered in studies that presented wearable data in clinical practice.

Unsurprisingly, skin temperatures directly provided by wearables at wearing sites, such as the wrist or chest, remain more variable in terms of validity and clinical utility. The mean skin temperatures were reported around 33.9 °C to 34.8 °C in reviewed studies [43,44], showing significant deviation from commonly used clinical values, particularly when determining fever. Therefore, several studies withheld skin temperature from clinical staff or discarded data from analyses [67-69], highlighting a cautious stance toward its clinical relevance. Some studies limited data collection periods, monitoring wrist skin temperature only during sleep to reduce daily activity influences [43]. However, studies have embraced more innovative strategies to actively use skin temperature, such as identifying elevated values as a predictive signal for fever [55], detecting abnormal circadian rhythms in patients with critical illness [49], and directly using its cutoff values to predict infection [44]. These methods view skin temperature as an independent output pathway of the thermoregulatory system, offering a potentially clinically useful route for its application. Notably, 1 study reported that both axillary and skin temperature emerged as reliable biomarkers, yet prioritized wearable-derived skin temperature over axillary measurements for its higher sampling frequency, continuous availability, and ease of future deployment [59]. Therefore, for clinical interpretation of wearable temperature data, health care providers should not be limited by absolute value comparability to traditional measurements but integrate trend-based and pattern-recognition approaches to expand clinical utility of wearable data across diverse monitoring contexts.

Filtering Anomalies Before Using Temperature Data From Wearables

Although medical-grade wearables exhibit accuracy, prolonged usage in real-world clinical environments still presents significant data quality challenges arising from patient nonadherence, poor skin contact, device malfunction, sensor drift, and signal artifacts. Efforts have been made by manufacturers to assign quality scores to each temperature reading via wearables' firmware [41,45,46,51]. However, the reliability of quality scores has not been adequately validated, and their calculations often lack transparency due to proprietary algorithms and patent protection. As indicated by Koenig et al [41], the wearables' quality assessment was generally plausible, but it occasionally misclassified vital signs by assigning good quality to incorrectly measured data and poor quality to plausible extreme values. Therefore, studies in this review differed in their use of quality scores. We highly recommend that future studies validate quality scores before deciding whether to incorporate them.

Identifying anomalies should be guided by both data characteristics and clinical domain knowledge, as anomalies may still fall within the physiological boundaries yet represent clinically significant events [15]. The most commonly used method in the reviewed studies relied on thresholds to identify invalid temperature data, which has significant limitations. Removing axillary temperature readings below 35.5 °C may overlook inadvertent hypothermia in patients with critical illness [70] or patients who had undergone surgery [66]. Moreover, recent studies suggest that human basal body temperature has declined over the past century [71]. A systematic review calculated the normal range for axillary temperature to be 35.01 °C to 36.93 °C [72], indicating that a fixed 35.5 °C may not be able to account for individual variations in baseline temperatures. Additionally, the high variability in skin temperature makes it more challenging to determine reasonable thresholds for outlier removal. Instead, specialized artifact detection algorithms have been developed in a broader context. For example, Bardia et al [73] developed algorithms to identify adjacent temperature readings with slopes exceeding 0.08 or an absolute change greater than 0.25 °C, which effectively filtered intraoperative temperature artifacts. Future efforts should develop and incorporate such standardized data cleaning frameworks based on specific clinical contexts and professional knowledge, enabling personalized anomaly detection while preserving clinically relevant events.

After identifying anomalies in temperature data, handling incomplete datasets remains challenging. Most reviewed studies simply excluded cases with high missingness or deleted anomalous window segments. While retaining only valid data is feasible for basic statistical comparisons, removing data disrupts time-series signal continuity and limits specific feature extractions that require continuous data as inputs, such as entropy metrics for nonlinear dynamics [13]. On the other hand, the decision to impute missing data also requires careful evaluation. A study comparing imputation techniques for wireless continuous vital signs found that linear interpolation reduced feature bias (eg, 2-hour window mean and slope) relative to no imputation, whereas other techniques (eg, last observation carried forward and spline interpolation) increased bias, with imputation errors growing significantly with gap length [74]. Some advanced strategies have emerged as alternatives to imputation. For instance, dimensionality and size reduction based on intrinsic and target similarity can be used to eliminate features and samples that are highly sensitive to missing values [75], a principle that may extend to physiological time-series modeling. In addition, algorithms with built-in tolerance to missing data may improve model robustness and generalizability. Overall, we recommend selecting the appropriate preprocessing approach based on the specific downstream task, following careful assessment of potential bias.

XSL•FO
RenderX

Advancing Temporal Pattern Mining and Interpretation for Wearables Data

Our review found that descriptive analytics remain the predominant approach for analyzing wearable-generated temperature data, with visual inspection of the trends and spikes in temperature curves being a common approach. This approach is intuitive, convenient, and easy to interpret in clinical practice, without requiring additional computational resources. However, it may not allow for detecting a specific pattern or predictive signals preceding infections [41]. In contrast, time series analysis and machine learning models for diagnostic or predictive applications were used in only one-third of the publications reviewed, indicating underutilization of these advanced analytical capabilities.

To leverage the hidden temporal patterns in high-frequency temperature data, machine learning and time series models represent an important methodological evolution. These methods extract temperature features that indicate circadian rhythm variations and pattern similarities, capturing subtle yet crucial indicators of infection that are not discernible through direct visual inspection. Beyond the temperature features identified in this review, studies have examined temperature dynamics in a broader context. For example, Papaioannou et al [76] assessed temperature complexity using wavelet transformation and multiscale entropy to classify patients with systemic inflammatory response syndrome, sepsis, and septic shock. Bhavani et al [77] identified 4 temperature trajectories from hourly recorded EHR data, revealing sepsis subphenotypes with distinct biomarker profiles. These advances highlight the need for further integration of advanced data analytics for temperature temporal pattern mining and knowledge discovery. These algorithms offer promising solutions to tackle data overload challenges by filtering meaningful and actionable information from massive wearable data; however, they still require further integration into computerized decision support systems to enable intelligent analysis and transform data into simpler and more usable forms.

Integration of Wearable Devices Into Clinical Practice

We found that several wearables have been used for temperature monitoring as a supplement to standard nursing measurements, but their integration into routine clinical practice remains limited. The wearable systems were deployed independently, with only 1 study enabling alerts through EHRs [17]. This may stem from health systems' requirement to establish a dedicated secure network for wearables, separated from the main network to prioritize data privacy [78]. However, this approach creates data silos. Although temperature is a key indicator for infection detection, final clinical diagnosis or treatment decisions require synthesis of wearable data with laboratory findings, clinical assessments, and patient history. Advancing system interoperability is essential to support comprehensive clinical decision-making rather than switching between systems to access fragmented data. Potential solutions include establishing standardized APIs through third-party integration platforms and developing plug-and-play interoperability standards [78]. Additionally, to streamline nursing workflow, more efforts are still needed to achieve automatic uploading of wearable data to nursing records, rather than requiring manual transcription of data from one screen to another. However, as previously discussed, such system integration must incorporate automatic artifact filtering algorithms to prevent recording erroneous data without professional oversight.

To better support clinical practice using wearables, we identified several gaps requiring further attention regarding data access interfaces, data latency, and data security. First, some studies deployed central monitoring systems at the nursing station, which enable simultaneous multipatient monitoring but prevent immediate access to real-time readings when assessing patients at bedside. A hybrid approach combining central and mobile interfaces would optimize both oversight and point-of-care accessibility. Second, some studies used batch uploads at fixed intervals, which conserve energy and extend battery life but may delay clinical reactions to patient deterioration. Transmission frequency must align with clinical context to ensure real-time data streaming, with transparent reporting enabling proper data latency assessment. Third, data security is a growing concern, yet only 10 studies reported specific protection strategies, with 50% (5/10) conducted in Europe under strict EU privacy regulations [20]. There remains a need for stronger adherence to safety and privacy regulations globally.

Overall, the clinical integration of wearables for fever and infection management remains predominantly at an early stage of maturity, aligning with existing evidence from digital health interventions for postoperative monitoring [79] and oncology care [20]. Although the scope of regulatory approval limited some devices' clinical application, the reasons more frequently reported for not providing data to support clinical decision-making were insufficient data accuracy and limited real-time availability [53]. We also noted that certain devices (eg, SensiumVitals, Everion, and Gen2, listed in Multimedia Appendix 3) are not intended for use in critical care patients, potentially associated with reduced measurement reliability under unstable hemodynamic conditions. This explains their limited use in ICUs (Figure 2) and underscores the need for caution when using wearables for patients who are clinically deteriorating in general wards and avoiding sole reliance on wearable data for clinical decisions. Beyond technical limitations, there are systemic barriers to overcome before wearables can become widely accepted with full clinical integration, such as data ownership and privacy, data standards and interoperability, and reimbursement policies [80]. Additionally, the geographic concentration of reviewed studies in well-resourced areas highlights potential equity challenges, as disparities in device access, digital literacy, and infrastructure may limit scaled implementation and exacerbate health inequalities. Nevertheless, the emergence of wearables in clinical settings shows a developmental trajectory outlined in the maturity framework, which delineates the accumulation of evidence throughout the device lifecycle from initial prototype to full clinical integration.

Future Directions

With the rapid iteration of wearable technology, novel devices are increasingly emerging. While existing evidence mainly focused on lightweight rigid wearables, we identified some

XSL•FO
RenderX

textile-based flexible wearables for remote monitoring of infectious diseases in the literature search. However, these textile-based devices are still in the proof-of-concept [81], technical testing [82], and animal experimental stages [83], possibly reflecting the current technological bottlenecks in achieving clinical accuracy and limited maturity in regulatory approval and clinical validation [84]. This development reflects an evolution in wearable technologies toward softer, lighter, and safer sensing materials. In future studies, our maturity framework could serve as a tool to support health care providers in evaluating novel wearables' readiness for clinical deployment and selecting suitable devices. Noncontact vital sign monitoring technologies, such as camera-based or robotic sensing systems, represent another emerging direction in continuous physiological surveillance in hospital environments [85] and may offer supplementary options for body temperature monitoring in special populations, such as neonates with fragile skin intolerant to adhesive sensors [86], although these technologies fall outside the scope of this review.

As wearables become increasingly used in clinical practice, nurses need to be better prepared for this transformation. Nurses are not only frontline users but also key researchers in this field, with nearly one-third of the studies reviewed being nurse-led. In future clinical deployment, large-scale data streams from wearables will require a robust infrastructure and storage capacity to prevent data loss or overwriting. These data could be incorporated into the clinical research data warehouse as a valuable source. Moreover, to harness the value of big data and AI, it is important for nurses to develop digital literacy and data science competencies to integrate nursing expertise into data interpretation. This will empower nurses to play an active role in wearable-driven health care transformation, rather than being passive end users of monitoring technology.

The observed lack of transparency highlights the need for reporting guidelines specific to clinical research using wearables. Our findings indicate low reporting rates on fundamental aspects, such as device grade (12/29, 41%) and regulatory status (10/29, 34%). While wearable data quality is crucial for appropriate clinical interpretation [87], many publications did not report data accuracy (11/29, 38%) and missing data (8/26, 31%). To improve rigor, the device grade, regulatory status, and clinical validation should be standard reporting elements. For feasibility and pilot studies, data transmission, latency, and loss rates could be taken into assessment and reporting. In predictive modeling research, reporting missing sensor data and any imputation methods is crucial. Data privacy and clinical accessibility could also be incorporated into reporting guidelines.

Limitations of This Review

This review has several limitations. First, we focused specifically on the use of wearables for monitoring body temperature in fever or infection management. The assessment of maturity is limited to this specific area, and maturity stages may differ in other fields. Second, we did not assess the quality or risk of bias of the included studies, which means our findings are based on all available evidence, regardless of its methodological rigor. Third, we only included studies published in English or Chinese, which may have excluded evidence published in other languages. Additionally, only a random 20% of the records were screened and extracted independently by 2 reviewers. While this approach is methodologically acceptable [88], it remains a potential source of bias. Furthermore, we identified the roles of nurses from the main texts, author, and affiliation information. However, confirming the presence of nurses among the authors was not always possible due to the lack of explicitly stated nursing qualifications.

Conclusions

This scoping review summarized ways of using temperature data from wearables across diverse clinical contexts, showing promise in optimizing fever or infection management in acute care hospitals, particularly when integrated with advanced data analytic approaches. However, the overall integration of wearables into clinical practice remains at an early stage of maturity. Key issues include data quality challenges, clinical interpretation of skin surface temperature, and interoperability between wearable systems and EHRs. Future efforts should prioritize standardized data cleaning frameworks and EHR interoperability, and facilitate clinical interpretation of wearable data to promote its active use in decision-making. These efforts will help to unlock the full potential of wearables in driving health care transformation.

Abstract

Background: Cardiovascular disease (CVD) remains the leading cause of death worldwide, yet participation in cardiac rehabilitation (CR) remains suboptimal. Wrist-worn wearables may support fully remote or hybrid CR through activity monitoring and individualized feedback, but the effectiveness and consistency of benefits remain uncertain.

Objective: This study aimed to evaluate the effectiveness of wrist-worn wearable–guided CR delivered through fully remote or hybrid programs initiated during phase II or III CR in patients with CVD.

Methods: A total of 8 databases were searched for randomized controlled trials published from January 1, 2015, through August 7, 2026. Eligible trials enrolled adults with CVD and integrated a wrist-worn wearable into fully remote or hybrid CR. Studies focused primarily on heart failure or using wearables only for outcome measurement were excluded. Primary outcomes were peak oxygen consumption (VO_2), 6-minute walk distance (6MWD), and daily steps. Random-effects meta-analyses used mean differences (MDs), except for quality of life, which used standardized MDs. Between-study variance was estimated using the DerSimonian-Laird method, pooled-effect CIs used the Knapp-Hartung adjustment, and 95% prediction intervals (PIs) used the Nagashima-Noma-Furukawa parametric bootstrap method. Risk of bias was assessed with Cochrane Risk of Bias 2. Subgroup and univariable meta-regression analyses explored study and intervention characteristics.

Results: A total of 18 trials involving 1993 randomized participants, reported in 20 publications, were included; 17 contributed to meta-analysis. Pooled estimates favored wearable-guided CR for peak VO_2 (10 studies; 591 participants; MD 1.69, 95% CI 0.46-2.92, 95% PI –2.21 to 5.39 mL/kg/min), 6MWD (9 studies; 1094 participants; MD 31.03, 95% CI 7.66-53.92, 95% PI –62.11 to 123.18 m), and daily steps (8 studies; 474 participants; MD 1062.8, 95% CI 383.5-1825.0, 95% PI –503.0 to 2860.0 steps/day).

XSL•FO
RenderX

All 3 PIs included the null, indicating uncertainty about consistency across future comparable settings. No clear pooled effects were observed for anaerobic threshold, BMI, waist circumference, grip strength, or quality of life. Subgroup differences were not statistically significant. In univariable meta-regression, a higher proportion of female participants was associated with greater peak VO_2 improvement, although this aggregate-level finding was exploratory.

Conclusions: Wrist-worn wearable–guided CR delivered through fully remote or hybrid programs may improve average exercise capacity and physical activity in patients with CVD. However, PIs included the null, indicating uncertainty about consistency across future settings. These programs may extend activity monitoring, individualized feedback, and behavioral support beyond center-based CR, but their multicomponent nature prevents attributing effects to wearables alone. Larger, rigorously designed trials with standardized protocols and outcomes should identify the patients and program components most likely to benefit. Future research should also evaluate long-term adherence, safety, equity, and implementation within routine multidisciplinary CR across diverse health systems.

KEYWORDS

cardiac rehabilitation; cardiovascular diseases; digital health; randomized controlled trials as topic; wearable electronic devices

Introduction

Cardiovascular disease (CVD) remains the leading cause of death worldwide. Annual deaths are projected to rise from 20.5 million in 2025 to 35.6 million in 2050, with global prevalence increasing by approximately 90% [1]. Its economic burden is also substantial; in the United States, annual cardiovascular health care costs are projected to reach US $1.49 trillion by 2050, with an additional US $361 billion in productivity losses [2]. Long-term risk reduction and functional recovery therefore remain major public health priorities.

Cardiac rehabilitation (CR) is a core component of secondary prevention, integrating individualized exercise, risk-factor management, education, and psychosocial support [3]. It reduces cardiovascular mortality and readmissions and improves exercise capacity and quality of life (QoL) [4,5], yet participation and completion remain suboptimal [6,7]. Travel, limited program availability, work and caregiving responsibilities, socioeconomic constraints, and physical limitations restrict engagement [8-10]. Home-based, community-based, remote, hybrid, and digitally supported models have therefore been developed to extend monitoring and behavioral support beyond centers [11-15].

Wearable devices are body-worn sensors that collect and transmit physiological or behavioral data, including chest-strap monitors, biosensors, smart garments, smartwatches, and activity trackers [15]. Previous reviews examined wearable activity monitoring during CR maintenance, heterogeneous wearable-assisted home CR, broader eHealth interventions, or mixed devices including pedometers and accelerometers [16-19]. They did not isolate actively guided wrist-worn programs initiated during phase II or III CR. Wrist-worn devices are clinically relevant because they are accessible, scalable, and can continuously monitor heart rate (HR) and activity with low user burden. Several recent randomized controlled trials (RCTs) also warrant updated synthesis.

Individual RCTs of wrist-worn wearable–guided CR have been small and inconsistent: Zhang et al [20] and Zheng et al [21] reported significant peak oxygen consumption (VO_2) gains, whereas Yagi et al [22] and Mitropoulos et al [23] did not. Effects on exercise capacity, physical activity, and related outcomes therefore remain uncertain.

This systematic review and meta-analysis evaluated wrist-worn wearable–guided CR delivered through fully remote or hybrid programs initiated during phase II or III CR in patients with CVD. We assessed exercise capacity, physical activity, and related outcomes and explored heterogeneity through subgroup and meta-regression analyses of participant, intervention, and comparator characteristics.

Methods

This systematic review and meta-analysis of RCTs followed PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 [24]. The completed expanded checklist is provided in Multimedia Appendix 1.

Eligibility Criteria

Eligibility was defined using population, intervention, comparator, outcomes, and study design framework. We included adults with CVD receiving wrist-worn wearable–guided CR delivered through fully remote or hybrid programs initiated during phase II or III. Phase denoted when the intervention began, not eligibility of all delivery settings. Both phases were included to span structured postacute rehabilitation through longer-term maintenance; phase was extracted as a prespecified subgroup variable. Intervention duration was unrestricted.

Eligible participants included patients with coronary artery disease, acute coronary syndrome, ischemic heart disease, and those who had undergone percutaneous coronary intervention (PCI) or cardiac surgery, such as coronary artery bypass grafting, valve surgery, or aortic surgery, or transcatheter valve intervention. Studies primarily focused on patients with heart failure were excluded; however, studies enrolling mixed populations of patients with cardiovascular disease remained eligible when patients with heart failure constituted only a subset of the overall population.

Eligible interventions used a wrist-worn smartwatch or smartband as a core component of structured remote or hybrid CR to guide exercise prescription, monitor physical activity,

XSL•FO
RenderX

provide individualized feedback, or manage adherence. Conventional center-based CR alone and wearable use solely for passive monitoring or outcome assessment were ineligible. Comparators included usual care, unsupported home exercise, passive or minimally supported monitoring, and structured center-based CR.

Eligible studies were full-text RCTs published in English or Korean from January 1, 2015, through August 7, 2026. Conference abstracts, study protocols, review articles, nonrandomized or observational studies, and secondary or overlapping reports without independent eligible outcome data were excluded. Gray literature, including conference abstracts, dissertations, and unpublished materials, was not included because the review was restricted to full-text, peer-reviewed RCTs providing sufficient methodological information for eligibility and risk-of-bias assessment.

Information Sources

We searched PubMed, Web of Science, CENTRAL, Embase, Scopus, CINAHL, KoreaMed, and KMbase. The original search (November 14, 2025) was updated on August 7, 2026, covering January 1, 2015, through August 7, 2026. Reference lists of included reports and relevant reviews were examined. Trial registries, regulatory databases, and gray literature were not searched.

Search Strategy

Following PRISMA-S (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Literature Search Extension) [25], database-specific strategies combined controlled vocabulary and free-text terms for CVD or cardiac procedures, wrist-worn wearables or remote monitoring, CR or related delivery models, and RCTs. Syntax, field tags, proximity operators, and filters were adapted by database. The August 7, 2026, update used the same concepts and updated date limits; overlapping records were deduplicated when day-specific restrictions were unavailable.

Complete original and updated strategies, platforms, dates, limits, filters, and yields are provided in Multimedia Appendix 2. No automated search tools were used; the strategies did not undergo peer review using the Peer Review of Electronic Search Strategies, and authors or manufacturers were not contacted.

Selection Process

Records were exported to EndNote (version 21; Clarivate) and deduplicated. Two reviewers (BRK and JHC) independently screened titles and abstracts; reports considered potentially eligible by either were retrieved. Four reviewers (BRK, JHC, S Young Lee, and KCS) independently assessed and cross-checked full texts, recorded exclusion reasons, and resolved disagreements by consensus. No automation or crowdsourcing was used, and no translation was required.

Data Collection Process

Three reviewers (BRK, JHC, and S Young Lee) extracted data using a standardized Excel form; 4 reviewers cross-checked entries and resolved discrepancies by consensus. Extracted variables covered study design; participant characteristics; CR phase and delivery model; intervention, wearable, feedback, exercise, and comparator characteristics; outcomes; and assessment timing.

Companion reports were linked as one study, with outcome data taken from the relevant report. Each cohort contributed only 1 estimate per outcome, preventing double counting. No automated extraction tools were used.

Data Items

Primary outcomes were peak VO_2, 6-minute walk distance (6MWD), and daily steps. Peak VO_2 was the highest directly measured oxygen uptake during maximal or symptom-limited cardiopulmonary exercise testing; relative values (mL/kg/min) were preferred, and equivalent VO_2 max measures were included. The 6MWD represented submaximal functional capacity, and daily steps represented habitual ambulatory activity rather than functional independence in activities of daily living.

Secondary outcomes included anaerobic threshold (AT), BMI, waist circumference, grip strength, and QoL. Peak VO_2 and AT were expressed in mL/kg/min, 6MWD in meters, daily steps in steps/day, BMI in kg/m^2, waist circumference in centimeters, and grip strength in kilograms. QoL was assessed using validated instruments, including the 36-Item Short Form Health Survey (SF-36), 12-Item Short Form Health Survey, Kansas City Cardiomyopathy Questionnaire, World Health Organization Quality of Life-Brief version, and EQ-5D. Additional outcomes reported by the included studies were recorded descriptively but were not included in the predefined quantitative syntheses.

We also extracted study setting and design; diagnosis; randomized, analyzed, and outcome-specific sample sizes; dropout; age; sex; intervention duration and dose; follow-up; and comparator components. Combined exercise included aerobic and resistance training; comparators were categorized as minimal/usual care, passive or less intensive wearable monitoring, or active structured CR.

Information that was missing or unclear in the published reports was recorded as not reported and was not imputed unless it could be directly calculated from the available data. When only the proportion of male participants was reported, the proportion of female participants was calculated as 100% minus the reported male proportion. Randomized, analyzed, and outcome-specific sample sizes were extracted separately when available; the sample size used in each meta-analysis was determined according to the population contributing to the corresponding outcome estimate, as described in the Synthesis Methods section.

Study Risk of Bias Assessment

Risk of bias was assessed at the outcome level using the revised Cochrane Risk of Bias 2 (RoB 2) tools in accordance with the Cochrane Handbook for Systematic Reviews of Interventions [26,27]. Four reviewers (BRK, JHC, S Young Lee, and KCS) independently assessed the studies assigned to them, with each outcome-specific assessment performed by at least 2 reviewers. The reviewers subsequently discussed their assessments, and disagreements were resolved by consensus.

XSL•FO
RenderX

The standard RoB 2 tool was used for parallel RCTs, the cluster-specific tool for the cluster RCT, and the crossover tool for the crossover RCT. Design-specific judgments, including recruitment timing and period or carryover effects, were mapped to harmonized D1-D5 labels for Multimedia Appendix 3.

Domain and overall judgments followed RoB 2 algorithms: low risk required all domains to be low; some concerns required at least one concern without a high-risk domain; and high risk reflected at least one high-risk domain or multiple concerns substantially lowering confidence. Plots used R (version 4.5.2; R Foundation for Statistical Computing) [28]; no automation was used.

Effect Measures

All outcomes were continuous. Mean differences (MDs) with 95% CIs were used when outcomes were reported using a common measurement scale. Accordingly, MDs were calculated for peak VO_2 and AT in mL/kg/min, 6MWD in meters, daily steps in steps/day, BMI in kg/m^2, waist circumference in centimeters, and grip strength in kilograms. For QoL, which was assessed using different validated instruments across studies, standardized mean differences (SMDs; Hedges *g*) with 95% CIs were calculated. Before calculating SMDs, the direction of each QoL scale was harmonized so that effect estimates had a consistent interpretation.

Positive MDs represented effects favoring the intervention for peak VO_2, AT, 6MWD, daily steps, and grip strength, whereas negative MDs represented effects favoring the intervention for BMI and waist circumference. For QoL, the direction of effect was defined consistently after harmonization of the scales. No prespecified thresholds were used to categorize pooled effects as small, moderate, or large.

Synthesis Methods

Outcome-specific meta-analyses included studies with clinically comparable measures and sufficient data to calculate an effect and variance. Otherwise, studies remained in the review and risk-of-bias assessment but not the synthesis. Postintervention values were preferred; change scores were used when unavailable. Units were converted as needed.

For studies reporting outcomes at multiple follow-up time points, only 1 assessment per outcome was included to avoid repeated inclusion of the same participants. The assessment conducted at or closest to the completion of the intervention was preferentially selected. When an assessment at intervention completion was unavailable, the earliest eligible postintervention assessment was used. For each outcome, the sample size corresponding to the reported summary statistics was used. The randomized sample size was used when results were reported according to the intention-to-treat principle, whereas the outcome-specific analyzed sample size was used when analyses were based on participants with available outcome data. Missing outcome data were not imputed unless the required statistics could be derived directly from information reported in the original article using established meta-analytic methods.

Multiple reports originating from the same trial cohort were linked and treated as companion publications. When companion reports provided data for different outcomes, data were extracted from the report relevant to each outcome. Each trial cohort contributed only one effect estimate to any given outcome-specific meta-analysis. For multiarm trials, only the comparison relevant to the eligibility criteria was included, and no shared intervention or comparator group was entered more than once in the same pooled analysis. Thus, no participant was double-counted within any outcome-specific meta-analysis.

MDs with 95% CIs were calculated for peak VO_2, 6MWD, daily steps, AT, BMI, waist circumference, and grip strength because these outcomes were reported using consistent measurement units. For QoL, SMDs using Hedges *g* with 95% CIs were calculated because different validated instruments were used across studies. Quantitative synthesis was restricted to validated overall or composite QoL scores with sufficient numerical data to calculate an effect estimate and variance. An unvalidated sum of SF-36 domain scores was not considered an eligible overall QoL score. Where necessary, score directions were harmonized so that higher values consistently represented better QoL.

Pooled effect estimates were calculated using inverse-variance random-effects models because clinical and methodological heterogeneity was anticipated across study populations and interventions. Between-study variance (τ^2) was estimated using the DerSimonian-Laird method, and 95% CIs for pooled effects were calculated using the Knapp-Hartung adjustment. Statistical heterogeneity was described using Cochran Q, τ^2, and I^2. I^2 was not interpreted using fixed low, moderate, or high categories because it represents the relative proportion of observed variability attributable to between-study heterogeneity rather than its absolute magnitude or clinical importance and can be imprecise when few studies are available. Heterogeneity was therefore interpreted jointly using τ^2, 95% prediction intervals, and clinical and methodological differences among studies [29,30].

For the main meta-analyses, 95% prediction intervals were calculated using the Nagashima-Noma-Furukawa parametric bootstrap method [31] to estimate the range in which the effect of a future comparable study might be expected. Prediction intervals were not calculated for subgroup analyses because of the small number of studies within individual subgroups and the resulting instability of subgroup-specific estimates. A reliable 95% prediction interval was not reported for QoL because marked between-study variability remained after exclusion of the study with an invalid SF-36 total score. Forest plots presented study-specific estimates, Knapp-Hartung-adjusted pooled estimates, and clearly labeled normal-normal framework (NNF) prediction intervals.

Subgroup and meta-regression analyses were planned to investigate potential sources of heterogeneity and patient- and intervention-level factors associated with intervention effectiveness. The specific outcomes eligible for these analyses were determined after data extraction based on the number of contributing studies and the availability of relevant subgroup and study-level covariate data, rather than on the magnitude or statistical significance of the pooled effects.

XSL•FO
RenderX

Subgroup analyses were conducted for peak VO_2 and 6MWD, for which sufficient studies were available, according to the CR phase at intervention initiation, provision of real-time feedback, type of wearable device, type of exercise, and comparator characteristics. Subgroup analyses were performed using restricted maximum likelihood estimation with the Knapp-Hartung adjustment. Differences between subgroups were evaluated using formal tests for subgroup interaction. The comparator-based subgroup analysis was added during the peer-review process and was therefore considered post hoc. Given the limited number of studies within individual subgroups, the findings were interpreted cautiously. A diagnosis-based subgroup analysis (eg, post-PCI, post–coronary artery bypass grafting, or mixed populations of patients with cardiovascular disease) was not performed because several studies enrolled heterogeneous populations of patients with cardiovascular disease and too few studies were available within specific diagnostic categories to support reliable subgroup estimates.

Univariable random-effects meta-regression analyses were conducted for peak VO_2 and 6MWD, for which sufficient study-level covariate data were available. These analyses were performed using restricted maximum likelihood estimation with the Knapp-Hartung adjustment. Mean participant age, proportion of female participants, and intervention duration were examined as potential moderators. Multivariable meta-regression was not performed because of the limited number of contributing studies. Meta-regression coefficients with 95% CIs and 2-sided *P* values were reported. Given the limited statistical power and use of aggregate study-level data, the meta-regression findings were interpreted as hypothesis-generating.

Sensitivity analyses were performed by excluding the cluster-randomized trial from the affected outcome-specific meta-analyses. A leave-one-out sensitivity analysis was additionally conducted for 6MWD by sequentially excluding each study and recalculating the pooled effect estimate and heterogeneity statistics. All analyses were performed using R version 4.5.2 (R Foundation for Statistical Computing) [28]. Statistical significance was defined as a 2-sided *P* value of <.05.

Reporting Bias Assessment

Small-study effects were assessed for outcome-specific meta-analyses including at least 10 studies through visual inspection of funnel plots and the Egger regression test. Accordingly, these assessments were performed for peak VO_2, which included 10 studies. Formal tests for funnel plot asymmetry were not performed for the remaining outcomes because fewer than 10 studies were available, resulting in limited statistical power and unreliable assessments of asymmetry. Funnel plot asymmetry was interpreted as potential evidence of small-study effects rather than definitive evidence of publication bias [26].

Certainty Assessment

The certainty of evidence was assessed for all predefined primary and secondary outcomes using the Grading of Recommendations Assessment, Development and Evaluation (GRADE) approach [32]. The assessed outcomes included peak VO_2, 6MWD, daily steps, AT, BMI, waist circumference, grip strength, and QoL. Four reviewers (BRK, JHC, S Young Lee, and KCS) participated in the assessment. Outcomes were independently evaluated in reviewer pairs using a structured Microsoft Excel form, and disagreements were resolved through discussion and consensus among all reviewers. Final judgments were summarized using GRADEpro guideline development tool [33].

The certainty of evidence for each outcome was evaluated across 5 domains: risk of bias, inconsistency, indirectness, imprecision, and publication bias. Because the evidence was derived from RCTs, the initial certainty was rated as high and was downgraded by 1 or 2 levels when serious or very serious concerns were identified within a domain. Downgrading decisions considered the outcome-level RoB 2 assessments, clinical and statistical heterogeneity, consistency in the direction and magnitude of effects, width of the 95% CIs, amount of available information, applicability to the review question, and evidence of possible publication bias or small-study effects. Prediction intervals were considered supplementary information when evaluating inconsistency but were not used as an independent criterion for downgrading. The overall certainty of evidence was categorized as high, moderate, low, or very low.

Results

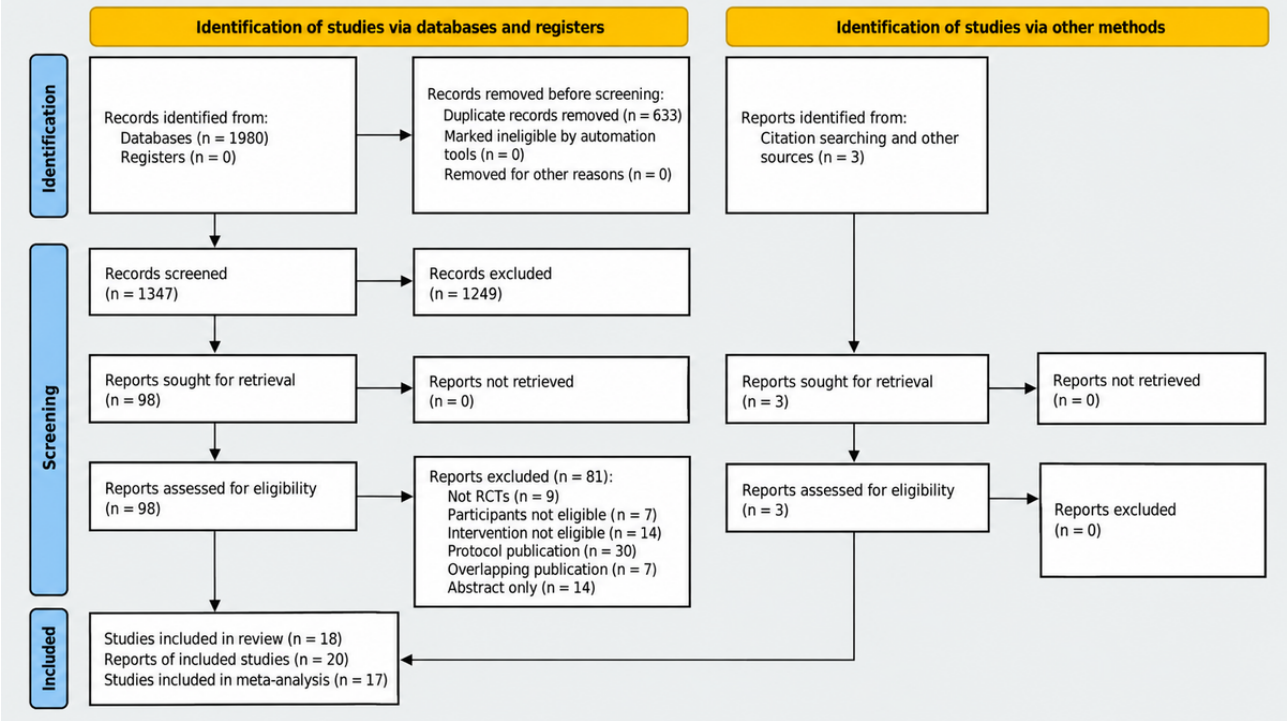
Study Selection

The original database search identified 1428 records, and the updated search conducted on August 7, 2026, identified 552 records, resulting in a total of 1980 records identified through electronic databases. Three additional reports were identified through other sources across the original and updated searches. After removal of 633 duplicate database records, 1347 database records underwent title and abstract screening, of which 1249 were excluded.

The remaining 98 database reports were sought for retrieval and successfully retrieved for eligibility assessment. The 3 reports identified through other sources were also retrieved and assessed. Thus, a total of 101 reports were assessed for eligibility, and 81 were excluded for the following reasons: not RCTs (n=9), not meeting the eligibility criteria for study participants (n=7), not meeting the intervention criteria (n=14), protocol publications (n=30), overlapping or salami publications without distinct eligible data (n=7), or abstract-only reports without sufficient full-text data (n=14).

The remaining 20 publications, representing 18 unique trials, were included in the systematic review [20-23,34-49]. The updated database search resulted in the inclusion of Nishio et al [38], while the supplementary manual search resulted in the inclusion of Claes et al [39]. Of the 20 included reports, 19 reports representing 18 unique trials contributed outcomes eligible for the RoB 2 assessment [20-23,34-47,49], while 18 reports representing 17 unique studies contributed data to the quantitative meta-analysis [20-23,34-47].

Lahtio et al [35] and Hakala et al [45] were identified as companion publications arising from the same cluster-randomized trial (ISRCTN61225589). Both reports were



XSL•FO
RenderX

retained because they provided distinct eligible outcomes: Lahtio et al [35] contributed data on 6MWD, BMI, and waist circumference, whereas Hakala et al [45] contributed data on daily steps. The reports were linked and treated as arising from a single underlying study.

Mitropoulos et al [23] and Ntovoli et al [48] were also identified as companion publications arising from the same trial cohort (NCT06071273). Ntovoli et al [48] did not report any of the outcomes predefined for this review and was therefore not included in the outcome-level RoB 2 assessment or quantitative meta-analysis. However, it was retained as a companion report in the systematic review and linked to Mitropoulos et al [23]. Accordingly, the cohort was counted as a single unique study.

One included study [49] did not contribute to the quantitative meta-analysis because it reported quality-adjusted life-years, a composite outcome incorporating both quality and duration of life that was not directly comparable with the conventional QoL outcomes reported by the other studies. Each unique study contributed only one effect estimate to any given outcome-specific meta-analysis; therefore, no participant was double-counted within the same pooled analysis. The study-selection process is presented in Figure 1.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 flow diagram of study selection. The PRISMA diagram shows identification, screening, eligibility, and inclusion. The review contained 20 publications from 18 trials; 17 trials contributed to the meta-analysis. RCT: randomized controlled trial.

Study Characteristics

Table 1 summarizes the characteristics of the 18 unique trials reported in 20 publications representing 18 unique trials, published between 2018 and 2025 [20-23,34-49]. At the unique-trial level, 6 studies were conducted in the United States [36,37,40,43,44,46], 2 each in China [20,21], the Czech Republic [34,41], and Japan [22,38], and 1 each in Greece [23,48], Finland [35,45], Uzbekistan [47], the Netherlands [49], and Belgium [42]. One multicenter study was conducted across Belgium and Ireland [39]. Companion publications from Greece [23,48] and Finland [35,45] were linked at the trial level, and each pair was counted only once in the country distribution.

RenderX

Table 1. Characteristics of 20 publications representing 18 unique RCTs conducted across multiple countries and published between 2018 and 2025, evaluating wrist-worn wearable–guided CR delivered through fully remote or hybrid programs in adults with CVD, with interventions initiated during phase II or phase III CR.

Study, country	Study design	Population (intervention vs control)[a]	Intervention characteristics	Comparator type and components	Outcomes assessed[b]	Outcome assessment/follow-up
Zhang et al [20], (2025) China	Single-center RCT[c]	CHD[d] (angina, MI[e], PCI[f]); n=35 vs 35; dropout: 3 vs 5 (8/70, 11.4%); age: mean 62.67 (SD 4.89) years vs mean 57.2 (SD 13) years; male sex: 56.2% vs 63.3%	Timing: at discharge; delivery: home-based CR[g] with wearable+app+ICT[h]; components: real-time feedback, remote supervision, PA[i] and hemodynamic monitoring, medication reminders, educational content; device: smartwatch (Le-W20 Heart Health Watch); real-time feedback: yes; exercise: aerobic; dose: not reported; duration: 3 months	Usual care (standard HBCR[j] without technological assistance)	Peak VO_2[k], AT[l], QoL[m]	3 months
Zheng et al [21], (2024) China	Single-center RCT	CHD (PCI); n=55 vs 55; dropout: 2 vs 2 (4/110, 3.6%); age: mean 63.49 (SD 9.53) vs mean 63.04 (SD 10.44) years; male sex: 60% vs 57%	Timing: post discharge; delivery: home-based CR with wearable+app+ICT; components: remote supervision, PA and HR[n] monitoring; device: smartband (model not reported); real-time feedback: no; exercise: aerobic; dose: 3-5 days/week, session duration not reported; duration: 3 months	Usual care (discharge instructions and a health guide handbook)	6MWD[o], peak VO_2, AT, QoL	3 months
Yagi et al [22], (2025) Japan	Single-center RCT	CVD[p] (angina, MI, CHF[q]); n=23 vs 21; dropout: 4 vs 1 (5/44, 11.4%); age: 73 vs 76 years; male sex: 68% vs 95%	Timing: after outpatient center-based CR; delivery: home-based CR with wearable; components: PA and HR self-monitoring; device: smartwatch (Fitbit Versa 3); real-time feedback: no; exercise: aerobic, resistance; dose: 30 min/session, 5 days/week; duration: 3 months	Usual care (supervised hospital-based CR without wearable support)	Peak VO_2, 6MWD, AT, grip strength	3 months
Mitropoulos et al [23], (2024) Greece	Single-center RCT	CAD[r] (MI); n=18 vs 18; dropout: 3 vs 3 (6/36, 16.7%); age: mean 54.1 (SD 8.5) vs mean 53.5 (SD 6.6) years; male sex: 73% vs 73%	Timing: less than 4 weeks after MI; delivery: home-based CR with wearable+app+ICT; components: real-time feedback, remote supervision, PA and hemodynamic monitoring; device: smartwatch (ScanWatch); real-time feedback: yes; exercise: aerobic, resistance, balance, flexibility; dose: 60 min/session, 3 days/week; duration: 6 months	Community-based CR (supervised gym-based exercise without hemodynamic monitoring)	Peak VO_2, daily steps	6 months
Wohlfahrt et al [34], (2024)[s] Czech Republic	Single-center, crossover RCT	MI; n=32 vs 32; dropout: 1 vs 2 (3/64, 4.7%); age: mean 51.6 (SD 10.2) vs mean 51.2 (SD 10.5) years; male sex: 90% vs 90%	Timing: 1 month after MI; delivery: home-based CR with wearable+app+ICT; components: remote supervision, PA monitoring; device: smartwatch (model not reported); real-time feedback: no; exercise: aerobic; dose: individualized daily step count target (derived from 6MWT[t]: 0.9 × 5 × 6MWT steps); duration: 3 months per period	Usual care (physical activity advice without wearable support)	Peak VO_2, 6MWD, QoL	3 months for the meta-analysis (first period before crossover); total trial duration, 6 months
Lahtio et al [35], (2023)[u] Finland	Single-center, cluster RCT	CHD (angina, MI, PCI, CABG[v]); n=29 (3 clusters) vs 30 (3 clusters); dropout: 3 vs 3 (6/59, 10.2%); age: mean 59.7 (SD 6.0) vs mean 59.2 (SD 6.1) years; male sex: 77% vs 86%	Timing: PCI or CABG 3-12 months prior to the study; delivery: home-based CR with wearable+app+ICT; components: remote supervision, PA and HR monitoring, educational content; device: smartband (Fitbit Charge); real-time feedback: no; exercise: aerobic, resistance, flexibility; dose: not reported; duration: 12 months	Usual care (conventional CR without remote technology)	6MWD, BMI, waist circumference, QoL	12 months
Beckie et al [36], (2023) United States	Multicenter RCT	CHD; n=23 vs 24; dropout: 1 vs 4 (5/47, 10.6%); age: mean 62.7 (SD 7.3) vs mean 59.7 (SD 10.5) years; male sex: 0% vs 0%	Timing: CHD with or without PCI within the prior 5 years; delivery: home-based CR with wearable+app+ICT; components: remote supervision, PA monitoring, educational content; device: smartwatch (Android model not reported); real-time feedback: no; exercise: aerobic, balance, flexibility; dose: not reported; duration: 3 months	Usual care (CR workbook/DVD with weekly telephone support)	6MWD, BMI, waist circumference, QoL	3 months

Study, country	Study design	Population (intervention vs control)[a]	Intervention characteristics	Comparator type and components	Outcomes assessed[b]	Outcome assessment/follow-up
Lindman et al [37], (2021) United States	Multicenter RCT	TAVR[w]; n=25 vs 25; dropout: 0 (0%); age: mean 76 (SD 7) vs mean 76 (SD 9) years; male sex: 64% vs 68%	Timing: 1 month post-TAVR; delivery: home-based CR with wearable+app+ICT; components: remote supervision, PA and HR monitoring; device: smartband (Fitbit Alta HR); real-time feedback: no; exercise: aerobic, resistance; dose: not reported; duration: 6 weeks	Usual care (activity monitor without feedback or exercise instructions)	Daily steps, 6MWD, grip strength, QoL	6 weeks
Chokshi et al [40], (2018) United States	Multicenter RCT	CHD (angina, MI); n=50 vs 55; dropout: 1 vs 0 (1/105, 0.9%); age: mean 60 (SD 9.5) vs mean 59.1 (SD 11.5) years; male sex: 72.0% vs 67.3%	Timing: recent-onset ACS[x] or coronary catheterization; delivery: home-based CR with wearable+app+ICT; components: remote supervision, PA monitoring; device: smartband (Misfit Shine); real-time feedback: no; exercise: aerobic; dose: not reported; duration: 16 weeks	Usual care (wearable step monitoring without personalized goals or feedback)	Daily steps	4 months
Batalik et al [41], (2020) Czech Republic	Single-center RCT	CVD (angina, MI, PCI, CABG); n=28 vs 28; dropout: 3 vs 2 (5/56, 8.9%); age: mean 56.5 (SD 6.9) vs mean 57.7 (SD 7.6) years; male sex: 80% vs 85%	Timing: CVD in the last 6 months; delivery: home-based CR with wearable+app+ICT; components: remote supervision, PA and HR monitoring; device: smartband (Polar M430); real-time feedback: no; exercise: aerobic; dose: 60 min/session, 3 days/week; duration: 3 months	Center-based CR (supervised outpatient exercise)	Peak VO_2, QoL	3 months
Avila et al [42], (2020)[y] Belgium	Single-center RCT	CAD; n=30 vs 30 vs 30; dropout: 4 vs 1 vs 5 (10/90, 11.1%); age: mean 62.2 (SD 7.1) vs mean 62.0 (SD 7.4) vs mean 63.7 (SD 7.4) years; male sex: 88% vs 90% vs 92%	Timing: after discharge from phase II center-based CR; delivery: home-based CR with wearable+app+ICT; components: remote supervision, PA and HR monitoring; device: smartwatch (Garmin Forerunner), sensewear mini armband (BodyMedia); real-time feedback: no; exercise: aerobic; dose: 30 min/session, 5 days/week; duration: 3 months	Center-based CR (supervised exercise); usual care (physical activity advice only)	Peak VO_2, daily steps, BMI, waist circumference, grip strength, QoL	12 months
Park et al [43], (2021) United States	Multicenter RCT	CVD; n=32 vs 28; dropout: 6 vs 3 (9/60, 15.0%); age: mean 66.7 (SD 8.6) vs mean 66.8 (SD 8.7) years; male sex: 73% vs 80%	Timing: after discharge from phase II center-based CR; delivery: home-based CR with wearable+app+ICT; components: remote supervision, PA and hemodynamic self-monitoring, educational content; device: smartband (Fitbit Charge); real-time feedback: no; exercise: aerobic; dose: not reported; duration: 2 months	Usual care (pedometer, step diary, and telephone support)	Daily steps, 6MWD	2 months
Duscha et al [44], (2018) United States	Single-center RCT	CVD (angina, MI, PCI, CABG, valve repair, CHF [4/25, 16%]); n=21 vs 11; dropout: 5 vs 2 (7/32, 21.9%); age: mean 59.9 (SD 8.1) vs mean 66.5 (SD 7.2) years; male sex: 81.2% vs 66.7%	Timing: after discharge from phase II center-based CR; delivery: home-based CR with wearable+app+ICT; components: remote supervision, PA monitoring; device: smartband (Fitbit Charge); real-time feedback: no; exercise: aerobic; dose: not reported; duration: 3 months	Usual care (physician-directed physical activity advice)	Peak VO_2, daily steps	3 months
Hakala et al [45], (2021)[u] Finland	Single-center, cluster RCT	CHD (angina, MI, PCI, CABG); n=29 vs 30 (same cohort as Lahtio et al[35]); dropout: 6/59 (10.2%); age: mean 59.7 (SD 6.0) vs mean 59.2 (SD 6.1) years; male sex: 76% vs 87%	Timing: CHD who attended the center-based CR program; delivery: home-based CR with wearable+app+ICT; components: remote supervision, PA and HR monitoring, educational content; device: wrist-worn smartband (Fitbit Charge), hip-worn accelerometer (Fitbit Zip); real-time feedback: no; exercise: aerobic; dose: not reported; duration: 12 months	Usual care (conventional CR without remote technology)	Daily steps	12 months

Study, country	Study design	Population (intervention vs control)[a]	Intervention characteristics	Comparator type and components	Outcomes assessed[b]	Outcome assessment/follow-up
Dodson et al [46], (2025) United States	Multicenter RCT	CHD (MI, PCI, CABG); n=298 vs 102; dropout: 27 vs 17 (44/400, 11.0%); age: 71.0 vs 71.0 years; male sex: 72.5% vs 73.5%	Timing: hospitalized for AMI[z], PCI, or CABG within prior 4 weeks; delivery: home-based CR with wearable+app+ICT; components: remote supervision, PA and HR monitoring; device: smartband (Fitbit Inspire); real-time feedback: no; exercise: aerobic; dose: 30 min/session, 5 days/week; duration: 3 months	Usual care (traditional ambulatory CR permitted)	6MWD, QoL	3 months
Madina et al [47], (2025) Uzbekistan	Single-center RCT	MI; n=150 vs 150; dropout: 0 (0%); age: mean 57.8 (SD 8.9) vs mean 59.1 (SD 9.5) years; male sex: 67.3% vs 62.6%	Timing: MI within the 3 months prior to study; delivery: home-based CR with wearable+app+ICT; components: remote supervision, PA and HR monitoring, early warning sign reporting, medication reminders, dietary advice; device: smartband (model not reported); real-time feedback: no; exercise: aerobic; dose: not reported; duration: 6 months	Standard CR (exercise program and monthly physiotherapist sessions without digital monitoring)	6MWD, QoL	6 months
Ntovoli et al [48], (2025)[aa] Greece	Single-center RCT	CAD (MI); same trial as Mitropoulos et al [23]; age: 18-45 years (26.7%), 46-55 years (20.1%), 56-65 years (40%), >65 years (13.3%); male sex: 80%	Timing: less than 4 weeks after MI; delivery: home-based CR with wearable+app+ICT; components: real-time feedback, remote supervision, PA and hemodynamic monitoring; device: smartwatch (ScanWatch); real-time feedback: yes; exercise: aerobic, resistance, balance, flexibility; dose: 60 min/session, 3 days/week; duration: 6 months	Community-based CR (supervised gym-based exercise)	Perceived well-being (PERMA profiler), CR adherence, percentage of peak HR, RPE[ab]	6 months
Brouwers et al [49], (2021) Netherlands	Multicenter RCT	CAD (ACS, PCI); n=153 vs 147; dropout: 4 vs 12 lost to FU[ac] (16/300, 5.3%); age: mean 60.8 (SD 9.3) vs mean 60.5 (SD 9.8) years; male sex: 87.6% vs 89.8%	Timing: at phase II of outpatient CR; delivery: home-based CR with wearable+app+ICT; components: remote supervision, PA and HR monitoring; device: smartwatch (Mio Alpha), hip-worn accelerometer (ActiGraph wGT3x-BT); real-time feedback: no; exercise: aerobic, functional, resistance; dose: not reported; duration: 3 months CTR[ad]+9 months relapse prevention	Center-based CR (supervised group-based exercise)	QoL	12 months
Nishio et al [38], (2025) Japan	Single-center RCT	CAD (PCI, CABG); n=25 vs 25; dropout: 1 vs 0 lost to FU (1/50, 2.0%); age: mean 63.8 (SD 6.4) vs mean 62.6 (SD 7.9) years; male sex: 95.8% vs 92%	Timing: outpatient phase III CR candidates, after baseline CPET[ae]; delivery: home-based CR with wearable+app+ICT; components: real-time PA and HR monitoring, remote supervision, weekly individualized text-message coaching, monthly videoconferencing; device: smartwatch (Fitbit Sense); real-time feedback: yes; exercise: aerobic; dose: ≥30 min/session, 5 days/week; duration: 3 months	Wearable-supported CPET-based home exercise without online coaching	Peak VO_2, AT, daily steps, BMI	3 months

XSL•FO
RenderX

Study, country	Study design	Population (intervention vs control)[a]	Intervention characteristics	Comparator type and components	Outcomes assessed[b]	Outcome assessment/follow-up
Claes et al [39], (2020) Belgium	Multicenter RCT	CVD (PCI/CABG/valve repair); n=60 vs 60; dropout: 7 vs 13 lost to FU (20/120, 16.7%); age: mean 61.7 (SD 14.5) vs mean 59.6 (SD 13.2) years; male sex: 81.7% vs 81.7%	Timing: initiated during the final 4 weeks of center-based phase II CR and continued into phase III; delivery: home-based CR with wearable+app+ICT; components: remote supervision, PA and HR monitoring, telecoaching, social networking, automated supportive text messages or emails; device: smartband (Microsoft Band 2); real-time feedback: no; exercise: aerobic; dose: 150 min/week moderate-intensity PA; duration: 6 months	Usual care (physical activity advice without structured CR)	Peak VO_2, daily steps, grip strength, BMI, QoL	6 months

[a]Unless otherwise indicated, values are presented as intervention vs control. For studies with more than 2 arms, values are presented in the order of the study arms.

[b]Measurement methods and units: peak VO_2 and VO_2 max were measured using cardiopulmonary exercise testing (CPET) and expressed in mL/kg/min. AT was determined during CPET and expressed in mL/kg/min. The 6-minute walk distance was measured using the 6-minute walk test and expressed in meters. Physical activity was assessed using the wearable device or accelerometer specified in each study and reported as steps/day, minutes/day, or minutes/week. Heart rate was expressed as beats/min; blood pressure, as mmHg; body weight, as kg; BMI, as kg/m2; waist, hip, and calf circumferences, as cm; grip strength, as kg; left ventricular ejection fraction, as a percentage; and glycated hemoglobin, as a percentage. Quality of life and other patient-reported outcomes were assessed using the validated instruments specified in the original studies.

[c]RCT: randomized controlled trial.

[d]CHD: coronary heart disease.

[e]MI: myocardial infarction.

[f]PCI: percutaneous coronary intervention.

[g]CR: cardiac rehabilitation.

[h]ICT: information and communication technology.

[i]PA: physical activity.

[j]HBCR: home-based cardiac rehabilitation.

[k]VO_2: oxygen consumption.

[l]AT: anaerobic threshold.

[m]QoL: quality of life.

[n]HR: heart rate.

[o]6MWD: 6-minute walk distance.

[p]CVD: cardiovascular disease.

[q]CHF: congestive heart failure.

[r]CAD: coronary artery disease.

[s]Wohlfahrt et al [34] used a crossover design. Data from the first 3-month period before crossover were used for the meta-analysis to avoid potential carryover effects. The 64 participants were randomized to 2 treatment sequences (32 vs 32).

[t]6MWT: 6-minute walk test.

[u]Lahtio et al [35] and Hakala et al [45] are companion publications arising from the same cluster-randomized trial (ISRCTN61225589). They reported different eligible outcomes and were treated as one unique underlying trial for study-level counting, including the country distribution. No participant was counted more than once within any outcome-specific meta-analysis.

[v]CABG: coronary artery bypass grafting.

[w]TAVR: transcatheter aortic valve replacement.

[x]ACS: acute coronary syndrome.

[y]Avila et al [42] used a 3-arm design. For each outcome-specific meta-analysis, only the eligible wearable-supported intervention arm and the corresponding usual-care comparator were included; no comparator group was entered more than once.

[z]AMI: acute myocardial infarction.

[aa]Ntovoli et al [48] and Mitropoulos et al [23] are companion publications arising from the same randomized trial (NCT06071273). Ntovoli et al did not report any of the outcomes predefined for this review and therefore did not contribute to the outcome-level Risk of Bias 2 assessment or quantitative meta-analysis. The reports were linked and treated as one unique underlying trial for study-level counting, including the country distribution.

[ab]RPE: rating of perceived exertion.

[ac]FU: follow-up.

[ad]CTR: cardiac telerehabilitation.

[ae]CPET: cardiopulmonary exercise testing.

Lahtio et al [35] and Hakala et al [45] were companion publications arising from the same cluster-randomized trial (ISRCTN61225589), while Mitropoulos et al [23] and Ntovoli et al [48] were companion publications arising from the same

XSL•FO
RenderX

randomized trial (NCT06071273). Each companion-publication pair was linked and treated as representing one unique underlying trial for study-level counting, including the country distribution.

Of the 18 unique trials, 10 were single-center RCTs [20-23,34,38,41,42,44,47], 7 were multicenter RCTs [36,37,39,40,43,46,49], and 1 was a cluster RCT reported in 2 companion publications [35,45]. Wohlfahrt et al [34] used a crossover RCT design, whereas the remaining individually randomized studies used parallel-group designs.

All eligible intervention groups implemented remote or hybrid CR incorporating a wrist-worn wearable device as a core intervention component [20-23,34-49]. The wearable technologies included smartbands [21,35,37,39-47] and smartwatches [20,22,23,34,36,38,48,49]. A small number of studies incorporated additional sensors for intervention delivery or outcome assessment [39,45,49]. Nishio et al [38] used a Fitbit Sense integrated with a real-time monitoring platform and compared additional online coaching with wearable-supported CR without coaching. Claes et al [39] evaluated the PATHway technology-enabled home-based CR platform, which incorporated a Microsoft Band 2, remotely delivered exercise sessions, physical activity monitoring, automated feedback, education, and behavioral support.

The comparator interventions included usual care, home-based exercise without wearable-guided support, passive or minimally supported wearable monitoring, and structured center- or community-based CR [20-23,34-49]. Thus, the presence of a wearable device was not necessarily exclusive to the intervention group. Rather, the eligible intervention groups actively integrated wearable-derived data into CR delivery through monitoring, feedback, coaching, exercise guidance, or adherence management.

In terms of intervention components, nearly all studies included remote supervision and physical activity monitoring [20,21,23,34-49]. Many studies also incorporated HR or hemodynamic monitoring [20-23,35,37-39,41-43,45-49], whereas real-time or individualized feedback was provided in a subset of studies [20,23,38,39,48]. Additional components included educational or behavioral-support content [20,35,36,39,43,45,47] and warning systems for abnormal physiological signals [20,47].

The exercise programs were predominantly aerobic, including the intervention evaluated by Nishio et al [38], although several studies implemented combined training incorporating aerobic and resistance exercise [22,23,35,37,39,48,49]. Some interventions additionally included balance or flexibility exercises [23,35,36,39,48]. When reported, the prescribed exercise dose generally ranged from 30 to 60 minutes per session, performed 3-5 times per week [22,23,34,38,41,42,46,48].

Intervention duration ranged from 6 weeks to 12 months, with most interventions lasting approximately 3-6 months [20-23,34,36,38-42,44,46-49]. Follow-up assessments were generally aligned with intervention completion, although some studies reported extended follow-up to 12 months [42,46,49]. When multiple assessment time points were available, the assessment conducted at or closest to intervention completion was preferentially selected for quantitative synthesis. When no assessment was reported at intervention completion, the earliest eligible postintervention assessment was used. In Avila et al [42], the relevant outcomes were available at the 12-month follow-up following a 3-month intervention.

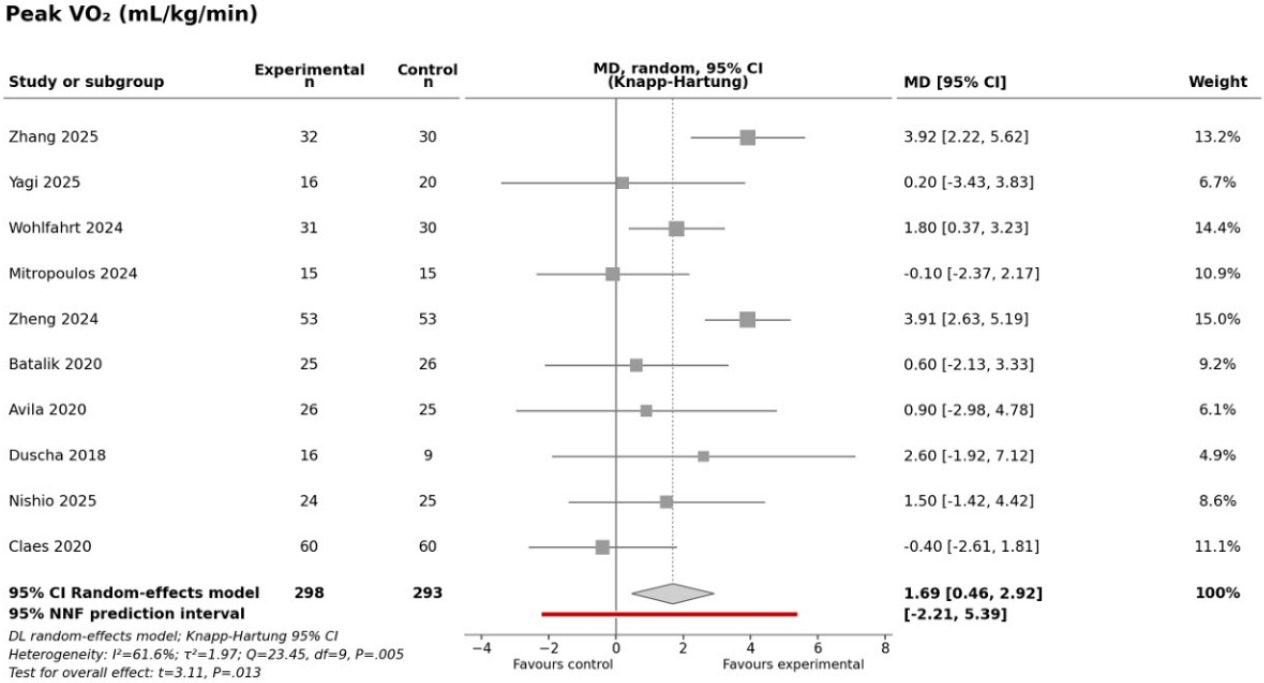
Overall, the 18 unique trials randomized 1993 participants with CVD receiving wrist-worn wearable–guided CR through fully remote or hybrid programs initiated during phase II or phase III CR. Of the 20 included publications, 18 publications representing 17 unique trials contributed data to at least 1 quantitative meta-analysis [20-23,34-47]. Because the number of participants contributing data differed across outcomes and assessment time points, outcome-specific sample sizes are reported with each meta-analysis. Across the included studies, mean participant age ranged from approximately 51 to 76 years, and the proportion of male participants varied substantially, ranging from 0% to approximately 96%; 1 study enrolled only female participants [36]. Individual study sample sizes ranged from 25 to 400 participants. Most participants had coronary artery disease or had undergone PCI or cardiac surgery.

Risk of Bias in Studies

Among the 20 publications representing 18 unique trials, 19 reports were included in the outcome-level RoB assessment. Ntovoli et al [48], a companion publication from the same trial as Mitropoulos et al [23], was not assessed because it did not report any of the predefined outcomes of interest. RoB was assessed separately for each outcome using the standard or design-specific Cochrane RoB 2 tool, as appropriate.

For peak VO_2, 4 of the 10 contributing studies were rated as having low overall RoB and 6 as having some concerns [20-23,34,38,39,41,42,44], with no studies rated as having high RoB. For 6MWD, 8 of the 9 contributing studies were rated as having some concerns and 1 as having high RoB [21,22,34-37,43,46,47]. All studies contributing to BMI [35,36,38,39,42] and waist circumference [35,36,42] were rated as having some concerns. For AT, 2 of the 4 contributing studies were rated as having low RoB and 2 as having some concerns [20-22,38]. For grip strength, 3 of the 4 contributing studies were rated as having some concerns and 1 as having high RoB [22,37,39,42].

In contrast, substantial RoB concerns were observed for daily steps and QoL. For daily steps, 7 of the 9 studies were rated as having high overall RoB [37,38,40,42-45], primarily because of bias due to deviations from intended interventions. For QoL, 10 of the 13 studies were rated as having high overall RoB [20,34-36,38,39,42,46,47,49], primarily because of bias in outcome measurement. The outcome-specific RoB assessments are summarized in Multimedia Appendix 3.



Results of Individual Studies

Outcome-specific summary statistics and effect estimates for each included study are presented in the forest plots (Figures 2-9) and the corresponding supplementary tables (Multimedia Appendix 4). For continuous outcomes, individual study effects are reported as MDs with 95% CIs for peak VO_2, 6MWD, daily

XSL•FO
RenderX

steps, AT, BMI, waist circumference, and grip strength. For QoL, individual study effects are reported as SMDs using Hedges *g* with 95% CIs because different validated instruments were used across studies. The number of participants contributing data to each outcome-specific effect estimate is also presented. Individual study findings varied in magnitude and, for several outcomes, in direction, as reflected in the forest plots and the between-study heterogeneity reported in the Results of Syntheses section.

Figure 2. Random-effects meta-analysis of peak oxygen consumption (VO2). Study and pooled random-effects mean differences (MDs) are shown with 95% CIs. DerSimonian-Laird (DL) estimated between-study variance. Pooled CIs used the Knapp-Hartung adjustment. The labeled normal-normal framework (NNF) 95% prediction interval represents a future comparable study.

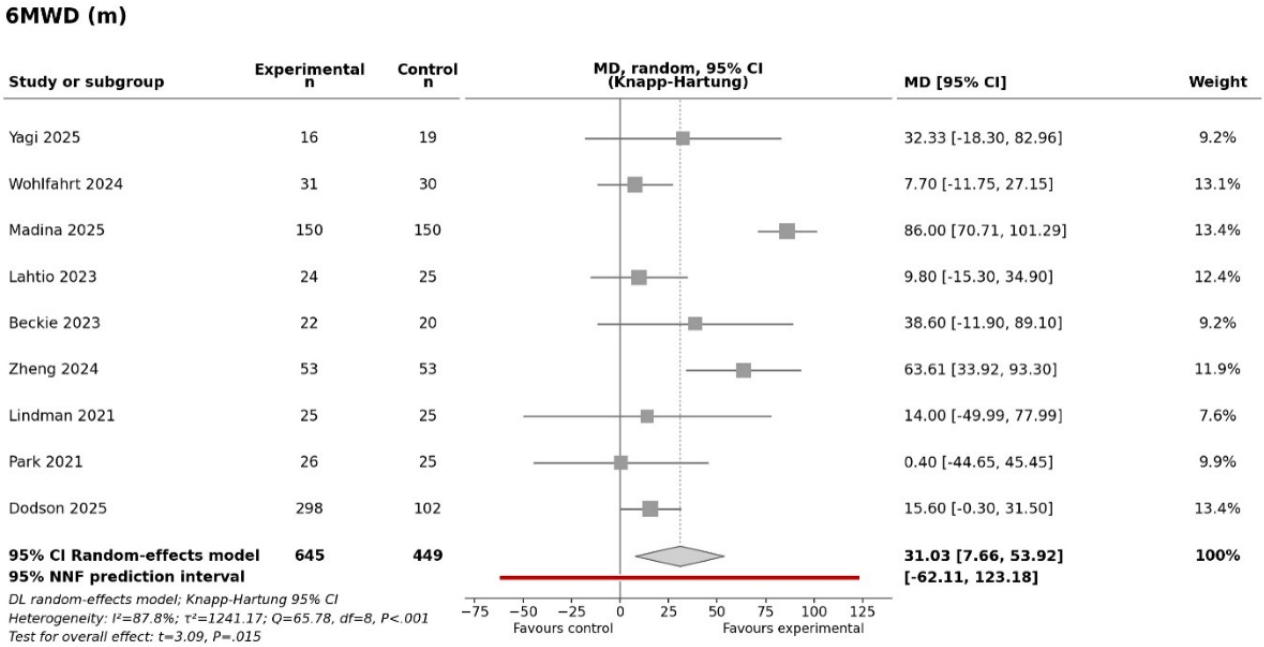
Results of Syntheses

Overview

For each outcome, the pooled estimate and 95% CI represent the estimated average effect across the included studies, whereas the 95% prediction interval describes the expected distribution of true effects across comparable clinical settings while accounting for between-study heterogeneity.

Primary Outcomes

Peak VO2



A total of 10 studies involving 591 participants were included in the meta-analysis of peak VO_2 [20-23,34,38,39,41,42,44]. On average, wrist-worn wearable–guided CR delivered through fully remote or hybrid programs was associated with greater peak VO_2 than the control interventions (MD 1.69, 95% CI 0.46-2.92 mL/kg/min; *P*=.01). Between-study variability was reflected by τ^2=1.97; I^2=61.6%; and Cochran Q=23.45 (*P*=.005). The NNF 95% prediction interval ranged from –2.21 to 5.39 mL/kg/min and included the null. Thus, although the estimated average effect favored the intervention, a benefit may not be observed consistently across future comparable settings (Figure 2).

6MWD

A total of 9 studies involving 1094 participants were included in the meta-analysis of 6MWD [21,22,34-37,43,46,47]. The pooled estimate indicated greater average 6MWD in the intervention groups than in the control groups (MD 31.03, 95% CI 7.66-53.92 m; *P*=.02). Between-study variability was reflected by τ^2=1241.17; I^2=87.8%; and Cochran Q=65.78 (*P*<.001). The NNF 95% prediction interval was wide and included the null (–62.11 to 123.18 m), indicating uncertainty in the effect expected in a future comparable setting despite the favorable average effect (Figure 3).

RenderX

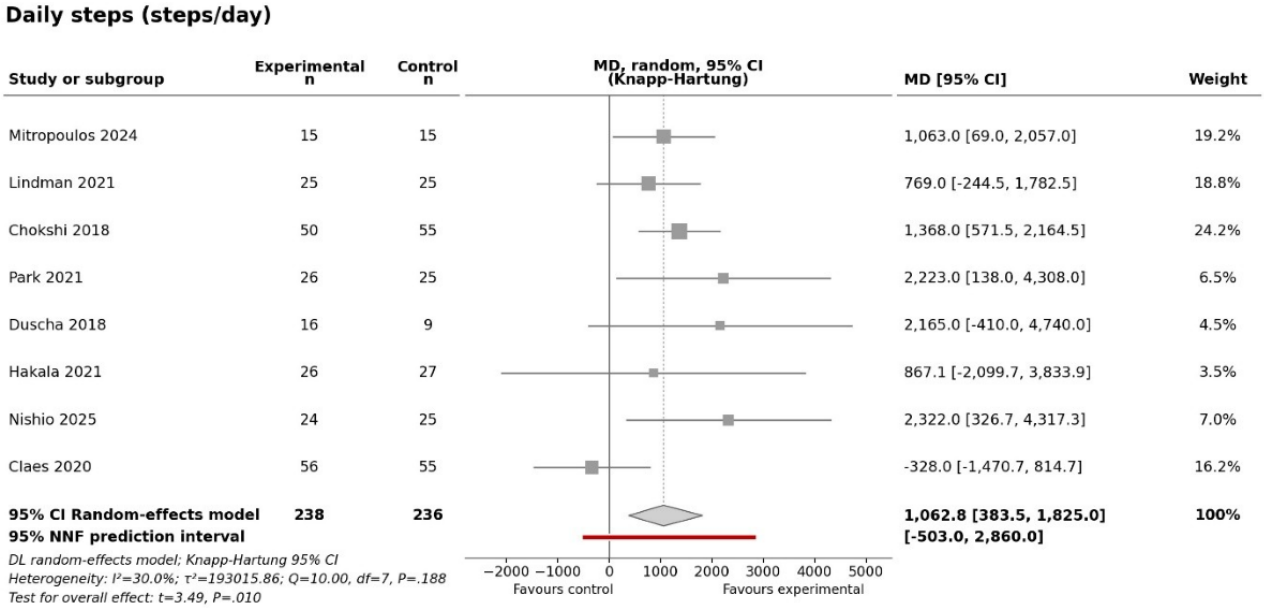

Figure 3. Random-effects meta-analysis of 6-minute walk distance (6MWD). Study and pooled random-effects mean differences (MDs) for 6MWD are shown with 95% CIs. DerSimonian-Laird (DL) estimated variance, pooled CIs used Knapp-Hartung adjustment, and the labeled normal-normal framework (NNF) 95% prediction interval represents a future comparable study.

Daily Steps

A total of 9 studies reported daily steps. Avila et al [42] was excluded from quantitative synthesis because the report did not provide sufficient numerical information to calculate a daily-step effect estimate and its variance. The remaining 8 studies involving 474 participants were included [23,37-40,43-45]. On average, the intervention groups accumulated more daily steps than the control groups (MD 1062.8, 95% CI 383.5-1825.0 steps/day; *P*=.01). Between-study variability was reflected by τ^2=193,015.86; I^2=30.0%; and Cochran Q=10.00 (*P*=.19). The NNF 95% prediction interval included the null (–503.0 to 2860.0 steps/day), suggesting that a benefit may not be observed consistently across future comparable settings (Figure 4).

Figure 4. Random-effects meta-analysis of daily steps. Study and pooled random-effects mean differences (MDs) in daily steps are shown with 95% CIs. DerSimonian-Laird (DL) estimated variance, pooled CIs used the Knapp-Hartung adjustment, and the labeled normal-normal framework (NNF) 95% prediction interval represents a future comparable study.

RenderX

Secondary Outcomes

AT

A total of 4 studies involving 256 participants were included in the meta-analysis of AT [20-22,38]. The pooled estimate favored the intervention but was imprecise and included the null after Knapp-Hartung adjustment (MD 1.02, 95% CI –0.22 to 2.21 mL/kg/min; *P*=.08). Between-study variability was reflected by τ^2=0.27; I^2=35.0%; and Cochran Q=4.62 (*P*=.20). The NNF 95% prediction interval also included the null (–2.05 to 3.65 mL/kg/min), providing no clear evidence of a consistent benefit (Figure 5).

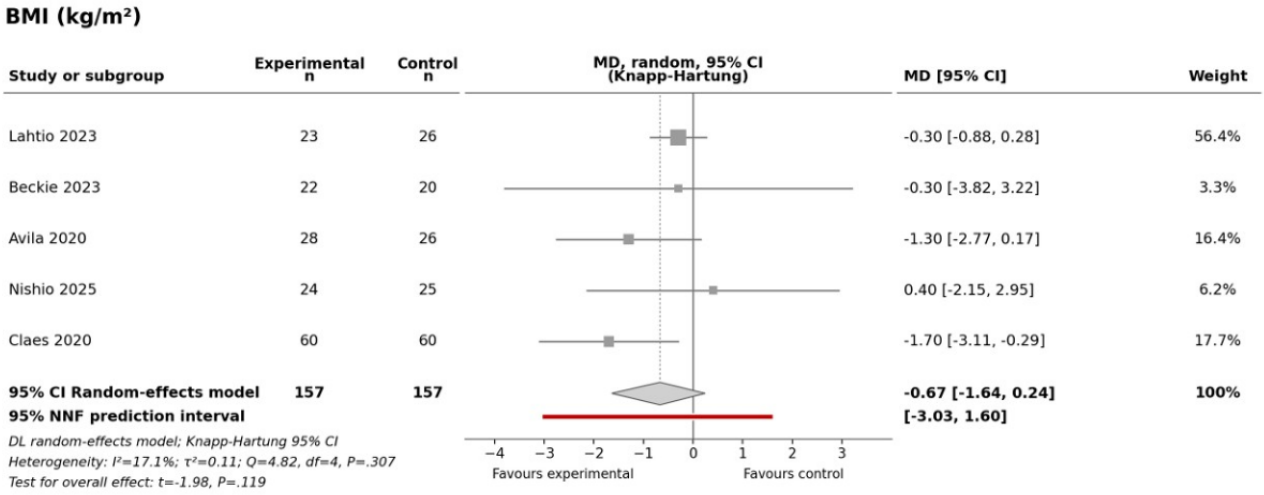

Figure 5. Random-effects meta-analysis of anaerobic threshold (AT). Study and pooled random-effects mean differences (MDs) in AT are shown with 95% CIs. DerSimonian-Laird (DL) estimated variance, pooled CIs used the Knapp-Hartung adjustment, and the labeled normal-normal framework (NNF) 95% prediction interval represents a future comparable study.

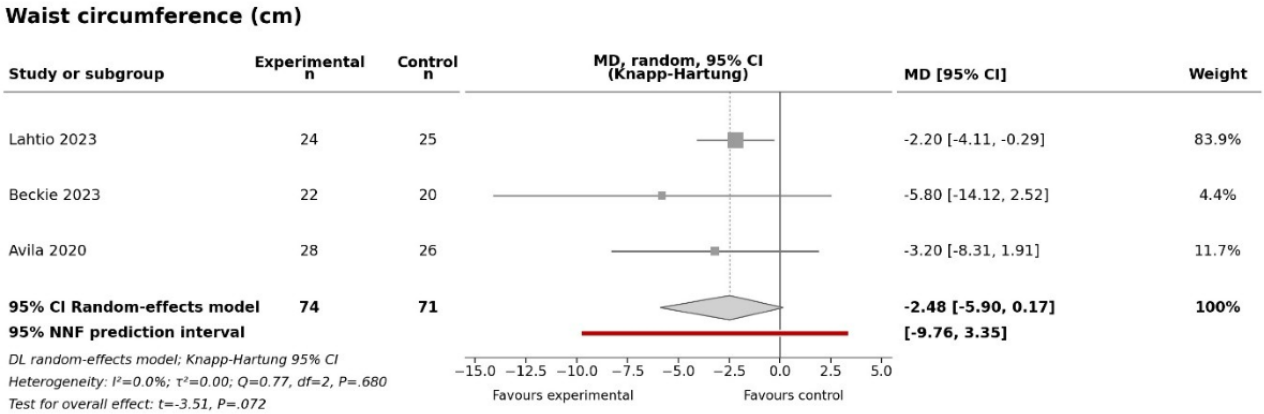
BMI

A total of 5 studies involving 314 participants were included in the meta-analysis of BMI [35,36,38,39,42]. The pooled estimate suggested a possible reduction but was imprecise and included the null after Knapp-Hartung adjustment (MD –0.67, 95% CI –1.64 to 0.24 kg/m^2; *P*=.12). Between-study variability was reflected by τ^2=0.11; I^2=17.1%; and Cochran Q=4.82 (*P*=.31). The NNF 95% prediction interval included the null (–3.03 to 1.60 kg/m^2), providing no clear evidence of a consistent reduction (Figure 6).

Figure 6. Random-effects meta-analysis of BMI. Study and pooled random-effects mean differences (MDs) in BMI are shown with 95% CIs. DerSimonian-Laird (DL) estimated variance, pooled CIs used Knapp-Hartung adjustment, and the labeled normal-normal framework (NNF) 95% prediction interval represents a future comparable study.



Waist Circumference

A total of 3 studies involving 145 participants were included in the meta-analysis of waist circumference [35,36,42]. The pooled estimate suggested a possible reduction but was imprecise and included the null after Knapp-Hartung adjustment (MD –2.48, 95% CI –5.90 to 0.17 cm; *P*=.07). The estimated between-study variance was zero (τ^2=0; I^2=0%; Cochran Q=0.77; *P*=.68), but this estimate was based on only 3 studies and should not be interpreted as evidence of identical effects. The NNF 95% prediction interval included the null (–9.76 to 3.35 cm), providing no clear evidence of a consistent reduction (Figure 7).

XSL•FO
RenderX

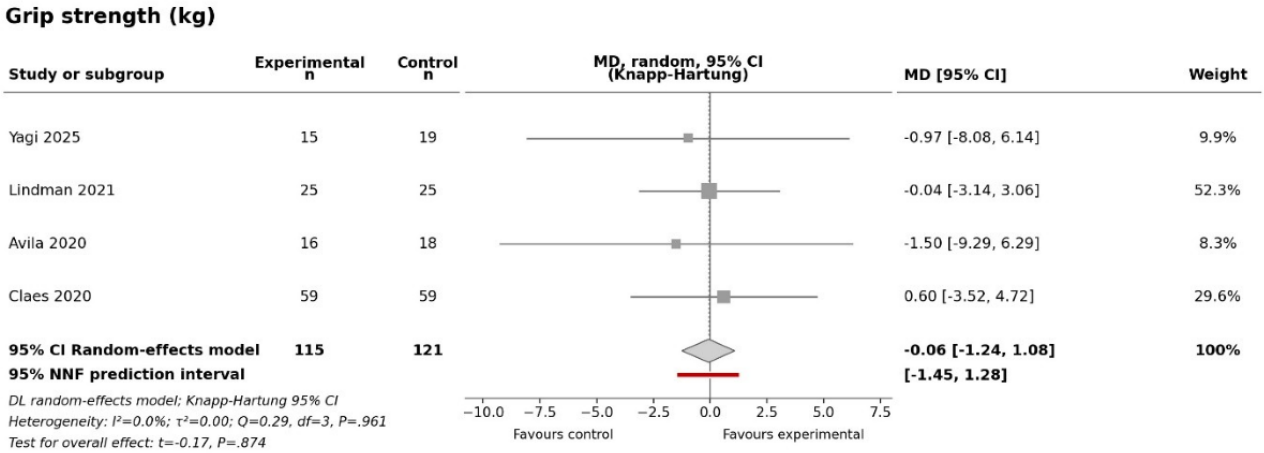


Figure 7. Random-effects meta-analysis of waist circumference. Study and pooled random-effects mean differences (MDs) in waist circumference are shown with 95% CIs. DerSimonian-Laird (DL) estimated variance, pooled CIs used the Knapp-Hartung adjustment, and the labeled normal-normal framework (NNF) 95% prediction interval represents a future comparable study.

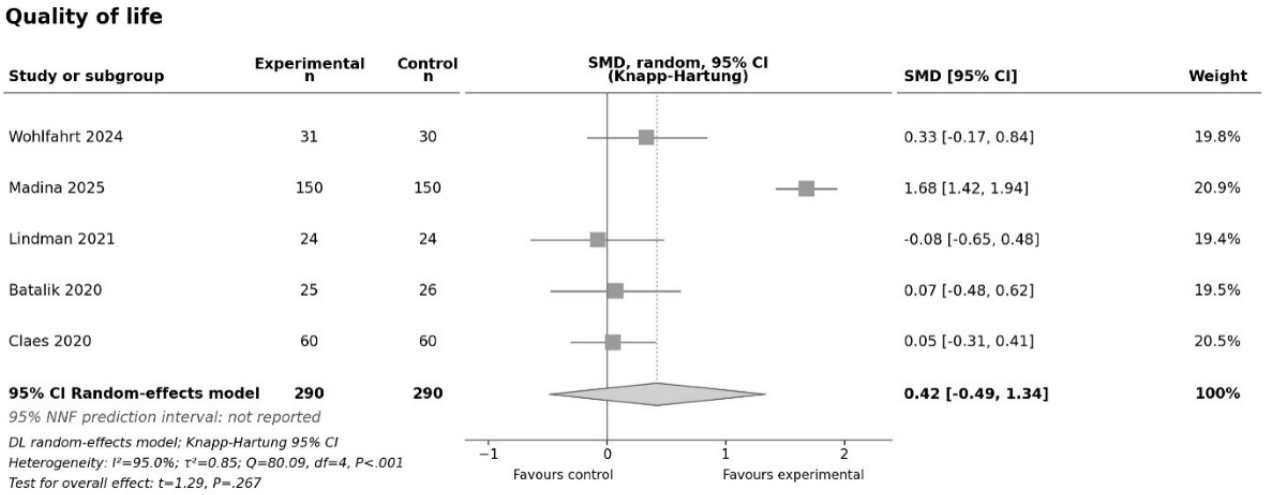
Grip Strength

A total of 4 studies involving 236 participants were included in the meta-analysis of grip strength [22,37,39,42]. The pooled analysis showed no evidence of an average between-group difference (MD –0.06, 95% CI –1.24 to 1.08 kg; *P*=.87). The estimated between-study variance was zero (τ^2=0; I^2=0%; Cochran Q=0.29; *P*=.96), although only 4 studies contributed. The NNF 95% prediction interval also included the null (–1.45 to 1.28 kg), providing no evidence of a consistent benefit (Figure 8).

Figure 8. Random-effects meta-analysis of grip strength. Study and pooled random-effects mean differences (MDs) in grip strength are shown with 95% CIs. DerSimonian-Laird (DL) estimated variance. Pooled CIs used Knapp-Hartung adjustment. The labeled normal-normal framework (NNF) 95% prediction interval represents a future comparable study.



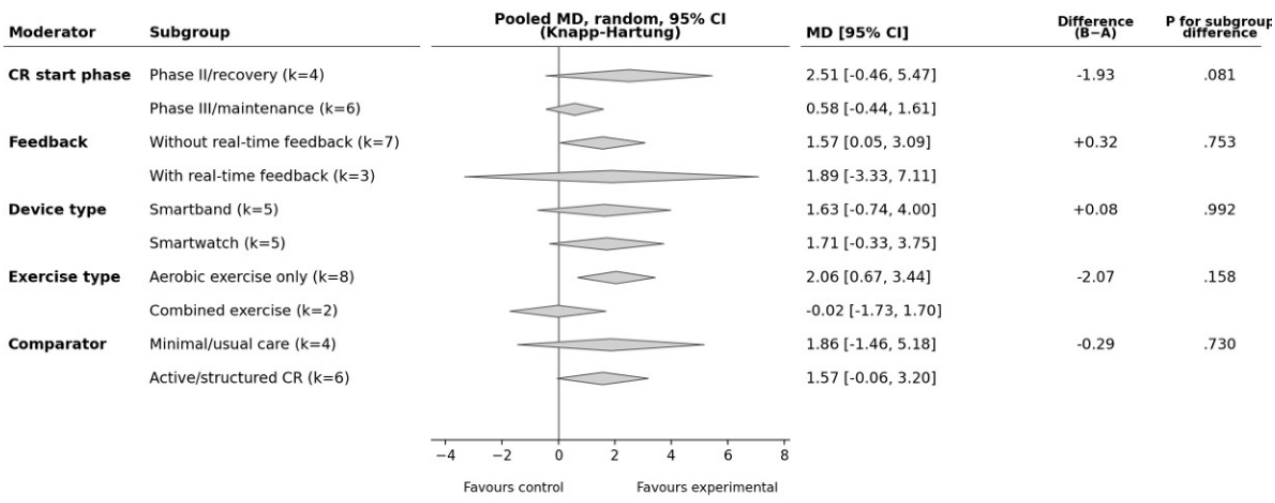
QoL

Although 13 studies reported QoL outcomes, only 5 studies involving 580 participants reported a valid overall or composite QoL score with sufficient numerical data for quantitative synthesis [34,37,39,41,47]. Zhang et al [20] was excluded because the reported SF-36 total score was not a validated summary score and was inconsistent with the stated 0-100 scoring range. The exploratory synthesis showed no clear average between-group difference (SMD 0.42, 95% CI –0.49 to 1.34; *P*=.27). Marked between-study variability remained (τ^2=0.85; I^2=95.0%; Cochran Q=80.09; *P*<.001), and a reliable NNF 95% prediction interval was not reported. Given the clinical and statistical variability across instruments and outcome domains, the pooled estimate was interpreted cautiously, and findings were considered primarily descriptive (Figure 9).

XSL•FO
RenderX

Figure 9. Random-effects meta-analysis of QoL. Study and pooled random-effects Hedges g standardized mean differences (SMDs) are shown with 95% CIs, and pooled CIs used Knapp-Hartung adjustment. Zhang et al [20] was excluded because its 36-Item Short Form Health Survey total was not validated. No reliable normal-normal framework (NNF) prediction interval was reported because variability remained marked. DL: DerSimonian-Laird.

Subgroup Analyses



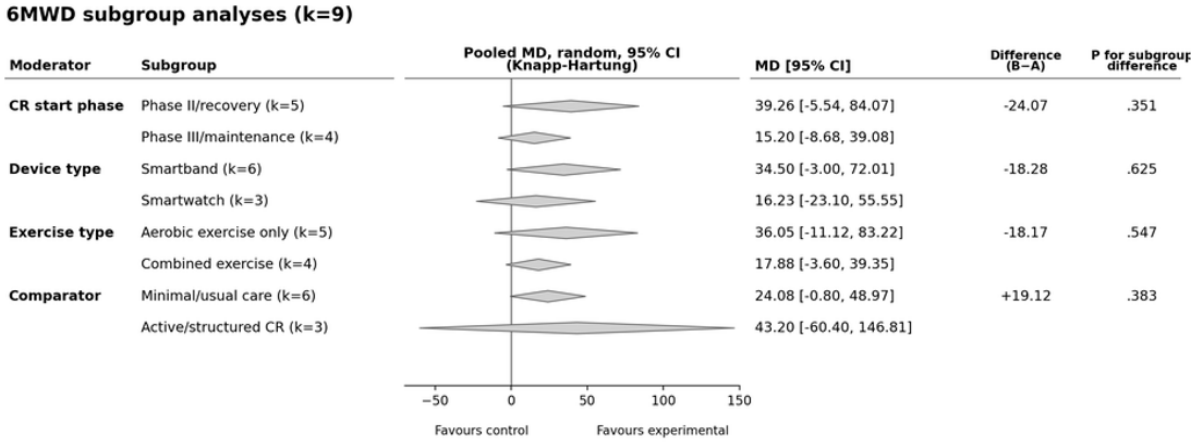
Peak VO2

Subgroup analyses for peak VO_2 were conducted according to the CR phase at intervention initiation, provision of real-time feedback, wearable-device type, exercise type, and comparator characteristics. With restricted maximum likelihood estimation and Knapp-Hartung-adjusted subgroup CIs, the average effect was numerically larger in studies in which CR was initiated during phase II (MD 2.51, 95% CI –0.46 to 5.47 mL/kg/min; 4 studies) than in those initiated during phase III (MD 0.58, 95% CI –0.44 to 1.61 mL/kg/min; 6 studies). However, the formal Knapp-Hartung interaction test did not demonstrate a statistically significant difference between the subgroups (interaction: *P*=.08).

The average effect was also numerically larger in studies using aerobic exercise alone (MD 2.06, 95% CI 0.67-3.44 mL/kg/min; 8 studies) than in studies using combined aerobic and resistance exercise (MD –0.02, 95% CI –1.73 to 1.70 mL/kg/min; 2 studies); however, the Knapp-Hartung subgroup difference was not statistically significant (interaction: *P*=.16).

No statistically significant subgroup differences were identified according to provision of real-time feedback (interaction: *P*=.75), wearable-device type (interaction: *P*=.99), or comparator characteristics (interaction: *P*=.73). Overall, none of the formal interaction tests reached statistical significance (Figure 10). The numerically larger effects observed with phase II initiation and aerobic-only exercise should therefore be considered hypothesis-generating, particularly given the small number of studies within some subgroups.

Figure 10. Subgroup analyses of peak oxygen consumption (VO2). Random-effects subgroup estimates used restricted maximum likelihood and Knapp-Hartung 95% CIs. No interaction was statistically significant (cardiac rehabilitation [CR] phase: P=.08; exercise type: P=.16). MD: mean difference.



XSL•FO
RenderX

6MWD

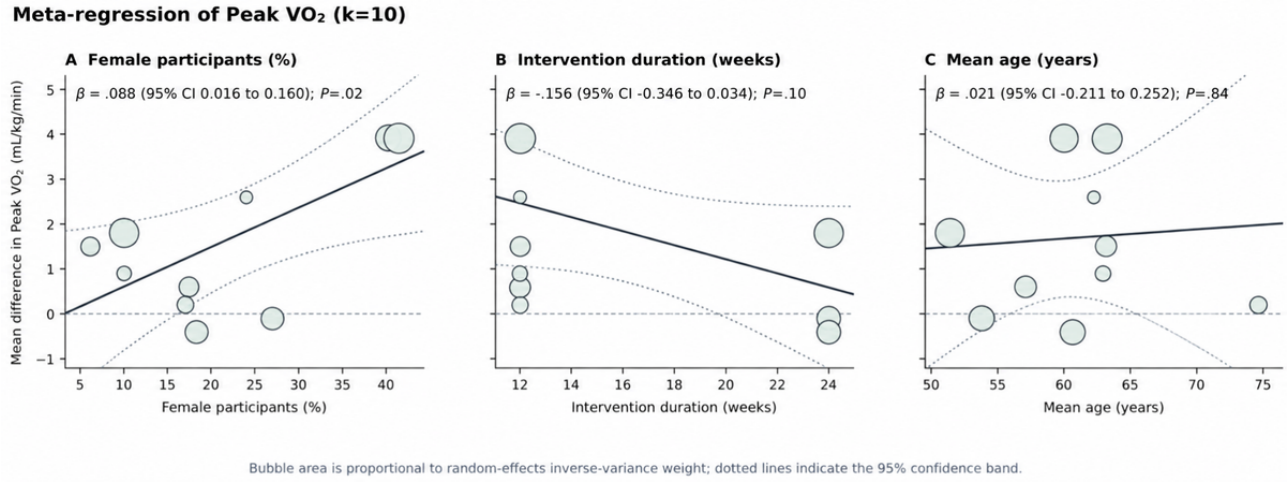
Subgroup analyses for 6MWD were conducted according to the CR phase at intervention initiation, wearable-device type, exercise type, and comparator characteristics. With restricted maximum likelihood estimation and Knapp-Hartung-adjusted subgroup CIs, the pooled MD was 39.26 (95% CI –5.54 to 84.07 m; 5 studies) for interventions initiated during phase II and 15.20 (95% CI –8.68 to 39.08 m; 4 studies) for interventions initiated during phase III (interaction: *P*=.35). The pooled MD was 34.50 (95% CI –3.00 to 72.01 m; 6 studies) for smartbands and 16.23 (95% CI –23.10 to 55.56 m; 3 studies) for smartwatches (interaction: *P*=.63). For aerobic exercise alone and combined exercise, the pooled MDs were 36.05 (95% CI –11.12 to 83.22 m; 5 studies) and 17.88 (95% CI –3.60 to 39.35 m; 4 studies), respectively (interaction: *P*=.55). For minimal or usual-care and active or structured CR comparators, the pooled MDs were 24.08 (95% CI –0.80 to 48.97 m; 6 studies) and 43.20 (95% CI –60.40 to 146.81 m; 3 studies), respectively (interaction: *P*=.38). None of the interaction tests were statistically significant (Figure 11).

Figure 11. Subgroup analyses of 6-minute walk distance (6MWD). Random-effects subgroup estimates for 6MWD used restricted maximum likelihood and Knapp-Hartung 95% CIs. No interaction was statistically significant. CR: cardiac rehabilitation; MD: mean difference.

Given the limited number of studies within several subgroups, all subgroup findings were interpreted cautiously. The comparator-based subgroup analyses were conducted post hoc in response to peer review. Prediction intervals were not calculated for subgroup analyses because subgroup-specific estimates were based on a limited number of studies. Study-level results for the peak VO_2 and 6MWD subgroup analyses are provided in Figures S1-S9 in Multimedia Appendix 4.

Meta-Regression Analyses

Peak VO2



Univariable random-effects meta-regression analyses were conducted across the 10 studies contributing to the peak VO_2 meta-analysis to examine associations with the proportion of female participants, intervention duration, and mean participant age.

A higher proportion of female participants was associated with a larger intervention effect on peak VO_2 (β=.088, 95% CI 0.016-0.160 mL/kg/min per 1-percentage-point increase in the proportion of female participants; *P*=.02). Thus, at the study level, a 10-percentage-point increase in the proportion of female participants corresponded to an estimated 0.88-mL/kg/min larger MD in peak VO_2. This finding should be interpreted cautiously because the analysis was based on aggregate study-level data and does not establish an individual-level sex-specific treatment effect.

Intervention duration showed a negative association with the intervention effect, but the association did not reach the prespecified 2-sided significance threshold (β=–.156, 95% CI –0.346 to 0.034 mL/kg/min per additional week; *P*=.10). Mean participant age was not associated with the intervention effect (β=.021, 95% CI –0.211 to 0.252 mL/kg/min per additional year; *P*=.84). The peak VO_2 meta-regression results are presented in Figure 12.

XSL•FO
RenderX

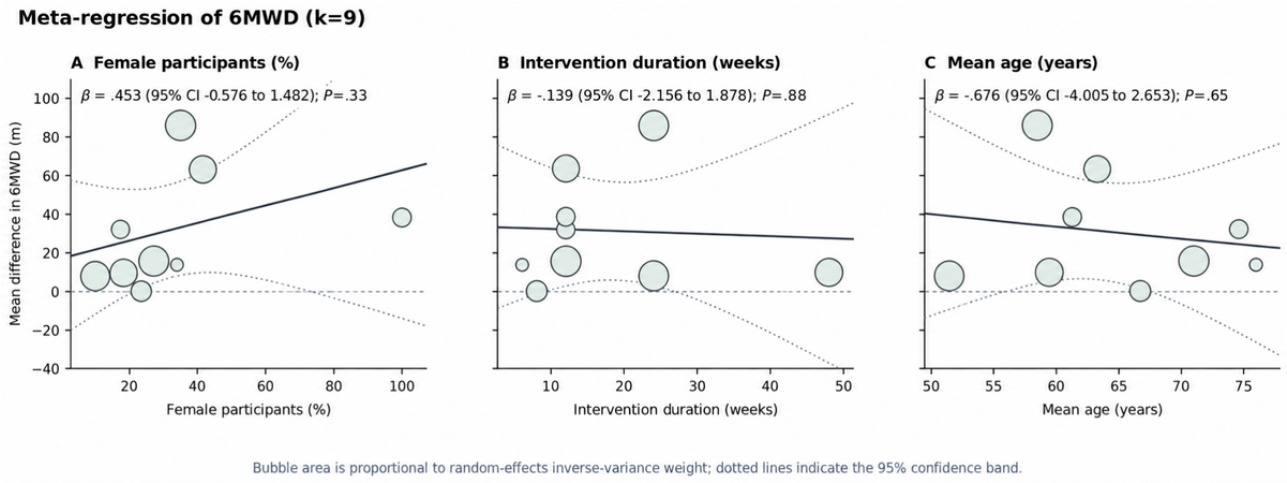


Figure 12. Univariable meta-regression analyses of peak oxygen consumption (VO2). Bubble plots show random-effects meta-regression of peak VO2 mean difference against female proportion, intervention duration, and mean age across 10 studies; area reflects inverse-variance weight; and dotted lines show 95% confidence bands.

6MWD

Univariable random-effects meta-regression analyses were conducted across the 9 studies contributing to the 6MWD meta-analysis. No statistically significant associations were identified for any of the examined study-level moderators. The proportion of female participants was not significantly associated with the intervention effect on 6MWD (β=.453, 95% CI –0.576 to 1.482 m per 1-percentage-point increase; *P*=.33). Intervention duration was also not associated with the effect estimate (β=–.139, 95% CI –2.156 to 1.878 m per additional week; *P*=.88), nor was mean participant age (β=–.676, 95% CI –4.005 to 2.653 m per additional year; *P*=.65). The 6MWD meta-regression results are presented in Figure 13.

Figure 13. Univariable meta-regression analyses of 6-minute walk distance (6MWD). Bubble plots show random-effects meta-regression of 6MWD mean difference against female proportion, intervention duration, and mean age across 9 studies; area reflects inverse-variance weight; and dotted lines show 95% confidence bands.

Given the small number of contributing studies, limited statistical power, and use of aggregate study-level covariates, all meta-regression findings were considered exploratory and hypothesis-generating. In particular, the association between the proportion of female participants and the peak VO_2 effect should not be interpreted as evidence that individual female participants experienced greater benefits.

Sensitivity Analyses

Exclusion of the Cluster-Randomized Trial

Sensitivity analyses excluding the cluster-randomized trial were conducted for 6MWD, daily steps, BMI, and waist circumference, which were the outcomes to which the trial contributed.

For 6MWD, exclusion of the cluster-randomized trial did not materially change the pooled average effect (MD 33.95, 95% CI 7.60-60.30 m; *P*=.02). Between-study variability remained (I^2=88.4%; τ^2=1343.55), and the NNF 95% prediction interval included the null (–67.52 to 135.99 m).

For daily steps, the pooled average effect remained statistically significant after exclusion of the cluster-randomized trial (MD 1084.5, 95% CI 294.6-1961.1 steps/day; *P*=.02). Between-study variability was reflected by I^2=39.9% and τ^2=265,305.58, and the NNF 95% prediction interval included the null (–704.8 to 3077.3 steps/day).

For BMI, exclusion of the cluster-randomized trial resulted in a larger estimated reduction, but the Knapp-Hartung-adjusted

XSL•FO
RenderX

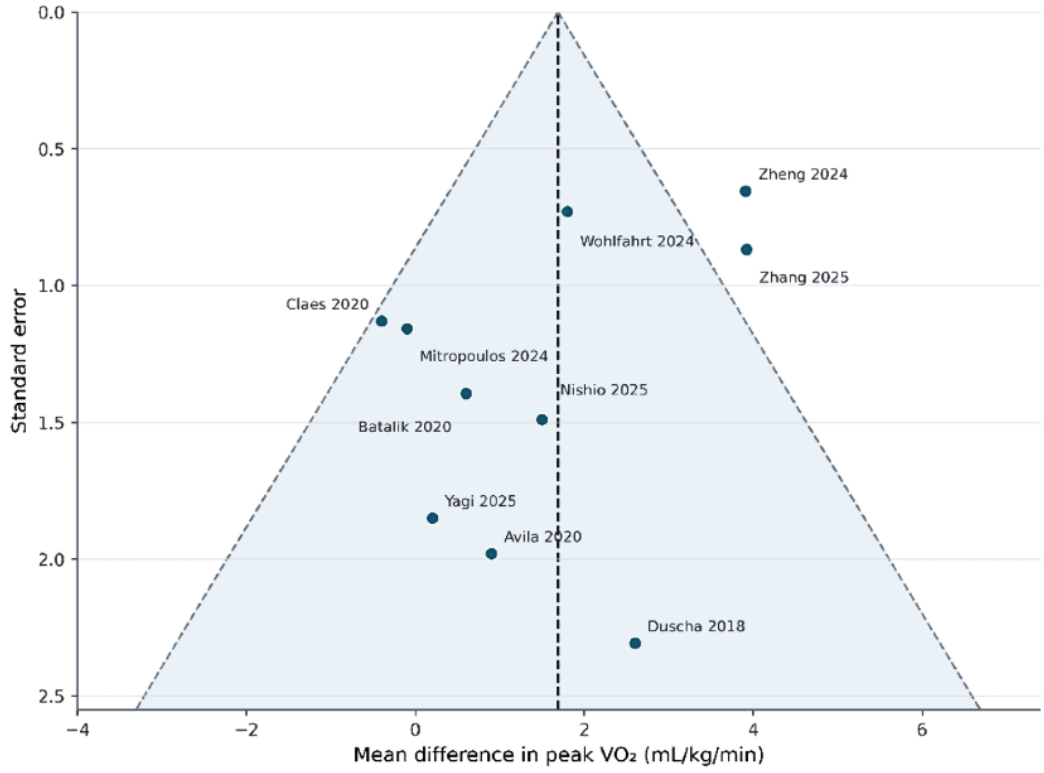
CI included the null (MD –1.18, 95% CI –2.48 to 0.35 kg/m^2; P=.08; I^2=0%; τ^2=0). The NNF 95% prediction interval also included the null (–3.68 to 1.71 kg/m^2).

For waist circumference, exclusion of the cluster-randomized trial moved the point estimate farther from the null (from –2.48 to –3.91 cm), but precision decreased because only 2 studies remained (MD –3.91, 95% CI –8.27 to 0.44 cm; P=.08; I^2=0%). An NNF prediction interval was not reported because only 2 studies remained, below the number for which the method has demonstrated adequate performance. Thus, the estimated effect became larger in magnitude, but the evidence became less precise and remained sensitive to a single-study exclusion.

Leave-One-Out Analysis for 6MWD

A leave-one-out sensitivity analysis was conducted for 6MWD by sequentially excluding each of the 9 contributing studies. The pooled MDs ranged from 20.95 to 34.44 m, remained positive, and retained 95% CIs that excluded the null in every analysis. The corresponding NNF prediction intervals nevertheless included the null throughout.

Exclusion of Madina et al [47] was accompanied by a decrease in I^2 from 87.8% to 42.5%, while the pooled MD remained statistically significant (MD 20.95, 95% CI 3.57-38.36 m). This finding indicates that the relative inconsistency among study results was lower after exclusion of this study; however, the change in I^2 was not interpreted as an absolute reduction in between-study heterogeneity. Exclusion of the other individual studies did not materially reduce I^2, which ranged from 87.2% to 89.4%; however, these relative inconsistency estimates were interpreted alongside $\tau^2$and the prediction intervals rather than as absolute measures of heterogeneity. The complete leave-one-out analysis is presented in Figure S14 in Multimedia Appendix 4.



Overall, the sensitivity analyses preserved the direction of the pooled effects for 6MWD, daily steps, and BMI. Knapp-Hartung-adjusted pooled effects remained statistically significant for 6MWD and daily steps after exclusion of the cluster-randomized trial, whereas the BMI estimate included the null. The waist-circumference estimate increased in magnitude but lost precision after exclusion of the cluster-randomized trial. Prediction intervals continued to include the null where estimable.

Reporting Biases

Potential small-study effects were assessed for peak VO_2, for which 10 studies were available. Visual inspection of the funnel plot suggested some asymmetry. Egger regression test yielded an intercept of –2.24 (P=.10), which did not reach the prespecified 2-sided significance threshold of P<.05. Together with the visual asymmetry, this suggested possible small-study effects, although the evidence was inconclusive. This finding should be interpreted cautiously because only 10 studies were available and funnel plot asymmetry may result from between-study heterogeneity, methodological differences, or other factors rather than publication bias alone (Figure 14).

Formal tests for funnel plot asymmetry were not performed for the remaining outcomes because fewer than 10 studies were included in each meta-analysis, resulting in limited statistical power and potentially unreliable assessments.

Figure 14. Funnel plot for the meta-analysis of peak oxygen consumption (VO2). The funnel plot shows peak VO2 mean differences against SEs for 10 randomized controlled trials. The vertical line marks the pooled mean difference, and diagonals mark the expected 95% limits. Mild visual asymmetry was not supported by Egger regression (intercept –2.24, SE 1.19; P=.10) and is not direct evidence of publication bias.

XSL•FO
RenderX

Certainty of Evidence

GRADE certainty ranged from very low to moderate. Peak VO_2 was moderate, downgraded for inconsistency because effects varied and the NNF 95% prediction interval included the null. 6MWD was moderate, downgraded for inconsistency because effects varied materially and the wide NNF interval included the null. Daily steps were low, downgraded 2 levels for very serious risk of bias, mainly from deviations from intended interventions.

AT and BMI were moderate, each downgraded for imprecision. Waist circumference was low, downgraded for risk of bias and imprecision; only 145 participants contributed, the Knapp-Hartung CI and NNF interval included the null, and cluster-RCT exclusion left 2 studies with less precision. Grip strength was low because of risk of bias and imprecision. QoL was very low because of very serious risk of bias, very serious inconsistency, and imprecision. Table S1 in Multimedia Appendix 4 provides detailed judgments.

Discussion

Principal Findings

This systematic review and meta-analysis found favorable average effects of wrist-worn wearable–guided CR delivered through fully remote or hybrid programs on peak VO_2, 6MWD, and daily steps in patients with CVD, with interventions initiated during phase II or phase III CR. No clear pooled effects were found for AT, BMI, waist circumference, grip strength, or QoL after applying a consistent Knapp-Hartung framework. The prediction intervals for all 3 primary outcomes included the null, indicating uncertainty about whether the favorable average effects would be reproduced in a future comparable setting. Certainty varied across outcomes, and findings for daily steps and QoL were further limited by risk-of-bias concerns. Subgroup and meta-regression findings remain exploratory.

The observed average improvements in peak VO_2 and 6MWD may be clinically relevant because both outcomes are associated with cardiovascular prognosis and functional independence. Peak VO_2 is a strong predictor of cardiovascular and all-cause mortality, and modest improvements in cardiorespiratory fitness have been associated with reduced mortality risk [50,51]. The pooled 6MWD estimate was also comparable to commonly reported thresholds for clinically meaningful change in CR populations [52]. These findings are consistent with CR guidelines that identify cardiorespiratory fitness and functional capacity as central treatment targets [3,8]. Nevertheless, the prediction intervals for both outcomes included the null. The pooled estimates should therefore be interpreted as favorable average effects, not effects expected to occur uniformly across future fully remote or hybrid programs.

Subgroup analyses showed numerically larger peak VO_2 improvements when wrist-worn wearable–guided CR was initiated during phase II rather than phase III and when interventions emphasized aerobic exercise rather than combined aerobic and resistance exercise. However, neither formal interaction test reached statistical significance. These findings should therefore be considered hypothesis-generating rather than evidence that CR phase or exercise type modifies intervention effectiveness. The larger numerical effect during phase II may reflect greater potential for physiological recovery during early outpatient rehabilitation, whereas phase III focuses primarily on the maintenance of previously achieved gains [8,53]. Similarly, aerobic training directly targets the central and peripheral determinants of maximal oxygen uptake [54], although resistance exercise remains important for muscular strength and overall function [55,56]. The small number of studies in some subgroups precludes recommending one CR phase or exercise modality over another.

No statistically significant subgroup differences were identified according to wearable-device type, real-time feedback, or comparator characteristics. Most devices shared core functions such as step counting and HR monitoring, which may have limited the ability to detect device-specific differences [57]. Moreover, the effectiveness of feedback may depend on its frequency, personalization, and integration into exercise prescription rather than simply on whether feedback is available [58]. Control interventions also ranged from usual or minimally supported care to structured center-based, community-based, or wearable-supported programs. Consequently, the absence of statistically significant subgroup interactions should not be interpreted as demonstrating equivalence among devices, feedback approaches, or comparator conditions.

Meta-regression associated higher study-level female proportion with greater peak VO_2 improvement, while age and intervention duration were not significant moderators. With few studies and aggregate covariates, these exploratory results are susceptible to ecological bias and do not establish greater individual benefit in women or absence of age- or duration-related effects. Remote or hybrid CR may nevertheless improve access for women facing logistical, caregiving, social, or referral barriers [59], a consideration distinct from the observed treatment-effect association.

The pooled analysis indicated a favorable average effect on daily steps with wrist-worn wearable–guided CR; however, confidence is limited because most contributing studies had high overall risk of bias and evidence certainty was low. The prediction interval included the null, indicating that benefit may not be observed consistently across comparable fully remote or hybrid settings. Wearable- and eHealth-supported rehabilitation may facilitate self-monitoring, goal setting, and feedback [58,60]. However, greater step counts do not necessarily indicate reduced sedentary time, higher activity intensity, or sustained long-term behavioral change because these dimensions were not assessed consistently.

The pooled estimates for AT, BMI, and waist circumference were imprecise and included the null after Knapp-Hartung adjustment. AT may respond differently from peak VO_2 depending on baseline fitness, exercise intensity, and measurement methods [61-63]. The anthropometric point estimates may reflect increased physical activity, as aerobic exercise and sustained activity have been associated with reduced central adiposity [64,65], but most included programs did not provide intensive dietary or weight-management

XSL•FO
RenderX

components. For waist circumference, excluding the cluster-randomized trial moved the point estimate farther from the null but reduced precision because only 2 studies remained. These secondary findings should therefore be considered uncertain and should not be attributed specifically to wearable use.

No clear improvement was observed in grip strength, which may reflect the limited emphasis on progressive resistance training in many wrist-worn wearable–guided CR programs. Step-based activity monitoring alone does not provide the training stimulus required to increase muscular strength [55,56]. The available evidence did not establish a clear effect on QoL. The exploratory pooled estimate was highly uncertain because most contributing studies had high overall risk of bias, between-study heterogeneity was extreme, and the certainty of evidence was rated as very low. Therefore, the nonsignificant pooled estimate should not be interpreted as evidence of no effect. Differences in generic and disease-specific instruments and the broader psychosocial and clinical determinants of QoL may also have contributed to the observed variability [66].

Previous reviews of wearable- and eHealth-supported cardiovascular rehabilitation generally found gains in physical activity or exercise capacity [9,10,16-19]. Alam et al [9] reported that quantitative syntheses tended to favor consumer wearables for steps and moderate to vigorous activity, and Heimer et al [10] found that eHealth-supported phase III CR improved activity and capacity with a small QoL benefit. Our QoL estimate was more uncertain, likely reflecting differences in populations, phases, program components, comparators, follow-up, and instruments. Telerehabilitation can extend CR beyond centers [67], but multicomponent benefits cannot be attributed to the wearable alone.

From a clinical perspective, wrist-worn wearable–guided CR may help extend activity monitoring and behavioral support beyond center-based sessions. This may be particularly relevant because conventional CR participation remains limited by travel distance, transportation, program availability, work and caregiving responsibilities, and physical limitations [8,68,69]. Wrist-worn devices have relatively low user burden and can be incorporated into daily life [70,71]. Their most appropriate role may therefore be to complement structured multidisciplinary CR by supporting individualized goals, activity monitoring, and communication between patients and rehabilitation teams rather than to replace supervised exercise prescription or comprehensive secondary prevention.

This review focused on a clinically relevant and scalable category of wearable technology and included only RCTs. Absolute effect measures enhanced clinical interpretability, and prediction intervals distinguished uncertainty surrounding average effects from the expected variation across comparable settings. Subgroup, meta-regression, and sensitivity analyses were used to explore potential sources of heterogeneity, and companion publications were linked to prevent double counting.

Limitations include material variation in effects, especially for 6MWD and QoL, arising from populations, CR phase, duration, prescriptions, wearable functions, comparators, and timing. I^2 was therefore interpreted with τ^2, prediction intervals, and clinical diversity. Few studies supported several outcomes and subgroups; aggregate meta-regression had limited power and could not establish patient-level modification. Risk-of-bias concerns included deviations, missing data, and outcome measurement. Heterogeneous multicomponent interventions prevented isolating wearable effects, and limited postintervention follow-up precluded conclusions about durability or cardiovascular events. The review lacked prospective registration and a published protocol; some exploratory-analysis eligibility was refined after extraction, and the comparator subgroup was post hoc. Restriction to peer-reviewed English- or Korean-language full texts and exclusion of gray literature may have increased dissemination bias; funnel plots and Egger regression could assess, but not establish, publication bias.

Conclusions

Wrist-worn wearable–guided CR delivered through fully remote or hybrid programs may improve average exercise capacity and physical activity in patients with CVD during phase II or III CR. Favorable pooled effects were observed for peak VO_2, 6MWD, and daily steps; however, the prediction intervals included the null, indicating that these benefits may not be consistently reproduced across future settings. No clear effects were observed for AT, BMI, waist circumference, grip strength, or QoL. When integrated into structured multidisciplinary CR, wrist-worn wearables may provide a scalable means of extending activity monitoring, individualized feedback, and behavioral support beyond supervised clinical encounters. Nevertheless, the limited evidence base, risk-of-bias concerns, intervention heterogeneity, and multicomponent nature of the programs warrant cautious interpretation. Larger, rigorous trials should determine which patients and intervention components derive the greatest benefit and how wearable-derived data can support adaptive, personalized CR.

Abstract

Background: Smartphone-based self-assessment methods, such as ecological momentary assessment (EMA), are increasingly used to measure perceived stress in research and emerging clinical applications. However, the proliferation of studies and methods has made it difficult for researchers and practitioners to maintain an overview and make informed methodological choices. An updated synthesis of smartphone-based self-report methods is therefore needed.

Objective: This scoping review aims to systematically map smartphone-based methods for assessing self-reported perceived stress in healthy adults during daily life, to describe measurement characteristics and methodological choices, and to narratively examine the extent to which validity and reliability evidence are reported.

Methods: Following PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) guidelines, we searched a total of 7 databases: Web of Science, Embase, MEDLINE, PubMed, IEEE Xplore, ACM, and PsycInfo. Eligible studies assessed general perceived stress in healthy adults using smartphone-based self-report measures in daily life. Screening was conducted independently by at least 2 reviewers at the abstract and full-text levels. Methodological characteristics of stress measurement were extracted and summarized descriptively.

Results: From 8777 deduplicated records, 108 studies met all eligibility criteria. Publication frequency increased notably over the review period. Most studies used observational designs, with EMA-style prompting schedules. Stress was typically assessed using very brief measures: most instruments (84/114, 74%) consisted of a single item, most commonly answered using a Likert-type scale or a visual analog scale. Measurement frequency ranged from once per week to multiple prompts per day, with intensive approaches (≥3 prompts per day) being most common. Despite the prevalence of these instruments, only a minority of studies reported validity or reliability measures. When provided, evidence typically consisted of correlations with established stress questionnaires or affective measures. A small subset conducted elaborate psychometric analyses or validation of instruments.

Conclusions: Smartphone-based stress assessment is widespread but methodologically heterogeneous. This review provides an updated methodological overview to support researchers in selecting or developing robust smartphone-based measures of perceived stress. Only a small minority of studies reported formal psychometric evaluations, highlighting the need for more systematic validation of smartphone-based stress assessment.

Introduction

Background

Stress is a multifaceted psychological and physiological response that plays a central role in mental and physical health. According to Cohen et al [1], stress can be described as the process in which "environmental demands tax or exceed the adaptive capacity of an organism, resulting in psychological and biological changes that may place persons at risk for disease." Chronic stress, without sufficient recovery, is indeed associated with numerous adverse outcomes, including infectious disease [2], cardiovascular disease [3], and depression [4], as well as substantial economic costs [5]. Hence, improving stress monitoring and interventions can have a substantial personal and societal impact.

Being a complex response, stress involves changes in autonomic nervous system activity, behavior, and subjective mood. Physiologically, it is associated with decreases in heart rate variability (HRV) [6], increases in electrodermal activity [7], and the release of stress-related hormones such as cortisol [8]. Equally important, however, is the psychological response: the subjective experience of feeling stressed, occurring when individuals perceive that demands exceed their resources [9]. Physiological and psychological stress measures are related, but they capture distinct processes on different timescales and, therefore, their correlation is often modest [10]. Physiological responses are also not stress-specific and are influenced by contextual variables, such as physical movement or high-arousal positive emotions [11]. Therefore, the accurate measurement of self-reported perceived stress (or subjective stress) remains crucial.

Several questionnaires assess perceived stress, including the Perceived Stress Scale (PSS) [12], the stress subscale of the Depression Anxiety Stress Scales (DASS) [13], and the Kessler Psychological Distress Scale (K10) [14]. Although these retrospective measures are widely used and psychometrically supported [15-17], they are limited by recall bias and low temporal resolution: they cannot capture rapid fluctuations in stress throughout daily life [18]. Ecological momentary assessment (EMA), also termed the experience sampling method (ESM), addresses these limitations by collecting repeated real-time reports of thoughts, emotions, and behaviors in natural environments, enhancing ecological validity and reducing recall-related bias [18]. With the widespread use of smartphones, EMA has become more feasible and scalable, expanding the possibilities for high-resolution monitoring of perceived stress [19-22]. Smartphone-based EMA methods have also been used to measure stress in patient populations, demonstrating the opportunities in clinical contexts [23]. Examples of populations that have been studied include patients with HIV [24] or tinnitus [25].

EMA and similar methods allow researchers and practitioners to collect self-reported stress data in real time, but several methodological challenges remain. EMA protocols rely on brief assessments that are administered repeatedly, often multiple times per day. To minimize participant burden and increase compliance, single-item measures or abbreviated versions of existing questionnaires are often used [20]. While the validity and reliability of brief EMA measures are generally supported, results vary across participants, topics, and studies [26,27]. In addition, when traditional (retrospective) questionnaires are shortened and adapted to a momentary assessment context, they may not automatically retain their psychometric properties [28]. The validity and reliability of EMA stress measures are a multifaceted problem. First, validity can be examined by studying whether the EMA measure correlates with a validated questionnaire, such as the PSS (convergent validity), and by investigating whether it correlates as theoretically expected with distinct but related constructs, such as positive and negative affect (criterion and discriminant validity) [28,29]. Second, the reliability of EMA measures can be investigated using multilevel approaches, as there is variability not only between participants but also within participants (due to repeated measurements) [28,29].

A systematic review by Þórarinsdóttir et al [20] showed that by 2016, smartphone-based self-assessment of stress had already proliferated, driven by widespread smartphone availability and growing interest in personalized health monitoring. Their review revealed heterogeneity in methodological choices such as scale type, number of items, and sampling frequency, and highlighted that many studies relied on unvalidated brief instruments. Consequently, to date, important questions remain regarding the validity and reliability of these measures.

Study Objectives

It is likely that over the past decade, since the review by Þórarinsdóttir et al [20], the scientific literature on smartphone-based self-assessment of stress has grown even more steeply, and more validated approaches have been developed. The lack of a recent comprehensive overview of smartphone-based methods for assessing perceived stress poses challenges for researchers seeking to make informed methodological decisions.

Thus, the present scoping review systematically maps the methods used to measure self-reported perceived stress via smartphones in healthy adults during daily life. Here, we focus on general perceived (or subjective) stress, as opposed to stress associated with specific events or domains, such as stress related to traumatic life events. Because the field is characterized by considerable methodological diversity in instrument content, response formats, sampling schedules, and implementation strategies, a systematic review is currently not feasible. Instead, a scoping review is the most appropriate way to map the existing evidence base. We aim to update the findings of Þórarinsdóttir

XSL•FO
RenderX

et al [20] by synthesizing the methodological characteristics of recent approaches and exploring the extent to which their validity and reliability have been studied.

Specifically, this review addressed the following research questions:

1. Which smartphone-based self-report methods have been used to assess perceived stress in healthy adults during daily life since 2016?
2. What are the methodological characteristics of smartphone-based stress assessment, including study characteristics (eg, study duration, sample size, population, and assessment context) and measurement characteristics (eg, item phrasing, number of items, response format, measurement frequency, and prompting method)?
3. What evidence regarding the validity and reliability of these instruments has been reported?

Methods

Review Framework and Protocol Registration

This scoping review was conducted in accordance with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 statement [30] and the PRISMA extension for Scoping Reviews (PRISMA-ScR) [31]. The tip sheets accompanying the PRISMA-ScR statement were also consulted. The PRISMA-ScR checklist can be found in Multimedia Appendix 1 [31]. The protocol was developed following the methodological guidelines of the Joanna Briggs Institute Scoping Review Methodology Group [32] and was preregistered on OSF Registries [33]. Compared with the preregistered protocol, only 2 minor deviations occurred. First, the ACM Guide to Computing Literature was searched instead of the ACM Full Text Collection. Because the ACM Guide to Computing Literature includes all records from the ACM Full Text Collection as well as additional records, this modification resulted in a more comprehensive search. Second, although participant age was extracted from included studies as planned, age data were not synthesized using descriptive statistics. Age was reported inconsistently across studies, with some reporting means and SDs, others reporting medians, and others reporting age ranges only. Because these data could not be summarized in a consistent manner across studies, age was not included in the final quantitative summary.

Eligibility Criteria

Following the population, concept, and context framework of the Joanna Briggs Institute [34], studies were eligible when they targeted healthy adults (population), assessed general perceived stress (concept), and used a smartphone-based self-assessment method administered during daily life (context). The population of healthy adults was defined as individuals aged 18 years or older without diagnosed physical or mental health conditions and without indications of unhealthy living circumstances (eg, homelessness), as outlined in the World Health Organization Housing and Health Guidelines [35]. To update the earlier review by Þórarinsdóttir et al [20], only records published between January 1, 2016, and the search date of June 14, 2024, were considered.

Studies were excluded if they met any of the following criteria: (1) wrong publication type (eg, nonempirical report such as a protocol or not written in English), (2) wrong population (eg, minors, unhealthy adults, or unhealthy housing conditions), (3) no measurement of general perceived stress levels in daily life (eg, stress not quantified, not general but specific stress, or not in daily life), (4) not a smartphone-based assessment (eg, stress not measured on a smartphone), (5) duplicate data (eg, in multiple publications reporting the same dataset, only the most complete version was retained, ie, the study with the most participants or the longest duration if sample size was equal), and (6) missing data on one or more of the main variables, preventing extraction of core characteristics (eg, stress item phrasing or sampling frequency).

Information Sources and Search Strategy

We searched generalist and domain-specific databases in psychology and technology. Searches were conducted in Web of Science Core Collection (via the Clarivate Web of Science platform), Embase and MEDLINE (via Embase), PubMed (via PubMed), PsycInfo (via Ovid), IEEE Xplore Digital Library (via IEEE Xplore), and the ACM Guide to Computing Literature (via ACM Digital Library). Because PubMed also includes all MEDLINE-indexed records, there was overlap between the searches conducted through Embase and PubMed, which was addressed during the deduplication process. However, PubMed also includes records that are not (yet) indexed in MEDLINE, thereby increasing the sensitivity of the search strategy.

No gray literature (eg, master's theses) was included because the review aimed to identify smartphone-based stress assessment methods that were described in sufficient methodological detail to allow extraction of key measurement characteristics and any available evidence regarding validity or reliability. No supplementary reference list searching, citation tracking, hand-searching, or expert consultation was performed.

The general search query was *(Stress* OR psychological stress OR emotional stress) AND (smartphone* OR "cell phone*" OR cellphone* OR "cellular phone*" OR mobile phone* OR iPhone* OR iOS OR Android OR mobile application* OR mobile app OR mobile apps OR ecological momentary assessment* OR experience sampling method* OR ESM OR EMA)*. Some databases required adaptation of the query to accommodate their specific search fields and operators. Prior to finalizing the strategy, we piloted the search string in all databases and refined it iteratively to maximize sensitivity (inclusion of all relevant studies) while maintaining sufficient specificity (limiting irrelevant results).

As an example, the full search strategy for PubMed was to enter the following search query in the basic search field: *(Stress*[Title/Abstract] OR "psychological stress"[Title/Abstract:~5] OR "emotional stress"[Title/Abstract:~5]) AND (smartphone*[Title/Abstract] OR "cell phone"[Title/Abstract:~5] OR "cell phones"[Title/Abstract:~5] OR cellphone*[Title/Abstract] OR "cellular phone"[Title/Abstract:~5] OR "cellular phones"[Title/Abstract:~5] OR "mobile phone"[Title/Abstract: ~5] OR "mobile phones"[Title/Abstract:~5] OR iPhone*[Title/Abstract] OR iOS[Title/Abstract] OR Android[Title/Abstract] OR "mobile*

XSL•FO
RenderX

application"[Title/Abstract:~5] OR "mobile applications"[Title/Abstract: ~5] OR "mobile app"[Title/Abstract:~5] OR "mobile apps"[Title/Abstract:~5] OR "ecological momentary assessment"[Title/Abstract] OR "experience sampling method*"[Title/Abstract] OR ESM[Title/Abstract] OR EMA[Title/Abstract])*. After conducting the search, the publication date filter was set from January 1, 2016, to June 14, 2024. All other database-specific search queries are available in the preregistered protocol [33].

Screening and Selection Process

For the screening and selection of studies, all retrieved records were imported into Rayyan (Rayyan Systems, Inc) [36] for deduplication and screening. After removing duplicate entries, the remaining unique records were first screened at the abstract level using the predefined inclusion and exclusion criteria. Abstract screening was conducted independently by 2 reviewers, who were blinded to each other's decisions. Records deemed potentially eligible proceeded to full-text screening, which was carried out using the same blinded dual-reviewer procedure. After both the abstract and full-text stages, any conflicts between reviewers were resolved through discussion until consensus was reached. Reviewers had an academic and professional background in psychology.

Data Extraction

Overview

The primary aim of the extraction process was to capture the methodological characteristics of smartphone-based stress measurement. Data extraction was first piloted on a subset of 10 studies by 1 reviewer, after which the variables to be extracted were discussed with a second reviewer and refined accordingly. After finalizing the extraction approach, 1 reviewer extracted data from all included studies, after which a second independent reviewer checked the dataset. Any discrepancies or irregularities identified during this check were resolved through discussion.

Study Characteristics

To describe the characteristics of studies on smartphone-based self-assessment of stress, several variables were extracted. The main variables were (1) study population (eg, university students or employees), (2) assessment context (eg, daily life or workplace), and (3) study duration. Studies were required to report these variables to be eligible for inclusion. Additional variables that were extracted but were less essential were (1) study location, (2) study design (eg, observational cohort or interventional), and (3) number of participants. Participant age was also extracted but not retained in the final quantitative summary because of inconsistencies in reporting formats across studies.

Characteristics of Stress Self-Assessment Methods

To characterize the measurement characteristics of smartphone-based self-assessment of stress, several variables were extracted. The main variables were (1) the number of items measuring stress, (2) the stress items, (3) the method for self-assessment (eg, Likert scale or binary yes-or-no response), (4) the number of times per day that stress was measured, and (5) mobile modality and prompting method (eg, measurement via text message or app notification). Studies were required to report these variables to be eligible for inclusion. An additional variable extracted was the smartphone operating system.

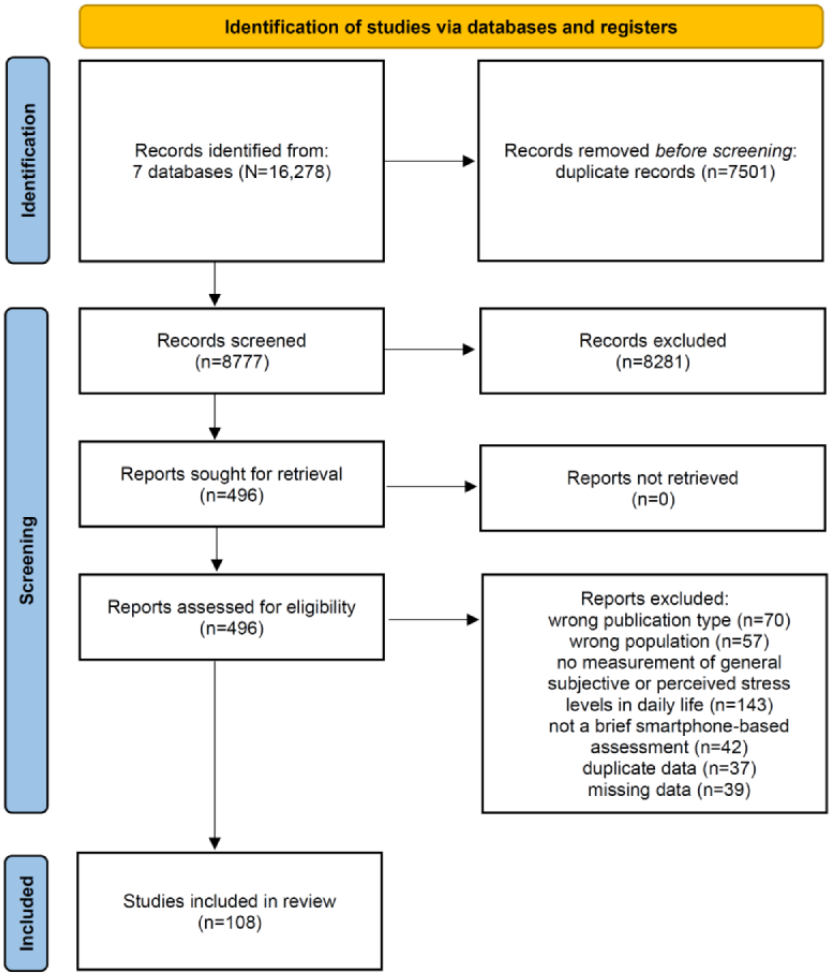
Evidence on Validity and Reliability

For each included study, we documented whether evidence regarding the validity or reliability of the stress measure was reported. When available, information was extracted on the type of evidence provided, the procedures used to establish validity or reliability, and any reported psychometric indexes.

Analysis Plan

The extracted data were summarized using descriptive statistics to provide an overview of study characteristics and characteristics of smartphone-based self-assessment methods. In line with scoping review methodology, neither a formal quality assessment nor a meta-analysis was undertaken. The evidence on validity and reliability was not formally appraised but instead synthesized narratively, due to the exploratory nature of the review and the limited reporting of psychometric properties. Given the wide range of reporting practices, from no evidence to a comprehensive psychometric evaluation, it was not feasible to quantify validity and reliability evidence systematically. Therefore, we provide a narrative overview of the strategies used to establish validity and reliability in the included studies and highlight illustrative examples.

All data processing and analysis were conducted using R (version 4.3.0; R Foundation for Statistical Computing) [37], along with the packages *readxl* [38], *writexl* [39], *officer* [40], and *flextable* [41]. To enhance comparability across studies, some variables were harmonized by reducing the level of detail when appropriate, such as by binning numeric variables into categories. Study duration was converted to an estimated number of days when reported in alternative units (eg, week, month, and year), using standard conversions (7, 30, and 365 days).



Results

Overview

After deduplication, 8777 records were screened. Of these, 496 progressed to full-text review, and 108 studies met all eligibility criteria and were included in the final synthesis. A PRISMA flow diagram of the screening and selection process is presented in Figure 1. The data table presenting all included studies can be found in Table S1 in Multimedia Appendix 2 [28,29,42-147]. The same table is included in Excel format with sorting and filtering functionalities in Multimedia Appendix 3 [28,29,42-147], to aid the closer investigation of individual studies.

XSL•FO
RenderX

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) diagram presenting the flow of the screening and selection process.

Study Characteristics

The 108 included studies were published between 2016 and mid-2024, with yearly publication counts of 5 (2016), 5 (2017), 2 (2018), 11 (2019), 13 (2020), 21 (2021), 17 (2022), 25 (2023), and 9 (2024). Most studies appeared in peer-reviewed journals (105/108, 97%), with a small number from conference proceedings (3/108, 3%). Geographically, the research was conducted primarily in North America (n=53) and Europe (n=38), followed by Asia (n=8), Oceania (n=3), the Middle East (n=1), South America (n=1), and multiregional studies (n=4).

Regarding study design, most publications used an observational cohort design (87/108, 81%), including longitudinal and EMA-based approaches, as well as studies that analyzed only one arm or group of an intervention. Other studies focused specifically on data collection for the development or training of machine learning models (n=7). Interventional studies were less common and included randomized (n=8), nonrandomized (n=1), and within-subject designs (n=3). Finally, 2 publications used a (multiple) n-of-1 methodology.

Although all studies involved healthy adults in daily life, the samples varied: 37 studies recruited university students, and 19 focused on working adults (of which 16 also investigated stress in the workplace). Others targeted specific subgroups, such as parents (n=8), older adults (n=2), romantic couples (n=2), or specialized populations (n=9), including pregnant women, smokers, drinkers, diet-interested individuals, meditators, and Native Americans residing on a reservation. Finally, 11 studies explicitly mentioned the COVID-19 pandemic as a context. Sample sizes varied widely, ranging from 1 to 21,923 participants, with a median value of 97 (IQR 50.25-182.50). Study duration (ie, the duration of smartphone-based stress assessment) ranged from 1 to 365 days with a median value of 14 (IQR 7-21.5).

Characteristics of Stress Self-Assessment Methods

Across all 108 studies, 114 instruments measuring perceived stress were identified. A total of 6 studies used 2 different instruments within the same protocol (eg, daily single-item EMA plus a weekly short scale). Most instruments (84/114, 74%) relied on a single-item measure. A total of 23 instruments used short scales of 2 to 4 items, and 7 used scales of 5 items or more. Note that only items specifically measuring stress were counted; often, other constructs were measured alongside stress.

The phrasing of the items (ie, the questions for the self-assessment) was grouped into 3 categories: (1) 60 out of 114 instruments measured stress in a momentary manner (eg,

XSL•FO
RenderX

"How stressed do you feel right now?" or "At the moment, I feel stressed"), (2) 30 instruments relied on a period-based assessment (eg, "How stressful has your day been so far?" or "How stressed were you in the last 30 minutes?"), and (3) 17 instruments relied on an appraisal-based approach in the style of typical stress questionnaires (eg, "I feel that I cannot cope with the things I have to do" or "I am on top of things"). Seven instruments combined multiple of these approaches within a single scale. Regarding the response format, Likert scales (75/114, 66%) and visual analog scales (VAS; 33/114, 29%) were most common. Less frequently used formats included pictorial scales (n=2) and binary yes-or-no responses, either alone (n=1) or combined with a Likert scale or a VAS (n=3).

Across the 108 included studies, measurement frequency varied. Most studies used an intensive approach of 3 or more measurements or a variable number of measurements each day (73/108, 68%), which is typical of EMA methodology. A considerable number of studies measured stress once (n=25) or twice (n=5) per day. Finally, 5 studies used a nonintensive approach of fewer than 1 measurement per day (eg, once per week).

Most studies (83/108, 77%) administered stress assessments using a mobile app with push notifications. Another 22 studies used SMS or messaging apps to deliver survey links to an online platform (eg, Qualtrics), sometimes automated using services such as SurveySignal. One study used the smartphone timer app as a reminder, and 2 studies delivered and received assessment items directly via text message. This made it technically possible to include participants with older cell phones instead of smartphones. Some studies specified whether they supported Android (Google) devices (n=27), iOS (Apple) devices (n=2), or both (n=23).

Evidence on Validity and Reliability

Overall, relatively few studies reported robust evidence on the validity or reliability of their smartphone-based stress measures. The available evidence ranged from indirect indications of validity, through correlational assessments with external measures, to more formal psychometric evaluations.

Several studies used items adapted from existing stress questionnaires, providing indirect evidence of validity insofar as the original instruments had undergone prior validation. Most commonly, researchers adapted items from the PSS [12] (eg, [28,42-52]). Other studies drew on items from the DASS [13] (eg, [53]), the Positive and Negative Affect Schedule (PANAS) [148] (eg, [52,54]), the Psychological Stress Measure-9 (PSM-9) [149] (eg, [55,56]), or the Stress and Coping Inventory (SCI) [150] (eg, [57]). Several studies also adopted a single-item stress question developed by the American Psychological Association (APA) [151] (eg, [58,59]). However, none of these instruments were originally designed or validated to capture momentary stress. Consequently, researchers modified the time frames and, in some cases, the response formats, to approximate momentary assessment, possibly raising questions about the validity of these adapted measures for real-time stress evaluation.

A subset of studies provided evidence for convergent, criterion, or discriminant validity, typically by correlating momentary stress ratings with established questionnaires or physiological markers. This is an important step toward establishing the validity of the measurement approach. For example, Gidlow et al [60], Feneberg et al [61], and Jones et al [62] reported significant associations with the PSS, and daSilva et al [63] found similar results for their pictorial stress scale. Other instruments that were used included the PSM-9 (eg, [64]), the Achenbach Adult Self-Report (ASR) [152] (eg, [65]), and the Subcomponents of Affect Scale (SAS) [153] (eg, [66]). Þórarinsdóttir et al [67], in a study explicitly designed to assess validity, reported correlations between smartphone-based stress assessments and the PSS, Eysenck Personality Questionnaire Neuroticism (EPQ-N) [154], and the Functioning Assessment Short Test (FAST) [155]. Other studies similarly used a battery of affective or stress-related instruments (eg, [28,29,68-72]).

Studies examining associations between smartphone-based stress measures and physiological indicators produced mixed findings. For example, Gidlow et al [60] and Feneberg et al [61] did not observe significant associations with hair cortisol. Giessing et al [73] similarly reported no associations with salivary cortisol or α-amylase. In contrast, Martinez et al [74] found a small but significant association between self-reported stress and HRV, and de Vries et al [75] reported comparable findings for some participants in a multiple n-of-1 study. Gordon and Mendes [76] also found some evidence of an association with heart rate and blood pressure reactivity.

Finally, a small number of studies conducted psychometric evaluations. At the basic level, this included estimating indexes of internal consistency or reliability. For multi-item measures, reliability was estimated using Cronbach α (eg, [56]) or multilevel McDonald ω to estimate between- and within-person reliability (eg, [43,51]). Within-person reliability was also estimated using variance decomposition techniques (eg, [52]). For single-item measures, researchers sometimes calculated intraclass correlations (ICCs) to quantify the proportion of variance attributable to between-person (as opposed to within-person) differences (eg, [72,77,78]). Lower between-person ICC values suggest that moment-to-moment, within-person changes account for most of the variability, which might be preferable in EMA studies aiming to capture momentary variations in stress.

At the most advanced level, a small number of studies performed comprehensive factor-analytic assessments to examine the underlying structure of the measurement instrument. Murray et al [28] validated an EMA-adapted version of the PSS (PSS-EMA), demonstrating reliability at both within- and between-person levels and confirming the scale's factorial structure using multilevel confirmatory factor analysis. They further established convergent and criterion validity through associations with related constructs, such as stress, anxiety, depression, and negative affect. Vikoler et al [29] validated the Di-Eu-Stress State (DESS) scale, a dedicated EMA measure designed to capture both stress (distress) and eustress. Their evaluation likewise included establishing within- and between-person reliability, multilevel confirmatory factor analysis, and associations with a range of constructs, such as stress, anxiety, depressiveness, and affect.

Discussion

Main Findings

This scoping review systematically mapped 108 studies that used smartphone-based methods to assess self-reported perceived stress in healthy adults during daily life. Findings are consistent with the observations made in the earlier review by Þórarinsdóttir et al [20], particularly regarding the heterogeneity of measurement strategies, scale types, number of items, and sampling frequency. In recent years, however, both the quantity and scope of research have expanded considerably. The present review identified 108 studies, compared with the previous set of 35 studies. Most studies used observational designs with EMA-style prompting schedules, often involving 3 or more assessments per day. Across studies, stress was predominantly measured using very brief instruments, with 74% (84/114) relying on single-item measures and most using Likert scales or VAS. Single-item measures have also proven dominant in EMA research in other domains such as pain, momentary depression, and happiness [19,156-158]

Despite the widespread use of these approaches, evidence on validity and reliability was still relatively limited. Some studies adapted items from established stress or affect scales, such as the PSS or PANAS, or reported correlations with validated stress measures and related constructs. Some studies examined reliability or ICC, and the present review did retrieve a small number of recent studies on validated EMA measures, including multilevel psychometric evaluations, such as PSS-EMA [28] and a newly developed EMA stress scale [29]. These efforts signal an emerging methodological maturation, although comprehensive validation remains the exception rather than the norm.

Implications for Selecting and Evaluating Instruments

Based on the present scoping review and existing guidelines on self-assessments in daily life, several pragmatic recommendations can be made for researchers who are entering the field and selecting or developing smartphone-based stress instruments.

First, several recommendations have been proposed for EMA research in general and apply to EMA stress research as well. These include alignment between the measurement approach and the research question [159]. Specific study aims will be paramount in guiding protocol development, including timing and sampling schemes for EMA research, such as event-contingent, time-contingent, or hybrid designs [159]. When applied to the stress field, momentary items (eg, “right now”) might be preferable for capturing rapid stress fluctuations or responses to specific events, as required in high-resolution EMA designs. Period-based items (eg, “in the last 30 minutes” or “today”; also referred to as a coverage model of EMA) may be appropriate for studies focusing on larger time frames but might introduce greater recall demands or bias [160]. Appraisal-based items (eg, “I feel like I cannot cope with the things I have to do”) can strictly speaking be either momentary or period based and are mainly characterized by their alignment with traditional appraisal-based questionnaires such as the PSS, often assessing multiple dimensions of stress. App-based data collection with either a custom-developed mobile app or a readily available app, preferably on both Android and iOS, provides optimal flexibility [19].

Second, in addition to study alignment, measurement properties are relevant to consider. Single-item instruments reduce burden and facilitate intensive sampling but may limit psychometric precision. Researchers should prioritize instruments with demonstrated psychometric quality or include convergent measures (standardized stress questionnaires and affective scales) to evaluate measurement validity in their sample. The current review has shown that some single-item measures do provide satisfactory correlations with extended instruments. In addition, reliable multi-item EMA instruments were identified, such as the PSS-EMA [28] or the DESS scale [29]. When aligned with the research design, such instruments may be preferable. When appropriate, physiological indicators such as HRV (eg, measured using a wearable) can also offer complementary information to enrich the dataset with data measured at a different temporal resolution [19,21,159]. Mobile apps can enable integration with smartphone sensors and wearables but may require technical expertise, impose operating system constraints, and increase participant onboarding demands. SMS- or messaging app–based assessments enhance inclusivity, especially for participants using older devices, but offer less flexibility and integration with contextual data.

Opportunities for Improving the EMA Tradition in Stress Research

More training on the design and implementation of EMA approaches is warranted. When assessing studies, not all methodological choices appear carefully considered or prepared. Within and outside the field of stress research, many EMA measures have used novel questions without substantial prior psychometric evaluation, which implies potential problems in terms of replication and validity of the findings [156,159,160]. In addition to training on the approach itself, providing device training has been recommended to assess comprehension and promote adoption [156,160]. In line with this, transparent reporting of implementation choices supports reproducibility and informs future study design and interpretation of findings. Several reporting checklists have already been developed in related fields but could be applied to daily-life stress monitoring [19,161-163].

Because reliability is sample dependent, documenting reliability coefficients is relevant [160]. Reliability can be quantified through Cronbach α or multilevel McDonald ω for multi-item scales. The amount of variance attributed to within- and between-person differences can be quantified using ICC for single-item measures. Factor-analytic approaches provide even stronger evidence of construct validity. Alternative approaches that have been proposed to support item validity are real-time cognitive interviewing, planned missingness designs, and tests of context-dependent differential item functioning and item parameter drift [160].

Progress can also be made by further integrating smartphone-based self-report methods with physiological, behavioral, and contextual data. There is evidence for the complementary relevance of stress physiology, although

XSL•FO
RenderX

temporal resolution is key and daily-life monitoring is challenging [8]. Wearable devices increasingly enable continuous monitoring of physiological parameters, and combining these multimodal data streams with EMA-based stress ratings offers opportunities for digital phenotyping and machine learning–based stress detection [164]. However, the validity of prediction models depends fundamentally on the quality of the EMA stress measures used as ground truth, underscoring the need for robust psychometric evaluation.

Limitations and Future Directions

Several limitations must be acknowledged. First, this review focused on general perceived stress in healthy adults, excluding large bodies of work on domain-specific stress (eg, trauma-related stress [165] or caregiver stress [166]), as well as studies involving clinical populations, minors, or unhealthy housing conditions. The review by Yang et al [23] supported the feasibility of stress monitoring in an adult patient sample but noted challenges related to the complexity of EMA data and completion rates. The approaches documented in the current review are nevertheless relevant to the broader domain of smartphone-based stress assessment and may provide additional insights into existing methodology. Second, due to the methodological diversity of included studies, we did not conduct a formal risk of bias assessment or quantitative synthesis of validity evidence. Although frameworks such as the Patient-Reported Outcomes Measurement Information System (PROMIS) [167] could facilitate structured comparisons of psychometric quality, their application requires a narrower, more homogeneous subset of studies. Another methodological limitation is that no interrater reliability coefficient was calculated during the screening of studies. Third, because of the high number of publications and to facilitate comparison, studies with missing data on key methodological variables (eg, stress item phrasing or measurement frequency) were excluded. Although this improved the interpretability of the descriptive synthesis, it may have introduced selection bias if reporting completeness was related to certain study characteristics. Finally, many studies in this review recruited university students or white-collar workers in high-income countries. Future work should include broader demographic and cultural contexts to enhance generalizability.

Conclusions

Smartphone-based self-assessment of perceived stress in daily life has become widespread, with notable growth over the past decade. The field of research is characterized by substantial study heterogeneity, with the use of single-item EMA measures and intensive sampling schedules nevertheless being most common. Some studies provide promising evidence for the validity and reliability of smartphone-based stress instruments, and a small number conduct rigorous multilevel psychometric evaluations. Nevertheless, comprehensive validation remains relatively rare.

Together, these findings indicate that smartphone-based stress assessment has become widely used, but studies are methodologically diverse and often rely on instruments whose psychometric properties have not been adequately established. Researchers should carefully align instrument selection with their study objectives and, whenever possible, prioritize measures with demonstrated validity and reliability or report psychometric indicators such as ICCs or multilevel reliability estimates. By synthesizing existing methods and the available validity and reliability evidence, this review supports more informed instrument selection and the development of robust, evidence-based strategies for mobile stress assessment. Future work would benefit from more systematic psychometric evaluation and transparent reporting of measurement characteristics to strengthen comparability across studies.

Funding

This study received internal funding from KU Leuven through the StressTRACS research project (C3/23/043). The funder had no involvement in the study design, data analysis, interpretation of findings, or preparation of the manuscript.

Data Availability

The dataset generated and analyzed in this scoping review is available in Multimedia Appendices 2 and 3.

Generative AI Use

The authors declare the use of generative AI in the research and writing process. In line with the Generative AI Delegation Taxonomy [168], the following tasks were delegated to generative AI tools under full human supervision: proofreading and editing (ie, improving sentence construction in sections). The generative AI tool used was Copilot GPT-5.2 (Microsoft). Responsibility for the final manuscript lies entirely with the authors. Generative AI tools are not listed as authors and do not bear responsibility for the final outcomes.

Abstract

Background: Anxiety and mood disorders, characterized by elevated negative affect (NA) and cognitive impairments, are highly prevalent among college students. Within-person (WP) NA variability, which captures moment-to-moment fluctuations in NA, provides unique insights into emotional processes that are not reflected in mean NA levels. Cognitive variability, particularly reaction time (RT) inconsistency, is increasingly recognized as a sensitive marker of cognitive health and functional integrity. Although prior research links NA to cognitive variability, the short-term dynamics of these associations in naturalistic settings remain understudied. College students provide an ideal population for examining these dynamics using ecological momentary assessment (EMA).

Objective: This study investigated the association between WP NA and RT inconsistency, hypothesizing that higher WP fluctuations in NA would predict increased RT inconsistency. We also examined the moderating roles of practice effects and covariates, including neuroticism, insomnia, and sex.

Methods: Using EMA, 99 university students completed morning and evening assessments over 14 days, including a cognitive task measuring RT inconsistency (standard deviation in trial-level RT) and self-reported NA. Multilevel modeling was used to assess WP fluctuations in NA and their impact on RT inconsistency, accounting for time (session number), between-person differences in NA, and covariates such as sleep problems, neuroticism, age, sex, and use of a touch device.

Results: WP fluctuations in NA significantly predicted increased RT inconsistency (exp(β)=1.022, 95% CI 1.008 - 1.037; *P*=.007), supporting the hypothesis that NA variability disrupts cognitive performance. Male students exhibited lower RT inconsistency than female students, with a small effect size (exp(β)=0.824, 95% CI 0.694 - 0.977; *P*=.049). Finally, EMA sessions were inversely associated with RT inconsistency, with a stronger effect up to session 3 (exp(β)=0.930, 95% CI 0.879 - 0.985; *P*=.03) than after session 3 (exp(β)=0.986, 95% CI=0.979 - 0.992; *P*<.001), indicating practice effects.

Conclusions: Momentary fluctuations in NA influence cognitive variability, particularly in the early stages of repeated cognitive tasks, underscoring the role of emotional processes in cognitive performance. Practice effects and individual differences, such as sex and insomnia, influence these associations. These findings highlight the use of EMA for understanding cognitive-affective processes and suggest potential intervention targets, such as addressing NA, to improve cognitive functioning in emotionally vulnerable populations like college students.

KEYWORDS

ecological momentary assessment; negative affect; cognition; emotions; questionnaire; neuroticism; anxiety; depression; insomnia; stress

Introduction

Anxiety and mood disorders, also known as emotional disorders, are the most common mental disorders and leading contributors to the global burden of disability [1,2]. Emotional disorders are often chronic and highly comorbid due to their shared features, including a high level of negative affect (NA) and strong reactivity to NA, also known as neuroticism [3]. Elevated NA is typically accompanied by both affective dysregulation and other cognitive impairments such as lower executive functioning, reduced attention capacity and processing speed, and impaired short-term memory, all of which are associated

XSL•FO
RenderX

with the severity of emotional disorders and the likelihood of relapse [4,5]. NA has been extensively linked to emotional disorders, yet its momentary fluctuations and their cognitive implications remain underexplored. This study bridges this gap by using ecological momentary assessment (EMA) to examine the real-time interplay between NA and cognitive variability.

Recent research using EMA has examined within-person (WP) variation in NA. Broadly, this body of work demonstrates that dynamic fluctuations in NA are associated with increased psychiatric symptoms [6-9]. Emotional inertia, or the tendency for emotional states to persist over time, represents another critical dimension of affective dynamics [10]. Prolonged negative emotional states may indicate difficulties in emotional recovery, contrasting with high emotional instability, which reflects rapid fluctuations in affect. Both extremes of these dynamics are linked to the risk of mood disorders [11]. EMA allows researchers to measure both affect inertia and affect fluctuations in real-time, offering a nuanced perspective on these emotional processes and their cognitive implications. This study focuses on momentary WP fluctuations in NA, which have been consistently linked to psychiatric symptoms. In prior EMA research, in a study of 40 individuals with depression and 40 healthy controls, participants with depression exhibited more variable NA [8]. In another EMA study (N=365), participants with a current depression and/or anxiety disorder had higher NA fluctuations, suggesting sensitivity to internal and external sources of stress coupled with poor emotion regulation skills [11]. Based on a meta-analysis of 79 studies on emotion dynamics and psychological well-being, low psychological well-being tends to occur when there are more variable and unstable emotions, especially negative emotions [7].

NA is consistently linked to cognition, but the mechanisms accounting for these relationships remain undercharacterized and poorly understood [12]. One theory is that the associations between NA and cognitive ability may reflect the underlying integrity of the nervous system and the efficiency of information processing [12]. Efficient information processing refers to the ability to quickly and accurately process stimuli and integrate them with appropriate responses. Furthermore, efficient information processing could explain why better cognitive ability is related to better physical and mental health [12]. However, the naturalistic, short-term (eg, day-to-day) time course of WP associations between NA and cognition remains unclear. This study integrates Barlow et al's [3] framework on neuroticism and affective variability and Jokela's [12] theory on neural efficiency to establish a unified understanding of how fluctuations in NA influence cognitive performance. Reaction time (RT) inconsistency serves as a sensitive indicator of these cognitive-affective dynamics, reflecting momentary fluctuations in attention and processing speed. By using EMA, we aim to elucidate the real-world implications of these theoretical constructs.

WP variation in cognition has been discussed in the literature in several ways, including (1) variability across tasks measured at a single time point, known as dispersion; (2) variability across trials within a single task, known as inconsistency; and (3) variability over time across repeated task administrations, referred to as fluctuations [13]. Cognitive dispersion and inconsistency have been shown to increase with age and may serve as important indicators of cognitive functioning across the lifespan [14-16]. In comparison to the number of studies on variation in cognition in older adults, much less is known about physical and mental health-related correlates of WP variation in cognition in emerging adults. Our study targets WP variation in cognition in college-age students using RT-based measurement, specifically, standard deviation in trial-level RTs. Standard deviation in RT, which we refer to as "RT inconsistency," is increasingly accruing evidence as an indicator of cognitive health, which also includes domains of executive functioning, attention, and memory [17]. RT inconsistency has potential for furthering our understanding of dynamic processes in health, cognition, and affect [18,19]. As a WP metric that can be readily assessed using EMA, RT inconsistency may yield novel insights in emerging adults who are experiencing stress and NA in their daily lives. Moreover, RT inconsistency, rather than mean RT, can represent a dimension of cognitive performance that is a dispositional characteristic reflecting underlying changes in psychological processes or neurological functioning [19]. However, while RT inconsistency is a valuable indicator of cognitive health, it is also important to study other factors, such as sleep, fatigue, and other learned behaviors. Our study controls for baseline insomnia and neuroticism in assessing the dynamic relationship between RT inconsistency and NA variability.

College students face significant academic, social, and personal stressors, including high levels of academic pressure, the transition to independent living, and the challenge of navigating new social environments [20]. These stressors contribute to emotional dysregulation, particularly fluctuations in NA, which can impair cognitive functioning such as attention and memory [21]. Furthermore, college students are a population with high rates of emotional disorders and treatment-seeking behaviors [20], making them an ideal group for studying the dynamic interplay between NA and cognition. These developmental transitions, along with the increased prevalence of anxiety and mood disorders, underscore the importance of understanding how fluctuations in affect influence cognitive performance during this critical period of young adulthood [22]. In a study of older and young adults who reported on daily stress and completed daily tasks of cognitive performance, WP variability in stress predicted cognitive fluctuations, evidenced by WP RT variability on a 2-back working memory task in both groups [23]. This is consistent with the attention-depletion hypothesis, which posits that stress-related cognitive interference disrupts attentional resources, weakening attention-dependent cognitive processing [23,24].

While the impact of stress on college students, the impact of NA on higher-level cognition [25,26], and the associations among stress, NA, and cognition in individuals with emotional disorders (see review by Pechtel and Pizzagalli [27]) have been well-established, there remains a surprising lack of published research using EMA to understand dynamic, short-term, WP connections among these factors. A better understanding of the mechanisms that connect momentary changes in affect and momentary changes in cognition is now possible through EMA. Specifically, a better understanding of RT inconsistency and its

XSL•FO
RenderX

relationship with NA may advance our understanding of psychological functioning and cognitive health [13,17]. Understanding the relationships between cognition, NA, and emotional disorder symptoms in college-age students and emerging adults could aid in providing targeted directions for treatments of individuals vulnerable to stress, NA, and disrupted cognitive performance.

In summary, symptoms of emotional distress are associated with elevated NA [3,28], greater NA variability and instability [29-31], and poorer cognitive performance [32]. However, NA and cognition are not typically measured together in high-frequency study designs, which obscures insights into the momentary effects of NA on cognition. This study addressed this gap by examining WP associations between NA and RT inconsistency in university students. Participants completed daily EMAs measuring NA and cognition. For each EMA, RT inconsistency was operationalized as the standard deviation in trial-level RTs [15,33,34]. RT inconsistency was chosen as the primary measure due to its sensitivity to moment-to-moment fluctuations in cognitive processing. Compared to other measures, such as working memory or attention switching, RT inconsistency captures variability in attentional control and neural efficiency [12], making it particularly relevant for studying the cognitive impact of NA.

Using a 14-day EMA design, we examined WP associations between NA and RT inconsistency in 99 university students. We hypothesized that momentary WP increases in NA would be associated with greater RT inconsistency at subsequent assessments. As a secondary hypothesis, we examined whether individual differences in sex, neuroticism, and insomnia severity were associated with RT inconsistency. Examining these processes in daily life may clarify mechanisms linking emotional distress to functional impairment.

Methods

Participants

Participants were sampled from (1) a psychology student subject pool at a large Midwestern university (n=78) and (2) a paid study in which individuals were recruited through university online classified advertisements and flyers posted around campus (n=72). Inclusion criteria included being a university student aged 18 years or older with an email address, access to the internet, and a device to complete study assessments. Exclusion criteria included individuals younger than 18 years.

Ethical Considerations

This study was reviewed and approved by the Indiana University Institutional Review Board as human subjects research (protocol numbers 2011722518 and 12537). All study procedures complied with institutional and federal guidelines for the ethical conduct of research involving human participants. Informed consent was obtained electronically from all participants prior to study enrollment. Participants were informed that participation was voluntary and that they could withdraw from the study at any time without penalty. Informed consent covered both the baseline assessment and the subsequent 14-day EMA protocol. To protect the privacy and confidentiality of participants, all data were deidentified. Identifying data (email addresses used for study communication) were stored separately from survey and cognitive task data on secure servers accessible only to the research team via 2-factor authentication. Participants recruited through the psychology subject pool received course credit for participation. Participants recruited through paid advertisements were compensated up to US $60 for completing at least 75% (18/24) of EMA assessments. No additional incentives were provided.

Procedure

The 14-day EMA protocol was chosen to capture meaningful WP variability while maintaining participant retention, as longer durations may lead to increased dropout rates and data loss [35]. The frequency of daily assessments (2 - 13 d) was selected to balance participant burden with the need to capture fluctuations in NA and cognitive performance. This schedule ensures adequate data collection while minimizing participant fatigue, which could compromise the quality of responses. The morning and evening sessions are consistent with prior EMA studies [23], and they allow us to assess affective and cognitive fluctuations at multiple time points.

Participants completed all study assessments on their personal devices. They were prompted to complete EMAs twice daily via email. We assessed for technical issues after each EMA and explored device compatibility in our prior work [36]. All assessments for the study were completed via Qualtrics and TestMyBrain.org. TestMyBrain.org is a citizen science research initiative that allows people to participate in studies in exchange for individualized feedback on their performance or self-reported characteristics [36-38]. Data from TestMyBrain.org have been shown to be of similar high quality to data gathered in a laboratory setting [37]. On day 1 (baseline), participants were emailed at 7 AM to complete their baseline assessment battery, and they were sent a reminder email at 5 PM to complete their day 1 battery by midnight. They were advised to complete the assessment battery when they had approximately 45 minutes of uninterrupted time, specifically, “in 1 sitting, without distraction.” On the following days, participants received daily links to their email addresses to complete study assessments in the morning and evening each day. Morning study reminders were sent at 7 AM and evening study reminders were sent at 4 PM. Participants were reminded to complete EMAs on days 2 to 13 when they had 5 minutes of uninterrupted time. On day 14 (termination), participants were sent links to complete their assessment battery at 7 AM, with a reminder at 5 PM to complete the assessments before midnight. They were advised to complete the battery when they had approximately 35 minutes of uninterrupted time. When participants missed more than 2 days in a row of tests, they were reminded by email to complete as many assessments as possible. Participants were compensated, either by course credit or electronic gift cards, approximately 2 days following the study termination.

Measures

This study is part of a larger study measuring cognition and emotions over time. Relevant assessments for this study are included in Textbox 1.

Textbox 1. Schedule of ecological momentary assessments.

Ecological momentary assessment days 1 - 14

- Day 1 (baseline)
  - Demographic questionnaire
  - Depression, Anxiety, and Stress (DASS)
  - Generalized Anxiety Disorder-7 (GAD-7)
  - Positive and Negative Affect Schedule—Short Form (PANAS-SF)
  - Multidimensional Emotional Disorder Inventory (MEDI)
  - Insomnia Severity Index (ISI)
  - Choice Reaction Time (Choice RT)
- Days 2 - 13
  - Morning (7 AM-12 PM)
    - PANAS-SF
    - Choice RT
  - Evening (4 PM-12 AM)
    - PANAS-SF
- Day 14
  - DASS
  - GAD-7
  - PANAS-SF
  - MEDI
  - Choice RT

Positive Affect and Negative Affect Schedule—Short Form (PANAS-SF)

The PANAS-SF is a widely used and extensively validated 20-item self-report scale assessing positive affect (PA) and NA [39]. Items are rated on a 5-point Likert scale ranging from 1 ("Very slightly or not at all") to 5 ("Extremely"), yielding scores from 10 to 50 for PA and 10 to 50 for NA. Higher scores indicate higher levels of affect for both subscales. The PANAS sampling schedule is described in Table 1. On day 1, participants were instructed to complete the PANAS based on how they felt in the past week. On days 2 to 14, participants were instructed to complete the PANAS based on how they felt at the time of EMA (ie, "right now"). In our sample, internal consistency was acceptable (Cronbach α=0.75).

RenderX

Table . Sample characteristics of participants who completed any ecological momentary assessments after baseline (day 1).

Variable	More than 50% (n=99)	Less than 50% (n=17)	*P* value[a]
Sample, n (%)			.10
Student	37 (37)	10 (59)	
Paid	62 (63)	7 (41)	
Age (y), mean (SD; range)	22.9 (7; 18.0-56.0)	21.9 (7.3; 18.0-47.0)	.07
Sex, n (%)	74 (75)	9 (53)	.08
Neuroticism[b], mean (SD; range)	16 (8; 1-33)	15 (9; 0-29)	.6
DASS-Depression[c], mean (SD; range)	9 (9; 0-38)	10 (11; 0-40)	.9
DASS-Anxiety[d], mean (SD; range)	8 (7; 0-38)	6 (8; 0-30)	.2
GAD-7[e] total, mean (SD; range)	6.2 (4.9; 0.0-21.0)	5.5 (4.7; 0.0-19.0)	.6

[a]Pearson chi-square test, Wilcoxon rank-sum test, and Fisher exact test.

[b]Multidimensional Emotional Disorder Inventory Neuroticism scale.

[c]DASS-Depression: Depression Anxiety and Stress Scale—Depression subscale.

[d]DASS-Anxiety: Depression Anxiety and Stress Scale—Anxiety subscale.

[e]GAD-7: Generalized Anxiety Disorder-7.

Insomnia Severity Index

The Insomnia Severity Index is a 7-item self-report scale validated for measuring the insomnia symptom severity over the previous 2 weeks [40-42]. Items are rated on a 5-point Likert scale ranging from 0 (“none”) to 4 (“very severe”), yielding total scores of 0 to 28. Total scores are interpreted such that 0 to 7 indicates the absence of insomnia, 8 to 14 indicates subthreshold insomnia, 15 to 21 indicates moderate insomnia, and 22 to 28 indicates severe insomnia. In the sample, internal consistency was good (Cronbach α=0.88).

Depression Anxiety and Stress Scales

The Depression Anxiety and Stress Scales (DASS) is a 21-item measure rated on a 4-point Likert scale from 0 (“does not apply to me at all”) to 3 (“applied to me very much, or most of the time”) [43]. It assesses levels of depression, generalized anxiety, and general NA or stress. Based on factor analytic work, the DASS demonstrates excellent psychometric properties [42,43]. In our sample, internal consistency was good (Cronbach α=0.89).

Multidimensional Emotional Disorder Inventory

The Multidimensional Emotional Disorder Inventory (MEDI) assesses transdiagnostic dimensions of emotional disorder psychopathology [44]. It consists of 49 items that are rated on a 9-point Likert scale from 0 (“Not characteristic of me/does not apply to me”) to 8 (“Extremely characteristic of me/applies to me very much”). The initial validation of the MEDI used factor analysis to determine the factor structure of 9 empirically supported transdiagnostic dimensions proposed by Rosellini and Brown [44]. These 9 dimensions include neurotic temperament, positive temperament, depression, autonomic arousal, somatic anxiety, social anxiety, intrusive cognitions, traumatic re-experiencing, and avoidance. The MEDI showed strong evidence of reliability and validity in its initial psychometric evaluation in clinical and outpatient samples [43]. We used the MEDI neuroticism subscale as our measure of neuroticism, with higher scores indicating a higher degree of neuroticism. In our sample, internal consistency was excellent (Cronbach α=0.94).

TestMyBrain Choice RT

TestMyBrain choice RT measures psychomotor response speed, response selection, and cognitive inhibition [45,46]. It was adapted for brief digital administration from Maljkovic and Nakayama [47] and demonstrates high between-person (BP) and WP reliability in EMA [48]. Each administration lasted approximately 2.5 minutes and included 4 practice trials followed by 24 task trials. On each trial, participants are presented with 3 vertically aligned squares (blue or yellow) containing an arrow pointing either left or right. One of the 3 squares is always of a different color from the other 2, and participants are asked to choose the direction of the arrow in the differently colored square as quickly as possible by clicking or tapping their touchscreen. Participants had 5000 ms to respond to each trial, with an intertrial interval of 700 to 1500 ms. RT inconsistency was computed for each EMA as the standard deviation of trial-level RTs.

Data Cleaning

EMA data cleaning aimed to maximize the signal-to-noise ratio by excluding data that were strongly suggestive of careless responding. From our full sample of 150 individuals, we first excluded participants who failed to complete EMAs after the baseline assessment (day 1). The remaining sample included 116 participants. Second, we excluded participants who failed to complete the morning EMA, including both choice RT and PANAS, in at least 50% (7/14) of assessments. Finally, we excluded EMA data when choice RT accuracy was less than 50% (ie, chance).

XSL•FO
RenderX

Missing data primarily arose from missed EMA assessments. Rather than imputing missing values, we used listwise deletion at the observation level within mixed-effects models, such that only available observations contributed to each model. In this study, missingness reflected missed EMA prompts rather than partially completed surveys, meaning that entire measurement occasions were absent rather than individual items within completed assessments. For this reason, we prioritized analyzing observed EMA data using mixed-effects models rather than imputing unobserved moments. Sensitivity analyses comparing models applying stricter data-cleaning criteria showed consistent results, suggesting minimal bias introduced by this criterion. After these cleaning procedures, 99 participants were included in the analyses.

Data Analyses

Prior to analysis, we conducted a power analysis to evaluate the sample size needed to detect WP associations between NA and RT inconsistency in multilevel models. Based on prior similar EMA studies, we anticipated effects in the small-to-moderate to moderate range [7,23]. Assuming a medium effect size (f^2=0.15), a 2-sided significance α level of .05, and a desired power of 0.80, a sample of approximately 80 to 90 participants with repeated observations was estimated to be sufficient to detect the primary WP effect. The final analytic sample included 99 participants contributing 1177 EMA observations, which provided adequate power to detect medium-sized WP effects. However, given early attrition and noncompliance, the study may be underpowered to detect small effects. Accordingly, nonsignificant findings should be interpreted cautiously.

Data were analyzed in RStudio Version 2023.06.0+421 using *tidyverse* for data wrangling and visualization (version 1.3.0) [49] and *lme4* for multilevel modeling (version 1.1 - 26) [50]. First, we standardized DASS and MEDI neuroticism for ease of interpretation. Next, general linear mixed models (ie, multilevel models where sessions were modeled as nested within persons) were used to examine the impact of WP fluctuations in NA on RT inconsistency, accounting for time (ie, session) in the study, BP differences in NA, sex, age, neuroticism, and insomnia.

Predictors were entered in stages to quantify incremental variance explained, and intercepts were allowed to vary for each participant (ie, as random effects). In model 0, we ran an empty means, random-intercept-only model to examine the overall pattern of individual differences in RT inconsistency. In model 1, a 2-piece discontinuous model of change by describing the change before and after EMA session 3 as 2 separate linear slopes was fitted to capture the apparent breakpoint in session 3 (Multimedia Appendix 1). In model 2, NA was added at levels 1 and 2. In model 3, level 1 and cross-level interactions were added between EMA session and NA. In model 4, sex, age, neuroticism, insomnia, and response device were added at level 2. These covariates were included to account for potential differences in cognitive performance related to maturation, sex, and the device used.

Comparison of model fit across models, including an alternative model describing change as a continuous slope, suggests that model 4 fit the data best based on the likelihood ratio test. The diagnosis of model assumptions (linearity, constant and normal distribution of variance, and independence of residuals across levels) for model 4, along with a check of collinearity and autocorrelation as well as model fit comparisons, is provided in Multimedia Appendix 1. Model 4 equations are provided below:

Level 1 (observation level)

Level 2 (person level)

(3)Slope 1: $\beta 1i=\gamma 10+\gamma 11(\overline{NA}i-15)$

(4)Slope 2: $\beta 2i=\gamma 20+\gamma 21(\overline{NA}i-15)$

(5)WP NA:$\beta 3i=\gamma 30$

(6)WP NA by Slope 1:$\beta 4i=\gamma 40$

(7)WP NA by Slope 2:$\beta 5i=\gamma 50$

Results

Of the 150 recruited participants, 22.7% did not complete any EMAs and are considered early dropouts (n=34). Early dropout was defined as completing a portion of the day 1 baseline measures but not beginning EMAs over the next 13 days. The majority of early dropouts were participants from the psychology study pool.

We compared the study pool and paid study samples before and after excluding early dropouts. Before excluding early dropouts, compliance and age differed between the samples (Table 2). The study pool sample tended to be younger and less compliant. As shown in Table 2, 40% (31/78) of the student sample dropped out after day 1, compared to only 4.2% (3/72) of the paid sample. After excluding early dropouts, age no longer differed between the samples (Table 1). Sex, levels of neuroticism, depression, and anxiety did not differ between the samples (Tables 1 and 2). This indicates that once participants began completing the study EMAs, they were not significantly more likely to be compliant if they were older or experiencing less depression and anxiety. The largest dropout occurred before beginning the EMA. Participants in the paid study were more likely to complete more than 50% of EMAs than those in the student sample. Morning assessments were chosen for data analyses to minimize potential confounds introduced by daily fatigue cycles or stress accumulation. Despite a dropout rate of 22.7% (34/150), comparisons between completers and noncompleters showed no significant differences in baseline characteristics, reducing concerns about systematic bias.

Next, we examined WP associations between NA and RT inconsistency. Results for models 1 to 4 are shown in Table 3. The intraclass correlation coefficient for RT inconsistency was 0.45 from model 0 (results not shown), indicating that 45% of its variance was due to BP mean differences. RT inconsistency decreased by 10.3% between sessions 1 and 2, but only by 1.3% after session 3 (model 1). Model 2 introduced both BP and WP NA as the main effects, while model 3 included their interaction with both slopes. Including interaction terms improved the model fit ($\Delta\chi^2_4$=11.58; *P*=.02).

We focus our interpretation on model 4, which examines whether RT inconsistency is predicted by WP fluctuations in NA, controlling for sex, age, insomnia level, and the response device used. Consistent with hypotheses, WP fluctuations in NA predicted RT inconsistency. Specifically, RT inconsistency increased by 2.2% when NA was higher than usual. Having a higher-than-usual NA during the first 2 sessions seems to attenuate its effect by 1.1%, but not so afterward. In addition, we observed significant main effects of our control variables: RT inconsistency was nearly 25% lower among individuals with moderate-to-severe insomnia, but using touch devices increased RT inconsistency by 11.8%. RT inconsistency was also 17% higher for women compared to men (*P*=.049).

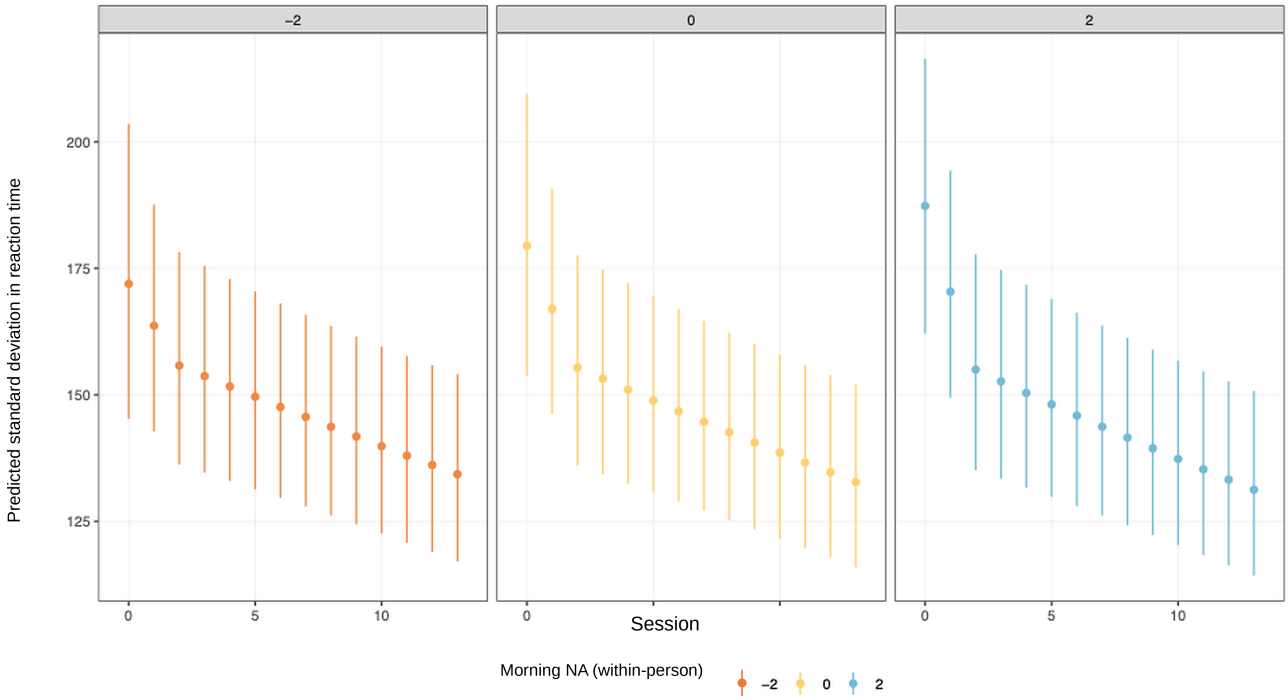
Discussion

Principal Findings

Attention dysregulation is a cardinal symptom of emotional disorders [51-53], and prior work demonstrates that trial-level RT variability reflects attentional control processes and underlying information processing efficiency [12,23,24,34]. Using a 14-day EMA with repeated cognitive (choice RT) and affective (PANAS) measures, the current study examined whether WP fluctuations in NA (deviations from an individual's mean NA) were associated with RT inconsistency in daily life. This approach allowed for an examination of the dynamic associations between cognition and affect as they unfold in naturalistic settings.

Consistent with our primary hypothesis, momentary WP fluctuations in NA predicted greater RT inconsistency, even after accounting for BP differences in NA, neuroticism, insomnia, age, sex, and device type. Additionally, individual differences in sex and insomnia severity were associated with RT inconsistency, partially supporting our secondary hypothesis. Together, these findings suggest that acute increases in NA relative to an individual's typical affect may disrupt attention and information processing above and beyond sleep problems or individual differences in emotional distress. These results extend prior work linking depression, anxiety [54,55], and stress [56-58] to cognitive complaints in young adults by showing that NA changes influence cognition at the momentary, WP level. Notably, the association between NA fluctuations and RT inconsistency was strongest during the early EMA sessions, suggesting that momentary affective states may be particularly disruptive to cognitive performance before participants become familiar and comfortable with a task.



Potential Mechanisms and Interpretation

There are several potential mechanisms that account for the association between momentary NA fluctuations and RT inconsistency. Much like anxiety's effects on performance [59], it is possible that the effects of NA on cognition depend on perceptions of task effort and difficulty, which may be influenced by practice. Early in the study, elevated NA fluctuations may more strongly tax attentional resources, whereas repeated exposure to the same tasks may reduce cognitive load. This is speculative and requires further testing.

An alternative explanation involves speed-accuracy tradeoffs. For example, at the beginning of the study, participants experiencing low and high NA may similarly prioritize accuracy. At the end of the study, participants experiencing high NA may be more likely to prioritize speed by rapidly tapping the screen, thereby reducing RT inconsistency [60-63]. Indeed, the interaction between earlier sessions and NA, while statistically significant, highlights the dynamic nature of cognitive performance over time. An interaction plot (Figure 1) illustrates how RT inconsistency changes across sessions at varying levels of NA, providing insights into the moderating role of practice. Future research is required to replicate these findings, test competing explanations for the interaction between NA fluctuations and practice, and examine generalizability in relation to other cognitive domains. Additionally, future work could incorporate multiple equivalent cognitive tasks to reduce task-specific learning effects and allow for a more accurate assessment of cognitive variability.

Strengths and Limitations

There are many strengths of the study and EMA approaches in general. EMA offers the opportunity to measure daily cognitive functioning in naturalistic environments, which can enhance our understanding of contemporaneous, WP relationships between cognitive and affective processes in clinical and community samples. In clinical assessments of cognition, there may be nuances that emerge outside the context of formal assessment, prior to the onset of a disorder. To be most useful, assessments of cognition should be easy to obtain in real-world settings at multiple points across time, but few validated tests exist. Our study used brief, repeated cognitive tasks that have been validated by our team [37,45,48,64-66] and are reliably administered on any mobile device (laptop, desktop, iPad, tablet, iPhone, and Android). Moreover, our approach used assessment at multiple timepoints, repeatedly, which allowed for measurement of intraindividual RT inconsistency across several timepoints, which is increasingly recognized as a warning sign of future cognitive decline and poorer prognosis. This approach allows for the detection of very subtle cognitive changes associated with depression and anxiety, as well as with aging-related changes in cognitive functioning.

Despite the many strengths of this study, several limitations should be considered. First, our sample was predominantly female and White, which limits generalizability. Future research should aim for greater diversity to validate these results in broader populations, including diverse age, gender, and socioeconomic groups. Our study also consisted of college-age, emerging adults [22]. The high dropout rate and reliance on psychology students as participants limit the generalizability of our findings. While dropout was partially mitigated by comparing baseline characteristics, the homogeneity of the sample restricts applicability to broader populations and reduces the sample size for analyses. In our study, paid participants showed lower dropout rates than psychology pool students. Participant fatigue and lack of strong incentives may have influenced results. Missing EMA assessments may introduce bias if missingness is systematically related to participants' affect or cognitive performance. We did not formally test whether missingness was completely at random, which limits our ability to rule out systematic patterns of missingness. However, our sample was primarily impacted by noncompliance in the EMA, which could be addressed by more frequent and personalized reminder emails or a more thorough introduction to the study during the consent process. Participants were instructed to complete the assessments when they were not distracted, but we cannot confirm that occurred, and participants completed assessments at inconsistent timings based on their schedules. In future work, text messages may prompt more immediate responses than email reminders.

As with other EMA, a lack of control over the participants' environment, device type, and network speed may have impacted our results [36,67]. A lack of experimental control is both a benefit and a limitation of EMA. Unfortunately, the study cannot determine if participants were actually trying their best or performing for course credit in an apathetic manner, and rely on data cleaning to ensure for data quality. Conducting EMA in real-world settings introduces variability due to environmental distractions (eg, noise and multitasking), device differences, and participant engagement. These factors, while enhancing ecological validity, may obscure the true relationship between NA and RT inconsistency. Future studies should consider standardized device protocols and environmental monitoring, as well as more self-reported focus checks.

Another important limitation of our design is that our choice RT task was repeated each day from days 2 to 13. Although our ongoing work addresses this, in this study, we did not alter stimuli in each EMA, which challenges efforts to disentangle

XSL•FO
RenderX

the effects of task-specific learning (ie, practice effects) from the effects of memory for task stimuli and associated responses. Practice effects may also arise from factors that we did not control for, such as participant fatigue and task repetition. Future studies should administer multiple psychometrically equivalent cognitive tasks during EMA to mitigate the effects of memory on performance [68]. Isolating the effects of learning on cognitive performance holds future promise to inform digital risk phenotyping. For example, emerging evidence in older adults suggests that individual differences in learning rate and peak (asymptotic) cognitive performance are related to biological age and clinical impairment [69].

As a final limitation of our study, focusing solely on RT inconsistency as a measure of cognitive performance variability may be too narrow. Cognitive variability can be captured by various other metrics, and additional cognitive tasks can provide a more comprehensive assessment of cognitive functioning over time. We chose RT inconsistency because it is rapid and inexpensive [34] compared to a full cognitive battery. Given the push toward more individualized care through the use of basic and clinical science [70], RT inconsistency may be a particularly useful metric, with the potential to change the way we view the connection between cognition and psychiatric symptoms.

Implications and Future Directions

In sum, momentary WP fluctuations in NA across 14 days predicted RT inconsistency, but the magnitude of this effect changed over the course of the study. These findings support the notion that NA is a form of cognitive load that disrupts cognitive performance, and even subtle fluctuations in NA are a form of stress that impacts cognitive functioning. These findings have implications for the mental health and academic performance of college students, given that internalizing conditions are on the rise and college students are increasingly seeking treatment for emotional disorders and attentional complaints. Perhaps interventions to target NA (enhancing PA, reducing NA, or directly targeting fluctuations in NA) could improve cognitive functioning in college students. For example, mindfulness-based stress approaches [71] and cognitive behavioral therapy have shown promise in reducing affective instability and improving cognitive function [72]. These interventions could be tailored to college students and emerging adults, a population particularly vulnerable to emotional and cognitive challenges, to enhance resilience and cognitive performance. By linking these findings to practical strategies, our long-term goal is to provide actionable insights for researchers and clinicians.

Additional research is necessary to examine the strength of these WP associations in relation to psychological symptoms, with potential implications for digital risk screening and preventative (eg, cognitive behavioral) intervention. Indeed, changes in affect and cognition frequently precede psychological symptoms [73,74], suggesting that momentary cognitive monitoring using scalable technologies may support early risk assessment. This study's focus on momentary NA fluctuations complements prior research on emotional inertia [10], which has been associated with prolonged emotional disturbances and reduced cognitive resilience. Future research should examine how inertia and NA fluctuations may interact to influence cognitive performance, using EMA to capture their dynamic interplay in real-world settings.

Finally, EMA can help identify patterns of emotional responses that may signal the need for early interventions aimed at improving emotional regulation. While we focused on WP differences in NA variability, BP effects may modulate outcomes. Additional work examining how stable traits, such as neuroticism, insomnia, and sex, interact with WP fluctuations in NA to influence cognitive variability would deepen our understanding of these dynamic relationships. Future directions include the integration of passive data to better understand cognition, stress, and sleep, as well as testing in clinical samples and aging samples to understand connections between depression, cognitive impairment, and cognitive decline. Moreover, longer (eg, longitudinal burst) time series data are recommended to enable personalized risk modeling.

Conclusions

This study provides preliminary evidence that momentary WP fluctuations in NA are associated with RT inconsistency in daily life, although the magnitude of this association changed over the course of the study. Our findings support the value of EMA and brief cognitive tasks to capture dynamic links between affect and cognitive functioning in real-world contexts. Future work using longer monitoring periods and passive data may further clarify how daily fluctuations in affect contribute to cognitive performance variability and psychiatric risk.

Acknowledgments

During the revision of this manuscript, the authors used generative artificial intelligence (AI) tools (ChatGPT) for editorial assistance and organization of revision materials. Generative AI was not used to generate data, conduct statistical analyses, or produce study results. The authors reviewed and edited all AI-assisted content and take full responsibility for the content of the manuscript.

Funding

This work is supported by the National Institute on Aging (K01 AG086598 to LAR).

Data Availability

Analysis code is available on OSF [75]. The participant-level data analyzed in this study are not publicly available because they contain intensive longitudinal ecological momentary assessment and cognitive task data. Deidentified data may be available from the corresponding author upon reasonable request, subject to institutional approvals and data-sharing agreements.

Abstract

Background: Reliable measurement of smartphone screen time is important for research examining associations between digital media use and health outcomes. Although objective monitoring tools reduce bias associated with self-report, the number of monitoring days required to reliably estimate typical smartphone use remains unclear. This question is particularly important for study design because longer monitoring periods increase participant burden and the likelihood of missing data.

Objective: This study aimed to determine the minimum number of valid monitoring days within a 7-day measurement period required to reliably estimate average daily smartphone screen time during the same 7-day period among primary caregivers of preschool-aged children using 2 objective methods.

Methods: This secondary analysis included caregivers participating in 2 observational studies conducted in the Eastern United States. Android users installed Chronicle, a passive sensing application that records raw Android UsageEvents data, which were preprocessed into smartphone session events (pickups where the device was unlocked). iOS users submitted daily screenshots of Apple Screen Time summaries. Reliability analyses included 100 Android Chronicle participants and 129 iOS Screenshot participants with at least 7 consecutive complete days of data. The primary outcome was day-level total smartphone screen time. For Android Chronicle, this was defined as the summed duration of device-unlock sessions across each calendar day, whereas for iOS Screenshot, this was defined as the daily total reported by Apple Screen Time. One-way random-effects intraclass correlation coefficients (ICC [1,1]) with 95% bootstrap CIs (500 resamples) were calculated separately for Android and iOS data. The Spearman-Brown prophecy formula was used to estimate the number of monitoring days required to achieve target reliability thresholds (ICC≥0.70, 0.80, and 0.90). Sensitivity analyses using the combined durations of sessions and glances produced similar conservative monitoring-day recommendations.

Results: Single-day ICCs were 0.69 (95% CI 0.63-0.76) for Android Chronicle and 0.71 (95% CI 0.65-0.77) for iOS Screenshot data. Point-estimate projections indicated that 2 monitoring days were sufficient to achieve an ICC≥0.80 for both data sources. Using the more conservative criterion that the lower bound of the projected 95% CI exceeded 0.80, 3 monitoring days were required for both Android and iOS data. Screen time was significantly lower on weekends than on weekdays, suggesting that monitoring periods should include at least 1 weekend day.

Conclusions: Among caregivers of preschool-aged children, relatively short objective monitoring periods may provide reliable estimates of average daily smartphone screen time within a 7-day monitoring period. Two monitoring days were sufficient under point-estimate projections, whereas 3 days were required using a conservative lower-bound criterion. These findings support the feasibility of brief smartphone monitoring protocols for estimating the 7-day average duration, while emphasizing the importance of including weekend representation and avoiding the extension of these estimates to longer-term habitual smartphone behavior or screen time metrics beyond duration without further evidence.

screen time; passive sensing; smartphone; sampling duration; reliability

Introduction

Background

Smartphone ownership is nearly universal in the United States, with more than 90% of adults owning a smartphone [1]. Alongside rising usage, growing evidence links smartphone use to a range of health and psychosocial outcomes [2-4]. However, progress in this area depends on the quality of the measures used to quantify smartphone behavior. In digital media research, screen time and related exposure variables are commonly used as predictors or outcomes, but many studies have relied on retrospective self-report measures [5-7].

Limitations of Self-Reported Smartphone Use

Self-reported media use is vulnerable to recall error, social desirability bias, and difficulty estimating frequent behaviors embedded in daily routines [8,9]. These limitations may be especially relevant for smartphone use, which often occurs through short, repeated interactions across varied contexts and alongside other activities [10]. A systematic review and meta-analysis found that self-reported digital media use correlated only moderately with logged use and was rarely an accurate reflection of objectively recorded behavior [7]. This suggests that self-reported and logged measures may not be interchangeable and supports the use of objective measurement when estimating smartphone exposure.

Objective Smartphone Measurement

Objective smartphone measures generally fall into several related approaches. On Android devices, timestamped operating-system event logs can be processed to construct smartphone use behaviors such as sessions, glances, and app use episodes [11]. Research tools such as Chronicle and the Effortless Assessment Research System (EARS) use these types of passive sensing data to provide detailed measures of device or app interaction [12-14]. Other intensive approaches, such as Screenomics, capture repeated screenshots to characterize digital context and content, offering rich behavioral detail but with greater privacy, storage, and processing demands [15]. In contrast, iOS research often relies on less granular approaches or participant-submitted screenshots of Apple Screen Time summaries because Apple restricts third-party access to detailed device activity data. Although these objective approaches reduce reliance on retrospective self-report, they still require decisions about the number of monitoring days needed to obtain reliable estimates.

Within-Person Variability and Monitoring Duration

Smartphone use also varies meaningfully within individuals across days and situations. Recent work distinguishing person-specific from situation-specific variation in media use found that a large share of media use variance occurs within persons across situations, underscoring the need for repeated measurement designs rather than single time point estimates [16]. At the same time, smartphone behavior may include habitual or automatic interactions triggered by contextual cues, making it difficult for participants to accurately recall or summarize their use [17]. Together, these features create a practical measurement challenge: researchers need objective monitoring protocols that are long enough to capture typical use, but not so long that they increase participant burden or missing data.

Prior studies have addressed similar questions using correlation-based approaches, examining the association between short-term and longer-term monitoring windows [18,19]. For instance, Wilcockson et al [18] found that 5 days of monitoring were sufficient to characterize weekly smartphone duration and 2 days were sufficient for checking behavior (pickups lasting <15 s). Although informative, correlations primarily capture rank-order consistency across individuals and do not directly estimate measurement reliability, absolute agreement, or the contribution of within-person variability.

Reliability-Based Study Planning

An alternative approach uses intraclass correlation coefficients (ICCs) and the Spearman-Brown prophecy formula [20,21]. ICC-based approaches are useful for planning measurement protocols because they quantify the proportion of observed variance attributable to stable between-person differences, provide an estimate of measurement error in the exposure, and can be paired with the Spearman-Brown formula to estimate how many repeated days are needed to achieve a prespecified reliability threshold. These methods are widely used in physical activity and other behavioral monitoring research to determine the minimum monitoring periods required for stable estimates of behavior [22-26], but have not been widely applied to objective smartphone screen time measurement.

Study Aim

In this study, we used the ICC and Spearman-Brown methods to estimate the minimum number of valid monitoring days required, within a 7-day monitoring period, to reliably estimate average daily smartphone screen time duration among primary caregivers of young children. Separate analyses were conducted for 2 objectively collected data sources: (1) passive sensing via the Chronicle app on Android devices and (2) screenshots of Apple Screen Time on iOS devices. Because these data sources reflect different platform-specific measurement approaches and were collected from distinct participant groups, the aim was not to test equivalence or directly compare Android and iOS estimates. Rather, our aim was to provide data-source–specific reliability estimates and practical guidance for researchers studying smartphone behavior in this population, where some days of monitoring may be missing, invalid, or incomplete.

Methods

Participants and Study Design

This secondary analysis used data from 2 observational studies involving caregivers of preschool-aged children: a pilot feasibility study [27] and an ongoing longitudinal cohort study [28] (R01HD112311). Both studies recruited nonrandom samples via social media across the eastern United States and used identical smartphone screen time assessment protocols. Inclusion criteria were (1) primary caregiver of a child aged 3 to 5 years, (2) ownership of a smartphone, and (3) ability to read and speak English. Remote data collection included surveys, ecological momentary assessments, and passive smartphone sensing.

Pilot study data were collected from September 2020 to February 2022 using a 30-day monitoring protocol, whereas cohort study data were collected from September 2024 to May 2025 using a 14-day monitoring protocol. Android Chronicle data were available from both studies, whereas iOS Screenshot data were collected only in the cohort study.

Ethical Considerations

Both parent studies were approved by the University of South Carolina Institutional Review Board (IRB) in August 2020 (Pro00092634) and December 2023 (Pro00133829). All participants provided informed consent before participation, and the IRB approvals covered secondary analyses of the collected data. Participant data were deidentified before analysis and stored on secure, access-restricted university servers. Smartphone data were processed using participant identifiers rather than names or directly identifying information. Participants received up to US $440 per assessment period for completing the broader study protocol, including parent surveys, daily diaries, ecological momentary assessments, and other remote data collection procedures. Smartphone screenshot submissions were completed as part of the compensated daily diary protocol (US $5 per completion). Chronicle data collection was not directly compensated.

Smartphone Screen Time Measurement

Android Chronicle

Android users installed Chronicle, a passive sensing application that records timestamped device interaction events [12]. Chronicle accesses raw Android event-log data through the Android UsageEvents framework, which captures application transitions, screen interactions, and device state events [13]. Data are uploaded at regular intervals to a secure server when the device is connected to Wi-Fi.

For the current analysis, raw Android event logs were used to derive smartphone interaction measures based on an adapted implementation of the framework proposed by Parry and Torth [11] for constructing meaningful smartphone use behaviors from Android event streams. This approach constructed smartphone sessions (device-unlock episodes), glances (brief screen activations without unlocking), and foreground app use episodes from timestamped event sequences (Figure 1).

The primary Android outcome was total daily smartphone session duration, aggregated by each calendar day. In a sensitivity analysis, we also examined combined session and glance duration. Conservative monitoring-day recommendations were unchanged; therefore, the primary analyses presented focus on session-derived estimates.

iOS Screenshot

Comparable passive sensing data were not available on iOS devices because Apple restricts third-party access to detailed app activity data. Therefore, iOS users submitted daily screenshots of their previous day's built-in Apple Screen Time summary via a daily diary survey link texted to their smartphones (Figure 2). Surveys were administered through Qualtrics and automatically distributed using an internal messaging system (WearData).

XSL•FO
RenderX

Figure 2. Example iOS Screenshot (Apple Screen Time).

Screenshots were manually reviewed for correct date, device, and completeness. They were excluded if the displayed date did not match the target reporting day (submitted day minus 1), if the image was a duplicate submission for an already processed day, if the image was unclear or unreadable, or if the hourly bar chart was incomplete or could not be reliably extracted. When multiple valid screenshots were submitted for the same participant-day, only one screenshot was retained. These checks were completed before aggregation to daily totals. We then applied a custom open-source Python script [29] to extract per-hour screen time values from the screenshot bar chart. Hourly values were summed to generate total daily screen time. To validate this approach, we compared the extracted totals against the daily totals displayed on a random sample of 100 screenshots. The mean difference was −2.7±11.7 minutes per day (relative difference of −0.01%±0.04%), with a Lin concordance coefficient of 0.998, demonstrating excellent agreement. This validation confirmed the accuracy of extracting

XSL•FO
RenderX

and summing hourly values from submitted screenshots relative to the daily total displayed by Apple Screen Time. However, it should not be interpreted as criterion validation of Apple Screen Time against raw device logs because Apple's underlying screen time definitions and algorithms are proprietary.

Data Processing and Cleaning

Android Chronicle data were processed using a reproducible preprocessing and cleaning pipeline. Raw Android event logs were first transformed into structured smartphone interaction events, including sessions, glances, and foreground app use episodes [30]. Although this study used session-derived duration measures as the primary outcome, app use episodes were retained during preprocessing and cleaning to support transparent reconstruction of smartphone interaction events and future analyses. Cleaning procedures then standardized timestamps and time zones, collapsed adjacent split app use segments, truncated predefined low-engagement or background applications, identified implausibly long events, and flagged incomplete or potentially unreliable days [31].

To reduce inflation of duration estimates, predefined low-engagement applications (eg, launcher, clock, screensaver, or other background-system applications) were truncated to a maximum duration of 10 minutes rather than excluded entirely. The truncation threshold was chosen in line with prior work using Chronicle data [13]. A list of these apps is available with the cleaning script linked above. Events with implausibly long durations (>3 h) were reviewed using prespecified rules based on Google Play Store app categories (GenreID), with prolonged durations considered plausible for "video players," "entertainment," "social," and "games" apps. All events lasting for more than 6 hours were considered implausible and truncated to 10 minutes. Prolonged inactivity gaps (>12 h without recorded Android events or device shutdown markers) were treated as likely periods of missing data. Days containing such gaps, as well as partial start and end days, were excluded from analysis.

To summarize the application of these rules, we examined the exclusion of partial or incomplete days across all available Chronicle records processed before analytic window selection. Across these records, 10% of participant-days were excluded because of partial coverage or prolonged inactivity gaps. To summarize the impact of long-session truncation on the data used in the primary reliability analyses, we examined the final 7-day analytic windows. Within these analytic windows, 9 of 64,644 pickup/session events (0.01%) exceeded 6 hours and were truncated. These rules were applied systematically using prespecified criteria to reduce implausible inflation of screen time estimates. We did not interpret uncleaned values as valid alternative estimates because they included incomplete days and anomalously long events that were considered likely data artifacts.

Screenshot-based iOS data required only verification of complete 24-hour coverage and of valid screenshot formatting before aggregation into daily totals. For the current analysis, we included only participants with at least 7 consecutive complete days of objective smartphone use data after cleaning. For participants with more than 7 consecutive complete days available, we selected the first 7 days from the first qualifying consecutive sequence after cleaning. This rule was applied consistently across participants and data sources to define a reproducible 7-day analytic window.

Statistical Analysis

Overview

We fitted a linear mixed-effects model (lme4) with data source (iOS vs Android), day type (weekend vs weekday), and their interaction as fixed effects, and a random intercept for participant to account for repeated daily observations within individuals. Fixed-effect estimates (*B*), standard errors (SEs), 95% CIs, and *P* values are reported.

We conducted separate analyses for Android Chronicle and iOS Screenshot data because these data sources were derived from different platform-specific measurement approaches. The aim was not to directly compare Android and iOS screen time estimates but to provide data-source–specific reliability estimates for 2 objective approaches to measuring daily smartphone use duration.

The primary outcome for both data sources was day-level total smartphone screen time in hours. In the Android Chronicle data, this was defined as the summed duration of device-unlock sessions for each calendar day. In the iOS Screenshot data, this was defined as the daily total reported by Apple Screen Time and extracted from participant-submitted screenshots. The following approaches were used, as described in the following sections.

ICC

A 1-way random-effects ICC for single measures with absolute agreement (ICC [1,1]) was calculated to quantify the proportion of variance attributable to stable between-person differences in daily screen time duration [20]. ICC (1,1) was selected because the aim was to estimate the reliability of a single day of monitoring sampled from a broader universe of possible days, rather than agreement between a fixed set of raters or measurement occasions. This provides a direct estimate of test-retest reliability for a single day of monitoring. ICCs were computed using the *irr::icc*() function in R (R Foundation for Statistical Computing) [32]. To quantify uncertainty around the single-day ICC estimate, we generated a 95% CI using nonparametric bootstrapping (resampling participants with replacement; 500 replicates). For each bootstrap replicate, the single-day ICC estimate was entered into the Spearman-Brown prophecy formula to generate projected ICC_k values and corresponding estimates of the number of monitoring days required to achieve target reliability thresholds, thereby propagating uncertainty from the single-day ICC through all projected reliability estimates.

Spearman-Brown Prophecy Formula

To estimate how reliability improves with additional days, we calculated the projected expected ICC for k=2 to 7 days using the following formula:

$$ICCk = k \cdot ICC1 / (1 + (k-1) \cdot ICC1)$$

where ICC_1 is the reliability from a single day of monitoring, and ICC_k is the projected reliability for k days [21,33]. Then,

XSL•FO
RenderX

for each bootstrap draw of ICC_1, we applied the following formula to estimate the number of monitoring days needed to reach thresholds of ICC=0.70, 0.80, and 0.90:

$$k* = ICCtarget(1-ICC1)\ ICC1(1-ICCtarget)$$

Here, ICC_{target} is the desired reliability level (0.70, 0.80, or 0.90), and k^* is the projected number of days needed to achieve that level. We summarized the resulting k^* distribution as the median (95% CI) and showed the full ICC vs days curves (with 95% bootstrap CI). For interpretation, we focus on the point at which the lower bound of the 95% CI of the projected ICC curve first reaches ≥0.80, a commonly accepted threshold for adequate reliability in behavioral research [34]. Projected monitoring durations were rounded up to the nearest whole day for practical interpretation.

The Spearman-Brown projections assume that repeated monitoring days function as exchangeable indicators of the same underlying average daily behavior. This assumption may be imperfect for smartphone screen time because use can vary systematically by day type. Therefore, the projected monitoring durations were interpreted as estimates of the number of valid days needed to estimate the average daily smartphone duration within the observed 7-day monitoring period. They were not interpreted as evidence that the same number of days would reliably estimate longer-term habitual smartphone use across weeks, seasons, or other contexts.

To assess potential differences between included and excluded participants, we compared available demographic characteristics by inclusion status within each data source. Because only 7 Android Chronicle participants were excluded, Android comparisons were interpreted descriptively. For iOS Screenshot participants, age was compared using a 2-tailed Welch *t* test, and categorical characteristics were compared using Fisher exact test. All statistical analyses were conducted in R (version 4.4.0), and statistical significance was set at $P<.05$.

Reporting Guidelines

This manuscript was reviewed using the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) checklist for observational studies. The completed checklist is provided in Checklist 1.

Results

Participant Characteristics

Of the 316 participants with objective smartphone use data available for screening, 229 (72.5%) were included in the final analytic sample (Table 1). For Android (Chronicle), 100 of 107 participants (93.5%) had at least 7 consecutive valid days after cleaning. For iOS Screenshot, 129 of 209 participants (61.7%) had at least 7 consecutive valid screenshots. Because only 7 Android Chronicle participants were excluded, included vs excluded comparisons were interpreted descriptively. Among iOS Screenshot participants, included and excluded participants did not differ significantly by age, sex, ethnicity, employment, or income (all $P>.05$), but differed by race ($P=.001$) and education ($P=.002$). Included iOS participants were more likely to be White and to have a college degree or higher than excluded iOS participants.

Table . Participant inclusion by smartphone data source.

Data source	Available for screening, n	Included, n (%)	Excluded, n (%)
Android Chronicle	107	100 (93.5)	7 (6.5)
iOS Screenshot	209	129 (61.7)	80 (38.3)
Total	316	229 (72.5)	87 (27.5)

For the final analytic sample, the mean age was 36.4 years (SD 5.7), and the sample was predominantly female primary caregivers (218/229, 95.2%), which is typical of child and family-based research [35]. Because data sources were platform-specific, Android and iOS users represent distinct subsamples, with some demographic differences (Table 2). In particular, iOS Screenshot participants were more likely to have a college degree or higher, be employed, and report household income of US $100,000 or more. These differences should be considered when interpreting any descriptive comparisons between platform and data-source groups. However, these differences were not adjusted for, as the focus of this analysis was on within-sample measurement reliability rather than between-group comparisons.

Table . Participant demographics by smartphone screen time data source.

Characteristics	Android Chronicle (n=100)	iOS Screenshot (n=129)
Age (y), mean (SD)	36.6 (6.8)	36.3 (4.7)
Sex, n (%)		
Female	94 (94)	124 (96.1)
Race, n (%)		
Black	19 (19)	15 (11.6)
White	74 (74)	104 (80.6)
Asian, more than 1 race, or other	7 (7)	10 (7.8)
Hispanic ethnicity (yes), n (%)	5 (5)	8 (6.2)
Education[a], n (%)		
High school or less	11 (11)	3 (2.3)
Some college or 2-year degree	39 (39)	20 (15.5)
College graduate or higher	50 (50)	106 (82.2)
Employment[a], n (%)		
Employed	54 (54)	98 (76.0)
Student	28 (28)	19 (14.7)
Unemployed	11 (11)	5 (3.9)
Other	7 (7)	7 (5.4)
Income[a], n (%)		
<US $20,000	10 (10)	2 (1.6)
US $20,000-$49,000	23 (23)	13 (10.1)
US $50,000-$99,000	39 (39)	39 (30.2)
≥US $100,000	28 (28)	75 (58.1)

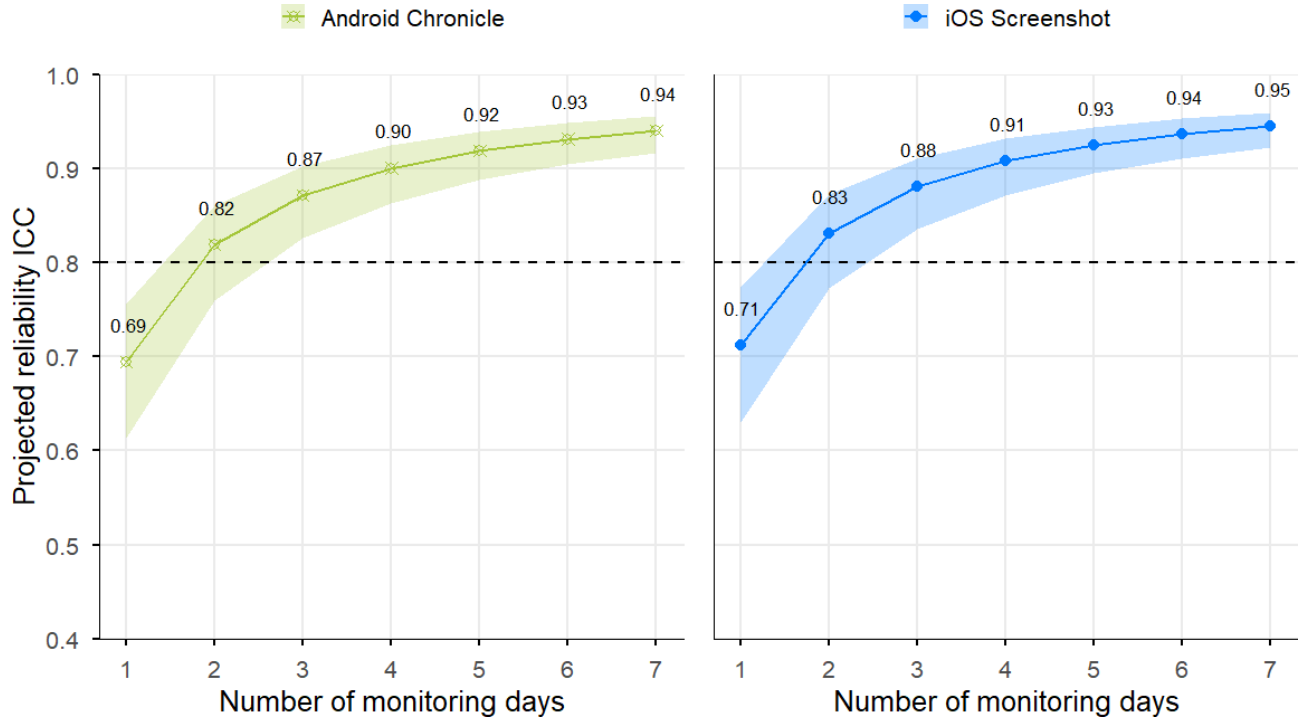
[a]Android Chronicle and iOS Screenshot participants differed on some demographic characteristics. In particular, iOS Screenshot participants were more likely to have a college degree or higher, be employed, and report household income ≥US $100,000.

Data Source and Day Type Differences

A linear mixed-effects model with a random intercept for participant, including both data source and day type as fixed effects, showed no significant difference in mean daily screen time between iOS and Android users (*B*=15.7 min, SE=21.4, 95% CI –26.2 to 57.5; *P*=.46). However, screen time was significantly lower on weekends than on weekdays (*B*=–16.1 min, SE=5.6, 95% CI –27.0 to –5.2; *P*=.004). The interaction between data source and day type was not significant (*B*=6.5 min, SE=11.3; *P*=.56), indicating that the weekend-weekday difference did not vary by data source. Reliability analyses were conducted across all 7 monitoring days rather than separately by day type because the aim was to estimate the reliability of a typical week of smartphone use. Mean daily screen time by day of the week is shown in Multimedia Appendix 1.

Reliability and Monitoring Duration

Table 3 presents the reliability results for daily smartphone screen time. For Android Chronicle data, the single-day ICC was 0.69 (95% CI 0.63-0.76). For iOS Screenshot data, it was 0.71 (95% CI 0.65-0.77). For interpretability, projected monitoring durations were rounded up to the nearest whole day when deriving practical recommendations. Using Spearman-Brown projections based on the point estimates, 2 monitoring days were sufficient for both Android Chronicle and iOS Screenshot data to achieve projected ICC≥0.80 (Figure 3). Using the more conservative lower-bound approach, 3 days were required for both data sources. Sensitivity analyses using combined session and glance duration produced a single-day ICC of 0.64 (95% CI 0.57-0.72). The projected monitoring durations were 1.3 (95% CI 1.0-1.7) days, 2.2 (95% CI 1.7-2.9) days, and 5.0 (95% CI 3.9-6.6) days for ICC thresholds of 0.70, 0.80, and 0.90, respectively. After rounding, both the point-estimate and conservative recommendations were 3 days to achieve ICC≥0.80.



XSL•FO
RenderX

Table . Single-day intraclass correlation coefficients (ICCs; 95% bootstrapped CI), and projected number of days needed for target reliabilities of 0.7, 0.8, and 0.9, by data source.

Data source	Single-day ICC (95% CI)	Projected number of days (95% CI)			Between-person variance	Within-person variance	Practical recommendation for ICC≥0.80[a]
		ICC=0.7	ICC=0.8	ICC=0.9			
Android Chronicle (n=100)	0.69 (0.63-0.76)	1.0 (0.8-1.3)	1.8 (1.4-2.3)	4.0 (3.1-5.1)	26,788	11,804	Point estimate: 2 days; conservative: 3 days
iOS Screenshot (n=129)	0.71 (0.65-0.77)	0.9 (0.7-1.3)	1.6 (1.2-2.2)	3.6 (2.8-4.8)	22,265	9018	Point estimate: 2 days; conservative: 3 days

[a]Projected monitoring durations were rounded up to the nearest whole day. Conservative recommendations were based on the lower bound of the 95% CI for projected ICC estimates.

Figure 3. Projected reliability of average daily smartphone screen time by number of monitoring days, estimated using the Spearman-Brown prophecy formula. Points show projected intraclass correlation coefficients (ICC [1,1]) estimates for 1 to 7 monitoring days, shaded bands show 95% CIs, and the dashed horizontal line indicates ICC=0.80.

Discussion

Principal Findings

This study examined the minimum number of monitoring days required to reliably estimate average daily smartphone screen time among primary caregivers of preschool-aged children using objective Android and iOS monitoring approaches. Daily screen time duration estimates demonstrated high reliability even with a small number of days. When using the point estimate, projections indicated that 2 monitoring days were sufficient for both Android Chronicle and iOS Screenshot data to achieve ICC≥0.80. When using the more conservative lower-bound criterion of the 95% CIs, 3 days were required for both data sources. These estimates should be interpreted as the number of valid days needed to estimate average daily smartphone duration within a 7-day monitoring period. Although the weekday-weekend difference was modest in absolute terms, screen time differed systematically by day type. Therefore, shortened protocols should include weekend representation. For a 3-day protocol, this would most pragmatically involve at least 2 weekdays and 1 weekend day.

Our findings align with prior research in other forms of objective behavioral monitoring, such as physical activity, where 3 to 7 days of accelerometer wear are typically recommended to obtain reliable estimates of movement behaviors [22-26]. Interestingly, smartphone screen time appears to require even fewer days, potentially reflecting a degree of stability of daily phone use, at least among primary caregivers.

Previous studies that estimated the number of days needed for reliable smartphone measurement relied on correlation-based analyses [18,19]. For instance, Wilcockson et al [18,19] found that 5 days were sufficient to characterize weekly usage using Pearson correlations. Although these studies provide valuable

XSL•FO
RenderX

early insights, correlation-based methods primarily reflect rank-order consistency and do not directly quantify measurement reliability. In other words, correlations measure whether individuals maintain the same relative position over time, but do not quantify measurement reliability in a statistical sense. In contrast, our approach uses ICCs, which directly estimate the proportion of total variance attributable to stable between-person differences in average daily screen time over a week [20]. Combined with the Spearman-Brown formula, this approach allows us to estimate how many days of monitoring are needed to achieve a desired level of reliability (eg, ICC≥0.80) while accounting for both within-person and between-person variability in screen time [34]. Although our results are similar to earlier findings, they provide a methodologically rigorous basis for these recommendations by directly estimating measurement reliability. This strengthens confidence in the use of short monitoring periods for future study design.

Objective methods for monitoring smartphone use have progressed rapidly, with built-in summaries (eg, iOS Screenshot) and passive sensing tools (eg, Android Chronicle) each presenting distinct advantages and trade-offs [36]. Built-in summaries, such as Apple's Screen Time, offer built-in, user-friendly reports of device and app activity, but rely on proprietary algorithms that define and categorize usage and can be updated without warning, limiting insight into what actually counts as screen time. Because Apple Screen Time algorithms are proprietary and Android Chronicle estimates were derived from reconstructed session events, it is difficult to determine whether observed differences in screen time estimates between data sources reflect true behavioral differences, sample differences, or platform-specific measurement differences. However, the purpose of this study was not to establish equivalence between Android and iOS estimates. Rather, we conducted separate analyses to provide reliability estimates for 2 distinct objective data sources commonly available to researchers studying smartphone use.

Passive sensing platforms such as Chronicle, Qustodio, and EARS can capture more granular event-level data and enable analyses beyond aggregate daily or hourly summaries [14,37]. However, these approaches often require complex processing pipelines and vary in validation, cost, and ease of implementation. A strength of the present study is the use of documented and reproducible processing procedures for both passive sensing and screenshot-based data. Future work should prioritize head-to-head comparisons of smartphone monitoring tools, validation of algorithmic definitions, and open standards for deriving digital behavior metrics.

Limitations

Several limitations should be noted when interpreting these findings. First, the sample consisted of primary caregivers of young children, the majority of whom were female and already participating in observational studies about family screen time. This raises questions about selection bias, observer effects, and generalizability to other populations. Caregivers of preschool-aged children may also have more constrained and predictable daily routines than adolescents, older adults, or adults without young children [38]. In addition, because inclusion required 7 consecutive valid monitoring days, the analytic sample may overrepresent participants with greater adherence or more complete data capture. This concern may be particularly relevant for iOS Screenshot data, where included participants differed from excluded participants in race and education.

Second, Android Chronicle and iOS Screenshot data came from different platform and data source groups, and iOS Screenshot data were collected only in the cohort study. These groups differed in several demographic characteristics, including education, income, and employment. Because the study was designed to estimate reliability separately within each data source rather than to compare platforms directly, these differences were not adjusted for statistically. However, they limit interpretation of any descriptive Android-iOS differences in screen time estimates.

Third, a single 7-day monitoring window may not capture longer-term habitual smartphone behavior, as routines and occasional deviations may vary across weeks or seasons. For participants with more than 7 consecutive complete days available, the analytic window was defined as the first 7 days from the first qualifying consecutive sequence after cleaning; therefore, we cannot rule out the possibility that smartphone behavior differed during other portions of the monitoring period. This limitation in the monitoring window is important for interpreting the Spearman-Brown projections. The Spearman-Brown approach assumes that repeated monitoring days are exchangeable indicators of the same underlying behavior, but this assumption may be imperfect when behavior varies systematically by day type or over longer time frames. Recent work in physical activity measurement has shown that Spearman-Brown projections from short observation windows can overestimate longer-term aggregate reliability, and has proposed directly estimating reliability using repeated observation windows [39]. The present study was not designed to support this type of repeated-window analysis. Therefore, our findings should be interpreted as estimates of the number of valid days needed to estimate average daily smartphone duration within a 7-day monitoring period, rather than the number of days needed to characterize longer-term habitual smartphone use.

Scope of Inference

The present findings apply specifically to total daily smartphone use duration measured over a 7-day monitoring window. Although total duration is a common and practical exposure metric, it does not capture other potentially important dimensions of smartphone behavior, including frequency of pickups, timing of use, fragmentation or clustering of use across the day, duration of individual sessions, app-specific use, or the content and context of interactions [40-42]. Reliability estimates for total daily duration should, therefore, not be assumed to generalize to these more granular behavioral metrics. Future work should examine how many monitoring days are needed to reliably estimate pattern-based and content-specific smartphone exposures, such as social media duration, messaging

XSL•FO
RenderX

frequency, nighttime use, checking behavior, or fragmented vs sustained use.

Conclusions

In conclusion, this study suggests that relatively few valid days of objective smartphone monitoring may be sufficient to estimate average daily smartphone screen time within a 7-day monitoring period among caregivers of preschool-aged children. These findings support the feasibility of brief monitoring protocols when some days are missing, invalid, or incomplete, helping to balance measurement reliability with participant burden and logistical constraints. However, these estimates should not be interpreted as establishing the number of days needed to measure longer-term habitual smartphone use or more granular smartphone behaviors beyond daily duration. Future studies with longer repeated monitoring windows should examine whether short-term reliability projections align with reliability across distinct weeks or longer time frames and across additional metrics.
