The mobile app, MyDataHelps, was used to collect and integrate active (baseline questionnaire and daily mood) and passive (wearable) data. The app was available on Android and iOS operating systems, and on the web. Step-by-step instructions were provided for the web-based baseline questionnaire. The app provided a daily prompt to complete the mood rating (scale of 1-10). Wearable data were uploaded daily to the mobile app and integrated into the data collection platform through automatic synchronization from the Fitbit device to the Fitbit app on the participant's mobile phone. To ensure the data synchronization from the Fitbit app to the MyDataHelps app, participants were required to have their mobile phone connected to the internet and Bluetooth enabled. The data synchronization process retrieved data stored on the device for up to 7 days. When gaps in data upload exceeded 3 days, the app sent a prompt to remind participants to synchronize their data.

Exit Interviews

At the end of the 30-day pilot study period, a subset of participants was interviewed by members of the research team (LK, WN, and A Aballa) at the participants' respective health

XSL•FO
RenderX

facilities. The interview guide consisted of questions on user experience, challenges, and recommendations regarding the content and technology.

The interviews were conducted by trained social scientists. Prior to the interview, the interviewers completed a 3-day training on research ethics and the interview guide. A pretest was conducted with HCWs who were not part of the study, and the interview guide was later revised to ensure the flow and clarity of the questions. The interviews took approximately 40 to 70 minutes.

Data Analysis

Feasibility of the pilot study was evaluated using baseline questionnaire response time, data completeness, recruitment results, and study attrition. For the baseline questionnaire, data completeness was calculated based on the proportion of visible questions answered, which excludes branching questions. Data completeness was also analyzed based on the number of days participants completed the daily mood rating and uploaded any steps, heart rate (heart rate intraday count), and sleep (duration) data. The average daily step count was also reported, excluding days with zero step count. The number of days participants wore the wearable for at least 10 hours was calculated using heart rate intraday minute count, as studies have suggested this is the minimal wear time to indicate a full day of use [30]. Descriptive statistics were calculated using R (version 4.1.1; R Core Team), and summary statistics were presented as mean and SD or median and IQR for continuous data, and frequencies and percentages for categorical data.

Acceptability of the baseline questionnaire and wearables was based on user experiences provided in qualitative exit interviews.

The interviews were recorded and transcribed verbatim, and a deductive thematic analysis approach was used to analyze the data with the support of NVivo Software (version 12; QSR International). Interviewers created field notes to capture participants' impressions and observations during the interviews. The analysis followed the key stages of thematic analysis: familiarization with the data, generating initial codes, searching for themes, reviewing and refining themes, and defining and naming themes [31]. In the initial phase, transcripts were read thoroughly, and data were coded line by line, with concepts and ideas identified. As the analysis progressed, codes were refined and grouped into potential themes, which were then reviewed and further developed to reflect deeper meanings. In the final phase, the themes were clearly defined and organized to capture the core ideas of the study based on the objectives of the study. The coding matrices and final themes were reviewed and refined by LK, A Aballa, WN, and RM to ensure the accuracy and depth of the analysis.

Ethical Considerations

The study obtained approvals from Aga Khan University Institutional Scientific Ethics and Review Committee (reference number 2021/IERC-166(V2)), the University of Nairobi and the Kenyatta National Hospital Ethics Review Committee (reference number KNH-ERC/A/473), regulatory bodies including the National Commission for Science Technology and Innovation (778557) and the Nairobi County and Nairobi Metropolitan Services (SMS; reference number EOP/NMS/HS/167), and hospital administrators in each study site. The study was conducted in accordance with the Declaration of Helsinki and written and informed consent was obtained from all participants. The consent form provided information on the study objective, willingness to participate, data safety, and confidentiality. For qualitative interviews, the consent included exit interview procedures and consent to be audio recorded. All participant data were deidentified using study identifier and not individual names, and data were securely transferred to the institution server. Due to budget constraints in maintaining prepaid data packages in LMICs, participants were compensated (KSh 500 or US $3.58 equivalent) for the purchase of prepaid data packages that were needed to support timely synchronization. Qualitative participants were compensated (KSh 1000 or US $7.06 equivalent) for their time. All participants were able to keep the wearable device at the end of the study.

Results

Participant Characteristics

The participants were primarily female (70%), with 69% reporting attainment of a bachelor's or master's degree (Table 2). The median age of the participants was 32 (IQR 29 - 36) years, and nurses (47%) were the largest health care cadre. The median duration of employment in health care was 8 (IQR 5 - 12) years. The retention rate for the 30-day study duration was 98% (n=50). Characteristics of those who participated in the qualitative interviews are in Table 2 and Figure 1.

Figure 1. Enrollment flow of participants. Health care workers participated in a 30-day mixed methods pilot study to assess the feasibility and acceptability of using a mobile app and wearables to capture survey-based and passively sensed data in Kenya.

Feasibility of Mobile App and Wearable for Data Collection

The median time to complete the baseline questionnaire was 1 (IQR 1 - 2, range 1-11) day, from the date the link was received to submission. All participants (N=51) completed 100% of questions in the Risky Families Questionnaire, Generalized Anxiety Disorder-7, Patient Health Questionnaire-9, and PTSD assessments, while 92% (n=47) and 84.4% (n=42) completed all questions in the Neuroticism, Extraversion, Openness to experience Five-Factor Inventory and World Health Organization Alcohol, Smoking and Substance Involvement Screening Test assessment, respectively.

The wearable was worn for >10 hours on 63% of study days (n=50). Nearly all participants uploaded step (n=50), heart rate (n=46), and sleep (n=45) data within 5 days of receiving the wearable. On average, participants completed 58.4% of the daily mood questions over the 30 days. Data on steps, heart rate, and

XSL•FO
RenderX

sleep were uploaded on 92.6%, 76.6%, and 49.8% of the days, respectively. The average number of daily steps was 8180 (SD 4872).

To further characterize variability in adherence, we examined the median (IQR) and distribution of the number of days each participant submitted data (Table 3 and Multimedia Appendix 1). Approximately half of the participants submitted heart rate (n=26) and step count (n=31) data on all 30 study days, indicating higher adherence for these 2 passively collected metrics (Multimedia Appendix 1). In contrast, submissions for mood and sleep and the number of days with >10 hours of data (ie, wear time) were more variable across participants and across days. Histograms of the number of submission days show a more dispersed pattern for these measures; however, the distributions were not strongly skewed toward a small subset of highly adherent individuals.

Table . Completeness of longitudinal data (n=50)[a,b].

Variable	Days, median (IQR)
Wear time >10 hours	21 (13 - 28)
Steps	30 (28 - 30)
Heart rate	30 (18 - 30)
Sleep	15 (7 - 23)
Mood	18 (13 - 23)

[a]Participants enrolled in a 30-day mixed methods pilot study focused on the feasibility and acceptability of using a mobile app to track survey- and wearable-based data in mental health research among Kenyan health care workers.

[b]Completeness was based on the average number of days over the 30-day pilot that participants wore the wearable for >10 hours; uploaded any step, heart rate, and sleep data; and completed the daily mood question.

Acceptability of Mobile App and Wearable for Data Collection

Theme 1: Experiences With Study Protocols

Qualitative interviews with participants on baseline questionnaires and protocols elicited both negative and positive experiences. The participants had mixed perceptions of the administration of the baseline questionnaire. The positive experience was attributed to the questionnaire's simple language, questions interlinked, making it easy to follow through, and flexible to complete at one's convenience due to the online format, while the challenge was attributed to the questionnaire being lengthy and challenging to complete in one sitting.

> *The questions were simplified so they were easy to understand and of course relate... the questions tied to the study.* [Pharmacist]

> *I think the baseline survey was so long. I didn't finish at once. I'm guessing maybe I started when I was a bit busy, but it was long. I almost gave up.* [Facility 1, male medical officer]

Theme 2: Intrinsic and Extrinsic Motivation

Participants expressed that the wearable and MyDataHelps app significantly increased their awareness of personal health behaviors, such as steps taken, water intake (which was an optional feature), and sleep patterns. The wearable had additional metrics that could be activated by participants, but the study focused on heart rate, sleep, and activity rate. The wearable device encouraged goal setting and helped track progress, providing users with regular reminders and alerts to stay on track.

> *It has come in handy in terms of reminding me how many steps I have done in a day... it updates me when to take my water.* [Physiotherapist]

> *It actually made me cautious about my sleep patterns and sleep hygiene.* [Clinical officer]

Congratulatory messages and goal reminders from the app positively affected participants' motivation. Many felt encouraged by progress notifications, which fostered a sense of accomplishment and supported mental wellness. This motivation extended to family and social contexts, as some participants began to actively engage in physical activities with family members.

> *I can walk, and it tells me congratulations you've done this many during the day apart from checking my mood, it's also checking my health.* [Nurse]

Additionally, the app was reported to facilitate self-monitoring, primarily through mood-tracking and daily health prompts. Participants accepted the mobile app because of its ability to track their mood at the end of each day, which helped them reflect on their mental health.

> *This feature encouraged daily self-reflection, allowing users to evaluate their day and develop an awareness of patterns in their mood.* [Nurse]

The wearable was acceptable based on features such as water resistance, as well as the ability to keep power for a long time. The straps were found to be light and easy to wear throughout the day and night. These features were encouraging for participants to have the wearable on throughout the day and night with ease and comfort.

> *The good thing is it keeps power very well. I charge maybe once in every two weeks.* [Nurse]

> *When I realized it had a function of water lock then I decided that I will not be removing it at all, so when I'm going to shower, I activate water lock, so I have it all the time.*

> *[Nurse]*

XSL•FO
RenderX

Theme 3: Technical and Usability Challenges

Despite the value of wearable devices, 48% (10/21) of the participants reported challenges with wearable design and technical requirements. Continuous Bluetooth connectivity was necessary for data syncing, which participants found inconvenient, especially when forgetting to activate Bluetooth for extended periods, sometimes leading to data collection gaps.

> *The only thing is that if you're not online or not connected with Bluetooth, you might not be able to enter data.* [Nurse]

Participants recommended providing additional reminders and motivational prompts to ensure adherence to the study. Two participants expressed a desire for more color varieties for the straps and to receive a replacement if the wearable broke, as replacements were not provided in this pilot.

Most of the participants noted some discomfort sleeping with the wearable on their wrist to record their sleep patterns in the initial days, but this improved with time.

> *It felt uncomfortable, you had had the watch the whole day, and sometimes at night, I would try but would wake up and remove it(watch) because it just felt uncomfortable.* [Nurse]

> *Then being plastic sometimes just gets sort of uncomfortable. So, you'd want to change from one hand to another.* [Nurse]

Participants encountered technical challenges with the mobile app, primarily regarding the requirement for consistent internet and Bluetooth connectivity. The app required participants to log in daily at a set time, but limited internet data constrained consistent access, which could delay synchronization of data to the mobile app or lead to a missed daily prompt. Participants struggled with the Bluetooth connectivity for synchronization of data and wished that the app could only work with internet access to synchronize.

> *It's only that it won't synchronize data when either your battery is low.* [Nurse]

> *The only thing is that if you're not online or not connected with Bluetooth, you might not be able to enter data* [Nurse]

Recommendations were provided on simplifying the app's connectivity requirements to reduce the dependency on Bluetooth and facilitate prepaid mobile data packages. Suggestions included the possibility of offline functionality for data logging, which could sync automatically when internet access is restored.

> *Bluetooth is necessary for pairing, but I wish it was not required. Just the bundle would have been enough because most of the time you realize you are online on your phone but using Bluetooth is a habit that most of us do not have.* [Clinical officer]

Discussion

Principal Findings

This pilot study supports the feasibility of deploying mental health surveys, collecting data through wearables, and integrating wearable and survey data within a single mobile platform under real-world infrastructure constraints among Kenyan HCWs. Participant retention and completion of the initial questionnaire were high, indicating strong initial engagement and comfort reporting on mental health symptoms. Daily adherence was moderate; approximately half of the participants submitted heart rate and step count data on all 30 study days, while mood, steps, and wear time (≥10 h/d) were more variable across participants and over time. Sleep data were only captured on about half of all study days. Together, these metrics suggest that while continuous daily engagement was not fully achieved, the high retention and collection of multidimensional data support that these technologies are logistically viable in similar LMIC settings. Moreover, participants reported largely positive experiences with the platform, especially appreciating the self-monitoring aspect and feedback features, further supporting the feasibility and acceptability of this approach.

Mental health research in HCWs is critical to identifying and reducing stress, burnout, and psychological harm in those who care for others, which in turn improves worker well-being and patient care. This pilot study revealed that HCWs were willing to provide sensitive mental health information, such as depression, anxiety, posttraumatic stress disorder, and substance use, within a day of enrollment. Studies in Africa have highlighted that the absence of native terminology for mental health and the existence of unwritten nondisclosure norms make it difficult to openly initiate conversations about mental health [32]. Willingness to provide sensitive information on mental health is a critical step in identifying people at risk for mental health disorders. In this pilot, the web-based mode of administration and the preenrollment sensitization process, which helped build rapport between the study team and participants while addressing their concerns and questions about data confidentiality, may have mitigated some stigma-related barriers to disclosure as other studies have suggested [33,34].

The use of wearables in mental health research to infer, monitor, and predict changes in health states over time is an emerging area. On average, studies that have used wearables to collect data among HCWs with small sample sizes or shorter duration of data collection have reported a retention rate of 83% - 98% [35,36], which aligns with the retention rate in this pilot. In our study, participants reported that motivation to know their health information was a contributor to high retention, and other studies have shown motivational support to be a contributor in reducing attrition [37]. In addition, all 51 participants completed the baseline questionnaire, a rate that was 2 times higher than a similar study conducted in the United States where the completion rate was 48% [38]. The differences could be due to the varied recruitment approaches. Unlike the US-based study that used a mainly monetary incentive-driven approach to recruit participants, our study used a multipronged recruitment

XSL•FO
RenderX

approach, including increased physical contact through sensitization, where we had one-on-one discussions with participants as opposed to sharing information via email or website, which could be more impersonal reimbursement for internet connectivity, email, and phone notifications. Similar studies have reported that adopting such a comprehensive approach during recruitment of participants for web-based surveys leads to better engagement [39].

In terms of adherence to daily data collection, our findings are consistent with results from similar digital health studies in both low- and high-income settings. For example, a 5-day pilot in Uganda reported high compliance with wearable use and daily diary completion, despite challenges with comfort during sleep [40]. Similarly, a 3-week study in rural Kenya demonstrated high step and sleep data completeness, but limited heart rate data availability [41]. The wear time observed in our study (63% of days with over 10 h of usage) is within the typical range of 50% - 70% reported in free-living environments [30]. Additionally, mood surveys were completed on two-thirds of the days, which is encouraging given the known challenges of sustaining engagement in digital health monitoring. For example, the average 30-day retention rates for mobile apps in general are less than 6% [42,43]. Collectively, these findings highlight the feasibility of digital monitoring among HCWs in LMICs.

Several barriers likely contributed to moderate adherence to the daily data collection, particularly for sleep and daily mood entries. Participants cited discomfort wearing the device overnight, contributing to reduced sleep data availability. Similar issues have been documented in other wearable studies [40,41] and highlight the importance of comfort for extended wear. Technical challenges with the wearable included instances where the device was accidentally switched from wrist mode to clip mode, which turns off sleep monitoring. Participants were guided on how to check if the wearable was in wrist mode during the initial onboarding to minimize potential data loss. However, this is an important consideration for future studies that leverage wearable devices with the functionality to switch modes. Regarding daily mood, reporting may have been impacted by notification delivery failures. Push notifications relied on continuous internet access, which was not always available. Interestingly, studies reporting higher adherence to daily mood diaries have reported using SMS as opposed to push notifications [44], which may circumvent the need for Wi-Fi. Participants also reported forgetfulness, competing work demands, and survey fatigue, which are consistent with prior research indicating that survey delivery mode, timing, and user workload influence daily self-report adherence [40,45]

Despite these challenges, our findings suggest strong participant engagement. Qualitative feedback revealed largely positive perceptions about using the mobile app and wearable device. Many participants appreciated tracking their health metrics and receiving motivational messages (eg, congratulatory prompts for meeting step count goals), indicating that these features likely enhanced engagement. Future studies that use wearables in mental health research may need to consider that beyond serving as an assessment tool, the wearable itself may also influence participant behavior. Increased awareness of sleep patterns and physical activity may motivate behavior change, which may function as an unintended intervention and potentially confer mental health benefits.

Limitations

The study was conducted on a small sample size, which is appropriate for a pilot study, but limits our ability to detect subgroup or temporal comparisons. In addition, the population was limited to 4 urban hospitals with an overrepresentation of nurses, which may limit the generalizability of the findings to rural areas and other cadres. In addition, the trial duration was only 1 month, which captures feasibility in the short term, but adherence patterns might change over longer periods. It remains unclear whether participants would continue using the app and wearable for an extended period of time (eg, months). Qualitative feedback was obtained from a subset of participants who completed the study; those who had more difficulties might have been less likely to participate in the interviews, potentially leading to a positive bias in qualitative results. Collectively, this pilot focused on the practical ability to deploy surveys, sustain device wear, and synchronize wearable data under real-world infrastructure constraints, rather than on deriving clinically interpretable mental health metrics such as heart rate variability or complete daily physical activity profiles, which were beyond the scope of this pilot. Future studies are warranted to better link wearable-derived measures with mental health outcomes and to evaluate clinically interpretable metrics in larger, more comprehensive studies. Despite these limitations, the study provides valuable preliminary evidence to inform the scaling of similar digital mental health studies in HCWs in LMICs.

Conclusion

This pilot study provides justification for the use of a mobile app and wearable in mental health research in LMICs. The high survey completion rate and study retention, as well as qualitative acceptability, reflect strong engagement and suggest that such technologies are logistically viable in similar contexts. Future studies looking to scale similar approaches should consider enhancing prompts, improving device comfort, and ensuring reliable internet connectivity or finding an alternative solution.

Abstract

Background: Palliative care is a key component of comprehensive humanitarian health; yet, access and service capacity remain limited in displacement settings, where fragile health systems struggle to meet the complex needs of people living with advanced illness. Digital health technologies have the potential to enhance the reach and delivery of palliative care; yet, their feasibility and acceptability in humanitarian settings remain underexplored.

Objective: We evaluated the feasibility and acceptability of mPallCare, a mobile health intervention integrating patient-reported symptom and outcome monitoring with a clinician dashboard, to support palliative care delivery in the Bidibidi Refugee Settlement, Uganda.

Methods: A 6-week, uncontrolled, exploratory concurrent mixed methods feasibility study was conducted, involving 32 participants with advanced cancer. Community health workers (ie, village health teams) used the mobile app to document patient-reported symptoms and multidimensional outcomes, which were accessible to clinical teams via a dashboard. Following the use of mPallCare, patient and clinical team participants participated in face-to-face interviews. Data collected via mPallCare were analyzed using descriptive statistics to assess feasibility (ie, compliance with reporting, with a feasibility threshold of ≥65% of scheduled reports), and interview data from a subsample of patient and clinical team participants were analyzed using framework analysis to assess acceptability.

Results: Participants completed 84.9% (163/192) of symptom reports and 59.4% (266/448) of outcome reports, with a combined 67% (429/640) of all scheduled reports completed. A modest decline in engagement with report submissions occurred across the 6-week study period. Commonly reported symptoms included headache (27/32, 84.4%), muscle pain (27/32, 84.4%), and dizziness (26/32, 81.3%). Interview findings indicated strong acceptability among patients and clinicians, who described improved communication, enhanced symptom management, and greater continuity of care. Reported challenges included initial navigation difficulties, limited translation accuracy, and technical synchronization issues. Participants and clinical leaders identified the

XSL•FO
RenderX

potential for integrating mPallCare within Uganda's district health information system to strengthen data use and visibility of palliative care within health reporting structures.

Conclusions: mPallCare is a feasible and acceptable digital health intervention for palliative care in a humanitarian setting. While initial uptake was high, sustaining engagement over time may require simplified reporting processes, enhanced language accessibility, and optimizing the mobile app's connectivity and usability. This feasibility phase highlights key priorities for scale-up, including integration with existing health information systems and adaptation for sustained, equitable use across low-resource and displaced populations.

KEYWORDS

digital health; palliative care; mobile health; humanitarian settings; refugee health

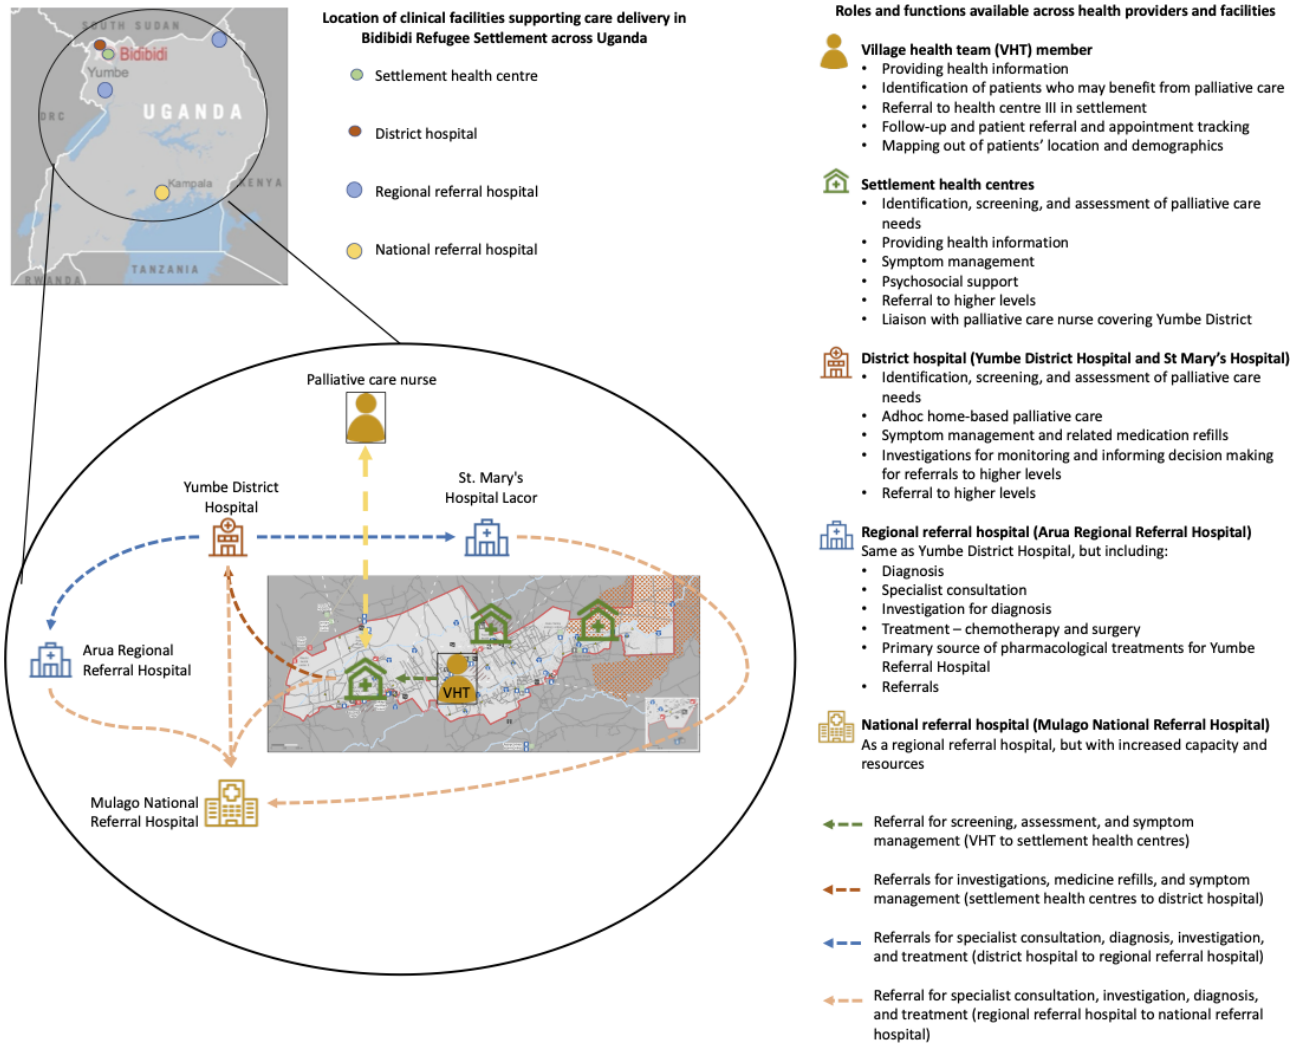
Introduction

Globally, record numbers of people are living in displacement from natural and man-made disasters, leading to an increase in humanitarian and fragile settings [1]. Refugees' and migrants' experiences in their origin country, alongside their migration journey and subsequent entry to a host country, can influence physical and mental health needs [2]. Humanitarian settings are further associated with higher mortality and morbidity than the general population [1,3,4], alongside high levels of mental health conditions that can further negatively affect health outcomes [1]. These conditions, by the nature of their disease course, require long-term engagement through management, promotion, and prevention, alongside treatment, rehabilitation, and an integrated palliative care approach [5]. In practice, however, humanitarian agencies in emergencies often focus on "lifesaving" interventions, with little consideration for preventative, curative, or palliative measures for conditions not regarded as immediately life-threatening [6,7]. This apparent dichotomy in service provision means people living with advancing conditions endure suffering, with some referred to as the "expectant" (ie, expected to die, without any form of palliation or end-of-life care) [7,8]. This directly contravenes humanitarian principles, which explicitly require the prevention and alleviation of human suffering [9]. Moreover, displacement settings of all types have increasingly taken on some form of semipermanence, with marginal prospects for pathways to resolution, leaving millions of people spending many years to decades living in these conditions [10].

There is a crucial need to integrate palliative care into both emergency responses and as part of care delivery for people living in humanitarian and fragile settings [11]. Although the need for health services research in humanitarian settings remains significant [12], a paucity of data remains due to the unique and sometimes dangerous nature of humanitarian aid settings, a lack of familiarity by many academics, and the fact that research is often not a key priority for humanitarian organizations [1]. An emerging research area is the role of digital technologies, which are becoming a pivotal part of humanitarian responses, providing access to often limited and critical support in the context of crises. Digital tools are being increasingly used to address persistent challenges in the humanitarian sector, such as inclusion [13]. For palliative care in low-resource settings, digital technologies can provide a means of augmenting care and providing timely data to inform clinical and policymaker decision-making. To enhance care continuity, innovative digital health technologies can be leveraged in humanitarian crises and displaced populations [14] to support key tenets of palliative care delivery, including information sharing, decision-making, and communication [15]. Digital health approaches are common across palliative care providers [16], can improve service delivery around components such as pain management [17], and are acceptable across key stakeholders that include patients, caregivers, health and care professionals, and policymakers [18]. Digital health approaches, such as remote symptom monitoring, are also increasing across low-resource settings to support palliative care delivery [19].

This study arises from a research program focused on developing digital health for palliative care in sub-Saharan Africa. This study was initiated during the COVID-19 pandemic, when physical distancing was required to reduce transmission and digital approaches were encouraged in humanitarian settings [20]. A consortium of key care delivery actors in Uganda and the wider Africa region was involved, including the African Palliative Care Association (APCA), the United Nations Refugee Agency, the International Rescue Committee, and national and local care delivery organizations supporting palliative care. This study aimed to determine the feasibility and acceptability of a mobile phone app and clinician dashboard to support remote monitoring of the symptoms and outcomes of patients receiving palliative care. We present the findings of this novel digital health approach and lessons from its pilot testing to support palliative care delivery in the Bidibidi Refugee Settlement in Uganda.

Methods



Overview

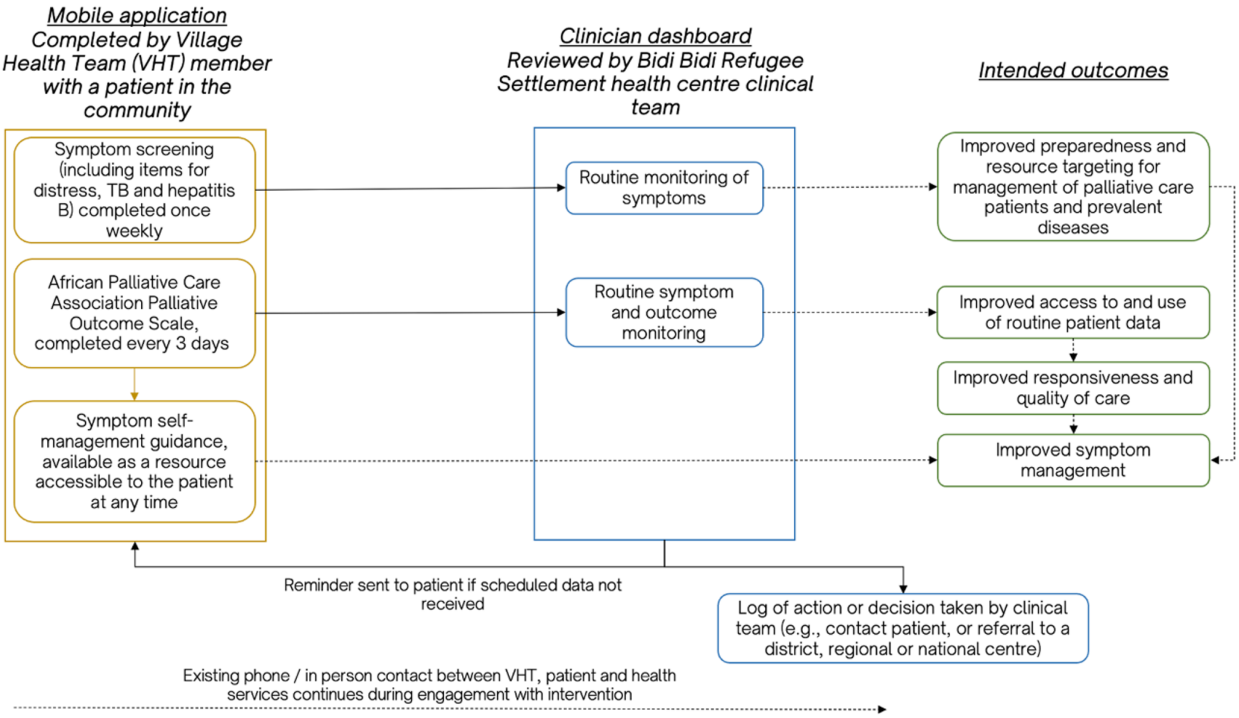
An uncontrolled, 6-week, exploratory concurrent mixed methods pilot feasibility and acceptability study was conducted, supplementing existing palliative care delivery in the Bidibidi Refugee Settlement. This design enabled complementary insights: quantitative findings identified patterns of engagement, while qualitative data explained underlying reasons and contextual influences. Uganda hosts one of the largest refugee populations globally, hosting more than 1.74 million refugees and asylum-seekers [21]. Most refugees come from South Sudan and the Democratic Republic of the Congo [21]. Bidibidi Refugee Settlement covers more than 250 km^2 and is the largest settlement in the country, hosting more than 246,000 refugees

XSL•FO
RenderX

across 5 areas, or zones, with a large majority of the population comprising women and children. Palliative care delivery within the settlement is currently overseen by one palliative care nurse based at a former district hospital (now regional referral hospital) in the nearest town, Yumbe (Figure 1). The palliative care nurse liaises with village health team (VHT) members and health care providers across the settlement. VHTs comprise community volunteers who help refugees and other community members access health services through, for example, providing health information and serving as a link between the village and health services. VHTs support palliative care delivery by identifying people with palliative care needs in the community and facilitating their access to care, in liaison with facility-based health workers in the settlement and the palliative care nurse. Opioid analgesics, including oral morphine, are available through the clinical teams within the settlement with palliative care nurse oversight. The structure of service delivery and referral relationships is summarized in Figure 1.

Figure 1. A schematic outlining the role of the village health team in identifying and supporting patients receiving palliative care in liaison with a palliative care nurse who supports referrals to a range of services available across various facilities, reflecting provision at the time of the study, with Yumbe District Hospital now a referral hospital with a hospital-based palliative care unit.

Intervention Development



The study is positioned within the first 2 stages of the Medical Research Council Framework for the Development and Testing of Complex Interventions [22], that is, to develop a novel intervention and to determine its feasibility and potential effectiveness in humanitarian settings. The project team included applied health researchers (University of Leeds, Makerere University, and Palliative Care Education and Research Consortium), APCA, palliative care providers (New Life Hospice, Yumbe Regional Referral Hospital Palliative Care Unit, and National South Sudan Palliative Care Association), a patient advocacy organization (the Uganda Cancer Society), and a digital technology company (Universal Doctors).

An initial platform structure using a mobile phone app and clinician dashboard was developed following guidelines for digital health use in palliative care in Africa previously developed by the team (Figure 2) [18]. This included the need to support reporting on physical, psychological, social, spiritual and practical symptoms, the provision of information about living with illness and enabling communication with palliative care services [18]. The resulting platform gathers patient-level symptom and outcome data via the mobile phone app, in addition to providing access to self-management guidance and support (ie, guidance on the management of common symptoms using both video- and text-based content). This approach is underpinned by evidence highlighting that routine symptom

XSL•FO
RenderX

and outcome monitoring and the provision of self-management resources can improve symptom management and quality of care delivery for people with palliative care needs [23,24].

Figure 2. Schematic to show the structure of the mobile phone app and dashboard discussed with key stakeholders, alongside preliminary hypothesized and intended outcomes.

To refine and finalize the digital health approach, an advisory group was formed and consulted. The group was facilitated by the APCA and included clinic staff from New Life Hospice and Yumbe Regional Referral Hospital Palliative Care Unit, Ministry of Health representatives, global health security and infectious disease experts from the Infectious Diseases Institute in Uganda, patient representatives supported by the Uganda Cancer Society, and gender, diversity, and inclusion experts. During a stakeholders workshop in Yumbe District, Uganda, and hosted by the APCA, the following topics were discussed: alignment of the intervention and its content with the refugee population, review and development of symptom and outcome measures that could be collected via the mobile phone app, and developing an implementation plan that built on and strengthened existing activity, while ensuring alignment with the Uganda Health Sector Integrated Refugee Response Plan [25]. The Refugee Response Plan recognizes the need for parallel provision of services across refugee and host communities, highlighting health technologies and health information as key pillars in developing health care for refugee populations. Following the meeting, the intervention was refined, with the symptom checklist expanded to ensure the inclusion of symptoms indicative of tuberculosis and hepatitis B, both prevalent in the settlement. Furthermore, options for the inclusion of symptom and outcome scales were discussed, including which items would be included in the mobile phone app, balancing established protocols for using the tools and existing workflows of VHTs in the community setting.

The mPallCare Intervention

mPallCare comprises 2 components: a mobile phone app to gather patient-reported data that is completed by a VHT member (ie, a volunteer community health worker) from the settlement clinical team, and a web-based clinical dashboard that displays the data gathered from the mobile app for clinical teams (as shown in Figure 2). Together, using the mobile app, a VHT and patient complete 2 forms: a symptom screening questionnaire and a multidimensional outcome measure designed for palliative care in Africa [26]. The symptom screening questionnaire was developed during the advisory group workshop and included symptoms commonly reported by patients receiving palliative care (eg, pain, dyspnea, nausea, and vomiting). Items also included symptoms indicative of COVID-19, 4 symptom screening items for tuberculosis as recommended by the World Health Organization [27], and 2 items related to symptoms that could be suggestive of hepatitis B (ie, clay-colored stools and yellowing of the skin; refer to Multimedia Appendix 1 for symptom screening items). Respondents were asked to respond (yes or no) to a total of 17 items, reporting whether they had been present over the previous week. The multidimensional outcome scale used is the APCA Palliative Outcome Scale (POS) [26], which assesses key palliative care domains using numeric rating scales. It includes 7 patient-focused questions that include the following:

1. Pain: captured using a scale (0=not at all; 5=overwhelmingly)
2. Other symptoms: “Have you been affected by other symptoms (such as nausea, breathlessness, etc)?" (0=not at all; 5=overwhelmingly)

XSL•FO
RenderX

3. Concern: Have you been feeling worried about your illness in the past 3 days? (0=not at all; 5=overwhelming worry)
4. Feelings: Over the past 3 days, have you been able to share how you are feeling with your family or friends? (0=not at all; 5=yes, I've talked freely)
5. Life: Over the past 3 days, have you felt that life was worthwhile? (0=no, not at all; 5=yes, all the time)
6. Peace: Over the past 3 days, have you felt at peace? (0=no, not at all; 5=yes, all the time)
7. Advice: Have you had enough help and advice for your family to plan for the future? (0=not at all; 5=as much as wanted)

Data reported via the mobile app are then displayed on a clinical dashboard, enabling a settlement clinical team to monitor patient symptoms and outcomes routinely, determine any changes or problematic symptoms, and devise an appropriate response plan. This may involve coordinating with external palliative care specialists located beyond the settlements to ensure comprehensive cancer care. The symptom and outcome reports were available in the mobile phone app in 4 languages (English, French, Swahili, and Juba Arabic), developed through forward and backward translation by professional translation services in Uganda. Aligned with Figure 2, this approach seeks to support the timely identification and management of symptoms and issues, as well as inform the coordination of, and referrals to, additional services and clinical sites when needed. This may potentially influence reductions in any symptom burden experienced by patients, as well as increase coordination and care continuity.

mPallCare also includes self-management resources developed by the research team, including an expert in physical activity in advanced disease (SB). Text- and graphic-based self-management content was developed for pain (eg, managing medications, relaxation, and distraction; adapted for the context from earlier work by the team) [28], breathlessness, fatigue and energy, and mobility. Following the submission of symptom and outcome reports using the mobile phone app, self-management related to any reported symptoms is displayed (eg, reporting pain displays pain self-management information). However, patients and health workers could access self-management information for all symptoms at any time as a standalone resource within the mobile phone app. Once reports are submitted, the data are available immediately via the clinic dashboard. The dashboard presents individual lines for each patient report received, with a flag system (ie, a red flag placed next to a patient report on the main dashboard) where any symptom or outcome item has been reported. Any member of the clinical team can review a report submitted by a VHT. On reviewing a report, the clinical team member is asked to detail what action they will take (ie, contact the patient, speak to a colleague, or do nothing), and there is space to add additional notes. This feature was included to enable other clinic team members to understand actions in response to reviewing a report.

A strong focus was placed on the user-friendliness of the graphic interface on the mobile phone app by the software developers. The technical requirements of the mobile phone app were devised around the setting in which its use was intended and made available for an Android smartphone with Android OS 4.0.3 or above. A secure server was set up to receive data reported via the mobile phone app. A web-based backend was developed to allow the clinical team members to log in and view the data submitted. All patient data submitted was deidentified before analysis to protect privacy and confidentiality.

Study Design

The mixed methods study sought to determine the feasibility of collecting palliative care patient-reported outcome data and symptomatology mapping, alongside qualitative investigation of the acceptability of the intervention to target users.

Sample

Participants were selected using a purposive convenience sampling approach, with all eligible patients on existing palliative care lists invited consecutively until the target sample was reached. The most proximate entry point of care for patients receiving palliative care in Bidibidi Refugee Settlement was from the camp-based health facilities via the Arua Regional Referral Hospital. From the hospital, patients are typically referred to New Life Hospice (based in Arua, Uganda) or Yumbe Regional Referral Hospital palliative care unit. We noted that it was common for New Life Hospice to screen camp-based patients from Bidibidi Refugee Settlement who were then referred to Yumbe Regional Referral Hospital palliative care unit, which is closer to their residence. Eligible participants were identified collaboratively with the incumbent health service provider (International Rescue Committee) from existing patient lists of those receiving care, generating an initial list of 32 eligible camp-based patients on the palliative care program from the 2 services, including both refugees and displaced Ugandan nationals. Both refugees and Ugandan nationals were included to reflect the integrated service delivery model operating across settlement and host communities, consistent with Uganda's national policy promoting equitable access to health services. This approach aligns with broader strategic frameworks developed by the United Na Country Team in Uganda and the Ministry of Health to strengthen integration between host and refugee populations and promote peaceful coexistence. This list was continually updated during the recruitment period to account for attrition through patient deaths or relocation from the settlement. The eligibility criteria used to generate the list are outlined in Textbox 1. The final sample of 32 participants reflects all patient participants approached who met the criteria and consented during the recruitment period.

XSL•FO
RenderX

Textbox 1. Eligibility criteria for patient study participants.

Inclusion criteria

- Aged 18 years or older
- South Sudanese or Ugandan nationals
- Receiving hospice care or palliative care from Arua Regional Referral Hospital, Yumbe District Hospital, or New Life Hospice
- Living with advanced cancer, defined as those with metastatic cancer (where, if possible, determined through histological, cytological, or radiological evidence) and/or receiving anticancer therapy with palliative intent
- Estimation of expected prognosis between 3 and 12 months
- Able to read and understand one of the languages available on the mobile phone app (ie, English, French, Swahili, or Juba Arabic) or have a carer who can read and understand one of the languages available
- Able to provide informed consent to participate and have sufficient cognitive ability to provide informed consent

Exclusion criteria

- Patients who are too ill to endure study procedures
- Dyads with visual impairments who are unable to read screen-based information
- Patients who may wish to return to their home countries over the next 3 months

Procedure

Before the commencement of patient enrollment, a training session was delivered for VHTs in May 2022. VHTs were provided with training manuals developed to support navigation and use of the mobile phone app, and an in-person training session took place. The training was attended by representatives from the regional referral hospital, the district health office, the Ministry of Health of Uganda and the Office of the United Nations High Commissioner for Refugees to ensure awareness of the project and commitment to its delivery. The care team for the settlement approached potential participants and generated a list of people who agreed to participate in the study. VHTs supporting participants across the different zones in the settlement attended the training session ahead of the study commencement. In total, 20 VHTs were trained on the study objectives, ethical principles (confidentiality and informed consent), procedures for administering symptom and outcome tools, and step-by-step use of the mPallCare app (research team of the University of Leeds, African Palliative Care Association, and UniversalDoctor) and dashboard. An IT specialist from the APCA led practical sessions that included simulated data entry (ie, using the app for submitting the patient outcome and symptom reports), troubleshooting exercises, and accessing self-management symptom guidance. From the training, it was highlighted that there was a risk that devices provided for the study could be at risk of being stolen, so they were retained in health centers rather than VHT homes when they were not being used. VHTs also requested a paper copy of the self-management resources, which were provided for the study. During the training, the initial list of identified patients was discussed and confirmed in partnership with representatives from Yumbe District Hospital, the International Rescue Committee, Arua Regional Referral Hospital, and New Life Hospice. Initial testing focused on advanced cancer, a common disease group in populations in refugee settlements in Uganda, alongside chronic hepatitis B, diabetes, severe injuries, and sickle cell anemia [29].

Following training, VHTs supported the identification and recruitment of eligible patients. Active recruitment and enrollment of patients took place between August and October 2022. VHTs worked with clinical teams to review health facility patient lists to identify those who met the eligibility criteria. Where eligible patients were identified, a VHT discussed the study, what participation entailed, potential risks and benefits of participation, and the process of data flow from the mobile phone app to the clinic, including where data are stored. If the patient agreed to participate, consent was obtained with a signature or thumbprint. We sought to recruit between 30 and 35 patients receiving palliative care, aligned with sample size requirements for feasibility studies [30]. For those who enrolled in the study, a baseline demographic questionnaire was completed capturing a participant's age, gender, highest level of education, home location (zone and block or TIN number), primary diagnosis, family size, Demographic and Health Surveys measure of socioeconomic status [31], and whether the patient had access to a mobile phone (as a proxy for familiarity with digital devices and to determine the future feasibility of patient-reported data). The Eastern Cooperative Oncology Group Scale of Performance Status [32] is also captured at this point, which describes a person's functional status based on their capacity for self-care, engagement in daily activities, and physical capabilities such as walking and working. A grade is provided from 0 (fully active, able to carry on all predisease performance without restriction) to 5 (dead), with graduated levels of function between the two values. Responses to the baseline demographic questionnaire were recorded by VHTs using a purpose-designed Microsoft Excel spreadsheet with logic and consistency checks to reduce errors.

Following the capture of sociodemographic information, the VHT worked through both the outcome and symptom reports with a patient. Following initial completion, it was expected that a VHT would complete 1 symptom report per week for each patient over the 6-week study period (6 reports×32 participants=192 expected symptom reports) and 1 outcome

XSL•FO
RenderX

report every 3 days (approximately 14 reports×32 participants=448 expected outcome reports). In total, 640 reports were planned across the study period. VHTs visited patients every 3 days to complete and update the outcome report, and once weekly to complete the symptom screening report for up to 6 weeks. During the study period, an IT specialist from the APCA monitored registrations of new patient participants to ensure active recruitment and responded to any queries related to device functionality and data synchronization.

Following the completion of 6 weeks of reporting, clinical officers from Bidibidi Refugee Settlement who were members of the research team (RR, NM, or TM; all male) conducted semistructured face-to-face interviews with patient participants at their homes. The semistructured format allowed for consistent coverage of key areas—such as patient participants' experience of completing reports with VHTs, exploring the perception of how data would be used, and any perceived influence it had on the care they received. Interviewers remained flexible around the presence of family members and caregivers during interviews. An interpretivist paradigm was deemed the most suitable approach to the qualitative component of the study, due to the nature of the exploration of feasibility and acceptability and the necessity of understanding individual experiences of mPallCare from the viewpoint of those who interacted and used the platform. This perspective emphasizes the significance of subjective interpretations, personal perceptions, and the meanings individuals attribute to their experiences [33].

A purposive sampling strategy was used to ensure representation of patient participants with diverse demographic and clinical characteristics relevant to the study aims, drawn purposively from the same feasibility cohort. We sought to capture variation across age and diagnoses (ie, different cancer types) in a subsample of 10 patients. We sought to understand their experience of the mobile phone app being used to obtain symptom and outcome data. Alongside patient interviews, clinical staff and VHTs involved at each site (n=10) were purposively sampled by site (geographic zones within the Bidibidi Refugee Settlement) and role (ie, VHT, clinical officer, and nurse) and participated in face-to-face interviews to explore their views of how the app had supported patient care and the experience of its implementation in routine care. Our sampling approach did not seek to achieve data saturation but rather capture a breadth of perspectives that could provide practical insights into user experience and inform future implementation and scale-up. This approach focused on identifying variation and key issues influencing acceptability and feasibility. Interviews were conducted by a female member of the research team with specialist palliative care clinical expertise and undertaking an MSc in Palliative Medicine (LN). Patient and clinical staff participants were not known to the research team. The research team members were fluent in the languages used during interviews. All interviews were audio-recorded and transcribed verbatim in the language used, then translated into English where required by the researcher who conducted the interview and included in parentheses alongside the original transcription. Transcripts were then checked against audio files by a second member of the research team involved in conducting interviews to ensure accuracy in the translation and transcription.

Analysis

All statistical analyses were conducted in SPSS (version 28.0; IBM Corp). Descriptive statistics were run on the demographic and clinical characteristics of the individuals who completed outcome and symptom reports. Compliance with the outcome and symptom reporting protocol was reported in terms of completed reports. Graphical representations were developed to chart app usage over the 6 weeks. Individual mean scores were calculated, as well as a grand mean for each outcome variable. The change in the outcome measures of Concern, Feelings, Life, Peace, and Advice was charted over time. Feasibility is defined as participants completing ≥65% of scheduled reports, reflecting a pragmatic, context-appropriate target informed by prior studies reporting completion rates between 60% and 80% in studies adopting digital health approaches in the collection of patient-reported outcomes for palliative care populations: for example, completion rates of 58% for weekly patient-reported online questionnaires [34], 73% for mobile phone–based data capture [35], and 78.4% of outcomes data via a patient portal [36]. While there are no comparable studies in the context of humanitarian settings, the conservative threshold reflects broader digital health implementation challenges common in the context of humanitarian settings [37], including availability, access, affordability, and rights. Acceptability of the intervention was explored through both patient and clinical team interviews on the experience of using the mPallCare over the study period.

Interview transcripts from patient and clinical staff were imported into NVivo 12 (QSR International) for framework analysis [38]. This approach guided a structured, transparent, and systematic comparison across participant groups while remaining grounded in participants' accounts. The framework approach also enabled the organization of data around predefined domains of interest (ie, usability, communication, and integration with care) while permitting the inductive identification of emergent themes reflecting user experience and contextual factors. MA and AA analyzed the interview transcripts. Separate analyses were undertaken for transcripts derived from patient interviews and those completed with clinical team staff and VHTs. For both sets of data, the same approach was adopted. A coding frame was developed using both deductive and inductive approaches, with an initial framework developed from a selection of 4 transcripts. For both, these were selected to ensure variation in the clinical sites and participants (for patients, varying by sex and age, and for clinical team members by role). The developed frameworks were discussed and, where necessary, adapted by the wider team, after which the remainder of the transcripts were analyzed. Where differences or uncertainty arose, these were discussed with the wider team. Comparative analysis in the patient and clinical team frameworks enabled common themes to be identified, as well as sample divergences. Illustrative quotes are reported for each theme, alongside the study participant ID and site, to demonstrate reporting from across the sample breadth.

Ethical Considerations

The protocol, interview guide, and consent materials were reviewed and approved by the Hospice Africa Uganda Research

XSL•FO
RenderX

Ethics Committee (reference HAU-2021‐4) and complied with the principles outlined in the Declaration of Helsinki. All study participants received verbal and written information about the study objectives, procedures, potential risks, and their right to withdraw at any time without consequence to their care. For participants with limited literacy, consent was read aloud in their preferred language and consent was recorded through signature or thumbprint. All data were deidentified prior to analysis, stored on encrypted servers, and accessible only to the research team. No financial compensation was provided to participants. The paper has been compiled in accordance with the COREQ (Consolidated Criteria for Reporting Qualitative Research; Checklist 1), ensuring transparency and completeness in the reporting of study design, conduct, and analysis.

Results

Overview

In total, 32 participants with advanced cancer took part, with the majority of these being female (n=19, 59.4%), Christian (n=19, 59.4%), and married (n=17, 53.1%). The ages of the participants ranged from 18 to 77 years, with an average of 48.5 (SD 16.9) years. The primary caregiver was most often their spouse (n=16, 50%), but children and parents were also commonly reported. Most participants also did not have access to a mobile phone (n=18, 56.3%). An initial list of participants comprising camp-based patients on the palliative care program included additional participants to accommodate challenges in recruitment. Participants initially identified on the list included those who died (n=6) and those who left the settlement (n=4) before study commencement. A breakdown of the demographic and clinical characteristics of the participants can be found in Table 1.

Table . Demographic and clinical characteristics (N=32).

Variables	Values
Age (y), mean (SD)	48.5 (16.9)

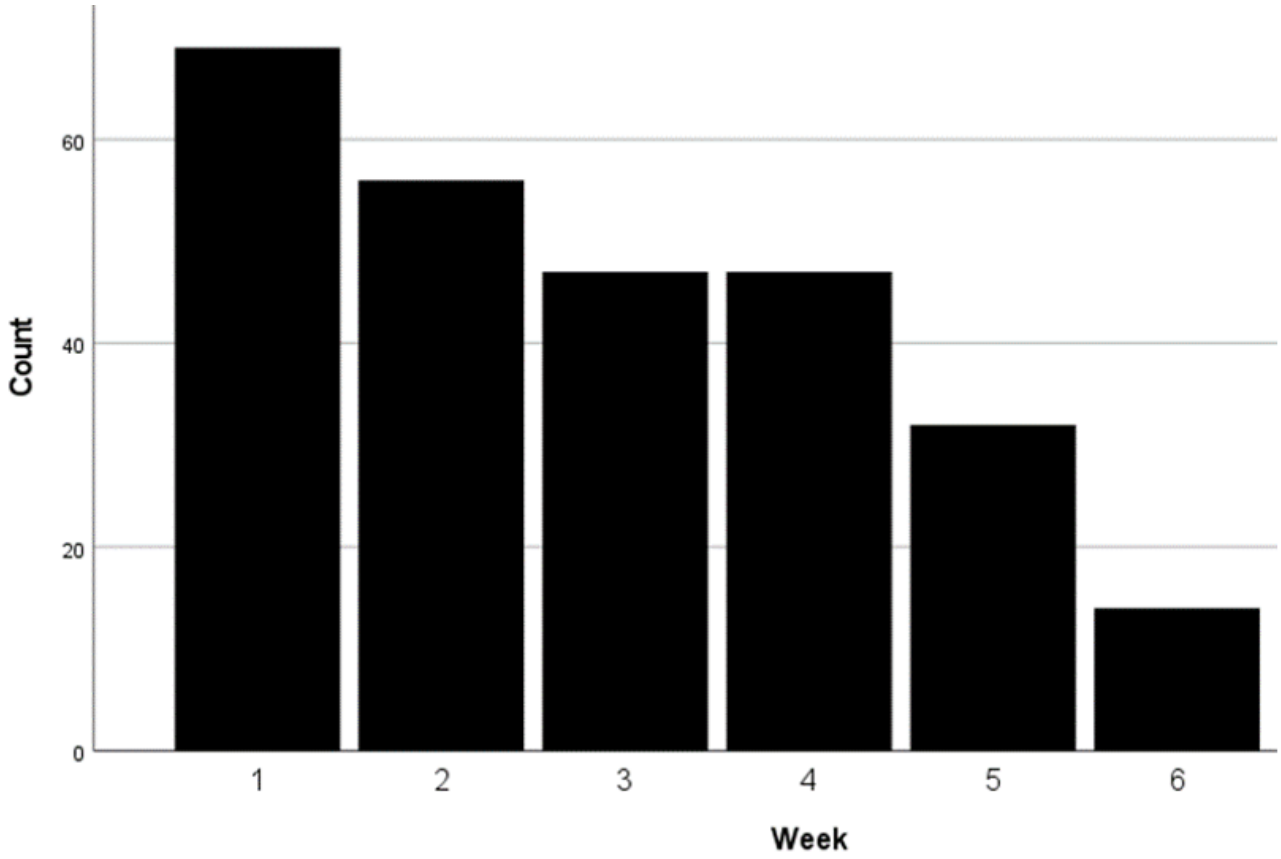
Outcome and Symptom Report Data

All patient participants (N=32) completed symptom and outcome reports. From a total of 192 possible symptom reports (32 participants × 6 time points), participants completed 163 reports (84.9%), an average of 5.1 reports per participant, with a range of 2 to 11 reports. From a total of 448 possible outcome reports (32 participants × 14 time points), participants completed 266 reports (59.4%), an average of 8.3 reports per person, with a range of 3 to 13 reports. In total, a combined 67% (429/640) of all scheduled reports were completed.

Figure 3 presents the frequency of responses from participants over the course of the study, which shows that as the study progressed, responses declined. Detailed findings from patient and clinical team interviews are provided below. Decline in engagement was reported relating to practical and technical barriers. Early difficulties with navigation and translation occasionally delayed data entry, and intermittent connectivity and dashboard errors resulted in missing or repeated reports. VHTs also described periods when device availability or competing health outreach duties limited the frequency of visits to patients. Collectively, operational factors may have contributed to the reduced number of submissions observed toward the end of the study.

Figure 3. Frequency of responses submitted via the patient mobile phone app across the 6-week study period.



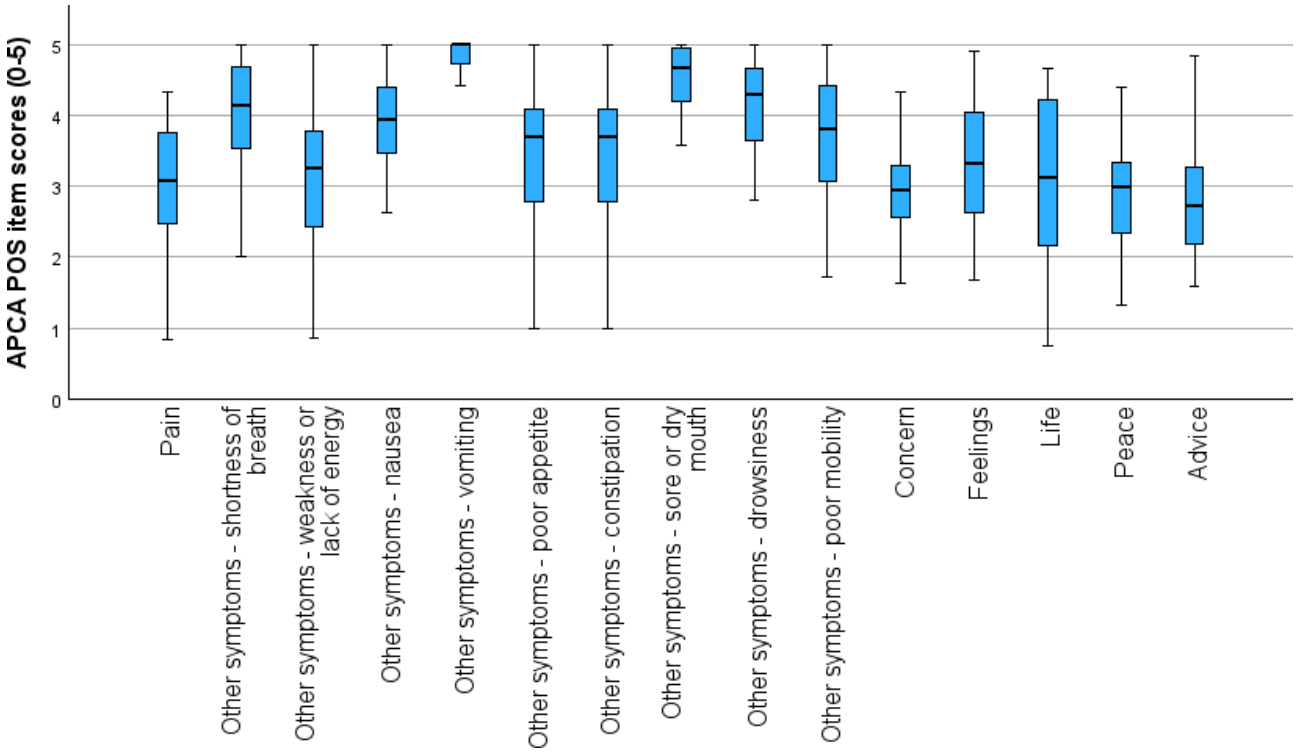


Figure 4 presents the individual mean scores of each outcome measure across the study period. The symptoms of vomiting, sore or dry mouth, and drowsiness had the highest scores, whereas the symptoms of weakness or lack of energy, constipation, and poor appetite had the lowest symptom scores, although these also had a wider range of scores. The scores for the measures for Feelings, Concern, Life, Peace, and Advice were clustered around 3.0. However, Figure 5 suggests that each of the outcomes of Pain, Feelings, Life, Peace, and Advice improves throughout the study but that Concerns around their illness increased over the study. However, these graphs also indicate there is substantial variability in individual scores, with some individual scores decreasing or increasing over time.

XSL•FO
RenderX

Figure 4. Boxplots showing the mean and range of scores of participants across the outcome measures, which include pain, other symptoms (shortness of breath, weakness or lack of energy, nausea, vomiting, poor appetite, constipation, sore or dry mouth, drowsiness, and poor mobility), Concern, Feelings, Life, Peace, and Advice. Higher scores indicate a more positive outcome and lower scores a more negative outcome. APCA: African Palliative Care Association; POS: Palliative Outcome Scale.

XSL•FO

Figure 5. Changes in participants' self-reported scores on the African Palliative Care Association Palliative Outcome Scale domains over the study period, with each gray line representing an individual participant's fitted trajectory of change in scores over time (in days). The blue line represents the overall fitted trajectory for the sample. Higher scores indicate a more positive outcome in each domain (A=Pain, B=Concern, C=Feelings, D=Life, E=Peace, F=Advice). APCA: African Palliative Care Association; POS: Palliative Outcome Scale.

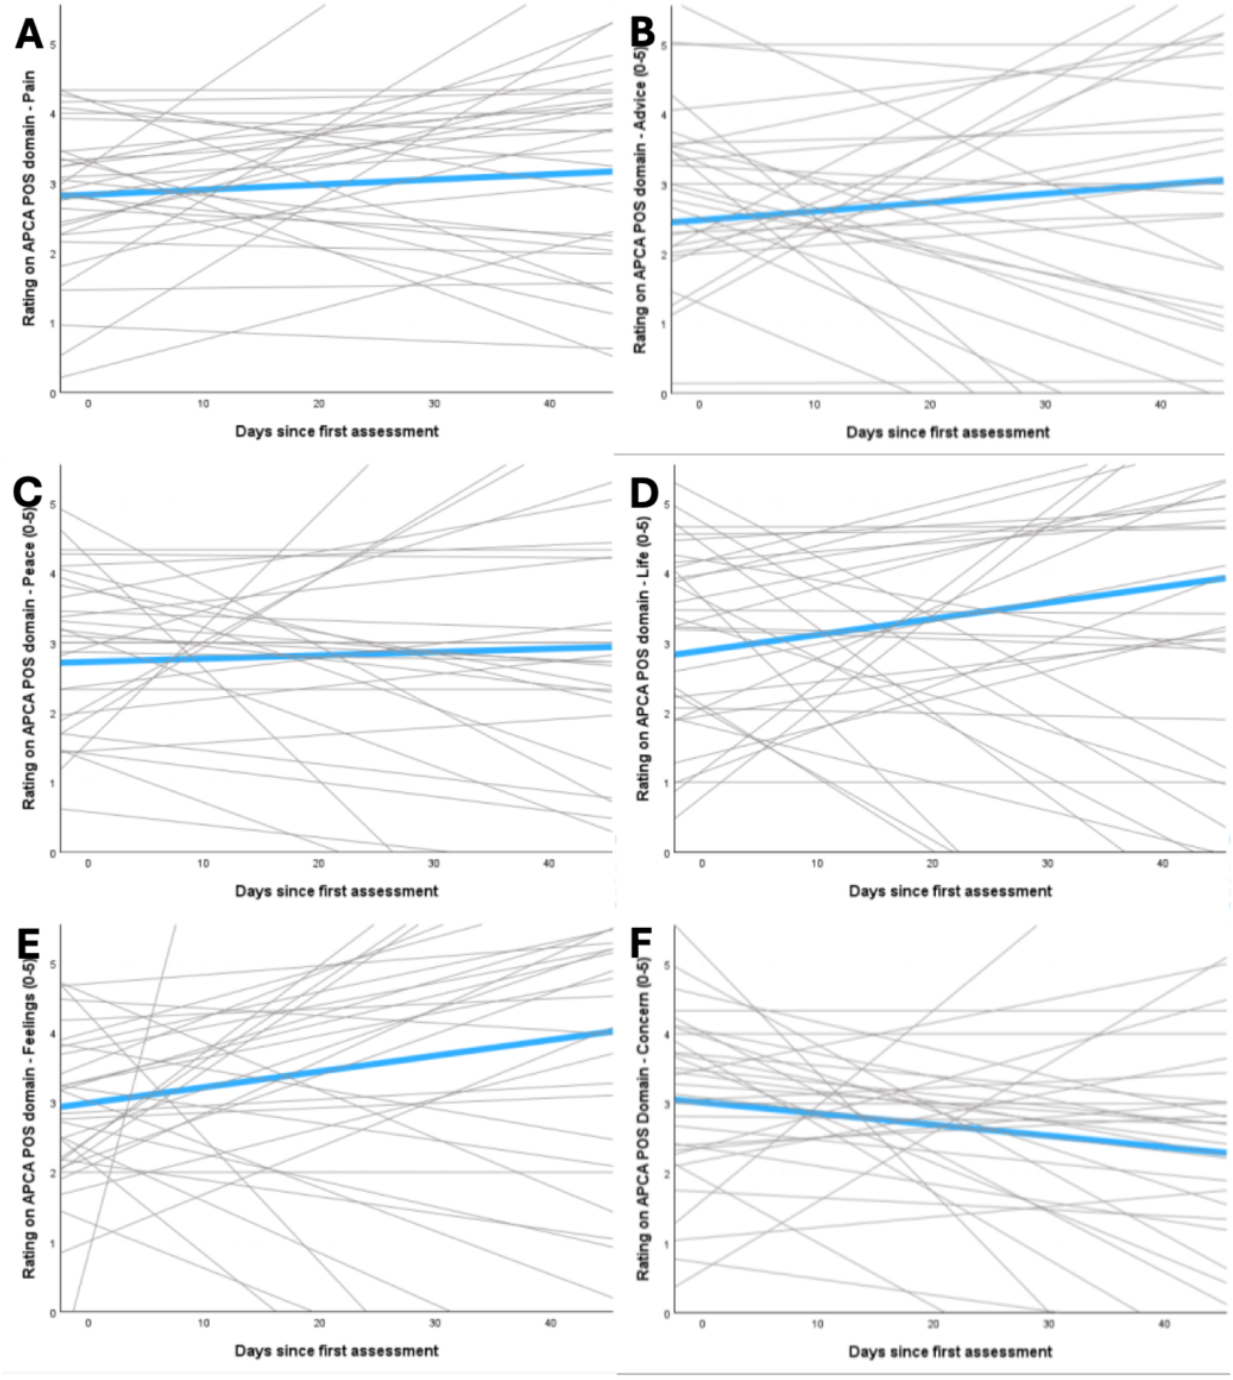

Table 2 outlines the symptoms reported by participants over the course of the study. Across all participants, the most commonly reported symptoms were headache, muscle pain, and dizziness; the least reported were colored stools, yellowing skin, and diarrhea, with fatigue not reported at all. The most reported symptoms over the course of the study were headaches, chest pain, weight loss, and abdominal pain, with diarrhea and foot blisters being the least commonly reported.

XSL•FO
RenderX

Table . Symptoms reported by participants.

Symptom	Number of participants reporting symptom (%)	Number of times symptom reported	Of those reporting symptom, average number reported
Headache	27 (84.4)	90	3.3
Muscle pain	27 (84.4)	73	2.7
Dizziness	26 (81.3)	76	2.9
Chills	25 (78.1)	59	2.4
Weight loss	24 (75.0)	75	3.1
Chest pain	24 (75.0)	75	3.1
Loss of appetite	24 (75.0)	69	2.9
Night sweats	22 (68.8)	35	1.6
Abdominal pain	22 (68.8)	68	3.1
Fever	20 (62.5)	40	2.0
Shortness of breath	19 (59.4)	46	2.4
Confusion	18 (56.3)	46	2.6
Cough	17 (53.1)	38	2.2
Eye soreness	14 (43.8)	32	2.3
Loss of smell	13 (40.6)	25	1.9
Hoarse voice	13 (40.6)	24	1.9
Painful throat	10 (31.3)	17	1.7
Nausea and vomiting	9 (28.1)	16	1.8
Welts or swelling	9 (28.1)	16	1.8
Prolonged cough	6 (18.8)	13	2.2
Feet blisters	6 (18.8)	8	1.3
Diarrhea	3 (9.4)	4	1.3
Colored stools	2 (6.3)	3	1.5
Yellowing skin	2 (6.3)	5	2.5
Fatigue	0 (0.0%)	--	--

Interviews With Patients and Clinical Teams

In total, 20 qualitative interviews were conducted; 10 with patient participants and 10 with members of the clinical team, including VHT members, nurses, and clinical officers. From the patient interviews, three key themes were generated from the analysis: (1) ease of use and perception of app usefulness, (2) understanding of the questions and perception of data use, and (3) impact of the intervention on health and care. From health professional interviews, three themes were generated from the analysis, namely (1) perception of impact of the intervention on patient care, (2) experiences of implementation, and (3) data robustness and reporting. Representative quotations are presented within the Results to illustrate key findings within each theme. The duration of interviews ranged from 20 minutes to 1 hour and 33 minutes for patient participants and 18 to 44 minutes for clinical team interviews. Exemplar quotes from patient and clinical team interviews are presented in Table 3.

XSL•FO
RenderX

Table . Exemplar quotes to accompany the narrative of findings from patient and clinical team interviews.

Theme	Supporting quotes
Patient interview findings	
Ease of use and perception of app usefulness	• Quote 1: “The fact that it was my first encounter with a smartphone, I found it challenging in the beginning, however with time with the help of the VHT I was able to somehow learn how to use the phone.” (Patient participant 4, female 77, cervical cancer) • Quote 2: “...to be able to communicate better to a wider population especially those who don’t understand English, picture illustrations would be added to make people understand better.” (Patient participant 2, female 40, cancer of the eye) • Quote 3: “I found some difficulties, especially with some of the words which I couldn’t as well understand. However, with the help of the VHT, they were interpreted. My suggestion is that the app should be changed to a language that we usually use here, for example, Juba Arabic and Bari to make it simpler.” (Patient participant 2, female 40, cancer of the eye)
Understanding of the questions and perception of data use	• Quote 4: “...some other things were okay to use that method and others were hard, for example, say, if say I’m worried, : “I found some difficulties, especially with some of the words which I couldn’t as well understand. However, with the help of the VHT, they were interpreted. My suggestion is that the app should be changed to a language that we usually use here, for example, Juba Arabic and Bari to make it simpler.” (Patient participant 2, female 40, cancer of the eye) • Quote 5: “...On about two occasions I received a call from the doctors saying that I needed to be reviewed, this made me think that they’d based on what I’d sent them to make that decision, hence, according to me, the scores when seen by the doctors were used make decisions on how I felt. I was told that they looked at the scores and indeed they had meaning, green, yellow and red; all had different meanings. The scores that I had sent at that time were yellow, I was told yellow was a sign that my sickness was increasing and so, there was need to review me so that I don’t enter red or get worse.” (Patient participant 2, female 40, cancer of the eye)

XSL•FO
RenderX

Theme	Supporting quotes
Impact of the intervention on health and care	• Quote 6: "...I began becoming open to the doctors and felt it easy to tell me my plight as I felt it, the fear of the doctors went away while using the app, I could say that the communication gap really went away during this time." (Patient participant 6, male 40, colorectal cancer) • Quote 7: "For sure, during that period, the VHT used to visit me frequently, sometimes 3 or 4 times to check on me, that made me feel closer to him and know him more. During those times, drugs used to come on time, and it became hard to miss as the doctors were always in close contact with me especially when I had not been able to reach the health center. Even the times when the doctor calls you to the health center, I used not to delay he knows how I feel so I just go come back in no time." (Patient participant 4, female 77, cervical cancer) • Quote 8: "It has created a strong bond between me and my doctors. For example, I am better understood in the health facility because I'm constantly monitored by the doctors. This as well led to me not delaying in the facility because the doctors already know how I feel even before I get there, this saves me the trouble of explaining myself every time when I come to the facility." (Patient Participant 10, female 40, breast cancer) • Quote 9: "There's that part that talked about how to manage a difficulty in breathing especially when working. When I followed the advice, the app gave me on how to control my breathing, that really improved my symptoms, and I was able to even become more productive. The symptom management further helped me realize that I can live with the disease which initially I thought it was a death sentence to me." (Patient participant 10, female 40, breast cancer) • Quote 10: "There was a question that accessed my mental health status, especially how I related with family members, if I talk to them and how close I was, this reminded me to always talk to them in case I'm not feeling okay or worried." (Patient Participant 2, female 40, cancer of the eye)
Clinical team interview findings	

XSL•FO
RenderX

Theme	Supporting quotes
Perception of impact of the intervention on patient care	• Quote 11: "I think I mentioned before we were able to stay in touch with patients even before their appointments; before we would only interact with these patients on their appointments right now they are being seen twice so the frequency with which you're interacting with the patient and progress is more by about 4 times instead of a one month review, you can review your patient like 4 times a month; a patient is interacting with you more not only on their treatments and what but also on other issues like psycho-socio, you're visiting them so definitely the connection was increased." (Health team participant 2, clinical officer) • Quote 12: "...it changed somehow because it was, I was actually now dealing more with, relying on what the VHT tells me and you know sometimes this information as you were asking whether they benefitted the patients to some extent you would wish this patient talks directly and you listen from this patient so that you get the quality of the information." (Health team participant 3, palliative care nurse)
Experiences of implementation	• Quote 13: "The design of the app was good but the challenge I found there was the severity of the sickness, like slightly, moderate severe, more severe those things in the beginning, translating it in the local language was a challenge. But now I myself I started making research from my colleagues; what do you mean by moderate in our language, severe and slightly and after coming up with the meaning of those word in our local language, I would then translate to the patients, then it became familiar but, in the beginning, these were a bit challenging." (Health team participant 8, village health team member) • Quote 14: "That challenge came with one of the patients; the patient was started on the program from the dashboard he just disappeared from the app, from the VHT side the information is there on the app again they told me that was a technical problem otherwise that thing of VHT not submitting a report; No. they have submitted the reports." (Health team participant 3, palliative care nurse)
Data robustness and reporting	• Quote 15: "Then the option, on the option of the actions to do for the patient depending on the assessment, if we could broaden it a bit. We had where either you go speak to the client as a professional, then you are going to call and then others; so, in the others is where you would put referrals. I think if we could have like referrals captured separately or linkage captured separately so that patients are linked to other sources of service like psycho-socio support; others were linked to protection; others were linked to livelihood so if we could have where we can capture this then it would be great for the design." (Health team participant 8, village health team member) • Quote 16: "...if we can along the way if you can find a way of having it reflect some elements of the DHIS too in the information system so that we can actually have this data fed into our reporting into the ministry as well. I know that will take improvements on both sides; an improvement onto updating and making our data collection for palliative care in the Ministry of Health system also up to date because right now it also looks shallow; it is also shallow so maybe that will take two sides so that when you have this patient's data you can easily extract it to inform the district and the Ministry of Health in terms of programs." (Health team participant 2, clinical officer)

Patient Interview Findings

Theme 1: Ease of Use and Perception of App Usefulness

The mobile phone app was accessed with the help of the VHT, in keeping with the intended use. Initial difficulties in navigating the app and understanding the input of data were easily overcome with support from a VHT and with repeated use (Quote 1 in Table 3). Some participants reported that self-management resources could be enhanced through the inclusion of visual aids such as pictures, as well as improving the format and presentation of information (ie, increasing font size and wider availability of accessibility options, such as pictorial and audio formats; Quote 2 in Table 3). All participants found the mobile phone app useful and particularly appreciated that symptom and outcome items were easy to understand, requiring only minimal explanations from the VHT, and relevant to their condition (Quote 3 in Table 3). Some participants indicated that translation into additional local languages may also improve the app.

XSL•FO
RenderX

Theme 2: Understanding of the Questions and Perception of Data Use

Participants generally agreed that the questions were easy to understand and context-appropriate, addressing their most troubling symptoms, such as pain, as well as what participants perceived as often-overlooked mental health concerns. Although the symptom and outcome items were easy to understand, the process of providing numeric ratings was unfamiliar and reported as difficult by some participants (Quote 4 in Table 3). However, participants reported confidence that data gathered via the mobile app would be accessed and used by clinical teams. This was reinforced when submitted reports were referred to by clinicians in subsequent meetings when discussing symptom management (Quote 5 in Table 3).

Theme 3: Impact of the Intervention on Health and Care

Some participants reported the intervention made respondents feel closer and more connected to their health care teams, making them feel more comfortable sharing symptoms and concerns with them (Quote 6 in Table 3). Participants also felt the app made the clinicians more knowledgeable about them as individuals, as well as their unique conditions. This was perceived as translating to quicker decision-making and improved access to medication and treatment (Quotes 7 and 8 in Table 3). The use of the app also contributed to patients' agency, as they felt better informed and empowered to self-manage symptoms and to communicate the same with caregivers, family members, and the hospital team, where necessary. Some participants reported beneficial outcomes from reviewing and applying the self-management guidance (Quote 9 in Table 3). The intervention was found to have supported a focus on the mental health and well-being of participants. Some participants reported that having easily accessible information about their health condition helped to allay worries and anxieties and made them feel that help was available if required. The mobile phone app was reported to have fostered better interactions between patients, their caregivers and health workers, enabling them to recognize the need to seek help and receive it in a timely manner (Quote 10 in Table 3).

Clinical Team Interview Findings

Theme 1: Perception of Impact of the Intervention on Patient Care

All participants from clinical teams reported that the intervention was beneficial to patient care. Participants reported feeling more connected with patients and valued the ability to assess changes promptly in a patient's condition that could enable a timely response (Quote 11 in Table 3). However, the routine reporting by VHTs for some participants meant feeling more detached from patients, having instead to rely on reports provided by VHTs (Quote 12 in Table 3).

Theme 2: Experiences of Implementation

A period of adaptation was required for VHTs when using the mobile phone app, particularly for determining appropriate words for translating symptom and outcome items into local languages (Quote 13 in Table 3). This was overcome in collaboration with colleagues, with increased understanding of items by patients. The platform experienced some technical challenges during the study, with some participants reporting that reports submitted to the platform could not be viewed (Quote 14 in Table 3). In some instances, this led to delays and extra costs relating to patient care, as the VHTs often had to be called in to verify information or repeat the visit to the patient.

Theme 3: Data Robustness and Reporting

The clinical team members reviewing reports felt that additional options could be added to indicate which action was taken in response to reviewing a report. This included options such as being able to capture interaction or activity with other service providers. This was seen as a way of improving the usefulness of the dashboard (Quote 15 in Table 3). Some participants queried the wider use and linkage of data with existing government health information systems. Future integration with district health information systems was also viewed as useful, enabling the integration of palliative care data in existing processes for the Ministry of Health of Uganda (Quote 16 in Table 3). Alongside considering integration, a few participants raised concerns about data privacy and the safeguarding of personal data.

Discussion

Principal Findings

The findings from this study highlight the feasibility and acceptability of mPallCare, a digital health intervention for symptom monitoring and outcome reporting among patients accessing palliative care in a refugee settlement in Uganda. Initial high engagement with symptom and outcome reporting occurred, though engagement declined modestly over the study period. Initial challenges relating to navigation and translation of content, intermittent technical issues, connectivity limitations and competing community health duties may have contributed to this decline. Commonly reported symptoms included headaches, muscle pain, and dizziness. While there was varied completion of outcome assessments, overall trends for the study cohort suggested improvements in outcomes relating to pain, ability to share feelings, life feeling worthwhile, feeling at peace (ie, an item relating to aspects of perception of self and world, relationship to others and spiritual beliefs) and accessing help and advice. Patients reported that the intervention fostered a stronger connection with VHT volunteers and clinical teams, improved symptom management, and enhanced patient empowerment. However, challenges such as initial difficulties with navigating the content of the mobile phone app, translation issues, and occasional technical problems—most commonly data synchronization errors between the VHT app and the clinician dashboard—were identified. Health care professionals reported that the intervention facilitated more timely clinical decision-making, though reliance on intermediary reporting by VHTs sometimes limited direct patient interaction. The initial exploration of the feasibility and acceptability of the intervention suggests that it may have the potential to improve patient-centered care, but considerations for accessibility, training, and integration with existing health services remain crucial. While there were no clear differences in feasibility or overall acceptability across patient subgroups, variations in

XSL•FO
RenderX

experience were noted between clinical roles. For example, nurses emphasized how reliance on intermediary reporting by VHTs occasionally limited direct engagement with patients, while VHTs described increased confidence and improved communication skills over time. These differences suggest the importance of exploring the delineation of complementary roles and feedback mechanisms between VHTs and clinical staff during future implementation.

In supporting the systematic collection of structured, patient-reported data, the intensive collection of longitudinal data by mPallCare can help to determine the temporal progression of patient-reported outcomes and better address individuals' changing needs. For example, data can directly inform decision-making by care teams, alongside supporting preparation for community visits (eg, ensuring adequate medical supplies to support identified issues with symptom management). The approach also provides a means of undertaking both comparative effectiveness research and quality assessment relating to service delivery. This aligns with the research imperative to develop the evidence base underpinning care delivery in the context of humanitarian emergencies and crises [39] and builds on emerging applications of digital technologies, such as virtual training for palliative care [6] and more general development of approaches, including electronic health records [40]. Routinely captured data, such as symptom and outcomes data gathered via mPallCare, also provides opportunities to support policymaker decision-making, providing quality and timely data that can inform planning, decision-making and resource allocation in low-resource settings [41,42]. Investment in digital approaches such as mPallCare can support the collection of useful, relevant and reliable data that can help to characterize the current delivery of palliative care and guide the development of effective health services [43] across humanitarian emergencies and crises. This can ensure that the delivery of care is data-driven and reflects the needs of the population [44].

Having established the feasibility and acceptability of mPallCare, the platform is currently being evaluated across 20 additional clinical teams in Uganda and additional countries in Africa, including both refugee settlements and clinical care facilities outside refugee settlements. The initial development and testing of mPallCare reported in this manuscript highlighted multiple technical and user considerations for its future development. The design and accessibility of the intervention continue to be refined, including increasing the number of languages available (including local languages such as Bari, Ma'di, and Lingala, which have been incorporated) and the ease with which additional languages can be added. Such consideration of the accessibility and contextual relevance of a digital health intervention is essential to facilitate user engagement [45]. The decline in outcome reporting, alongside a slight increase in reported outcomes for most items, requires further research. The decline in outcome reporting over the 6-week study period warrants further reflection. Several factors may have contributed to this pattern. First, disease progression and declining physical function among participants with advanced illness likely limited their ability to engage consistently toward later data collection points. Similar declines in engagement have been observed in other mobile health interventions for people with serious illness, where symptom burden and reduced energy constrain sustained participation [35,46]. Second, competing priorities and workload among VHT members, who were responsible for data collection across multiple community programs, may have reduced the frequency of visits and the submission of reports. Third, technology fatigue and waning motivation once the initial novelty subsides—commonly noted in digital health studies—may have contributed to attrition, especially where perceived direct benefits to users were limited [47,48]. Intermittent network connectivity and temporary dashboard access problems also presented practical barriers. These findings mirror broader evidence from low-resource and humanitarian settings, where infrastructure limitations, connectivity challenges, and high clinical workloads hinder sustained digital engagement [37,49]. Future iterations of mPallCare will explore ways to mitigate these barriers, such as streamlined reporting schedules, automated reminders, stronger feedback mechanisms between clinicians and community teams, and increased user feedback on clinical action taken in response to submitted data.

In terms of the observed upward trends in Feelings, Peace, and Life, formal minimal clinically important differences (MCIDs) for the APCA POS have not been established. The palliative patient-reported outcome measures literature recommends interpreting change using anchor- and distribution-based approaches and explicitly estimating MCIDs for context-specific use [26,50,51]. Recent work for related instruments (eg, the Integrated Palliative Care Outcome Scale) is beginning to define MCIDs at the domain level (eg, dyspnea [52]) but comparable thresholds are not yet available for APCA POS. Accordingly, our findings should be interpreted as directional evidence consistent with expected benefits of structured symptom and outcome monitoring and regular follow-up—namely, improvements in psychological and existential well-being—rather than definitive proof of clinically important change. Future studies could prespecify MCID estimation for APCA POS (eg, using patient global impression of change anchors or distribution-based rules such as the SD of baseline or change scores), to enable a formal determination of clinical significance in humanitarian and low-resource settings.

Sustainability of digital health interventions in humanitarian settings remains a key challenge. The long-term viability of mPallCare may depend on factors critical to scale-up and sustainability, including ongoing technical support, training of community health workers, reliable internet access, and integration with national information systems to ensure interoperability and avoid duplication [53]. Sustaining engagement also requires ongoing supervision and feedback loops between VHTs and clinical teams, supported by consistent funding for device upkeep, data storage, and connectivity. These resource requirements mirror lessons from other digital health programs, where interventions that became embedded within Ministry of Health systems, supported by local champions and recurrent budget lines, were most likely to persist beyond pilot phases [54]. Successful integration will further depend on addressing key operational enablers and constraints. These include ensuring interoperability with existing digital systems

XSL•FO
RenderX

such as District Health Information System 2 (DHIS2), maintaining compliance with national data protection policies, and sustaining Ministry of Health engagement for oversight and governance. Establishing clear data sharing agreements and local technical stewardship will be essential for scaling mPallCare responsibly and sustainably. In Uganda, mPallCare continues to be developed in partnership with the Ministry of Health of Uganda to ensure alignment with priorities for palliative care and refugee health, while exploring routes to integrate mPallCare with existing health information systems. This reflects both stakeholder enthusiasm and a feasible next step identified during qualitative interviews, where several clinical participants suggested integration with the national DHIS2 to strengthen data use and visibility of palliative care within national reporting structures. Furthermore, future work will evaluate the impact of mPallCare on patient-level outcomes, including symptom burden, quality of life, and timeliness of clinical review. This may require an approach such as a pragmatic, longitudinal mixed methods study design that incorporates repeated measures of patient-reported outcomes and clinician response times, with potential progression to a cluster randomized controlled trial following optimization.

Although evidence on digital health to support palliative care in humanitarian settings remains limited, our findings resonate with emerging work demonstrating how technology can strengthen communication and continuity of care in crisis contexts. In Lebanon, a mobile health tool for noncommunicable disease management among Syrian refugees improved documentation and patient satisfaction, though uptake was constrained by fragmented systems and parallel reporting [55]. Similarly, virtual learning networks have been found to build palliative care capacity among humanitarian health workers in Bangladesh, yet implementation was hindered by unstable connectivity and high staff turnover [6]. These studies, like the present one, highlight both the promise and fragility of digital innovation in settings characterized by workforce pressures and infrastructure limitations. This tension extends to telemedicine initiatives [56], which can be constrained by ad hoc funding and weak evaluation frameworks; yet evaluation is essential to avoid entrenching inequities [57]. mPallCare contributes to this body of evidence, illustrating that digital platforms can feasibly support palliative care when coupled with community engagement and integration within existing systems. Sustainability, however, remains central as most digital health projects undertaken in low- and middle-income countries falter beyond pilot phases [53]. For mPallCare, longevity may depend on embedding within national infrastructures such as DHIS2, maintaining technical and workforce capacity, and ensuring stable financing for maintenance and connectivity.

As mPallCare continues to develop, ethical considerations will be central to sustainability given its role in the context of often severe resource constraints. Routine symptom and outcome monitoring may highlight numerous issues for which a clear service response is not available. For example, outcome items relating to advice, concerns and being at peace were all scored relatively low by participants, yet there are many challenges in responding to these issues, such as accessing psychological support in the context of refugee settlements [58]. This creates a moral tension between the humanitarian principles of beneficence and nonmaleficence in resource-constrained contexts, where raising awareness of unmet need risks compounding distress if appropriate support cannot be mobilized [8,11]. During the study, interim mitigation was achieved through escalation pathways: VHTs could refer urgent clinical issues directly to the regional palliative care nurse, who provided intermittent outreach and psychosocial support. However, these mechanisms were limited by staffing and distance, highlighting the structural constraints of delivering equitable palliative care in humanitarian settings [11]. Future phases of mPallCare may address this ethical challenge through aligning system-level digital monitoring and response capacity. This could include, for example, developing simplified triage algorithms that prioritize symptoms or concerns requiring immediate action. Embedding such approaches within broader capacity-building efforts—particularly training frontline workers in basic psychological first aid and ensuring referral linkages for complex cases—will be essential to ensure that data collection translates into meaningful and safe care responses. Recognizing such ethical tensions, strategies to mitigate unmet needs are being incorporated into ongoing work. These include establishing partnerships with existing psychosocial and mental health programs operating within refugee settlements, embedding referral pathways into the digital platform, and curating evidence-informed digital self-help materials accessible directly through the mobile app. In addition, collaboration with the Ministry of Health aims to ensure that symptom and outcome data inform broader service planning, enabling scarce resources to be targeted toward the most pressing needs. Such measures seek to balance the ethical imperative of monitoring suffering with a commitment to providing or facilitating meaningful forms of support.

Implementation strategies and their evaluation form an essential element of digital health intervention development [59]. Continued evaluation to optimize how mPallCare can influence service responses within highly constrained resources will be essential to optimize its use in care delivery, alongside further understanding its role in enabling access to contextually appropriate self-management support. Additionally, the influence of different models of care delivery, staffing, local and broader policies, and case mix of patients beyond people living with advanced cancer can be explored through future scale-up and evaluation. Findings from Bidibidi Refugee Settlement provide valuable insights, but they will not be directly generalizable to all humanitarian settings. Contextual factors such as population stability, digital infrastructure, language diversity, and existing palliative care provision will influence implementation elsewhere. Nevertheless, the core principles of participatory design, health worker–led data collection, and integration with existing health systems may be broadly transferable to other displacement contexts. Furthermore, this is a small, uncontrolled feasibility study conducted over a 6-week period; findings are descriptive and not intended to infer efficacy. The limited sample size and reliance on VHT-facilitated reporting may have influenced patient responses. Furthermore, we used an uncontrolled, 6-week feasibility study, where findings are descriptive and not intended to infer efficacy or long-term sustainability. The short follow-up

XSL•FO
RenderX

period and absence of a control group limit the generalizability of results beyond the study setting and timeframe. Future research using longitudinal or controlled designs will be required to evaluate sustainability and clinical impact. Despite these limitations, the study provides essential early evidence to guide refinement and larger-scale evaluation of mPallCare.

Conclusion

This study underscores the feasibility of mPallCare, a palliative care–focused digital health intervention evaluated in the context of a refugee settlement in a low-resource setting. Routine symptom and outcome data collection was feasible, and key areas for further development were identified. The accessibility of mPallCare continues to be developed, including adding additional languages and planning for integration with existing health information systems. While this initial evaluation suggests mPallCare may foster improved patient-provider communication and support symptom management, challenges such as declining engagement over time, technical issues, and balancing the roles of VHTs and clinical teams must be addressed to optimize its implementation in clinical care. Ongoing adaptation and refinement will be critical to ensure mPallCare can support care delivery across diverse humanitarian and low-resource settings. Future research should continue to ensure continued evaluation throughout the ongoing scaling of mPallCare while maintaining a focus on usability and alignment with clinical workflows, including accommodating differing levels of staffing and resources to respond to identified symptoms and outcomes. The future success of mPallCare may be determined by its ability to support varied services and resource constraints, align with national health information systems, and effectively support patient-centered decision-making for palliative care delivery in the context of humanitarian and low-resource settings.

Acknowledgments

The authors thank the African Palliative Care Association (APCA), the Uganda Ministry of Health, and Village Health Teams (VHTs) for their collaboration and support throughout this study. We also extend our thanks to the humanitarian and clinical partners, including the International Rescue Committee, Yumbe Regional Referral Hospital and New Life Hospice. Generative artificial intelligence tools were not used in the preparation of this manuscript.

The authors thank the African Palliative Care Association (APCA), the Uganda Ministry of Health, and Village Health Teams (VHTs) for their collaboration and support throughout this study. We also extend our thanks to the humanitarian and clinical partners, including the International Rescue Committee, Yumbe Regional Referral Hospital and New Life Hospice. Special thanks also to Nickson Mutaasa, who provided help and support in the organisation and delivery of the research project.

Funding

MA is supported by Yorkshire Cancer Research University Academic Fellowship funding. RAP was supported by the National Institute for Health and Care Research (NIHR) Applied Research Collaboration Northwest London. The views expressed are those of the author and not necessarily those of the NIHR or the Department of Health and Social Care. Abstract

Background: Screening for, detecting, and managing pregnancy hypertension is a core function of antenatal care. To reduce both training requirements and the risks of measurement error in blood pressure (BP) values, automated and semiautomated BP devices have been validated in pregnant women with normal BP and pregnant women with hypertension and introduced for serial antenatal measurement of BP.

Objectives: The study aimed to (1) determine whether or not repeated BP measurements reduced the presence of terminal digit preference and (2) discern whether or not there was evidence of threshold avoidance in the Community-Level Interventions for Preeclampsia (CLIP) trials compared with the purely observational Pregnancy Care Integrating Translational Science, Everywhere (PRECISE) cohorts.

XSL•FO
RenderX

Methods: The BP 3AS1-2 and CRADLE Vital Signs Alert low-cost Microlife BP devices were used by trained research staff in the CLIP trials conducted in India, Mozambique, Nigeria (pilot trial only), and Pakistan and the PRECISE cohorts of unselected pregnant women and nonpregnant women of reproductive age recruited in the Gambia, Kenya, and Mozambique. Both devices algorithmically calculate systolic blood pressure and diastolic blood pressure values displayed on digital read-outs. All BP readings were entered manually into a digital platform, which averaged them as the BP for that visit; the first and second readings were averaged unless they were more than 10 mm Hg different, which triggered a third reading, and the second and third readings were averaged.

Results: A total of 51,875 participants had their BP measured 438,404 times. Using raw BP values, there was terminal digit preference (129,539/911,500, 14.21% vs 10%; *P*<.001 values ended in zero). A total of 28,929 out of 437,446 (6.61%) dBP values were 62 mm Hg, compared with 9310 of 195,349 (4.77%) from the averaged values (*P*<.001); errors were obviated by averaging BP values. There was evidence of both threshold preference and avoidance in the CLIP trials and the PRECISE cohort.

Conclusions: Given the excess of 62 mm Hg values, there is a shared inherent algorithmic error in the calculation of dBP in the BP 3AS1-2 and CRADLE Vital Signs Alert devices. Averaged BP measurements are important to reduce the impact of user errors in manually recording BP values. We recommend that automated and semiautomated BP devices should be connected wirelessly to automatically transfer readings to digital health records to further optimize care.

KEYWORDS

Africa; blood pressure devices; pregnancy; South Asia; terminal digit preference; threshold avoidance; women of reproductive age

Introduction

Pregnancy hypertension (defined as systolic blood pressure [sBP] of at least 140 mm Hg or diastolic blood pressure [dBP] of at least 90 mm Hg) is associated with approximately 46,000 maternal and 500,000 perinatal deaths annually; more than 99% of those deaths occur in low-income and middle-income countries [1,2]. Pregnancy hypertension is classified as chronic (pre-existing) hypertension, gestational hypertension, and preeclampsia [2]. Screening for, detecting, and managing pregnancy hypertension is a core function of antenatal care [2,3].

To improve access to BP and other vital signs measurement in low-income and middle-income countries, the semiautomated, low-cost Microlife BP 3AS1-2 and CRADLE Vital Signs Alert (VSA) devices were developed and have been validated in pregnant women with normal BP and pregnant women with hypertension [4,5]. In the context of the CLIP (Community-Level Interventions for Preeclampsia) trials, per protocol use of the Microlife BP 3AS1-2 device within a digital health package deployed by community health workers conducting antenatal contacts in women's homes cost-effectively improved maternal and perinatal survival [6-11].

There are a number of caveats when measuring BP. First, individuals should rest for at least 5 minutes, and their left arm should be supported, with the cuff at the level of their heart. Second, at least 2 measurements of BP should be taken, and if there is discordance between the first and second reading, at least 1 additional measurement should be taken, with the final 2 values of both sBP and dBP being averaged [12]. BP readings that are not wirelessly connected to a digital application are susceptible to a number of errors, such as terminal digit preference (ie, disproportionately enumerating numbers that end in "0" or "5") and threshold avoidance (ie, enumerating numbers just below the threshold that mandates a clinical response) [13].

In this study, we studied all the sBP and dBP values of the pregnant women who participated in the CLIP trials (including the Nigerian pilot trial) and the nonpregnant women of reproductive age and pregnant women who participated in the PRECISE (Pregnancy Care Integrating Translational Science, Everywhere) network. We aimed to (1) determine whether or not repeated BP measurements reduced the presence of terminal digit preference; and (2) discern whether or not there was evidence of threshold avoidance in the CLIP trials compared with the purely observational PRECISE cohort.

Methods

Study Design

This is a secondary analysis of data collected in the 4 countries and 27 intervention clusters of the CLIP cluster randomized controlled trials [14], in India (Karnataka: n=6) [6], Pakistan (Sindh Province: n=10) [7], Mozambique (Maputo and Gaza Provinces: n=6) [8], and Nigeria (Ogun State: n=5) [9], and from all participants in the 3-country PRECISE Network [15], in Gambia (n=3 primary health centers, Farafenni District), Kenya (n=2 primary health centers, Kilifi County), and Mozambique (n=2 primary health centers, Maputo Province; Table S2 in Multimedia Appendix 1). A STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) checklist is provided (Checklist 1).

The CLIP Trials

In brief, pregnant women (aged 15 - 49 y in India, Pakistan, and Nigeria; and 12 - 49 y in Mozambique) were enrolled in the CLIP trials when they first declared their pregnancy and following informed consent [6-9]. The CLIP intervention consisted of community engagement and community health

XSL•FO
RenderX

worker-provided mobile health-guided clinical assessment, initial treatment, and referral to facility [14].

The CLIP intervention was implemented in primarily rural areas of India (February 2014-October 2016), Pakistan (February 2014-December 2016), Nigeria (March 2014-January 2016), and Mozambique (February 2015-February 2017). Within each country, clusters consisted of an established unit of the health system (ie, primary health center in India, union council in Pakistan, administrative post in Mozambique, and local government area in Nigeria).

In intervention clusters, community health workers (accredited social health activists, India; agentes polivalentes elementares, Mozambique; nurses, midwives, community health extension workers, and health assistants, Nigeria; and lady health workers, Pakistan) were trained to provide mobile health–guided contacts that were pregnancy hypertension-oriented, antenatal and postpartum care at home (India, Pakistan, and Mozambique) or at a primary health center (Nigeria). Women in control clusters received usual care, advocated by the World Health Organization. In none of the study countries did community health workers usually either manage pregnancy hypertension or carry with them blood pressure measurement devices or antihypertensive medication.

Digital health-guided clinical assessments were recommended every 4 weeks until 28 weeks of gestation, every 2 weeks from 28 to 35 weeks, weekly from 36 weeks until delivery, once within 24 hours of birth, and postnatally around postpartum days 3, 7, and 14; in Nigeria, visits were opportunistic when women attended the primary health center [16,17].

For generalizability, as sBP can be identified by the return of a radial pulse without the requirement for a stethoscope, the CLIP trial protocol selected a sBP of at least 140 mm Hg as the threshold at which community health workers would respond by initiating referral. In addition, community health workers were directed by the app to either administer oral methyldopa 750 mg for sBP of 160 mm Hg or higher; administer intramuscular magnesium sulfate 10 g for suspected severe preeclampsia (miniPIERS [mini Pre-eclampsia Integrated Estimate of Risk] for an adverse maternal outcome of at least 25%, severe systolic hypertension [at least 160 mm Hg], eclampsia, stroke, or vaginal bleeding); or refer the woman to a comprehensive emergency obstetric care facility for suspected preeclampsia or increased risk of stillbirth (4+ dipstick proteinuria value, or absent fetal movements for at least 12 h) [10,14].

The PRECISE Observational Cohorts

Briefly, in each participating country, 2 cohorts of women were recruited to optimize the identification of social, clinical, and biomarker determinants of the placental disorders of pregnancy, with purposeful sampling of both urban-dwelling and rural-dwelling women [18].

First, unselected pregnant women planning to give birth in the facility (primary health center) were approached and recruited at the time of their booking visit for antenatal care [18]. Consenting women answered an in-depth questionnaire regarding social determinants and clinical history, underwent a targeted examination (eg, biometry, BP, and pulse oximetry), and provided biological samples (blood, urine, and vaginal swabs). Participants were followed up (1) for a second antenatal research visit in the third trimester, at least 4 weeks after the first visit (questionnaire, targeted examination, and phlebotomy); (2) the birth episode (both antepartum and postpartum; questionnaire, targeted examination, phlebotomy, vaginal swabs, placental, membrane, and cord blood samples); and (3) 6 weeks to 6 months postpartum (with their infant, if alive; questionnaire, targeted maternal and infant examination, phlebotomy, vaginal swabs, and heel-prick samples).

Second, for comparison and to understand the lives and biology of sub-Saharan African nonpregnant women of reproductive age (16 - 49 y); such women were identified as either accompanying the pregnant women described in Table 1 or attending for family planning services (Kenya and Mozambique) or recruited in their homes by research staff accompanying the district health surveillance system team (the Gambia). Consenting women answered an in-depth questionnaire regarding social determinants and clinical history, underwent a targeted examination (eg, biometry, BP, and pulse oximetry), and provided biological samples (blood, urine, and vaginal swabs) [18].

[e]Not applicable.

[f]GA: gestational age.

[g]TOP: termination of pregnancy.

Neither patients nor the public were involved in the design, or conduct, or reporting, or dissemination plans of this audit.

BP Measurement Protocol

The Microlife BP 3AS1-2 device was used in the Indian, Mozambican, and Pakistani CLIP trials, and its successor, the CRADLE VSA, in the Nigerian CLIP pilot trial, and the PRECISE pregnancy and nonpregnancy cohorts. Both devices are inflated manually and use the steady deflationary phase to detect BP, algorithmically calculating systolic and diastolic values from the measured mean arterial pressure and displaying the sBP and dBP and heart rate values on digital read-outs on the front of the device.

The research staff (community health workers in CLIP and nurses in PRECISE) were trained to have women rest seated for 5 minutes, and then to measure BP in a standardized fashion, with the left arm supported and the cuff at the level of the heart, at least twice. All BP readings were entered manually into a study-specific digital platform, which averaged them as the BP for that visit; the first and second readings were averaged unless they were more than 10 mm Hg different, in which instance a third reading was requested by the study digital platform, and the second and third readings were averaged [12].

Statistical Analyses

All BP readings were used for the analyses.

We determined the incremental change in sBP and dBP between the first and second measurements, the second and third measurements, and the first and third measurements, if a third measurement was taken.

Individual BP value frequencies were displayed for both sBP and dBP for each study site, cumulatively for both the CLIP trials and the PRECISE cohorts, and cumulatively for the combined dataset. This was to identify if there was any evidence of terminal digit preference and threshold avoidance. Through that step, evidence of terminal digit preference was confirmed, overreporting of the dBP value of 62 mm Hg became apparent (see the “Results” section), and, in the CLIP dataset, suspicion of threshold avoidance at 140 mm Hg systolic was observed.

XSL•FO
RenderX

We compared the directly observed counts for dBP of 62 mm Hg versus the averaged count for dBP of 62 mm Hg from the duplicate measurement (ie, 1 and 2 of two measurements or 2 and 3 of three measurements) using a Fisher exact test and the Koopman asymptotic score to calculate 95% CI for the relative risk. The percentage of values ending in "0" and "5" was calculated and compared with the expected value of 10% (assuming a uniform distribution of digits) using both raw and averaged measurements using a 1-sample test for proportion.

To assess threshold avoidance in the CLIP dataset (where an intervention was associated with systolic hypertension), we fit a segmented regression model to the number of BP measurements per unit. Specifically, we used a Poisson model with the following covariates: BP level, threshold (above and below 140 mm Hg), and an interaction between these terms. We display fitted values from these models graphically and use a likelihood ratio test comparing models with and without the segmentation to assess evidence of the possible discontinuity corresponding to threshold avoidance. We compared these results with the CLIP dBP values and PRECISE sBP and dBP values, where no relevant clinical decision thresholds were set.

All analyses were performed in R statistical software version 4.0.3 (R Foundation for Statistical Computing). $P<.01$ was used for statistical significance to adjust for multiple comparisons.

Ethical Considerations

The CLIP trials were approved by the University of British Columbia Research Ethics Board (H12-03497) and within each country (MDC/IECHSR/2013‐14/A, KLE University, Belgavi, India; 2590-Obs-ERC-13, Aga Khan University, Karachi, Pakistan; 219/CNBS/13, the Mozambique Ministry of Health, National Bioethics Committee for Health, Maputo, Mozambique; and OOUTH/DA.326/T/1/, Olabisi Onabanjo University Teaching Hospital, Sagamu, Nigeria). The PRECISE study was approved by King's College London (HR-17/18‐7855) and within each country (2018/REC-74, Aga Khan University Hospital, Nairobi, Kenya; SCC 1619, the Gambia Government/the Medical Research Council, the Gambia Joint Committee, Banjul, the Gambia; and 545/CNBS/18, the Mozambique Ministry of Health, National Bioethics Committee for Health, Maputo, Mozambique). All women provided signed informed consent before taking part in either the CLIP trials or the PRECISE study. All data were deidentified and anonymized. CLIP trial participants were not compensated, other than support for urgent transfers to health facilities when complications were noted or per protocol when risks were identified. PRECISE participants were supported to attend study visits (transport and meals) and were supported for urgent transfers to health facilities as indicated by clinical concerns.

Results

Data were available for 51,875 eligible women, who were recruited from communities and primary health centers in 6 countries (the Gambia, India, Kenya, Mozambique, Nigeria, and Pakistan), with a median of 2841 (IQR 610‐7862) women per included cohort. In total, 911,500 discrete sBP or dBP values were available for analysis.

Some individual-level characteristics of the participating women varied between cohorts (Table 1; Table S2 in Multimedia Appendix 1). Women tended to be in their mid-to-late 20s, were variably nulliparous (range 6.4%-39.5%), and, if pregnant, were recruited from 10.8 to 42.6 weeks' gestation. Pregnant participants generally delivered at term. Miscarriage and termination of pregnancy rates reflect generally late booking for antenatal care, as most miscarriages occur before 12 weeks of gestation. Maternal mortality varied from 0% to 0.27%, stillbirths from 2.2% to 5.1%, and neonatal deaths from 0.32% to 5% (Table 1; Table S2 in Multimedia Appendix 1).

First BP measurements tended to be higher compared with subsequent measurements, but not consistently (Table 2; Table S3 in Multimedia Appendix 1). 25,693 of 183,504 (14%) measurements were taken in triplicate. The raw and averaged BP profiles from the CLIP trials and PRECISE Network (Figure 1) examined BP distributions, terminal digit preference, and the unanticipated rate of dBP values at 62 mm Hg.

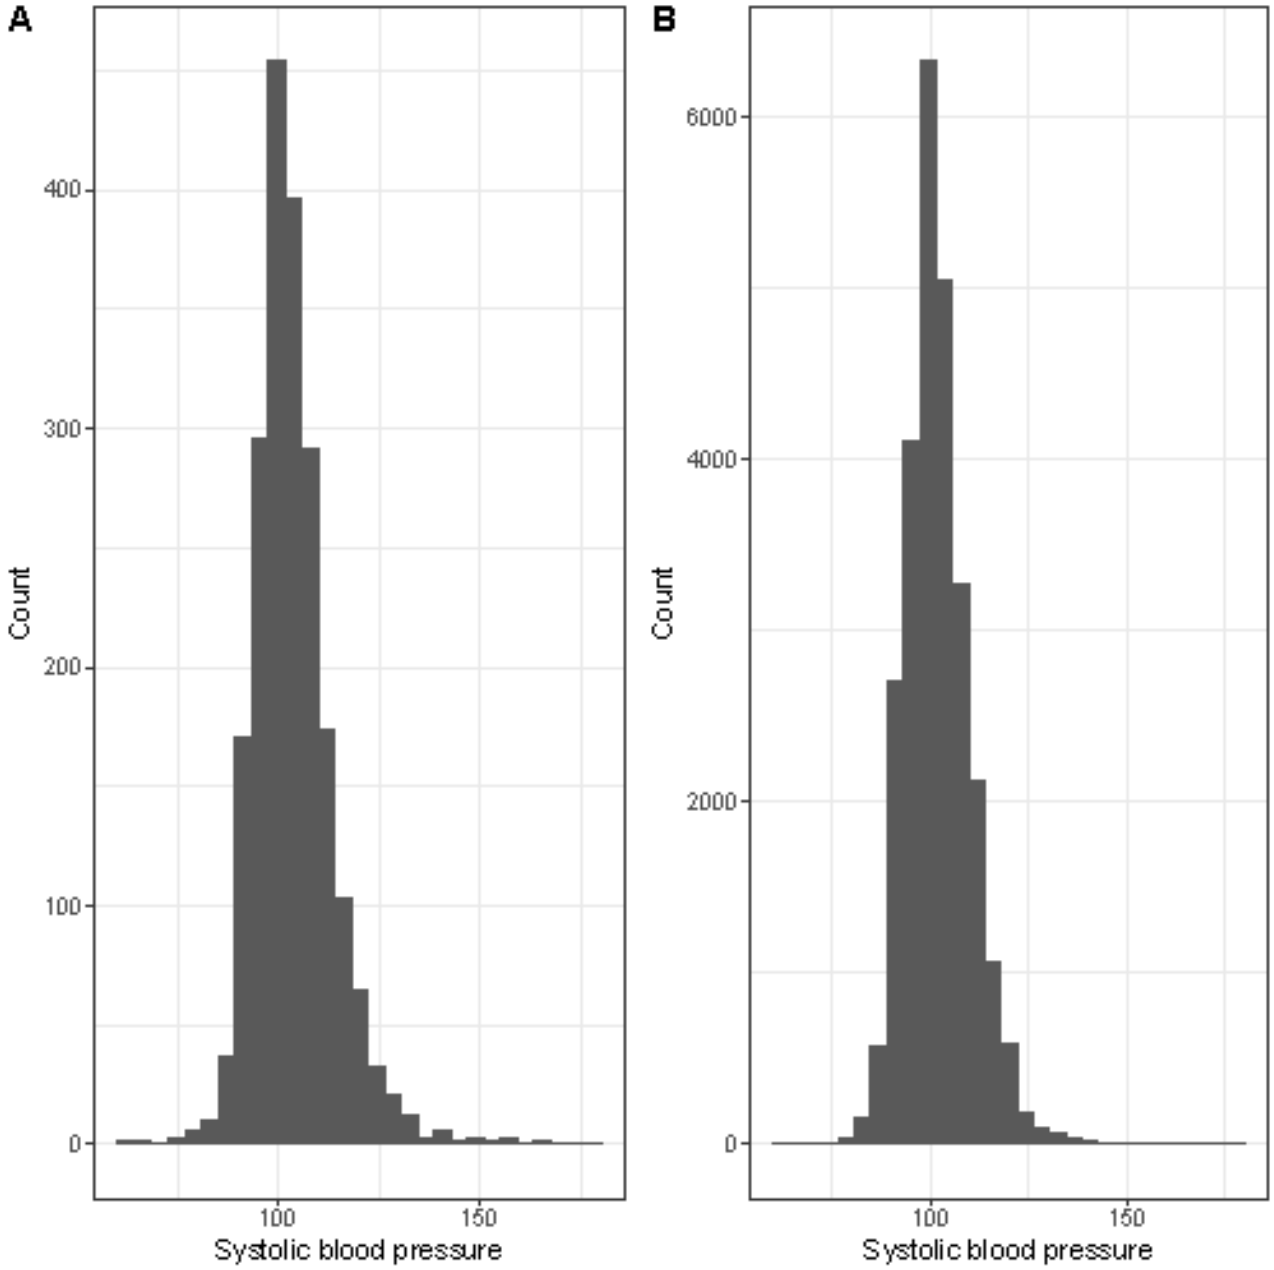
Figure 1. Blood pressure value profiles from the CLIP trials and PRECISE Network. (A) Raw systolic blood pressure values; (B) raw diastolic blood pressure values; (C) averaged systolic blood pressure values; (D) averaged diastolic blood pressure values. CLIP: Community-Level Interventions for Preeclampsia; PRECISE: Pregnancy Care Integrating Translational Science, Everywhere.



There was clear evidence of terminal digit preference for raw values ending in "0" (129,539/911,500, 14.2%) and "5" (98,359/911,500, 10.8%) versus 10% expected (Table 2; Table S3 in Multimedia Appendix 1; *P*<.001 for both "0" and "5"); these were obviated in the averaged values for "0" (39,607/390,697, 10.1%) and "5" (36,457/390,697, 9.3%).

There was a greater than expected frequency of dBP values of 62 mm Hg (raw observations: 28,929/437,446, 6.6% vs averaged observations: 9310/195,349, 4.8%, *P*<.01; relative risk 1.094, 95% CI 1.09 - 1.10; Table 2; Table S3 in Multimedia Appendix 1; Figure 1). These errors in data recording into digital platforms were largely obviated by averaging the sBP and dBP values (first and second or, if required, second and third; Table 2; Table S3 in Multimedia Appendix 1; Figure 1). The sBP values corresponding to these 62 mm Hg diastolic values varied considerably and were approximately normally distributed (Figure 2); in both cohorts, very few of these values were at least 140 mm Hg (53, 0.2% in CLIP; 17, 0.7% in PRECISE) or at least 160 mm Hg (0.1% in both cohorts).

XSL•FO
RenderX

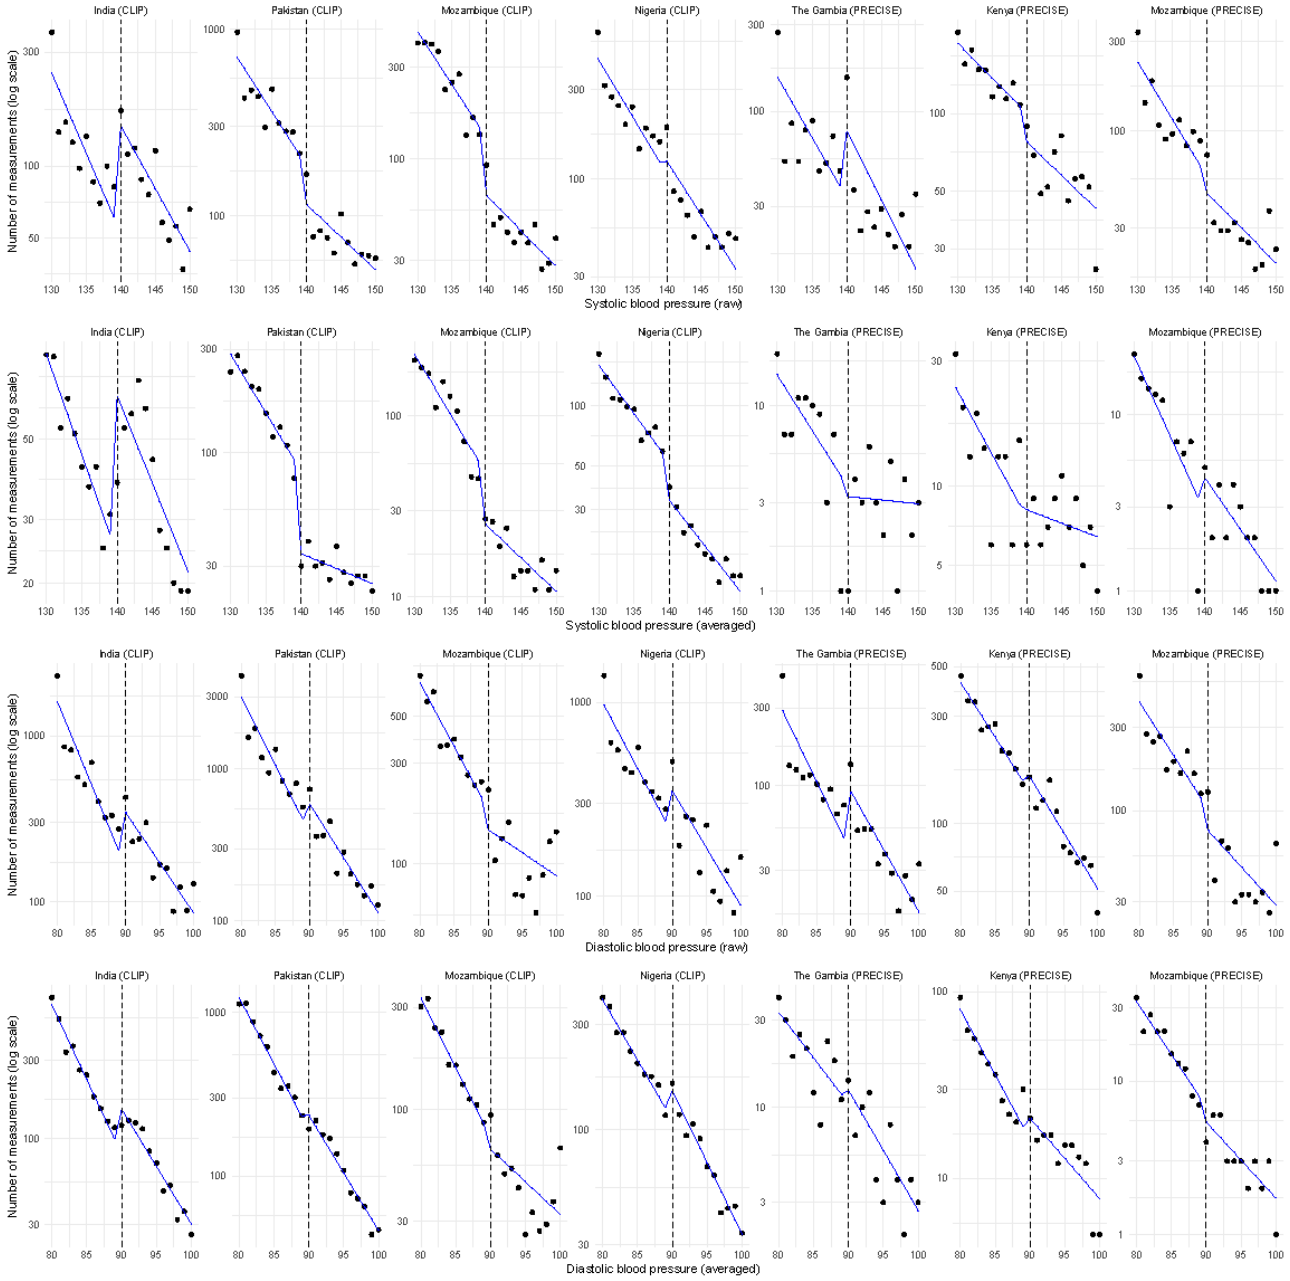


Figure 2. Systolic values corresponding to diastolic blood pressure of 62 mm Hg in (A) CLIP (Community-Level Interventions for Preeclampsia; 55 and 31 of 26,474 ≥140 mm Hg and ≥160 mm Hg, respectively) and (B) PRECISE (Pregnancy Care Integrating Translational Science, Everywhere; 15 and 2 of 2094 ≥140 mm Hg and ≥160 mm Hg, respectively).

For sBP readings, there was evidence of both threshold (140 mm Hg) preference (India; *P*=.02) and threshold avoidance in Mozambique (CLIP, *P*=.007; PRECISE, *P*=.006) and Pakistan (*P*<.001), but for neither the Gambia (*P*=.31), Kenya (*P*=.85), nor Nigeria (*P*=.50; Figure 3). These observations were modified by averaging values (the Gambia *P*=.05; India *P*=.47; Kenya *P*=.05; Mozambique CLIP *P*=.01, PRECISE *P*=.35; Nigeria *P*=.76; and Pakistan *P*<.001; Figure 3). For dBP readings, there was evidence of threshold (90 mm Hg) preference (India *P*<.001; Pakistan *P*<.001) and avoidance (Mozambique CLIP *P*<.001, PRECISE *P*=.008), but neither for the Gambia (*P*=.11), Kenya (*P*=.70), nor Nigeria (*P*=.05; Figure 3). Generally, these observations were modified by averaging values (the Gambia *P*=.44; India *P*<.001; Kenya *P*=.06; Mozambique CLIP *P*<.001, PRECISE *P*=.49; Nigeria *P*=.08; Pakistan *P*=.03; Figure 3).

Figure 3. Threshold preference and avoidance in the CLIP (Community-Level Interventions for Preeclampsia) trials and PRECISE (Pregnancy Care Integrating Translational Science, Everywhere) network. The blue lines are fitted values from segmented Poisson regression models.

Discussion

Principal Results

Using BP data from 51,875 prospectively recruited eligible women living in 5 low- and middle-income countries, 911,500 discrete sBP or dBP values were analyzed in this study. Our protocol of repeating (up to 3 times) and averaging BP measurements (values 1 and 2 of 2, or 2 and 3 of 3) clearly improves the quality of data and clinical guidance that are derived from use of these 2 devices. This was true for the terminal digit preference and the algorithmic issue that resulted in the excess of dBP values of 62 mm Hg, but not for threshold avoidance.

Comparison With Prior Work

Reassuringly for clinical use of these two devices, 62 mm Hg diastolic readings were rarely (≥0.7%) associated with a sBP value of at least 140 mm Hg, and only 0.1% were associated with systolic readings of at least 160 mm Hg that increase the risk for fatal intracranial bleeding [19]. In addition, it might be useful to assess whether or not the 62 mm Hg issue is shared between other Microlife automated and semiautomated BP devices.

Within the CLIP trials, the addition of the traffic light display may underlie why there was no evidence of threshold avoidance in the CLIP Nigeria pilot trial. The CLIP Nigeria pilot trial was the sole part of the CLIP endeavor that used the then-new CRADLE VSA device [9], compared with the BP 3AS1-2 device used in the other CLIP trials. In India (threshold

XSL•FO
RenderX

preference), and Mozambique and Pakistan (threshold avoidance) were clearly seen for systolic, but less so diastolic, hypertension, as the protocol was sBP-driven [6-8,10]. The display of an amber or red light that was visible to others in the room when the BP was taken may have provided important shared information to guide shared decision-making about initiating transfers of care and, in some cases, methyldopa and magnesium sulfate therapy. However, both systolic threshold preference and threshold avoidance were observed in Gambian and Mozambican, but not Kenyan, PRECISE cohort. Diastolic preference and avoidance were both seen, but were of lower magnitude than for sBP values. It would be interesting to understand why the Gambian research staff and the Indian Accredited Social Health Activist workers preferred a value diagnostic of hypertension, while Mozambican research staff and *Agentes Polivalentes Elementares* and Pakistani lady health workers displayed threshold avoidance. Were there differences in the training about the importance of detecting hypertension, or were there concerns about the additional workload associated with making such a diagnosis [15,20-22]?

Previously in the CLIP dataset, we have identified that lowering both sBP and dBP thresholds by 5 mm Hg (ie, 135 mm Hg and 85 mm Hg, respectively, for nonsevere hypertension; and 155 mm Hg and 105 mm Hg, respectively, for severe hypertension), for measurements taken in community settings would improve the detection of pregnant women at risk of the complications associated with pregnancy hypertension, especially preeclampsia [23].

Strengths and Limitations

The strengths of this study include prospective data collection by trained individuals, a shared standardized BP measurement protocol, geographical collection of data from women living in 2 South Asian and 4 sub-Saharan countries (2 from west, and one each from east and southern Africa), and its large sample size. The two study designs, cluster randomized controlled trials (CLIP) and prospective observational cohort (PRECISE), provided additional insights into the role of threshold avoidance with and without the traffic light display introduced in the CRADLE VSA device.

Our limitations include the absence of a wirelessly connected device for comparison, by which means we could have tested the hypothesis that the terminal digit preference and threshold avoidance could be overcome by wireless data collection onto digital health platforms. In addition, we were unable to examine the reasons behind the differences in response to BP thresholds (ie, preference: the Gambia, India vs avoidance: Mozambique, Pakistan vs none: Kenya, Nigeria) between study sites. Such insights would help to overcome threshold avoidance, in particular, in the interim before wireless connectivity between BP devices and digital health platforms becomes routine. Threshold avoidance is a safety signal as women at risk may not have been referred when appropriate.

Conclusions

In summary, the BP 3AS1-2 and CRADLE VSA have been used reliably in a number of other clinical trials and studies with largely positive results [24-27]. They have provided generally reliable, low-cost BP monitors that can be safely deployed from households to facilities in low- and middle-income countries. The addition of the traffic lights in the CRADLE VSA appears to have reduced the risk of threshold avoidance. However, in this study, we have identified opportunities for further improvements that relate to terminal digit preference and the algorithm issues around 62 mm Hg. In the interim, clinicians and fellow researchers should use our protocol for using these devices 2 to 3 times to reduce errors.

Acknowledgments

The authors thank the governments of the Gambia; India; Kilifi County, Kenya; Mozambique; Ogun State, Nigeria; and Sindh Province, Pakistan, for their permission to integrate the CLIP trials and PRECISE study into their health systems with in-kind support. The authors thank the families of the 152 women, 2777 fetuses, and 2688 neonates who died during the study period and who were willing to share their stories despite their grief.

The members of the CLIP Trials Study Group are as follows:

CLIP Mozambique:

Esperança Sevene; Eusébio Macete; Khátia Munguambe; Charfudin Sacoor; Anifa Vala; Helena Boene; Felizarda Amose; Rosa Pires; Zefanias Nhamirre; Marta Macamo; Rogério Chiaú; Analisa Matavele; Faustino Vilanculo; Ariel Nhancolo; Silvestre Cutana; Ernesto Mandlate; Salésio Macuacua; Cassimo Bique; Sibone Mocumbi; Emília Gonçalves; Sónia Maculuve; Ana Ilda Biz; Dulce Mulungo; Orvalho Augusto; Paulo Filimone; Vivalde Nobela; Corsino Tchavana; Cláudio Nkumbula.

CLIP Pakistan:

CLIP Data Safety and Monitoring Board (DSMB):

Romano Nkumbwa Byaruhanga; Brian Darlow; Eileen Hutton; Mario Merialdi; Lehana Thabane.

The members of the PRECISE Network are as follows:

PRECISE The Gambia:

Umberto D'Alessandro; Anna Roca; Hawanatu Jah; Abdoulie Bah; Yorro Bah; Brahima Diallo; Gibril Gabbidon; Lawrence Gibba; Yahaya Idris; Fatoumata Kongira; Melisa Martinez-Alvarez; Modou FS Ndure; Baboucarr Njie; Andrew Prentice; Abdul Sesay; Sambou Suso; Fatima Touray.

PRECISE Kenya:

Marleen Temmerman; Angela Koech; Consolata Juma; Thomas Mendy; Moses Mukhanya; Isaac Mwaniki; Grace Mwashigadi; Joseph Mutunga; Emily Mwadime; Marvin Ochieng; Patricia Okiro; Geoffrey Omuse; Onesmus Wanje.

PRECISE Mozambique:

Esperança Sevene; Anifa Vala; Helena Boene; Carla Carrilho; Salesio Macuacua; Sonia Maculuve; Inacio Mandomando; Lazaro Quimice; Corssino Tchavana.

PRECISE Supporting Institutions and Investigators:

Prestige Tatenda Makanga; Liberty Makacha; Reason Mlambo; Peter von Dadelszen; Laura A. Magee; Rachel Craik; Marie-Laure Volvert; Hiten Mistry; Meriel Flint-O'Kane; Amber Strang; Marina Daniele; Lucilla Poston; Rachel Tribe; Sophie Moore; Tatiana Salisbury; Aris Papageorghiou; Alison Noble; Hannah Blencowe; Veronique Filippi; Joy Lawn; Matt Silver; Joseph Akuze; Ursula Gazeley; Ben Barratt; Judith Cartwright; Guy Whitley; Sanjeev Krishna; Marianne Vidler; Jing (Larry) Li; Jeffrey N Bone; Mai-Lei (Maggie) Woo Kinshella; Domena Tu; Ash Sandhu; Kelly Pickerill; Donna Russell.

Funding

Funding was received from the University of British Columbia, a grantee of the Bill & Melinda Gates Foundation (OPP1017337), and the UK Research and Innovation Global Challenges Research Fund (through the Medical Research Council, MR/P027938/1). The funders of these studies had no role in study design, data collection, data analysis, data interpretation, or writing of the report.

Authors' Contributions

The corresponding author and LAM designed the study and wrote the first draft of the manuscript. The corresponding author had access to all data in the study and final responsibility for the decision to submit for publication. JNB was the primary statistician and data visualization for these analyses. AS was primarily responsible for data curation for both studies. All African and South Asian authors were involved in project management and primary data collection, with central coordination by MV (CLIP trials) and MLV and HDM (PRECISE). All authors contributed to the review and editing of the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Oral cancer is a major public health concern in low- and middle-income countries, where access to specialist care and early detection remains limited. Mobile health technologies supported by artificial intelligence (AI) offer a scalable approach to extend screening services into underserved communities. In Thailand, village health volunteers (VHVs) are key frontline workers who provide preventive services and bridge gaps between rural populations and specialist care.

Objective: This study aimed to describe the technical development of RiskOCA (Risk Assessment for Oral Cancer using Artificial Intelligence), a smartphone-based, AI-assisted oral cancer screening platform, and evaluate its usability when deployed by VHVs in a rural Thai province.

Methods: RiskOCA was developed using a 3-tier architecture comprising a patient-facing interface for risk factor profiling and guided imaging, an embedded deep learning engine (DeepLab v3+with ResNet-50 backbone) for lesion detection, classification, and segmentation, and a secure specialist portal for expert review of all cases. The AI model was trained on 2226 annotated intraoral images and validated for real-world use. Field testing was conducted in the Phu Kamyao district, Phayao province, where 1242 adults (≥40 y) were screened with assistance from VHVs. Usability was evaluated through a structured 25-item questionnaire completed by 250 VHVs, with responses rated on a 5-point Likert scale.

Results: The AI model achieved a mean classification accuracy of 93.22% (SD 0.88%) across 3 diagnostic categories. Usability evaluation indicated high satisfaction across all domains, with an overall mean score of 4.17 out of 5. The highest ratings were for the app's impact on older adult surveillance (mean 4.30), while all domains were rated "satisfied" or "very satisfied."

Conclusions: RiskOCA demonstrated strong technical performance and high user acceptance among VHVs, supporting its feasibility for community-based oral cancer screening. By integrating AI-assisted triage with expert review, the platform has the potential to reduce diagnostic delays, expand screening coverage, and serve as a scalable model for oral cancer prevention in resource-limited settings.

Introduction

Background

Oral cancer continues to be a major global health burden, particularly in low- and middle-income countries where access to early detection and specialist care remains limited. In Southeast Asia, oral health is often underprioritized in public health policy, despite its growing impact on population well-being. In 2020, the region reported more than 900 million cases of oral disease and nearly 100,000 deaths due to lip and oral cavity cancers—conditions that disproportionately affect rural populations [1]. In response, the World Health Assembly and the World Health Organization Southeast Asia Regional Committee have called for oral health to be integrated into universal health coverage and noncommunicable disease frameworks [2]. Nevertheless, geographic, financial, and

XSL•FO
RenderX

infrastructural barriers continue to prevent timely access to screening and care in remote communities.

The early detection of oral squamous cell carcinoma (OSCC) and oral potentially malignant disorders (OPMD) is essential to reducing disease burden, improving survival outcomes, and preserving function. However, timely diagnosis is often hindered by low health literacy, insufficient clinical workforce capacity, and delayed referrals [3,4]. In rural Thailand and similar settings, the challenge lies not only in detection but also in delivering equitable access to specialist assessment and follow-up. One promising strategy to address this gap is task-shifting, wherein screening responsibilities are extended to trained community health workers—such as Thailand's village health volunteers (VHVs)—who serve as trusted frontline actors in noncommunicable disease surveillance and public health promotion [5].

Thailand's VHVs, recognized as a cornerstone of its universal health coverage success, play a pivotal role in linking underserved communities with formal health care systems [6]. Their responsibilities include conducting home visits, collecting health data, and facilitating screening initiatives across a range of conditions, including hypertension, diabetes, and cervical cancer. Leveraging this existing infrastructure for oral cancer screening could offer a scalable, sustainable approach to early detection—particularly if supported by digital health tools that enable accurate assessment and specialist consultation.

Mobile health (mHealth) technologies have emerged as effective solutions to expand health care access in resource-limited settings. Mobile apps can support self-screening, risk stratification, and community-based triage and have shown promise across various domains, including infectious disease surveillance and chronic care [7,8]. In the context of oral cancer, smartphone-based platforms can enable nonspecialists to identify suspicious lesions and trigger referral pathways earlier in the disease course. Yet, despite advances in design and accuracy, few tools have been evaluated for usability or real-world effectiveness in frontline settings, particularly among nonexpert users, such as VHVs [9].

Recent developments in artificial intelligence (AI)—especially deep learning—have demonstrated strong diagnostic potential in analyzing clinical images of oral lesions [10,11]. However, most AI models remain isolated in research settings, with limited translation to community health workflows. To have a public health impact, these technologies must be embedded within systems that are accessible, usable, and clinically meaningful for those operating outside hospital environments [12].

To address this challenge, we developed RiskOCA (Risk Assessment for Oral Cancer using Artificial Intelligence), a smartphone-based app designed to support AI-assisted screening and referral for oral cancer [13]. The platform integrates risk factor profiling, guided intraoral imaging, and lesion analysis via deep learning, with all submitted cases reviewed by oral cancer specialists. Crucially, RiskOCA was designed using a user-centered approach to enable VHVs—as well as other frontline workers—to participate in the early detection process, thereby bridging the gap between remote communities and oral cancer specialists.

Objectives

This paper presents the technical development and usability evaluation of RiskOCA, with a focus on its system architecture, user interface design, and field-based testing among VHVs in a rural Thai province. By examining how VHVs interact with the app and assess its usability, the study provides insights into the potential of AI-integrated mHealth tools to strengthen community-based cancer screening and reduce diagnostic delays in resource-limited settings.

Methods

Ethical Considerations

This study comprised three main components: (1) system development, which included the architecture, AI model, platform technology stack, and data security protocols; (2) user interface and experience design, guided by a user-centered approach to ensure accessibility and cultural relevance; and (3) user evaluation, which involved field-based testing among community participants and VHVs in a rural Thai province. All procedures were conducted in accordance with ethical standards for research involving human participants.

The study was approved by the Regional Health Promotion Center 1, Department of Health, Ministry of Public Health, Thailand (approval No. 20/2565, dated April 29, 2022). Informed consent was obtained from all participants prior to participation using both written and verbal processes conducted in the local language (Thai). Written informed consent was documented using an Institutional Review Board–approved consent form. In addition, trained VHVs provided a standardized verbal explanation of the study purpose, procedures, potential risks and benefits, data handling practices, and the voluntary nature of participation.

The consent process explicitly informed participants that their clinical images and associated data would be used for AI-based risk assessment and may be included in anonymized datasets for research and model development. Participants were informed that no personally identifiable information (PII) would be used for AI training, that participation could be declined or withdrawn at any time without consequence, and that no financial compensation was provided.

Verbal consent was recorded by study staff using a consent checklist confirming that key information had been explained and understood. Participant understanding was assessed through interactive dialogue, during which participants were encouraged to ask questions and were asked to confirm their understanding of the core elements of the study, including data use and privacy protections, before enrollment proceeded.

To ensure confidentiality, all PII (eg, names, national ID numbers, and contact details) was removed or stored separately prior to analysis. The research team only had access to the fully anonymized data. Participants did not receive any compensation for their data being included in this study.

XSL•FO
RenderX

System Development

Architecture Overview

RiskOCA is a smartphone-based digital platform designed to support oral cancer risk assessment and guided self-examination, particularly among adults in underserved and remote communities. The system architecture comprises four core components: (1) an individual risk profiling module, which collects personal health data and behavioral risk factors (eg, tobacco and alcohol use, betel nut chewing, denture wear); (2) a user-facing mobile web app, which guides individuals step by step in capturing high-quality intraoral images using smartphone cameras; (3) an embedded AI engine, a deep learning model that detects and segments potentially malignant lesions in submitted images; and (4) a specialist review portal, which enables trained oral medicine professionals to verify AI-generated findings and provide clinical recommendations.

Images flagged as high-risk by either the AI system or the reviewing specialist are referred for follow-up, which may include a clinical examination and histopathological confirmation. All user data are securely transmitted and stored in compliance with national ethical and privacy guidelines. By integrating automated triage, guided self-screening, expert validation, and follow-up pathways, RiskOCA offers a scalable framework to enhance the early detection and surveillance of oral cancer in low-resource settings.

Platform Technology Stack

RiskOCA was built on a 3-tier architecture, which separates the system into the presentation layer (frontend), app layer (business logic), and data layer (storage and management). This modular architecture facilitates scalability, maintainability, and efficient system updates.

At the presentation tier, the front-end interface was developed using the Ionic framework, enabling cross-platform deployment on both Android and iOS devices from a single codebase. The interface uses standard web technologies (HTML5, CSS3, and JavaScript) to ensure responsiveness and consistent user experience across device types.

The application tier incorporates an application programming interface layer implemented in PHP (version 7.4.5), which manages all business logic, handles interactions between the frontend and the backend, and processes communications with the AI engine and clinician portal.

The data tier is hosted on an Apache web server and uses a MySQL relational database for storing user records, clinical metadata, AI results, and clinician annotations. The database is configured with utf8_general_ci character encoding to support multilingual content, including Thai and English. Database management is performed via phpMyAdmin (version 5.0.2), which facilitates tasks, such as schema definition, data linking, and automated backups. Together, this stack—Ionic (user interface/user experience), PHP (logic or application programming interface), and MySQL (data storage)—provides a robust, scalable, and cost-effective foundation for RiskOCA's deployment in real-world health systems.

AI Model Description and Performance

A central feature of RiskOCA is its integration of a deep learning model to enable automated, image-based screening for oral lesions. The model is based on the DeepLab v3+ architecture with a ResNet-50 backbone, a widely used configuration for semantic segmentation tasks. It was optimized for intraoral images captured in nonclinical environments, accommodating variability in lighting, positioning, and mucosal anatomy [14]. The AI system performs three key functions: (1) lesion detection—identifying the presence of any abnormal lesion in the image; (2) classification—categorizing lesions into one of 3 diagnostic classes: normal oral mucosa, OPMD, or OSCC; and (3) segmentation—generating a pixel-level mask that outlines the lesion boundaries to assist with visual interpretation and confirmatory review.

The dataset included 2591 images, each accompanied by expert-annotated segmentation masks. Images were acquired from multiple oral cavity regions using both clinical-grade single-lens reflex cameras and consumer mobile phone cameras, reflecting real-world variability in image acquisition. All images were resized to 342×512 pixels before being input to the model. To mitigate potential data leakage, substantially similar or near-duplicate intraoral photographs from the same participant were identified through manual review and consensus by 2 board-certified oral and maxillofacial pathologists and removed prior to model training and cross-validation. The model was finally trained and evaluated on 2226 labeled intraoral images (normal: n=667, OPMD: n=1310, OSCC: n=249).

A 5-fold stratified cross-validation was used to evaluate the robustness and generalizability of the DeepLab v3+model with a ResNet-50 backbone. In each fold, 20% of the data served as the held-out test set, while the remaining 80% were split into training (70%) and validation (10%). Model selection was based on validation loss, and the final performance for each fold was evaluated on the independent test set. To derive an image-level screening label from the segmentation output, a lightweight postprocessing rule was applied to summarize pixel-level predictions into one of the 3 diagnostic categories. Specifically, the predicted label was assigned according to the dominant predicted lesion class in the segmentation map, with the suppression of very small and isolated predicted regions to reduce spurious micro-segmentations. This strategy provides both an interpretable lesion outline and a single screening label suitable for community-based triage.

Across the 5 cross-validation folds, the model achieved an overall classification accuracy of 93.22 (SD 0.88%). Class-specific performance was stable and strong for normal and OPMD and clinically meaningful for OSCC. Normal classification achieved a precision of 90.82% (SD 2.41%), recall of 92.65% (SD 1.65%), and F_1-score of 91.70% (SD 1.17%). OPMD classification achieved a precision of 94.96% (SD 0.67%), recall of 94.73% (SD 1.93%), and F_1-score of 94.83% (SD 0.88%). For OSCC, the model achieved a precision of 90.78% (SD 2.16%), recall of 86.78% (SD 5.17%), and F_1-score of 88.67% (SD 3.23%).

XSL•FO
RenderX

The pooled confusion matrix across all held-out test images from the 5 folds (n=2226) is shown in Table 1. Most images were correctly classified, with diagonal counts of 618 normal, 1241 OPMD, and 216 OSCC cases. The predominant OSCC error mode was misclassification as OPMD (24/249, 9.6%), whereas the misclassification of OSCC as normal occurred less frequently (9/249, 3.6%). In the context of community-based screening with specialist review, the misclassification of OSCC as OPMD would still flag abnormality and prompt follow-up, whereas OSCC misclassified as normal represents the more clinically concerning miss category.

Table . Pooled confusion matrix (all test images across 5 folds; counts).

Ground truth	Prediction		
	Normal, n (%)	OPMD[a], n (%)	OSCC[b], n (%)
Normal	618 (92.7)	42 (6.3)	7 (1.0)
OPMD	54 (4.1)	1241 (94.7)	15 (1.2)
OSCC	9 (3.6)	24 (9.6)	216 (86.8)

[a]OPMD: oral potentially malignant disorders.

[b]OSCC: oral squamous cell carcinoma.

Segmentation performance was consistent across folds, with a pixel-wise micro mean intersection over union of 92.32% (SD 0.55%) and a micro mean F_1-score of 96.01% (SD 0.30%). Per-class pixel intersection over union was the highest for normal (95.75%, SD 0.28%) and remained moderate for lesion classes (OPMD: 69.30%, SD 1.28%; OSCC: 65.15%, SD 4.34%). The lower and more variable intersection over union for OSCC indicates greater heterogeneity in lesion boundaries, which is expected given the diversity of tumor morphology and extent.

Security and Privacy

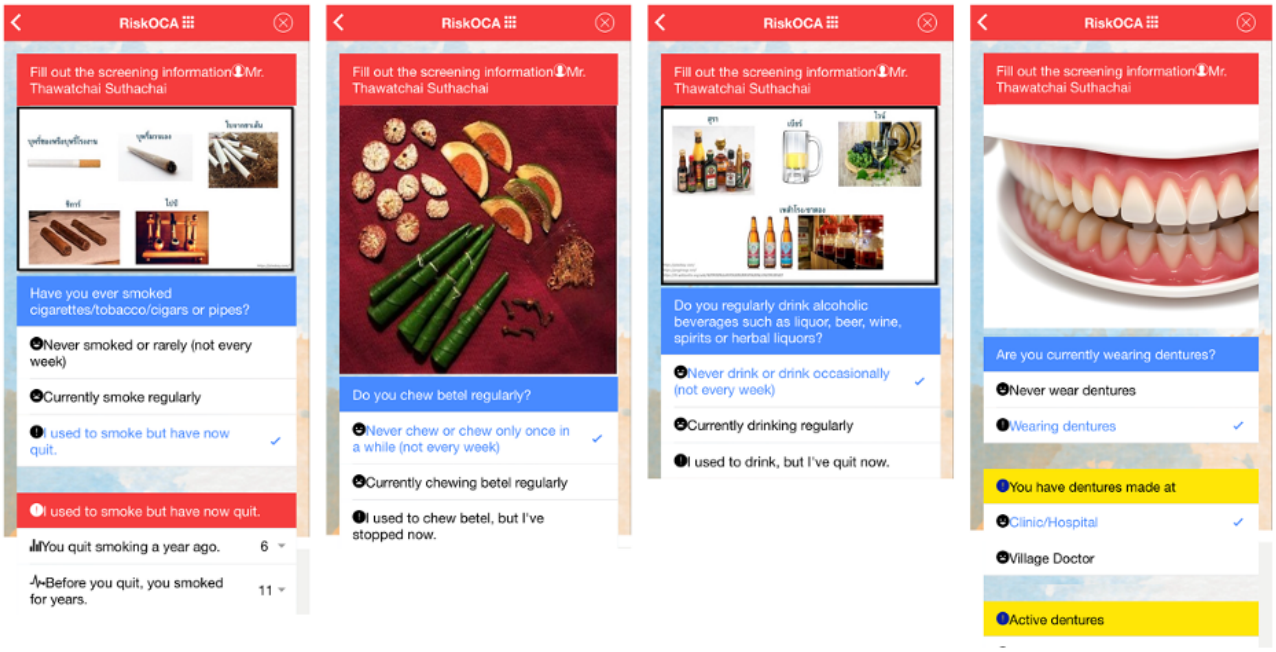
RiskOCA was designed with a security-first approach, emphasizing data confidentiality, integrity, and user consent. Prior to using the platform, participants must review and electronically consent to a clearly worded form detailing the study purpose, data handling policies, potential risks, and the voluntary nature of participation.

PII, including full name, national identification number, contact information, and demographic details, is collected during user registration to support clinical follow-up, referral coordination, and linkage with health care services. However, no PII is attached to image data at the point of image submission or during AI-based risk assessment. Instead, each participant is assigned a unique alphanumeric study ID, which is used to link clinical images and questionnaire data while decoupling them from direct personal identifiers.

To further protect privacy, all submitted images are stripped of embedded metadata, including GPS location, device identifiers, and timestamps, prior to storage and analysis. All data transmissions occur over HTTPS using TLS 1.3 encryption. PII and anonymized clinical data are stored in logically separated, encrypted MySQL databases, accessible only to authorized personnel under role-based access controls.

Clinical reviewers and AI developers are provided access only to anonymized cases and are not able to view names, national ID numbers, or contact information. All system access, AI outputs, and expert reviews are logged and auditable. RiskOCA complies with national data protection regulations and aligns with international best practices for health data governance. Participants may request the deletion of their data at any time via an embedded secure request form on the platform.

User Interface and Experience Design



Patient Interface for Risk Assessment

The RiskOCA platform was designed using a user-centered design approach, with a strong emphasis on accessibility, cultural relevance, and ease of navigation for diverse user populations, particularly in rural and underserved areas. The patient-facing interface supports guided data entry, risk assessment, and health education through intuitive, mobile-optimized screens. The app is designed to be used independently by patients or with assistance from VHVs, ensuring inclusivity for users with varying levels of digital literacy.

Upon launching the app, users are prompted to enter their full name and national ID number for clinical identification and follow-up purposes, which is essential for individuals undergoing screening for oral potentially malignant disorders or oral cancer. Real-time input validation is implemented to prevent incorrect or incomplete ID entry. Once validated, users proceed by selecting their province, district, and sub-district, and then enter additional demographic information, including phone number, gender, date of birth, and ethnicity. These entries are facilitated through standardized input menus, including dropdowns and scrollable selection wheels optimized for mobile devices (Figure 1).

XSL•FO
RenderX

Figure 1. Oral cancer risk assessment user interface.

Following demographic data entry, users are guided through a structured oral cancer risk assessment, consisting of four culturally and clinically relevant domains [15]:

1. Tobacco smoking: Users are asked if they have ever smoked cigarettes, cigars, pipes, or used tobacco leaves. Based on their response—"Never or only occasionally," "Currently smoke regularly," or "Used to smoke but quit"—the interface dynamically adapts to show follow-up questions. For current users, sliders allow the input of number of units smoked per day and duration of smoking (years). Former users are asked how many years ago they quit and for how long they smoked.
2. Betel nut chewing: Users indicate whether they have regularly chewed betel nut. If applicable, the app collects data on frequency per day and duration in years, again using slider-based inputs. Those who quit are asked about cessation timelines.
3. Alcohol consumption: The app asks whether the user currently drinks alcoholic beverages, such as spirits, beer, wine, or herbal liquors. For current drinkers, follow-up fields collect details about the type of alcohol, frequency (daily, weekly, and monthly), and duration. Former drinkers are asked to specify the duration of prior use and time since quitting.
4. Wearing dentures: Users report whether they currently wear dentures. Those who do are asked about the source of fabrication (clinic or hospital vs local practitioner), fit quality (well-fitting or loose), and duration of denture use in years.

Each question concludes with a visual confirmation indicator (✓) and a "Confirm" button, ensuring users understand and acknowledge their responses before proceeding.

After completing the risk assessment, the app displays personalized feedback based on the presence of any risk factors. If risk factors are identified, a warning message is shown: "You should receive an oral screening by a dentist, or dental health professional." Users are prompted to enter their current address for follow-up and are provided with a link to self-examination instructions for oral cancer. If no risk factors are present, the message displayed is: "You are not in a risk group, but it is recommended to have an oral health check-up every 6 months." The app then concludes with a thank-you message.

Throughout the interface, the design prioritizes simplicity and responsiveness, using mobile-friendly controls such as sliders, scroll menus, and contextual prompts. This ensures that the app can be comfortably used by individuals with varying levels of digital literacy.

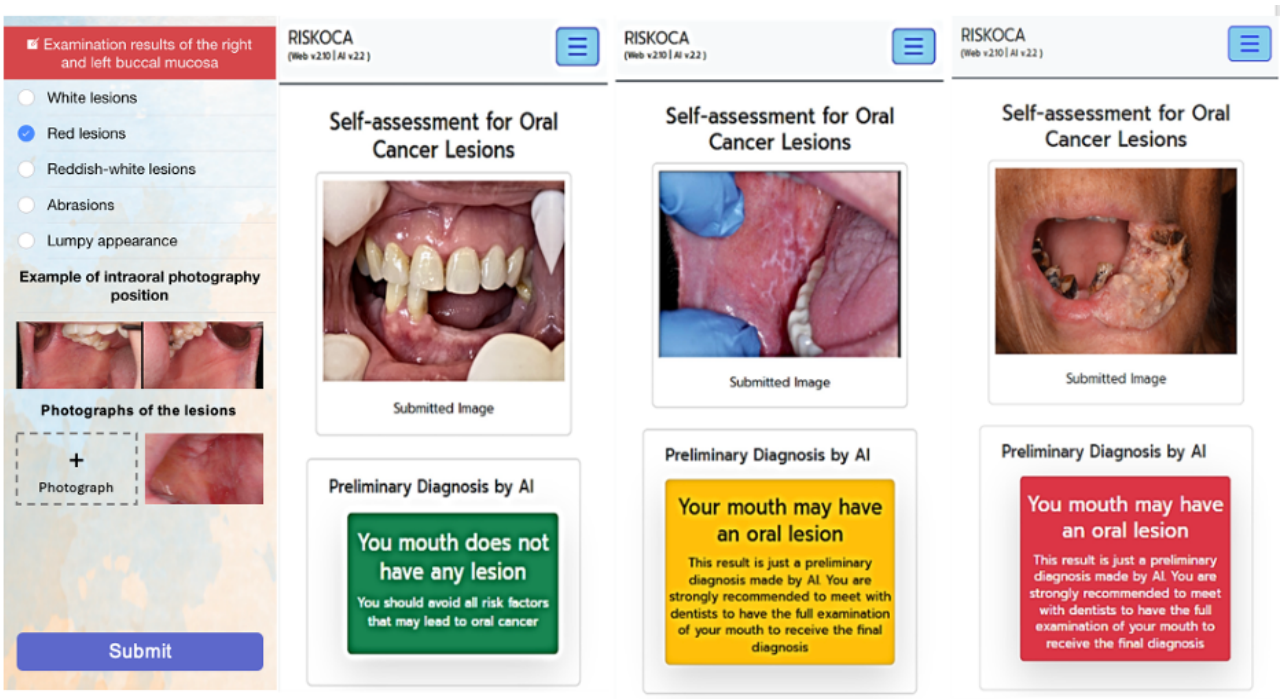
Clinical Screening Interface

The RiskOCA platform includes a secure, role-specific interface designed for the members of the oral health care team—including licensed dentists and trained VHVs—to facilitate oral cancer screening. To ensure authenticated and traceable access, users must complete a 1-time registration process by providing their full name, national identification number, affiliated health care facility, and, for dentists, their professional license number.

Upon successful login, users are directed to the patient entry screen, where they input the full name and national identification number of the individual undergoing screening. Once patient identification is confirmed, VHVs—under dentist supervision—can record lesion findings by selecting from 9 predefined anatomical sites commonly associated with OPMDs and oral cancer:

1. Upper and lower lips
2. Right and left buccal mucosa
3. Upper and lower gingiva (gums)
4. Retromolar trigone (area behind the last molars)
5. Hard palate
6. Soft palate
7. Dorsal and lateral surfaces of the tongue

XSL•FO
RenderX



8. Ventral (underside) of the tongue
9. Floor of the mouth

Each lesion is then visually categorized into 1 of 5 clinical types:

1. White lesion
2. Red lesion
3. Mixed red and white lesion
4. Ulcerative lesion
5. Mass or lump

Photographs of the lesions are captured using a smartphone under natural lighting, with auxiliary light sources used as needed. Images captured were obtained exclusively using mobile devices operated by VHVs. To reduce variability and support consistent image quality, VHVs received structured training on capturing intraoral photographs from 9 predefined anatomical sites, with specific guidance on lighting conditions, image focus, framing, and resolution requirements prior to uploading images to the RiskOCA platform. Despite these measures, differences in clinical context and acquisition conditions between training and field images may influence model performance and are acknowledged as a consideration for generalizability. These images are securely transmitted to the Intercenter Center for Oral Health server, where they undergo AI-based evaluation and expert review to support the referral and care pathway (Figure 2).

Figure 2. Oral examiner and artificial intelligence (AI) analysis interface.

AI Output and Patient Feedback Interface

Upon image submission, the embedded AI model performs real-time analysis to classify the case into 1 of the 3 risk categories: no visible lesion, suspected OPMD, and suspected OSCC. These preliminary classifications are immediately displayed to the user in the form of a simple, color-coded message and visual overlay indicating lesion location (if applicable). To ensure clinical safety and reduce false positives or negatives, all images—regardless of AI output—are forwarded to participating oral health specialists for manual validation through the dentist interface.

If the AI detects a suspected OPMD or OSCC, the app flags the case and initiates a follow-up protocol. Users with flagged findings receive a notification recommending further evaluation. In parallel, system administrators contact the participant directly and facilitate referral to the nearest designated oral cancer center for in-person examination and, if necessary, biopsy confirmation.

To support public awareness and encourage proactive behavior, the platform also includes embedded educational content, including short videos and visual guides. These materials explain the etiology of oral cancer, common early warning signs (eg, white or red patches, ulcers, and unexplained lumps), and evidence-based self-care recommendations. This dual function—automated risk assessment and patient education—aims to increase health literacy while expediting the path to diagnosis and treatment in high-risk individuals.

Expert Review and Diagnostic Confirmation

All images analyzed by the AI model—regardless of classification (normal, OPMD, or OSCC)—were subjected to independent expert review. Two board-certified oral medicine specialists, each with more than 5 years of clinical experience in the diagnosis and management of OPMD and oral cancer, participated in the expert review process.

The specialists independently reviewed all submitted images through a secure clinician portal without access to AI-generated classifications or outputs. Reviews were based on standard clinical visual assessment of intraoral photographs. Cases identified by either the AI model or specialists as suspicious for OPMD or OSCC were referred for further clinical evaluation and biopsy confirmation when indicated.

XSL•FO
RenderX

Among the 1242 adult community members screened, the AI model flagged 8 cases as suspected OPMD and 8 cases as suspected OSCC. Independent specialist review identified 10 cases of OPMD and 6 cases of OSCC. Biopsy-confirmed diagnoses demonstrated that 0.81% (n=10) of the participants had OPMD and 0.48% (n=6) had OSCC with clinically significant lesions.

There were no instances in which normal cases were misclassified as normal by either the AI model or the specialists, and no OSCC cases were missed by either approach. Two cases initially classified by the AI model as OSCC were subsequently identified by specialists and biopsy-confirmed as OPMD, representing the primary source of discordance. No cases classified as normal by the AI model or specialists were later found to harbor a clinically significant disease.

For cases deemed suspicious based on the AI model or specialists, the RiskOCA administrative team contacted the participants and coordinated referral to the nearest designated oral cancer center. There, patients underwent comprehensive clinical evaluation, including biopsy and histopathological analysis, which served as the diagnostic gold standard. Histopathological confirmation allowed for definitive diagnosis, and in several cases, the final outcomes extended beyond the initial screening categories of OPMD and OSCC—highlighting the complexity and spectrum of oral mucosal pathology encountered in community-based screenings. This multitiered workflow—integrating AI triage, expert review, and histological confirmation—ensures clinical accuracy while maintaining accessibility for early detection in at-risk populations.

User Evaluation

Community Participants for Screening

A total of 1242 adult community members residing in the Phu Kamyao district, Phayao province, were recruited to undergo oral cancer screening using the RiskOCA app. This rural district was selected due to its limited access to oral health care services and the high prevalence of behavioral risk factors associated with oral cancer. Participants were eligible if they were aged 40 years or older, had permanent residency in the study area, were capable of providing informed consent, and were able to use a smartphone independently or with assistance from a trained volunteer.

Prior to the screening activities, all VHVs participated in a structured training session designed to ensure safe and consistent use of the RiskOCA app. The training consisted of a 1.5-hour session that included (1) a lecture on basic oral cancer knowledge, common clinical presentations, and associated risk factors; (2) an introduction to the RiskOCA app interface and workflow for risk assessment; and (3) hands-on practice using a mouth simulation model. During the hands-on component, VHVs were trained—under dentist supervision—to capture standardized intraoral photographs and to record lesion-related findings within the RiskOCA app. Following the training, VHVs facilitated participant recruitment, introduced the RiskOCA app, and supported community members during image capture and questionnaire completion as needed.

Village Health Volunteers for Usability Evaluation

A total of 250 VHVs participated in the usability evaluation of the RiskOCA app. These VHVs were the frontline users responsible for guiding community members through the self-screening process, and they played a key role in oral cancer risk surveillance in the region.

All VHVs were recruited from the same rural district and had prior experience with basic health education and mobile technology. As part of the study, they received hands-on training in using the app, including functionalities related to user registration, image capture, data entry, and interpretation of AI-generated outputs.

Following their use of the app in real-world screening activities, VHVs completed a structured usability questionnaire designed to assess the app's interface, functionality, alert system, ease of use, and perceived value for oral cancer surveillance. Their feedback was used to evaluate the app's practicality, acceptability, and potential for broader community-based deployment.

Usability Evaluation

To evaluate the usability and user satisfaction of the RiskOCA app, a structured questionnaire was administered to all participating village health volunteers following their use of the platform. The questionnaire assessed key domains, including interface design, functional performance, automated alert features, ease of use, perceived impact on community surveillance, and overall satisfaction.

User satisfaction and usability were assessed using a 25-item questionnaire adapted from the Mobile App Usability Questionnaire (MAUQ) [16]. The MAUQ aligns with established usability principles, including effectiveness, efficiency, and satisfaction, as outlined in ISO 9241‐210 human-centered design standards. The original MAUQ framework was supplemented with context-specific items addressing oral cancer risk assessment and older adult surveillance to reflect the intended use of the RiskOCA platform in community-based screening. The content validity of the adapted instrument was evaluated by a panel of 6 experts, including public health specialists, oral cancer clinicians, and mHealth or informatics experts. Item-level content validity index values ranged from 0.87 to 0.92, and the scale-level content validity index was 0.91. Minor wording revisions were made following expert review to enhance clarity and contextual appropriateness. A pilot test involving 25 community participants was conducted to assess clarity, feasibility, and reliability. The average time required to complete the questionnaire was approximately 5 minutes, and no major difficulties were reported. Internal consistency reliability was evaluated using Cronbach α, with an overall coefficient of 0.89 and domain-specific values ranging from 0.87 to 0.92, indicating good-to-excellent reliability across all domains.

The instrument was organized into six domains based on thematic relevance:

XSL•FO
RenderX

1. General usage: This domain evaluated users' perceptions of the screen layout and the logical sequencing of on-screen functions during navigation.
2. Functionality: This domain covered the ability to enter and retrieve data during and after examinations, collect risk factor information, raise user awareness regarding oral cancer, and summarize screening outcomes across all oral anatomical sites.
3. Automated alert system: This domain assessed the system's ability to generate timely prompts, such as identifying missing or incomplete records, assisting with national identification number verification, and alerting users when data were omitted.
4. Ease of use: Items in this domain focused on minimizing data entry burden, supporting note-taking features for enhanced documentation, and evaluating the system's technical responsiveness (eg, loading speed and screen transitions).
5. Impact on older adult surveillance: This domain explored the app's utility in identifying risk factors, reducing the cost of screening and care, and improving data reliability compared to traditional paper–based methods.
6. Overall satisfaction: This final domain gauged users' general impressions of the app, its usefulness in promoting older adult participation, its effectiveness compared to conventional methods, and their willingness to recommend or reuse the app in future screening activities.

Each item was rated on a 5-point Likert scale, with response options ranging from 1=very dissatisfied, 2=dissatisfied, 3=moderately satisfied, 4=satisfied, to 5=very satisfied. This scale enabled the quantifiable measurement of subjective perceptions regarding the app's effectiveness, usability, and practical relevance in a community screening context. This comprehensive Likert-scale–based evaluation enabled the robust analysis of the system's usability across multiple dimensions. The approach also accounted for users with varying levels of digital literacy, including those less experienced with smartphone technology. Mean scores were calculated for each domain as well as for the full scale. Descriptive statistics were used to analyze participant responses across all 25 items. In addition, subgroup analyses were conducted to explore differences in satisfaction scores by age group and self-rated smartphone usage ability. Mean scores across subgroups were compared using one-way ANOVA. Statistical significance was set at $P<.05$. All analyses were conducted using SPSS (version 22.0; SPSS Inc).

Results

General Information of App Users

This satisfaction assessment was conducted as part of the project titled "Development of a Mobile Application for Self-Surveillance of Potentially Malignant and Oral Cancer Lesions Among the Elderly and At-Risk Groups." The evaluation took place at the Phu Kamyao district, Phayao province, Thailand. According to Table 2, all 250 training participants were village health volunteers. The majority (50.8%) of them were aged between 30 and 39 years and had a self-rated ability and experience in using smartphones at a "fair" level (49.6%).

Table . General information of app users (n=250).

General information	Users, n (%)
Age (y)	
20 - 29	25 (10)
30 - 39	127 (50.8)
40 - 49	54 (21.6)
50 - 59	32 (12.8)
≥60	12 (4.8)
Total	250 (100)
Smartphone usage ability and experience	
Beginner	95 (38.0)
Fair	124 (49.6)
Moderate	24 (9.6)
Good	7 (2.8)
Expert	0 (0)
Total	250 (100)

User Satisfaction Results

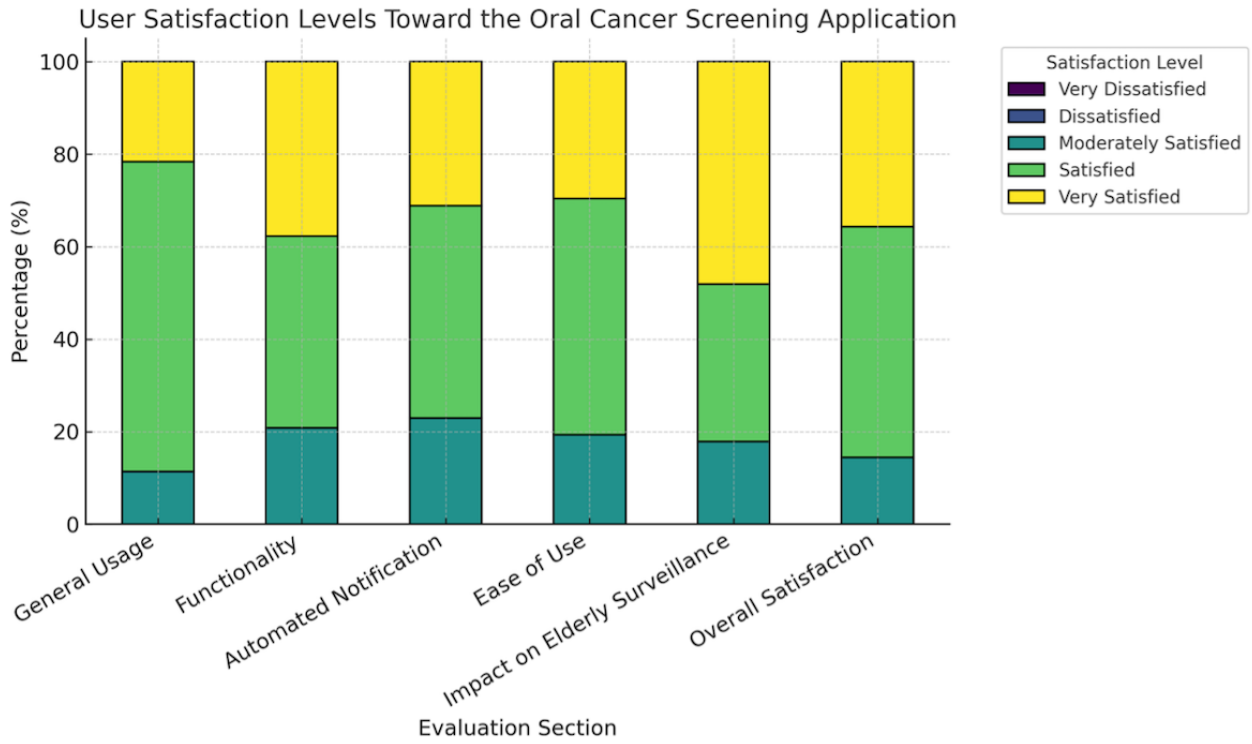
The analysis of the mean satisfaction scores across all 6 domains revealed consistently positive user perceptions of the app. The impact on older adult surveillance domain received the highest average score (mean 4.30, SD 0.75), suggesting that users strongly agreed that the app enhanced their ability to identify risk factors, improved data reliability compared to paper-based methods, and contributed to reducing the cost of screening and care. The overall satisfaction domain also achieved a high rating (mean 4.21, SD 0.68), indicating strong endorsement of the

XSL•FO
RenderX

app's usefulness, ease of use, and potential for broader implementation and recommendation (Table 3).

XSL•FO
RenderX

Table . Percentage of user satisfaction levels toward the oral cancer screening app among older adult participants (n=250).



Section and item	Very dissatisfied, n (%)	Dissatisfied, n (%)	Moderately satisfied, n (%)	Satisfied, n (%)	Very satisfied, n (%)	Average score (out of 5)

Section and item	Very dissatisfied, n (%)	Dissatisfied, n (%)	Moderately satisfied, n (%)	Satisfied, n (%)	Very satisfied, n (%)	Average score (out of 5)
25. Overall satisfaction with the app	0 (0)	0 (0)	25 (10)	155 (62.0)	70 (28.0)	4.18
Subtotal (16-25)	0 (0)	0 (0)	362 (14.48)	1245 (49.8)	893 (35.72)	4.21
Overall mean score						4.17

The stacked bar chart (Figure 3) illustrates the percentage of older participants reporting different levels of satisfaction with the oral cancer screening app. Responses were collected using a 5-point Likert scale (very dissatisfied to very satisfied) across 6 key domains: general usage, functionality, automated notification, ease of use, impact on older adult surveillance, and overall satisfaction. The majority of users reported being "satisfied" or "very satisfied" in all domains, with the highest satisfaction observed in the "impact on elderly surveillance" domain. No participants reported being dissatisfied or very dissatisfied.

Figure 3. User satisfaction levels toward the oral cancer screening app across 6 evaluation domains (n=250).

The domains of functionality (mean 4.17, SD 0.75), ease of use (mean 4.10, SD 0.69), and general usage (mean 4.10, SD 0.57) were all rated in the "very good" range, reflecting high user satisfaction with the system's operational features, visual structure, and user interface design. The automated alert system domain scored slightly lower (mean 4.08, SD 0.73) but still within the "very good" threshold, suggesting that users appreciated the built-in prompts and notifications but may have encountered occasional challenges with error messages or input validation mechanisms.

Overall, the combined mean score across all domains was 4.17 (SD 0.68), indicating a high level of satisfaction among users. These findings affirm that the app was not only functionally effective but also well received by users, including those with limited digital proficiency.

Subgroup Analysis of User Satisfaction

Subgroup analyses were conducted to examine differences in overall satisfaction scores by age group and self-rated smartphone experience (Table 4). No statistically significant differences in overall satisfaction were observed across age groups or across levels of smartphone experience. These findings indicate that user satisfaction with the RiskOCA app was consistent regardless of age or prior smartphone proficiency. Importantly, mean satisfaction scores across all subgroups remained within the "very good" range, suggesting that the app was well accepted even among VHVs with limited smartphone experience. This consistency supports the usability of the app across a heterogeneous community health workforce.

Table . Mean overall satisfaction scores by age group and smartphone experience among village health volunteers (n=250)[a].

Subgroup	Number, n	Mean (SD)	*P* value
Age group (y)			.27
20 - 29	25	4.19 (0.71)	
30 - 39	127	4.21 (0.85)	
40 - 49	54	4.20 (0.75)	
50 - 59	32	4.11 (0.62)	
≥60	12	4.15 (0.53)	
Smartphone experience			.31
Beginner	95	4.14 (0.70)	
Fair	124	4.16 (0.63)	
Moderate or good	31	4.21 (0.59)	

[a]*P* values were calculated using 1-way ANOVA.

Implementation Challenges and Practical Considerations

Although overall usability was high, several implementation challenges were observed during field deployment. Among the 250 VHVs participating in the usability evaluation, all were able to complete the core screening workflow, including participant data entry, intraoral image capture, and image submission. Based on field observations, the complete screening process was typically completed within approximately 15 minutes per participant, including cases where assistance was required.

No errors in data entry or image submission were observed during the evaluation period. However, a subset of VHVs required assistance when using the RiskOCA app. The most commonly observed challenges included difficulty in capturing adequately focused intraoral images (n=25), inconsistent lighting conditions during image acquisition (n=12), and unfamiliarity with smartphone interface navigation (n=9). In such instances, real-time assistance was provided by supervising dental staff or trained team members, particularly during the initial use of the app.

Minor technical issues, including temporary internet connectivity interruptions and delayed image uploads, were occasionally encountered in areas with unstable network coverage. These issues were typically resolved through repeated upload attempts or by completing submissions once connectivity was restored. No critical system failures, data losses, or breaches of data integrity were observed during the study period.

Discussion

This study presents a comprehensive evaluation of the technical development and usability of RiskOCA, a smartphone-based oral cancer screening app deployed among VHVs in a rural Thai setting. The findings demonstrate that the app is both feasible and well-accepted, with consistently high satisfaction scores across domains, such as functionality, ease of use, and overall system performance. Importantly, the platform was designed not only as a digital tool but as part of a broader community–based strategy to strengthen the early detection of oral potentially malignant disorders and oral cancer in resource-limited settings.

User acceptance is a critical determinant of success in the development and deployment of mHealth apps [17]. Even technically robust systems may fail to achieve impact if end users find them difficult to use, culturally inappropriate, or poorly integrated into their daily workflows. Previous studies on digital health tools have highlighted that usability, perceived usefulness, and trust strongly influence adoption, particularly in community-based and resource-limited settings [18,19]. In the context of oral cancer screening, where nonspecialist users, such as VHVs, play a central role, ensuring high levels of satisfaction and ease of use is essential for long-term sustainability. The positive feedback from VHVs in this study, therefore, provides an encouraging indication that RiskOCA is acceptable to frontline health workers and has the potential to be successfully scaled in real-world public health systems.

The involvement of VHVs as primary users underscores the value of leveraging task-shifting models in public health. Thailand has long integrated VHVs into its universal health coverage framework, and their role in RiskOCA parallels the use of community health workers in other global initiatives, such as mobile-based cervical cancer screening in sub-Saharan Africa [20] or breast cancer awareness apps in South Asia [21]. Similar to these initiatives, RiskOCA illustrates how mHealth interventions can expand screening coverage, raise the awareness of modifiable risk factors, and create a direct digital pathway between at-risk populations and oral health specialists.

From an implementation perspective, RiskOCA was designed as a modular mHealth platform to support scalability and future functional extensions beyond oral cancer triage. Key design considerations include a flexible system architecture, standardized data structures, and role-based user interfaces that can accommodate additional AI models, clinical workflows, and screening use cases. This design approach enables the potential integration of AI-assisted screening for other oral and maxillofacial conditions, such as oral potentially malignant disorders surveillance, periodontal risk assessment, or referral

XSL•FO
RenderX

prioritization for other noncommunicable oral diseases. Anticipating such extensions also underscores the importance of governance frameworks, clinician oversight, and continuous model validation to ensure safety, equity, and clinical relevance as new AI functionalities are introduced within community-based mHealth systems.

A key strength of RiskOCA lies in its potential for scalability and sustainability. The modular architecture allows adaptation across regions, while its integration into existing VHV workflows ensures cost-effectiveness and cultural alignment. Moreover, the dual-layer verification—AI-assisted triage supplemented by universal expert review—enhances diagnostic reliability and reduces the likelihood of false negatives, thereby supporting more timely referral and treatment. By embedding digital innovation into community-driven workflows, RiskOCA has the capacity to reduce diagnostic delays and narrow inequities in specialist access for rural populations.

Despite these strengths, several limitations should be acknowledged. First, only participants flagged as abnormal by the AI system and/or specialists underwent biopsy confirmation; therefore, not all 1242 participants received a gold-standard diagnostic assessment. As a result, true sensitivity and specificity of RiskOCA in the community setting cannot be fully determined, and undetected false-negative cases may exist. Second, variability in image quality—due to differences in lighting, positioning, and smartphone hardware—may affect AI performance. While the deep learning model demonstrated strong accuracy, the greater interpretability of AI outputs is needed to improve user trust and clinical decision support. The current reliance on stable internet connectivity may limit deployment in areas with poor network coverage. Addressing these issues will be critical for large-scale implementation. Another limitation of this study is that usability evaluation relied primarily on self-reported satisfaction measures, and objective usability metrics—such as task completion time per participant, standardized error rates, and formal usability testing protocols—were not systematically recorded. Future studies should incorporate structured usability testing frameworks to quantitatively assess efficiency, learnability, and error recovery, particularly as the platform is scaled to broader community and clinical settings. In addition, this study did not include a direct comparison between AI-assisted screening and traditional oral cancer screening methods conducted by VHVs. Future research should therefore consider randomized controlled trials in which VHVs are assigned to use either the RiskOCA app or conventional visual oral examination protocols. Such comparative designs would allow the rigorous evaluation of screening effectiveness, including detection rates of suspicious lesions, referral accuracy, diagnostic concordance with dentists, and biopsy-confirmed outcomes. Evidence from these trials would be essential to establish the added clinical value of AI-enabled screening over existing community–based practices.

Although a formal cost-effectiveness analysis was beyond the scope of this usability study, the RiskOCA app has the potential to offer cost advantages compared with traditional oral cancer screening pathways. The development of RiskOCA was funded by the Ministry of Public Health of Thailand, with the intention that the app be provided free of charge to users and community health workers. As a result, no direct costs are incurred by villagers or VHVs for app access or routine screening activities. In contrast, traditional oral cancer screening often requires patients to travel to health care facilities or necessitates outreach visits by dentists and health care teams to community settings, both of which involve transportation costs, personnel time, and logistical coordination. By enabling VHVs to conduct preliminary screening using widely available smartphones, RiskOCA may reduce unnecessary referrals, optimize the use of specialist resources, and lower indirect costs associated with delayed diagnosis. Nonetheless, future studies incorporating randomized controlled designs should include formal economic evaluations to quantify cost-effectiveness, taking into account implementation, maintenance, training, and health care system–level outcomes. In addition, structured questionnaire surveys and mixed method evaluations capturing the perspectives, perceived challenges, and recommendations of both VHVs and dentists would provide valuable implementation insights, supporting contextual adaptation and scale-up of similar mHealth initiatives across diverse health care settings.

This study was conducted in a single rural district in northern Thailand, which may limit the generalizability of the findings to other regions with different demographic characteristics, health care infrastructures, digital literacy levels, or patterns of oral cancer risk. Although the setting reflects a high-need population with limited access to oral health care, further studies are warranted to evaluate the performance, usability, and implementation feasibility of the RiskOCA platform in urban settings, other rural regions, and across different health system contexts. Multisite and cross-regional evaluations will be essential to confirm the scalability and adaptability of this community-based AI-assisted screening approach.

Future development should also focus on larger-scale deployment and longitudinal evaluation to validate RiskOCA's impact on referral rates, confirmed diagnoses, and patient outcomes. Integration with national eHealth records could support coordinated care and surveillance, while the development of multilingual interfaces and culturally adapted educational modules would enhance accessibility for ethnolinguistic minorities. Together, these efforts will be essential to ensuring RiskOCA's adaptability, effectiveness, and sustainability in diverse low- and middle-income country contexts.

In summary, this study demonstrates that RiskOCA is technically feasible and acceptable to frontline health volunteers. By bridging community-level screening with specialist expertise, the platform represents a scalable and policy-relevant model for strengthening early oral cancer detection in underserved populations. Its successful deployment highlights the broader potential of AI-integrated mHealth systems to transform community-based cancer prevention and control globally.

Abstract

Background: The timed up-and-go (TUG) test is a mobility-related functional task commonly performed in clinical practice for a variety of clinical applications. By instrumenting the TUG test with sensors, creating an instrumented TUG (iTUG), additional parameters can be extracted, which may add clinical value. Instrumented insoles are among the most promising wearable devices that are currently being explored for clinical purposes.

Objective: The study aims to assess additional parameters obtained by instrumenting the TUG test with pressure-sensing insoles for monitoring fracture healing and to analyze whether these parameters reveal differences between patients with and without union of tibial or malleolar fractures.

Methods: Patients with tibial or malleolar fractures and matched controls were enrolled. Patients' TUG test data were collected as follows: (1) longitudinally—at 6 weeks, 3 months, and 6 months after surgery—and (2) cross-sectionally—at 6 months after surgery when patients were referred for nonunion treatment. All participants performed the TUG test using instrumented insoles. TUG tests were video-recorded and analyzed in terms of the time taken to complete each part of the TUG test (conventional TUG). The insole data-derived outcome measures were maximal force during sit-to-stand and stand-to-sit movements, stance time and stride time during walking, and asymmetry of the previously mentioned parameters (iTUG).

Results: Twenty-seven patients with fracture, a similar number of healthy adults, and 9 patients with fracture nonunion were assessed. All TUG parameters improved throughout the healing process (all $P<.001$). The greatest improvements were detected between 6 weeks and 3 months (all $P<.001$). Among the classical TUG parameters, between 3 and 6 months, only the total TUG time, walking time, stand-to-sit time, and total number of steps significantly improved ($P=.004$, $P=.01$, $P=.03$, and $P=.002$). Based on the additional iTUG measures, 6 months after surgery, the loading of the injured side was reduced in patients compared with healthy controls during sit-to-stand and stand-to-sit movements ($P<.001$). Six months after surgery, patients with fracture nonunion had significantly poorer performance in terms of all of the TUG test parameters, except for stance time, than patients with fracture union.

Conclusions: This study indicates the potential for using functional outcomes to identify patients at risk of nonunion. Additional tasks and functional outcomes require further investigation.

Introduction

Fracture Nonunion

Bone fracture nonunion is a serious complication associated with high socioeconomic costs [1]. It is estimated that diaphyseal nonunion of the tibia and femur occurs in 4.6% to 8% of patients following intramedullary nailing of closed fractures performed in accordance with current standards, whereas the risk is even higher in open fractures [1]. Risk factors for nonunion include severe fractures (eg, open fractures and multiple fractures), a high BMI, smoking, and alcoholism [2]. While women experience fractures more frequently, men are more prone to

XSL•FO
RenderX

nonunion [2]. The nonunion rate is greatest in the navicular bone, tibia and fibula, and femur [2]. In routine clinical practice, radiographs are used to monitor fracture healing. Considering that delayed healing can lead to nonunion, patients are often monitored for an extended period, and interventions such as ultrasound stimulation or shock wave therapy are sometimes prescribed with the aim of inducing union [3]. Revision surgery with a bone graft is usually arranged once healing within a reasonable time seems unlikely [4]. Considering that mineralization of the callus in and around the fracture gap does not take place immediately, radiographs can only show bone healing with a time delay [5]. Moreover, radiographs require X-rays, which are carcinogenic [6]. To find better alternatives, functional outcome measures, such as patient-reported outcome measures, have been suggested to monitor fracture healing [7-9]. However, no correlation was shown between differences in adverse event rates and differences in patient-reported outcome measures in orthopedic trauma randomized controlled trials [10]. Although analyses of movement quality are rarely performed in daily clinical practice for the quantification of actual physical function, they may be suitable for predicting fracture nonunion, as discussed in the literature [11-13].

The TUG Test

The timed up-and-go (TUG) test is a simple, short functional assessment that covers multiple mobility-related aspects. It has high reliability and validity [14]. This test includes rising from a chair, walking (straight and turning), and sitting down. The outcome measure of this test is the time needed to complete the test. When the TUG test is video-recorded, additional outcome measures can be assessed via video analysis, including the time it takes to perform each subtask and the number of steps [14]. The TUG test is known to be a reliable measure in different populations, such as older adults and patients with a history of a stroke, spinal cord injury, or cerebral palsy [15]. Endurance training, resistance training, and physical therapy are known to reduce the time it takes for older adults, patients with chronic stroke, and patients with Parkinson disease to perform the TUG test [16-18]. The time it takes to complete the TUG test can provide information about future fracture risk above that provided by bone mineral density, as it has been shown in 2 studies [19,20].

In recent decades, sensors, such as inertial measurement units and instrumented insoles, have been increasingly used during TUG tests [21,22]. These additions make it possible to extract additional outcome parameters, such as gait parameters [23,24], joint kinematics [25], angular velocities [26], and accelerations [27]. Compared to the traditional TUG test, the predictive value of the instrumented TUG (iTUG) was higher for fall prediction owing to the additional extracted, mainly temporal and velocity, parameters [22]. Patients with idiopathic normal-pressure hydrocephalus, Parkinson disease, and orthopedic conditions may complete the iTUG test as a means to screen for treatment and disease-related changes in mobility [21]. The results of the iTUG test after total knee or hip joint replacement improved over the course of rehabilitation and provided additional information [28,29]. However, it is not yet clear whether changes during fracture healing can similarly be quantified with the iTUG test or whether there are advantages of the iTUG test over the conventional TUG test.

Improvements After Injury

Instrumented gait analysis with motion capture systems or wearables can be used to quantify improvements in the gait pattern throughout the healing process of tibial and malleolar fractures [11,30]. There is also potential to analyze other mobility-related movements, such as standing and rising from a chair. In particular, the analysis of the vertical ground reaction force of these movements is of interest, as patients can choose how to distribute the load between the injured and uninjured sides, which is not the case with walking once they can walk without crutches. When patients begin to walk without crutches after the injury, the improvements in maximal loading during walking are rather small because they will always reach loading values of 100% of their body weight during the single-support phase. The normative values for loading lie between 100% of body weight at slow speeds and 125% at fast speeds [31]. Therefore, other movements might be even more sensitive for monitoring fracture healing at later stages of healing.

Hypotheses

Hence, this study analyzed whether the TUG test performed with instrumented insoles can be used to monitor the healing status of tibial and malleolar fractures and whether it has advantages over the conventional TUG test. This information could aid in the process of deciding when to revise or intervene during the fracture healing process. It was hypothesized that (1) longitudinal changes in mobility throughout the tibial fracture healing can be assessed in terms of iTUG test results; (2) 6 months after a tibial fracture, the performance of several iTUG parameters returns to that of sex- and age-matched healthy controls; and (3) several parameters measured in the iTUG test can distinguish between patients with and without union 6 months after a tibial fracture.

Methods

This longitudinal, observational, exploratory study was registered with the German Clinical Trials Register (DRKS-ID: DRKS00025108). The STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) checklist is provided as a download (Checklist 1).

Participants

Patients with tibial or malleolar fractures who underwent surgical treatment at Saarland University Hospital between February 2022 and January 2024 were included and assigned to the longitudinal patient group. Patients who were younger than 18 years could not provide informed consent, had limited mobility before the fracture, had other injuries that could affect mobility, or were pregnant were excluded. Patients were recruited during their hospital stay after undergoing surgical treatment for their fracture. Radiographs in 2 planes obtained 6 months after the fracture were examined by experienced trauma surgeons to determine whether the fracture had healed.

In addition, a group of patients with fracture nonunion was recruited from those treated in the outpatient nonunion clinic.

XSL•FO
RenderX

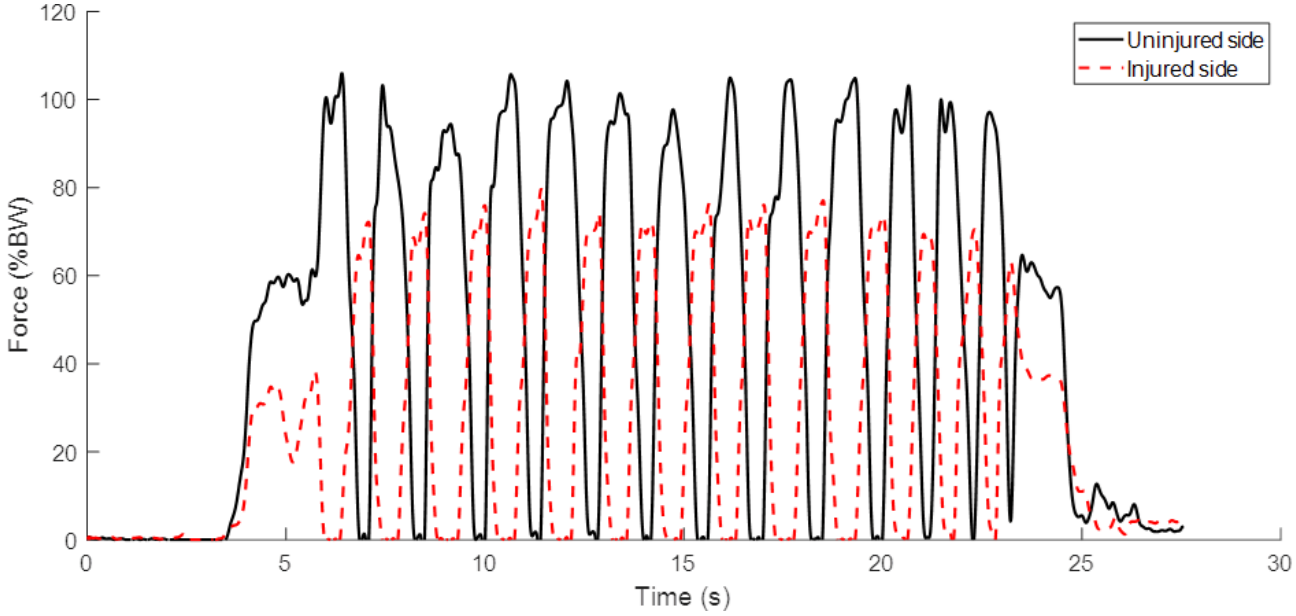
As only less than 10% of patients develop nonunion, a longitudinal study would take several years to reach a sufficient number of patients with fracture nonunion. At Saarland University Hospital, where this study was conducted, patients who were originally treated in other hospitals can present to seek advice and further treatment for their nonunion in the specialized nonunion outpatient clinic, which serves a larger region. To increase the number of patients with fracture nonunion in this study, the authors added a cross-sectional group of patients from this outpatient group, for whom longitudinal measurements were impossible, because they had initially been treated elsewhere. These patients received only one measurement, as they underwent their revision surgery shortly after, and their further treatment was again conducted at the hospital where they had originally been treated. The inclusion criteria for this cross-sectional nonunion group were surgery 4 to 10 months earlier and nonunion as diagnosed by an experienced trauma surgeon. The exclusion criteria were below 18 years of age, inability to provide informed consent, limited mobility before the fracture, other injuries that could affect mobility, or pregnancy.

Healthy controls were sex- and age-matched to the longitudinal patient group. These participants were recruited among the spouses of the patients, hospital employees, and acquaintances of the study team and were measured between February 2022 and April 2024. Healthy participants were excluded if they were below 18 years of age, were unable to provide written informed consent, or had limited mobility. They underwent only a single measurement, as changes were not expected over time without a fracture.

Study Protocol

Patients in the longitudinal patient group were assessed during each outpatient visit, which was usually scheduled approximately 6 weeks, 3 months, and 6 months after surgery. The first visit had to take place between 30 and 60 days after surgery, the second visit between 75 and 105 days, and the third visit between 135 and 235 days. Only patients who took part in all 3 assessments within these time frames were included in the analysis. In the patients with fracture nonunion group and the healthy control group, only one measurement was performed. During the experiment, all participants wore instrumented insoles (OpenGO insoles, Moticon GmbH) containing 16 pressure sensors in both shoes. Before the start of each measurement, the insoles were fitted in accordance with the shoe size of each participant and calibrated to each participant's body weight using the insole software calibration function. All patients and participants wore sports shoes with a soft sole. The participants were asked to sit down on a wooden chair measuring 45.7 centimeter in height with their back against the backrest of the chair. At the start of the TUG test, they had to rise from the chair, walk for 3 meters, turn around a marked spot on the floor, walk back to the chair, and sit down again with their back against the backrest. They were instructed to perform this assessment at their preferred speed and to turn in their preferred direction. If patients still used crutches in their daily lives, they were allowed to use crutches to perform the task. The tests were video-recorded (HERO7 Silver, GoPro Inc).

Data Analysis



The total TUG time, time per subtask, and the number of steps were extracted from the video recordings using the open-source software Media Player Classic–Home Cinema (MPC-HC, version 1.7.13; open source, MPC Community Forum) based on Savoie et al [32], but with slight adjustments. The first video frame in which the patient moved the upper part of the trunk forward marked the start of the TUG test. The frame in which they started to walk (heel rise, which was followed by toe-off) marked the start of the next subtask. The moment the patient placed the supporting leg for the first single step, in which the hips or legs began a turning movement in their preferred turn direction, marked the start of the turn. The end of the turn was analogously defined as the touchdown of the swing leg after the last individual step in which the hips or legs were still in a turning motion. Since the turn and sit-down movements at the end of the TUG test are generally performed in combination, the start of this stand-to-sit movement was defined as the landing of the supporting leg on the first single step, when the hips or legs were again in a turning movement. The test was completed when the patient's back touched the backrest. The numbers of left and right steps were counted from the start of the TUG test (forward movement of the trunk) until the end of the TUG test (patient's back touched the backrest) and then summed.

The raw data from the insoles were downloaded with the manufacturer's software. A custom MATLAB (version 2021b; MathWorks) script was written to extract the sit-to-stand and stand-to-sit movements and the steps. Data were filtered with a fourth-order Butterworth filter with a 6-Hertz cutoff frequency. The sit-to-stand and stand-to-sit movements were manually detected in the ground reaction force curves of both feet, whereafter the peak in the signal was detected and used as the maximal force during sit-to-stand and stand-to-sit movements (see Figure 1 for an example of the forces during the TUG test). The manual detection of these movements was performed to ensure that these movements were also detected when no force was applied to the insole on the injured side or when the data from both feet were not correctly synchronized by the software. A threshold of 30 N in the vertical force data was used to detect the initial and final contact of each step that occurred between the sit-to-stand and stand-to-sit movements. The vertical force data were normalized to the percentage of body weight to allow for comparisons between participants. From the sit-to-stand and stand-to-sit movements, the maximal force was extracted for both the injured and uninjured legs. From the walking phase, the maximal force and stance and stride times were extracted for each stride. An average of these parameters was calculated per side. Additionally, the asymmetry of all of these parameters was calculated as a percentage using the following equation:

$$\text{Asymmetry} = (\text{uninjured side} - \text{injured side}) 0.5 \times (\text{uninjured side} + \text{injured side}) \times 100$$

Statistical Analyses

Statistical analyses were performed with JASP (version 0.17.3.0). The data were tested for a normal distribution with the Shapiro-Wilk test. Differences in demographics between patients with union and healthy controls, as well as between patients with union and those without union, were assessed with an independent *t* test in the case of a normal distribution; otherwise, a Mann-Whitney *U* test was used. A repeated-measures ANOVA was performed to analyze whether the extracted parameters of the longitudinal patient group improved throughout the healing phase, with the extracted TUG parameters as the within-subject factors. Effect sizes were calculated according to eta-squared. Post hoc testing was performed with Bonferroni corrections. The parameters assessed at 6 months after surgery in the group of longitudinal patients with union were compared with those of healthy controls via an independent *t* test or a Mann-Whitney *U* test in cases of violation of normality. Additionally, the longitudinal patient group at 6 months was compared with patients with nonunion at 6 months after surgery via an independent *t* test or a Mann-Whitney *U* test in the absence of a normal distribution. Effect sizes were calculated using the Cohen *d* method. The magnitude of Cohen *d* was categorized as follows: small (d=0.2), medium (d=0.5), and large (d≥0.8). Significance was set at a *P* value <.05 for all tests.

Ethical Considerations

The study protocol was approved by the Institutional Review Board of the Saarland Medical Board (Ärztekammer des Saarlandes, Germany, application number 30/21). Written informed consent was obtained from all participants before the start of the measurements. Participants had the opportunity to opt out at any time without needing to provide reasons. This observational, prospective longitudinal cohort study was conducted in accordance with the Declaration of Helsinki. The data were pseudonymized. The participants did not receive any financial or nonfinancial compensation for their participation in the study.

Results

Demographics

Twenty-seven patients (Table 1) with union of a tibial or malleolar fracture were assessed 3 times during the healing process. Twenty-seven healthy adults, matched for sex and age with the longitudinal patient group, served as the control group. Additionally, 9 patients with nonunion were included in the nonunion group. There were no significant differences in demographics between the longitudinal patient group and the control group or between the longitudinal patient group and the patients with fracture nonunion group (Table 1).

Longitudinal Changes in the Performance of the (Instrumented) TUG Test

The longitudinal patient group was assessed on days 42, 86, and 182, on average, after surgery. At 6 weeks after surgery, 22% (6/27) of the patients performed the test without crutches. At 3 months, this number increased to 85% (23/27), and at 6 months, none of the patients used crutches anymore. Repeated-measures ANOVA revealed significant changes in all parameters throughout healing. Post hoc tests revealed that all parameters significantly improved between 6 weeks and 3 months after surgery. Between 3 and 6 months, only the total TUG time, walking time, stand-to-sit time, and total number of steps significantly improved (Table 2 and Figures 2 and 3).

Figure 2. Timed up-and-go test parameters extracted from the video recordings. (A) Total time; (B) sit-to-stand time; (C) walking time; (D) turning time; (E) stand-to-sit time; (F) total number of steps. The thin blue lines represent the results for each patient, and the thicker blue line represents the average of the longitudinal patients. The whiskers show the 95% CIs of the longitudinal data. The horizontal black dotted line represents the average of the matched controls, and the 95% CIs are in light gray. The red circles are the data points of the patients with fracture nonunion. NU: nonunion group.

The maximal force during walking had the greatest effect size, followed by the total TUG time (Table 2). The remaining effect sizes of the parameters extracted from the video recordings are comparable to those of the parameters extracted from the instrumented insoles. However, between 3 and 6 months after surgery, significant changes were observed only in the following video-based parameters: the total time, walking time, stand-to-sit time, and the total number of steps.

RenderX

Group Differences in the Performance of the TUG Test

Six months after surgery, the maximal force during the sit-to-stand and stand-to-sit movements of patients with union was significantly lower than that of the matched controls, and the asymmetry of these parameters and the stance time were significantly greater in the patients with union (Table 3). The other TUG test parameters were similar to those of healthy controls. The comparison of patients with and without union at an average of 182 and 200 days after surgery, respectively, revealed significant differences in almost all the parameters, except for stance time and stance time asymmetry (Table 3). It should be noted that 2 of the patients with fracture nonunion performed the test with crutches, whereas the patients with fracture nonunion all performed the test without crutches at 6 months after surgery. The parameters extracted from the videos showed the 3 greatest effect sizes of all parameters. These were the total time, the time walking, and the time turning. A large effect was also observed for the stand-to-sit time (Cohen d>0.8). Nonetheless, the effect sizes of the force-related parameters were also large, except for the asymmetry of the maximal force during walking. Among the forces, the largest effects were found for the maximal force sit-to-stand, maximal force walking, and the asymmetry in the maximal force sit-to-stand, but their effect sizes were smaller than those of the video-related parameters.

Discussion

Principal Results

All TUG test parameters, extracted from both video recordings and instrumented insoles, improved throughout the healing process of tibial and malleolar fractures. Six months after surgery, there were still significant differences between patients and healthy controls. Compared with that of matched controls, the maximal loading on the injured side was significantly lower during sit-to-stand and stand-to-sit movements. No differences in video-based parameters were detected between patients and

XSL•FO
RenderX

healthy controls. Patients with fracture nonunion performed significantly worse in 13 of the 15 assessed parameters of the TUG test than patients with union at 6 months after surgery.

Longitudinal Findings

The longitudinal patient group showed significant improvements in all the assessed parameters between 6 weeks and 3 months. However, between 3 months and 6 months, only 4 TUG parameters improved, all of which were video-based parameters. Most of the changes in the TUG test parameters occurred during the first 3 months. Similar findings were reported in patients with hip fractures, whose time to perform the TUG test mainly improved during the first 3 months [33]. For monitoring improvement over time, the conventional TUG test might be sufficient. However, based solely on the TUG test parameters extracted from the video recordings in this study, the performance of patients returned to normal within 6 months. Nonetheless, by instrumenting the TUG test, we were able to show that the maximal loading during sit-to-stand and stand-to-sit movements did not return to control-like values within 6 months. The time required to perform the TUG test returned to normal values within 6 months; however, the patients still tended to unload the injured side during the sit-to-stand and stand-to-sit movements, activities where they can choose how to distribute their load. The iTUG provided limited additional information compared to the video-based TUG, but the differences in loading during sit-to-stand and stand-to-sit movements may provide valuable information. Physical therapy should focus on reducing the asymmetry during these movements to prevent future complaints because of an asymmetric movement pattern. The asymmetric loading pattern could be used for further therapy planning.

The maximal loading parameters during sit-to-stand and stand-to-sit movements showed only very limited nonsignificant improvements between 3 and 6 months, and at 6 months, they were still significantly different from controls. It has previously been reported that the gait pattern 6 months after a tibial shaft fracture was still significantly different from that of healthy controls [34]. Nonetheless, no differences in temporal gait parameters were found in another cohort assessed 5 years after a tibial shaft fracture [35]. Therefore, the recovery time may be prolonged and last longer than 6 months.

Sit-to-stand and stand-to-sit movements might be valuable for monitoring the progress of fracture healing throughout the rehabilitation process because patients can choose how to distribute their weight between the injured and uninjured sides. Shortly after surgery, most patients receive partial-weight-bearing (20 kg) instructions for the first 6 weeks. At 6 weeks, patients are allowed to increase the loading of the leg. As soon as patients start to walk without walking aids (usually somewhere between 6 weeks and 3 months), they load at least 100% of their body weight on the injured side because of single-limb support phases during walking. Therefore, from that moment on, the improvements in maximal loading will be only minor. Since sit-to-stand and stand-to-sit movements are normally performed with loading on both legs, patients can choose to load the injured leg less during these movements. This is indeed the case in this study, as there is still considerable asymmetry between the loading of the injured and uninjured legs at 6 months after surgery during the sit-to-stand and stand-to-sit movements. It is not clear whether this is because of existing complaints such as pain or because patients are still very careful or even afraid to load the injured leg during these movements. Another possible cause is unawareness of unloading due to habituation. Both young and older healthy adults have good perception of weight distribution during the sit-to-stand task [36]. However, how patients with lower extremity injuries perceive their weight distribution is unknown. Furthermore, a cause for the lower maximal force could be related to decreases in strength and power after fracture. After a hip fracture, at least up to 13 weeks after surgery, women have reduced leg extension power on the injured side [37]. It is also known that the ground reaction force during the sit-to-stand movement is related to leg strength and power in older adults [38]. Therefore, potentially lower strength in the injured leg could also have led to the lower maximal force during sit-to-stand and stand-to-sit movements. The actual reason for less maximal loading of the injured side during these movements is crucial to planning physical therapy throughout the rehabilitation process.

Nonunion

The differences between patients with and without union suggest that the iTUG test might have potential to identify patients at risk of nonunion earlier than is currently possible [39,40]. However, further investigation is warranted in longitudinal studies examining the relationship between retrospective TUG results and the diagnosis of union vs nonunion. There were no changes in the instrumented insole data between 3 and 6 months, and there were only small changes in the video-extracted parameters. It might be possible to identify patients at high risk of developing nonunion at 3 months, which may provide additional information when deciding whether there is an indication for revision surgery. Based on the effect sizes, the most suitable parameters would be the total time to perform the TUG test, the total walking time, the turning time, and the force-related parameters from the instrumented insoles during the sit-to-stand and stand-to-sit movements. If patients at risk of developing nonunion can be identified earlier, additional treatment could be started earlier during the rehabilitation process, potentially preventing nonunion and the accompanying decrease in quality of life [41] and increase in societal cost [42]. Other possible noninvasive treatments that are known to improve fracture healing in more than 80% of patients are extracorporeal shockwave therapy [43], pulsed electromagnetic fields [44], and low-intensity pulsed ultrasound [45].

Alternative Tests Using Smart Insoles

Since this study has shown that sit-to-stand and stand-to-sit movements are valuable for monitoring rehabilitation progress after tibial and malleolar fractures, different assessments, such as the 5 times sit-to-stand test and the 30-second sit-to-stand test, may also be applicable for monitoring rehabilitation progress and determining whether the patients' performance returns to that of healthy adults. These tests involve multiple consecutive sit-to-stand and stand-to-sit movements, and the changes observed between consecutive sit-to-stand movements may differ throughout the rehabilitation process. This group of

XSL•FO
RenderX

parameters could have additional clinical value and should also be explored. Differences between similar repeated movements could result from fatigue or pain and are therefore expected to be greater at the beginning of the rehabilitation phase or in patients with nonunion.

The generalizability of the results cannot be judged from the present findings, but the authors believe that similar findings may be obtained from other patient collectives.

Limitations

A limitation of this study is that different types of fractures were assessed together in the analysis. Owing to the small sample of the tibial fractures, it was not possible to analyze each fracture type separately. The different fracture types might have altered the results. However, these differences are expected to be minor. In addition, only patients without mobility limitations before the fracture were included in this study, but previous minor changes in gait and movement may have affected the findings in individual patients. It is therefore important to consider the patient's mobility level before the fracture and surgery when monitoring rehabilitation. Overall, despite this being among the largest sample sizes for a nonunion group, the sample size is still small, and future studies should aim to collect larger sample sizes. Besides that, the patients with fracture nonunion were measured in a larger time frame (4-10 mo after surgery) and compared to patients with union whose measurements were taken about 6 months after surgery. This difference might have led to a chronological bias. However, since all patients with fracture nonunion had a persisting fracture gap, both groups had a similar fracture-healing status, and the effect is therefore expected to be small. Due to the small sample size, there is a risk of bias due to multiple analyses. It should be noted that muscle strength measurements are impossible in patients with fracture, as they pose a risk to the healing fracture and may result either in refracture or in implant failure. Instrumented insoles have been criticized for delivering estimates rather than measurements due to measurement error. Data have been shown to be influenced by age, body weight, body height, hand grip strength [46], the walking slope [47], and the walking surface [48]. The data delivered by instrumented insoles may be less accurate than the data recorded by force plates, and this fact should be acknowledged when interpreting the results of this study. In future studies, the pain level could be assessed each time, which was not done in this study, as the authors frequently observe patients with a nonunion who do not report any pain. However, to quantify these experiences, future studies could include such questions.

Conclusions

Both the conventional TUG test and the iTUG test can be used to monitor functional changes throughout the healing process of tibial and malleolar fractures. Instrumenting the TUG test with pressure-sensing insoles provided additional information, which made it possible to detect differences in loading during sit-to-stand and stand-to-sit movements between patients assessed 6 months after their surgery and controls. Most of the extracted TUG test parameters differed between the patients with and without union 6 months after surgery. These differences could be detected with both the conventional TUG test and the iTUG test. The TUG test might have the potential to identify patients at risk of developing nonunion earlier. This study indicates the potential of using functional outcomes to identify patients at risk of nonunion. Further investigation of additional tasks and functional outcomes is needed.

Acknowledgments

The authors acknowledge Dr Sonja Baumgartner, Jan Kattanek, Andrey Lange, Dr Jan Laqua, Diana Mergen, and Dr Caroline Stoll for assistance with patient recruitment and measurements. No generative AI was used in the manuscript.

Funding

This work was funded by the Werner Siemens Foundation for the project "Smart Implants 2.0." The funder had no involvement in the study design, data collection, analysis, interpretation, or the writing of the manuscript.

Data Availability

The dataset analyzed during the present study is available from the corresponding author upon reasonable request. Access may be granted based on a collaboration agreement. The requesting institution needs to fall within the eligibility criteria under German data protection law.

Abstract

Background: Optimal bowel preparation (BP) is crucial for a successful colonoscopy. Although multiple factors influence BP quality, including patient adherence to laxatives and dietary instructions, the stool state during BP should be properly evaluated to perform a colonoscopy of sufficient quality. Therefore, we developed a smartphone app to evaluate a patient's stool state during BP and a viewer to enable real-time monitoring by medical staff.

Objective: This study aimed to assess the feasibility of performing colonoscopies of appropriate quality using the app-and-viewer system.

Methods: This prospective observational study was conducted between November 2022 and December 2023, involving patients scheduled for colonoscopy at 10 Japanese institutions, comprising 6 tertiary hospitals, 3 regional general hospitals, and 1 community-based clinic. Patients who (1) underwent a colonoscopy at participating institutions, (2) were aged between 20 and 70 years, and (3) owned smartphones compatible with Android or iOS were included in the study. The patients downloaded the app on their smartphones and captured images of their stools during BP, while the medical staff reviewed the evaluation of the stools by the app via the viewer system. The primary end point was defined as the proportion of patients with a Boston Bowel Preparation Scale (BBPS) score of ≥6 among those who successfully used the app. Secondary end points included mean BBPS score, rate of an excellent BBPS score (≥8), adenoma detection rate, cecal intubation rate, and withdrawal time in negative colonoscopy. Additionally, we evaluated the usability of the app, medical staff workload burden with the app, and viewer usage via questionnaire surveys.

Results: A total of 343 patients were enrolled, and 326 were ultimately included in the analysis. Overall, 99.1% (323/326, 95% CI 97.3%-99.8%) of the patients achieved the primary end point. The mean BBPS score was 8.5 (SD 1.0), and the proportion of

XSL•FO
RenderX

excellent BBPS scores was 87.4% (285/326). The adenoma detection rate, cecal intubation rate, and mean withdrawal time in negative colonoscopy were 46.9% (153/326, 95% CI 41.4%-52.5%), 99.7% (325/326, 95% CI 98.3%-99.9%), and 10.7 (SD 5.9) minutes, respectively. In the questionnaire survey, 98.5% (321/326) of the patients reported that the tutorial was easy to understand, 96.0% (313/326) found stool image capture easy, and 87.8% (286/326) reported reduced anxiety regarding BP. Furthermore, 90.5% (295/326) of the patients indicated that they would like to use the app again for future colonoscopies. Among medical staff, 92.5% (62/67) considered the viewer system necessary, 89.6% (60/67) found it easy to use, and 89.6% (60/67) reported a reduction in workload burden.

Conclusions: AI-based stool state assessment using the app and the viewer during BP was feasible across diverse BP methods and clinical environments. Favorable BP outcomes and high usability among patients and medical staff support the potential use of this approach in real-world colonoscopy practice.

Introduction

The latest cancer statistics report high mortality and morbidity rates for colorectal cancer (CRC) worldwide [1]. Colonoscopy aids in the detection and resection of precancerous lesions, thereby reducing CRC-related morbidity and mortality [2-8]. Colonoscopy quality indicators include the adenoma detection rate (ADR), cecal intubation rate, withdrawal time, and bowel preparation (BP) [9-11]. Notably, the quality of BP is crucial for the other indicators to be maintained appropriately [12-15]. For instance, BP is associated with an improvement in ADR and with a decreased risk of CRC mortality [16].

Multiple factors affect BP quality, including patient adherence to laxatives and dietary instructions [17-19]. Accordingly, enhancing patient education using booklets, visual aids, short messages, or smartphone apps has proven effective [20-25]. Additionally, evaluating the stool state during BP is important to achieve appropriate BP quality. In Japan, BP is commonly performed at home or in the hospital. At home, patients use visual scales to assess their stool; in hospitals, the assessment may be conducted by the medical staff, contingent on the facility's protocols. In both methods, colonoscopy is initiated when the stool is clear and watery. However, evaluating the stool state during BP can be burdensome for patients and medical staff, and an accurate evaluation may sometimes be difficult. Some patients may also feel embarrassed about having their stool evaluated by the medical staff; likewise, the medical staff may experience psychological discomfort when assessing the patient's stool. Therefore, we previously developed a smartphone app incorporating AI to evaluate stool state during BP to address these issues, and the effectiveness of this app was demonstrated in a single-center study [26]. While the app was effective in assessing BP at the hospital, its feasibility at home or under diverse laxatives and toilet environments remains unknown. Furthermore, we developed a viewer system that connects to the app and enables the medical staff to easily monitor the patient's stool state during routine tasks without directly checking the app screen. This system is intended to improve workflow efficiency in clinical settings.

Accordingly, in this study, we aimed to assess the feasibility of performing colonoscopy of appropriate quality using our app and viewer system.

Methods

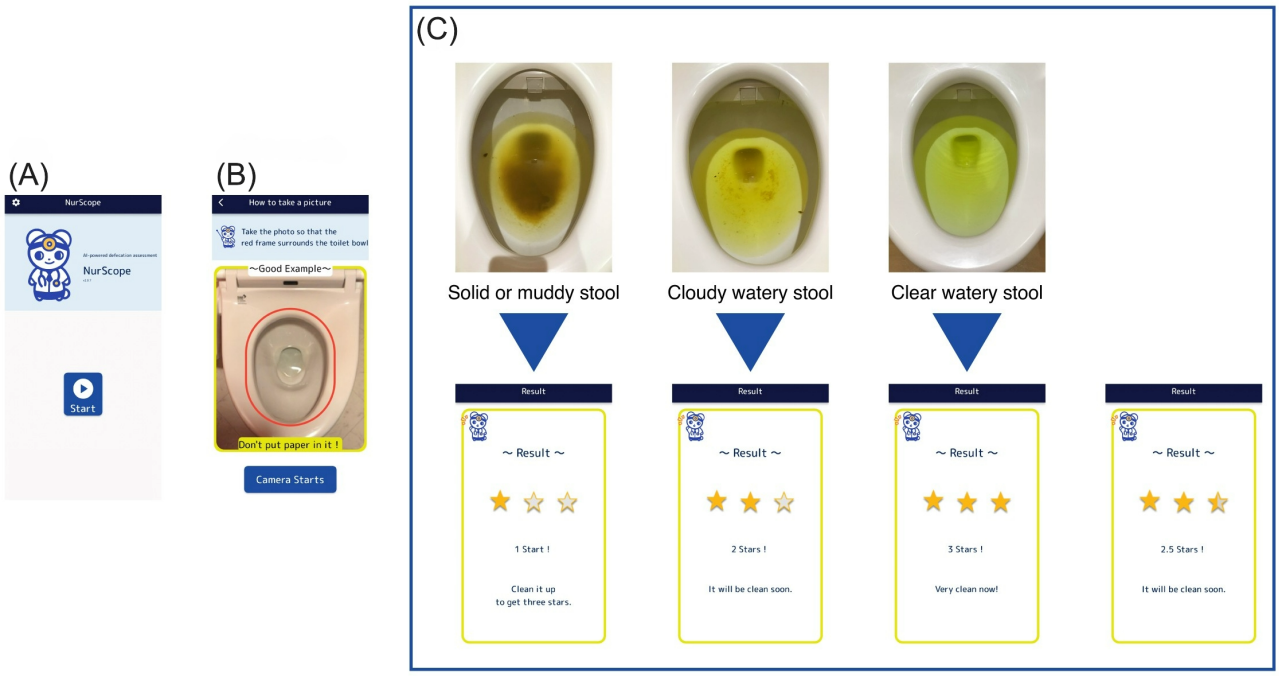
Study Design

This multicenter prospective study was conducted at 10 Japanese institutions, comprising 6 tertiary hospitals, 3 regional general hospitals, and 1 community-based clinic, between November 2022 and December 2023. Consecutive patients scheduled to undergo colonoscopy at participating institutions during the study period were screened for eligibility. Eligible patients were approached by the medical staff at each institution and invited to participate in the study.

Ethical Considerations

This study was conducted in accordance with the principles outlined in the Declaration of Helsinki and the Japanese Ethical Guidelines for Clinical Studies Involving Human Subjects. The study protocol was approved by the Institutional Review Board of the National Cancer Center (2022‐023). Written informed consent was obtained from all participants prior to study enrollment. All data were deidentified before analysis to protect participant privacy and confidentiality. Participants did not receive any financial compensation for participation in this study.

Patient Selection



Patients who met the following criteria were included in the study: patients (1) who underwent colonoscopy at participating institutions, (2) aged between 20 and 70 years, and (3) who owned smartphones with Android or iOS compatibility. Patients were excluded from the study if they met any of the following criteria: (1) had a known entire or subentire circumferential CRC, (2) previously underwent colorectal resection (excluding appendectomy), (3) had inflammatory bowel disease, (4) had colorectal disease with active bleeding, (5) had an Eastern Cooperative Oncology Group performance status of ≥2, or (6) had severe dementia.

RenderX

Instructions to Use the App and the Viewer

The screen displayed in the app is shown in Figure 1. The user was asked to start the app and tap the "Start" button. The user was presented with a screen explaining how to capture a picture. The user was cautioned to take a picture such that the red frame displayed on the screen aligned with the toilet bowl. Then, the user was asked to tap the button "Camera starts" to switch to the screen for taking pictures and touch the camera symbol to capture a picture. The captured stool images were graded on a 4-star scale: 1 star (solid or muddy stool), 2 stars (cloudy watery stool), 3 stars (clear watery stool), and 2.5 stars. Images evaluated as 1 or 2 stars indicated that the stools were insufficient to perform colonoscopy, whereas those evaluated as 3 stars indicated that the stools were sufficiently clear to perform colonoscopy. Images evaluated as 2.5 stars indicated clear watery stools excreted immediately after solid or muddy stools, or clear watery stools excreted despite a total defecation frequency of less than 5 times: this 2.5-star rating was included to ensure the reliability of the 3-star evaluation.

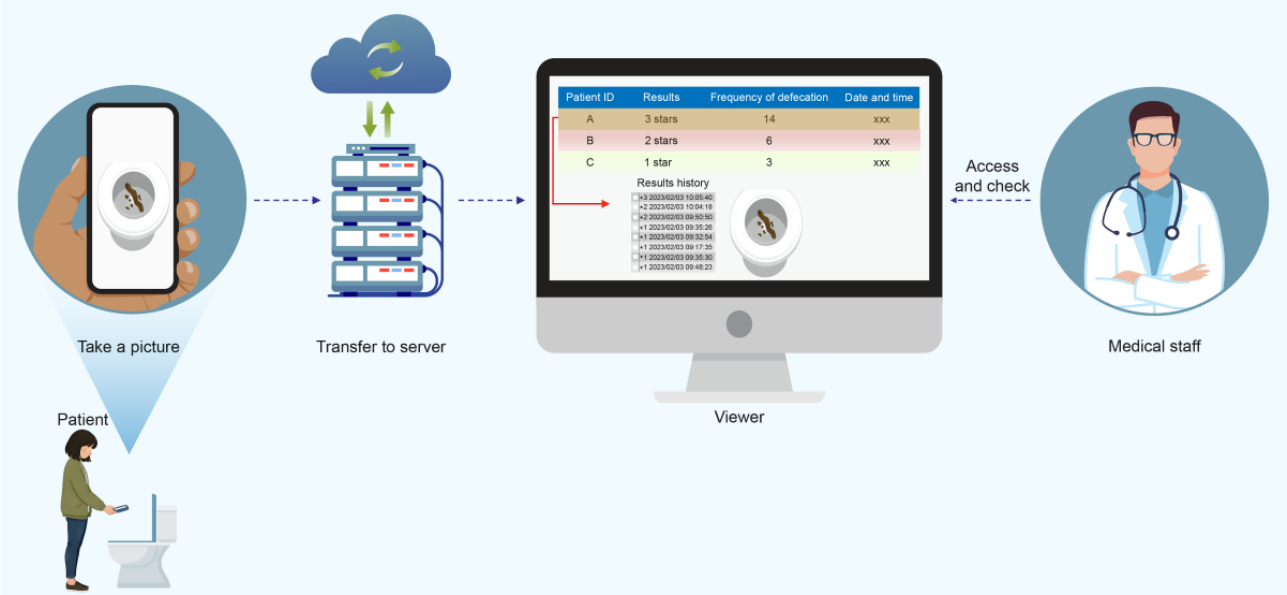

Figure 1. App screen display. (A) Start screen, (B) tutorial screen before taking pictures, and (C) screen displaying the result of stool image evaluation.

The viewer system is shown in Figure 2. Medical staff accessed the viewer using a dedicated personal computer independent of the electronic medical record system at each institution. A unique patient ID was issued when a patient downloaded the app. The viewer screen showed the lists of patient ID, number of defecations, and evaluation of the latest stool state by the app. The medical staff selected the patient ID and checked the number of defecations, stool images, and the app's evaluation. Further, the medical staff who participated in the study noted the patient ID in advance and checked the patient's stool state and the app's evaluation through the viewer during the BP, as necessary.

XSL•FO
RenderX

Figure 2. Overview diagram of the viewer system. Medical staff can check the number and timing of the patient's defecations, as well as the app's evaluation results, by entering the patient ID into the viewer.

Bowel Preparation

BP procedures followed the usual practices established at each institution. The method of laxative intake (same-day or split-dose method), the location where BP was performed, and the consumption of a low-fiber diet were determined by each institution. Patients received picosulfate, sennoside, magnesium oxide, or elobixibat the day before colonoscopy, as needed. On the day of colonoscopy, the patient was administered one of the following laxatives (Table S1 in Multimedia Appendix 1): polyethylene glycol with ascorbic acid (MOVIPREP; EA Pharma Co), magnesium citrate (MAGCOROL; Horii Pharmaceutical Ind), polyethylene glycol (NIFLEC; EA Pharma Co), oral sulfate solution (SULPREP; Fuji Pharma), or magnesium citrate plus sodium picosulfate (PICOPREP; Nippon Chemiphar Co). BP solutions were generally administered on the day of colonoscopy. However, when BP was performed over 2 days, including the day before and the day of colonoscopy, the regimen was determined according to the protocol of each participating institution. Prior to BP, patients downloaded the app to their smartphones and reviewed the instructions for use displayed within the app. Once BP was initiated, patients used the app to capture images of their stools every time they defecated. Colonoscopy was performed when the app presented 3 stars within 3 hours of administration. Contrastingly, when the app did not display 3 stars within 3 hours after BP initiation, additional procedures (such as additional laxative administration or enema) were conducted at the discretion of the doctor. If the app displayed 3 stars after additional procedures, a colonoscopy was subsequently performed. Colonoscopy was performed at the discretion of the doctor for patients who could not tolerate these procedures or who were not presented with 3 stars even after additional procedures.

End Points

Considering that the quality of colonoscopy strongly depends on the degree of bowel cleansing, the Boston Bowel Preparation Scale (BBPS) was used to assess the quality of colonoscopy in this study [27]. The BBPS score was recorded by the endoscopists who performed the colonoscopy. Endoscopists were not blinded to study participation status or app evaluations. The primary end point was defined as the proportion of patients with a BBPS score of ≥6 among patients who successfully used the app. The secondary end points were the mean BBPS score; rate of excellent BBPS score (BBPS score ≥8); mean BBPS score of each segment (right colon, transverse colon, and left colon); ADR; cecal intubation rate; mean withdrawal time in negative colonoscopy; rate of fair, good, or excellent on the Aronchick scale [28]; mean time from laxative administration to colonoscopy initiation; proportion of patients with 3 stars, 2.5 stars, 2 stars, and 1 star for the app's evaluation; proportion of cases with a BBPS score ≥6 when colonoscopy was performed for each evaluation in the app; diagnostic performance of the app for predicting adequate BP (BBPS score ≥6); mean BBPS score for each evaluation; and adverse events in colonoscopy. Additionally, we surveyed patients and medical staff who participated in this study to assess the usability and effectiveness of the app and viewer system using a questionnaire. These end points were also evaluated in patients who could successfully use the app, referring to patients who could launch the app by themselves, capture their stool images, and confirm the app's evaluation. Successful app use was defined as obtaining at least 5 appropriate stool images during BP. If patients missed a stool image, they could self-report it using a dedicated function within the app. Cases were still considered successful even if some images were of poor quality, captured the stool only partially, or contained nonstool objects, provided that at least 5 appropriate stool images were ultimately obtained. We also calculated the proportion of patients who failed to use the app among all enrolled patients.

Statistical Analysis

For the primary end point, the target value was defined as 95% or above according to the European guideline [10]. The threshold value for the proportion of patients with a BBPS score

XSL•FO
RenderX

of ≥6 among patients who successfully used the app was 90%. Considering an expected value of 95%, a one-sided alpha of 2.5%, and a power of 90%, the number of patients required was calculated to be 316 by a method based on binomial distribution. The target number of patients was set to 340 to account for patients who could not use the app successfully. All statistical analyses were performed using SAS (version 9.4).

Results

Patient Characteristics

A total of 343 patients were enrolled in this study. After the exclusion of 17 patients, 326 eligible patients were included in the final analysis. The median patient age was 57 (IQR 48-63; range 26 - 69) years, and 57.7% (n=188) were men (Table 1). Among the 326 patients, 99.4% (n=324) underwent same-day BP, and 68.4% (n=223) underwent BP at home. In addition, 8.6% (n=28) of the patients had a history of inadequate BP during a previous colonoscopy.

Study Flow

As shown in Figure 3, 326 patients successfully used the app and underwent colonoscopy following the app's evaluation. Furthermore, 245 patients were conferred 3 stars within 3 hours of the start of laxative administration and subsequently underwent colonoscopy, whereas 81 patients did not receive 3 stars even 3 hours after laxative initiation. Of these, 63 patients who could not tolerate the additional procedure underwent colonoscopy at the discretion of the doctor, whereas 18 patients underwent additional procedures. Of these 18 patients, 15 were further evaluated with 3 stars, and a colonoscopy was performed. The remaining 3 patients who were not graded with 3 stars underwent colonoscopy at the discretion of the doctor.

Figure 3. Status of the patients in the study flow from laxative administration to colonoscopy. BP: bowel preparation; TCS: total colonoscopy.

Outcome

Among the entire cohort, 99.1% (323/326, 95% CI 97.3%-99.8%) of the patients had a BBPS score of ≥6 (Table 2), indicating that the primary end point was met because the lower limit of the 95% CI exceeded the prespecified threshold of 90%. The mean BBPS score was 8.5 (SD 1.0), and the proportion of excellent BBPS score was 87.4% (285/326). The mean BBPS scores of the right, transverse, and left colons were 2.8 (SD 0.5), 2.9 (SD 0.3), and 2.9 (SD 0.4), respectively. The proportion of fair, good, or excellent Aronchick scale scores was 98.8% (322/326). The ADR, cecal intubation rate, and mean withdrawal time in negative colonoscopy were 46.9% (153/326, 95% CI 41.4%-52.5%), 99.7% (325/326, 95% CI 98.3%-99.9%), and 10.7 (SD 5.9) minutes, respectively. The proportions of patients with 3 stars, 2.5 stars, 2 stars, and 1 star for the app's evaluation were 79.8% (260/326), 5.8% (19/326), 12.6% (41/326), and 1.8% (6/326), respectively. The proportion of cases with a BBPS score of ≥6 when colonoscopy was performed for each evaluation in the app was 100% (260/260), 100% (19/19), 95.1% (39/41), and 83.3% (5/6) for the 3 stars, 2.5 stars, 2 stars, and 1 star, respectively. The mean BBPS score for each evaluation outcome was 8.6 (SD 0.8), 7.9 (SD 1.2), 8.4 (SD 1.2), and 7.5 (SD 2.9) for 3 stars, 2.5 stars, 2 stars, and 1 star, respectively. The mean time from laxative administration to colonoscopy initiation was 305 (SD 89) minutes. The incidence rates of adverse events in colonoscopy, particularly bleeding, perforation, and ischemic colitis, were 0.6% (2/326), 0% (0/326), and 0% (0/326), respectively. The diagnostic performance of the app for predicting a BBPS score of ≥6 is summarized in Table S2 in Multimedia Appendix 1. The sensitivity, specificity, positive predictive value, and negative predictive value were 80.5%, 100%, 100%, and 4.5%, respectively.

Questionnaire Survey

Table 3 presents the results of the survey to assess the usability and effectiveness of the app and viewer system using a questionnaire administered to patients. Overall, 96.0% (313/326) of the patients answered that downloading the app was easy, 98.5% (321/326) reported that the description screen was easy to understand, and 96.0% (313/326) expressed that they could take pictures of their stool without any problems. Of the 15.6% (51/326) of patients who felt uncomfortable with the medical staff checking their defecation, 98.0% (50/51) of those answered that using the app would solve this problem. Furthermore, 37.7% (123/326) of the patients answered that they had no confidence in evaluating their own stool state, and 87.8% (108/123) of those patients answered that using the app would solve this problem. Ultimately, 90.5% (295/326) of the patients indicated a preference for using the app during their next colonoscopy.

Table . Questionnaire survey for patients (n=326).

Questionnaire results	Participants, n/N (%)
Question 1. Did you download the app without any problems?	
Yes	313/326 (96.0)
No	13/326 (4.0)
Question 2. Was the app tutorial screen easy to understand?	
Yes	321/326 (98.5)
No	5/326 (1.5)
Question 3. Was it easy to take stool images?	
Yes	313/326 (96.0)
No	13/326 (4.0)
Question 4. Was the evaluation of the app easy to understand?	
Yes	310/326 (95.1)
No	16/326 (4.9)
Question 5. Would you feel uncomfortable if your stool was checked by medical staff during the BP[a]?	
Yes	51/326 (15.6)
No	275/326 (84.4)
Did you feel that the app would improve your discomfort?[b]	
Yes	50/51 (98.0)
No	1/50 (2.0)
Question 6. Do you have any concerns about being able to evaluate your own defecation during the BP?	
Yes	123/326 (37.7)
No	203/326 (62.3)
Did you feel that your anxiety would be relieved by the app?[c]	
Yes	108/123 (87.8)
No	15/123 (12.2)
Question 7. Would you like to use the app for your next colonoscopy?	
Yes	295/326 (90.5)
No	31/326 (9.5)

[a]BP: bowel preparation.

[b]This question was administered to participants who answered "Yes" to question 5.

[c]This question was administered to participants who answered "Yes" to question 6.

Table 4 presents the results of the questionnaire survey administered to the medical staff. Overall, 83.6% (56/67) of the medical staff checked the patients' stool state during daily work. Among them, 17.9% (10/56) answered that they felt a psychological burden, and 55.4% (31/56) answered that they felt a physical burden in checking patients' stool state in their daily work. Notably, 89.6% (60/67) of the medical staff indicated that the implementation of the app would alleviate these burdens. For the viewer system, 89.6% (60/67) of the medical staff reported that it was easy to use, while 92.5% (62/67) indicated that it was necessary for BP.

[b]This question was administered to participants who answered "Yes" to question 1.

Discussion

This multicenter prospective study successfully evaluated the performance of the app across various types of laxatives, toilet bowls, and diverse patient populations. Among 326 patients who successfully used the app, 99.1% (n=323) patients achieved a BBPS score ≥6, which exceeded the set expected value. Additionally, several key quality indicators, including an ADR of 46.9% (n=153) and a cecal intubation rate of 99.7% (n=325), exceeded the target values recommended by American and European guidelines [9,10]. These results demonstrated the feasibility of app-guided BP management while maintaining high-quality colonoscopy indicators across multiple institutions and environments.

Notably, this study demonstrated the effective use of our app across a wide range of clinical settings. Specifically, we validated our app under diverse BP protocols and toilet environments and demonstrated that it could be applied to BP management in various clinical contexts. The following 2 main findings of this study support the versatility of the app, which is critical for its implementation in real-world clinical practice.

First, we evaluated the app's assessment of BP using a variety of laxatives. In Japan, 6 major types of laxatives are commonly used for BP [29], of which 5 were used in this study. Additionally, the timing of administration, use of a low-fiber diet, and administration of laxatives on the day before colonoscopy were determined according to the protocols of each institution. Regardless of the type of laxative used and a wide variety of BP methods, a stool state evaluation rated as 3 stars using the app indicated that colonoscopy could be performed with a BBPS score ≥6 in 100% (260/260) of cases. Moreover, the mean BBPS score of patients rated as 3 stars was ≥8 (SD 0.8; excellent BBPS score). Even in real-world clinical settings, which exhibit variability in the types of laxatives used and BP methods, the 3-star rating by the app was shown to be highly correlated with an excellent BBPS score. These findings suggest that the app can assist BP across a broad range of institutional practices (eg, clinics and general hospitals) and diverse patient needs (eg, preference and tolerability for specific laxatives and low-fiber diets) while maintaining an adequate quality of colonoscopy. Although the app evaluations were associated with BP quality, the app was not designed to directly predict BBPS score. Instead, the app was intended to evaluate stool state to verify whether BP was sufficient to proceed with colonoscopy. In the present study, 95.1% (39/41) of the patients with a 2-star evaluation and 83.3% (5/6) of those with a 1-star evaluation still achieved a BBPS score ≥6. Consistent with these findings, the app showed a high positive predictive value (100%) but a low negative predictive value (4.5%) for predicting a BBPS score of ≥6 above. These results suggest that while a 3-star evaluation reliably identified patients with adequate BP (BBPS score ≥6), lower star evaluations did not necessarily indicate inadequate BP (BBPS score <6). Although the number of patients with a 1-star evaluation was small, these findings suggest that a substantial proportion of patients with lower star

XSL•FO
RenderX

evaluations ultimately achieved adequate BP. This may reflect limitations of the star-based evaluation, as well as the imperfect relationship between stool state immediately before colonoscopy and overall bowel cleanliness assessed by the BBPS. Nevertheless, further refinement of the stool-state assessment algorithm may improve its ability to distinguish between different stool states during BP. In the present study, some patients with 1-star or 2-star evaluations still achieved a BBPS score of ≥6, suggesting that additional preparation may have been unnecessary in a subset of cases. Therefore, there remains room for improvement in the diagnostic discrimination of the app, particularly in reducing potential additional preparation (eg, additional laxative intake or enema). To further clarify the diagnostic characteristics of the app, sensitivity, specificity, positive predictive value, and negative predictive value for predicting a BBPS score of ≥6 are summarized in Table S2 in Multimedia Appendix 1.

Second, the study included both hospital-based and home-based BP settings, reflecting diverse real-world environments with potential variability in toilet conditions. Unlike our previous study [26], this study also included patients who underwent BP at home. Evaluations for BP at hospitals were conducted using toilet bowls available at each of the 10 participating institutions. Meanwhile, evaluations for BP at home were performed using toilets installed in each patient's home. Thus, the app assessed a wide variety of toilet bowls. In both settings, when the evaluation of the app was 3 stars, colonoscopy was performed with a BBPS score of ≥6 in 100% (260/260) of the cases. Furthermore, the mean BBPS score for patients rated as 3 stars was ≥8 (SD 0.8) in both settings, indicating that an excellent BBPS score was achieved. Therefore, even across a wide variety of toilet environments with differences in shape, color tone, and lighting conditions, the app was able to evaluate stool state consistency; when the stool was rated as 3 stars, colonoscopy could be performed with an adequate BBPS score. These findings suggest that the app may be applicable across diverse clinical and home-based environments and support its potential feasibility in real-world clinical practice.

Using a similar approach to this study, 2 recent reports have demonstrated the effectiveness of AI-based smartphone apps in improving BP quality [30,31]. In previous studies, the developed app had a binary classification function directly determining whether the bowel cleansing quality was adequate based on the stool state. Consequently, the mean BBPS score achieved with those apps was 7.2 (SD 1.4) and 6.7 (SD 1.3), respectively. In contrast, our app evaluated each defecation individually during the BP process, considering the number of defecations. The app was used to assess stool state throughout the BP process, followed by colonoscopy. In our study, a mean BBPS score of 8.5 (SD 1.0) was observed, which was higher than the values reported in previous studies. These findings suggest that it is difficult to accurately predict the quality of BP solely based on a single stool state and that evaluating all defecations may support more appropriate BP management throughout the BP process.

The observed rate of the BBPS score of ≥6 in this study was notably high (99.1%, 323/326), exceeding both the minimum (≥90%) and target (≥95%) standards recommended by the European guideline [9,10]. Several factors may have contributed to this finding. First, patients aged 70 years or older were excluded from this study. Because advanced age is a known risk factor for inadequate BP, this exclusion may have contributed to the favorable BBPS outcomes. However, this exclusion criterion was not intended to select patients with better BP quality. Instead, this decision was based on the low smartphone ownership rates among older individuals in Japan at the time of study protocol development (38.3% among individuals in their 70s and 11.0% among those in their 80s), as well as our previous single-center experience showing that all patients who were unable to appropriately operate the app were aged 70 years or older [26,32]. Therefore, older patients were excluded because they were considered more likely to have difficulty appropriately using the app in this study. In addition, the use of the app itself and the awareness that stool images and app evaluations could be reviewed by medical staff through the viewer system may have increased patient awareness and adherence to BP instructions (ie, observation effect).

Although the mechanisms underlying the potential benefits of the app were not directly evaluated in this study, several possible explanations and future perspectives may be considered. Several mechanisms may explain how the app could support BP management. First, the viewer system enabled real-time monitoring of stool state during BP, allowing medical staff to review temporal changes and provide timely instructions when needed. Second, the use of the app itself may have promoted behavioral reinforcement and improved adherence to BP instructions. In addition, future expansion of app functions, such as automated reminders for examination schedules and dietary instructions, may further support behavioral modification during BP. Third, the app may help reduce uncertainty in BP assessment. In Japan, stool state is commonly evaluated during BP; however, assessment methods may vary across institutions and between patients and medical staff. By providing standardized stool state assessment and visualization of temporal changes in stool state, the app may help reduce variability and uncertainty in BP management.

Although our app evaluates the stool state over time during BP, the responsibility for deciding whether to proceed with colonoscopy based on the app's evaluations or to implement additional procedures if the BP is insufficient lies with the medical staff. Therefore, a viewer system was introduced in this study to enable an efficient review of temporal changes in stool state and the corresponding evaluations during BP. In the questionnaire survey, most medical staff reported no issues with the usability of the viewer and responded that the viewer was necessary during BP. Particularly, the reasons cited for the necessity of the viewer were that its use enabled real-time monitoring of BP, allowing timely instructions for patients during the BP process, and that it had the potential to reduce patient waiting times before colonoscopy. Thus, by enabling a standardized assessment of the stool state and real-time monitoring, the combined use of the app and viewer system introduces a new framework for quality assurance in BP.

Finally, the usability of our app was evaluated using questionnaires administered to patients and medical staff. Most patients were able to use the app without any issues, and

XSL•FO
RenderX

discomfort with having their stool state assessed by medical staff, as well as anxiety about evaluating their own stool state, was alleviated using the app. The observed reduction in patient anxiety during BP suggests that the app may also help lower the psychological barriers to undergoing colonoscopy. Furthermore, answers from medical staff suggested that using the app might help reduce their physical and psychological burdens. This reduction implies that the app can support a more efficient clinical workflow. In health care systems experiencing workforce shortages, especially in aging populations, tools that facilitate task shifting and reduce manual workloads are essential. In this regard, our app may provide a practical solution for supporting efficient BP management without compromising the quality of care.

Nevertheless, this study has some limitations. First, the study was not designed as a randomized controlled trial and therefore lacks direct comparison with BP without the use of the app. Future randomized controlled trials comparing outcomes with and without the app are essential to validate the clinical usage of the app more robustly. Second, we did not specifically assess the usability of the app in patients aged 70 years or older. This subset of patients was excluded from the study because smartphone ownership rates among older individuals in Japan were relatively low at the time of study initiation, and many older patients were unfamiliar with smartphone app operation. In addition, in our previous single-center study, all patients who were unable to appropriately operate the app were aged 70 years or older. However, smartphone ownership among older individuals in Japan has increased substantially in recent years. According to national data from 2024, smartphone ownership rates have risen to 67.5% among individuals in their 70s and 30.7% among those in their 80s [33]. Therefore, with further improvements in user interface design and usability support, the applicability of the app to older patients and populations with lower digital literacy may expand in the future. Third, this study was conducted exclusively in Japan. Therefore, the generalizability of the results to other countries remains unclear. Furthermore, because BP protocols and toilet environments differ across countries and regions, further validation studies are needed to confirm whether the app can achieve similar performance outside Japan. Fourth, endoscopists who assigned BBPS were not blinded to study participation status or app evaluations. Therefore, the possibility of observer bias in BBPS assessment cannot be excluded because the primary end point relied on endoscopist-assigned BBPS. Although all participating endoscopists received standardized instruction on BBPS assessment, including washing and suctioning of residues before scoring, such training cannot completely eliminate the possibility of assessment bias in a nonblinded study. Fifth, the primary end point analysis included only patients who successfully used the app. Therefore, the observed results may overestimate the feasibility of app-guided BP management in real-world settings.

In conclusion, the proportion of patients with a BBPS score of ≥6 for colonoscopy using the app exceeded the expected value in addition to the threshold value. In this multicenter prospective study, AI-based stool state assessment using the app and viewer during BP was feasible across diverse BP methods and clinical environments. Favorable BP outcomes and high usability among patients and medical staff support the potential usage of this approach in real-world colonoscopy practice.

Acknowledgments

The authors thank all participating patients and nurses who answered the questionnaire. The authors also thank Junko Iwase for supporting data management; Natsuko Iwasaki, Mayumi Yamada, and Yuya Ikeda of the Clinical Research Support Office, National Cancer Center Hospital East, for generously providing the EDC system and for their invaluable support with data management; and Astellas Pharma Inc. for supporting the implementation of this study. The authors also wish to thank Editage [34] for English language editing.

Generative AI tools (ChatGPT, OpenAI) were used to assist with language editing and improvement of manuscript readability. The authors reviewed and edited all AI-generated content and take full responsibility for the final content of the manuscript.

Abstract

Background: Mobile health (mHealth) technologies are increasingly integrated into perioperative care to enhance patient engagement and communication. Prior studies in surgical and medical specialties suggest that mHealth platforms may be associated with reductions in hospital stay and readmissions; however, evidence supporting their impact in otolaryngology, particularly in sinonasal surgery, remains limited.

Objective: The aim of this study was to evaluate the association between perioperative enrollment in CareSense, a patient-facing mHealth platform, and postoperative health care utilization outcomes, including hospital readmissions, emergency department (ED) visits, and length of stay (LOS), among adults undergoing sinonasal surgery.

Methods: This is a retrospective cohort study performed at a single tertiary care academic medical center between May 2021 and January 2024. All adult patients (≥18 years) who underwent sinonasal surgery with two fellowship-trained rhinologists during the study period were included. CareSense was offered to all patients at the time of surgical scheduling, and enrollment was voluntary. Patients were categorized into CareSense participants and nonparticipants. Primary outcomes were all-cause hospital readmissions and ED visits within 30, 60, and 90 days following surgery. Secondary outcomes included the length of hospital stay among readmitted patients. Clinical, demographic, and outcome data were obtained through retrospective electronic health record review. Univariate analyses compared outcomes between groups, and multivariable logistic regression using generalized estimating equations was performed to estimate the association between CareSense participation and outcomes while adjusting for age, sex, hypertension, and diabetes.

Results: A total of 1135 patients were included, of whom 340 (30%) enrolled in CareSense and 795 (70%) did not. Compared with nonparticipants, CareSense participants had lower adjusted odds ratio (OR) for readmission for any cause at 30 days (OR 0.24, 95% CI 0.08 - 0.75; *P*=.007), 60 days (OR 0.40, 95% CI 0.19 - 0.83; *P*=.01), and 90 days (OR 0.54, 95% CI 0.29 - 0.99; *P*=.04). Among patients who were readmitted, mean LOS was shorter in the CareSense group than in the nonparticipating group (0.17 vs 1.68 d; *P*<.001). The majority of readmissions in both cohorts were unrelated to complications of the index sinonasal procedure.

Conclusions: This study demonstrates the benefit of CareSense in lowering postoperative readmission rates and LOS for sinonasal surgery patients, illustrating the role of medical health technology in improving patient care and quality outcomes. Perioperative enrollment in a patient-facing mHealth platform was associated with lower postoperative health care utilization and shorter hospital length of stay following sinonasal surgery. Given the voluntary nature of enrollment and the observational design, these findings should be interpreted as observation findings and hypothesis-generating for prospective studies to more definitively assess the causal impact of mHealth interventions and to identify which components of digital perioperative care most effectively improve outcomes in otolaryngologic surgery.

Introduction

Continuous improvement in patient care and clinical outcomes remains a central goal in health care, and advances in digital technology have created new opportunities to support this aim by improving communication, education, and patient engagement. The World Health Organization defines mobile health (mHealth) as "medical and public health practice supported by mobile devices, such as mobile phones, patient monitoring devices, personal digital assistance, and other wireless devices" [1,2]. As mobile phone usage steadily increases worldwide, leveraging this development offers the potential for rapid dissemination of health information and remote patient engagement, which may enhance medical care as evidenced during the COVID-19 pandemic [3].

Over the past decade, mHealth interventions have been increasingly incorporated into routine care across multiple specialties [4]. Emerging evidence suggests that these platforms may be associated with improvements in health care utilization outcomes, including reduced length of stay and lower readmission rates in orthopedic and cardiovascular populations [5-8]. In otolaryngology, mHealth tools have been adopted for perioperative communication and symptom monitoring; however, evidence evaluating their association with postoperative health care utilization remains limited, particularly for patients undergoing sinonasal surgery [9-11].

CareSense is a patient-facing mHealth platform designed to support perioperative care through automated educational content and reminders delivered via text message or email, with parallel clinician-facing dashboards for monitoring patient-reported information. The platform aims to improve patient preparedness and adherence with visits and surgeries by facilitating perioperative education and communication, while enabling tracking of patient progress and satisfaction. The aim of this study was to evaluate the association between perioperative enrollment in CareSense and postoperative health care utilization outcomes, including hospital readmissions, emergency department visits, and length of hospital stay, among adults undergoing sinonasal surgery.

Methods

Study Population

A retrospective observational cohort study was conducted at a single tertiary academic medical center between May 2021 and January 2024. Beginning May 2021, the Department of Otolaryngology–Head and Neck Surgery at Houston Methodist Hospital began offering CareSense (MedTrak, Inc) to all patients undergoing sinonasal surgery. Clinical, demographic, and outcome data were obtained through retrospective review of the electronic health record (EHR). All patients ≥18 years of age who underwent sinonasal surgery with two fellowship-trained rhinologists were included. Patients were divided into 2 groups: those who elected to participate in CareSense and those who did not. Enrollment in CareSense was voluntary and occurred at the time of surgical scheduling.

Ethical Considerations

This study was reviewed and approved by the Houston Methodist Research Institute Institutional Review Board (PRO00036908) with a waiver of informed consent due to its retrospective design and use of existing clinical data. All data were analyzed in a deidentified format to protect patient privacy and confidentiality. No compensation was provided to the participants.

Mobile Health Technology

CareSense is a digital platform used to deliver standardized perioperative educational content and automated reminders to patients undergoing surgery. Enrolled patients received procedure-specific "pathways," defined as preset configurations of communication and information delivery tailored to the planned surgery (eg, sinus surgery or septoplasty). Each pathway provided surgery-specific perioperative instructions and educational materials, including preoperative preparation, postoperative expectations, warning signs of complications, and medication courses. Message timing and content were predefined and delivered consistently across enrolled patients via text message or email. Communication formats included brief text notifications, longer-form educational emails, and physician-defined survey questions, with selected responses generating alerts within a clinician-facing Care Navigator dashboard. Details of the sinus surgery and septoplasty pathways are provided in Multimedia Appendices 1 and 2, respectively. Patients without access to a mobile phone or email address were not eligible for enrollment.

Outcome Measures

The primary outcomes evaluated were readmission rates and emergency visits to any of our hospital system sites within 30, 60, and 90 days of discharge following sinonasal surgery. Readmissions were defined as any unplanned inpatient or observation admission occurring after surgery. Emergency department (ED) visits were defined as encounters that originated in the ED and resulted in discharge without inpatient admission. Outcome ascertainment was performed through system-wide EHR review, capturing events occurring within the same integrated health system. The secondary outcome was postoperative length of stay (LOS) among patients who were readmitted, used as a surrogate for the complexity and acuity of the readmission. Outcomes were assessed at fixed postoperative intervals; variation in individual follow-up duration beyond these windows was not evaluated. All patients were followed through the EHR for a minimum of 90 days postoperatively within the integrated health system, with outcome ascertainment limited to encounters captured during these predefined intervals.

Statistical Analysis

Demographic and comorbidity data were available for all patients. Differences in baseline patient characteristics between CareSense participants and nonparticipants were assessed using an independent-samples *t*-test for continuous variables and χ^2 tests for categorical variables. Univariate analyses using χ^2 testing were performed to compare outcome measures between the two cohorts. Given the low frequency of procedure-related

XSL•FO
RenderX

events, analyses of surgery-related readmissions were conducted descriptively rather than through inferential subgroup modeling. To partially address confounding related to voluntary enrollment, multivariable logistic regression using generalized estimated equations (GEE) was used to estimate the association between CareSense participation and postoperative outcomes while adjusting for prespecified covariates, including age, sex, hypertension, and diabetes. Covariates were prespecified a priori based on clinical relevance and prior literature evaluating postoperative health care utilization [12-14]. Odds ratios (ORs) with 95% CIs were reported. All statistical tests were two-sided, with an α level of .05 considered statistically significant. Univariate analyses were performed using Jamovi [15], and multivariable analyses were conducted in RStudio (version 4.3; R Core Team, 2023).

Results

Study Population

A total of 1135 patients underwent sinonasal surgery from May 2021 to January 2024. Among these patients, 340 (30%) elected to participate in CareSense, whereas 795 (70%) did not participate. Enrollment in CareSense increased over time, with an 80.7% increase from 2021 to 2024.

Of the 340 patients enrolled in CareSense, 202 (59%) were assigned to the sinus surgery pathway and 138 (41%) to the septoplasty with turbinate reduction pathway (Multimedia Appendix 1 and Multimedia Appendix 2, respectively). Patient demographics and baseline characteristics are summarized in Table 1.

[b]COPD: chronic obstructive pulmonary disease.

[c]GERD: gastroesophageal reflux disease.

XSL•FO
RenderX

Overall, the mean age of participating patients was 47.1 (SD 17.2) years, and that of nonparticipating patients was 51.1 (SD 17.8) years (*P*<.001). Males accounted for 420 of 795 (52.8%) patients in the nonparticipating group and 202 of 340 (59.4%) patients in the participating group (*P*=.04). There were no statistical differences in race and ethnicity between groups.

The nonparticipating group had a higher prevalence of hypertension (365/795, 45.9% vs 127/340, 37.4%, *P*=.008) and type 2 diabetes (150/795, 18.9% vs 41/340, 12.0%, *P*=.005). There were no significant differences between groups with respect to asthma, atherosclerosis, chronic obstructive pulmonary disease, gastroesophageal reflux disease, heart failure, and hyperlipidemia. Self-reported alcohol use, tobacco use, and illicit drug use did not significantly differ between groups.

Outcome Measures

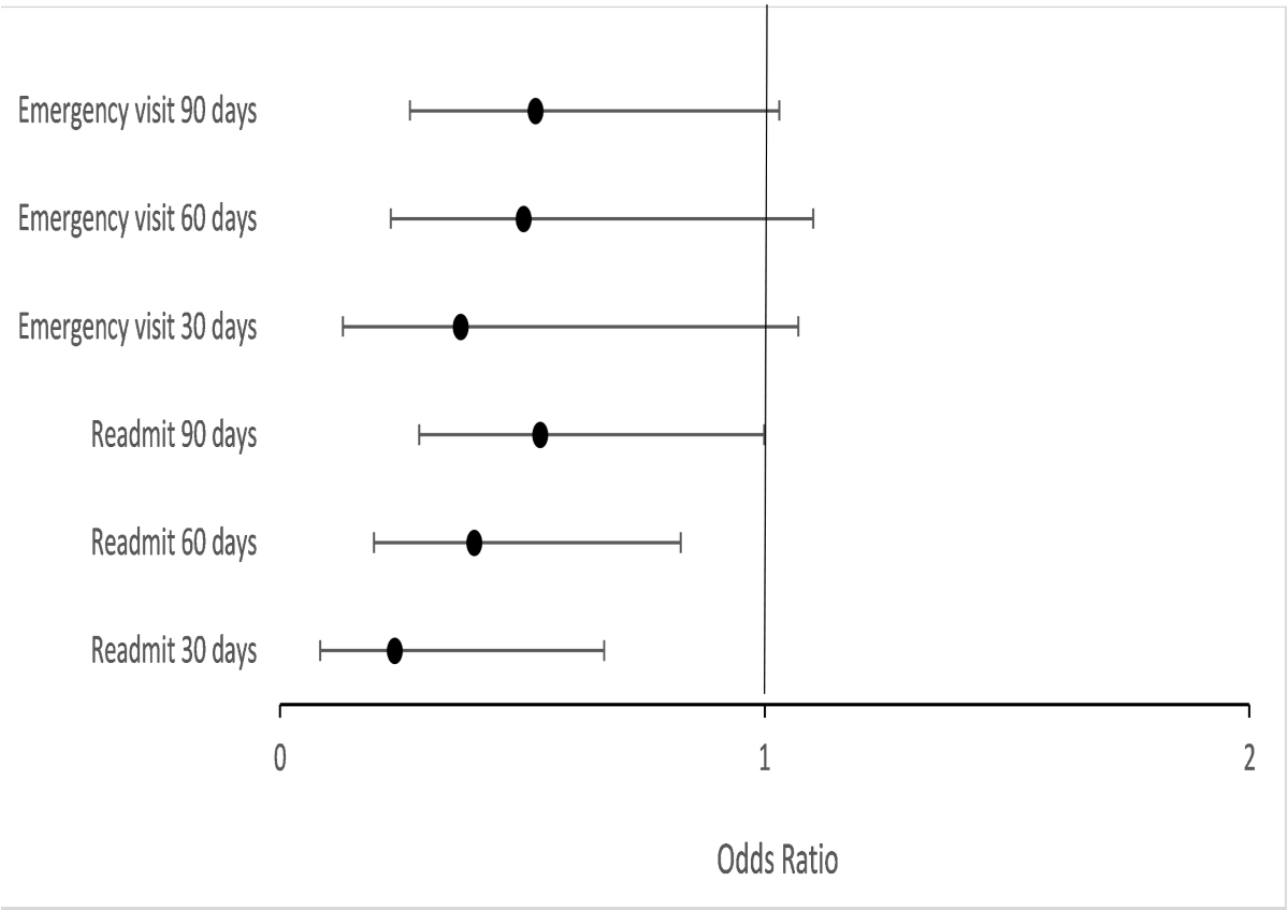
Readmission rates are presented in Table 2. At 30 days postoperatively, readmission rates were 5.8% (46/795) in the nonparticipating group and 1.2% (4/340) in the participating group (*P*<.001). At 60 days, readmission rates were 7.9% (63/795) in the nonparticipating group and 2.9% (10/340) in the participating group (*P*=.002). At 90 days, readmission rates were 8.9% (71/795) in the nonparticipating group and 4.1% (14/340) in the participating group (*P*=.005).

Table . Comparing the likelihood of readmissions and emergency visits between patients who were and were not enrolled in CareSense.

Outcome variables	Patients, n (%)		*P* value
	Control (n=795)	Intervention (n=340)	
Readmission (days)			
30	46 (5.8)	4 (1.2)	<.001
60	63 (7.9)	10 (2.9)	.002
90	71 (8.9)	14 (4.1)	.005
Emergency visit (days)			
30	27 (3.4)	4 (1.2)	.04
60	40 (5.0)	8 (2.4)	.04
90	52 (6.5)	11 (3.2)	.03

ED visit rates demonstrated a similar pattern. At 30 days, ED visit rates were 3.4% (27/795) in the nonparticipating group and 1.2% (4/340) in the participating group (*P*=.04). At 60 days, visit rates were 5.0% (40/795) in the nonparticipating group and 2.4% (8/340) in the participating group (*P*=.04). At 90 days, visit rates were 6.5% (52/795) in the nonparticipating group and 3.2% (11/340) in the participating group (*P*=.03).

To further characterize postoperative health care utilization, an exploratory descriptive analysis was performed examining readmissions related to complications of the index sinonasal procedure. Among the 202 patients enrolled in the CareSense sinus surgery pathway, 14 (7%) experienced a readmission, compared with 7 (5%) of the 138 patients enrolled in the septoplasty pathway (*P*=.45). Of all readmissions in the participating group, 6 of 25 (24%) were related to postoperative complications of the index procedure, including 5 cases of uncontrolled epistaxis and 1 nasoseptal abscess. In the nonparticipating group, 21 of 125 readmissions (17%) were procedure-related (*P*=.41), most commonly due to uncontrolled epistaxis (18 cases), with additional causes including sinusitis flares requiring intravenous antibiotics (2 cases) and septal hematoma (1 case). When related to the index procedure, readmissions were predominantly attributable to uncontrolled epistaxis in both cohorts. Unrelated admissions included asthma exacerbations, chest pain, abdominal pain, and COVID-19–related illness.



The mean postoperative LOS among patients who were readmitted was 1.68 days in the nonparticipating group compared with 0.17 days in the participating group (*P*<.001).

Multivariable Analysis

After adjusting for age, sex, hypertension, and diabetes, multivariable logistic regression demonstrated that CareSense participation was associated with lower odds of readmission at 30 days (OR 0.24, 95% CI 0.08 - 0.75; *P*=.007), 60 days (OR 0.4, 95% CI 0.19 - 0.83; *P*=.01), and 90 days (OR 0.54, 95% CI 0.29 - 0.99; *P*=.04) when compared to the nonparticipating group (Figure 1). Although not statistically significant, CareSense participation trended toward an association with lower odds of emergency department visits at 30 days (OR 0.37, 95% CI 0.13 - 1.07; *P*=.07), 60 days (OR 0.5, 95% CI 0.23 - 1.1; *P*=.09), and 90 days (OR 0.53, 95% CI 0.27 - 1.03; *P*=.06) when compared to the nonparticipating group (Figure 1).

Figure 1. Forest plot illustrating the odds of readmissions and emergency visits between patients who were and were not enrolled in CareSense at 30, 60, and 90 days.

Discussion

The rapid expansion of mHealth technologies has raised important questions regarding their role in improving clinical outcomes and health care utilization. Prior studies have reported associations between mHealth interventions and improved outcomes across multiple medical and surgical domains, including chronic pulmonary disease, heart failure, diabetes, and orthopedic surgery [5,16,17]. These effects have been attributed to improved access to health information, enhanced communication between patients and care teams, and increased patient engagement, which may collectively support self-management and appropriate health care utilization [18,19]. However, evidence evaluating mHealth interventions in otolaryngologic surgery, particularly with respect to postoperative health care utilization, remains limited.

In this retrospective observational study, perioperative enrollment in CareSense was associated with lower rates of all-cause hospital readmissions and ED visits at 30, 60, and 90 days following sinonasal surgery, as well as shorter hospital LOS among patients who were readmitted. These findings suggest that the use of a perioperative patient engagement platform may be associated with reduced postoperative health care utilization in this population. From a health systems perspective, even modest reductions in readmissions and length of stay may have meaningful implications for cost and resource utilization, given that a single inpatient hospital day in the United States is estimated to cost between US $2000 and $3000 [20].

Notably, the majority of readmissions observed in both cohorts were unrelated to the index sinonasal procedure. This finding suggests that the observed associations may not reflect a direct effect on surgical complications, but rather broader differences in postoperative care-seeking behavior and health system utilization. Importantly, procedure-related readmissions were uncommon and were predominantly driven by postoperative epistaxis in both cohorts, suggesting that differences in overall health care utilization were not driven by an increase in surgery-specific complications. Enrollment in CareSense may serve as a proxy for patient engagement, with participating patients potentially more likely to manage symptoms proactively, adhere to discharge instructions, or seek outpatient guidance before presenting for acute care. The platform's structured perioperative education and automated communication may also help establish expectations and provide reassurance during recovery, thereby reducing uncertainty-driven utilization of emergency services. One study of a perioperative mHealth intervention demonstrated reductions in postoperative care needs and improvements in patient self-management, even when effects on disease-specific outcomes were modest [21]. These findings support the hypothesis that digital perioperative engagement may influence health care utilization by addressing information gaps and postoperative uncertainty rather than directly preventing surgical

XSL•FO
RenderX

complications. Collectively, these features may support patient confidence and self-efficacy before and after surgery, contributing to reduced reliance on acute care services in the postoperative period.

Baseline differences between participating and nonparticipating patients indicate that there should be cautious interpretation. Patients who enrolled in CareSense were younger and had lower rates of hypertension and diabetes, characteristics that may independently influence postoperative outcomes and health care utilization. Although multivariable adjustment was performed, residual confounding is likely in any observational study of voluntary technology adoption. The demographic profile of CareSense participants aligns with prior literature demonstrating greater uptake of digital health tools among younger patients [22,23]. Interestingly, a higher proportion of CareSense participants were male, which contrasts with prior studies reporting higher digital health engagement among younger women [22,23]. Additionally, nonparticipating patients had higher rates of chronic comorbidities such as hypertension and diabetes mellitus, which are known to adversely impact postoperative outcomes in several surgical populations, although an association with sinonasal surgery outcomes has not been well established [24-27]. Importantly, even after adjusting for these measured differences, CareSense participation remained associated with lower odds of postoperative readmission at multiple time points. Despite these differences, CareSense participation remained associated with lower odds of readmission across multiple time points after adjustment, consistent with prior reports of CareSense-associated benefits in orthopedic surgery populations [5].

This study has limitations. Selection bias is inherent to voluntary mHealth enrollment, and unmeasured factors such as health literacy, social support, and baseline health care engagement may have influenced the observed associations. Outcomes were limited to encounters captured within a single integrated health system, and healthcare utilization outside the system was not assessed. Procedure-related readmissions accounted for a small proportion of events, limiting the power to evaluate surgery-specific complications. Additionally, sinonasal disease–specific patient-reported outcome measures and endoscopic findings were unavailable, precluding assessment of symptom severity or disease control as mediators of postoperative utilization. Patients without access to a mobile phone or email address were not eligible for CareSense enrollment, raising the possibility that unmeasured social determinants of health contributed to group differences.

Despite these limitations, this study provides evidence from a large real-world cohort that perioperative enrollment in a patient-facing mHealth platform is associated with reduced postoperative health care utilization following sinonasal surgery. These findings are observational and hypothesis-generating, and they highlight the need for prospective multicenter studies to more definitively evaluate causal relationships with pre-specified subgroups, characterize engagement intensity, and identify which components of digital perioperative care are most effective. Future studies could prospectively assess subgroup effects by surgical procedure, baseline health status, and measured engagement metrics (eg, message opens or survey completion), to better understand which patients derive the greatest benefit from perioperative mHealth support. As mHealth platforms become increasingly integrated into routine surgical care, understanding their role in optimizing postoperative outcomes and health care utilization will be essential.

Abstract

Background: Physical activity (PA) alleviates many treatment-related side effects in gynecologic cancer survivors, yet long-term PA levels remain low. Mobile health interventions can support self-management and increase PA levels; however, evidence from real-world, year-long engagement with smartphone apps in this population is still limited.

Objective: The aim of this study is to describe 12-month user engagement with the PA component of a smartphone app implemented within a partially nurse-led routine follow-up in a real-world cohort of gynecologic cancer survivors.

Methods: This descriptive study analyzed server-generated log data from the intervention arm of the prospective, multicenter, quasi-experimental LETSGO (Lifestyle and Empowerment Techniques in Survivorship of Gynecologic Oncology) trial (NCT04122235). Between December 2019 and July 2022, 378 cancer survivors (ovarian, endometrial, cervical, vulvar, or vaginal cancer) from 5 Norwegian hospitals were enrolled in the intervention arm and were offered the app plus a Garmin Vivofit 4 activity tracker alongside standard consultations. Primary outcomes for this study were (1) weekly PA registrations (objective step counts from the activity tracker and self-reported PAs) and (2) temporal patterns of step logging during each cancer survivor's first 52 weeks postenrollment. Secondary analyses compared baseline characteristics of app users (≥2 wk of PA logging) and nonusers.

Results: Of 378 eligible participants (mean age 63, SD 13 y; BMI 28.5, SD 6.4 kg/m²), 272 (72%) logged at least 2 weeks of PA, and 225 (60%) synchronized objective step data. Mean daily steps were 5657 (SD 2799; median 5533, IQR 3499 - 7498). Step tracking dominated app use (mean 21, SD 16 logged wk), followed by self-reported walking (mean 23, SD 19 wk) and resistance training (mean 15, SD 16 wk). Weekly step-logger counts fell around study weeks 16, 32, and 44, but rebounded by 30 to 50 participants within 3 weeks, indicating episodic rather than permanent disengagement. App users were younger (mean difference –6.7 y, 95% CI –9.6 to –3.9; P<.001), more often employed (χ^2_1=12.7; P<.001), and more likely to have higher education (χ^2_2=13.6; P<.001) than nonusers. Tumor type and treatment modality were not associated with engagement.

Conclusions: In a routine-care setting, nearly three-quarters of gynecologic cancer survivors engaged repeatedly with an app-supported PA module over 12 months, although mean PA levels were modest and participation was more prevalent among younger, employed, and more highly educated participants. Engagement followed an ebb-and-flow pattern, suggesting that built-in re-engagement prompts and equity-focused onboarding are needed to sustain and broaden participation. These findings support the feasibility of blended mobile health follow-up while highlighting the importance of adaptive strategies to promote long-term PA adherence and bridge the digital divide among cancer survivors.

Introduction

Survivorship rates after gynecologic cancers are rising globally, leading to a growing number of women living with long-term treatment sequelae [1]. Gynecologic cancer survivors frequently experience treatment-related late effects that can significantly impact their quality of life, with fatigue, neuropathy, lymphedema, sexual dysfunction, cognitive impairment, anxiety, and depression being among the most commonly reported [2-8].

Regular physical activity (PA) has been shown to alleviate many late effects, providing both psychological and physiological benefits [9]. In addition, PA is associated with improved health-related quality of life and a reduced risk of cancer-related morbidity, making it a crucial component of survivorship care [10,11]. Consistent with this, objectively measured PA has recently been associated with a lower risk of cardiovascular disease in cancer survivors [12]. In recent years, increasing emphasis has been placed on promoting self-management in cancer rehabilitation, with a focus on fostering a healthy lifestyle [13], of which PA is a central element. Despite these recognized benefits and the growing focus on self-managed survivorship care, PA engagement among gynecologic cancer survivors remains low, often due to treatment-related side effects, fear of injury, and limited referral pathways to exercise professionals [14-16]. This persists despite contemporary practice guidance recommending routine brief PA promotion and formal referral within multidisciplinary oncology care [17].

Mobile health (mHealth) interventions, including smartphone apps and wearable PA trackers, have emerged as promising tools for promoting PA among cancer survivors [18]. These technologies facilitate real-time feedback, goal setting, and self-monitoring, which may enhance motivation and adherence to PA recommendations [19]. A systematic review by Khoo et al [20] found that mHealth interventions effectively increased PA levels in cancer survivors. In practice, though, these benefits depend on continued use. Engagement with mHealth typically declines after an early peak, and maintaining use over time has proved more difficult than achieving initial uptake [21,22]. The decline is rarely steady: many patients stop for a period and then start again, so looking only at average use can mask meaningful patterns of disengagement and re-engagement [23]. Even so, real-world evidence on how cancer survivors engage with these tools over the long term (≥12 mo) remains limited, particularly among gynecologic cancer survivors [18,24].

Existing evidence on mHealth interventions in populations with cancer is primarily based on controlled trials with selected, potentially more motivated populations, which may limit the generalizability of findings to broader cancer survivor groups [25]. Uptake of digital health also tends to be lower among older, less-educated, and lower-income survivors, widening a digital divide that real-world programs need to address [26]. To address this evidence-practice gap, the LETSGO (Lifestyle and Empowerment Techniques in Survivorship of Gynecologic Oncology) project was developed as a pragmatic program embedded in routine, partly nurse-led follow-up across multiple Norwegian hospitals, with app support to promote self-management among gynecologic cancer survivors [27]. A key feature of the app was its PA component, which included goal setting, PA tracking, and structured exercise programs tailored to users with varying levels of prior PA experience. Implemented without exclusions based on baseline PA levels, LETSGO enabled evaluation of real-world engagement with digital PA tools in a clinically heterogeneous cohort of gynecologic cancer survivors.

Accordingly, the aim of this study was to explore user engagement with the PA component of the LETSGO app over the first 12 months of follow-up. Specifically, we examined how participants interacted with the PA module by assessing PA logging frequency, the types of PA recorded, and patterns of objectively recorded steps over time.

Methods

Study Design and Setting

This study is part of the LETSGO project, a prospective, multicenter, quasi-experimental clinical cohort study (ClinicalTrials.gov identifier: NCT04122235) evaluating a follow-up program for patients with gynecologic cancer, which includes alternating nurse-led and physician-led follow-up consultations at the intervention hospitals [28]. The nurses focused on coaching techniques and were supported by a mobile app. The complete study spans 3 years, comparing the combined intervention (nurse-led consultations and a mobile app) with standard follow-up care at control hospitals [27]. Patients followed the intervention or the standard pathway according to their treatment hospital rather than through individual randomization [28].

This study provides a descriptive analysis of 1-year usage data from the PA component of the LETSGO app. Data were collected from participants in the intervention group from 5 hospitals, who had access to the LETSGO app as part of their follow-up care. Usage patterns and PA logging behavior were examined based on app-generated log data collected over each participant's first 12 months in the study. Server log data (eg, PA registrations in the app) were collected automatically through a secure server using an encrypted connection.

Inclusion and Exclusion Criteria

Participants were eligible if they were aged 18 years or older, were within 3 months of completing primary treatment for a histologically verified gynecologic malignancy (ovarian, endometrial, cervical, vulvar, or vaginal cancer), and had entered the survivorship follow-up phase of care.

Participants were excluded if they had disease progression at the time of enrollment, were participating in other clinical trials, required ongoing intravenous therapy treatment, or had

XSL•FO
RenderX

undergone trachelectomy for cervical cancer. Any participant who experienced cancer recurrence or progression during the study was subsequently excluded and referred for appropriate treatment.

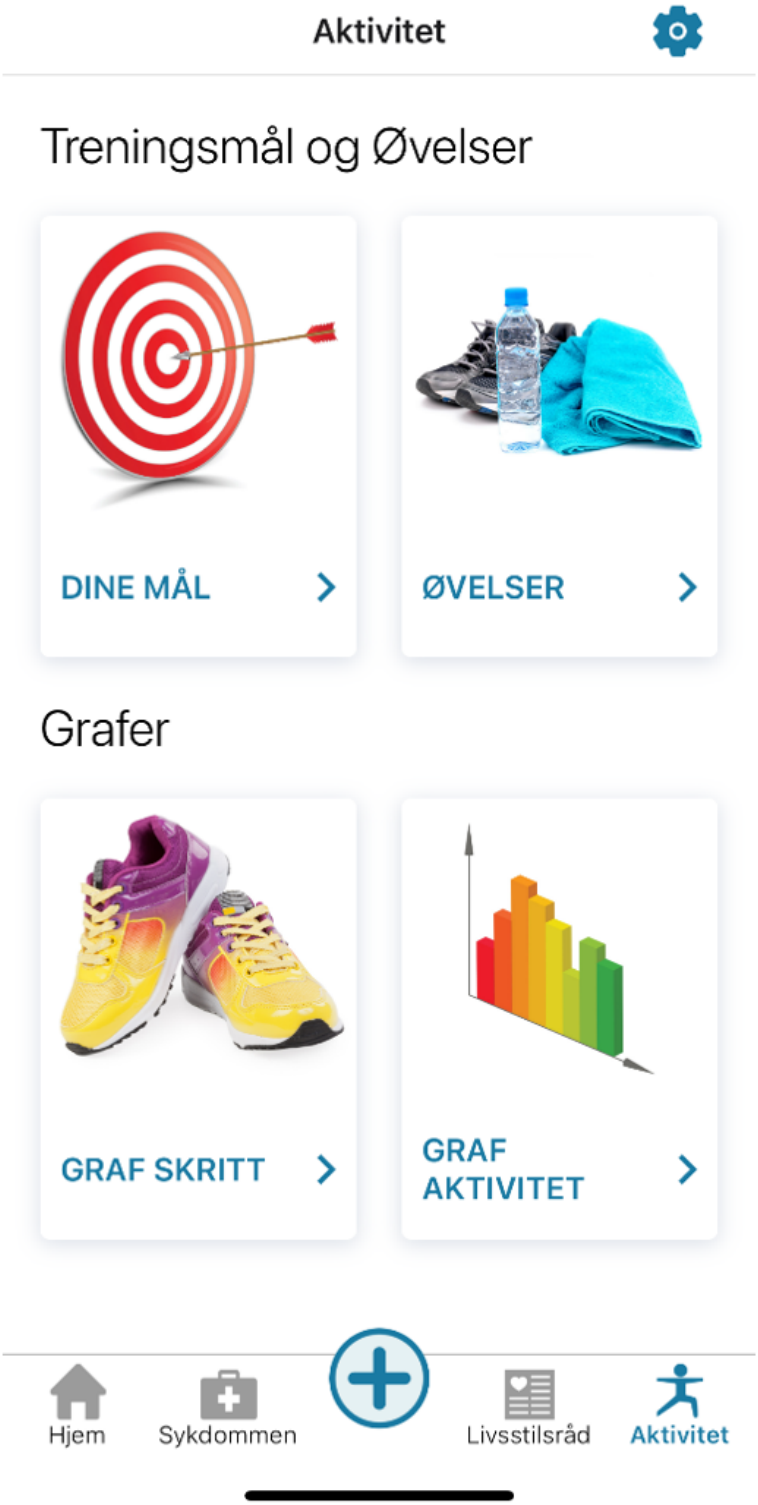
Participant Characteristics

The 378 enrolled participants were gynecologic cancer survivors with endometrial, ovarian, cervical, vulvar, or vaginal cancer.

Sampling Procedures

Between December 2019 and July 2022, all eligible patients entering survivorship follow-up at the 5 intervention hospitals were identified and invited consecutively by clinical staff, using information from medical records and multidisciplinary team meetings; no random selection or prespecified quota was applied. The 378 enrolled participants received access to the LETSGO app as part of their routine follow-up care.

Sample Size, Power, and Precision



No a priori sample-size calculation was performed for this analysis; the parent LETSGO trial was powered for its primary outcome of change in patient empowerment, which required 377 participants per group [28]. As a descriptive study, this analysis included all 378 survivors enrolled in the intervention arm during the recruitment period, representing the full available population.

Ethical Considerations

The LETSGO study was approved by the Regional Committee of Medical Research Ethics in Norway (2019/11093) and received additional approval from the institutional review board and the data protection officer at each study site. The study was conducted in accordance with Norwegian data protection regulations, and all participants provided written informed consent. Participants were informed of their right to withdraw from the study at any time without consequences for their further treatment. All data were deidentified prior to analysis, with participants assigned a unique study identifier; no directly identifiable personal information was included in the analytic dataset. No financial compensation was provided to participants for their involvement in the study. No identifiable participants or users appear in any figure or the supplementary material in Multimedia Appendix 1; Figure 1 shows only the app interface.

Figure 1. Overview of the physical activity interface of the LETSGO (Lifestyle and Empowerment Techniques in Survivorship of Gynecologic Oncology) smartphone app used by gynecologic cancer survivors. The interface includes sections for setting training goals (*Dine Mål*), accessing structured exercise programs (*Øvelser*), and monitoring activity data through graphical representations of step count (*Graf Skritt*) and logged activities (*Graf Aktivitet*).

The LETSGO Intervention

A detailed description of the intervention hospitals and their roles in the LETSGO trial is provided in the protocol paper by Vistad et al [27]. In this study, only aspects relevant to the implementation of the digital follow-up program and the PA component are presented.

Throughout the follow-up period, participants alternated between nurse-led and physician-led consultations, with nurses conducting every second scheduled consultation. The nurse-led consultations incorporated motivational strategies to promote PA engagement and support participants in managing late effects of cancer treatment. The program's intervention model draws on self-determination theory [29], which posits that sustained

XSL•FO
RenderX

behavior change is promoted when 3 basic psychological needs are supported: autonomy, competence, and relatedness.

At their first nurse-led consultation, participants were introduced to the LETSGO app with several features, including structured information on PA, goal-setting features, and progress tracking. The app was supplemented by a Garmin activity tracker (Garmin Vivofit 4; Garmin Ltd), which enabled users to track their step counts and synchronize PA data with the app. During this consultation, nurses assessed participants' prior PA levels and collaboratively set individualized PA goals tailored to their motivation and perceived barriers. Nurses assisted participants in downloading the app and pairing their Garmin Vivofit 4 activity tracker with the app during this initial consultation.

At follow-up consultations, nurses reviewed each participant's app-logged PA data together with the participant, discussed progress toward individualized goals, and adjusted targets as needed. All study nurses had completed a 2-day intensive training course covering PA counseling, individualized goal setting, autonomy-supportive communication, and motivational interviewing techniques, reinforced by a mandatory e-learning program. Nurses applied an autonomy-supportive communication approach inspired by motivational interviewing [30], emphasizing participant empowerment and self-efficacy in PA adherence. Within the self-determination theory framework, autonomy was supported through this communication style and through participant-led goal setting; competence was fostered through individualized, graded exercise prescriptions and self-monitoring of progress via the app; and relatedness was maintained through the ongoing nurse-led consultations that provided a consistent relational context for PA support. Participants without smartphones (n=35) were provided with printed material containing the same PA guidance.

PA Component of the App

The PA component of the LETSGO app was designed to support gynecologic cancer survivors in maintaining or increasing their PA levels during follow-up care. The app, available on smartphones and tablets, provided participants with structured exercise programs, goal-setting functionality, and self-monitoring tools to facilitate engagement in PA.

The PA goals and exercises section included 2 features: "your goals" and "exercises" (Figure 1). In the goal-setting module, participants recorded their weekly PA goals. The exercise module included structured resistance and endurance training programs, accompanied by written instructions and video demonstrations, suitable for both beginner and advanced levels. Detailed descriptions of the app's training content, including resistance and endurance training modules, are provided in Multimedia Appendix 1.

The activity graphs section included a "step graph" that displayed step-count data and an "activity graph" that showed the frequency and distribution of different logged PAs (Figure 1).

The PA component of the LETSGO app incorporated several behavior change techniques (BCTs) from the BCT Taxonomy v1 [31]. Participants engaged in self-monitoring of behavior by reviewing weekly step counts and logging PA frequency through in-app graphs. Goal-setting (behavior) was supported through individual PA targets set collaboratively with the nurse at each consultation and revisited at follow-up. Graded task difficulty was embedded in the structured resistance and endurance exercise programs. Prompts and cues were delivered via push notifications, encouraging weekly activity logging.

Measures and Covariates

The primary outcome of this study was participant engagement with the PA component of the LETSGO app over each participant's first 12 months in the study. For descriptive analyses, an active week was defined as a study week with at least one logged PA registration, including tracker-synchronized step data and/or self-reported PA. Weekly activity was used as the unit of analysis to describe the frequency of app interaction over time.

In addition to overall engagement, the study examined the types of PAs registered in the app, including steps, jogging, cycling, resistance training, yoga or Pilates, swimming, group classes, and other self-reported activities. Step registrations were objectively measured using a Garmin Vivofit 4 activity tracker, while all other PAs were self-reported by participants. For step-based analyses, Garmin Vivofit 4 data were available in the LETSGO server log as weekly synchronized registrations. For each such week, the server provided a precomputed average daily step variable, defined as the total number of steps recorded during that calendar week divided by 7. Thus, the denominator for weekly average daily steps was always 7 calendar days within a synchronized week.

Secondary outcomes included differences in demographic characteristics between participants who engaged with the app (logged at least 2 weeks of PA app usage) and those who did not, as well as temporal patterns in step-logging frequency and the total number of daily steps recorded over the 12-month period. This threshold was chosen pragmatically to distinguish repeated use from no use or a single, isolated week of use.

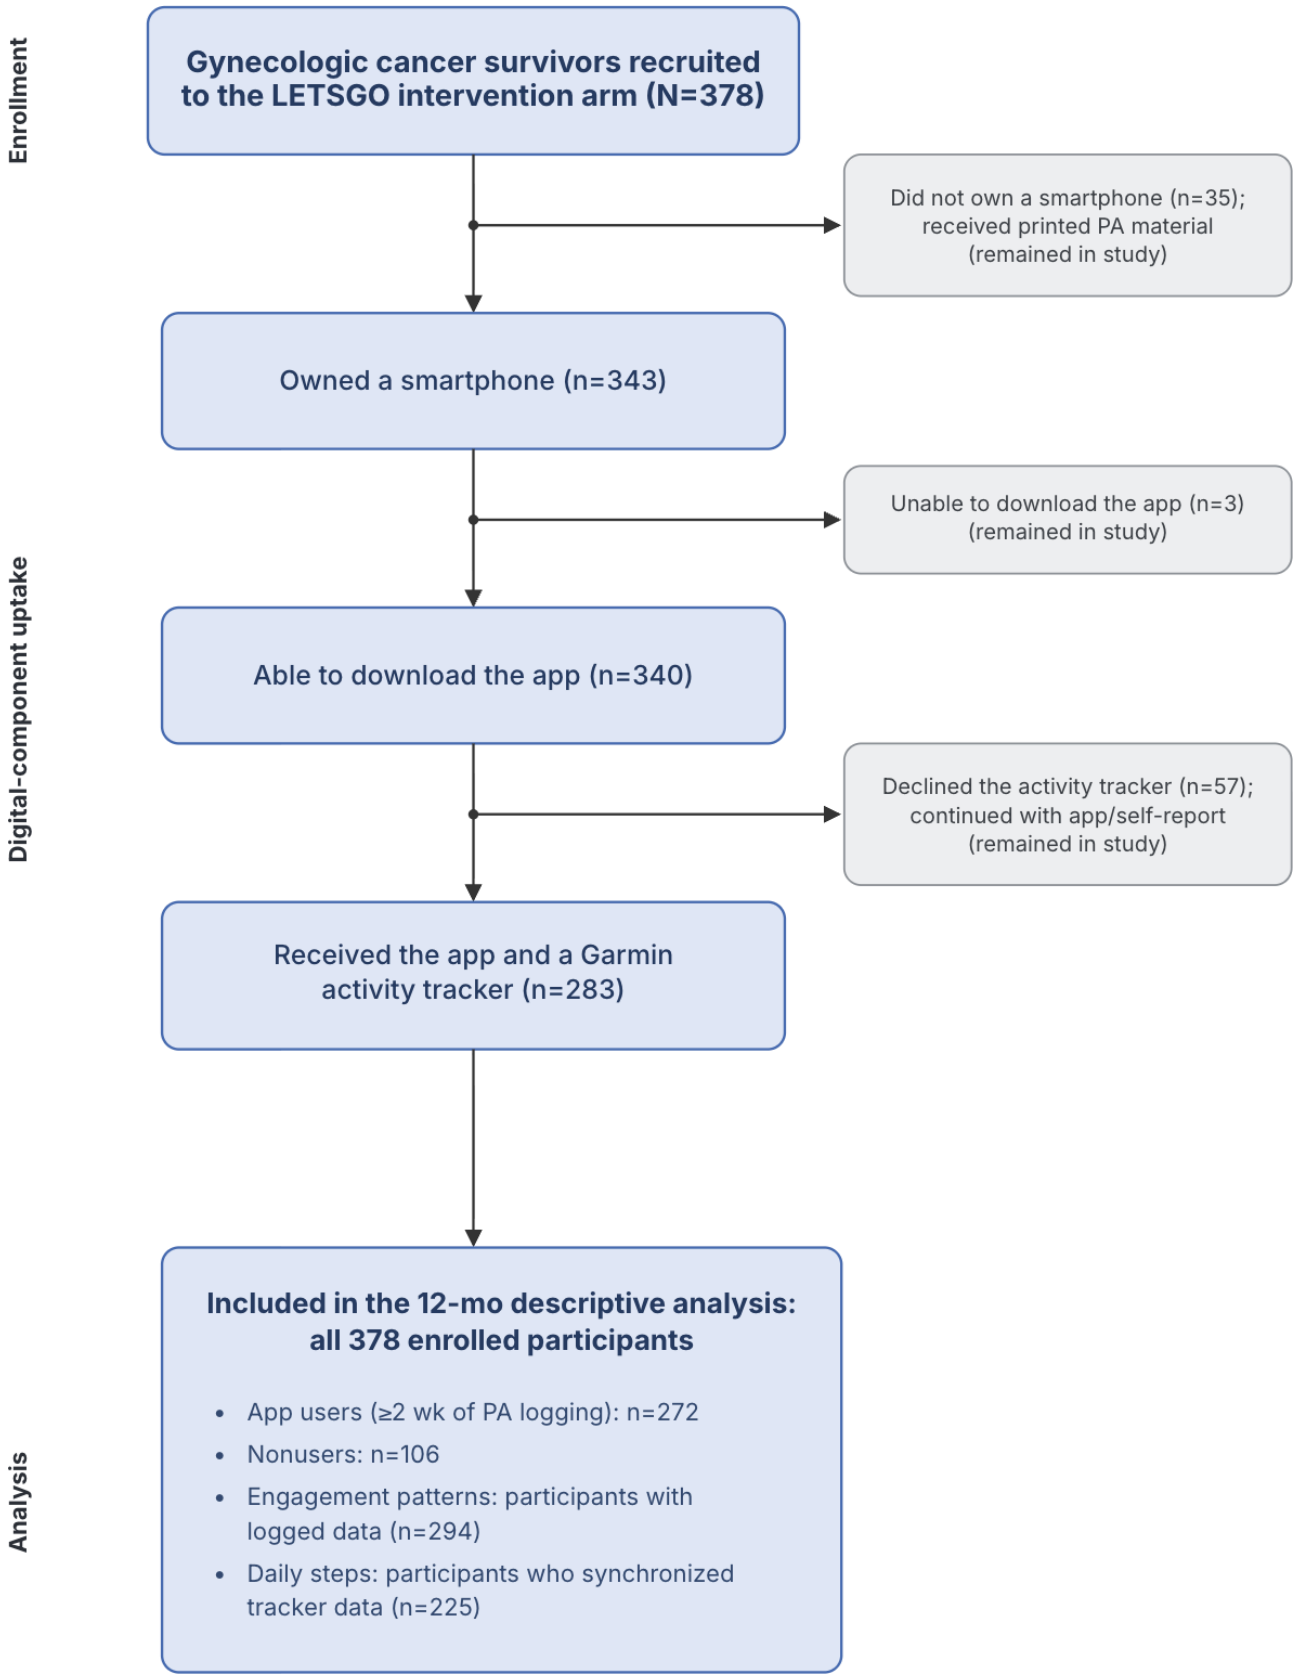
Baseline covariates considered as potential correlates of engagement were age, body weight, BMI, educational level, employment status, tumor type, and treatment modality. Age (from the date of birth), tumor type, and treatment modality were obtained from the patients' medical records, and educational level and employment status were obtained from baseline questionnaires [27,28]; BMI was calculated from weight and height (kilograms per square meter).

Data Analysis

All statistical analyses were conducted using SPSS (version 29; IBM Corp), and figures were created using GraphPad Prism (version 8.0.1; GraphPad Software). Descriptive statistics were used to summarize demographic and clinical characteristics. The normality of continuous variables was assessed using histograms and measures of skewness and kurtosis. Independent *t* tests (2-tailed) were performed for normally distributed variables, while the Mann-Whitney *U* test was used for nonnormally distributed variables. Associations between categorical variables were examined using the Pearson chi-squared test. Statistical significance was set at $P<.05$ for all analyses. The methods were structured and reported in

XSL•FO
RenderX

accordance with the APA Journal Article Reporting Standards for Quantitative Research (JARS-Quant) [32]. This study was reported in accordance with the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) guideline for cohort studies (Checklist 1). Missing baseline data were quantified; the missing-data mechanism was assessed with the Little test for data missing completely at random, and a multiple-imputation sensitivity analysis (m=20, chained equations, pooled with Rubin rules) was performed for the variables with missing data.



Results

Study Participants

Figure 2 displays participant flow through the digital pathway of the LETSGO intervention. Of the 378 recruited participants, 343 (90.7%) owned a smartphone, and 340 (89.9%) were able to download the app. A total of 283 (74.9%) received both the app and a Garmin activity tracker.

XSL•FO
RenderX

Figure 2. Participant flow through the LETSGO (Lifestyle and Empowerment Techniques in Survivorship of Gynecologic Oncology) intervention arm. The chart shows enrollment, uptake of digital components (smartphone, app, and Garmin activity tracker), and analysis. Counts beside the main pathway indicate the number of participants who did not take up a given component; all 378 enrolled participants were included in the 12-month descriptive analysis. PA: physical activity.

The baseline demographic and clinical characteristics, overall, and by app-engagement group, are summarized in Table 1.

Participants who engaged with the PA component of the app were significantly younger than those who did not (mean difference –6.7 y, 95% CI –9.6 to –3.9; t_{376}=–4.6; P<.001). No

XSL•FO
RenderX

significant differences were observed for body weight (mean difference 0.2 kg, 95% CI −4.5 to 4.8; *P*=.94) or BMI (mean difference −0.3 kg/m², 95% CI −1.9 to 1.3; *P*=.73).

There were significant associations between educational level (χ^2_2=13.6; *P*<.001) and engagement with the app for PA, and between employment status (χ^2_1=12.7; *P*<.001) and engagement with the app for PA. There were no significant associations of cancer diagnosis or treatment modality with engagement with the app for PA.

Missing baseline data for educational level, employment status, and weight or BMI are summarized in Table 1; all other variables (age, tumor type, and treatment modality) were complete.

Table . Baseline demographic and clinical characteristics of gynecologic cancer survivors in the LETSGO[a] intervention arm, overall, and by app-engagement group[b].

Variable	Total (N=378)	App user (n=272)	Non–app user (n=106)	*P* value

[a]LETSGO: Lifestyle and Empowerment Techniques in Survivorship of Gynecologic Oncology.

[b]Percentages may not sum to 100 due to rounding.

[c]Includes chemotherapy only or any other combination of treatments, including hormonal treatment.

[d]Not all participants reported their employment and education levels; thus, the total is lower than the total number of participants. App user: a participant who logged physical activity (PA) in the app in ≥2 distinct wk during their first 52-wk postenrollment (counting objective step synchronizations and/or self-reported PA registrations). Non–app user: a participant with <2 wk of PA logging in the app (ie, 0 or 1 wk).

PA Logging and Volume

Table 2 presents the number of participants who recorded different PAs in the LETSGO app on a weekly basis, along with the mean number of PA registrations per participant, where each registration represents 1 week of recorded activity.

Step tracking was the most frequently used feature, recorded by 225 (60%) participants, with an average of 21 (SD 16) weeks of registration. Walking (n=53; mean 23, SD 19 wk) and resistance training (n=39; mean 15, SD 16 wk) were the most commonly reported self-logged activities. Other types of PA,

XSL•FO
RenderX

such as bicycling, yoga, and swimming, were logged by fewer participants, with an average of 10 to 30 participants.

Table . Engagement with objective step tracking and self-reported physical activity types in the LETSGO[a] app over 52 weeks, among gynecologic cancer survivors (N=378)[b].

Modality	Participants, n (%)	Weeks logged per participant	
		Mean (SD)	Median (IQR)
Objective (wearable-synchronized)			
Steps	225 (60)	21 (16)	18 (7 - 35)
Self-reported			
Walking	53 (14)	23 (19)	21 (3 - 41)
Resistance training	39 (10)	15 (16)	7 (2 - 21)
Bicycling	30 (8)	13 (14)	8 (3 - 17)
Other	24 (6)	15 (17)	10 (3 - 25)

Swimming	9 (2)	7 (6)	6 (2 - 12)

[a]LETSGO: Lifestyle and Empowerment Techniques in Survivorship of Gynecologic Oncology.

[b]Percentages are based on the total cohort (N=378). Weeks logged represents the number of distinct weeks during which a participant recorded the modality, averaged across participants who ever logged it.

Table 3 presents the weekly duration of performed PAs recorded in the LETSGO app. Participants registered an average of 5657 daily steps (SD 2799, 95% CI 5291 - 6023; median 5533, IQR 3499 - 7498). Walking had the highest reported average weekly duration of 172 (SD 116) minutes, followed by other self-reported activities (118, SD 80 min) and yoga or Pilates (93, SD 78 min). Resistance training, group classes, and bicycling ranged from 54 (SD 36) to 74 (SD 30) minutes per week, while jogging and swimming had the lowest average durations, at 37 (SD 20) and 40 (SD 16) minutes, respectively.

Table . Weekly physical activity volume by modality recorded in the LETSGO[a] app over 52 weeks, among gynecologic cancer survivors (N=378)[b].

Modality	Participants, n	Weekly dose	
		Mean (SD)	Median (IQR)
Objective, steps/d			
Steps	225	5657 (2799)	5533 (3499 - 7498)
Self-reported, min/wk

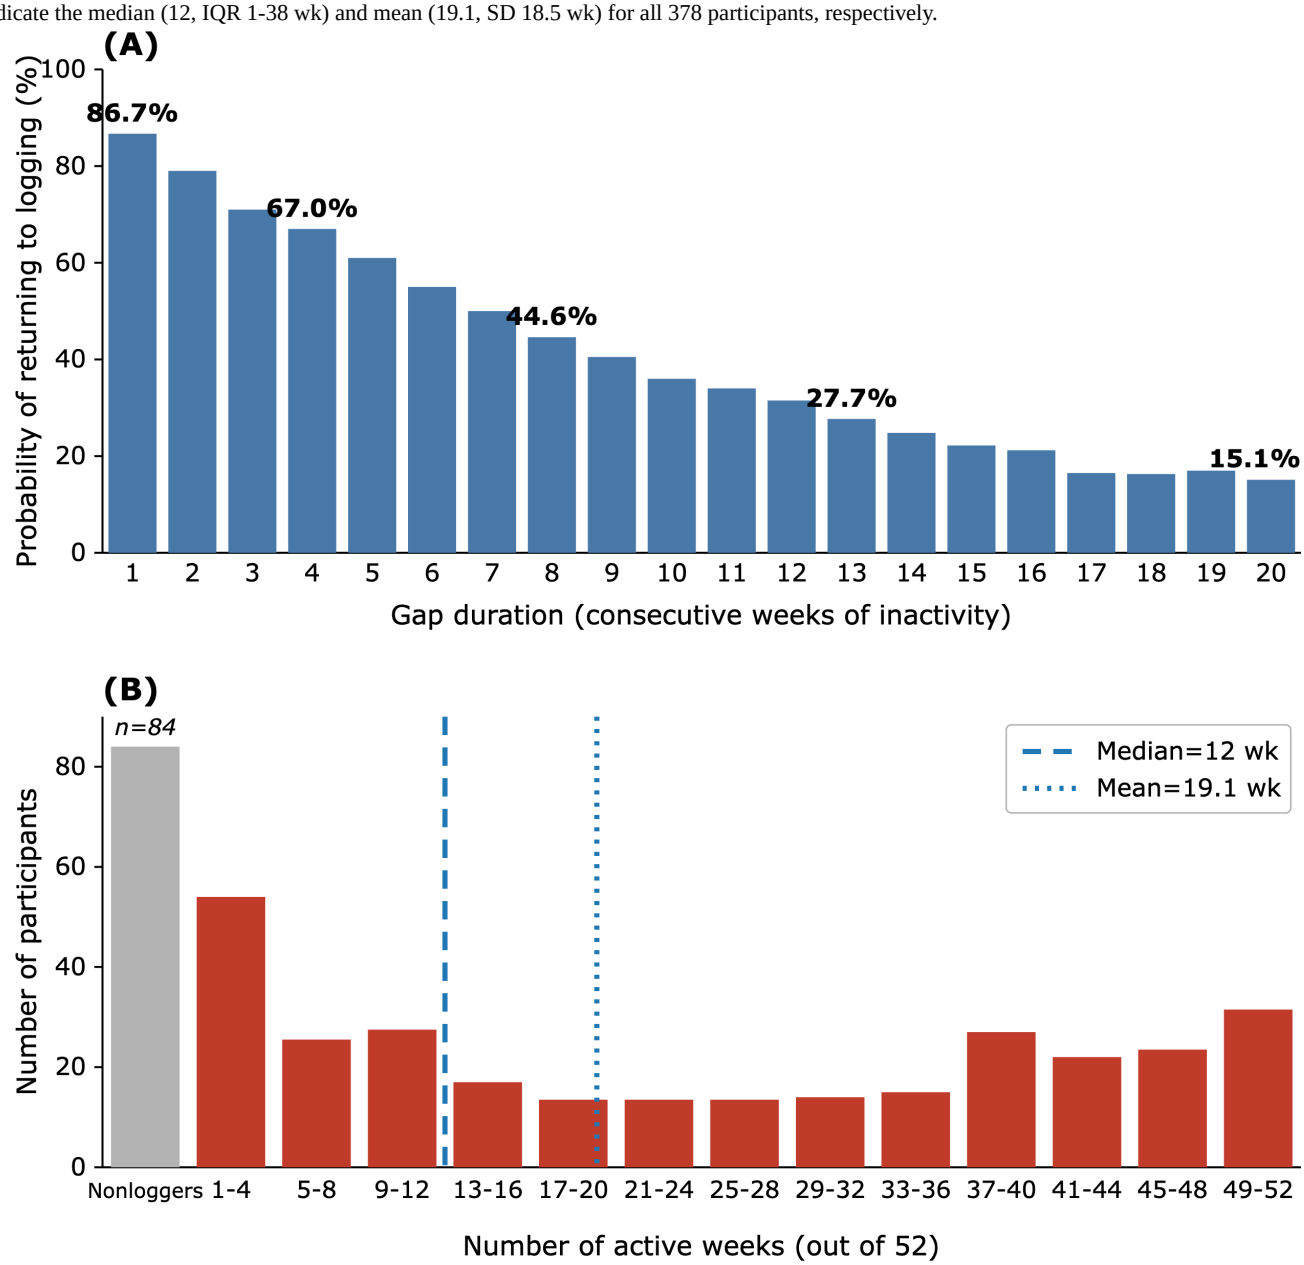
[a]LETSGO: Lifestyle and Empowerment Techniques in Survivorship of Gynecologic Oncology.



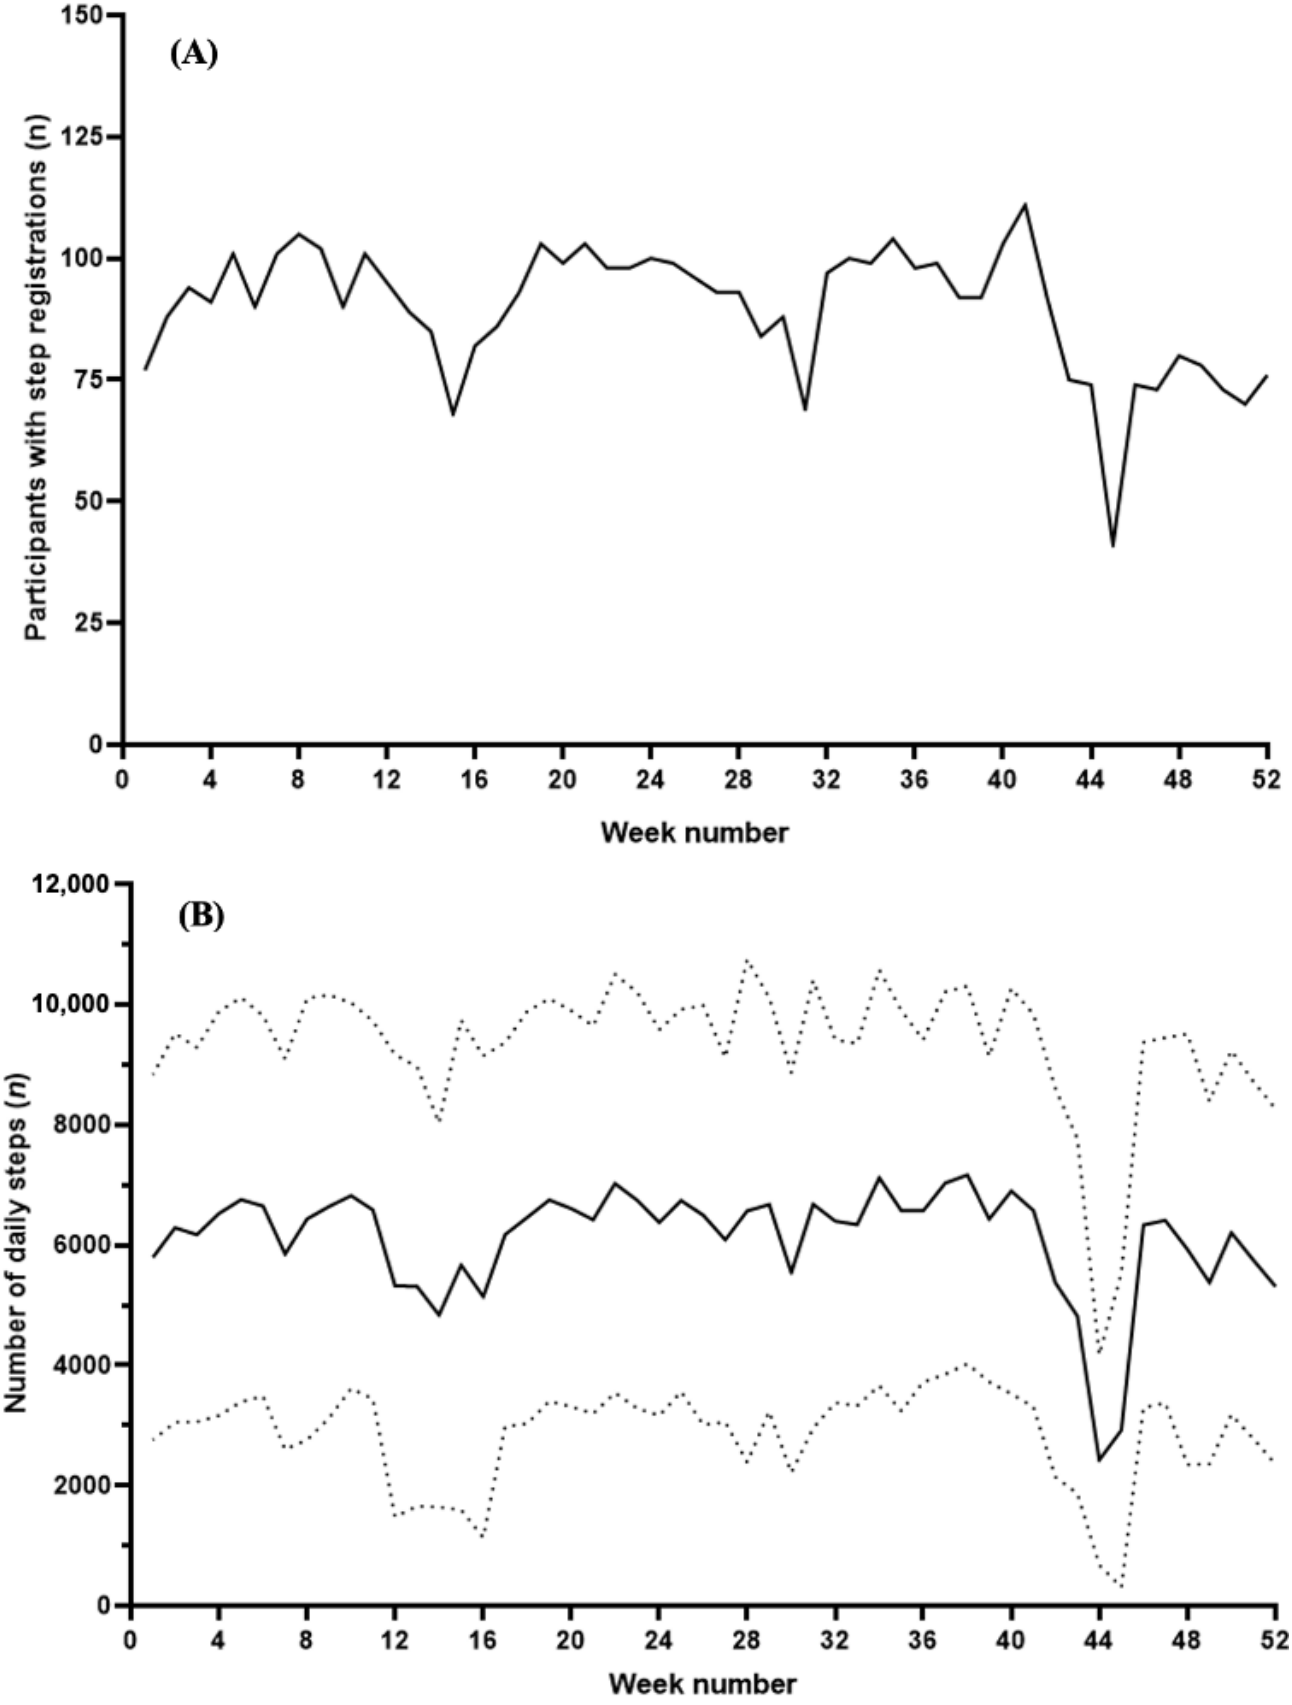
[b]n is the number of participants who logged that modality at least once over 52 weeks (for steps, the number of participants who synchronized step data ≥1 time). The weekly dose for self-reported modalities is the average number of minutes per week during weeks when that modality was logged, averaged across participants who ever logged it. Steps are the participant-level mean daily steps across weeks with synchronized data. All values reflect weeks in which physical activity was recorded and are not averaged across the entire 52-week follow-up.

XSL•FO
RenderX

Engagement Patterns Over Time

Among all 378 enrolled participants, the median number of active logging weeks was 12 (IQR 1 - 38; mean 19.1, SD 18.5) out of 52 available weeks. The distribution was bimodal, with concentrations at both the low end (0 - 4 active wk, n=138) and the high end (41 - 52 active wk, n=76; Figure 3B). Among the 294 participants who logged at least one activity registration, the median was 23.5 (IQR 8 - 41) active weeks, and only 8 (3%) logged every week without interruption.

Figure 3. Episodic engagement with the physical activity component of the LETSGO (Lifestyle and Empowerment Techniques in Survivorship of Gynecologic Oncology) app over the first 12 months (52 wk) among gynecologic cancer survivors (N=378). (A) Probability of returning to activity logging after an inactivity gap of a given duration (n=294 participants with logged data). Participants who experienced a gap were classified as having "returned" if at least 1 additional log registration followed the gap, or as "not returned" if the gap extended to the end of the 52-week follow-up. (B) Distribution of the total number of active logging weeks (out of 52) across all 378 enrolled participants. The gray bar represents the 84 participants who never logged any activity. Red bars show the distribution among the 294 participants with logged data in 4-week intervals. Dashed and dotted lines indicate the median (12, IQR 1-38 wk) and mean (19.1, SD 18.5 wk) for all 378 participants, respectively.



Re-engagement after inactivity gaps was common. After gaps of 1 or more weeks, 86.7% (248/286) of participants returned to logging. Return probability remained above 50% for gaps up to 7 weeks and was 27.7% (33/119) for gaps of 13 or more weeks (Figure 3A).

Figure 4A presents the number of participants who registered their step counts over the first 12 months of the study. Weekly registrations remained stable with fluctuations, showing declines around weeks 16, 32, and 44, followed by partial recovery.

Figure 4B displays the average number of daily steps recorded by the LETSGO app. Step counts fluctuated throughout the study period, with declines occurring during the same weeks as the drop in registrations. The lowest step counts were observed in the final quarter of the study.

XSL•FO
RenderX

Figure 4. Weekly objective step engagement over the first 12 months (52 wk) among gynecologic cancer survivors in the LETSGO (Lifestyle and Empowerment Techniques in Survivorship of Gynecologic Oncology) intervention arm. (A) Number of participants registering step data each week. (B) Weekly mean daily steps. (B) The solid line represents the weekly mean number of daily steps, and the dotted lines represent the mean and 1 SD. Across the 225 participants who synchronized step data, the overall mean was 5657 daily steps (SD=2799).

Sensitivity Analysis

The Little test did not reject the assumption that the baseline data were missing completely at random (χ^2_4=7.13; *P*=.13). Because missingness was nonetheless somewhat more frequent among nonusers than among app users, we performed a multiple-imputation sensitivity analysis (*m*=20 imputations; chained equations; pooled with Rubin rules); the associations between engagement and educational level and employment status remained significant in each imputed dataset and after pooling (education: combined *P*=.001; employment: *P*<.001).

Discussion

Principal Findings

This 12-month real-world follow-up study of 378 gynecologic cancer survivors shows that almost three-quarters of those offered the LETSGO app engaged with its PA component at least twice, and that 225 participants synchronized their objective step counts via an activity tracker. Mean daily steps remained modest (≈5700, SD 2800) and fluctuated over time, with notable dips around weeks 16, 32, and 44 before a partial rebound. App engagement was higher among younger, employed, and more highly educated participants, whereas tumor type and treatment modality were not associated with usage.

Variability in Digital Adherence

Despite evidence that mHealth interventions can increase PA levels [20], engagement remains highly variable between individuals, across studies, and over time. A 2024 systematic review by Montalescot et al [33] highlights the complexity of adherence in digital cancer care, noting that most demographic and clinical factors, including age, sex, and tumor type, show inconsistent associations with app usage. Moreover, sustaining long-term adherence to mHealth interventions remains challenging, as documented in a recent review by Amagai et al [21], which is consistent with the "law of attrition" proposed by Eysenbach [22] for eHealth interventions.

Findings from the present LETSGO cohort sharpen this picture of heterogeneity. Of the 378 participants offered the app, 272 (72%) engaged with the PA module at least twice, and 225 (60%) synchronized tracker–derived step counts during their first 12 months of individual follow-up. Participants predominantly engaged in low-impact, ambulatory PAs, with walking accounting for the majority of all recorded sessions. Yet engagement was far from uniform: users registered a mean of 21 (SD 16) weeks of step data, but the range spanned from a single upload to more than 50 weeks. Among those who logged walking, the average duration was approximately 172 minutes per week. In contrast, muscle-strengthening activities were reported less frequently, with a mean of 15 (SD 16) logged weeks and an average of approximately 61 minutes per week, rarely meeting the recommended minimum of 2 or more sessions per week [9]. Other modalities, including cycling, yoga or Pilates, swimming, and group exercise classes, were recorded sporadically by a small subset of participants (≤30). These usage patterns may reflect both technological and behavioral factors. First, automated step-count synchronization reduces the self-monitoring burden relative to manual registration, which likely contributed to the higher adherence to step tracking observed in this study [34]. Second, resistance training is a comparatively complex modality, often requiring equipment, technique mastery, and greater self-efficacy, especially for beginners. Accordingly, cancer survivors often prefer walking, which is perceived as simple, safe, and equipment-independent [16,35].

The objectively measured mean of 5657 steps per day places the cohort in the "low-active" range [36]. This step volume is below the approximate threshold of 7000 steps per day, estimated to align with the 150 minutes of moderate-intensity PA per week [36] recommended for cancer survivors by the American College of Sports Medicine and the American Society of Clinical Oncology [9,37]. However, it is comparable to those reported in other real-world accelerometer-based studies in mixed cancer populations, which typically range from 4500 to 6000 steps per day [38,39]. Epidemiological data indicate that most of the reduction in all-cause mortality risk among cancer survivors is realized at approximately 5000 to 6000 steps per day [39]. Notably, the cohort's mean of 5657 steps per day falls within this range, indicating that participants were likely engaging in a level of PA associated with meaningful health benefits in this population. Collectively, these findings highlight that PA logging was dominated by walking and that targeted strategies to increase resistance training frequency may be necessary to achieve the full spectrum of benefits outlined in current exercise-oncology guidelines [9,37].

Episodic Use and Re-Engagement

Real-world data from other studies confirm that engagement often wanes and is episodic rather than continuous. In the 12-month IMPACT randomized controlled trial of a mobile PA program for young adult cancer survivors, median weekly log-ins fell from 89% (23/26) of study weeks in months 0 to 6 to 42% (11/26; IQR 2 - 22 wk) during months 7 to 12, with only a subset of participants sustaining regular use [40,41]. High attrition is likewise a recurring theme in the broad review by Amagai et al [21] of 62 mHealth trials, most of which were only "partially successful" at preserving long-term engagement. The LETSGO data align with these findings: the weekly number of participants uploading step data fell at several points, most notably around study weeks 16, 32, and 44, yet recovered by 30 to 50 participants within the next 1 to 3 weeks (Figure 4). These rebounds imply that a meaningful proportion of participants who became "inactive" subsequently re-engaged, illustrating that lapses frequently reflect temporary disengagement rather than permanent dropout. This ebb-and-flow dynamic suggests that blended-care models are well positioned to support re-engagement.

This analysis quantified this re-engagement pattern directly. Among the 294 participants with any logged data, 286 experienced a gap of at least 1 week; of these, 86.7% (248/286) returned to logging after a gap of at least 1 week, and the return probability remained above 50% for gaps up to 7 consecutive weeks. Even after gaps exceeding a full follow-up quarter (≥13 wk), 27.7% of participants resumed logging (Figure 3A). The distribution of active weeks was bimodal, with clusters at both

XSL•FO
RenderX

the low end (0 - 4 wk, n=138) and the high end (41 - 52 wk, n=76), indicating 2 distinct engagement profiles rather than a uniform decline (Figure 3B). These patterns are consistent with emerging evidence that mHealth engagement is better characterized as a dynamic, nonlinear process than as a simple trajectory of decline [23]. In a systematic review and meta-analysis of app-based chronic disease interventions, Meyerowitz-Katz et al [42] reported a pooled dropout rate of 43%, yet this binary framing of "retained versus dropped out" does not capture the cyclical re-engagement observed here. Perski et al [23] have similarly argued that engagement with digital behavior change interventions involves a dynamic interplay between usage behavior and subjective experience that fluctuates within and across individuals over time. These data lend empirical support to this conceptualization and suggest that the conventional emphasis on preventing attrition may be usefully complemented by strategies that facilitate re-engagement after inevitable lapses, such as the just-in-time adaptive interventions described by Nahum-Shani et al [43].

Because each cancer survivor's "week 0" corresponded to their enrollment date over the study period, these drops cannot be ascribed to calendar seasons but instead indicate phase-specific motivational cycles. Consistent with the mixed evidence in the review by Montalescot et al [33], tumor type and treatment modality were not associated with app use, yet analyses identified modest socioeconomic gradients: app users were younger (by ≈6.7 y) and more likely to be employed or highly educated than nonusers (Table 1). These gradients underline the persistent digital divide that many mHealth survivorship programs must still address. The BCTs embedded in the LETSGO app—self-monitoring, goal setting, graded exercise prescription, and behavioral prompting—are consistent with engagement-sustaining mechanisms identified in systematic reviews of mHealth PA interventions in cancer survivors [44,45]. The progressive structure of these techniques may partly explain the declining-but-sustained engagement pattern observed over 12 months, as goal review and graded task progression provide ongoing behavioral reinforcement beyond the initial novelty period of app adoption.

Implications for Intervention Development

Together, the literature and these findings converge on 3 imperatives. First, engagement trajectories must be monitored continuously, recognizing that cancer survivors' needs and motivation ebb and flow. Second, interventions should build in flexible re-engagement mechanisms, whether automated prompts, personalized feedback, or brief human contact, to draw inactive users back at critical junctures. Third, broad eligibility alone is insufficient; programs should include targeted digital-literacy assistance, alternative low-tech access routes, and tailored outreach to ensure that socioeconomically disadvantaged cancer survivors can initiate and sustain use on equal terms with their more advantaged peers.

The observed sociodemographic gradients in app use, with older, less educated, and unemployed participants consistently less likely to engage, likely reflect intersecting barriers including lower digital literacy, reduced familiarity with wearable technology, and differential access to smartphones [46]. These findings align with broader evidence of a persistent digital divide in cancer survivorship care, where older age, lower education, and socioeconomic disadvantage are consistently associated with reduced uptake of digital health tools [46,47]. Importantly, device access alone does not guarantee meaningful engagement, as barriers to uptake and sustained use operate independently of access [47]. Future survivorship programs should incorporate equity-focused implementation strategies, such as assisted device onboarding, nurse-guided digital literacy support, simplified app interfaces, and nondigital participation pathways for those unable or unwilling to engage with mHealth tools.

Strengths and Limitations

One of the main strengths of this study is its pragmatic, real-world implementation: LETSGO was embedded in routine nurse-led survivorship care and accepted participants regardless of baseline PA level or smartphone ownership. This yielded a large, clinically heterogeneous cohort (N=378) that mirrors the breadth of gynecologic cancer follow-up, enhancing external validity. The study also combined objectively synchronized step data with self-reported PA logs, providing complementary assessments of total PA level and mode diversity while reducing recall bias. In addition, the 12-month duration, longer than most oncology mHealth trials [18,24], made it possible to examine engagement trajectories across a whole year and to document the characteristic ebb-and-flow pattern of digital adherence. Finally, evaluating the app within a blended model of autonomy-supportive nurse consultations plus digital self-monitoring offers implementation insights that are immediately transferable to other survivorship settings.

Although the LETSGO study used a longitudinal, quasi-experimental design with matched control hospitals, this analysis focuses only on the intervention arm's PA module; therefore, it cannot establish causal relationships between app use and changes in PA or health outcomes. Wear-time compliance was not verified; therefore, gaps in step data may reflect tracker nonwear, true inactivity, or technical issues with the device, app, or server synchronization. In addition, weekly average daily steps were derived from server-generated weekly step totals divided by 7 calendar days; therefore, average daily step counts may have been underestimated. All nonstep activities were self-reported, making their duration estimates subject to recall and social-desirability bias. Despite open eligibility, engagement remained higher among younger, employed, and better-educated cancer survivors, indicating a residual digital divide and potential selection bias. Some baseline data were missing (10% - 11% for BMI, educational level, and employment status), somewhat more often among nonusers than app users, and although the Little test did not reject the assumption that these data were missing completely at random, we used multiple imputation as sensitivity analysis, which reproduced the socioeconomic associations, indicating that the findings are robust to missing data. Phase-specific dips in engagement could not be separated from contextual factors, such as treatment milestones or holidays, because analysis weeks were aligned with individual enrollment dates. Data collection spanned from December 2019 to July 2022, overlapping substantially with the COVID-19 pandemic (Norwegian lockdowns: March 2020-September 2021); pandemic-related

XSL•FO
RenderX

restrictions on movement, facilities, and clinical workflows may have affected both PA levels and app engagement in ways that cannot be disentangled from individual engagement trajectories. Finally, the study took place within the Norwegian health care system; extrapolating results to regions with different infrastructures or lower smartphone penetration should be approached with caution.

Overall, the study provides a realistic demonstration of embedding a blended mHealth intervention in routine survivorship care while also highlighting methodological and equity-related challenges that future controlled and implementation-focused research will need to address.

Conclusions

The LETSGO program showed that a heterogeneous cohort of gynecologic cancer survivors engaged with an app-supported PA module for up to 12 months. Although mean PA levels remained modest (mean 5657, SD 2799 steps/d; low-active range) and engagement fluctuated, nearly three-quarters of the participants interacted with the PA component of the app at least twice, and 60% (n=225) synchronized their objective step data with the app. Engagement lapses were typically temporary, with recurrent dips followed by re-engagement, indicating a dynamic of ebb and flow rather than definitive dropout. App use centered on walking, whereas resistance training was less frequent, with the recommended 2 or more sessions per week. Socioeconomic gradients in use, favoring younger, employed, and more highly educated participants, highlight the persistent digital divide. Collectively, these findings confirm the feasibility of pragmatic, blended digital follow-up in survivorship care, while also signaling the need for adaptive re-engagement strategies and equity-focused implementation supports, alongside targeted content to increase adherence to resistance training.

Acknowledgments

The authors express their gratitude to all the gynecologic cancer survivors who participated in the LETSGO (Lifestyle and Empowerment Techniques in Survivorship of Gynecologic Oncology) study and contributed their time and data. They are also thankful to the dedicated clinical staff at participating hospitals for their collaboration in implementing the intervention as part of routine follow-up care. Special thanks are extended to the nurse coordinators for their integral role in supporting participant engagement and ensuring the smooth integration of the digital tools into standard care. Finally, the authors acknowledge the contributions of the LETSGO project team and the technical partners involved in app development and data management.

The authors declare the use of generative AI (GenAI) in the research and writing process. According to the GAIDeT taxonomy (2025), the following tasks were delegated to GenAI tools under full human supervision: proofreading and editing. The GenAI tool used was Claude (Opus 4.8). Responsibility for the final manuscript lies entirely with the authors. GenAI tools are not listed as authors and do not bear responsibility for the final outcomes.

Funding

The LETSGO (Lifestyle and Empowerment Techniques in Survivorship of Gynecologic Oncology) study was funded by the Norwegian Cancer Society (grant 198057), the UNI Foundation (grant 3287), and the South-Eastern Norway Regional Health Authority (grant 2019073). The funders had no role in the study design, data collection, data analysis, interpretation of data, or preparation of the manuscript.

Data Availability

The data that support the findings of this study are available upon reasonable request from the corresponding author. The data are not publicly available due to privacy or ethical restrictions.

Authors' Contributions

SB and IV conceptualized the study, registered the protocol, supervised the execution of the project, and assisted with manuscript writing. MS contributed to the development of the app, implemented the intervention, and assisted with manuscript writing. SHF analyzed and interpreted the data and wrote the manuscript. All authors read and approved the final version of the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: The integration of mobile health apps (MHAs) into nursing practice is essential for improving efficiency, conserving resources, and enhancing patient care. To promote the acceptance of these apps in clinical care, it is important to assess current acceptance levels and identify influencing factors.

Objective: This study investigated the acceptance of MHAs and related factors among nurses in hospitals affiliated with Kashan University of Medical Sciences, Iran.

Methods: In this cross-sectional study, 250 nurses were selected via stratified random sampling in Kashan in 2022. Data were collected using the Nurses' Mobile Health Device Acceptance Scale (NMHDA-S) and the Probable Predictors Questionnaire. The data were analyzed using SPSS (version 16; IBM Corp), 1-way ANOVA, independent *t* test, Pearson correlation coefficients, and multiple linear regression.

Results: The findings showed that nurses had a mean acceptance score of 4.207 (SD 0.740) on a Likert scale from 1 to 7 (95% CI 4.115 - 4.299) regarding the use of MHAs. Multiple linear regression analysis indicated that 4 variables significantly predicted acceptance of MHAs (R^2=0.230, $F_{4,245}$=18.308, P<.001): interest in participating in relevant educational programs (β=0.392, P<.001), encouragement from health care professionals to use MHAs (β=0.133, P=.02), male participant (β=−0.116, P=.04), and duration of daily internet use (β=0.117, P=.04).

Conclusions: Although MHA acceptance among clinical nurses in Kashan is moderate, adoption can be enhanced through targeted training, facilitated internet access, and gender-specific incentive policies, particularly for female staff.

KEYWORDS

mobile apps; acceptance; nurses; attitude; Iran

Introduction

The increasing prevalence of smartphones and mobile health apps (MHAs) among health care professionals highlights the growing integration of health information technology into clinical practice [1]. Nurses are encouraged to incorporate various forms of health information technology into their clinical practice for several reasons [2]. One primary reason is the nature of the nursing profession, which requires unrestricted mobility within the clinical setting [3]. On the other hand, the global shortage of nurses is a major challenge [4]. A study conducted in 2020 revealed that most nurses (52.4%) had a negative attitude toward adopting and using MHAs [5]. In addition, a study conducted in Iran [6] reported that approximately 63.4% of nurses did not use MHAs on their smartphones.

The absence of MHAs in the clinical setting can lead to several challenges associated with the use of paper. These challenges include significant time consumption, frequent visits to nursing

XSL•FO
RenderX

stations for recording and retrieving information, and an increased risk of forgetting important details. Moreover, the use of paper increases the likelihood of errors in data recording and management, which may have serious consequences for patient safety. In this context, implementing MHAs at the patient's bedside is essential and represents an inevitable solution. These technologies have led to fundamental improvements in the quality of nursing care and are straightforward and easily accessible [7]. Therefore, health care managers across various levels need to adopt MHAs to increase the quality-of-care services and address the issues arising from traditional paper-based systems. The initial step in addressing this challenge involves assessing the current acceptance of MHAs among nurses and identifying the factors that influence this acceptance [8].

The concept of acceptance concerning technologies such as MHAs is framed primarily through behavioral models, with the expectation-confirmation model (ECM) serving as the foundation for this study. To capture the unique aspects of the nursing context thoroughly, our ECM framework intentionally incorporates established components from the technology acceptance model and the unified theory of acceptance and use of technology (UTAUT). These include constructs such as perceived ease of use and social influence. This integrated theoretical approach operationalizes acceptance by measuring a range of multidimensional factors, thus ensuring that the model is directly aligned with the clinical environment, including effectiveness, usage, performance, and anxiety related to new technology [9,10].

Numerous studies have explored the factors influencing the acceptance of MHAs. However, a notable limitation of these studies is the inconsistent prioritization of identified factors among health care professionals [8,11,12]. For example, Lwoga and Lwoga [13] and Chopdar et al [14] emphasized perceived security risk, whereas Lau et al [15] reported no significant correlation between this factor and the acceptance of MHAs. Sezgin et al [16] emphasized the characteristics of the user interface as an important factor influencing the use of MHAs. However, the results of Hsiao and Chen [17] revealed that this factor does not have a significant influence. In addition, there is a discrepancy in the literature regarding the influence of organizational characteristics on the use of MHAs. While Zhou et al [18] demonstrated a significant effect, Hsiao and Chen [19] noted that this factor was not significant.

Despite the expanding body of literature on MHAS acceptance, most studies have been conducted in developed countries with well-established health information infrastructures. In contrast, developing nations such as Iran face distinct infrastructural, sociocultural, and economic challenges during the digital transformation of their health care systems. Kashan, a prominent center for medical education and clinical care in central Iran, offers an ideal environment for investigating these transitional dynamics. The 5 hospitals affiliated with Kashan University of Medical Sciences include a wide range of clinical wards and diverse nursing demographics, making them an ideal setting for a comprehensive examination of digital health adoption in a resource-limited environment. Given inconsistencies in the existing literature on the impact of attitudes on performance and the lack of comprehensive studies in such contexts, this research was conducted to assess the acceptability of using MHAs and related factors among clinical nurses across all 5 hospitals in Kashan, Iran. The results of this study can serve as a foundation for developing educational interventions and policy decisions to advance the implementation of digital health in nursing practice.

Methods

Study Design and Setting

The present study is a descriptive cross-sectional study. In this study, the sample size was calculated on the basis of a pilot study conducted with 30 nurses, which produced a mean acceptance score of 4.055 (SD 0.722). With a confidence level of 95% and an accuracy estimate (d) defined as a conservative fraction of the SD ($d = 0.124 \times 0.722$), consistent with established methodological guidelines for achieving high precision in continuous data [20,21], Cochran formula was used to calculate the required sample size, resulting in a total of 250 participants (Equation 1).

The inclusion criteria included Iranian citizenship, a university degree in nursing, no known psychological disorders based on self-reports (such as mood disorders or anxiety disorders), at least 6 months of clinical experience, current employment in clinical roles in inpatient departments, and consent to participate in the study. Refusal to complete the data collection instruments was also considered as an exclusion criterion. A stratified random sample by department was conducted among eligible nurses in different clinical wards of hospitals affiliated with Kashan University of Medical Sciences. This sampling process was conducted over 2 months, from August to October 2022.

$$n=z2\times SD2d2$$

Equation 1 shows the Cochrane formula for sample size.

Data Collection Process

After approval from the Research Council and the Ethics Committee of Kashan University of Medical Sciences, the first author of the article approached the nursing offices of 5 hospitals (Shahid Beheshti, Naghavi, Matini, Kargarnejad, and Seyed Al Shohada Hospitals) with an introductory letter. After the study procedure was explained and permission from hospital management was secured, a comprehensive list was compiled detailing all clinical departments, including the names and total numbers of active nursing staff in each unit. To ensure proportional representation in line with the inclusion criteria and the target sample size, a proportionate number of eligible nurses from each department was then selected via simple random sampling. After consent was obtained from the head nurses, the first author of the article visited the departments at the beginning of each shift in accordance with the work schedules of the selected nurses. After providing consent, the selected nurses were instructed to complete the data collection instruments. The instruments were collected at the end of each shift. If the scales were not completed within the specified time frame, an agreement was reached with the respective nurse regarding the time of submission. In cases where the selected sample was unavailable or uncooperative, another nurse from

XSL•FO
RenderX

the same department was randomly selected. All data collection instruments were completed by the nurses themselves and were based on self-reports.

Data Collection Instruments

In the present study, data were collected via the probable predictors of acceptance of MHAs by nurses using the Nurses' Mobile Health Device Acceptance Scale (NMHDA-S) [8] (Multimedia Appendix 1).

The probable predictors of acceptance of mobile health programs, according to the nurses' questionnaire, are divided into 4 sections:

1. Personal and professional information, including age, gender, marital status, education level, department, work experience, frequent shift work, having young or adolescent children, and holding a managerial position
2. Knowledge of MHAs, assessed via a single self-reported item rated on a 7-point scale, specifically asking: "Please indicate your level of knowledge regarding MHAs on a scale of 1 to 7"
3. A history of familiarity with MHAs, including observations of health care professionals or acquaintances using MHAs, participation in relevant courses, specialized university training, encouragement to use MHAs by health care professionals, involvement in relevant research, mandatory use of specific MHAs in the workplace, instances of patient inquiries about MHAs, the presence of individuals with educational or professional backgrounds in information technology or related fields among first-degree relatives or close friends, and their willingness to engage with topics about new technologies
4. Use of MHAs, including professional and personal use, smartphone ownership, duration of smartphone usage, device operating system, types of devices used, duration of daily internet use, and interest in participating in relevant educational programs

This questionnaire was developed in Persian by the researchers of the present article on the basis of a comprehensive literature review, including relevant articles and questionnaires, as well as a survey of nursing and health information management professionals. The qualitative content validity was confirmed by 10 faculty members from Kashan University of Medical Sciences. The reliability of the questionnaire was evaluated via the test-retest method with a group of 20 nurses over a 1-week interval. The degree of agreement between the 2 measurements was determined by calculating the intraclass correlation coefficient for quantitative variables (such as knowledge of MHAs) and the κ statistic for categorical variables (such as familiarity factors with MHAs). Notably, all the responses regarding personal and professional variables remained consistent across both assessments. The intraclass correlation coefficients for the quantitative variables were found to exceed 0.95, whereas the κ statistics for the categorical variables surpassed 0.97.

The NMHDA-S was used to evaluate the acceptance of MHAs among nurses. This scale was originally developed in Persian on the basis of the constructs of the ECM and was psychometrically evaluated by Mirabootalebi et al [8] in 2024. The NMHDA-S consists of 33 items categorized into 5 subscales: usage and performance (10 items), social influence (7 items), perceived ease of use (5 items), effectiveness (7 items), and new technology anxiety (4 items). The respondents rated each item on a 7-point Likert-type scale. To determine the total acceptance score, the mean of all the items is calculated, resulting in a continuous score ranging from 1 to 7, where higher values indicate greater acceptance. Subscale scores are derived via the same mean-based procedure. The scale's construct validity has been confirmed, and it demonstrates high internal consistency, with Cronbach α and McDonald ω coefficients of 0.938 and 0.953, respectively. These indices were estimated to be above 0.88 for all the subscales [8].

Data Analysis

The data were analyzed using SPSS version 16. Acceptance scores were rated on a 7-point scale (1 to 7), and the 95% CI was calculated for the target population. Skewness and kurtosis indices were used to assess the data distribution, with a range of ±2 indicating a normal distribution. To prioritize the scale factors, a stepwise multiple linear regression analysis was performed to determine the contributions of various factors to acceptance, including usage and performance, social influence, perceived ease of use, effectiveness, and new technology anxiety.

The effects of the factors were analyzed in 2 phases to identify predictors. In the first phase, univariate analyses, including independent *t* tests, one-way ANOVA, and Pearson correlation coefficients, were conducted to assess the relationship between each factor and MHA acceptance. Variables with a significance level of <0.20 were subsequently entered into a stepwise multiple linear regression model. To ensure the validity of the regression results, key assumptions were rigorously evaluated. Multicollinearity was assessed using variance inflation factors (VIFs) and tolerance indices, while autocorrelation among the residuals was examined using the Durbin-Watson statistic. The normality and homoscedasticity of the residuals were evaluated using objective statistical measures—specifically, skewness and kurtosis values within ±2 were considered indicative of normal distributions. This analysis was further supported by visual inspection of residual histograms and normal probability (P-P) plots. For all analyses, a *P* value of <.05 was considered statistically significant.

Ethical Considerations

All necessary approvals were obtained from the Research Council (number 039, dated 2022) and the Ethics Committee of Kashan University of Medical Sciences (code 40138). The first author explained the study to each nurse individually in a quiet, private, and comfortable room within the department. The key points discussed included the purpose of the study, the expected actions required for participation, the estimated time needed to complete the instruments, measures to ensure the confidentiality of the data, the absence of negative consequences if they choose not to participate in the study, the individuals and departments overseeing the study, and their right to withdraw from participation at any time. After these

XSL•FO
RenderX

explanations, each nurse provided verbal consent and then signed a written informed consent form.

Results

Participant Characteristics

Among the 306 eligible nurses, 250 (81.7%) participated in the study, resulting in the analysis of 250 samples. The mean age of the participants was 35.624 (SD 7.582) years. Table 1 presents the personal and professional information, knowledge of MHAs, history of familiarity with MHAs, and usage of MHAs. The mean knowledge score of MHAs was calculated to be 2.976 (SD 1.210) on a 7-point scale (1 to 7).

[a]MHA: mobile health app.

[b]NMHDA-S: Nurses' Mobile Health Device Acceptance Scale.

Acceptance Levels

The mean acceptance score for using MHAs in nursing was 4.207 (SD 0.740; on a scale of 1 to 7), indicating a moderate level of acceptance among clinical nurses. This rate was estimated to be 4.207 (95% CI 4.115-4.299) within the target population. All quantitative variables in the current study had a normal distribution based on the criteria included in the methodology (skewness and kurtosis within ±2). Stepwise multiple linear regression was used to prioritize the subscales of the acceptance scale. The results revealed that the contributions of each subscale, including usage and performance, social influence, perceived ease of use, effectiveness, and new technology anxiety, to explaining the variations in acceptance ratings were 1.9%, 5.5%, 12.6%, 76.9%, and 3.1%, respectively. Consequently, effectiveness proved to be the most important subscale.

Predictors of Acceptance

A significant univariate association was found between acceptance scores and several factors, including gender (P=.03), education level (P=.001), observations of health care professionals or acquaintances using MHAs (P<.001), participation in relevant courses (P=.002), encouragement to use MHAs by health care professionals (P<.001), instances of patient inquiries about MHAs (P=.002), the presence of individuals with educational or professional backgrounds in information technology or related fields among first-degree relatives or close friends (P<.001), professional (P=.001), and personal use (P=.03), duration of daily internet use (P=.009), interest in participating in relevant educational programs (P<.001), willingness to engage with topics about new technologies (P<.001), and knowledge of MHAs (P=.002; Tables 2 and 3).

Table . Correlation of acceptance scores for using mobile health apps (MHAs) in care with quantitative variables among Iranian nurses, Kashan, 2022 (N=250).

Variable	*r* values[a]	*P* value
Age (y)	–0.01	.87
Work experience (y)	0.052	.41
Duration of smartphone usage (y; n=231)	0.128	.04
Interest in participating in relevant educational programs [1-5]	0.419	<.001
Willingness to engage with topics about new technologies [1-5]	0.276	<.001
Knowledge of MHAs [1-7]	0.196	.002

[a]Pearson coefficient.

A stepwise multiple linear regression was performed to further examine the relationships between the independent variables and acceptance scores. The VIFs for all the variables were <5, and their tolerances exceeded 0.10, indicating an absence of multicollinearity. The Durbin-Watson statistic was 1.943, which falls within the acceptable range of 1.5 to 2.5. Before conducting the final regression analysis, the underlying assumptions were thoroughly verified. The Durbin-Watson statistic was within the acceptable range, confirming the absence of autocorrelation. The VIF values indicated no multicollinearity. For the regression residuals, both skewness and kurtosis were within the acceptable range of ±2, suggesting normality. Additionally, examination of residual histograms and normal P-P plots further confirmed that the assumptions of normality and homoscedasticity were fully satisfied. Consequently, the assumptions of multiple linear regression were satisfied, confirming the validity of the model. The results show that the simultaneous inclusion of 4 variables in the model is significant ($F_{4,245}$=18.308, *P*<.001) and explains 23% of the observed variance in acceptance scores. These variables include interest in participating in relevant educational programs, encouragement to use MHAs by health care professionals, gender, and duration of daily internet use. The variable with the greatest influence is interest in participating in relevant educational programs, which accounts for 17.6% of the observed changes. Interest in participating in relevant educational programs, encouragement by health care professionals to use MHAs, and duration of daily internet use positively influence acceptance. In addition, being a man is associated with greater acceptance (Table 4).

[a]R^2=0.230, $F_{4,245}$=18.308, P<.001.

[b]Unstandardized coefficients.

[c]Standardized coefficients.

[d]VIF: variance inflation factors.

[e]Not applicable.

[f]Reference group=no.

[g]Reference group=man.

When controlling for other variables, the average acceptance score for MHAs among female nurses was 0.226 points lower than that of male nurses. In contrast, nurses who received encouragement from health care professionals to use MHAs experienced an average increase of 0.235 points in their acceptance scores. For each 1-unit increase in interest in participating in related educational programs, the acceptance score increased by an average of 0.310 points. Additionally, each extra hour of daily internet usage corresponds to an average increase of 0.086 points in the acceptance score. In this model, the unstandardized coefficients (B) represent the absolute change in the dependent variable per unit change in the independent variable, measured in the original units of the independent variable. The standardized coefficients (β) are dimensionless values that normalize the variables by their SDs, allowing them to be assessed on a common scale. While B quantifies the absolute magnitude of change, β is used to interpret the relative importance and compare the predictive power of the independent variables, regardless of their measurement units. According to the β coefficients in Table 4, interest in participating in relevant educational programs has the highest relative explanatory power in the model.

Discussion

Acceptance of MHAs Among Nurses

The present study aimed to investigate the acceptance of MHAs and associated factors among clinical nurses in Iran. The principal findings indicate moderate acceptance of MHAs among the surveyed nurses, with a mean score of 4.207 (SD 0.740) out of 7.

A study conducted by Shanmugapriya et al [22] in India reported that 71.6% of nursing students strongly agreed, 27.8% agreed, and only 0.6% expressed no opinion regarding their acceptance of MHAs. In addition, Kürtüncü et al [7] reported a mean total score of 124.69 (SD 15.98; ranging from 0 - 128) for Turkish nurses on the MHAS acceptance model, indicating a high level of acceptance in this group. The researchers explained that the reason for the high level of acceptance among Turkish nurses was related to their high use of smartphones [7]. In Iran, the acceptance of MHAs among nurses was found to be moderate, possibly due to the lack of necessary infrastructure, absence of established guidelines, and insufficient knowledge [6]. In simpler terms, nurses are still not sufficiently equipped for digital transformation in health care and face several challenges, including limited digital skills, restrictions on smartphone usage, and financial constraints. By examining these specific behavioral factors in a resource-limited context such as Iran, this study

XSL•FO
RenderX

goes beyond incremental findings to provide a comprehensive understanding of the unique challenges of digital health adoption in developing health care systems. It is recommended that incentives be offered to nurses to help offset the costs of using their personal smartphones for clinical tasks [23].

The findings of the current study suggest that the dimensions of "effectiveness" and "perceived ease of use" contribute significantly to the variations in acceptance scores. In contrast, "usage and performance" was responsible for the least variation in these scores. These results are consistent with those of previous studies. Hsiao and Chen [19] highlighted the impact of maturity and perceived usefulness on technology acceptance. Recent evidence on the adoption of health care technology indicates that perceived usefulness and perceived ease of use play significant roles in technology acceptance and the intention to use these innovations [24]. Additionally, recent studies focusing on nurses and health care professionals emphasize that perceived usefulness is an essential factor influencing both technology acceptance and the intention to use it [24,25]. In a review paper, Nezamdoust et al [26] identified 8 key themes influencing nurses' use of MHAs: ease of use, usefulness, security and privacy, feasibility and performance, design and user interface, effectiveness, infrastructure, adaptability, and social norms. The findings of this and other studies indicate that perceived usefulness, perceived ease of use, and maturity are important determinants of clinical nurses' acceptance of MHAs. Owing to living in the information and technology era and recognizing the benefits of using MHAs, nurses are increasingly inclined to use similar systems. Therefore, it is clear that perceived ease of use and usefulness play important roles in the acceptance of MHAs and ultimately encourage their increased or continued use.

In the present study, "usage and performance" made the smallest contribution to explaining the difference in caregiver acceptance of MHAs. Consistent with these findings, Hsiao and Chen [19] concluded that individual habits do not significantly influence the acceptance or performance of MHAs. In addition, Sezgin et al [16] reported no significant relationships between outcome acceptance, habits, self-efficacy, expected performance, creativity, and community influence on behavioral intentions. Chen et al [27] also concluded that security risk has a negative effect on the intention to use. However, some studies support the rejection of the hypothesis of the present study. Recent findings indicate that privacy and performance risks negatively impact trust and the intention to adopt digital health technologies, suggesting that perceived risk reduces acceptance [24]. Studies by Lwoga and Lwoga [13] and also Chopdar et al [14] have emphasized the influence of perceived security risk. The factors influencing usage and performance include personal habits, security risk, and social approval. The underutilization of MHAs can be attributed to several challenges, such as the absence of robust policies, lack of practical and user-friendly apps, and nurses' unawareness of the potential benefits of MHAs. These issues likely play an important role in the resulting usage scores.

On the basis of the results of the present study, "interest in participating in relevant educational programs," "encouragement to use MHAs by health care professionals," "gender," and "duration of internet use per day" were identified as factors influencing nurses' acceptance of using MHAs in their nursing practice. The greatest contribution was "interest in participating in relevant educational programs," which was significantly positively correlated with the acceptance rate.

Kaya et al [28] reported a significant association between in-service training and changes in nurses' attitudes toward themselves, computers, and information technology devices. This technology requires training and attention to organizational and environmental factors to increase technology anxiety among nurses. In addition, it is important to create a supportive organizational culture that promotes technical skills and provides adequate time and resources for learning [29,30]. In a 2019 study [31], 69.5% of nurses could not use technology effectively and correctly. One of the main reasons for this is nurses' lack of computer skills. Addressing this issue through continuous education for nurses can help bridge the generational and educational divide, ultimately alleviating their anxiety about using new technologies. Lifelong education for nurses plays a critical role in improving their acceptance of technology, especially in the face of constant changes in patient care, advancements in knowledge, and evolving practices and policies. In addition, supervisor and peer support can encourage nurses to embrace information technology by actively promoting MHA, effectively integrating it into clinical practice, and recognizing the resulting performance improvements.

The present study revealed that encouraging the use of MHAs among health care professionals has a positive and significant effect on acceptance rates. Recent evidence indicates that social factors significantly influence users' intention to adopt technology, whereas attitudes remain a key contributor in these contexts [32]. Recent studies have shown that social influence significantly predicts the intention to use emerging technologies [33]. The findings of the study by Alasmari and Zhang [34] are consistent with those of the present study. The acceptance of MHAs by nurses is significantly influenced by various factors, including use by nursing colleagues, other health care professionals, and care managers. For example, colleagues who integrate smartphones into their clinical practice can be role models for nurses and encourage them to use similar technologies. In addition, the positive experiences and satisfaction of colleagues and managers with MHAs can help reduce nurses' technology-related anxiety and reservations and thus increase their overall acceptance of these tools. In particular, sharing positive experiences with experts can be a strong motivator for nurses. When selecting MHAs, nurses usually consult more experienced colleagues, often giving considerable weight to their recommendations. Consequently, a positive view from peers can significantly increase nurses' acceptance of technologies. When colleagues endorse specific technologies, this promotes a sense of approval among health care professionals. Conversely, peer resistance to MHAs can have a negative effect on acceptance and usage.

In the statistical model outlined in the present study, the "duration of daily internet usage" is found to have a positive effect on the acceptance score. Shanmugapriya et al [22] reported that there is a statistically significant correlation between the acceptance of MHAs and the time spent on nursing

XSL•FO
RenderX

studies (internet-based learning). A 2020 study [35] identified several significant predictors of acceptance of MHAs among patients with cancer, including age, education level, and access to the internet. In addition, the duration of daily internet use increased among nurses using smartphones, which in turn impacted their acceptance of these apps. Smartphones provide easy access to the internet and allow nurses to access important online resources, such as treatment and medication guidelines, directly from their workplace. This capability enhances the ease of access and utilization of digital information in the clinical setting. In addition, smartphones facilitate communication with colleagues, physicians, and patients via various platforms, such as email, messaging applications, and telemedicine services.

This study revealed that men had a greater level of acceptance. A 2019 study [34] revealed that men tended to use mobile learning technologies more strongly than women did. In addition, a study by Nunes et al [36] confirmed the significant influence of men on the acceptance of MHAs. In this context, Al-Azawei [37] pointed to gender difference as a moderator in the relationship between the model constructs. However, in this study, this moderating effect was found to be minimal with respect to the relationship between e-learning self-efficacy and learning management system acceptance. Self-efficacy had a stronger effect on the intention to use learning management system in men than in women, suggesting that men have relatively higher levels of acceptance [37]. However, a 2024 study [38] examining students' intentions to use online learning through educational technology applications based on the UTAUT model revealed a significant influence of women on acceptance. Recent evidence suggests that both gender and age can affect the relationship between self-efficacy and technology adoption, with self-efficacy remaining a crucial factor in users' intentions to adopt technology [39]. Furthermore, the findings indicate that specific computer effectiveness has a more pronounced effect on perceived ease of use than does general remaining efficacy. Among cofactors, general computer self-efficacy emerged as a significant predictor of perceived usefulness for both men and women. Additionally, while perceptions of general computer self-efficacy were lower, it still had a notable influence on the intention to use technology. Conversely, specific computer self-efficacy demonstrated a stronger indirect effect on behavioral intentions among women, although both genders reported similar levels of self-efficacy [40]. The results can serve as a reference for hospitals and clinical training organizations. When integrating nursing technologies into nurses' clinical practice, it is important to consider user characteristics and relevant moderators when specific groups are targeted through MHAs. Studies suggest that men are more at ease with and acclimatized to technology than women are. In addition, societal expectations around gender roles can influence how people perceive and interact with technology. In a country with cultural characteristics similar to those of Iran, it seems that women's greater anxiety about new technology and men's greater belief in their self-efficacy contribute to these results. Further research is needed, as there is a lack of robust evidence in this area for different societies. Analyzing the underlying causes in Iranian society highlights the need for qualitative approaches.

Importantly, several factors may contribute to the discrepancies between the results of the current study and those of previous related research. These factors include the timing and location of the studies, the type of statistical tests, the presence or absence of established national guidelines, differences in the relevant target groups, and the specific characteristics of those populations.

The substantial sample size and the ability to conduct multiple analyses are notable strengths of the current study. Several factors may play important roles for health care professionals, including task mobility, individual performance, technological maturity [19], self-efficacy, responsiveness [41], organizational support, environmental and organizational influences, adaptability [17], and acceptance of MHA; however, these factors were not explored in the current study. In this context, the final multiple linear regression model (Table 4) explained only 23% of the variance in the acceptance score, indicating that 77% of the variance is explained by other variables not included in the model. Consequently, the interpretation of these results should be approached with more caution, as the identified predictors provide only a partial explanation of MHAS acceptance. Furthermore, the timing of sampling during the COVID-19 crisis disrupted the usual structure of hospital departments, changed the composition of human resources, and significantly increased the occupational stress among nurses in this setting [42]. As a result, the unwillingness of a considerable number of nurses to participate in the study probably affected the generalizability of the findings, which is recognized as a limitation of this study. It is recommended that a study be conducted under normal conditions, free from the constraints imposed by pandemic crises, to address the limitations of the current study. In addition, conducting a qualitative study with a grounded theory approach would be valuable for an in-depth investigation of the factors influencing the acceptance of MHAs by nurses in different societies, including Iran.

This study has several limitations. First, the data were collected concurrently with the COVID-19 crisis, during which the nursing staff experienced a high workload and occupational stress [42], potentially affecting participation and responses. A substantial proportion of eligible nurses were unwilling to cooperate, which may have introduced response bias. Furthermore, the participants' knowledge of MHAs was assessed using a single-item question, which may not have captured the full multidimensionality of this construct. It is strongly recommended that future studies evaluate this variable via more appropriate, comprehensive, and highly precise measurement tools.

Conclusions

The present study revealed moderate acceptance of MHAs among nurses in hospitals affiliated with Kashan University of Medical Sciences. The key factors that positively and significantly contribute to the acceptance rate include "interest in participating in relevant educational programs," "encouragement from health care professionals to use MHAs," and "duration of daily internet use." In addition, the acceptance rate is significantly higher among men than women. Facilitating interest in participation in relevant training courses, alongside

XSL•FO
RenderX

the provision of adequate internet access and the implementation of incentive policies targeting all nursing professionals, especially women, may increase the acceptance of MHAs in the delivery of care. Therefore, health policy makers and nursing managers should recognize the importance of this issue when designing continuing education programs for nurses, formulating policies related to incentive structures, and establishing supportive infrastructure in hospitals. By implementing effective strategies, they can improve the acceptance of MHAs among nurses in the clinical setting.

Acknowledgments

The authors would like to thank all the nurses who participated in the study and the Vice Chancellor for Research and Technology of Kashan College of Medical Sciences. The authors acknowledge the generous scientific support of the Clinical Research Development Unit of Matini/Kargarnejad Hospitals, Kashan University of Medical Sciences, Kashan, Iran. Generative AI tool was not used in any stage of preparing the article.

Funding

The present article is based on the findings of the first author's doctoral dissertation, which was approved by the Research Council of Kashan University of Medical Sciences and Health Services (number 039, dated 2022) and conducted with financial support from the Vice-Chancellor for Research and Technology of Kashan University of Medical Sciences.

Abstract

Background: Local anesthetics (LAs) are widely used in clinical practice, but their administration carries the risk of LA systemic toxicity, a potentially fatal complication. Calculating maximum safe doses is complex and error-prone when considering multiple patient-specific factors. Most existing tools and mobile apps have not been scientifically validated and may propose unsafe doses. The Local Anesthetics Dose Calculator (LoAD Calc) mobile app was developed at the Geneva University Hospitals to calculate maximum safe doses by integrating comprehensive patient parameters.

Objective: The primary objective was to evaluate the overdose rate using the LoAD Calc app compared with traditional calculation methods. Secondary objectives were calculation time, user confidence, app usability, and interpractitioner variability.

Methods: This single-center unblinded randomized controlled trial recruited 50 anesthesiologists to use either LoAD Calc or their usual calculation methods. Assessment was conducted in-person using a web-based platform. Participants completed 10 clinical vignettes featuring various patient characteristics, comorbidities, and medication interactions requiring maximum safe dose calculations for lidocaine, levobupivacaine, and ropivacaine. The primary outcome was the overdose rate, defined as exceeding the maximum safe doses calculated using a comprehensive set of rules incorporating all patient-specific factors. Secondary outcomes included overdose rates using 2 simplified weight-based methods, underdose rates, calculation time, and self-reported measures of confidence and app usability. Overdose rates were compared using chi-square tests with 95% CIs; calculation time and confidence were assessed using Student *t* test.

Results: All 50 participants completed the study. Using the full set of calculation rules, the overdose rate was significantly lower when LoAD Calc was used (30/250, 12.0% vs 198/250, 79.2%; relative risk [RR] 0.15, 95% CI 0.11 - 0.21; *P*<.001). This was consistent across all 3 LAs: ropivacaine (5/100, 5% vs 64/100, 64%; *P*<.001), levobupivacaine (19/100, 19% vs 90/100, 90%; *P*<.001), and lidocaine (6/50, 12% vs 44/50, 88%; *P*<.001). When considering simplified weight-based methods, overdose rates remained significantly lower when LoAD Calc was used (actual weight: 8/250, 3.2% vs 95/250, 38.0%; RR 0.08, 95% CI 0.04 - 0.17; *P*<.001; ideal body weight: 10/250, 4.0% vs 151/250, 60.4%; RR 0.07, 95% CI 0.04 - 0.12; *P*<.001). Underdose rates were similar (25/250, 10.0% vs 27/250, 10.8%; *P*=.77). Calculation time was also similar (mean 111, SD 56 s vs mean 115, SD 89 s; *P*=.53). LoAD Calc users reported higher confidence (mean 8.5, SD 0.9 vs mean 6.3, SD 1.7; *P*<.001), and the app achieved a median System Usability Scale score of 98 (IQR 95-100).

Conclusions: LA overdoses were significantly less likely when the LoAD Calc app was used in simulated clinical vignettes, without increasing calculation time or underdose rates. Given its high usability score and the improvement in practitioner confidence, clinical implementation could be considered and may contribute to improving patient safety and dose calculation standardization.

Introduction

Local anesthetics (LAs) are widely used by clinicians across various settings, including operating rooms and office-based procedures [1,2]. In anesthesia practice, local and regional anesthesia have become integral components of perioperative management for elective surgical procedures [3]. While generally safe and effective, LA overdose can expose patients to serious complications, particularly local anesthetic systemic toxicity (LAST), which manifests as neurological and cardiac toxicity and can be potentially fatal [4,5].

To prevent LAST, the American Society of Regional Anesthesia and Pain Medicine (ASRA) recommends several safety measures, including ultrasound guidance, incremental and fractional injection with intermittent aspiration, the use of intravascular markers, and the administration of the lowest effective LA dose [6].

In clinical practice, dose calculations are typically performed according to empirical guidelines, with many clinicians relying on mental calculations or basic calculators. However, the mental calculation of maximum safe LA doses is challenging and error-prone, particularly when multiple variables must be considered simultaneously, including patient weight, age, comorbidities, LA type and concentration, injection site vascularity, and potential drug interactions [7,8]. When LA mixtures are used, complexity grows substantially, thereby significantly increasing the risk of calculation errors. To address this challenge, tools such as nomograms and mobile apps have been developed to facilitate dose calculations [9]. However, most have not been scientifically validated for clinical implementation, and preliminary assessments suggest that they allow the calculation of doses that could exceed safe limits and potentially lead to LAST [10].

A mobile health (mHealth) app, Local Anesthetics Dose Calculator (LoAD Calc), was developed at the Geneva University Hospital to assist anesthesiologists in calculating safe maximum LA doses [10]. This app integrates various patient parameters and enables calculations for LA mixtures. The hypothesis was that automating LA dose calculation would reduce overdose rates without increasing the risk of underdosing or calculation time. The primary objective of this study was to evaluate whether the LoAD Calc app reduces overdose rates compared to traditional calculation methods. Secondary objectives included assessing the impact on calculation time, user confidence, app usability, and whether the app standardizes LA dosing in clinical practice.

Methods

Study Design and Participants

This single-center, parallel-group randomized controlled trial was conducted at the Geneva University Hospitals. The study protocol was previously published [11]. This paper was designed according to the CONSORT-EHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and Online TeleHealth) checklist (Checklist 1) [12]. Relevant elements from the CHERRIES (Checklist for Reporting Results of Internet E-Surveys) were included due to the use of online questionnaires [13]. The trial was conducted in an unblinded design, as it was not possible to conceal the intervention type from participants.

All resident physicians and registrars in the anesthesiology department were eligible for participation. All participants were employed at the Geneva University Hospitals, a tertiary academic center, and were therefore subject to the same institutional workload and mandatory continuing medical education requirements. Regional anesthesia is routinely performed as part of standard perioperative care at this institution. The sole exclusion criterion was current or prior use of the LoAD Calc app, determined through screening questions.

Ethical Considerations

The regional ethics committee (Commission Cantonale d'Éthique de la Recherche [CCER], Geneva, Switzerland) issued a declaration of no objection (CCER 2022 - 01577), as the study did not fall within the scope of Swiss federal law on human research [14]. This exemption was appropriate as the study involved only health care professionals in a simulated setting, with no patient data collected. All participants received a written information sheet and provided explicit consent before participating. Consent was obtained through an online platform, where participants clicked an "I agree to participate" button before proceeding. They were informed that participation was entirely voluntary and that they could withdraw at any time without consequence. Unique anonymous identifiers were used throughout; no personal identifying information was linked to study responses. The investigator (MS) who analyzed the data had no means of linking the anonymous identifiers to individual participants, and the final dataset used for analysis was fully anonymized. Participants received no financial compensation or other material incentives. The only benefit offered was the advancement of scientific knowledge.

LoAD Calc App Description

LoAD Calc is a multiplatform mobile app (iOS and Android) developed at the Geneva University Hospitals, as previously described in detail [10]. Briefly, the user selects the LAs and their concentrations, enters the patient's weight and height, and selects sex and the presence of relevant dose-modifying factors, including age over 70 years, comorbidities (renal insufficiency defined as glomerular filtration rate <50 mL/min, hepatic insufficiency defined as prothrombin time <50%, severe heart failure defined as left ventricular ejection fraction ≤30%, and pregnancy), and concomitant medications known to decrease LA metabolism (major CYP1A2 and CYP3A inhibitors). If one dose-modifying factor is present, the maximum dose is reduced by 20%; if 2 or more are present, it is reduced by 30%. The results are displayed as maximum safe volumes in milliliters, which is the clinically relevant unit for anesthesiologists. The app works offline and was developed using the Dart programming language with the Flutter open-source development kit (Google LLC). Screenshots of the app interface are provided in Multimedia Appendix 1. Version 1.2.1 of LoAD Calc was evaluated in this trial, and no updates or changes were made to the app's functionality or content during the study period. The complete calculation rules and algorithms are

XSL•FO
RenderX

detailed in this paper and the referenced development paper [10]. The source code is available upon request from the corresponding author.

Clinical Vignettes

Ten clinical vignettes (Multimedia Appendix 2) were developed by one of the authors (PEF), featuring realistic scenarios requiring LA dose calculations for 3 commonly used agents: lidocaine, levobupivacaine, and ropivacaine. The vignettes included various patient characteristics, comorbidities, and medication interactions requiring dose adjustments. These vignettes have already been described in a previous paper [15]. For each vignette, 3 authors (PEF, TSB, and MS) were required to determine the maximum dose of LA the simulated patient should receive according to the rules used to develop the LoAD Calc app, without using the app. Any disagreement prompted a review of the vignette. Final vignette approval was only possible if a consensus was reached.

Sample Size and Randomization

The sample size calculation was performed using Stata (version 17.0; StataCorp LLC). A minimum clinically meaningful difference of 10% in overdose rates was assumed based on clinical judgment, with an SD of 10% and a power of 90%, yielding a required sample size of 46 participants (23 per group). This was rounded to 50 to account for potential attrition.

Participants were randomized into one of 2 groups. The control group used their usual methods for calculating maximum safe LA doses, while the LoAD Calc group used the LoAD Calc mobile app preinstalled on a standardized dedicated smartphone. Randomization was stratified based on participants' positions (resident vs registrar) using Stata's balanced randomization mechanism by MS. Unique identifiers consisting of 12 random alphanumeric characters were generated and prerandomized to the respective groups. These identifiers served as login credentials for the web-based platform (described later) and automatically assigned participants to their respective groups (resident vs registrar and LoAD Calc vs traditional method).

Recruitment

Participants were recruited one at a time from the anesthesiology department of the Geneva University Hospitals between February 2024 and February 2025 and were temporarily relieved from their clinical duties. Participants were enrolled by MS, TSB, AS, and PEF. Potential participants first received an information sheet summarizing the study details and data protection measures. The information sheet did not identify which calculation method was the intervention of interest, maintaining a neutral presentation to minimize participant bias regarding the comparison. If they consented to participate, they were accompanied by an investigator to a dedicated room equipped with a computer. Participants were asked to put their personal phones in airplane mode and to give their professional phones to a colleague to avoid interruptions during the approximately 1-hour session. They were then asked to randomly choose a sealed, opaque envelope containing the credentials necessary to log in.

Online Platform

A dedicated web-based platform was developed by one of the authors (MS) using the Joomla! 4.3 content management system (Open Source Matters). The platform was hosted on a Swiss server (Kreativmedia GmbH) and secured using RSFirewall 3 (RSJoomla) and AdminTools 7 (Akeeba Ltd). Prior to implementation, the platform design and questionnaire interface were reviewed and tested by all authors to ensure usability and technical functionality. The study home page provided general information about the research and enabled participants to login. An initial questionnaire, managed using Shondalai Community Surveys 6 (Bulasikku Technologies Pvt Ltd), facilitated participant consent collection, exclusion criterion verification, and demographic data gathering. Then, an introductory screen displayed information regarding the clinical vignettes participants were about to encounter and specified the calculation method they were to use (LoAD Calc app for the experimental group vs the participant's preferred method for the control group). At this stage, those allocated to the LoAD Calc group were given a smartphone preinstalled with the LoAD Calc app. Participants received no prior training or instruction on the app and used it for the first time during the study session. The clinical vignettes were presented one by one in randomized order using Shondalai Community Quiz 7. A timer automatically started once each vignette page was loaded and stopped upon validation of the entered dose. After completing the vignettes, participants allocated to the LoAD Calc group completed the validated French version of the System Usability Scale (SUS) [16,17]. Participants allocated to the control group were asked which methods they used to calculate LA doses. Finally, both groups answered a question based on a 10-point Likert scale to assess their confidence in the method they used to carry out the maximum safe LA dose calculations, ranging from 1 (absolutely not confident) to 10 (perfectly confident). All participants were invited to provide open-ended comments or feedback about their experience with the calculation method or app if they wished to do so.

All data were stored in an encrypted MySQL-compatible database (MariaDB 10, MariaDB Foundation).

Overdose and Underdose Definitions

When using LAs, anesthesiologists decide to administer a specific volume (mL) rather than a particular quantity (mg). Thus, although toxicity is related to the quantity of LA used, it is clinically more relevant to determine the maximum volume (mL) of LA that should be used for a particular case.

To determine the maximum safe dose of LA for each vignette, quantities (mg) were computed using 3 different calculation methods before being converted to milliliters according to the LA's concentration. The comprehensive method utilized the full set of calculation rules incorporated in the LoAD Calc app as previously described [10], including patient-specific factors such as age, comorbidities, and drug interactions. Two simplified methods were also employed: one based on actual weight (AW) and the other on ideal body weight (IBW) using the usual formula:

XSL•FO
RenderX

Maximum dose (mg)=Weight (AW∨IBW) (kg)×Dose limit for chosen LA (mg/kg)

This multimethod approach reflects the complexity of LA dosing in clinical practice, where various calculation methods coexist. While the comprehensive, most conservative method served as the primary evaluation criterion due to its rigorous safety assessment, the simplified methods were used to reflect common clinical practices, where weight-based calculations are more commonly employed without taking other factors into account [18].

If the volume obtained by converting the maximum safe quantities of LA into milliliters was an integer, it was considered the maximum safe volume without any further change. If the result was a decimal value, it was first rounded down to the nearest integer to be consistent with the rules used to develop the LoAD Calc app. However, to avoid being too conservative, a value of 1 mL was then added, and the final value (either in milliliters or its equivalent in milligrams) was considered the maximum safe dose for the purpose of this study. Any dose higher than this value was considered an overdose. All maximum safe doses are reported in Table 1.

An underdose was defined as the maximum acceptable volume minus 20% (or its corresponding LA quantity in milligrams), rounded down to the nearest integer. This was an empirical choice since anesthetic underdose can only be determined clinically.

Table . Patient characteristics and maximum safe local anesthetic doses according to actual weight (AW), ideal body weight (IBW), and the full set of calculation rules.

Vignette (unit)	Weight (kg)	Height (cm)	Local anesthetic assessed	Mixture	Relevant characteristics	Maximum safe dose		
						Full rules	AW	IBW
1 (mg)	55.0	174	Ropivacaine	No	None	165	165	210
2 (mL)	51.5	159	Levobupivacaine	Yes	>70 years	10	14	14
3 (mg)	60.0	170	Lidocaine	Yes	Pregnancy	50	80	90
4 (mL)	70.0	170	Levobupivacaine	No	>70 years, renal failure	19	28	27
5 (mg)	120.0	180	Levobupivacaine	No	CYP1A2 inhibitor	115	240	145
6 (mL)	80.0	175	Ropivacaine	Yes	Liver cirrhosis	19	40	29
7 (mg)	60.0	175	Levobupivacaine	No	>70 years, heart failure	86.25	120	142.5
8 (mL)	75.0	170	Lidocaine	Yes	None	8	12	8
9 (mg)	90.0	160	Ropivacaine	No	>70 years	127.5	270	157.5
10 (mL)	80.0	157	Ropivacaine	No	None	30	48	30

Outcome Measures

The primary outcome was the overall overdose rate computed using the full calculation rules. The secondary outcomes were the overall overdose rate according to AW and IBW, the overdose rate according to each LA studied, the overall underdose rate, and the variability of results between participants.

The time taken to complete these calculations, the app's usability (according to the SUS), and the physicians' confidence (on a score ranging from 0 to 10) in the method they used to determine the maximum safe LA doses were also analyzed.

Statistical Analysis

Data were extracted from the encrypted MySQL-compatible database (MariaDB) into CSV files and imported into Stata 19 BE (StataCorp LLC) for data curation and statistical analysis. The primary statistical analysis was conducted by MS, who was blinded to group assignment.

Descriptive statistics were used to detail participants' characteristics. Normality was checked first graphically and then, in case of doubt, using the Shapiro-Wilk test. Values were reported accordingly.

The chi-square test was used to compare overdose and underdose rates; risk ratios with 95% CIs were also reported. The time required to complete the vignettes and participant confidence in the methods they used to determine LA doses were assessed using Student *t* test. Box plots were used to graphically display variability.

A post hoc sensitivity analysis was performed to assess the potential influence of outliers on the primary outcome. Participants with at least 1 dose value exceeding 3 SDs above their group's mean for that vignette were excluded.

Missing values were reported as such. No imputation method was used. Double-sided *P* values less than .05 were considered significant.

Results

Fifty anesthesiologists (30 residents and 20 registrars) consented to participate. The flow of participants through the trial is

XSL•FO
RenderX

presented in Figure 1. Only 14% (7/50) had already heard about the LoAD Calc app. None of them had ever installed or used the app before participating in the study. Thus, all 50 anesthesiologists were included. Their characteristics are detailed in Table 2.

Figure 1. CONSORT (Consolidated Standards of Reporting Trials) flow diagram of participant enrollment, randomization, allocation, follow-up, and analysis. LoAD Calc: Local Anesthetics Dose Calculator.

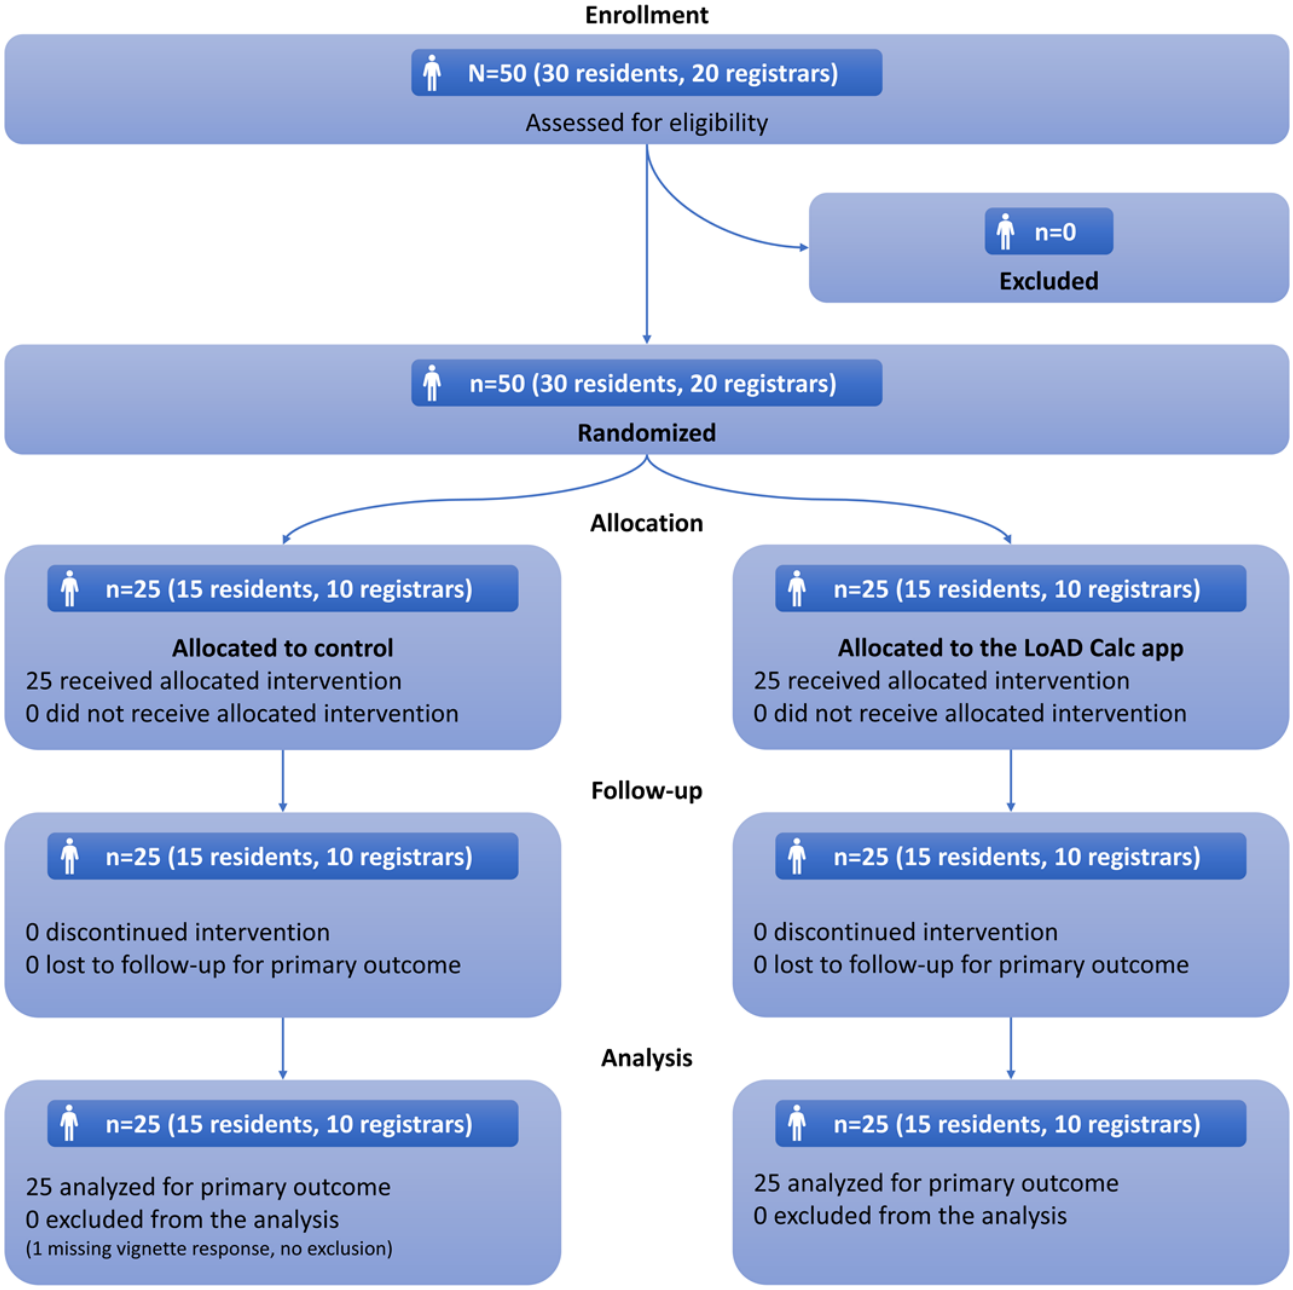

Table . Participant characteristics.

Characteristics	Overall (N=50)	Control group (n=25)	LoAD Calc[a] group (n=25)
Residents, n (%)	30 (60)	15 (60)	15 (60)
Gender (woman), n (%)	23 (46)	10 (40)	13 (52)
Age (y), median (IQR)	34 (32-37)	33 (32-35)	35 (33-38)
Years since diploma, median (IQR)	8 (6-10)	7 (6-10)	9 (6-10)
Years of anesthesiologic practice, median (IQR)	5 (2-7)	5 (3-6)	5 (2-8)

[a]LoAD Calc: Local Anesthetics Dose Calculator.

XSL•FO
RenderX

One participant, who belonged to the control group, did not answer one of the 10 clinical vignettes. All other participants answered all questions. The proportion of missing data was thus 0.2% (1/500 total responses).

When considering the full calculation rules, the overdose rate was significantly higher in the control group than in the LoAD Calc group (198/250, 79.2% vs 30/250, 12.0%; relative risk [RR] 0.15, 95% CI 0.11 - 0.21; *P*<.001). This difference was consistent for all 3 LAs (Table 3).

A post hoc sensitivity analysis, excluding participants with at least 1 dose value exceeding 3 SDs above their group's mean for that vignette (n=4 in the control group, n=6 in the LoAD Calc group), yielded consistent results for the primary outcome (control: 165/210, 78.6% vs LoAD Calc: 15/190, 7.9%; RR 0.10, 95% CI 0.06 - 0.16; *P*<.001).

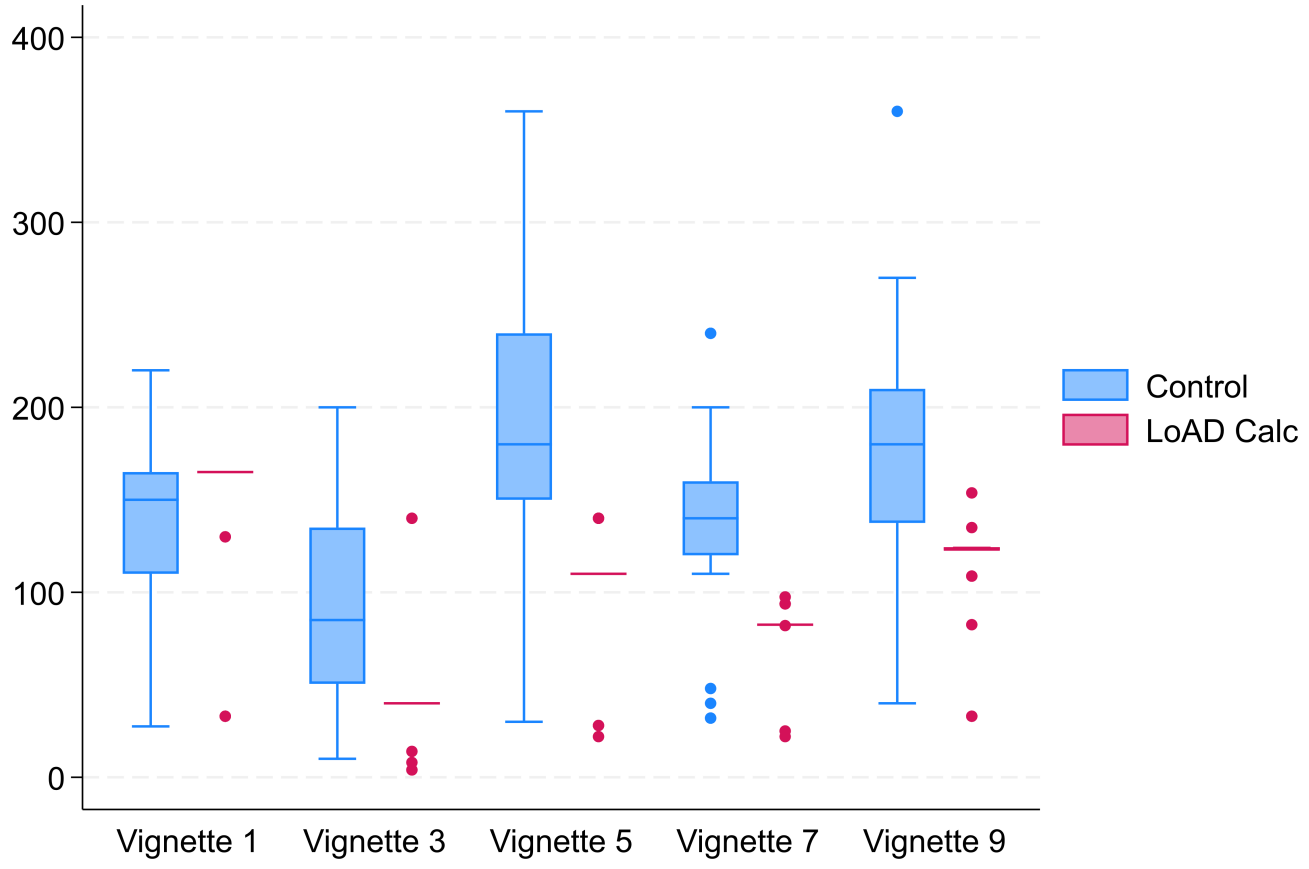
Table . Overdose rates according to the full set of calculation rules.

Local anesthetic	Control, n (%)	LoAD Calc[a], n (%)	Relative risk (95% CI)	*P* value
Ropivacaine (n=100)	64 (64)	5 (5)	0.08 (0.03 - 0.19)	<.001
Levobupivacaine (n=100)	90 (90)	19 (19)	0.21 (0.14 - 0.32)	<.001
Lidocaine (n=50)	44 (88)	6 (12)	0.14 (0.06 - 0.29)	<.001
Overall (N=250)	198 (79.2)	30 (12)	0.15 (0.11 - 0.21)	<.001

[a]LoAD Calc: Local Anesthetics Dose Calculator.

The underdose rate was similar in both groups (27/250, 10.8% in the control group vs 25/250, 10.0% in the LoAD Calc group; RR 0.93, 95% CI 0.55 - 1.55; *P*=.77).

When AW was the only parameter taken into account, the overdose rate was 38.0% (95/250) in the control group vs 3.2% (8/250) in the LoAD Calc group (RR 0.08, 95% CI 0.04 - 0.17; *P*<.001). A similar difference was observed when considering IBW, with an overdose rate of 60.4% (151/250) in the control group vs 4.0% (10/250) in the LoAD Calc group (RR 0.07, 95% CI 0.04 - 0.12; *P*<.001).



There was no difference in the mean time required to complete vignettes (mean 115, SD 89 s in the control group vs mean 111, SD 56 s in the LoAD Calc group; *P*=.53).

Participants felt significantly more confident when using the LoAD Calc app than when using other methods (mean 8.5, SD 0.9 vs mean 6.3, SD 1.7; *P*<.001).

The median SUS score (rated by the 25 participants who used the LoAD Calc app) was 98 (IQR 95-100).

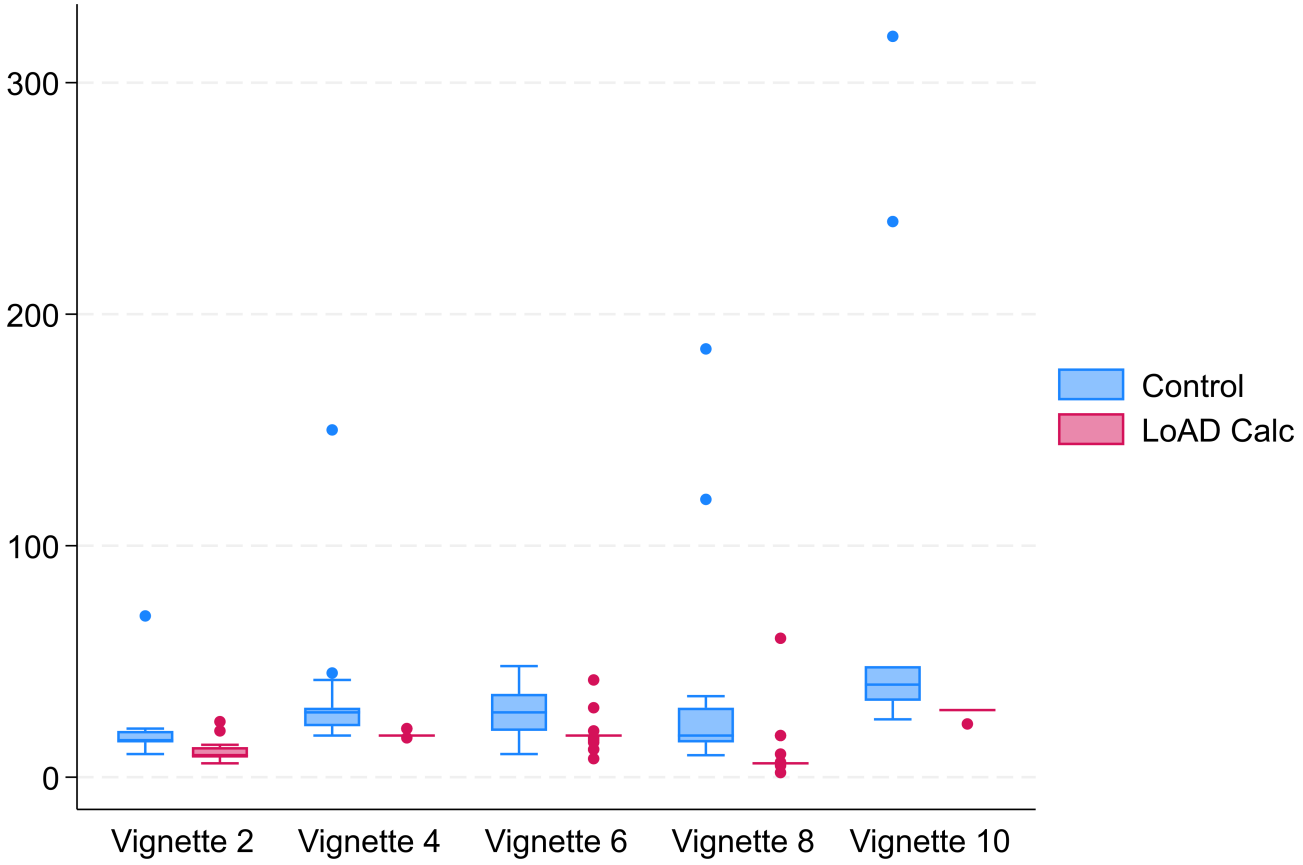


Figure 2 (quantities) and Figure 3 (volumes) show that variability was more limited when the LoAD Calc app was used.

Figure 2. Box plot of the quantities (in mg) recorded by study participants. LoAD Calc: Local Anesthetics Dose Calculator.

Discussion

Principal Results

Using the LoAD Calc app significantly reduced overdose rates compared to traditional methods. This difference was consistent across all 3 LAs studied and remained significant even when using simplified calculation methods based solely on AW or IBW. These results demonstrate that the app's benefit is not an artifact of the chosen reference standard but extends to more commonly used calculation approaches, confirming the initial hypothesis that this mHealth app supports the safer calculation of maximum LA doses in simulated scenarios without increasing the risk of underdosing.

The reduction in overdose rates observed using LoAD Calc could contribute to reducing the risk of LAST, even though potentially unsafe doses do not systematically result in toxicity [19]. By standardizing dose calculations and systematically integrating patient-specific risk factors, the app could constitute an additional safety barrier in locoregional anesthesia practice. In addition, this mHealth app could also reduce interpractitioner variability and contribute to improving the overall quality and standardization of care [20].

Several tools have been developed to assist practitioners in calculating LA doses. The Williams nomogram and the WiMP formula (weight×maximum dose/percentage concentration) [9,21], while useful, do not allow for the integration of all patient-specific variables necessary for optimal calculation. Similarly, existing mobile apps such as MDCalc's Anesthetic Dosing Calculator [22], the Podiatry Institute's LA Toxic Dose Calculator [23], and SafeLocal by Johns Hopkins Digital calculate doses based on actual body weight without adjustment [24], do not account for comorbidities or drug interactions, and have not been validated for clinical practice. Preliminary assessments of these apps suggest that most permit the calculation of doses exceeding safe limits and could potentially lead to LAST [10].

Regarding weight calculation recommendations, there is currently significant heterogeneity in the literature. Different weight calculation methods have been proposed, including IBW calculated using formulas such as Devine [9], adjusted body weight [25], or lean body weight as recommended by the 3rd ASRA Practice Advisory [6], which can be calculated using the Boer formula [26]. These variations highlight the need for clarification and standardization of recommendations. The rules integrated into LoAD Calc, although very restrictive and prioritizing safety, may require adaptation based on the evolution of international consensus to promote wider adoption.

In contrast to these existing tools, the LoAD Calc app distinguishes itself by its ability to simultaneously integrate multiple patient-specific parameters: IBW, cardiac, renal or hepatic insufficiency, pregnancy, advanced age, and potential drug interactions. Each parameter is clearly defined in the app, enabling standardized use. Moreover, unlike nomograms and other apps that do not address this complexity, LoAD Calc allows the calculation of maximum safe doses for a mixture of 2 LAs, a particularly useful functionality in clinical practice but complex to perform mentally [27].

XSL•FO
RenderX

The results also demonstrate excellent app usability, with a median SUS score of 98 (IQR 95-100), reflecting very high user satisfaction. This high usability likely stems from the iterative user-centered design approach employed during app development [28], which prioritized clinicians' needs and workflow integration. App use did not increase the time required to complete calculations, a crucial element for clinical acceptability [29]. Furthermore, participants reported significantly higher confidence in their calculations when using the app, suggesting that the tool may enhance clinicians' situational awareness and help avoid calculation errors during locoregional anesthesia procedures.

The mHealth apps have become an integral part of modern clinical practice and are already well adopted by anesthesiologists [30]. These tools enable rapid access to information, particularly at the patient's bedside, and offer valuable support for improving daily medical practice and decision-making [31]. By standardizing complex calculations and reducing cognitive load, such apps may also decrease practitioner stress [32], which could ultimately improve both the quality of care and clinician well-being.

Several perspectives for future development, research, and implementation can be envisioned. The LoAD Calc app is currently based on 3 LAs, namely lidocaine, levobupivacaine, and ropivacaine, and could be expanded to include additional agents. Future versions could also allow mixing of more than 2 LAs and incorporate repeated doses with time intervals, common scenarios in obstetric anesthesia or when combining spinal anesthesia with peripheral nerve blocks. Integration with electronic medical records could facilitate the automatic retrieval of patient data. While currently targeting anesthesiologists, the tool could benefit other specialties using LAs daily, such as surgeons, ophthalmologists, or dentists, though adaptation to their specific practices would be necessary. Real-world observational studies are necessary to evaluate the app's impact on clinical outcomes, particularly LAST incidence, as well as user satisfaction and sense of safety. Long-term evaluation should assess adoption patterns, adherence factors, and the standardization of dose calculations in practice. Multicenter studies would establish the generalizability of results across different contexts, while cost-effectiveness analysis would guide larger-scale implementation decisions. For wider adoption beyond research settings, the app would require recognition as a medical device with appropriate regulatory approval.

Limitations

Several limitations must be acknowledged. First, the trial was conducted exclusively within the Anesthesiology Department of Geneva University Hospitals over a limited period. Since all participating physicians belonged to the same institution, their responses may have been influenced by shared departmental practices or organizational culture, which may limit the generalizability of the results. Second, participants were placed in a simulated environment using clinical vignettes. Therefore, real-world clinical conditions might influence how clinicians calculate maximum LA doses differently than observed in this controlled setting. Time pressure, frequent interruptions, and the complexity of real clinical situations could modify observed performances. Third, some observed outliers with unexpectedly high values likely resulted from participants confusing milligram and milliliter units when entering their answers, despite clear instructions specifying which unit to use for each vignette. A post hoc sensitivity analysis excluding these participants confirmed that our primary conclusions were not affected by these extreme values. Another limitation lies in the choice to include only anesthesiologists, either in training or already certified, many of whom use LAs daily. The perception and use of the LoAD Calc app could differ in other medical specialties with different practices and needs regarding local anesthesia. Extending app use will therefore require understanding the specific needs of other clinical disciplines and adapting the tool accordingly.

Conclusion

This study demonstrates that LoAD Calc, an mHealth app designed to calculate maximum safe LA doses including mixtures, significantly reduces calculation-related overdose rates in simulated scenarios compared to traditional calculation methods, without increasing calculation time and with excellent usability. Clinicians also reported greater confidence when using LoAD Calc compared to traditional methods. These findings suggest that the app may support safer and more standardized LA dose calculations in clinical practice. However, as this was a vignette-based simulation study, further research in real-world clinical settings is needed to determine whether these improvements translate into enhanced patient safety and reduced risk of LAST.

Abstract

Background: Atrial fibrillation (AF) and atrial flutter (AFL) are common arrhythmias associated with the risk of ischemic stroke, which can be reduced with anticoagulation therapy. Thus, early diagnosis of AF and AFL is essential. However, diagnosis may be challenging due to the paroxysmal and asymptomatic nature of these arrhythmias.

Objective: Current diagnostic workflows involve time-consuming and resource-intensive manual review of noisy signals and prolonged recordings. We evaluated a mobile system that combines a wireless wearable single-lead chest strap electrocardiogram (ECG) and a novel deep neural network (DNN)–based artificial intelligence (AI) method for detecting AF/AFL episodes, AF/AFL burden, and rhythm change and estimated the delay in the detection of rhythm change from AF/AFL to sinus rhythm. We also assessed the rhythm classification performance.

Methods: A total of 116 patients with recent-onset AF or AFL undergoing cardioversion were monitored using a mobile single-lead chest strap ECG system. Simultaneously, a 3-lead Holter ECG served as the reference. The DNN-based AI analyzed the single-lead chest strap ECG data to detect AF/AFL, non-AF/AFLrhythm, and noninterpretable segments, as well as to estimate AF/AFL burden and detect rhythm change. Performance metrics included sensitivity, specificity, positive predictive value, negative predictive value, and intraclass correlation coefficient for AF and AFL burden estimation.

Results: The sensitivity and specificity for detecting AF/AFL were 91.9% (204.9/223.0 h) and 99.6% (242.4/243.5 h), respectively. The sensitivity for detecting AF was 96.2% (191.5/199.0 h), whereas it was 55.8% (13.4/24.0 h) for detecting AFL. The positive predictive value and negative predictive value for AF/AFL detection were 99.5% (204.9/206.0 h) and 93.1% (242.4/260.5 h), respectively. The intraclass correlation coefficient between the AF/AFL burden estimated by the DNN-based AI method and that derived from the physician-interpreted reference ECG was 0.96 (95% CI: 0.94 - 0.97; P<.001). Rhythm change detection occurred within 1 minute in most cases.

Conclusions: The mobile single-lead chest strap ECG system powered by a DNN-based AI algorithm demonstrated strong performance in detecting AF, estimating AF burden, and recognizing rhythm change to sinus rhythm. This AI-driven approach enables automated and accurate rhythm analysis, supporting clinical decision-making. Further validation in real-world ambulatory settings is warranted.

KEYWORDS

atrial fibrillation; single-lead electrocardiogram; ambulatory monitoring; automatic rhythm detection; artificial intelligence; deep neural network

Introduction

Atrial fibrillation (AF) is the most common cardiac tachyarrhythmia worldwide. It is characterized by uncoordinated electrical activation of the atria and irregular rhythm. AF is often accompanied by atrial flutter (AFL). Both AF and AFL reduce quality of life and are associated with significant morbidity and mortality [1-6]. The most severe complication related to AF is ischemic stroke. At least two-thirds of AF-related strokes can be prevented with proper anticoagulation treatment if AF is diagnosed early enough [1,6-10]. AFL is also associated with increased stroke risk, although the risk is somewhat lower than the risk related to AF [11]. Therefore, a similar risk evaluation and anticoagulation policy is recommended for AF and AFL [8]. With an aging population, the prevalence of AF and AFL is increasing, and screening for AF in patients at high risk for stroke is recommended [8,12-15]. The European Society of Cardiology guidelines recommend opportunistic screening for AF in individuals aged over 65 years [8]. The diagnosis of AF and AFL requires a high-quality electrocardiogram (ECG) recording which must be interpreted by a physician [8]. However, the diagnosis of AF and AFL is challenging, as they are often paroxysmal and frequently asymptomatic. Traditional 12-lead and ambulatory ECGs are limited by their time frame and are far from ideal prolonged everyday monitoring [8].

The diagnosis of AF and AFL in current clinical practice typically prompts the initiation of anticoagulation therapy if specific risk factors for stroke are present [8,9]. In addition to the presence of AF and AFL, AF and AFL burden contribute to the stroke risk. AF and AFL burden refers to the cumulative time spent in AF or AFL during a monitoring period. It reflects both the frequency and duration of AF episodes. This measure has been proposed as one of the metrics for guiding personalized AF and AFL management [8].

Several types of wearable sensors are available and capable of capturing ECG signals. These may be used for arrhythmia detection in paroxysmal AF and AFL. However, longer recordings generate more data, and interpretation represents a substantial workload for physicians, increasing resource use and health care costs.

Particularly, increasing the duration of recordings require the use of automatic and reliable data analytics to reduce manual effort and minimize resource waste. Various automated algorithms are available for analyzing extended ECG data, and several studies have evaluated their effectiveness in arrhythmia detection [16-22]. However, data from wearable devices, which are usually equipped with dry electrodes, often contain extensive noise and artifacts, which can negatively impact detection accuracy and further increase the workload required to analyze the recordings. The development of advanced artificial intelligence (AI) has provided new tools for automated data analysis.

In this study, we used a mobile single-lead chest strap ECG system that combines a wireless, mobile phone–connected consumer-grade ECG device with an automatic deep neural network (DNN)–based artificial intelligence (AI) method. The DNN-based method was originally developed for analyzing 3-lead ambulatory ECG recordings to detect AF and AFL.

The aim of this study was to evaluate the diagnostic performance of this DNN-based method when applied to wearable single-lead ECG data, including its ability to detect AF/AFL episodes; estimate AF/AFL burden; identify rhythm changes and associated detection delays; and classify recordings into the AF/AFL, non-AF/AFL, and noninterpretable categories.

Methods

Study Population and Participation Criteria

This study is part of a larger research project Wearables and Biomarkers in Detecting Atrial Fibrillation (WB-AF). It is registered in the ClinicalTrials database (NCT04917653).

Data collection was conducted at the emergency care department of Kuopio University Hospital. A total of 291 volunteer patients were screened between June 2022 and July 2023. The inclusion criteria were recent-onset (<48 h) AF or AFL confirmed by a 12-lead ECG, age ≥18 years, and being scheduled for cardioversion during the index treatment period at the emergency department. The type of cardioversion included but was not limited to electrical synchronized defibrillation, antiarrhythmic medication, and spontaneous rhythm change. Successful rhythm change was not a requirement for inclusion.

The exclusion criteria were BMI ≥35 kg/m^2, a cardiac pacemaker, or a medical condition requiring immediate treatment. Patients with BMI ≥35 kg/m² were excluded for practical reasons related to device fit and stability, as the chest strap ECG sensor may not reliably fit or remain in place in individuals with severe obesity. This exclusion was applied to ensure proper functioning of the recording setup.

Initially, 127 patients were recruited in the study. Eleven patients were excluded due to technical issues related to data acquisition. In 9 cases, data were missing because of a bug or instability in the measurement application. In 2 cases, problems related to device use led to complete corruption of the recorded data. The final study population comprised 116 patients with AF or AFL. Of these, 109 patients successfully resumed sinus rhythm (SR) and had both AF/AFL and SR data available, while 7 patients had only AF/AFL data due to unsuccessful cardioversion.

Clinical data were extracted from medical records and patient interviews. Symptoms reported during ECG recordings were documented using a structured questionnaire designed for this study. The CHA_2DS_2-VA score (congestive heart failure, hypertension, age ≥75 years, diabetes, prior stroke or transient ischemic attack, vascular disease, age 65-74 years) was used to estimate the risk of stroke. This scoring system is in line with

XSL•FO
RenderX

clinical guidelines and accounts for several risk factors. In this system, 2 points each are assigned for age ≥75 years and a history of stroke or transient ischemic attack, and 1 point each is assigned for age between 65 and 74 years, congestive heart failure, hypertension, diabetes mellitus, and vascular disease. In accordance with clinical guidelines, a score of ≥2 indicates an elevated stroke risk and most likely indicates the need for anticoagulant therapy [8].

Mobile Single-Lead Chest Strap ECG System and Automated DNN-Based AI Method for Rhythm Detection

Our mobile single-lead chest strap ECG system consisted of 3 main components: a wearable single-lead chest strap ECG sensor, a dedicated mobile phone application for data collection, and a DNN-based AI method for analytics. The ECG sensor, along with an elastic chest-worn belt designed for consumer use (Movesense Medical, Movesense Ltd.), recorded single-lead ECG signals at a sampling rate of 256 Hz. Data were transmitted wirelessly via Bluetooth to a mobile phone, which ran an in-house–developed mobile application responsible for data collection. The data were then forwarded to a DNN-based AI method operating on a dedicated computing platform.

In this study, we used a DNN model based on a residual network architecture developed in our research group. A similar residual network has been successfully applied to ECG arrhythmia classification tasks in earlier work, including the study by Hannun et al [23].

The DNN-based AI method was trained using ECG data from a total of 15,816 recordings obtained from 15,242 patients across 7 heterogeneous datasets collected using different clinical devices. Of these, 10,248 recordings originated from publicly available annotated AF/AFL datasets, and 5568 recordings were derived from locally collected clinical datasets from Kuopio University Hospital and from our previous studies. The training data consisted of multilead ECG recordings, including standard 12-lead ECGs and ambulatory ECG recordings with durations ranging from 30 minutes to 24 hours (Holter-type recordings), reflecting typical real-world clinical conditions. Recordings were acquired using different ECG systems with sampling rates ranging from 125 to 500 Hz and most commonly included leads I, II, and V3, although lead configurations varied slightly between datasets. Across the training dataset, 3180 patients had AF or AFL, while the remaining recordings represented non-AF/AFL rhythms. The training dataset did not include any single-lead ECG recordings.

The model processes raw ECG input in 10-second segments, each consisting of 3 input channels sampled at 125 Hz. In the original model architecture, these channels correspond to 3 distinct ECG leads. Because the chest strap device used in this study provides only a single-lead ECG signal, the same waveform was replicated across all 3 input channels when applying the model to chest strap recordings. This design choice was made to preserve compatibility with the original, previously validated 3-channel network architecture without modifying the model structure or retraining the network.

No additional patient-related information was required, enabling fully automated analysis based solely on the ECG waveform. Each 10-second segment was classified into 1 of 3 categories: AF/AFL; non-AF/AFL, including SR; or noninterpretable due to poor signal quality.

The model produces an independent rhythm classification for each 10-second segment. To improve clinical relevance and reduce short detections, the model output was subsequently postprocessed to account for temporal continuity of rhythms. Specifically, consecutive 10-second segments classified as AF/AFL were combined into continuous episodes. AF/AFL detections shorter than 30 seconds (fewer than 3 consecutive AF/AFL-positive 10-second segments) were excluded to align with commonly used guideline-based definitions that require at least 30 seconds of continuous single-lead ECG for AF diagnosis [8]. Closely spaced AF/AFL segments separated by short gaps were merged into unified episodes. Performance metrics were calculated on the basis of the total duration of correctly and incorrectly classified 10-second segments and are reported as hours correctly classified divided by total hours (h/h). AF burden was defined as the total duration of AF/AFL during the ECG recording period.

Reference for Rhythm Detection and Quality Analysis

Written informed consent was obtained from all patients after eligibility was confirmed in the emergency department. Immediately after consent was obtained, patients were equipped with both the mobile single-lead chest strap ECG device and a 3-lead ambulatory Holter ECG device, and continuous ECG monitoring was initiated.

ECG monitoring continued throughout the treatment period, including during cardioversion and subsequent observation, and the devices were removed prior to hospital discharge. All analyses of algorithm performance were performed retrospectively after data collection was complete.

The concurrently recorded 3-lead Holter ECG was used as the reference standard. Reference ECG data were recorded at a sampling frequency of 250 Hz using an ambulatory Holter device (Faros 360, Bittium), capturing leads I, II, and V3. Synchronization between the single-lead and 3-lead recordings was initially based on timestamps and was manually verified by aligning the recordings to the documented time of cardioversion.

All reference ECG recordings were manually interpreted by an experienced physician trained in ECG interpretation. The physician annotated rhythm categories (AF, AFL, and SR) and the timing of cardioversion. The same physician also visually assessed the single-lead chest strap ECG recordings for signal quality. Periods of at least 10 seconds considered noninterpretable due to poor signal quality were labeled as noninterpretable, whereas shorter noisy periods were assumed to represent the same rhythm as that observed immediately before and after the segment. These physician-labeled annotations served as the reference for evaluating the performance of the DNN-based method in detecting noninterpretable segments.

RenderX

Statistical Methods

Rhythm detection performance was evaluated using both time-based and episode-based (patient-level) approaches.

In the time-based analysis, the mobile single-lead chest strap ECG data were analyzed as consecutive 10-second intervals. Each interval classified by the DNN-based AI method was compared with the corresponding reference rhythm derived from the 3-lead Holter ECG. A classification was considered correct if the rhythm category (AF/AFL, non-AF/AFL, or noninterpretable) matched the reference for the same time interval.

In the episode-based analysis, ECG recordings were evaluated at the patient level to assess whether AF or AFL was detected during reference-confirmed AF/AFL episodes. A patient was considered correctly identified as AF/AFL-positive if the DNN-based method detected at least 1 AF/AFL segment within a reference-confirmed AF/AFL episode. Performance was assessed against the reference using sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV), and Youden index. For episode-based AF/AFL detection, the Youden index was calculated to summarize the overall balance between sensitivity and specificity. Sensitivity was also calculated separately for AF and AFL.

Performance metrics included sensitivity, specificity, PPV, NPV, F_1-score, and Cohen kappa. For proportion-based metrics (sensitivity, specificity, PPV, and NPV), 95% CIs were calculated using Wilson score intervals. For F_1-scores, 95% CIs were estimated using nonparametric bootstrap resampling (2000 iterations). Cohen kappa was used to assess the agreement between rhythm categories (AF/AFL, non-AF/AFL, or noninterpretable) assigned by the DNN-based AI method and the reference.

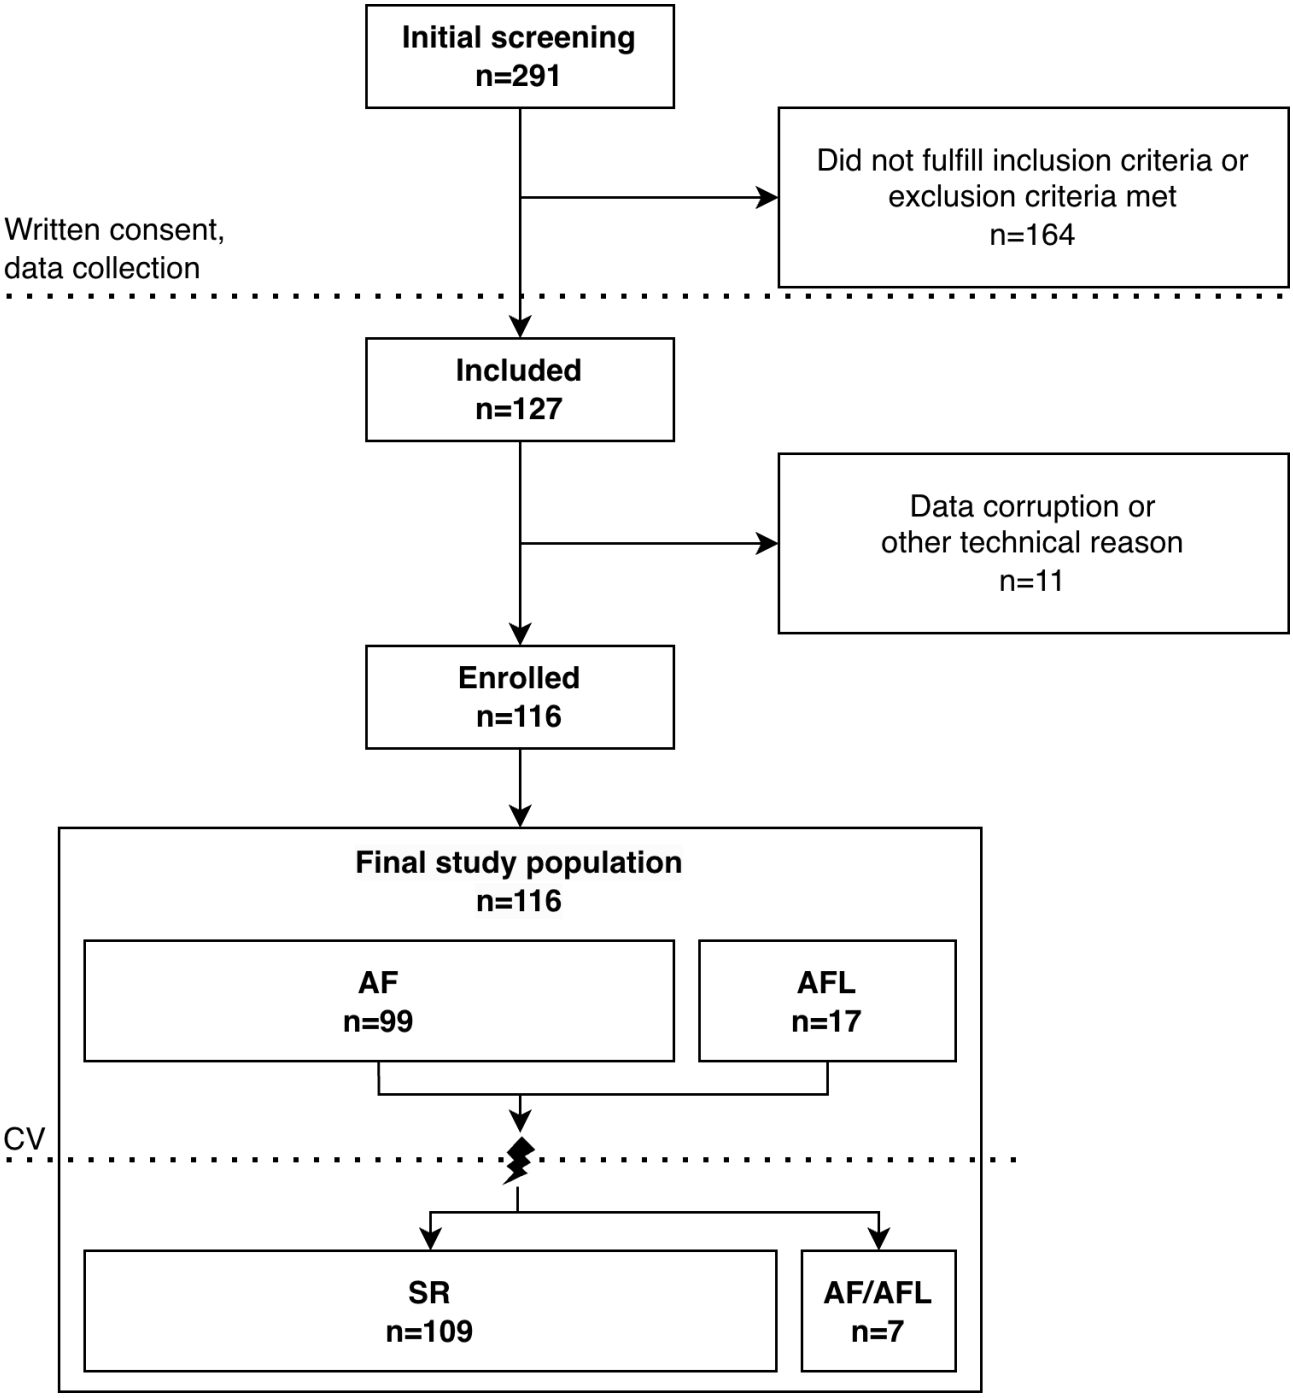
The AF/AFL burden estimated by the DNN-based method was compared with the reference AF/AFL burden derived from the 3-lead ECG using Bland-Altman analysis, reporting the mean difference (bias) and 95% limits of agreement (mean difference ± 1.96 SD). Agreement was further assessed using the intraclass correlation coefficient (ICC) based on a 2-way mixed-effects model with absolute agreement and single measurements (ICC model 3.1). Bland-Altman and scatter plots were used for visualization [24].

Delay in rhythm change detection was defined as the time difference between the first SR segment identified in the reference 3-lead ECG after conversion from AF/AFL and the time point at which the DNN-based method first classified the rhythm as SR in the single-lead ECG after postprocessing. Delays were calculated for each AF/AFL-to-SR transition event and summarized descriptively. A 2-sided significance level of $P<.05$ was used.

Ethical Considerations

This study received approval from the Ethics Committee of the Northern Savo Hospital District (Approval number: 2061/2020). Prior to enrollment, all participants were provided with detailed written information about the study procedures, and written informed consent was obtained from each participant. Participation was voluntary, and participants had the right to withdraw from the study at any time. This study complied with the ethical principles set forth in the Declaration of Helsinki for research involving human participants.

All data were anonymized prior to analysis, and no identifiable personal information was included in the dataset. Data were handled and stored in accordance with applicable data protection regulations. Participants did not receive any financial compensation for participation in this study.



Results

Study Population

The final study population comprised data collected from 116 patients diagnosed with AF (n=99) or AFL (n=17) who were scheduled for SR restoration. The data collection flowchart is presented in Figure 1. SR was achieved in 109 patients. The mean age was 65.1 (SD 11.4) years (range 24-90 years), the mean BMI 27.5 (SD 4.2) kg/m² (range 18.8-34.9 kg/m²), and 60.3% (70/116) of the patients were male (Table 1). Hypertension was the most prevalent comorbidity present in 51.7% (60/116) patients, 90.5% (105/116) had a prior history of AF or AFL, and 9.5% (11/116) presented with first-diagnosed AF/AFL. The most frequently reported symptoms prior to hospital admission were palpitations (88.8%, 103/116), fatigue (50%, 58/116), and decline of general condition (44.8%, 52/116). The CHA_2DS_2-VA score was 0, 1, and ≥2 for 27 (23.3%), 32 (27.6%), and 57 (49.1%) of the 116 patients, respectively.

points), and age >75 years (2 points).

ECG Data Characteristics, Quality, and Rhythm Classification

A total of 466.3 hours of concurrent single-lead chest strap ECG and reference 3-lead ECG data were collected, which included 223.0 hours (47.8%) of AF/AFL, consisting of 199.0 hours (42.7%) of AF and 24.0 hours (5.1%) of AFL as defined by the reference. Additionally, 219.0 hours (46.9%) of data represented SR based on the reference ECG. The physician identified 24.5 hours (5.3%) of single-lead chest strap ECG data as noninterpretable (Table 2).

Table . Confusion matrix for rhythm classification by the deep neural network (DNN)–based artificial intelligence method compared with the reference 3-lead Holter electrocardiogram[a].

DNN prediction	AF[b] (Holter)[c]	AFL[d] (Holter)	Non-AF/AFL (Holter)	Noninterpretable (physician)
AF/AFL	191.5 (41.1)	13.4 (2.9)	0.06 (0.0)	1.0 (0.2)
Non-AF/AFL	2.6 (0.6)	10.2 (2.2)	214.1 (45.9)	1.9 (0.4)
Noninterpretable	4.9 (1)	0.4 (0.1)	4.8 (1)	21.6 (4.6)

[a]Values are reported as number of hours (%) of total recording time (ie, 466.3 h).

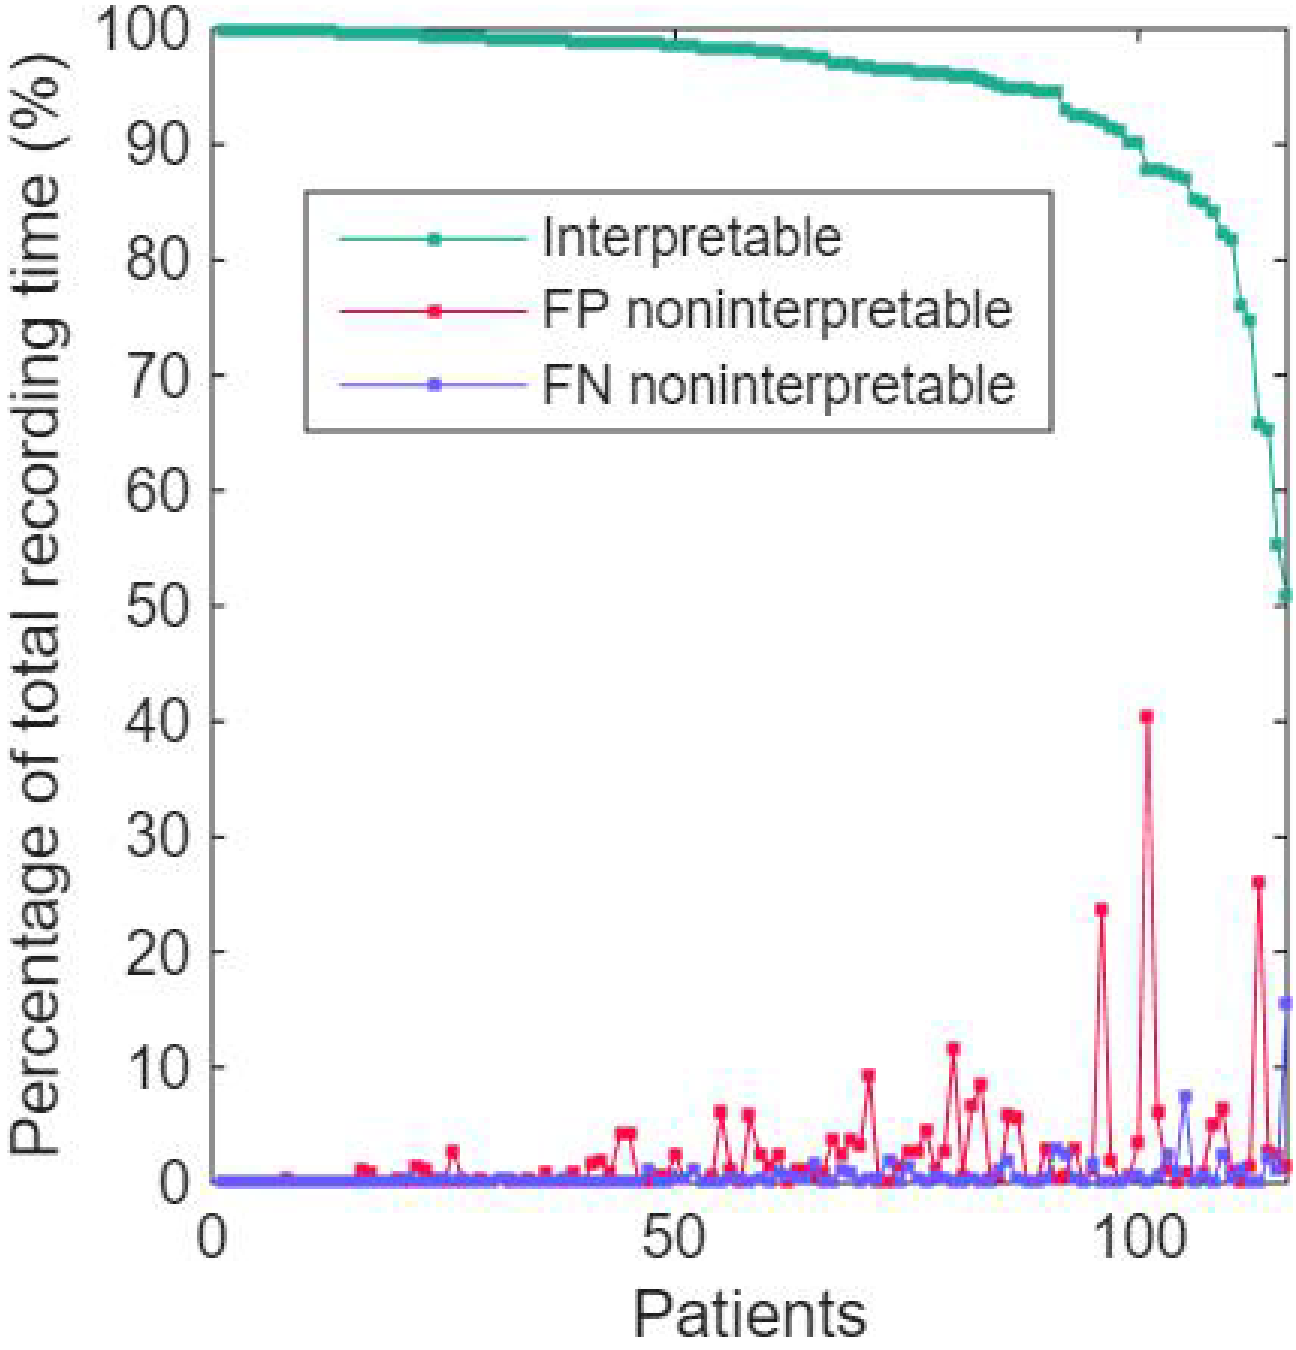
[b]AF: atrial fibrillation.

[c]Holter: Holter monitor.

[d]AFL: atrial flutter.

The time-based performance of the DNN-based AI method in detecting AF/AFL, non-AF/AFL, and noninterpretable episodes is presented in the confusion matrix (Table 2), providing an overview of the classification results. The DNN-based AI method correctly classified 204.9 of 466.3 hours (43.9%) as AF/AFL. Misclassification into this category was minimal, comprising 0.06 of 466.3 hours (0%) of non-AF/AFL rhythm and 1.0 of 466.3 hours (0.2%) of noninterpretable data (Table 2). For SR, the DNN-based AI method correctly identified 214.1 of 466.3 hours (45.9%) as non-AF/AFL but misclassified 12.8 of 466.3 hours (2.7%) of actual AF/AFL and 1.9 of 466.3 hours (0.4%) of actual noninterpretable data into this category.

Additionally, the DNN-based AI method classified 31.7 of 466.3 hours (6.8%) of the data as noninterpretable, whereas the physician classified 24.5 of 466.3 hours (5.3%) as noninterpretable on the basis of visual assessment of the single-lead ECG (Table 2). Of the algorithm-labeled noninterpretable data, 21.6 of 466.3 hours (4.6%) were also considered noninterpretable by the physician.



The difference was due to different signal quality thresholds and handling of short noisy segments between the algorithm and the physician. The physician labeled noisy periods of at least 10 seconds as noninterpretable, whereas shorter noisy segments were assumed to represent the surrounding rhythm. The DNN-based method evaluated each 10-second segment independently and could classify individual segments as noninterpretable even when adjacent segments were interpretable.

The DNN-based method assigned a rhythm label of AF/AFL and non-AF/AFL to 1.0 (0.2%) and 1.9 (0.4%) of 466.3 hours, respectively, which the physician considered noninterpretable due to poor signal quality. Conversely, the algorithm classified 4.9 hours (1.1%) during AF, 4.8 hours (1%) during SR, and 0.4 hours (0.1%) during AFL as noninterpretable despite the reference rhythm being known from the Holter ECG (Table 2). Importantly, this difference did not meaningfully affect the AF/AFL burden estimation, as reflected by the high agreement between methods (ICC 0.96).

For most participants, the proportion of single-lead chest strap ECG data considered interpretable on the basis of physician review exceeded 95% of the total recording time, and false-positive and false-negative noninterpretable classifications were generally low (Figure 2). In 3 patients, more than 20% of the recorded data were falsely classified as noninterpretable by the DNN-based AI method. In these patients, the total recording duration ranged from 1.0 to 5.0 hours, of which 0.4 to 2.2 hours were falsely classified as noninterpretable.

XSL•FO
RenderX

Figure 2. Proportion of interpretable single-lead electrocardiogram (ECG) data and classification errors per patient. Each data point represents 1 patient (N=116). Patients are ordered from left to right according to decreasing proportion of ECG data considered interpretable on the basis of physician review of the single-lead chest strap recordings. The y-axis shows the percentage of total recording time per patient. The green curve represents the proportion of data considered interpretable according to physician review. Red points indicate false-positive noninterpretable classifications (segments classified as noninterpretable by the DNN but considered interpretable by physician review), and blue points indicate false-negative noninterpretable classifications (segments classified as interpretable by the DNN but considered noninterpretable by physician review). FP, false positive; FN, false negative.

Performance of the DNN-Based AI Method for Time-Based Rhythm Detection

The performance of the DNN-based AI method in detecting rhythm categories showed an overall accuracy of 94.4% (440.3/466.3 h). Cohen kappa was 0.90, indicating excellent agreement between the DNN-based AI method and the reference.

For AF/AFL detection, the DNN-based AI method achieved a time-based sensitivity of 91.9% (204.9/223.0 h) and a specificity of 99.6% (242.4/243.5 h), with a PPV of 99.5% (204.9/206.0 h) and an NPV of 93.1% (242.4/260.5 h), yielding an F_1-score of 0.96 (Table 3). More specifically, the DNN-based AI method achieved a time-based detection sensitivity of 96.2% (191.5/199.0 h) for AF and 55.8% (13.4/24.0 h) for AFL, indicating stronger performance in identifying AF than AFL. For SR detection, the DNN-based AI method achieved a sensitivity of 97.8% (214.1/219.0 h) and a specificity of 94.1% (232.8/247.5 h), with a PPV of 93.6% (214.1/228.8 h) and an NPV of 97.9% (232.8/237.7 h), yielding an F_1-score of 0.96 (Table 3).

XSL•FO
RenderX

The performance of the mobile single-lead chest strap ECG system compared with the physician's interpretation for detecting noninterpretable cases was lower, with a time-based sensitivity of 88.2% (21.6/24.5 h) and a specificity of 97.7% (431.9/442.0 h; Table 3). This category had a PPV of 68.1% (21.6/31.7 h) and an NPV of 99.3% (431.9/434.8 h), yielding an F_1-score of 0.77. These results highlight the challenges in detecting and categorizing ambiguous or unclear cases. Detection results for the noninterpretable data category of the DNN-based AI method are presented in Figure 2.

Table . Performance metrics of the deep neural network (DNN)–based artificial intelligence method for rhythm detection from single-lead chest strap electrocardiogram data.

Metric[a]	AF[b]/AFL[c]	Non-AF/AFL	Noninterpretable
Sensitivity	204.9/223.0 (91.9, 95% CI[d] 91.6 - 92.2)	214.1/219.0 (97.8 95% CI 97.6 - 97.9)	21.6/24.5 (88.2, 95% CI 87.2 - 88.8)
Sensitivity for AF[e]	191.5/199.0 (96.2, 95% CI 96 - 96.5)	—[f]	—
Sensitivity for AFL[e]	13.4/24.0 (55.8, 95% CI 54 - 57.6)	—	—
Specificity	242.4/243.5 (99.6, 95% CI 99.5 - 99.6)	232.8/247.5 (94.1, 95% CI 93.9 - 94.4)	431.9/442.0 (97.7, 95% CI 97.6 - 97.8)
PPV[g]	204.9/206.0 (99.5, 95% CI 99.4 - 99.5)	214.1/228.8 (93.6, 95% CI 93.3 - 93.9)	21.6/31.7 (68.1, 95% CI 66.6 - 69.6)
NPV[h]	242.4/260.5 (93.1, 95% CI 92.8 - 93.3)	232.8/237.7 (97.9, 95% CI 97.7 - 98.1)	431.9/434.8 (99.3, 95% CI 99.3 - 99.4)
F_1-score[i]	0.96 (95% CI 0.95 - 0.96)	0.96 (95% CI 0.95 - 0.96)	0.77 (95% CI 0.76 - 0.78)
Proportion of data	222.9/466.3 (47.8)	219.0/466.3 (46.9)	24.5/466.3 (5.3)

[a]Performance metrics are based on 10-second segments and reported as correctly classified hours divided by total hours (%).

Performance of the DNN-Based AI Method for Detection of AF/AFL Episodes, Rhythm Change, and AF/AFL Burden

For episode detection, the sensitivity and specificity of AF/AFL detection were 97.4% (113/116) and 98.2% (107/109), respectively, with a PPV of 98.3% (113/115) and an NPV of 97.3% (107/110). When calculated solely for AF cases (excluding AFL), the sensitivity was 100% (100/100) for AF episode detection and 81% (13/16) for AFL episode detection (Table 4). The Youden index for AF/AFL detection was 0.96. The delay in rhythm change detection after rhythm change was less than 1 minute in most cases (Figure 3).

[e]ICC: intraclass correlation coefficient.

XSL•FO
RenderX

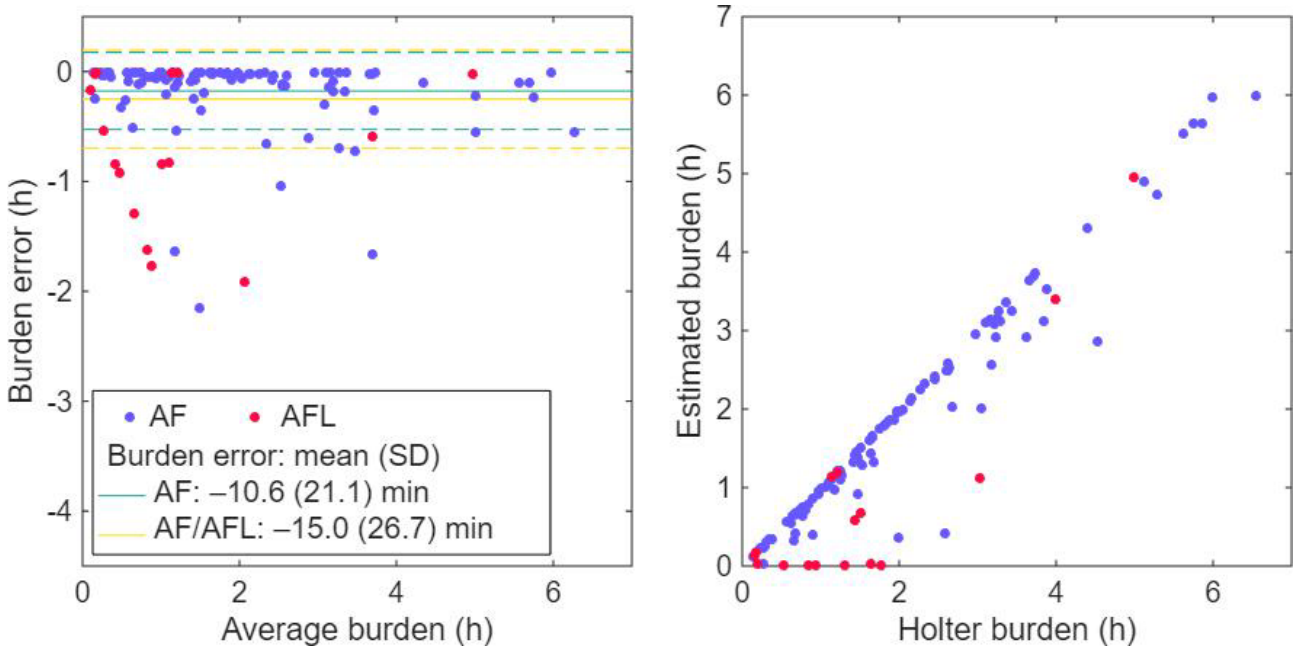

Figure 3. Distribution of delay in rhythm change recognition from AF/AFL to sinus rhythm following cardioversion or spontaneous rhythm change. AF, atrial fibrillation; AFL, atrial flutter.

The mean AF/AFL burden estimated by the mobile single-lead chest strap ECG system was 1.8 (SD 1.5) hours, whereas the corresponding burden derived from the reference ECG was 2.0 (SD 1.5) hours (Table 4). The mean difference in AF/AFL burden was −15.0 (SD 26.7) minutes, and for AF alone, it was −10.6 (SD 21.1) minutes. The Bland-Altman analysis demonstrated a mean bias of −0.25 hours for AF/AFL burden estimation, with 95% limits of agreement ranging from −1.12 to 0.62 hours. The Bland-Altman plot and scatter plot comparing the AF/AFL burden estimates between the DNN-based method and the reference are shown in Figure 4. Agreement between the methods was high, with an ICC of 0.96 (95% CI 0.94 - 0.97; P<.001) (Table 4). Visual inspection of the Bland-Altman plot did not suggest the presence of proportional bias across the range of AF/AFL burden values.

RenderX

Figure 4. Bland-Altman plot and scatter plot of atrial fibrillation (AF) and atrial flutter (AFL) burden estimated from single-lead chest strap electrocardiogram (ECG) using a deep neural network–based artificial intelligence method compared with the reference 3-lead Holter ECG. The left panel shows the Bland-Altman plot, and the right panel shows the correlation between the estimated and reference AF/AFL burden.

Discussion

Principal Findings

The main finding of this study was that the DNN-based AI method applied to data obtained from a mobile chest strap ECG system demonstrated high diagnostic accuracy for detecting AF episodes, identifying rhythm changes from AF to SR, and estimating AF burden, with adequate sensitivity and specificity and strong agreement with the reference method. The mobile single-lead chest strap ECG system detected AF episodes more accurately than AFL episodes.

Our findings demonstrate high performance in the use of wearable devices and AI algorithms for AF detection, comparable to or exceeding results reported in previous studies [16-21,25-31]. For instance, the BASEL Wearable Study demonstrated that various consumer-grade smart devices achieved reasonable sensitivity (up to 85%) and specificity (up to 75%) for AF detection, although the rate of inconclusive recordings by the automated detection method was relatively high (ranging from 17% to 26%, depending on the device). However, manual review indicated that a majority of the tracings were interpretable [25]. Similarly, Pan et al [32] showed that using longer, 7-day recordings, smartwatch-based single-lead ECG can detect AF episodes with a duration of >5 minutes with a sensitivity of 89.7% and specificity of 67.4%. Moreover, the systematic review and meta-analysis by Manetas-Stavrakakis et al [31], which evaluated the diagnostic accuracy of AI-based technologies for AF detection, reported pooled sensitivity and specificity values of 92.3% and 96.2% for single-lead ECG, respectively.

Recent clinical studies further support the feasibility of artificial intelligence–based atrial fibrillation detection using single-lead ECG. De Guio et al [33] demonstrated enhanced detection of AF using a cloud-based AI platform applied to single-lead ECG recordings, highlighting the clinical applicability of AI-assisted rhythm analysis in simplified ECG configurations. Zhao et al [34] also developed a temporal convolutional network model for AF detection using single-lead ECG and reported high diagnostic accuracy, supporting the applicability of advanced neural network architectures to wearable ECG data.

In comparison, our study demonstrated even higher sensitivity (96.2%) for AF detection and comparable sensitivity (91.9%) and specificity (99.5%) for AF/AFL detection using the mobile single-lead chest strap ECG system, further encouraging the potential of consumer-grade devices in clinical settings in providing more information for diagnostics about AF estimation and the burden of AF.

The DNN-based AI method was trained using ECG data from a diverse patient population worldwide, incorporating various device types and lead configurations, including 3- and 4-lead Holter monitors and 12-lead ECG recordings. The model was evaluated using a single-lead ECG configuration that was not represented in the training data, as the chest strap lead does not correspond directly to any of the training leads. This setup allowed assessment of whether the model had learned features that generalize beyond specific lead configurations. The observed performance suggests that the model captures AF/AFL-related features that are transferable across different electrode placements, which may support its applicability across heterogeneous wearable ECG devices.

However, AFL detection was less reliable than AF detection, as reflected by the substantially lower sensitivity for AFL. This finding is clinically relevant and likely reflects the inherent limitations of single-lead ECG morphology in recognizing atrial flutter. Unlike AF, which is characterized by highly irregular RR intervals, AFL often presents with more regular ventricular response and subtle atrial activity patterns that can be difficult to distinguish from SR when only a single lead is available. In

XSL•FO
RenderX

addition, the DNN-based model used in this study was primarily trained on 3-lead ECG data, which provide richer spatial information on atrial activity. The transition from a 3-lead training environment to a single-lead wearable setting may therefore limit the ability to identify characteristic flutter wave morphology.

Furthermore, single-lead wearable ECG recordings are more susceptible to motion artifacts and noise, which may affect the detection of AFL compared to AF and contribute to a higher proportion of noninterpretable segments. Similar challenges have been reported in previous studies, where AI models trained on multilead ECG data demonstrated reduced performance when applied to single-lead recordings, particularly for arrhythmias with overlapping waveform characteristics [35,36]. From a clinical perspective, these findings suggest that while the system performs robustly for AF detection and AF burden estimation, caution is warranted when interpreting potential AFL cases. In situations where AFL is suspected or diagnostic uncertainty remains, confirmation using higher-quality or multilead ECG recordings may be necessary. These results also highlight the need for further development of AI models specifically optimized for single-lead ECG data to improve AFL detection in wearable monitoring settings.

The high sensitivity and specificity for AF detection suggest that the DNN-based AI method is robust and reliable for identifying AF episodes when data quality is sufficient. Accurate detection of rhythm changes between SR and AF is essential for identifying paroxysmal AF. In AF screening, the primary aim is to detect AF episodes and rhythm changes from SR to AF. Additionally, for assessing AF burden, it is important to detect both AF episodes and rhythm changes in both directions, from SR to AF and from AF to SR. In this study, only rhythm changes from AF to SR were detected due to the study protocol. However, given the high time-based detection performance with an accuracy of 94.4%, we assume that the DNN-based AI method is also capable of detecting rhythm changes from SR to AF.

AF burden is recognized in current clinical guidelines as an important predictor of stroke risk and a relevant factor in clinical decision-making [8]. Therefore, estimating AF burden from single-lead ECG data is particularly valuable for the continuous monitoring and management of AF and may serve as a complementary tool in clinical evaluation. Pan et al [32] showed sufficient correlation regarding AF burden between single-lead ECG and reference Holter ECG with an ICC of 0.927 over a 7-day monitoring period. Moreover, Hennings et al [37] demonstrated a high correlation (Pearson correlation coefficient 0.998) between an AI-based tool used to detect AF burden and manual assessment of AF burden in 7-day Holter ECG recording, with minimal negative bias of AF burden. Similarly, in our study, the ICC was 0.96, with a low rhythm change recognition time and low negative bias. In most cases, rhythm changes were detected immediately or at least within 1 minute after cardioversion. The high level of agreement between the AF burden measurements obtained using the mobile single-lead chest strap ECG system and the reference Holter ECG reinforces the validity of this approach for single-lead ECG usage. Notably, we used a dry-electrode ECG instead of a Holter monitor. This method is particularly suitable for long-term monitoring and is more comfortable than Holter monitors with potentially irritating wet electrodes. Moreover, the use of ECG allows for the diagnosis of AF according to current clinical guidelines [8].

Study Limitations

Despite the promising results, there are some limitations to consider. The study population was limited to patients with recent-onset AF or AFL who presented to the emergency department, which does not represent the broader population with paroxysmal or persistent AF/AFL with fluctuating rhythm. Patients were permitted to move freely during the study recordings. However, while hospitalized, they were primarily lying in the supine position, which affects the conclusions regarding the use of the devices in real-world settings. Additionally, studies involving a more diverse patient population and longer monitoring periods in real-world ambulatory settings are needed to validate the generalizability and long-term performance of this approach.

Conclusions

The high sensitivity and specificity for AF detection and strong correlation for AF burden suggest that the mobile chest strap ECG system, in which a DNN-based AI method is used with single-lead chest strap ECG, is promising for identifying AF episodes, rhythm change, and AF burden. A majority of the data was analyzable, and no complaints or discomfort regarding the wearables or study devices were reported.

Our study indicates the potential of consumer-grade single-lead ECG devices combined with an advanced detection algorithm for the detection and monitoring of AF/AFL, independent of the specific ECG device. This approach offers promising complementary tools for the continuous monitoring, diagnosis, and personalized management of AF and AFL.

Abstract

Background: Dementia has an impact on the physical activities performed daily in a social context. Sleeping and resting, in general, are also affected by dementia. Monitoring techniques based on miniaturized wearable sensors and on sensorized environments allow for actigraphic recordings and location tracking. The availability of contemporaneous physical activities profile led to quantify, in the social actigraphy approach, the level of correlation between individuals living in the same environment.

Objective: This study has two main objectives: (1) to define a methodology for actigraphic recordings, based on wearable accelerometers, and on location tracking, based on Bluetooth wearable technology, and to apply it in a well-defined social context, a long-term care residential unit for people with dementia; and (2) to quantify test-retest reliability of the indices obtained by the monitoring methodology.

Methods: Persons with dementia living in the long-term care unit have been equipped with miniaturized wearable sensors, an accelerometer at their dominant wrist, and a Bluetooth beacon at their ankle for 7 days. The raw recordings allowed for computing indices related to physical activity intensities, to the occurrence of walking bouts, to the efficiency of sleep and waking phases, to social interactions between individuals, and to locations preferably occupied. The 7-day session was repeated at short (3 weeks) and long (3 months) terms in order to quantify the test-retest reliability of the indices.

Results: Twenty-five persons with dementia were enrolled, 4 of them dropped out, and valid data were obtained, in the different sessions, from 19 to 21 individuals of the recruited group. Control data from 10 age-matched healthy participants were derived from published datasets. As a group, compared with age-matched healthy participants, persons with dementia showed a comparable duration of phases of no activity and of light activity (energy cost lower than 3 metabolic equivalents of tasks [METs]), a relevantly lower duration (−84.3%) of phases of moderate activity (energy cost ranging from 3 to 6 METs), and substantial absence (−100%) of phases of vigorous activity (larger than 6 METs); moreover, daytime and nighttime were characterized by comparable wake and sleep, respectively, efficiency; finally, as to the social interactions, persons with dementia showed a lower correlation of their motor activity profiles (−53.1%). The test-retest reliability was excellent for physical activity indices (intraclass correlation coefficients ranging from 0.76 to 0.98), good for social indices (0.65 - 0.67), excellent for sleep or wake efficiency (0.74 - 0.89), and fair for location tracking indices (0.37 - 0.78).

Conclusions: The considered methodology, particularly concerning accelerometry, proved to be feasible, informative, and with a good to excellent test-retest reliability. Interestingly, the methodology clearly identified behaviors, such as wandering, in a minority of individuals inside this study's group of persons with dementia, thus supporting a possible clinical use of the methodology.

Introduction

The number of people with dementia is estimated to increase from 57.4 million cases worldwide in 2019 to 152.8 million cases in 2050, with the female-to-male ratio of 1.69 in 2019 being substantially stable and the projected increases in cases largely attributed to population growth and population aging [1].

One of the most relevant aspects in the management of individuals with dementia, even in mild-to-moderate stages, is related to movement [2]. The transition from a life without illness to a life dealing with alterations in spatial-temporal orientation or critical judgment and perception of dangers requires a delicate balance between the freedom the person still demands (moving around the house, walking, or going out) and the dangers they are exposed to, such as the risk of falls, disorientation, and domestic and road accidents. For these reasons, both in domestic and residential settings, there is a significant use of physical or pharmacological restraint, which sometimes may also be improper or untimely [3-5]. Alternatively, or as an integration to such restraints, there are environmental and behavioral management strategies, involving architectural or environmental adaptations that reduce risks and dangers, and/or facilitation, validation, and orientation support strategies [6]. Accordingly, special Alzheimer Units ("Nuclei Alzheimer"), long-term residential wards specific for persons with dementia, introduced by the Italian region Lombardy legislation in the mid nineties [7], are specifically designed and organized to promote free movement and activity in a safe and supervised environment, and where specific interventions may be carried out with safety and efficiency.

In order to support supervision of motor behaviors [8], particularly in nursing settings, easily manageable methodologies can help the caregivers. Current technologies based on wearable accelerometers support activity tracking [9,10]. Interestingly, these approaches may support group studies which provide information about the interplay among persons, thus implementing the so-defined social actigraphy [11]. Additionally, systems based on wearable Bluetooth beacons and antennas [12], similar to the contact tracing methods adopted during the COVID-19 pandemic [13], can support indoor location tracking in order to identify the room or environment the participant is currently in [14-16]. Such possibilities of using continuous measures of the quantity and quality of movement and tracking of location represent a relevant contribution to assessments based on tests, surveys, and questionnaires [17]. The integration of an activity tracking system and a location tracking system has already been considered in order to compute activity-related indices specific to indoor location. This approach proved to be able to better distinguish between at-risk patients who can gain independence vs the patients who are rehospitalized [18], and, when applied to a longitudinal study, provided information concerning patients receiving rehabilitation at a nursing facility [19].

When considering instrumented monitoring of activity and location, it is important to underline the inherent variability associated with free behavior, which requires us to monitor human behavior for a relevant time duration, starting from a single day [20], the basic circadian cycle, up to 1 week [11] and more [21], to obtain reliable and valid outcome indices converging to stable values [22,23]. Still, outcome indices show interindividual and intraindividual variability that would require proper experiments to be characterized in terms of test-retest reliability. Such variability thresholds allow for the identification of only significant deviations that may be predictive of critical situations, such as abnormal movement patterns or deviations from usual behaviors, suggestive of a changed, eventually worsened, condition. Intraindividual test-retest variability has already been considered for physical activity questionnaires on persons with dementia [24-26] and for actigraphic outcome indices related to movement [27-29].

The objective of the present study is to define a composite method for actigraphic monitoring [11,30] and indoor location tracking in a community residence and to perform an experimental campaign in an Alzheimer Unit, a long-term residential care facility for persons with dementia, to quantify the test-retest reliability of the resulting indices.

Methods

Ethical Considerations

This study and related documents were approved by the local Ethics Committee (Comitato Etico IRCCS [Istituto di Ricovero e Cura a Carattere Scientifico] Regione Lombardia, Sezione IRCCS Fondazione Don Carlo Gnocchi, ID 07_07/04/2021, April 7, 2021, amended on May 26, 2023). Due to severe dementia, informed consents were obtained from legal tutors of the participants. Any data or information was recorded in an anonymized form. No compensation was provided to participants.

Participants

Participants were recruited from the Alzheimer Unit of the Palazzolo Institute, Don Carlo Gnocchi Foundation, Milan. As it is a pilot study, no minimum sample size has been identified, but all resident guests of the experimental site were contacted for possible enrollment.

The inclusion criteria were an autonomous locomotor capacity (even with the help of walking aids such as, for example, a cane or a crutch) and the frequentation of common areas of the residential unit. The exclusion criteria were the presence of behavioral disorders incompatible with the research objectives (delirium, psychomotor agitation requiring psychoactive pharmacological interventions, acute clinical events limiting autonomous movement, and nonneurological pathologies strongly limiting motor activities), the need for assistance for walking by a caregiver, any dermatological problems preventing contact with wearable sensors, any confined conditions or quarantine for COVID-19 risk management.

Reference data from age-matched healthy participants were extracted from previously published datasets [11,30] in order to build a control group with a comparable average age.

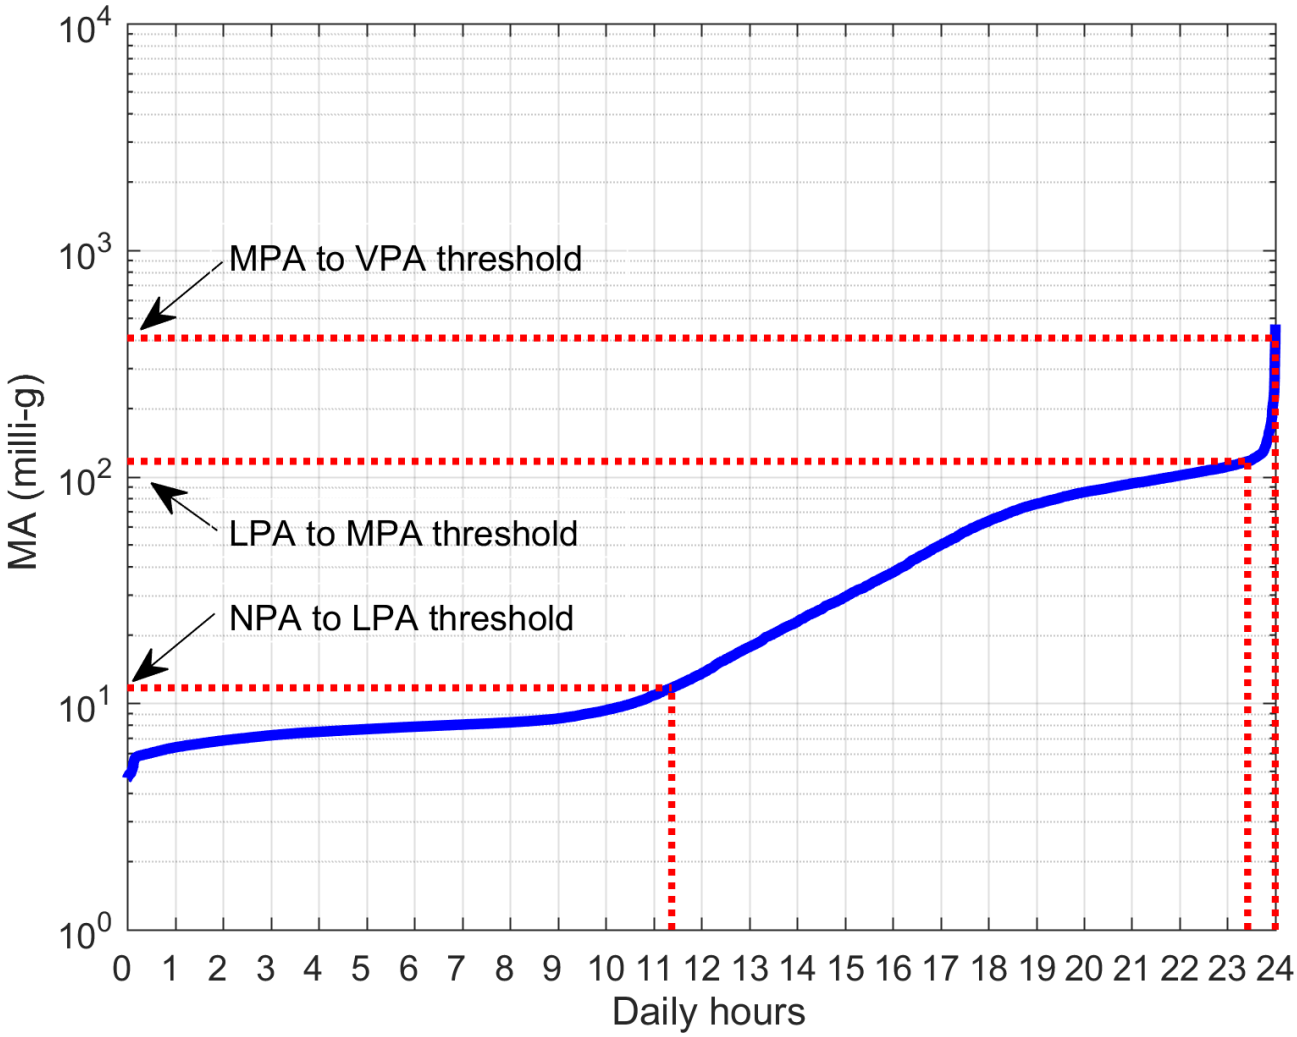
Clinical and Functional Assessment

The chosen assessment battery included Hendrich II Fall Risk Model [31], Tinetti Scale [32] when applicable, Barthel Index [33], Mini-Mental State Examination [34], Clinical Dementia Rating [35], and Scheda di Osservazione Intermedia di Assistenza [36]. Moreover, an Event Monitoring Diary (clinical events, changes in pharmacological and nonpharmacological interventions, falls, discomfort, and/or incongruous interaction with sensors, and temporarily leaving the ward) was compiled during the experiment.

Actigraphic Monitoring

Participants wore, at their dominant wrist, a wristwatch-like waterproof device including a triaxial accelerometer for 1 week. Accelerometric raw data (measurement unit is one thousandth of earth gravity constant g, termed in the following as milli-g), sampled at 50 Hz, were stored in a resident memory (Geneactiv, Activinsights). The device was not to be removed unless the participant was willing to. The 3 acceleration components allowed for the computation of the vector norm, from which the motor activity (MA) index was derived as the SD of the vector norm in 1-minute epochs [37], thus resulting in a 7-day MA profile composed of 1440 values per day (Figure 1).

Figure 1. Seven-day profile of the MA index of a guest of the long-term care residential unit. Y-grid dotted lines in green and red mark, respectively, values 100 (transition value from LPA to MPA) and 350 (transition value from MPA to VPA) milli-g above black dotted baselines. LPA: light physical activity; MA: motor activity; milli-g: measurement unit is one thousandth of Earth gravity constant g; MPA: moderate physical activity; VPA: vigorous physical activity.

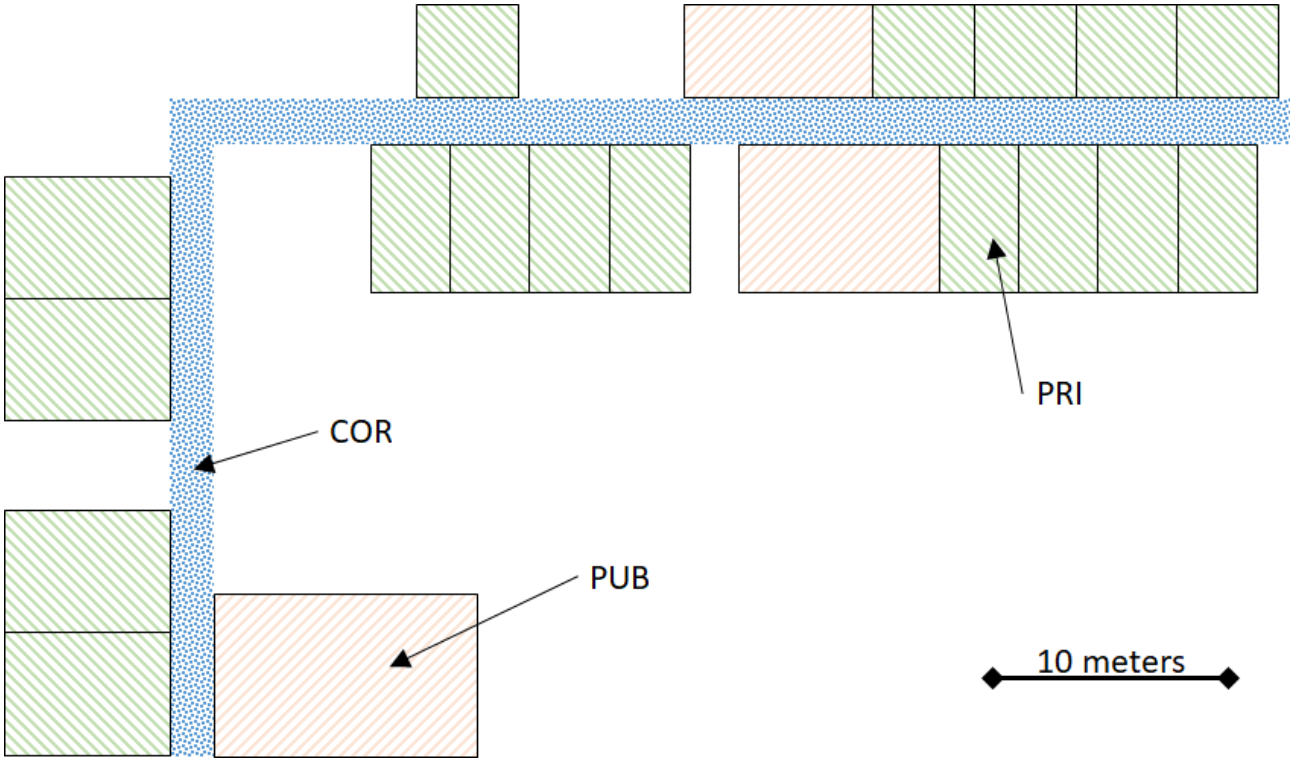


A sorting operation on the MA profile produced a distribution plot (Figure 2) which, through proper thresholds (10 milli-g for transition from no to light physical activity [LPA], 100 milli-g for light to moderate, and 350 milli-g for moderate to vigorous, for a sensor located on the nondominant wrist) [38], eventually corrected for dominant side (previous threshold values multiplied by $Coeff_{Dominant}$=1.16926), allowed computation of physical activity indices: the percentage duration of the phases with no physical activity (NPA), LPA, moderate physical activity (MPA), and vigorous physical activity (VPA).

An additional analysis was performed on the raw acceleration profile to detect the occurrence of regular patterns that are likely to be associated with a pseudoperiodic function such as locomotion. The raw signal was windowed in 4-second epochs, and an autocorrelation analysis was applied to the signal window. The possible occurrence of lagged peaks of the autocorrelation function was searched, adopting a threshold of 0.7 (a perfect periodic phenomenon has a unitary peak value, while white noise is denoted by null values of the autocorrelation function), which had been set, based on trial-and-error attempts [39]. The duration of such pseudoperiodic behavior (PPB) phases was quantified by their percentage duration (PPB).

XSL•FO
RenderX

Figure 2. The distribution of the MA values measured for 7 days is presented in Figure 1. The predefined MA thresholds (identified by values on the y-axis) allow for quantifying the duration (as an interval on the x-axis) on a daily basis of the phases of NPA, LPA, MPA, and VPA (this latter one is almost absent in the shown example as well as in the whole dataset). LPA: light physical activity; MA: motor activity; MPA: moderate physical activity; NPA: no physical activity; VPA: vigorous physical activity.



Two more indices were computed to quantify the quality of nighttime sleep and daytime wake time: nighttime sleep efficiency (SEff), the percentage duration of NPA phases between 11 PM and 7 AM, the a priori "night" time interval, which is related to SEff [40]; analogously, daytime wake efficiency (WEff), the percentage duration of LPA, MPA, or VPA (ie, the complementary duration of no activity phases) between 9 AM and 7 PM, the a priori "day" time interval, which quantifies WEff. The choice of the strict timing for "day" and "night" time intervals was based on the daily routines established within the long-term care unit: all guests are expected to be in bed during the "night" interval and awake during the "day" interval, while this assumption is not true for transition intervals (7 AM-9 AM and 7 PM-11 PM).

Location Tracking

The chosen location tracking system is composed of individual wearable devices and a network of environment fixed-position antennas (TapMyLife Inc). Monitored participants wore a miniaturized Bluetooth beacon (dimensions 32 mm × 23 mm × 3.3 mm, weight 4.0 grams) at one of their ankles by means of a biocompatible plastic bracelet. Such a device continuously emits a unique ID code, possibly received by a Bluetooth receiving antenna positioned nearby (according to the Bluetooth technology, approximately up to 10 meters in open space). All environments where participants resided (private bedrooms and any common spaces they spend time in, such as dining rooms, living rooms, corridors, etc) were equipped with Bluetooth receiving antennas: 1 antenna for each private room (PRI; 13 double rooms and 4 single rooms), 2 antennas for each large public room (3 PUBs), and 7 antennas along the main corridor, as shown in Figure 3. The frequency of the Bluetooth emitter is partly determined by the asynchronous Bluetooth protocol, generally in the magnitude order of 1 Hz. As a single Bluetooth emission can be received by several antennas, a proprietary signal algorithm identified the closest antenna and updated the beacon location (ie, the identified receiving antenna position) only when the beacon switched to a new antenna. Therefore, the source raw data provided by the location tracking system was natively asynchronous, and the current location of a beacon was determined by the position of the last antenna that detected the beacon itself. In order to summarize the location data, the percentage values of time spent in PRIs, common living rooms (PUBs), and corridors were computed.

XSL•FO
RenderX

Figure 3. Schematic map of the long-term care residential unit where the monitoring experiments took place. Different colors or patterns allow for identification of PRIs, PUBs, where social daily activities take place, and corridors. COR: corridor; PRI: private room; PUB: public room.

Experimental Sessions

The single monitoring experiment lasted for 7 days. Three experimental sessions were performed in July (Session A), September (Session B), and October (Session C) 2023. For short-term repeatability assessment (3-week time interval), Sessions B and C were compared. For long-term repeatability assessment (3-month time interval), the Sessions A and C were considered.

Outcome Variables

The variables computed starting from the actigraphic recordings were:

- NPA, LPA, MPA, and VPA: the percentage duration of NPA (1 metabolic equivalent of task [MET], MA≤10), LPA (1 - 3 MET, 10<MA≤100), MPA (3 - 6 MET, 100<MA≤350), and VPA (>6 MET, MA>350) [38], where MET stands for metabolic equivalent of task, a standardized unit of measurement for the energy cost of physical activity, being 1 MET equal to the metabolic energy expended while sitting at rest;
- PPB: the percentage duration of pseudoperiodic behavior, whose occurrence was identified in 4-second epochs of the acceleration norm in which the autocorrelation coefficient was larger than 0.7 [39];
- CC: the cross-correlation coefficient between contemporaneous physical activity MA profiles in couples of participants [11], its unit is a real value from 0 (absence of cross-correlated physical activities) to 1 (perfectly synchronous physical activity);
- SEff: nighttime sleep efficiency, the percentage of time between 11 PM and 7 AM in which MA was classified as NPA [40];
- WEff: daytime wake efficiency, the percentage of time between 9 AM and 7 PM in which MA was classified as LPA, MPA, or VPA;
- PRI, PUB, and corridor: the percentage duration of time spent in PRIs, that is, bedrooms (PRI), in PUBs, that is, social spaces where guests of the long-term care residential unit had their meals and performed leisure activities (PUB), and in public spaces, that is, main corridors.

Indices were computed on the 7-day-long recording. When the full-length recordings included a portion of scratch recording for any reason, for example, because of participants taking off the sensor, the scratch portion was removed from the recording, and the remaining time duration was further reduced to the highest possible multiple of 24 hours. The previous algorithm allowed for the computation of the indices on recordings whose length was a multiple of the basic 24-hour circadian cycle.

Statistical Analyses

The difference between outcome variables as obtained from control data and from pooled experimental data was quantified as percentage variation of median values and presented as boxplots. The difference was assessed by the Wilcoxon rank sum test (as implemented by “ranksum” function in MATLAB software, version R2016a, The MathWorks Inc), a nonparametric test for 2 independent populations.

Test-retest reliability was presented as scatterplots and assessed through the intraclass correlation coefficient (ICC). ICC was computed with a 95% CI, using a 2-way mixed-effect, absolute agreement, single measurement model. Significance level was set at 0.05. The significance level was corrected for multiple comparisons according to Bonferroni-Holm.

XSL•FO
RenderX

The adopted guidelines for interpreting ICC [41] meant “poor” for values less than 0.40, “fair” for values between 0.40 and 0.59, “good” for values between 0.60 and 0.74, and “excellent” for values between 0.75 and 1.00.

Results

The setup of technical infrastructure (BLE antennas) took place at the beginning of 2023. The data collection phase lasted from June to October 2023. The 30 guests of the long-term care residential unit were considered for this study. It was not obtained or was not possible to obtain informed consent from 5 persons, who were therefore not recruited for this study. A total of 25 guests of the long-term care residential unit provided informed consent, through their legal tutors, to participate in this study. Their demographic data and clinical scores are summarized in Table 1. Noticeably, some clinical tests were not administered (marked as “n.adm.” in the table) to some persons because of their inability to receive them. At the time of the first experiment, 4 participants denied their participation by refusing to be equipped with the sensors. Therefore, the experimental group included 21 participants (15 women and 6 males); their age was 83.4 years on average, SD 10.1 years, ranging from 69 to 97 years plus 1 younger outlier aged 55 years. Four participants rejected the wrist sensor after a variable duration from 2 days to 6 days (but the collected data lasted more than 24 hours, thus they were allowed to be included in the analysis). At the time of the second experiment, 2 more participants denied their participation and dropped out, and a third one rejected the wrist sensor after 2 days of data collection. At the time of the third experiment, 2 participants rejected the wrist sensor after 1 or 2 days, and 1 participant removed the wrist sensor, and it was lost. Therefore, the dataset for the analysis included recordings from 21 participants for the location tracking, while the actigraphic assessment included 21 participants in the first experiment, 19 participants in the second experiment, and 18 participants in the third experiment. All the observed sensors’ rejections were clearly expressed by the participants with signs of discomfort about that “alien” presence at their wrist or ankle. Though it was not possible to clarify with them the reason why, while possible explanations, such as a tight strap or bracelet, were excluded by the experimenter’s supervision. Therefore, the rejections were considered a behavioral aspect of the dementia condition.

[f]Indicates participants dropped out before Session A experiment.

[g]N.adm.: not administered.

No major health episode possibly influencing mobility was observed (and recorded in the Event Monitoring Diary) among the participants during the 3-month span in which experiments took place.

The control group included 10 healthy persons living in their own homes, 5 males and 5 females, aged 82.1 years on average (SD 2.1 years), ranging from 80 to 87 years, and were extracted from the dataset of a previously published study [11,30]. For the interaction outcomes (CC index), reference data from 40 healthy individuals (20 females and 20 males), whose mean age was 72 years, SD 7.6 years, ranging from 58 to 87 years) from another study [11] were considered.

The summary of all results is presented in Table 2.

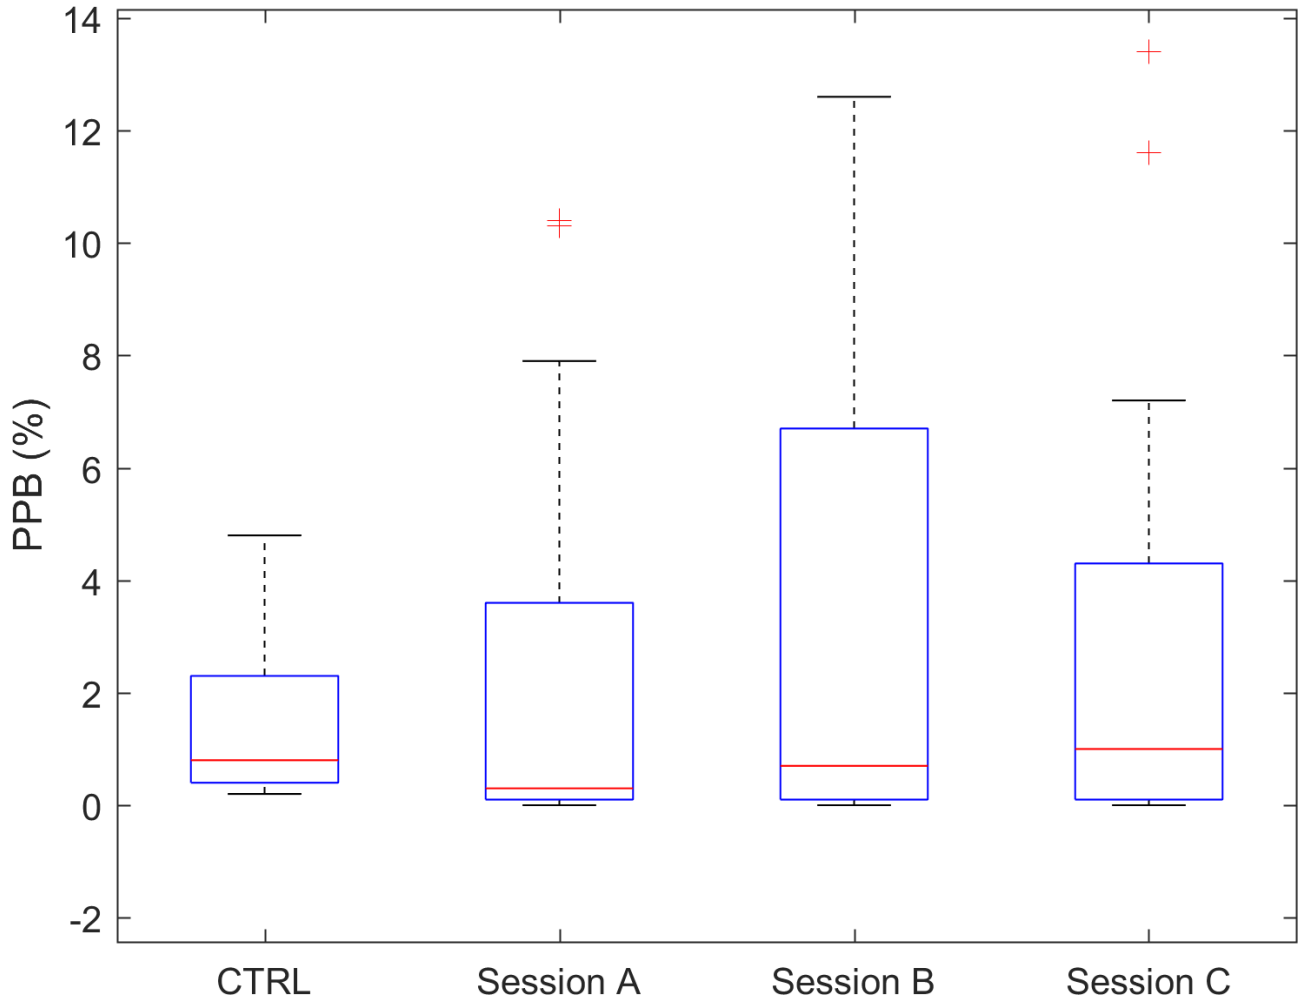
The analytical presentation of selected indices' values is provided in the form of a boxplot, which also displays any potential outliers. The ICC values are interpreted as "excellent" when larger than 0.75, "good" when between 0.60 and 0.74, "fair" when between 0.40 and 0.59, and "poor" otherwise.

As to indices related to levels of physical activity (NPA, LPA, MPA, and VPA), the experimental group, compared to control data, showed significantly lower (−84.3%) moderate activity (MPA, Figure 4) and absent vigorous activity, while lightly longer durations of NPA and light activity (LPA) were not significantly different from control data. Both short-term and long-term ICC of indices related to levels of physical activity evidenced excellent test-retest reliability.

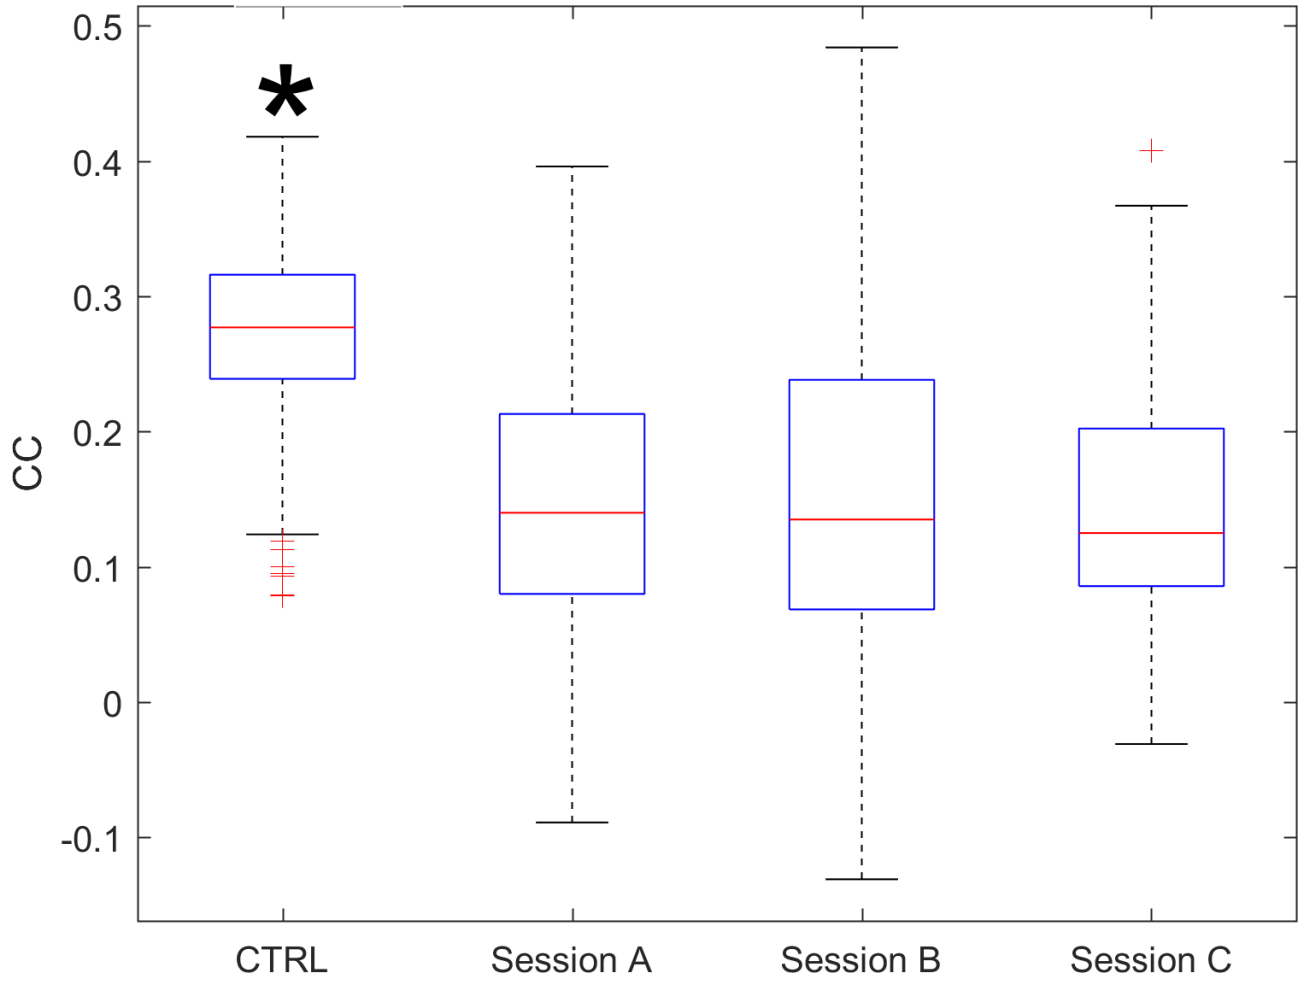
XSL•FO
RenderX

Figure 4. MPA index for CTRL and for the 3 sessions of the experimental group. Red "+" marks indicate outlier individuals. The asterisk indicates that control data have significantly (P<.05) higher values than the experimental group. CTRL: control data; MPA: moderate physical activity.



The PPB index, related to the percentage of time spent in steady walking, did not show a statistically significant difference between the control and experimental group, though in the latter group, the median values of the index were reduced by −37.5%. A perusal of the index values' distributions (Figure 5) lets us also detect the presence of a large number of cases showing larger values, and sometimes extremely larger values, than normal PPB values, in contrast with the average trend. The latter observation accounts for the so-called "wandering" behavior adopted by a subgroup of cases, who spent most of their time walking along the unit's corridor. The test-retest reliability of the PPB index was excellent.

The CC index, quantifying the accordance between the activity profiles of different participants, is compared with control data obtained from healthy age-matched individuals not living together (retrieved from the study by Rabuffetti et al [11]). The CC values (Figure 6) of the experimental group were significantly smaller, about half of the control values' (−53.1%), and demonstrated a good test-retest reliability.



XSL•FO
RenderX

Figure 5. PPB index for CTRL and for the 3 sessions of the experimental group. Red "+" marks indicate outlier individuals. CTRL: control data; PPB: pseudoperiodic behavior.

XSL•FO
RenderX

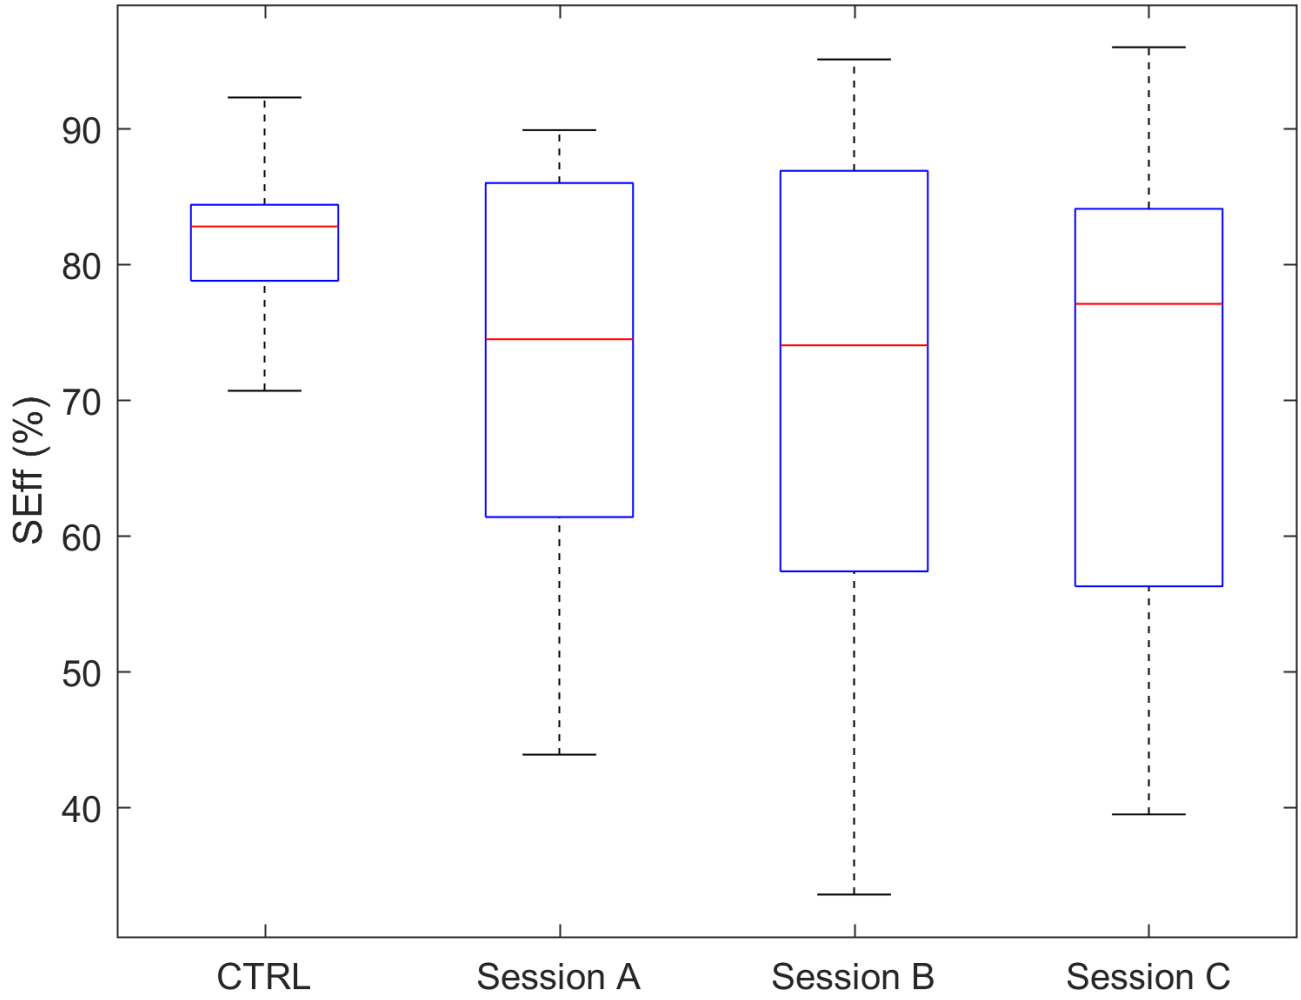


Figure 6. CC index for CTRL and for the 3 sessions of the experimental group. Red "+" marks indicate outlier individuals. The asterisk indicates that control data have significantly (P<.05) higher values than the experimental group. CTRL: control data; CC: cross-correlation coefficient.

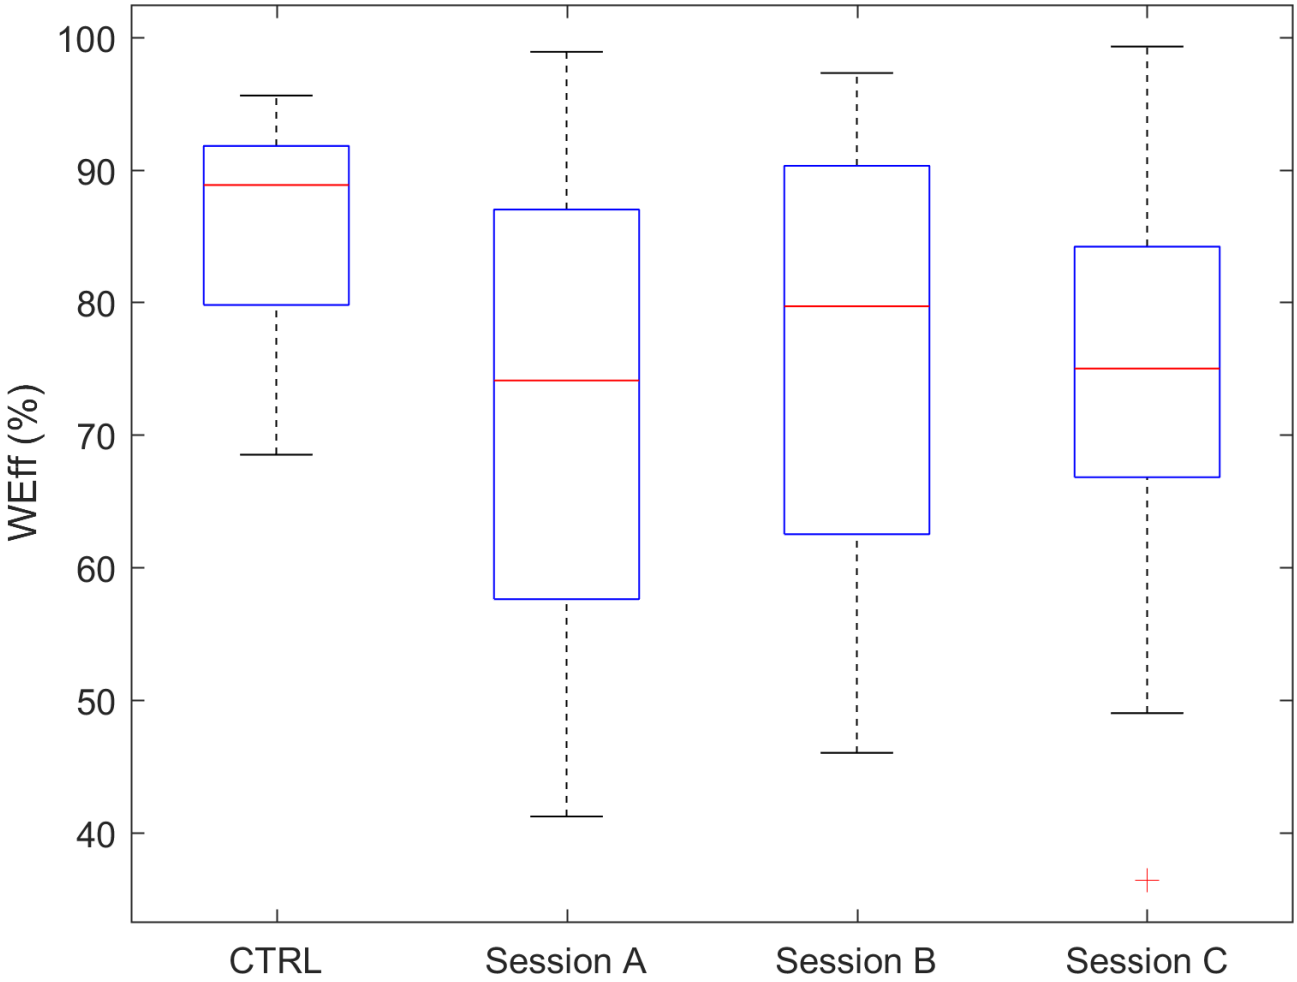
The indices quantifying efficiency of wake time (WEff) and sleep time (SEff), that is, the percentage of the a priori fixed duration of, respectively, daytime and nighttime, showed a tendency toward a smaller efficiency in the experimental group than in controls, which failed to achieve statistical significance after correction for multiple comparisons. Though a perusal of values' distributions for SEff (Figure 7) and WEff (Figure 8) pointed out the occurrence of a not negligible number of individuals showing fairly reduced efficiency indices' values. Interestingly, although these 2 indices did not show a between-group significant difference, their test-retest reliability proved to be excellent (ranging from 0.74 to 0.89).



XSL•FO
RenderX

Figure 7. SEff index for CTRL and for the 3 sessions of the experimental group. CTRL: control data; SEff: sleep efficiency.

XSL•FO
RenderX

Figure 8. WEff index for CTRL and for the 3 sessions of the experimental group. CTRL: control data; WEff: wake efficiency.

The indices related to location tracking (PRI, PUB, and corridor) could not be compared to control data, which were unavailable due to the specific nature of the measurement. There was no significant intersession difference, and the test-retest reliability was generally fair (it was good just in 1 of 6 ICC values).

These location tracking indices' boxplots and the between-sessions scatterplot are available as a slide presentation in Multimedia Appendix 1.

Discussion

Features of the Proposed Monitoring Methodology

Instrumented methods for physical activity detection and tracking are valuable tools for studying individuals with dementia [42], complementing self-report measures such as questionnaires and surveys.

The presented method has provided a quantification of various aspects concerning physical activities during wake time, sleep, and social interactions among the components of the participants' group. Besides the characterization of average behaviors as quantified by the various indices, it is worth noting that distinctive individual behaviors, different from the average patterns, were consistently identified as well, as shown also by the high test-retest reliability of the computed indices. In fact, this sensitivity aspect supports the use of such methods not only in group studies but also in clinical settings where accurate individual characterization and management are essential.

The indices considered in this study were intended to depict a multidimensional figure of each measured participant. Along with indices related to levels of physical activity (NPA, LPA, MPA, and VPA) [38], indices concerning sustained walking (PPB), social interaction (CC) [11], quality of nighttime rest (SEff), and daytime vitality (WEff) were included.

The indices' definitions are generally self-explanatory. Only the rigid identification of wake-time as daytime and sleep-time as nighttime adopted in the wake and SEff indices may be regarded as a critical choice. An alternative choice would be a functional identification of wake epochs and sleep epochs [43]. In fact, the relatively simple original definition of SEff in sleep studies (percentage of time asleep on the total time spent lying in bed, with these 2 measures obtained, respectively, from EEG (electroencephalography) polysomnography and observation log) required a redefinition of the indices when wrist accelerometry was introduced [44]. Interestingly, a literature review [45] has highlighted that the use of wrist accelerometry in sleep studies offers several advantages, such as high participant compliance, but also drawbacks, including the potential under- or overestimation of sleep indices. In this study, a rigid timeline approach was adopted to meet the requirements of clinical partners, who were specifically interested in monitoring residents' compliance with the daily routines

XSL•FO
RenderX

established within the long-term care unit. According to these routines, all guests are expected to be in bed during the "night" interval (11 PM-7 AM) and awake during the "day" interval (9 AM-7 PM). The "day" and "night" time-intervals are separated by 2 transition time intervals, during which "go-to-bed" (7 PM-11 PM) and "get-out-of-bed" (7 AM-9 AM) events may occur. Interestingly, these events do not occur simultaneously across the guests. Consequently, the inclusion of the transition intervals within either the "day" or "night" intervals would have implied the risk of false positive or false negative classifications. Importantly, omitting the transition intervals does not compromise the reliability of the efficiency indices, which are computed over time windows of 8 hours ("night") and 10 hours ("d"). These durations are consistent with the minimum actigraphic recording time of 8 hours required to obtain reliable indices [46]. Therefore, we consider the rigid timeline approach reasonable and justify the inclusion of the transition intervals as a strategy to improve the reliability of the computed indices.

Features of the Implemented Experiments

The indices obtained in the experimental group were compared with proper age-matched normative data extracted from already available datasets [11,30]. The only exceptions are for the CC index whose normative data were from a younger group (mean age 72, SD 7.6, range 58-87 years) [11], and for the location tracking indices which were based on a specific local network of BLE antennas and therefore did not allow neither the recording of normative data in the long-term care residential unit, nor the option to set up a duplicate of the residential unit for healthy older adults, was considered.

The installation of the system of BLE antennas was performed in the weeks preceding the experiments without major interference with the daily flow of activities in the care unit. The accuracy of the system (ie, the correct classification of the room where the specific BLE beacon was in) was obtained as a result of a calibration procedure following the installation. The experimental data collection was carried out smoothly without any potentially confounding events, particularly, as described by the clinical logs, the participants constantly resided in the long-term care unit without leaving it. The participants occasionally received nursing assistance in their activities, particularly hygiene-related ones, in which partly passive movements could be interpreted as LPAs. However, these nursing activities were limited in time (few minutes), therefore were not considered to alter the experimental outcome significantly. All accelerometric recordings were a posteriori checked for identifying sensor removal (a constant baseline clearly distinguishes these from actual measurement, even from a still sleeping participant) and eventually tagged to exclude these time intervals from further analyses.

Discussion on Outcome Indices Compared With Reference Data

The indices related to physical activity (NPA, LPA, MPA, and VPA) evidenced significant differences between the group of persons with dementia and age-matched healthy participants: a slightly larger, though not significantly different after *P* value correction, duration of phases of NPA, a comparable LPA, a significantly reduced duration of MPA, and a substantially absent VPA. This figure is compatible with a commonly expected behavior in a nursing ward: increased sleep or rest, even in a seated position, particularly during the day [47], and drastically reduced activities requiring a relevant physical involvement [48]. A perusal of the individual data allowed us to identify individuals who showed activity profiles that differ from average behavior: particularly, 2 cases evidenced a very low value of NPA, which was compensated in 1 case (S18) by large values of LPA, while the other case (S23) evidenced the largest values of MPA. Interestingly, S18 had the lowest Barthel score among participants, while S23 was the youngest and had the lowest Tinetti score.

The index PPB, related to a pseudoperiodic motor behavior, is to be interpreted as an index of steady walking. Indeed, while the PPB index was, on average, not significantly different between controls and this study's group, a small subgroup of participants showed higher than normal PPB (S25, S23, and S07 above all controls in all 3 sessions, S13, S06, and S09 above at least 9 of 10 controls in all 3 sessions). The motor behavior of these participants resembles the so-called "wandering" behavior [49,50], a continuous, uninterrupted walking along the allowed paths, such as up and down a main corridor. Specifically, in this study's group, 6 individuals had this wandering behavior, clearly detectable in PPB scatterplots. Interestingly, this behavior is very consistent and can be observed also in repeated sessions, weeks, or months apart.

The CC index, quantifying the accordance between MA profiles of any possible couple of participants, is the key variable in the so-called social actigraphy approach [11] that aims at identifying congruent synchronized behaviors induced by the social proximity (in the original paper due to the marriage or cohabitation, in this study due to the common belonging to the community living in the long-term residential unit). In the presented data, the CC index showed significantly lower values in the experimental group, compared to reference data published in literature [11]. This result was initially unexpected, since a simple assumption implies that a tight social community, such as the one composed of guests of a nursing home, should be characterized by higher between-subjects CC values. The presented data evidenced, on the contrary, that participants with dementia show larger between-subjects differences in the MA profiles (corresponding to lower CC values) than observed in healthy participants. This outcome is surprising when the attention is all upon the social context, with common activities such as having meals together or participating in socialization events, since it would imply a certain "temporal synchronization" of motor behaviors. On the contrary, this result could be explained by the fact that people with dementia are known to often show apathy and withdraw from social interactions [51], and sometimes individuals with dementia may even show sociopathic traits [52].

The index SEff showed, on average, comparable values between healthy participants and persons with dementia. Interestingly, a large number of this study's group was characterized by lower-than-normal values, thus evidencing a troubled management of the hours eligible for sleep or at least rest. The repeatability of these lower-than-normal values lets us identify a subgroup of the guests of the residential ward that need special

XSL•FO
RenderX

attention concerning the management of the nighttime. Without entering into specific details, several actions can be performed, including a revision of pharmacological or nonpharmacological interventions [53-55]. Nonetheless, the present method lets us consider also more practical choices such as a change of the bedroom and related roommate. The index WEff evidenced a tendency, not statistically significant after *P* value correction, of lower-than-normal values for people with dementia, implying reduced percentage of activity time and increased resting, possibly daytime napping [56]. Symmetrically with previous comments on SEff, it is possible to identify a small subgroup that evidenced a higher-than-normal WEff, thus presenting themselves as the guests who never sleep during the day and are always active.

The indices related to location tracking (PRI, PUB, and corridor), that is, the percentages of total time spent in specific indoor locations, have no reference normative data. The interpretation of the observed values relies on comparison with other indices. The PRI values, representing the time spent in PRIs, were found to be slightly larger than NPA, the time characterized by no activity. This result is consistent with the fact that PRIs were mostly used for resting and sleeping. Conversely, the sum of PUB and corridor durations (ie, the time spent in any public space) was found to be slightly lower than the sum of LPA, MPA, and VPA durations (ie, the time spent at any level of activity), thus implying that MA might occur even in PRIs.

Test-Retest Reliability of Outcome Indices

The ICC values of the physical activity indices (NPA, LPA, and MPA) were excellent either in the short-term or in the long-term, with just a slight decrease of the values in the latter case. No ICC was computed for the VPA because vigorous activity was substantially absent in all cases. When considering PPB as a proxy for the amount of performed steady gait, the ICC was excellent in both short-term and long-term, and, to our surprise, it scored a higher value in the long-term. We are not willing to interpret this latter point as significant of some underlying phenomenon; rather, we consider it the result of a stochastic effect. Lower, but still good, ICC values were observed for the social actigraphy index CC. In fact, the CC values were substantially unchanged in all sessions, both after 3 weeks and after 3 months. As the CC values depicted a figure of a substantial absence of relations among the MA profiles of participants, even compared with control data, our interpretation is that people with dementia living in long-term care residences show signs of social withdrawal in their lifestyles as well as peculiar behaviors that may occur, such as the wandering one that largely differs from the inactive one which characterizes the majority of guests. Excellent ICC values were observed for SEff in the short-term. Indeed, participants tended to keep their night habits, which included either high SEff behaviors or persons who spent a large part of the night asleep. It is to be noted that the clinical management rules of the experimental residential unit excluded a general use of antipsychotics [57], thus increasing the possibilities for a person to be free to stay awake and even wander, as it was seldom observed, during the night. The test-retest reliability of WEff was between good and excellent. As for night habits, even during the daytime, participants had different behaviors (some stayed awake the whole day and others had frequent day naps). Those behaviors were individually consistent and repeatable. The location tracking variables, that is, the percentage time spent in different locations inside the residence unit, showed mainly fair values of reliability. The relatively lower values of the location tracking indices' ICC disagreed with the higher ICC values of the accelerometer-based indices. It is an open question how much of this low reliability of the location tracking indices is due to the actual, and different from the acceleration, nature of measured variables, and how much is due to a different behavioral performance. As, occasionally, we observed that the system delayed the detection of a displacement of a participant, that is, of the Bluetooth tag he wore, from one space to another one, we believe that these technical occurrences might have decreased the overall reliability of the Bluetooth measure, leading therefore to a decrease in the reliability of the variables which were derived from that system.

The obtained ICC values should be compared to ICC values found in the literature. When considering indices obtained by a questionnaire, a published study reported ICC ranging from 0.53 to 0.68 for total sedentary time, while for more focused domain-specific sedentary times, ICC ranged from 0.36 to 0.76 [24]. Another study concerning a self-administered questionnaire quantifying physical activity indices reported ICC values ranging from 0.56 to 0.91 for physical activity indices [25]. A questionnaire administered to caregivers of persons with dementia scored an ICC ranging from 0.87 to 0.95 [26]. When considering sensor-based assessments, a study on patients with knee osteoarthritis reported ICC ranging from 0.70 to 0.93 for physical activity indices [29]. In a gait monitoring approach in older adult participants, it was observed that higher repeatability was observed among the prefrail or frail group (ICC>0.78) compared to nonfrail individuals (0.39<ICC<0.55) [28]. In a study, in which the accelerometer data were processed with different algorithms, the test-retest reliability of the physical activity indices was generally very good to excellent (ICC=0.70 - 0.90) [27]. All considered, the test-retest reliability found in the present study is comparable with the already published literature.

Limitations

The presented experiment has some limitations. First, the location tracking method required the installation of a hardware infrastructure embedded in the building, which is not movable to another setting (this limitation obviously does not apply to the wrist accelerometer setup). As a consequence, control data obviously cannot be obtained from healthy age-matched individuals living in the same environment. This limitation might be overcome in the future, in the light of a rapidly evolving technological advancement, if detection antennas for an ultrawide band become ubiquitous indoors [58] or with AI-enabled surveillance cameras, provided that privacy concerns are solved [59]. Second, the activity tracking method had a compliance which was not 100% because some individuals did not agree to wear the wrist sensors or removed them during the experiment, resulting in a generic discomfort, though the clinical partners had preliminarily warned about these refusals as a consequence of the dementia affecting the unit residents. In the

XSL•FO
RenderX

latter cases, when the wrist sensors measured for more than 24 hours, the data were retained for multiples of 24-hour durations, and outcome variables were computed on the available full days. Nonetheless, such occurrences were seldom observed. Despite the authorization given by the legal tutors, our participants, persons with dementia, were still able to refuse to participate or at least to reject the wrist or ankle sensors because they felt disturbed by their presence. The dimension and location of the sensors might play a role in their refusal, so it may be expected that future technological developments, letting smaller sensors be embedded in the garments or fixed into adhesive patches, will reduce this noncompliance. Interestingly, compliance problems arose mostly for the wrist sensor, as the participant could perceive and grasp it. Third, the control group for the accelerometric data was built from an available dataset of healthy older adults living in the community [11,30] to be comparable as to average age, but the age range was narrower (80 - 87 years), 9 of 25 participants were above the maximum control age and 7 of 25 participants were below the minimum control age. This is due to the difficulty in recruiting healthy older adults in their nineties living in the community [60] while younger healthy older adults were excluded in order to have a matched average age. Fourth, the choice of monitoring activities with wrist accelerometry (adopted in 22% of the published actigraphic studies) was critically compared with the option of performing waist accelerometry (in 48% of the studies) [61], as an accelerometer on the waist is closer to the body center of mass and, therefore, considered more informative about physically engaging activities. The wrist choice was justified by the relevance of upper limb movements in older adult residents in a long-term care unit, as locomotor activities might be quite reduced, and by feasibility reasons, as an accelerometer positioned on the lower back with a belt would greatly interfere with autonomous bathroom activities of older adults, would not have had a stable position, and would be disturbing when lying in the bed. Moreover, the integration of a gyroscope sensor into the monitoring watch was not useful, and therefore dropped, as gyroscopes are mainly involved in activity classification, which was not an objective of this study.

Conclusions

In conclusion, the method involving activity tracking by a wearable accelerometer and location tracking through the detection of a wearable Bluetooth beacon by a network of Bluetooth antennas was proven to be feasible. The computed indices quantified the activities and social behaviors of the long-term care unit guests, providing a novel multidimensional characterization of the individual guest behavior, which considers the physical activities, the WEff or SEff, as well as the social interactions in terms of agreement between the activity profiles among participants. Though the results about activity levels in persons with dementia are in line with intuitive knowledge (ie, people with dementia move less than age-matched healthy participants), the assessment provided novel evidence against intuitive knowledge when quantifying the strict and continuous social interactions involved in a residential long-term unit. Such interactions, quantified by the CC index, resulted in lower values than those observed among healthy older adult couples not even living together. Apart from behavioral evidence, the fundamental novel information provided by this study consists of the quantification of the test-retest reliability of the computed indices, which resulted in good to excellent values, thus possibly supporting future power analyses in designing longitudinal studies on the activity tracking and localization of persons affected by health problems or frailty, and particularly by dementia or cognitive decline. These test-retest features complement the ones already available in the literature concerning studies on healthy adults [27], on walking bouts in frail older adults [28], and in people with orthopedic problems [29]. The results presented here will possibly support future studies able to characterize the effects of aging and changing social situations with a longitudinal design, or the effect of a possible therapy in a randomized controlled trial design. Interestingly, the methodology proved to be able to clearly identify behaviors, such as, for example, the wandering behavior, expressed by a minority of individuals inside this study's group of persons with dementia, thus supporting a possible use of the methodology in clinical settings, either as a way to characterize the individual or a means to detect changes in their behavior. Moreover, the computed indices might support a clinical team in improving the guests' experience [62] and in tailoring a personalized and coordinated across-subject rehabilitation program.

Acknowledgments

The authors wish to thank Piero Votta, Prof; Alberto Marzegan, DrEng; and Virginia Bandini, DrEng, for their help in the experimental setup installation. No generative artificial intelligence tools were used in this study.

Abstract

Background: Digitalization and mobile health (mHealth) technologies hold promise for improving home care delivery. However, many mHealth initiatives fail to achieve their goals. Understanding the reasons behind these failures is critical for informing the successful implementation of mHealth in primary and home care settings.

Objective: This study aimed to explore the implementation process of a tablet computer with an mHealth app providing mobile access to the electronic health record (EHR) in home care, identifying barriers and facilitators to its uptake.

Methods: A tablet with EHR access was introduced at 4 primary care centers and 1 municipal home care organization in Sweden. Participants were nurses and physicians working at the study sites. Focus group discussions and interviews were conducted to obtain a rich understanding of implementation-related issues experienced by the health care professionals. Qualitative content analysis was conducted using the Consolidated Framework for Implementation Research to guide interpretation.

Results: Eighteen health care professionals (16 nurses and 2 physicians) participated in the study. The implementation of the mHealth app was largely unsuccessful. Key barriers included limited functionality of the app, technological immaturity, and unstable infrastructure. Organizational context influenced uptake, especially due to differing EHR systems and varying levels of user engagement. Users who were involved in the development process were more positive, despite the absence of certain functionalities, while those excluded struggled with adoption. Long development and implementation timelines and limited training reduced enthusiasm and negatively affected user engagement. Additional challenges included insufficient implementation planning, lack of leadership engagement, and inadequate resources for support and training.

Conclusions: For mHealth implementations to succeed, tools must meet users' needs and integrate seamlessly with existing eHealth ecosystems and infrastructures. Premature implementations can lead to change fatigue and diminish future engagement. Investments in user-centered design, thorough testing, organizational readiness, and sustained support are essential to realize the potential of mHealth in home care.

KEYWORDS

home care; primary care; work environment; CFIR; mHealth; eHealth; qualitative evaluation; electronic health record

Introduction

As populations age, the need for primary care and home care increases [1], yet resources remain scarce, with serious recruitment challenges concerning educated personnel [2,3]. According to the Swedish Association of Local Authorities and Regions, in the future, such care must be provided closer to the patients. Further, a holistic approach, greater use of digitalization, more collaboration among departments and specialties, and improved patient access are considered necessary. This sentiment is echoed in the World Health Organization's global strategy on digital health, where the purpose of the strategy is to "strengthen health systems through the application of digital health technologies for consumers, health professionals, health care providers and industry towards empowering patients and achieving the vision of health for all" [4]. Electronic health records (EHRs) are used in everyday care throughout Sweden [5]. Most regions use one EHR system throughout hospitals, primary care, and psychiatric care, making patient records available in the entire region. Elder care, however, is the responsibility of municipalities that fall under different legislation [6], and often use separate EHR systems [7-9].

XSL•FO
RenderX

The concept of mobile health (mHealth) has emerged as a subcategory of eHealth and can be defined as medical and public health practice supported by mobile devices [5,10]. The use of smartphones and tablets in health care is increasing. The use of mobile devices for home care in Swedish municipalities has increased significantly in the past few years; in 2020, 41% of the municipalities provided health care staff the possibility to read and write information using a mobile device, compared to 5% in 2015 [11,12]. By 2024, 70% of the municipalities used mobile devices in home care [12].

Further digitalization and the introduction of eHealth and mHealth have been seen as means to optimize health care [4]. Expectations are high that they will be the solution to many of the problems that exist in health care today [13]. However, many projects are unsuccessful [14], and challenges of digitalization have been raised [15]. There are several reasons why implementations of eHealth in health care fail [16,17]. By studying and analyzing why an eHealth or mHealth implementation is unsuccessful, we could learn how successful digitalization in primary and home care can be achieved.

A Cochrane review of mHealth apps showed that the complexities of health care delivery and human interactions defy simplistic conclusions on how health workers will perceive and experience their use of mHealth. Perceptions reflect the interplay between technology, contexts, and human attributes. Detailed descriptions of the program, implementation processes, and contexts, alongside effectiveness studies, will help to unravel this interplay to formulate hypotheses regarding the effectiveness of mHealth [18]. Despite the increasing use of mHealth [19], limited research on mobile EHRs exists, mostly focusing on in-hospital use for bedside EHR access [20,21]. Studies indicate that usability issues of mobile EHRs combined with low digital literacy negatively impact nurses' adoption of the tools [21], and may even have a negative impact on nurses' work environment despite the aim to better support their work [22].

This study was designed to evaluate an mHealth app that provides health care professionals (HCPs) with mobile access to the EHR and describe its impact on work processes and work environment. The project was, however, terminated prematurely since HCP did not adopt and use the system. The collected data were instead analyzed to understand the reasons for the implementation failure.

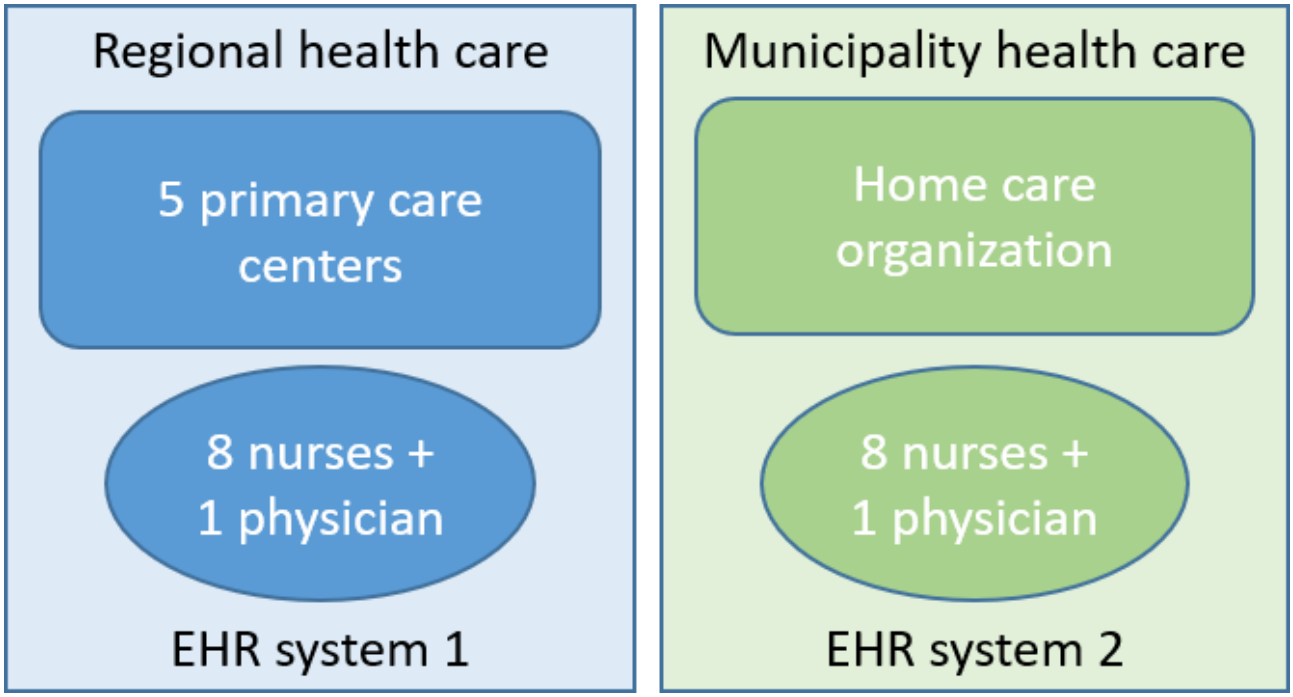
We aim to understand the reasons for an unsuccessful mHealth implementation and potential success factors by describing lessons learned from the implementation process of a tablet computer with an mHealth app that provides mobile access to EHR in home care.

Methods

Overview

A qualitative approach has been applied to understand the HCPs' expectations before implementation and their experiences of using the system. Individual interviews and focus group interviews have been used to obtain a rich understanding of the implementation-related issues. Due to the limited number of users of the mHealth app, a qualitative approach was deemed suitable to gain an in-depth understanding of the factors causing the failed implementation. The Consolidated Framework for Implementation Research (CFIR) by Damschroder et al [23] was used to guide our analysis.

Study Setting



The study was conducted in a public municipality home care organization (MHCO) and the home care sections of 4 public academic primary care centers (PCCs) in a rural part of Region Stockholm.

The home care organization provides medical and supportive care for a diverse range of patients, predominantly older adults but also younger individuals with medical needs. The MHCO has the main responsibility for home care, whereas the PCCs provide some home care, for example, the first 2 weeks after discharge from the hospital and the support and service for persons covered under the Swedish Act Concerning Support and Service for Persons with Certain Functional Impairments. At the time of this study, there was no interaction between the PCCs and the MHCO.

The PCCs all use the same EHR system, accessible through the mHealth app, whereas the MHCO has a different EHR system, lacking accessibility through the mHealth app. Figure 1 presents an overview of the study setting.

XSL•FO
RenderX

Figure 1. Study setting describing the regional and municipality settings and included study participants. EHR: electronic health record.

The Intervention

The intervention consists of a tablet computer with several apps (eg, decision support, online prescription tools, and online supplies ordering), and the new mHealth app that provides mobile access to the EHR (example screenshots from the app are in Multimedia Appendix 1). In the following text, we will refer to the latter as "the mHealth app" and use the term "the mobile tool" when referring to the tablet with all its apps.

The mHealth app on the tablet computer was developed after an initiative by professionals (2 doctors and 2 nurses) at one of the participating academic PCCs. They saw a need for easy access to information, including patient data, and to carry out all parts of their home care work, including documentation, while in the patient's home. The HCP took an active part in an initial need and requirement analysis, and the mHealth app was then developed from their ideas. The first author was involved in some of the app's needs and requirement analysis. Professionals provided feedback on functionality and design but were not further involved in the mHealth app's development. No structured usability assessments were performed.

The project was carried out through a collaboration between academic PCCs and the IT unit of Region Stockholm, along with the private company Chorus, which was responsible for the technical development of the app. As an innovation project, each participating entity covered its own costs. The aim of the pilot project was to evaluate the tool's effectiveness and its potential for broader implementation within the region, with the long-term goal of generating both clinical benefits and economic value. The mobile tool was tested at selected academic PCCs, and the responsibility for approval and rollout was shared between the involved academic PCCs and the IT unit of Region Stockholm.

The mHealth app provided mobile access to the EHR used in regional home care. This included, for example, access to patient record entries, information about the patients to be visited during the day, and the possibility to write patient record entries while in the patient's home, a task otherwise done after returning to the office, as previously described in our study outlining the matching of the functionality of the app to the home care work processes [24]. While the previously published study described the work process in primary care in detail, matching it to the functionality of the study, it did not go into details on the users' experiences and reasons for the failed implementation. Due to technical difficulties, not all parts of the EHR were accessible through the mHealth app. The app did not provide information on patients' medications, referrals, or radiology results because the EHR from which the mHealth app collected the medical data did not support this output. However, it was possible to access information on the patients' previous outpatient and inpatient care visits, diagnoses, and laboratory tests. Thereby, some, but not all the HCPs' needs were met by the mHealth app. The mHealth app was intended to be further developed, and the implementation was therefore initiated.

The tablet computer also provided access to several clinical decision support systems and a mobile web-based prescription system that is used for some of the patients in home care, thus enabling the HCP to manage part of those patients' medications. Thereby, the diverse functions of the tablet computer provided HCPs with a multifaceted mobile tool for home care visits.

There were no costs involved for the users. Use of the mobile tool was strongly encouraged but voluntary.

The mobile tool was first implemented in the home care section of the PCC, which was part of the development of the mHealth app and in one of the other PCCs. In both participating PCCs where the mobile tool was first implemented, some HCPs were avid advocates for the mHealth app.

XSL•FO
RenderX

At a later stage, the mobile tool was implemented in the MHCO and the remaining PCCs. There were no advocates for the mHealth app at either of these workplaces. The mHealth app was further developed later to improve stability and implemented and used in in-hospital care for bedside record access in the Stockholm region. In 2020, Region Stockholm ceased all support of the mHealth app, and it is currently not in commercial operation.

Data Collection

Data for this study were collected through focus groups and semistructured interviews with nurses and doctors working in home care where the mobile tool was introduced. The first author (LJH, female) was responsible for the data collection, with the assistance of 2 Master's students (both female, health informatics students). All 3 had both training in and experience of qualitative data collection, and were supported by the last author (MH, female) with extensive experience in qualitative research. LJH was working as a general practitioner in the region at the time of the study and was well-known to all study participants. An overview of the timeline and data collection is presented in Table 1. Before implementation, a workshop was held where questions were asked regarding the time spent on administrative work related to home visits, experienced stress, use of decision support tools, and the experienced quality of documentation and communication between HCPs.

Table . Overview of the data collection timeline, including the method used, setting, and time for data collection.

Data collection	PCC1[a]	PCC2	PCC3	PCC4	MHCO[b]
Development of an app	2014 - 2015	—[c]	—	—	—
Focus group on expectations	November 2015	May 2016	April 2017	April 2017	April-May 2017
Individual interviews	May 2016	February 2017	February 2018	March 2018	February 2018
Focus group on completion of study	October 2016	—	—	—	—

[a]PCC: primary care center.

[b]MHCO: municipality home care organization.

[c]No data were collected using that method at that specific unit.

The mobile tool was introduced and demonstrated during a workshop where participants had the opportunity to practice using it. The demonstration was conducted by guiding participants through the different functionalities step by step, ensuring a comprehensive understanding of its features and applications. This hands-on approach facilitated engagement and allowed attendees to gain practical experience with the tool.

The original plan was to conduct data collection through (1) preimplementation focus groups, (2) individual interviews after 6 months of use, and (3) a second round of focus group interviews after 12 months of use. The different qualitative methods were chosen to gather a rich dataset; the focus group interviews enabled discussion and exchange of opinions between participants, whereas the interviews allowed more detailed exploration of individual HCPs' experiences of using the mobile tool. We also recognized that individual interviews provide an opportunity for participants to express thoughts and concerns they might be reluctant to share in a focus group setting with other participants present.

Interview guides were developed for individual and focus group interviews (Multimedia Appendices 2 and 3). All interviews and focus groups were recorded and transcribed. Notes were also taken during focus groups and included in the material. All interviews were held in Swedish. The individual interviews lasted 20 - 30 minutes and the focus group interviews lasted 1 - 1.5 hours. Data collection was conducted where most convenient for the participants, that is, at the PCCs or the MHCO's office. Data collection was conducted during working hours. Participant checking of the transcribed interviews was not done to reduce the burden on the study participants.

Preimplementation focus group interviews were held in all the PCCs and the MHCO, where the positive and negative expectations were discussed and reflected upon by HCP who would use the mobile tool.

Individual interviews with nurses and physicians were conducted according to plan to capture the staff's experiences using the mobile tool and its impact on work processes.

Interviews were conducted when the mobile tool had been used for at least 6 months. All interviews were conducted by the first author and the Master's students in the research team. The Master's students conducted interviews in the MHCO. One of the Master's students continued working in the project as a research assistant after graduation and also contributed to the data analysis.

All eligible nurses and physicians working in the setting were invited and accepted to participate in the study. Study participants were approached via email and in-person by the first author through the managers of the MHCO and PCCs. The same participants at each site participated in both the focus groups and interviews.

A second set of focus group interviews was planned at the end of the study, when the mobile tool had been used for 1 year. The PCC involved in the mHealth app's development started testing earlier than the other clinics, and a focus group interview was held a year after they started using the mobile tool to capture their long-term experiences. When the 6-month interviews were conducted at the other clinics, they had stopped using the mobile tool, and the decision was made not to conduct the planned

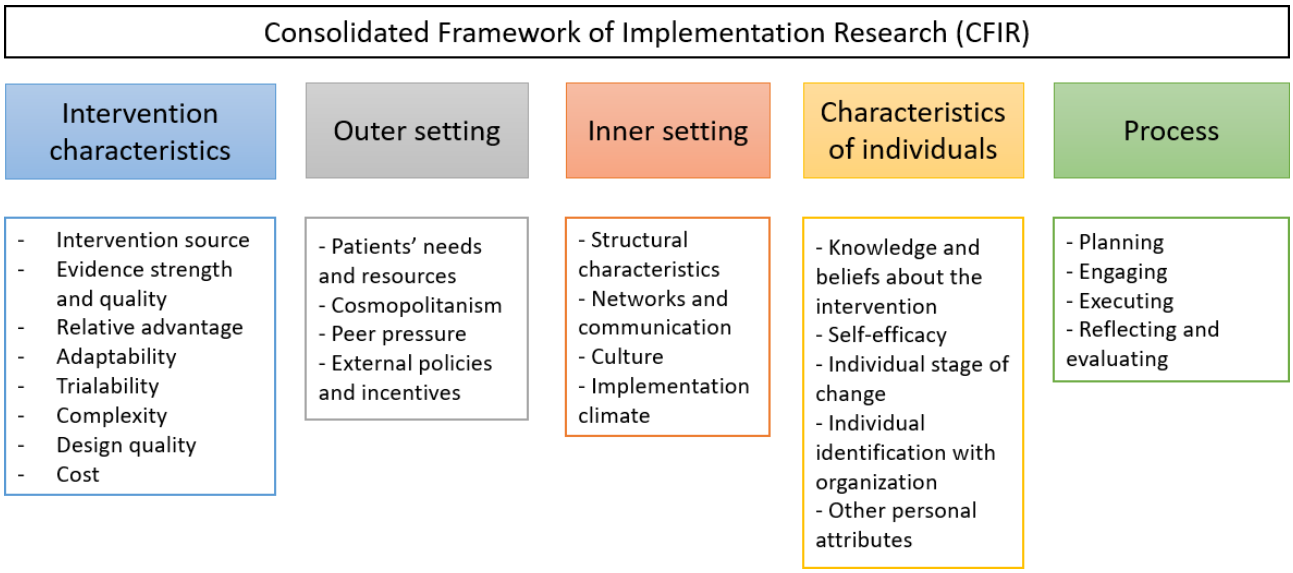
XSL•FO
RenderX

focus group interviews, as they would not gain further experiences of using the mobile tool.

Data Analysis

All interviews were transcribed verbatim and analyzed using a deductive content analysis approach [25]. The CFIR [23] was used to structure the analysis. The data analysis performed in this study does not include any quantification of responses regarding specific categories.

CFIR identifies 5 domains that are essential to implement an intervention [23]:



1. Intervention characteristics—features of the intervention itself, such as complexity, evidence strength and quality, and adaptability.
2. Outer setting—the external environment influencing implementation, such as external policies and incentives.
3. Inner setting—organizational factors such as culture, leadership, and available resources within the implementing organization.
4. Characteristics of individuals—traits and actions of the individuals involved in the implementation, including knowledge, beliefs, and self-efficacy.
5. Process—the planning, execution, and reflection processes involved in implementing the intervention.

In CFIR, a domain represents a broad category of factors or determinants that affect the implementation process. A construct, on the other hand, refers to a specific factor within a domain that provides more detailed insight into the aspects of implementation. An overview of the CFIR domains and their constructs is presented in Figure 2.

The 3 authors all actively participated in the analysis. Initial coding was performed by LJH, MH, and one of the Master's students who continued working on the project as a research assistant after graduating. First, all materials were read and reread, and meaning-bearing units were identified. Each coder coded and categorized the meaning-bearing units individually into 1 of the 5 domains of the CFIR framework. HH joined the analysis at this stage, and the 3 authors discussed the coding until a consensus was reached on the interpretation. Where appropriate, relevant CFIR constructs were used to signify our findings, but we did not systematically search for constructs in the material.

Due to the relatively small number of participants, achieving full data saturation was not possible. However, we ensured sufficient information power by including all eligible HCPs across multiple roles and settings. Thematic consistency across discussions suggests key insights were captured despite the limited number of study participants.

Figure 2. An overview of the Consolidated Framework for Implementation Research, including the 5 domains and their constructs.

Ethical Considerations

The Research Ethics Committee at Karolinska Institutet has granted ethical approval for this study (DNR 2015/1457-31/5). All study participants provided written or oral informed consent before participating in the study. In accordance with the Swedish Ethical Review Authorities' requirements, participants were informed that their participation was voluntary and that they could choose to revoke their participation at any time. Transcribed interviews and focus groups were deidentified to protect the participants' privacy, and confidentiality was preserved when reporting results. Study participants did not receive any compensation for their time.

Results

Overview

The 18 participants in the study were all nurses and physicians working in home care in either the home care section of the participating PCCs or the MHCO. A total of 8 nurses and 1 physician from the PCCs (PCC1=2 nurses and 1 physician, PCC2=1 nurse, PCC3=3 nurses, and PCC4=2 nurses), and 8 nurses and 1 physician from the MHCO participated in the study (Figure 1). Participants were predominantly female (17/18, 94.5%), and age ranged between 43 and 64 years. Due to the small number of participants in the study, we chose not to collect

XSL•FO
RenderX

and report further detailed characteristics of the individual study participants to ensure their anonymity.

Using the 5 domains of CFIR, we present our analysis of the HCPs' expectations before implementation and their experiences during the implementation of the mobile tool. We identify the key barriers causing the implementation to fail and the aspects that had a positive influence.

Intervention Characteristics

Before the implementation, HCPs' expectations were high, yet the interviews after 3 and 6 months of using the app revealed that many of the expectations were unmet. Textbox 1 presents an overview of the constructs related to the characteristics of the intervention, with further details from the qualitative analysis presented below.

Textbox 1. Identified categories related to the Consolidated Framework for Implementation Research domain intervention characteristics, divided by expectations before and experiences after implementation.

Expectations before implementation

- Relative advantage
  - Reduction of cognitive workload
  - Time-efficient and timely
  - Real-time access to information
  - Lack of information and functionality
- Complexity
  - Increased complexity and double documentation with many mobile apps
  - Workarounds to adapt to the system may increase cognitive workload
- Design quality
  - Slow and frustrating
  - Immature and unstable

Experiences after use

- Relative advantage
  - Reduction of the cognitive workload
    - Finish work on the site
    - No need for reminders
  - Access to important functions and information
  - Missing functions
  - Reduces unnecessary lab tests and orders
  - Note formatting is worse
- Complexity
  - Adaptations of work processes are required
    - Condensed documentation
    - Preliminary documentation on site
- Design quality
  - Poor design or unclear layout
  - Design improved during the project
  - Immature and unstable

XSL•FO
RenderX

Preimplementation Expectations

HCP had high hopes that the mobile tool would support their work and serious concerns that the technology would not meet their expectations.

Relative Advantage

During the preimplementation focus group interviews, the HCP expressed high expectations that the new mobile tool would help reduce their cognitive workload by allowing them to complete tasks (eg, ordering materials or sending referrals) and finish documentation at the patients' home:

> *To complete the documentation before leaving the patient's home. It would be a dream. You forget so much on the way back to the office.* [Nurse, MHCO]

Real-time access to information would make it possible to make more informed decisions and reduce the need to call colleagues to find information, for example, from the EHR. However, there were also concerns:

> *It's faster to write a post-it note. If it [the mobile tool] doesn't provide everything we need, it may end up in the office* [Nurse, PCC 1]

Staff already knew that some important functionality (eg, the medication list and referrals) would not be available, and concerns were that this would limit the app's usefulness:

> *Frankly, it feels a bit underdeveloped. Several things are missing, like the medication list and x-ray results, which is important when you visit the patient and need to discuss prior events or plans.* [Physician, PCC 1]

Complexity

There were also concerns that missing functionality would result in workarounds and the need for double documentation that might increase the administrative and cognitive workload, especially concerning medications and the lack of necessary templates in the medical record:

> *Above all, I would like access to the medication list. I know I won't, but it would make my job much easier since I organize the patients' pill box dispensers in their homes.* [Nurse, PCC2]

Design Quality

Before the implementation, there were some apprehensions regarding the system's maturity and that it might be slow and frustrating:

> *...that the software is only half-developed and not fully functional. (Physician, PCC 1). Several HCP were worried that the testing would be hampered due to immature technology: If it's malfunctional you won't use it much.* [Nurse, PCC 1]

Intervention Experiences

Overview

The semistructured interviews and the focus group showed that the users' needs and requirements were not sufficiently met by the mobile tool, largely because the mHealth app was not sufficiently adapted to the users' needs. There was, however, a notable difference between how the mobile tool was perceived by the HCP who worked where the intervention was first implemented and who had taken a more active role in the needs analysis and requirements specification, compared to those working where the intervention was later implemented. Those involved in the mHealth app's development and who were part of the initial implementation considered the app much more useful than those who had not been part of the development.

Relative Advantage

One of the nurses responded as follows:

> *Patient visits have become more complete, new questions that arise can be answered quickly.* [Nurse, PCC 1]

The HCP experienced that the mobile tool facilitated work processes and found it fulfilling to be able to answer questions from patients immediately. Another positive effect of the intervention was that it reduced the cognitive workload:

> *I don't need to bring notes that I will later have to remember to document separately on every patient.* [Nurse, PCC 2]

However, not all needs and requirements were met. The concerns about missing functions that were expressed before the implementation were confirmed. Several of the participants stated that the mHealth app needed further development and additional functions:

> *Honestly, it feels undeveloped. Several things are missing, like the medication list and x-ray results, which are important when you're in the patient's home.* [Physician, PPC 1]

Complexity

The limitations in functionality, with missing templates, lack of dictation functionality, and technical challenges with the smaller keyboard on the tablet computer, proved to be a confining factor:

> *The templates are a bit too, well...wrong. So, it becomes very limited, and then it feels easier to take notes by hand.* [Nurse, PCC 1]

Many of the HCPs also felt that their documentation became more concise, and that the on-site documentation in the app was preliminary and needed further development when they returned to the office:

> *The documentation may be a little shorter, sometimes the record entries become shorter.* [Nurse, PCC 1]

For some, the limitations in documentation functionality resulted in them not using that at all:

> *And still, for me, it is faster to dictate than to write. So, I do not write any record entries in the app. I use it to read record entries in the patient's home. Then it works well for the most part.*" [Physician, PCC 1]

XSL•FO
RenderX

Design Quality

The users were not impressed by the app's layout, especially the design of the laboratory results:

> *But you get for example all the hemoglobin results one after the other. It's difficult to read. Seven or eight rows of results for each blood test.* [Nurse, PCC 1]

The users did, however, feel that the design improved somewhat during the project.

Most of the HCPs experienced difficulties with the functionality and deemed the app immature and unstable.

> *Sometimes the internet connection has been bad. Sometimes the application does not work despite an adequate internet connection. It has happened that I have been able to access the medical record, but then it just stops working. I tap and tap but nothing happens. That's it.* [Physician, PCC 1]

Another user stated:

> *All too often it has not worked. Either the internet connection has been inadequate or there is no explanation why I can't log in.* [Nurse, PCC 1]

Outer Setting

In this domain, the expectations of the intervention coincided with the actual experiences of the intervention to a large extent. Textbox 2 shows the categories identified in the outer setting domain.

Textbox 2. Identified categories related to the Consolidated Framework for Implementation Research domain outer setting, divided by expectations before and experiences after implementation.

Expectations before implementation

- Technical infrastructure
  - Previous experiences among the staff with poor internet connectivity in the home care areas caused worry
- Patient needs and resources
  - Health care professionals looked forward to being able to use the mobile device as a tool for learning and patient communication
  - Being able to answer the patients' questions immediately

Experiences after use

- Technical infrastructure
  - Poor internet connectivity
- Patient needs and resources
  - Supports better work processes and improves patient safety.
  - Facilitates patient participation.

Preimplementation Expectations

HCPs were expressing concerns regarding the internet connectivity in the area but were also looking forward to using the mobile tool to meet the needs of their patients.

Technical Infrastructure

Network connectivity is limited in parts of the rural areas of the study setting, and since many of the HCPs had previous experiences with problems due to poor internet connectivity, concerns were expressed before the implementation:

> *The fear is the network connection. That's the thing, and it's hard to solve.* [Nurse, PCC 2]

Patient Needs and Resources

HCPs were hoping that the mobile tool would enable them to improve their communication with patients as well as the patients' participation in their care by using it as both a tool for learning:

> *And you may be able to show patients how to easily access sites for healthcare e-services* [Nurse, PCC 1]

and a means to answer questions asked by the patient:

> *Medical record entries may be useful when you're in the patient's home. Like if a patient asks, ' What did the doctor say at the last visit? I did not understand.'* [Nurse, MHCO]

Intervention Experiences

The HCP's expectations regarding the outer setting were fulfilled to a high degree.

Technical Infrastructure

The limited network connectivity was a real challenge when using the mobile tool. One of the users stated:

> *Our damn bad network connection has proven to be a huge, huge problem.* [Nurse, PCC 2]

Patient Needs and Resources

The staff experienced that the mobile tool supported better work processes and thus improved patient satisfaction:

XSL•FO
RenderX

> *communication with the patient runs smoother because I'm able to answer questions on-site, eg, concerning lab results.* [Nurse, PCC 1]

However, when the mHealth app did not work, it also sometimes rendered other, less positive questions from patients:

> *I've appreciated being able to answer a question that the patient has asked. But sometimes you get questions about the application when it doesn't work. A patient asked me - But if it does not work, why do you use it?* [Physician, PCC 1]

Inner Setting

Overview

All HCPs experienced that the mHealth app was not adapted to their workflow. Therefore, the mobile tool was not seen as entirely useful. This was especially apparent in the MHCO and for the participating physicians since important functions for their workflow were lacking to a larger extent than for the nurses in the PCCs. There were also implications that the implementation process would have benefited from a stronger commitment from the organization and some of the HCPs from the MHCO experienced that there was not enough time for training and preparation before the implementation. Textbox 3 gives an overview of the categories in this domain.

Textbox 3. Identified categories related to the Consolidated Framework for Implementation Research domain inner setting, divided by expectations before and experiences after implementation.

Expectations before implementation

- Structural characteristics
  - Concerns that there would be no time to complete the additional tasks required to manage the system
  - Concerns that the lack of home care visits would make the system less useful and rarely used

Experiences after use

- Structural characteristics
  - With more home care visits, the need for the system increased
- Networks and communications
  - Unclear responsibility and support functions
- Implementation climate
  - Same job, new technology

Preimplementation Expectations

Overview

There were no mentions of the inner setting during the preimplementation workshops, and predominantly concerns were raised.

Structural Characteristics

Staff from the PCCs expressed concerns that the app might not be very useful and that there would be few opportunities for usage due to the few home care visits in primary care. There were also concerns that the management of the app would create additional tasks that there would not be any time for:

> *We might not have time for the increased administration.* [Nurse, MHCO]

Intervention Experiences

The concerns were mostly addressed, but issues related to the support within the organization were also experienced.

Structural Characteristics

Staff who had used the mobile tool for some time reflected that it would be more useful with additional home care visits:

> *If I was to have homecare visits a whole day, day after day, then I think it would be good to be able to do all the documentation immediately. Then I think it really would improve patient safety.* [Nurse, PCC1]

Networks and Communications

The responsibility for technical support of the mobile tool and mHealth app was unclear to many of the participating HCP:

> *But I don't know where to turn for help when it doesn't work. Therefore, I have unfortunately not used it for more than a month.* [Nurse, PCC2]

Another person stated:

> *Well, it's like; who can you ask?!* [Nurse, MHCO]

Implementation Climate

In many ways, the implementation of the mobile tool did not change the HCP's perceptions of their work:

> *It's simply a new technology for the same job.* [Physician, PCC 1]

XSL•FO
RenderX

Characteristics of Individuals

As previously described, the user's tolerance for challenges differed. Some continued using the mobile tool despite difficulties, whereas others stopped using it. The categories related to this domain are presented in Textbox 4.

Textbox 4. Identified categories related to the Consolidated Framework for Implementation Research domain characteristics of individuals, divided by expectations before and experiences after implementation.

Expectations before implementation

- Knowledge and beliefs about the intervention
  - Concerns that the technology will steal time and focus from the patient
  - Concerns of becoming too dependent on the technology
  - Concerns that the project will amount to nothing
- Self-efficacy
  - To dare to try the new technology
- Individual stage of change
  - Looking forward to getting to test
- Individual identification with organization
  - Worry about personal responsibility for the devices

Experiences after use

- Knowledge and beliefs about the intervention
  - Positive that this type of intervention could provide benefit
  - Unreliable technology has required patience and persistence
  - Needs further development and additional functions
- Self-efficacy
  - Embarrassing when technology does not work
  - Improved work processes improve patient safety, credibility, and work satisfaction
  - Confidence in using mobile technology
- Individual stage of change
  - Not used to this way of working
  - Creates a need for new knowledge
  - Have not used the technology

Preimplementation Expectations

Before the implementation began, users expressed eagerness to test the tools they had been waiting for, despite the already described concerns relating to, for example, internet connectivity and mHealth functionality.

Knowledge and Beliefs About the Intervention

HCPs expressed concerns about whether the mobile tool would influence their relationship with the patients, worrying that the technology would shift time and focus from the patient to the technology. They expressed that "there might be too much focus on technology during the visits" (physician, PCC1), and that there could be a "risk for less contact with the patient if the tablet takes more time" (nurse, PCC4).

Another concern expressed was the risk of becoming too dependent on the technology:

> *To become dependent on the tablet, and then when it breaks down you don't know what to do.* [Nurse, MHCO]

Participants also expressed concerns that the technology might never be ready for use or that its functionality would be reduced to the point that the system would become unusable.

Self-Efficacy

Before implementation, the HCPs' expectations varied. Some were confident in their ability to use it, while others were a bit more hesitant and stressed that daring to try would be important:

> *One way is to just start using the tablet; perhaps it'll go better than we think…* [Nurse, MHCO]

XSL•FO
RenderX

Individual Stage of Change

Similarly, individuals' readiness to try the technology varied, but most were eager to start testing the mobile tools.

> *To dare to start using it and see what happens. I think there are several areas of use. You can find all sorts of online services [mentions Swedish e-health services such as the national patient portal, portals for ordering materials, and online prescription tools]. And perhaps you can help the patient to find the patient portal [1177.se] by using the tablet.* [Nurse, PCC 3]

Those involved from the start were more positive and eager to test the mobile tools, having waited a long time for the pilot to start, whereas the others were more hesitant.

Individual Identification With the Organization

Concerns regarding personal responsibility for the device were only raised during the preimplementation focus groups. Participants had concerns that they might forget the tablet at the patient's home, drop it, and break the screen. They worried this could be either a waste of resources for the organization or that they would personally be responsible for the costs.

Intervention Experiences

Although the participants' characteristics did not necessarily change during the implementation, their self-efficacy and beliefs about the intervention appear to have been affected.

Knowledge and Beliefs About the Intervention

The study participants remained positive that the intervention could provide benefits, for example, by making work processes more time efficient and improving patient safety. One of the participants who had used the tool the most said:

> *I don't have to prepare, which usually takes 5 minutes, to print eg, the list of medications, and the latest lab results* [Physician, PCC1]

Care planning in the patients' home was also experienced as more efficient:

> *I can finish it at the patient's home, with the patient. You can discuss what to do next, and then that's done.* [Physician, PCC 1]

To complete the work while in the field was experienced as reducing the risk of forgetting tasks or losing information:

> *[...] and for the patients and the staff [at the nursing home], that they don't have to remind me, 'did you remember that? now this hasn't arrived, why not?,' 'Oh, I didn't order that, I forgot, or I didn't see the note….' It feels more organized.* [Nurse, PCC 1]

However, dealing with unreliable technology required patience and persistence from HCP.

> *The biggest challenge has been not to lose your patience. It's like well, now it doesn't work. I must try the next time again, and the time after that. And that has been difficult since I usually only do this kind of work once a week, so it has been a challenge to not just give up but to instead try and try again.* [Nurse, PCC 1]

Only the most enthusiastic users had the patience to continue trying despite the unstable technology. The other users, especially those who worked in the MHCO, gave up on the first hurdle and never used the mobile tool.

Self-Efficacy

Unstable technology also affects the HCP's sense of professionalism and could be a cause for embarrassment in front of patients:

> *It feels embarrassing when it doesn't work when you use the tablet. I can live with that, but it's a little embarrassing. Then it would've been better not to have it [the mobile tool]* [Physician, PCC 1]

One of the HCPs had problems using the mobile tool in the presence of the patient's relatives:

> *That makes me stressed because the technology is new to me. When five people ask me questions at once. I haven't been able to handle that. [regarding not finding the necessary information on the mobile tool].* [Physician, PCC 1]

Those who did use the mobile tool found that it improved work processes, patient safety, credibility, and work satisfaction.

> *What's been very positive is that I can finish my work in the patient's home. I know that I won't forget anything. The patient won't be left without medications, which is good. Because it has been stressful before, I haven't always had the time to finish the work immediately when I'd returned to the workplace… so, I find it to be satisfactory as well, to be able to finish the job and not have any loose threads.* [Nurse, PCC 1]

They also felt confident using the mobile technology:

> *It's been good. It's easy to connect and I think it works well. I've not experienced any challenges* [Nurse, PCC 2]

However, there was a significant discrepancy between the two contexts, where the HCPs in the PCCs were much more positive. In the MHCO, most of the HCPs did not use the mobile tool at all.

Individual Stage of Change

As mentioned earlier, not all HCPs used the mobile tool:

> *I may have a maximum of five [patients]. And then I might as well remember that information or make some notes until I dictate [the record entries]* [Physician, PCC 1]

One reason was that the users were not used to this way of working. In some cases, the users did not like how record entries were presented:

> *I could edit the record entries later if I only write a few keywords [while in the patient's home]. But I don't know, I don't find the entries aesthetically*

XSL•FO
RenderX

> *appealing. I think they look much better when I do it my way.* [Nurse, PCC 2]

In other cases, they had no prior experience writing directly in the medical record, being used to dictating all record entries:

> *Well, I don't have that much experience. I know how to use the iPad, but it feels like I only use it to read record entries, not to write them myself. I usually don't [write record entries] so I don't do it here either.* [Physician, PCC 1]

The users believed there were other possible areas where the mobile tool could be useful:

> *I think it's more that you don't have enough imagination. You need to find other examples of what you can use it for. You just must use it more and discover even better ways of using it.* [Nurse, PCC1]

It was believed that it would be better to use the mobile tool regularly to reach its full potential:

> *If I had to use this every day, then maybe I would become more comfortable with it* [Nurse, PCC 1]

Process

The implementation process was not addressed in interviews with HCP, as this was not the focus of the original project. We will reflect on the implementation process in the discussion.

Discussion

Principal Findings

The implementation of the mHealth app was unsuccessful, despite reports of positive experiences and potential benefits. The main reason for the failed implementation was that the app did not sufficiently support the users' needs. Immature technology and unstable technical infrastructure also contributed. The findings from this implementation study highlight the critical importance of aligning digital health interventions with user needs and existing infrastructure, particularly in the context of aging populations and resource-constrained health care systems. For digitalization to be effective and sustainable, strategic approaches must prioritize usability, cross-organizational compatibility, and user involvement throughout development and implementation. Moreover, adequate resourcing—including time, training, and leadership engagement—is essential to prevent change fatigue and to ensure long-term adoption and impact of mHealth technologies.

Before implementation, HCPs had high expectations that the app would facilitate work processes and reduce cognitive workload by allowing real-time access to information. There were also concerns, mainly due to prior experiences of poor internet connectivity and immature and unstable technology, but also that the app might increase the workload, shift time, and focus from the patient, and that the project would amount to nothing. Ultimately, both expectations and concerns were confirmed. Another preimplementation concern expressed by some HCPs was that they would become too dependent on the new technology. This was not brought up again postimplementation, and we interpret this as being due to the failed implementation. The concern could have negatively influenced the HCP's willingness to adopt the technology, but likely this was not the most important factor for the failed implementation.

Some users, particularly those involved in the mHealth app's development, found value in the app despite its shortcomings and kept trying time after time, undeterred by the immature technology. However, users who worked in the MHCO and had not been involved in the design process gave up at the first hurdle and did not use the mobile tool. Data on usage of the mHealth app, for example, the number of log-ins per day or number of active users, were not available during the implementation process. Access to such data could potentially have guided the implementation process so that action could have been taken when usage was low [26].

End user involvement in the design process, often referred to as participatory design [27-29], has proven to be essential in both ensuring that the software meets the end user's needs and supports their work processes, and increases acceptance among the users [30,31]. In addition to the difference in participation during the development process, the MHCO also used another EHR system in their daily work that was not integrated with the mobile system. The benefit of being able to at least begin documentation in the patient's home was lost to them, further lowering their incentives to engage with the system. Lack of interoperability and integration between eHealth systems has previously been identified as an important barrier to successful implementation [16]. Physicians who made few home visits and used dictation for EHR documentation in everyday work found the mHealth app less useful. Again, the importance of capturing the perspectives of all potential end users in the design process was highlighted [31,32].

There are several lessons to be learned from this. First, that outcome depends on context, and second, that user engagement in both the development and the implementation processes is crucial for a successful implementation. In our study, both lack of user involvement [30,33] and poor interoperability [7,17] hurt the acceptability of the system, contributing to a system that did not support the user's work processes [24]. The importance of an interoperable digital health ecosystem is stressed in the World Health Organization digital health strategy, defining it as a "digital interoperable information technology infrastructure that is primarily used by the health care community across all care settings, in particular by health care providers, health service providers and patients" [4]. With such an infrastructure in place, the integration and implementation of the mHealth app would likely have been more successful. The lengthy development and implementation process also affected user engagement negatively. Studies of user involvement's relationship with user satisfaction have indicated that user involvement can overcome frustration from delays and prolonged projects [30]. In our study, we did see higher user satisfaction and tolerance among users who had been more actively involved in the design process, but it was not enough to overcome the implementation challenges completely. Additionally, for less engaged staff, the barrier to start using a new technology was high, and they also had a greater need for additional support, whereas users with high engagement, often

XSL•FO
RenderX

referred to as “champions” in the implementation science literature, kept trying regardless and often found new areas of use for the technology. The most common reason for discarding an eHealth service is issues with the technology [19,34]. eHealth services often are premature and thus do not adequately support the work in home care [19]. Technical issues [19] include everything from a lack of suitable infrastructure to usability issues, the latter referring to whether the product provides the right utility and the degree to which it helps users reach their goals in an effective, efficient, and safe manner, while still being easy to learn and remember how to use [35]. Usability of the mHealth app should have been evaluated more extensively before the implementation, for example, through user-driven scenario-based usability testing [36], or expert- or user-driven heuristic evaluations [37,38].

In our case, considerable problems with internet connectivity, immature technology, and a lack of functionality contributed to the low app usage.

Other studies and reviews confirm the challenges described by the users in this study. User involvement, interoperability, reliability of connection, and technology and infrastructure can be considered facilitators if handled appropriately in the implementation of eHealth, or barriers if they are not considered [12,17]. In a review of 43 studies of mHealth implementation experiences from primary health care services, the main results were that health workers appreciated mHealth when it improved feedback, speed, and workflow [17]. Challenges stated were that mHealth sometimes created more work, resulting in some preferring paper instead. Some health workers found the decision support opportunities useful, and others thought it threatened their clinical skills [18]. The aspect of workflow was found substantial for the success or failure of eHealth interventions particularly if workload increased, if workflow was interrupted, and if there was an alignment with clinical processes [17].

CFIR Suitability for mHealth Implementation

CFIR is developed to study implementation processes, not specifically new technology. We chose to include “technical infrastructure” as a new construct in the domain “Outer setting” since the effect of new technology depends on its functionality. A more specific focus on the usability of the eHealth or mHealth intervention could also be included under intervention characteristics, but we chose to use the “design quality” construct here.

The implementation process is crucial for the success of an implementation and for a successful implementation, all stages of the implementation must be properly executed. Our study was not originally designed to study the implementation process, and subsequently, material on some aspects of the implementation process is missing since no questions regarding those aspects were asked in the interviews. We see, however, that the implementation of the mobile tool most likely would have benefited from better planning, execution, support functions, and resources. When implementing complex interventions, feasibility and pilot studies are essential [35,39]. This is especially important when implementing mHealth where lack of usability is often the cause of failed implementations. This could be further specified in the CFIR domain “process” when studying new technology. A specific challenge of implementing the mHealth app in a rural home care area was the physical distance between units and the challenges of keeping day-to-day contact with and providing support to the HCP. The need for a specific facilitator role, that is, a person dedicated to supporting the implementation process and ensuring problems are identified and addressed, was apparent, as is also stressed in other implementation theories, for example, the Promoting Action on Research Implementation in Health Services (PARIHS) framework [40]. In line with the integrated-Promoting Action on Research Implementation in Health Services (i-PARIHS) framework and other implementation models, the facilitator role typically requires a combination of technical, organizational, and interpersonal competencies. Core competencies include basic technical troubleshooting and familiarity with the intervention, skills in user training and coaching, and the ability to communicate effectively across different organizational levels, including leadership. Responsibilities often span the entire implementation process: supporting planning and readiness activities before rollout, providing hands-on assistance and problem-solving during implementation, and ensuring ongoing support and feedback loops during maintenance. While the exact scope and emphasis of these tasks must be adapted to the local context and resources, these elements are commonly highlighted as critical for successful implementation.

There is a strong belief in the potential for eHealth and the introduction of new technology to revolutionize health care and that it will be necessary for health care and primary care in the future [4]. The introduction of new technology, however, often fails [17,41], and there is a risk that premature implementation of new technology will exhaust HCP for future projects and implementation. The challenges and concerns must be considered to move forward successfully [15]. According to the CFIR [23,42] and i-PARIHS [40] frameworks, the individuals’ previous experiences and beliefs about the intervention will impact the implementation’s success. When HCPs are exposed to immature digital solutions with poor usability, we may risk a negative impact on future implementation and innovation projects. To avoid this, we conclude that it is important to ensure that new technology has the necessary functionality and stability before implementation and that there are routines in place in the organization to guide decision-making and implementation processes. Structured contingency planning for technical failures, such as providing clear fallback procedures, timely support, and communication strategies, could sustain user engagement by reducing frustration, maintaining workflow continuity, and reinforcing trust in the implementation process despite technological setbacks.

Strengths and Limitations

The study was guided by the CFIR framework, which is a well-established model for understanding implementation processes [23]. This adds theoretical rigor and structure to the analysis, ensuring that a broad range of influential factors is considered. In our analysis, we used the original CFIR framework which was available when we began our analysis. More recent versions of the framework [42] have added new constructs; however, the domains remain the same, and we

XSL•FO
RenderX

believe that using the most recent version of CFIR would not have substantially influenced our results.

The use of interviews (both individual and focus group) allowed for an in-depth exploration of the HCPs' experiences and perspectives. This is particularly useful given the small number of users of the mHealth app, making qualitative methods appropriate for capturing rich, detailed insights. The study also collected data from both nurses and physicians across different settings (PCCs and MHCO), which ensured a variety of perspectives were included in the analysis. The small sample size (8 nurses and 1 physician from each of the two groups) may limit the generalizability of the findings to other settings or health care systems. Additionally, the majority of participants were female, which may impact the diversity of perspectives, yet it reflects the current workforce in Swedish home care. To maintain anonymity, the study does not report detailed demographic information about participants, such as years of experience, which could be useful for understanding how these factors might influence perceptions of the mHealth app. We also do not include any quantification of responses, which means that while rich qualitative data were captured, the relative importance of different factors or themes was not assessed. This could limit the ability to weigh certain barriers or facilitators more heavily than others; however, considering the qualitative nature of our dataset, we argue that this is the best approach as quantifying the results may be rather misleading. Using a validated instrument to measure health care professionals' self-efficacy could be a way to further understand how self-efficacy impacts adoption and abandonment, and how it may change over time during an implementation project. This should be explored further in future research.

A strength of the study is that the data collection spanned several years, and follow-up interviews after 6 months of using the mobile tool captured longer-term experiences and effects, offering insights into sustained usage and challenges. However, the study took place from 2015 to 2017, with final data collection in 2018, which could render the results of the study out of date. Yet the findings remain highly relevant in today's digital health landscape. Despite technological advancements, the fundamental implementation challenges we identified, such as poor alignment with clinical workflows, limited user engagement, inadequate training and support, and insufficient organizational readiness, persist in contemporary mHealth and eHealth initiatives. Implementation projects continue to experience implementation challenges across diverse settings, also in large-scale initiatives. For example, recent EHR rollouts in Sweden [43], Norway [44], and Finland and Denmark [45] encountered major disruptions due to user dissatisfaction, lack of preparation, and technological shortcomings. These cases underscore the enduring importance of addressing the sociotechnical and organizational dimensions of digital health implementations.

The first author was involved in the needs and requirement analysis for the mHealth app and also conducted the interviews. This dual role might introduce potential bias into the data collection and analysis process, as prior involvement may influence how the data are interpreted or what aspects are emphasized. Throughout the analysis process, we have been vigilant about this, and the involvement of Master's students with no prior connection to the project facilitated an unbiased data collection. The first author's familiarity with the context and the app has also been an enabling factor, to both data collection and by facilitating insights into both the design and implementation processes that would otherwise have been challenging to obtain in retrospect.

These strengths and limitations provide important context for interpreting the findings of the study and considering its applicability to broader implementation efforts.

Conclusions

We conclude that new technology must be stable and have the desired functionality before implementation for success. The functionality of a new technology must support the users' needs and be sufficiently integrated with other IT systems in the health care organization. How the implementation process is executed is important, but the implementation will not be successful if the new technology does not properly support the users' needs. In the case presented here, implementation failed because the technology was unstable and thus unreliable, not sufficiently supportive of the users' needs, and not adapted to the users' workflow. There were, however, positive experiences too, and mHealth still has a strong potential to support HCPs working in home care. To achieve this potential, we must ensure that sufficient resources are allocated to both design and development, evaluation and feasibility studies, and support and engagement during the implementation of mHealth in the future.

Acknowledgments

We thank Gabor Revay and Richard Scholvin at the Department of eHealth and IT, Region Stockholm, Health Care Service, Sweden, for their support and work on the project. We also thank the Master's students Sofia Rosborg (who continued working as a research assistant in the project) and Malin Lindberg for their contributions to the project.

We used generative artificial intelligence technology Grammarly (Grammarly Inc) to enhance the grammatical accuracy and vocabulary richness.

Funding

This work received funding from Innovationsfonden (20151143), FORTE – the Swedish Research Council for Health, Working Life and Welfare supports "MobEVAL" (2017- - 01962), and AFA Försäkring "ePrIm" (190210).

Abstract

Background: Integrating electronic patient-reported outcomes (ePROs) into electronic health records (EHRs) can enhance the quality of patient care. However, collecting longitudinal ePRO data throughout treatment and posttreatment surveillance remains challenging in patients with breast cancer. To address this, we implemented an automated system that enables ePRO acquisition and seamless integration into the EHR. The system delivers questionnaire weblinks via a mobile messaging app, allowing patients to complete ePROs before clinic visits, with responses automatically transferred to the EHR.

Objective: This study aimed to assess patient response rates to the ePRO system and identify key factors influencing the response rate among patients with breast cancer who received radiotherapy and postradiotherapy follow-up.

Methods: We conducted a retrospective analysis of prospectively collected ePRO data by using the BREAST-Q questionnaire, a validated patient-reported outcome measure for breast surgery, from patients who received adjuvant radiotherapy at our institution between May 2023 and April 2024. At a preradiotherapy or postradiotherapy visit, each patient was asked to complete the questionnaire via a weblink sent to their mobile messaging app, KakaoTalk. The questionnaire was dispatched from minutes to several days before each visit. The response rate was calculated as the percentage of patients whose responses were successfully recorded in the EHR among those who were requested to respond. A complete response (CR) was defined as completion of all required questionnaire items. CR rates were analyzed according to clinical factors using univariate and multivariate logistic regression.

Results: Data from 1488 patients were analyzed, encompassing 2431 encounters (median 1, IQR 1-2 per patient). The median age of the patients was 51 (range 23-83) years, with 65.1% (n=968) patients aged 40 to 59 years. Comorbidities were present in 15% (223/1488) of the patients. The CR rate for the first, second, and third ePRO encounters was 89.9% (1338/1488), 98.3% (735/748), and 97.3% (180/185), respectively. Among first-time respondents, younger patients had a significantly higher CR rate (patients aged <60 years: 100/1104, 90.9%; patients aged ≥60 years: 334/384, 87%; *P*=.03). The timing of the questionnaire dispatch also affected the CR rate (*P*<.001). The CR rate was the highest when questionnaires were sent more than 1 hour before the visit (547/583, 93.3%) or in the afternoon of the previous day (505/545, 92.7%) and the lowest when sent 2 or more days before (100/130, 76.9%) or within 1 hour before the appointment (92/112, 81.7%). Both age (*P*=.006) and timing (*P*<.001) remained significant in the multivariate analysis.

XSL•FO
RenderX

Conclusions: This study demonstrates the feasibility of integrating ePRO into EHR through a mobile messaging app–based system, with high patient adherence. Response rates were significantly influenced by patient age and the timing of questionnaire dispatch. These findings provide practical insight for optimizing ePRO implementation in routine oncology care.

Introduction

Background

Breast radiotherapy is an essential element in the management of breast cancer, as it enables breast conservation by eliminating microscopic tumor foci following tumor resection and prevents locoregional recurrence, leading to improved survival [1,2]. With advances in multimodality treatment, survival outcomes for patients with breast cancer have substantially improved over the past decades [3,4]. As survival extends, radiotherapy regimens have evolved to minimize treatment-related toxicity while maintaining tumor control [5]. Therefore, capturing toxicity profiles and patient satisfaction is critical for optimizing radiotherapeutic approaches. To achieve this, the incorporation of patient-reported outcomes (PROs) has become increasingly important for individualized counseling and shared decision-making [6].

Despite growing consensus on the value of electronic PROs (ePROs), their routine adoption in oncology remains limited. Collecting longitudinal ePRO data across active treatment and long-term follow-up is particularly challenging, as survivors of breast cancer often require monitoring for more than a decade after completion of primary treatment [7,8]. Previous studies have highlighted several barriers to sustained ePRO use, including workflow burden on clinicians, lack of integration with electronic health records (EHRs), and patient fatigue over repeated reporting [9-12]. Most existing ePRO systems operate as stand-alone or web portal–based platforms, requiring separate log-ins or additional applications, which hinders seamless use during clinical visits [9-11]. As a result, adherence to ePRO completion varies widely, ranging from 27% to 95% across populations with cancer [13-17], and evidence on how to maintain high adherence in daily oncology practice is still lacking.

To address these gaps, we developed and implemented an automated EHR-integrated ePRO system that delivers questionnaires via KakaoTalk (Kakao Corp), the most widely used mobile messaging app in South Korea [18]. This study evaluated the feasibility of this platform by assessing response rates and identifying clinical and contextual factors associated with ePRO adherence among patients receiving postoperative adjuvant breast radiotherapy and follow-up. For an assessment of the feasibility of the ePRO system, the response rate was considered the primary indicator, as it reflects both patient adherence and the sustainability of the platform in routine clinical practice. Consistent with previous ePRO implementation studies [9,10,14,15,17], the response rate has been widely used as a practical measure of feasibility, representing patient engagement, system usability, and operational sustainability within clinical workflows. A consistently high response rate across visits would indicate that the system can be feasibly integrated into long-term follow-up, whereas lower or variable rates would highlight barriers that require further optimization. In addition, factors influencing feasibility were examined by analyzing both clinical and contextual variables that might affect adherence. Clinical variables, such as age, type of surgery, histology, and comorbidities, were considered because they may influence treatment-related experiences and patients' ability to engage with the ePRO systems. Contextual factors, including previous exposure to other ePRO systems and the timing of questionnaire requests, were analyzed because they are expected to directly influence adherence and response behavior.

Study Objective

This study aimed to evaluate the feasibility of integrating an ePRO system directly into the EHR through a mobile messaging app by assessing patient adherence and identifying clinical and contextual factors associated with ePRO completion among patients with breast cancer undergoing postoperative adjuvant radiotherapy and follow-up.

Methods

Participants and Study Design

This study was conducted at the Samsung Medical Center, a large tertiary referral hospital in South Korea, with a comprehensive cancer center located in Seoul. Located in an urban area, the institution serves as a nationwide referral center, providing care to a high volume of patients with cancer from both urban and rural regions. As of 2021, approximately 31,000 patients—representing about 11% of all patients with cancer in South Korea—were treated at the Samsung Medical Center [19]. Between May 2023 and April 2024, ePRO questionnaires were distributed to patients visiting the Department of Radiation Oncology for postoperative adjuvant radiation treatment for breast cancer. These visits included both preradiotherapy evaluations and postradiotherapy follow-ups for surveillance. A weblink connected to the ePRO questionnaires was sent to each individual's KakaoTalk mobile messaging app before their appointment with the attending physician, and patients were asked to respond to the questionnaires through the app. KakaoTalk is a free mobile messaging app used by more than 90% of the Korean population across all age groups and has been widely incorporated into both personal and institutional services. Its functions extend beyond instant messaging to include secure log-in verification, payment systems, and government or health care notifications [20,21]. Because of its

XSL•FO
RenderX

nationwide penetration and user familiarity, the app enables seamless integration of digital health tools, such as ePRO questionnaires, without requiring additional software installation or user registration. The dispatch of the questionnaires was managed by nurses or physicians through a system deployed in the EHR before each patient's visit. The timing of sending the questionnaire varied depending on the sender's preference, ranging from days to minutes before the visit, with no predefined time points. On the day of the visit, an outpatient receptionist or nurse checked whether the questionnaires had been completed. If the questionnaires were incomplete, the receptionist or nurse briefly asked the patient to complete them before the physician's session.

During the study period, the adaptation of the ePRO platform into daily clinical practice varied among the radiation oncologists in our department. Some began using the platform at the beginning of the study period, while others adopted it later. Once a radiation oncologist initiated use of the system, all eligible patients assigned to them were requested to complete the ePRO questionnaires, regardless of individual characteristics. As a result, not all patients with breast cancer visiting our department were uniformly invited to complete ePRO questionnaires. Instead, the number of patients with breast cancer undergoing radiotherapy who were requested to submit ePROs increased toward the latter part of the study period.

After an outpatient visit for preradiotherapy evaluation, patients received radiation treatment according to our institutional protocol. Radiotherapy was administered once daily for 5 consecutive days, with 3 to 19 fractionations over a period of 1 to 4 weeks. Fractionation schedules were determined based on tumor stage, surgery types, the inclusion of regional nodal irradiation, and other risk factors. After completing the treatment, patients were followed up for 2 to 3 weeks after treatment and subsequently every 6 months. ePRO data were collected at the preradiotherapy visit, the immediate postradiotherapy visit at 2 to 3 weeks after treatment, and every 6 months thereafter. As each patient was required to respond to a questionnaire at each hospital visit, 1 or more questionnaires were requested to be completed by each patient during the period of this study.

A System for ePRO Collection and Storage in the EHR

A system for ePRO acquisition and integration with the EHR was developed as an in-house model at our institution. The system links our hospital's EHR with the individual's mobile messaging app for collecting and storing ePRO data. Data entry is performed through the messaging app on the patient's mobile phone, while the data presentation and storage are conducted in our hospital's EHR. A section dedicated to ePRO is integrated into the EHR, allowing physicians and other medical staff to send new ePRO questionnaires on request and view each patient's responses at any time (Figure S1 in Multimedia Appendix 1). When medical staff select ePRO questionnaires and dispatch them through the EHR, a weblink for the ePRO questionnaires is sent to the patient's messaging app. The patient can open the link by entering their date of birth and submit their response to the questionnaire, which is in the form of checkboxes (Figure S2 in Multimedia Appendix 1). The patient's responses are automatically transferred to the ePRO section of the EHR and stored in the hospital's data warehouse. This process of entering, transferring, and storing ePRO data occurs simultaneously in real time, enabling physicians to view the content and time stamp of the data in the EHR.

For the PRO instrument used in this study, we used the Korean version of BREAST-Q (version 2.0) postoperative scale, including modules for breast-conserving therapy, mastectomy, and reconstruction. Among the domains of these modules, the following were used for our patients: satisfaction with breasts, satisfaction with implants, physical well-being of the chest or upper body, and adverse effects of radiation [22,23]. Patients who visited for preradiotherapy evaluation were asked to complete a questionnaire without the domain of adverse effects of radiation, while those attending for postradiotherapy surveillance received a questionnaire that included the domain.

Assessment of the Response Rate and Influencing Factors

Response rate was calculated as the percentage of patients whose responses were successfully recorded in the EHR among those who were requested to respond to the questionnaires. The response rate for each survey encounter was assessed and compared according to the number of encounters, from the first to the third. Because the current analysis was based on surveys conducted over 1 year, most of our patients encountered the questionnaires 1 to 3 times according to the scheduled follow-up interval. We classified response status into 3 categories: complete response (CR; all questions answered), partial response (PR; at least 1 question answered but not all), and no response (NR). In addition, when analyzing significant factors influencing CR, we divided our patients into 2 groups: complete responders and noncomplete responders, with partial responders and nonresponders merged into the noncomplete responder group.

To determine the significant factors influencing CR, we compared the CR rate according to various factors, focusing only on patients who encountered the survey for the first time. Specifically, to assess the impact of questionnaire request timing before a visit appointment, the timing was categorized into 5 groups: within 1 hour of the appointment time (≤1 hour on the day), more than 1 hour before the appointment on the visit day (>1 hour on the day), in the afternoon of the day before the appointment (PM the day before), in the morning of the day before the appointment (AM the day before), and 2 or more days before the appointment day (≥2 days before). In addition, patients who had previous experiences responding to questionnaires requested from other departments in our hospital were categorized as previous other ePRO (+), while those without the experiences were categorized as previous other ePRO (–). Finally, patients with any of the following diseases were categorized as having comorbidity: diabetes, cardiovascular disease, chronic pulmonary disease, hepatic disease, renal disease, or other cancers.

Statistical Analysis

For the univariate analysis, Fisher exact test was used to compare the CR according to clinical and contextual variables, including age, type of surgery, histology, comorbidities, previous

XSL•FO
RenderX

ePRO experience, and the timing of questionnaire requests. Age was categorized using a 60-year cutoff for univariate analysis and treated as a continuous variable in multivariate models. Patients with missing data for a given variable were excluded from the study. Factors with $P<.10$ in univariate analyses were included in the multivariate logistic regression model to adjust for potential confounding effects. All P values were 2-sided, with $P<.05$ considered statistically significant. All analyses were performed using SPSS software (version 27; IBM Corp).

Ethical Considerations

This study was approved by the institutional review board of the Samsung Medical Center (institutional review board approval number 2024-07-147-001). The analysis was conducted retrospectively using deidentified ePRO data collected during routine clinical care, and the need for informed consent was waived by the institutional review board. All patient information was deidentified before analysis to ensure privacy and confidentiality. No personal identifiers were included in the downloaded dataset. No compensation was provided to patients for participation, as the data were collected as part of standard clinical procedures without additional burden or intervention.

Results

Patients' Characteristics

A total of 2334 patients with breast cancer attended our department during the study period. Of the 2334 patients, 1491 (63.9%) with nonmetastatic breast cancer were invited to complete the ePRO survey. This difference reflects the gradual adoption of the ePRO system among physicians, as the platform was implemented in stages and not all attending radiation oncologists had begun using it at the start of the study period. A total of 3 (0.2%) patients were excluded from the analysis due to missing time records of their questionnaire responses, resulting in 1488 (99.8%) patients being included in this study. Among them, 740 (49.7%) encountered 1 survey, 563 (37.8%) encountered 2 surveys, 175 (11.8%) encountered 3 surveys, and 10 (0.7%) encountered 4 surveys, resulting in 2431 survey encounters.

The characteristics of the 1488 patients are summarized in Table 1. The median age was 51 years, with most of the patients (n=968, 65.1%) aged between 40 and 59 years, and 41 (2.8%) patients were aged 75 years or older. Most patients underwent breast-conserving surgery (n=1186, 79.7%) and had invasive carcinoma (n=1342, 90.2%). Comorbidities were found in 223 (14.9%) patients, including diabetes (n=98, 6.6%); cardiovascular disease (n=67, 4.5%); chronic disease of the liver, lung, or kidney (n=63, 4.2%); and other cancers (n=26, 1.7%).

[a]The timing of the questionnaire requests before a visit appointment was categorized as follows: within 1 hour of the appointment time (≤1 hour on the day), more than 1 hour before the appointment on the visit day (>1 hour on the day), in the afternoon of the day before the appointment (PM the day before), in the morning of the day before the appointment (AM the day before), and 2 or more days before the appointment day (≥2 days before).

Response Rate and Influencing Factors

Of the 1488 patients who encountered the questionnaires for the first time, 1338 (89.9%) exhibited CR, 35 (2.4%) submitted PR, and 115 (7.7%) did not respond to the questionnaire. The response status and rates according to the number of survey encounters are shown in Figure 1.

XSL•FO
RenderX

Figure 1. Rates of complete response (CR), partial response (PR), and no response (NR) for electronic patient-reported outcomes surveys across first, second, and third requests.

In the univariate analysis of factors influencing CR, the following were statistically significant: patient's age, type of visit, and the timing of the questionnaire requests before a visit appointment (Table 2). The CR rate was 90.9% (1004/1104) in patients younger than 60 years and 87% (334/384) in those aged 60 years or older (P=.03), indicating that older age was associated with lower completion. A significantly lower CR rate was also observed in patients receiving the questionnaire at the preradiotherapy visit (837/946, 88.5%) compared to the postradiotherapy visits (501/542, 92.4%; P=.02).

≥2 d before	100 (76.9)	30 (23.1)	

[a]CR: complete response.

[b]The timing of the questionnaire requests before a visit appointment was categorized as follows: within 1 hour of the appointment time (≤1 hour on the day), more than 1 hour before the appointment on the visit day (>1 hour on the day), in the afternoon of the day before the appointment (PM the day before), in the morning of the day before the appointment (AM the day before), and 2 or more days before the appointment day (≥2 days before).

Notably, the timing of the questionnaire requests had a strong influence on CR. Patients who received the questionnaire more than 1 hour before the appointment or in the afternoon of the previous day showed the highest CR rates at 93.3% (547/583) and 92.7% (505/545), respectively. In contrast, the lowest rates were seen in those who received the questionnaire 2 or more days before (100/130, 76.9%) and within 1 hour of the appointment (94/115, 81.7%; *P*<.001).

In the multivariate analysis, age and the timing of the questionnaire requests remained significant influencing factors for CR. Old age (odds ratio 0.98, 95% CI 0.96-0.99; *P*=.006) and questionnaire request timing of ≤1 hour on the day of the visit, AM the day before, or ≥2 days before the appointment (odds ratio 0.32, 95% CI 0.22-0.45; *P*<.001) were significantly associated with a lower CR rate (Table 3).

XSL•FO
RenderX

Table 3. Multivariate analysis of factors affecting the complete response to the electronic patient-reported outcome questionnaire.

Characteristics	Odds ratio (95% CI)	*P* value
Age (y): continuous	0.98 (0.96-0.99)	.006
Type of surgery: breast-conserving surgery vs mastectomy or reconstruction	0.64 (0.39-1.05)	.08
Type of visit: preradiotherapy evaluation visit vs postradiotherapy follow-up visit	1.33 (0.90-1.97)	.15
Timing of the questionnaire requests[a]: ≤1 h on the day or AM the day before or ≥2 d before vs >1 h on the day or PM the day before	0.32 (0.22-0.45)	<.001

[a]The timing of ePRO requests before a visit appointment was categorized as follows: within 1 hour of the appointment time (≤1 hour on the day), more than 1 hour before the appointment on the visit day (>1 hour on the day), in the afternoon of the day before the appointment (PM the day before), in the morning of the day before the appointment (AM the day before), and 2 or more days before the appointment day (≥2 days before).

Discussion

Principal Findings

Patients using our ePRO system, which links a commercial mobile messaging app with our hospital's EHR, showed an 89.9% (1338/1488) CR rate for the BREAST-Q questionnaires. Responses of patients who visited our radiation oncology department for breast cancer management were successfully recorded. The response rate to the questionnaires increased as the number of survey encounters increased. Age of 60 years or older was associated with a lower rate of CR; however, 87% (334/384) of participants of this age group provided appropriate responses to the questionnaires delivered through their mobile messaging app, even if it was their first time encountering the questionnaires using the app. Notably, the timing of the questionnaire requests significantly influenced the CR rate, with a higher CR rate of more than 92% observed when the questionnaires were requested more than 1 hour before the scheduled visit or in the afternoon of the day before the appointment. Given these findings, our ePRO system shows potential as a feasible platform for ePRO collection and integration with the hospital's EHR. In addition, the factors identified as significantly affecting the CR rate of the questionnaires can be used to guide improvements in responses to ePRO questionnaires in daily practice.

Comparison With Prior Work

The significance of PRO measurement in oncology care has been increasingly emphasized in recent years [24]. In this regard, the European Society for Medical Oncology released a clinical practice guideline concerning the use of PRO in the continuum of cancer care, emphasizing the essential role of symptom monitoring via PRO measurements [25]. ePRO offers several advantages, such as greater patient preference and acceptability, lower human resource costs, and higher data quality [9,11]. Various forms of ePRO collection platforms, including web-based and app-based systems, have been developed and used [13,14,26]. In addition to the data collection system, integrating the data into the EHR is essential to facilitate the incorporation of ePRO into clinical practice [9-12].

In this analysis, we found favorable patient adherence to our ePRO system, with more than 89.9% (1338/1488) CR rate for the ePRO questionnaires, even at the first encounter. This promising result is attributed to adopting a system that uses the KakaoTalk messaging app, which was familiar to our patients [18]. Patients were able to access the questionnaires using the existing app on their smartphone, without the need to install an additional app for ePRO. Because the message with the questionnaire link was sent under the hospital's name, our patients likely accepted it confidently, without concerns about cybercrimes. Moreover, given that more than 94% of Koreans own a smartphone, ePRO questionnaires delivered via the mobile app could effectively encourage responses from our patient population [27]. According to previous studies, ePRO adherence rate among patients with cancer has been reported to range between 27% and 95% [13-17]. In a study conducted in the United States, ePRO adherence rates ranged from 27% to 70%, following administration either on-site via tablet or remotely via a patient portal. There were significant differences in response rates depending on patient age and race, with older patients aged 65 years and older and non-White individuals being negatively associated with adherence to ePRO [14]. Meanwhile, a Japanese study reported a 95% ePRO adherence rate via a mobile messaging app, LINE, from 40 participants, which was similar to our patients' adherence rate [16]. Considering that LINE is used by more than 70% of the Japanese population, the familiarity with the ePRO acquisition tool likely contributed to the high ePRO adherence in their study [28]. Taken together, these findings suggest that selecting appropriate tools for ePRO administration based on respondents' demographic or cultural characteristics is essential for achieving favorable ePRO acceptance.

Older age has been reported to be significantly associated with lower adherence to ePRO [13,14,17]. In a prospective study conducted among French patients aged 75 years and older, 26% of the participants accepted ePRO, which was conducted remotely using a web-based app [13]. More than 52% of the participants did not respond to the ePRO due to technological issues, such as a lack of internet access or discomfort with using the internet [13]. In addition, a study performed in the United States showed that patients aged 65 years or older exhibited a 6% decrease in adherence to ePRO, which was a significant difference compared to younger patients [14]. Similarly, in our study, patients aged 60 years or older showed a significantly lower CR rate for ePRO than those younger than 60 years. However, considering that 87% (334/384) of the older participants completed the questionnaires, the ePRO acceptance using our system appears favorable even among older patients. In our study, ePRO was requested from all patients attending

XSL•FO
RenderX

our department, without selection based on their smartphone possession or daily internet use. Furthermore, given that more than 90% of Koreans aged 60 years or older use smartphones [29,30] and most are reported to be familiar with KakaoTalk [31], the ePRO acceptance among our older participants likely reflects the real-world feasibility of implementing ePRO in clinical practice for older Korean patients, particularly when it is delivered through the familiar messaging app. In the meantime, we also found that 13% of patients in this older age group did not properly respond to ePRO, suggesting that there is room for improvement in enhancing ePRO adherence among older patients. It is uncertain why these patients did not respond to the ePRO measurements, as we did not assess the reasons for nonresponse to the questionnaires. However, referencing previous studies, various factors have been identified that affect ePRO acceptance in older patients, including frailty level, socioeconomic status, technological barriers, and the modes of ePRO administration [13,30,32]. Future studies are needed to determine the causes of nonadherence to ePRO and to provide the most appropriate ePRO collection modalities based on the individual characteristics of older Korean patients undergoing cancer treatments.

Optimizing ePRO Response Through Timing

Interestingly, we found that the timing of ePRO requests was significantly related to the patient's CR rate. The most appropriate time for requesting ePRO questionnaires was either more than 1 hour before the appointment or in the afternoon on the day before the scheduled visit. This finding suggests that patients may feel more comfortable and have sufficient time to review and respond to ePRO requests when they are delivered within this timeframe. Delivering ePRO questionnaires more than 2 days before a scheduled visit may have hindered appropriate responses, possibly due to difficulties in locating our ePRO request message among other personal messages. As our patients' ePROs were collected remotely using a mobile app and their completeness was rechecked on-site in our clinic, it is likely that our ePRO acceptance rate is higher than that reported in settings relying solely on remote ePROs collection. This may be indirectly supported by the CR rate of 76.9% (100/130) among our patients who received ePRO questionnaires more than 2 days before an appointment. However, from another perspective, the combination of remote ePRO collection via a messaging app, requested within a specific timeframe, and on-site feedback appears to be an effective strategy for maximizing ePRO acceptance, as indicated by a CR rate of more than 93.8% (547/583) among our patients.

Strengths and Limitations

A key strength of this study is the provision of real-world data on ePRO adherence and the identification of significant factors influencing adherence among 1488 patients with nonmetastatic breast cancer following implementation of an in-house ePRO platform. Because our ePRO platform uses a messaging app that is largely familiar to Koreans, we observed a favorable acceptance for the ePRO. However, we acknowledge the limitations of this study. Our data were retrospectively derived from a single institution over a 1-year data collection period. Therefore, the data may be insufficient to capture long-term ePRO adherence among general patients with breast cancer. In addition, reasons for PR or NR to ePRO questionnaires were not available, as this analysis was conducted retrospectively. Because the causes of incomplete ePRO are important for identifying areas of improvement in enhancing ePRO adherence, further assessments are necessary among those submitting PR or NR to ePRO questionnaires in future studies. Furthermore, because our ePRO platform relies on a specific mobile messaging app—KakaoTalk, which is predominantly used in South Korea—its general acceptance in other countries remains uncertain. Therefore, the generalizability of our findings to other populations with different digital habits may be limited. In addition, technological barriers or disparities in mobile access may have also influenced patient participation and response accuracy. Moreover, as all our ePRO data were self-reported, reporting bias may have been introduced. Future research involving institutions that use different platforms or serve more diverse populations is needed to explore the generalizability of our findings.

Conclusions

The collection of ePRO data and its integration into EHR was successful with our ePRO platform, achieving an overall CR rate of 89.9% (1338/1488). Patient age and the specific timeframe for ePRO requests were significant factors influencing complete ePRO acceptance. Patients aged 60 years or older showed significantly lower ePRO adherence. In addition, a specific timeframe, including more than 1 hour before a clinical visit or in the afternoon on the day before the appointment, was associated with a significantly higher CR rate for ePRO. These factors are expected to improve ePRO acceptance among patients with nonmetastatic breast cancer.

Abstract

Background: Sufficient bowel preparation is critical for increasing the quality of colonoscopy. However, current bowel preparation guidelines have limitations. We used a constructed and validated convolutional neural network model to assist patients in assessing the adequacy of bowel preparation and guide the use of laxatives based on individual variations.

Objective: This research intended to explore the influence of AI-guided bowel preparation on patients' use of laxatives and bowel cleansing quality.

Methods: We conducted a prospective randomized controlled trial that included patients who had a colonoscopy at the First Affiliated Hospital of Zhengzhou University and used sodium phosphate solution for bowel cleansing. Included individuals were randomly categorized into 2 groups: the AI-guided group, which used an AI program to assess the adequacy of bowel cleansing and stopped the use of laxatives once the assessment was passed, and the control group, which evaluated bowel preparation adequacy based on standard practices and used the recommended doses of laxatives. The primary outcomes were the amount of laxatives used and the rate of adequate bowel cleansing based on the Boston Bowel Preparation Scale (BBPS). Other outcomes included overall BBPS scores, BBPS scores by colon region, adenoma detection rate (ADR), polyp detection rate, and advanced ADR, as well as adverse reactions and compliance.

Results: This study included 513 patients (AI-guided group: n=255, 49.7%; control group: n=258, 50.3%). The volume of bowel-cleansing solution consumed by patients in the AI-guided group was 1245.5 (SD 377.2) mL, significantly lower than the 1586.2 (SD 50.4) mL in the control group (P<.001). Reduced use of laxatives was independently predicted by younger age, lower BMI, and higher defecation frequency. The rate of adequate bowel preparation in the AI group was not inferior to that in the control group (238/255, 93.3% vs 229/258, 88.8%, respectively; 1-sided P<.001 for noninferiority). No significant differences were observed in segmental or total BBPS scores, ADR, polyp detection rate, and advanced ADR between the 2 groups. Additionally, the medication adherence rate in the AI-guided group was significantly higher than in the control group (247/255, 96.9% vs 236/258, 91.5%, respectively; P=.009), whereas the incidence of adverse reactions was notably lower (5/255, 2% vs 15/258, 5.8%, respectively; P=.02).

Conclusions: Using the AI-driven bowel preparation program to assist patients in personalized bowel preparation can reduce unnecessary use of laxatives while achieving results comparable to those of standard practices.

Trial Registration: ClinicalTrials.gov NCT06610630; https://clinicaltrials.gov/study/NCT06610630

Introduction

Colorectal cancer (CRC) is a malignant neoplasm that originates from the epithelial lining of the colon and rectum, with incidence and mortality rates rising each year [1]. Approximately 90% of CRCs develop from colorectal polyps, particularly adenomatous polyps [2,3]. If polyps are removed during the polyp stage via colonoscopy, this can prevent 70% to 90% of CRCs [4,5]. However, there is currently a high rate of missed polyps during colonoscopy. Research indicates that the miss rate for polyps after colonoscopy might reach 22% to 28%, with adenoma miss rates ranging from 12% to 26% [6]. These missed polyps and adenomas increase the risk of developing CRC [7,8]. Thus, it is evident that high-quality colonoscopy is essential for preventing CRC [9].

Quality control indicators for colonoscopy encompass adenoma detection rate (ADR), withdrawal duration, cecal intubation rate, and bowel preparation quality [10,11]. Among these, sufficient bowel preparation is fundamental for enhancing colonoscopy quality [12]. Although guidance through images and patient education can generally meet the requirements for bowel preparation, 20% to 25% of patients still have inadequate bowel preparation [13,14]. The underlying reason is that the adequacy of bowel preparation currently relies heavily on the patients' subjective judgment, which can vary between observers. Therefore, a more objective and consistent assessment of bowel preparation, along with personalized guidance, is urgently needed in clinical practice.

AI has emerged as an auxiliary tool for this purpose. AI applications can use image recognition technology to assess bowel preparation adequacy in real time through a smartphone, allowing for objective assessment of bowel preparation and personalized guidance for cleansing. This approach aims to improve patients' bowel preparation and optimize their cleansing experience. In this study, we hypothesized that not all patients need to consume the recommended doses of laxatives to achieve adequate bowel preparation. We used a developed AI platform to evaluate the adequacy of bowel cleansing in real time. Once the assessment was passed, the use of laxatives was stopped. This study sought to investigate the use of laxatives under AI direction and evaluate its impact on the quality of bowel preparation in patients.

Methods

Study Design

This was a prospective randomized controlled trial conducted from October 2024 to March 2025 at the First Affiliated Hospital of Zhengzhou University. This study included patients undergoing colonoscopy who were using sodium phosphate for bowel preparation. This study was registered in ClinicalTrials.gov with the registration number NCT06610630.

Ethical Considerations

This study was approved the First Affiliated Hospital of Zhengzhou University's ethics committee (2024-KY-1219-001) and aligned with the Declaration of Helsinki. All participants provided written informed consent prior to enrollment via a form that explicitly outlined study objectives, procedures, potential risks and benefits, and participants' unrestricted right to withdraw at any time without penalty. All participant data were fully anonymized before analysis to protect confidentiality. Participants did not receive any financial compensation or other incentives for taking part in this study.

Study Population

The research population consisted of individuals who had painless colonoscopy at the First Affiliated Hospital of Zhengzhou University from October 2024 to March 2025 using sodium phosphate for bowel preparation. Patients were recruited from the appointment registration office of the Digestive Endoscopy Center. During the study period, patients scheduled for painless afternoon colonoscopy and prescribed sodium phosphate solution for bowel preparation were systematically screened by trained research staff according to the predefined inclusion and exclusion criteria. Eligible patients must (1) use sodium phosphate for bowel cleansing, (2) perform bowel preparation in the morning and undergo colonoscopy in the afternoon, and (3) be able to use a smartphone autonomously or with help. The ability to use a smartphone was assessed during participant screening by trained staff. After standardized verbal instructions and a brief demonstration of the AI program, participants were evaluated on whether they, either independently or with assistance from an accompanying family member or caregiver, could complete the key steps required for using the program, including scanning the QR code, taking stool photographs, uploading images, and checking the feedback results. Patients who were unable to complete these steps and had no available assistant were considered unable to use the smartphone-based program. Individuals were excluded from the study if they refused to participate or met one or more of the following conditions: (1) contraindications to oral sodium phosphate solution, such as renal failure, congestive heart failure, bowel obstruction, congenital megacolon, or ascites; (2) allergy to components of sodium phosphate; and (3) history of colorectal surgery.

AI Bowel Preparation Assessment Program

We used an AI platform developed based on a convolutional neural network (CNN) model accessible via QR code scanning with a mobile phone and provided by Xiamen Innovision Medical Technology in China. The CNN model was constructed for the intelligent evaluation of images of patients' bowel preparation defecation. During the model training phase, a total of 4302 images were collected, and the size of the training set was determined through accuracy analysis. An incremental training strategy was adopted where 250 images were added to the training set each time, and the 10-fold cross-validation method was used to evaluate model performance under different sample sizes. The results showed that, with the increase in the number of training samples, model accuracy improved in stages: it increased rapidly in the initial stage, and when the sample size reached approximately 2500, accuracy increased to 97%. Thereafter, the slope of the curve approached 0, indicating that model performance gradually stabilized. Further verification demonstrated that, when the training set contained 3000 images or more, model accuracy could stably exceed 95%, and the total

XSL•FO
RenderX

number of images used for final modeling exceeded 4000 [15]. To further evaluate its diagnostic performance, the model was tested on an independent dataset of 750 images that was not used for model training. The CNN model achieved a sensitivity of 93.02%, specificity of 92.56%, and overall accuracy of 92.80% for binary classification of bowel preparation images, supporting its reliability for real-time assessment of bowel cleansing adequacy.

Image annotation was completed by a nurse with 20 years of clinical experience who uniformly labeled the images to classify them into 2 categories: “qualified” (passing) or “unqualified” (not passing). During model initialization, parameters were randomly configured; in the training process, annotated images were input into the network to iteratively optimize the parameters. After training, the CNN model could realize automatic binary classification of newly uploaded bowel preparation images. To enhance clinical practicality, this study encapsulated the CNN model into a web service based on the MobileNetV3 architecture so as to meet the simultaneous use needs of a large number of patients and achieve real-time provision evaluation results. Compared with other CNN architectures, MobileNetV3 effectively addresses the efficiency bottleneck of traditional classification models through a lightweight network design (smaller scale and fewer parameters).

During use, after scanning the QR code, the system displays examples of how to take a photo of the stool and instructions for uploading the image to the system. After the image is uploaded, patients automatically receive an evaluation outcome of “pass” or “not pass.” Regarding those who have a “not pass” outcome, the system provides prompts to guide them in taking remedial measures, such as increasing physical activity, gently massaging the abdomen, and increasing fluid intake to enhance the efficacy of bowel cleansing.

Bowel Preparation

Unblinded researchers used the SPSS (version 26.0; IBM Corp) software to generate the block randomization sequence with a block size set to 4. The allocation results were stored by independent statisticians (nonresearch staff). Independent third-party personnel prepared opaque sealed envelopes numbered by ID (containing group assignment slips) and delivered them to staff at the endoscopy registration office. The researchers had no prior knowledge of the group allocations. Staff at the appointment registration office randomly assigned participants to the AI-guided group or control group based on the allocation results, with a 1:1 allocation ratio between the 2 groups. All participants were given a bowel preparation instruction sheet when scheduling their colonoscopy, and trained physicians provided verbal explanations of the content, including recommendations for a low-fiber diet prior to the procedure, instructions for preparing the laxative solution, and methods for assessing the sufficiency of bowel preparation. All participants adhered to a low-fiber diet the day before bowel preparation and used sodium phosphate oral solution for cleansing. The standard sodium phosphate bowel preparation protocol is as follows: the first bowel preparation is scheduled for 8 AM, during which 45 mL of sodium phosphate solution are diluted in water to prepare approximately 800 mL of bowel-cleansing solution, which should be consumed within 30 minutes. The second dose is administered at 10 AM using the same method. After starting bowel preparation, patients in the AI group uploaded images of their stool using the app each time they had a bowel movement. Once the stool image was uploaded, the app displayed the assessment results as follows. On the basis of the uploaded image, a “pass” result was given if the assessment indicated that the preparation met the requirements for the procedure, and patients could proceed to the hospital for their appointment. An assessment of “not pass” was given when, based on the uploaded image, the assessment indicated that the preparation did not meet the requirements. Recommendations included increasing physical activity; gently massaging the abdomen in a clockwise direction; and, if necessary, increasing the use of laxatives. Patients were instructed to take another photo in their next bowel movement for reassessment until they received a “pass” result. Once a “pass” result was determined, patients were advised to stop taking the laxatives. In the control group, individuals assessed their bowel preparation based on the provided instructions without the assistance of the AI app.

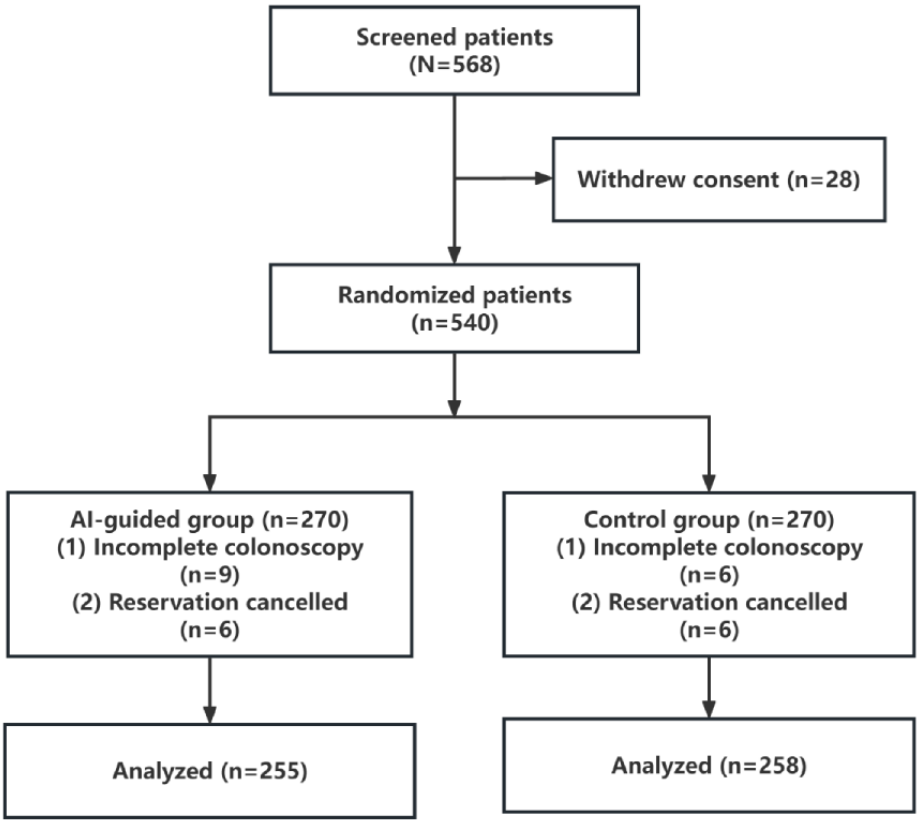
Data Collection

The primary outcomes were the actual volume of bowel-cleansing solution consumed and the proportion of patients achieving adequate bowel preparation. The volume of bowel-cleansing solution was recorded as the total amount of prepared sodium phosphate solution ingested before colonoscopy. Reduced laxative use was defined as consumption of at least 25% less than the standard 1600-mL bowel-cleansing solution. Endoscopists and nurses were completely unaware of the group assignments. Outcome assessors—specifically, 2 independent endoscopists—had no access to group information, and patients were only exposed to the interventions designated for their respective groups. Two endoscopists evaluated the patients’ bowel preparation status using the Boston Bowel Preparation Scale (BBPS) [12,16]. The ultimate decision was made by a senior endoscopist if they could not come to an agreement. The definition of sufficient bowel preparation was a total BBPS score of 6 or higher, with each segment score being 2 or higher [17]. Secondary outcomes included total BBPS score, segmental BBPS scores, polyp detection rate (PDR), ADR, advanced ADR (aADR), medication adherence, patient-reported acceptance of the AI program, and adverse events. PDR was defined as the proportion of patients with at least one detected polyp, and ADR was defined as the proportion of patients with at least one detected adenoma. Advanced adenomas were defined as adenomas larger than 10 mm, those with high-grade dysplasia, or those with villous features [18]. Medication adherence in the AI-guided group was defined as following the AI program instructions, including discontinuing medication after receiving a “pass” result or implementing remedial measures after receiving a “not pass” result. Medication adherence in the control group was defined as completing the full prescribed dose of bowel-cleansing solution, namely, 1600 mL. Patient-reported acceptance of the AI program was assessed in the AI-guided group based on whether patients could successfully use the program without additional instructions

XSL•FO
RenderX

and whether they were willing to use the AI program again for future bowel preparation. Adverse events were recorded through patient self-report and structured inquiry before colonoscopy. These included symptoms occurring during bowel preparation, such as nausea, vomiting, abdominal pain, bloating, dizziness, and palpitations. The incidence of adverse events was defined as the proportion of patients reporting at least one of these symptoms. Regarding clinical characteristics, daily defecation frequency was categorized into 3 levels: low frequency (fewer than 3 times per week), medium frequency (2 times per day to 3 times per week), and high frequency (more than 2 times per day).

Statistical Analysis



The sample size was calculated based on data from previous studies and pilot test results. We set the adequate bowel preparation rate for the control group at 85% assuming an adequate bowel preparation rate of 90% for the AI group. The noninferiority margin was set at −5 percentage points. Using PASS (version 11; NCSS, LLC) for calculations, we established that a sample size of 230 per group would achieve 90% statistical power and a significance level of .025 to detect noninferiority between the groups. Considering a 10% attrition rate, at least 512 patients were required. Data analysis was conducted using SPSS (version 26.0) and R (version 4.5.0; R Foundation for Statistical Computing). Categorical data were reported as counts and percentages, and the chi-square test, continuity-corrected chi-square test, or Fisher exact test were used to compare the 2 groups. For continuous variables, normal distribution was represented as means and SDs, whereas skewed distribution was reported as medians with IQRs. Group comparisons were made using *t* tests, Welch *t* tests, or nonparametric tests (Mann-Whitney *U* tests). A 2-tailed *P* value of less than .05 was considered statistically significant for conventional between-group comparisons. We used a one-sided test to evaluate the noninferiority of AI-guided bowel preparation vs the control group. Noninferiority was concluded if the lower bound of the 95% CI for the difference in adequate bowel preparation rate did not cross the –5–percentage point margin. To find predictors of reduced laxative use in the AI-guided group, logistic regression analysis was used.

Results

Patient Characteristics

A total of 540 patients were randomly assigned to both groups, of whom 27 (5%) were excluded due to incomplete cecal intubation for reasons such as rectal cancer. Ultimately, the study comprised a total of 513 patients (n=255, 49.7% in the AI-guided group and n=258, 50.3% in the control group; Figure 1). There were no significant variations among the 2 groups' baseline features, including age, sex, BMI, indications for colonoscopy (screening, surveillance, and diagnosis), daily defecation frequency, and relevant medical history (history of abdominal surgery, coronary heart disease, diabetes, and hypertension; Table 1).

Volume of Laxatives Consumed

In the control group, all participants (258/258, 100%) consumed the recommended dosage of sodium phosphate solution for bowel preparation. In the AI-guided group, 48.6% (124/255) of the patients reduced their use of laxatives. The average volume of laxatives consumed in the AI-guided group was 1245.5 (SD 377.2) mL, which was significantly lower than the 1586.2 (SD 50.4) mL consumed in the control group (P<.001). The multivariate analysis revealed that reduced use of laxatives was independently predicted by younger age, lower BMI, and higher defecation frequency (Table 2).

Bowel Preparation Quality and Colonoscopy Results

No significant difference was observed in the proportion of patients achieving sufficient bowel preparation between the AI-guided group and the control group (238/255, 93.3% vs 229/258, 88.8%, respectively; *P*=.07). The noninferiority analysis demonstrated that the AI-guided group was noninferior to the control group as the CI did not exceed the noninferiority margin of –5 percentage points and the one-sided *P* value was statistically significant (*P*<.001; 95% CI −0.0038 to 0.0971). Additionally, the average BBPS scores for each colon region, ADR, PDR, and aADR did not differ significantly between the 2 groups (Table 3).

XSL•FO
RenderX

[a]BBPS: Boston Bowel Preparation Scale (each colon segment of the BBPS ranges from 0 to 3, and the total BBPS score ranges from 0 to 9, with higher scores indicating better bowel preparation quality).

Patient-Reported Acceptance, Medication Adherence, and Incidence of Adverse Events

A total of 94.9% (242/255) of patients were able to successfully use the AI bowel preparation program without additional instructions. In total, 96.5% (246/255) of patients expressed a willingness to use the AI bowel preparation program for their next bowel cleansing. In addition, the medication adherence rate in the AI-guided group was significantly higher than that in the control group (247/255, 96.9% vs 236/258, 91.5%, respectively; *P*=.009), whereas the incidence of adverse reactions was notably lower (5/255, 2% vs 15/258, 5.8%, respectively; *P*=.02). Specifically, the incidence of reported adverse reactions in the AI-guided group vs the control group was as follows: 1.6% (4/255) vs 4.7% (12/258) for nausea (*P*=.045), 1.2% (3/255) vs 3.9% (10/258) for vomiting (*P*=.052), and 1.2% (3/255) vs 4.7% (12/258) for bloating (*P*=.02).

Discussion

In this research, we used a developed and validated AI bowel preparation program to assess stool status in real time and guide patients in personalized bowel cleansing. In the AI-guided group, 48.6% (124/255) of the participants reduced the use of laxatives. The proportions of adequate bowel cleansing, BBPS scores, and ADR did not vary significantly between the AI-guided group and the control group. This suggested that AI-guided bowel cleansing can provide patients with a more personalized bowel preparation plan, reducing unnecessary use of laxatives.

In previous studies, to help patients prepare their bowels better, a number of therapies have been investigated. For example, visual aids [19] and educational videos [20] have been used to guide bowel cleansing in a more understandable manner. Additionally, patient education has been reinforced through phone calls [21,22] or smartphone apps [23-25] to enhance bowel preparation quality. However, these studies have primarily focused on enhancing patient education and do not provide real-time assistance for patients to assess the sufficiency of their bowel preparation. In recent years, research has suggested that AI-driven smartphone apps can evaluate bowel preparation adequacy in real time, thereby improving patients' bowel preparation [26,27]. However, these studies have only focused on how AI programs can provide recommendations for additional laxative use for patients with inadequate bowel preparation. Different individuals may respond differently to laxatives. For instance, patients with constipation or older adults may require more laxatives, whereas those with normal bowel habits or irritable bowel syndrome may achieve adequate preparation with less. Currently, limited research has explored the feasibility of an AI bowel preparation program providing tailored recommendations for increasing or decreasing laxative use based on individual responses.

We proposed a new approach for bowel preparation based on an AI bowel preparation program. After a successful AI assessment, patients could stop taking laxatives, whereas those who did not pass would take additional remedial measures to achieve adequate preparation. The final results showed that participants in the AI-guided group could perform bowel preparation in a way comparable to conventional practices after consuming an average of approximately 1.25 L of bowel-cleansing solution. This significantly reduced the volume of cleansing solution used compared to the 3-L or 4-L polyethylene glycol solution or the 1.6-L sodium phosphate solution recommended by guidelines and other studies [28-30]. This suggests that the AI bowel preparation program has significant potential for guiding individualized laxative use. In the logistic regression analysis, younger age, lower BMI, and higher defecation frequency were identified as independent predictive factors for reduced laxative use. Future research could establish a predictive model for bowel-cleansing agent dosage by increasing the sample size and considering other relevant factors, providing patients with reasonable laxative use plans in situations in which using AI programs is not feasible.

In terms of bowel preparation quality across the 2 groups, the AI-guided group exhibited superior rates of sufficient bowel

XSL•FO
RenderX

preparation and BBPS scores compared to the control group. However, these differences lacked statistical significance. Despite thorough explanations and education, some patients may not have used the AI bowel preparation program correctly. Data indicated that 1.2% (3/255) of the patients took a photo of an empty toilet bowl, which could have led to inaccuracies in the AI assessment. Additionally, some patients who did not pass the assessment after taking the laxatives failed to follow the recommended remedial measures for bowel preparation. Ultimately, only 4.7% (12/255) of the patients undertook additional remedial actions and postponed their colonoscopy, whereas other patients who did not pass the assessment proceeded with their scheduled colonoscopy, which may have led to an underestimation of the effectiveness of the AI-guided program. The colonoscopy results, such as ADR, PDR, and aADR, did not exhibit substantial variations between the 2 groups. Previous studies have suggested that enhanced educational methods such as telephone or WeChat education could achieve higher ADR [21,23]. A possible reason for this is that bowel preparation quality was comparable in both groups, and the ADR among the endoscopists at our center was relatively high (89/255, 34.9% in the AI-guided group and 88/258, 34.1% in the control group), which may have led to an inability to observe differences in ADR and other colonoscopy outcomes.

In the AI-guided group, patients had a generally positive attitude toward the use of the AI program. Most were able to successfully use the AI program for bowel preparation after a simple explanation and introduction. Nevertheless, some older individuals were excluded from the study because they were unable to use smartphones or unable to use them with assistance from others. To address this issue, first, the future program interface should be designed to be more concise, with visual operation instructions to ensure that it is easy to understand and use. Second, for older patients who still cannot master smartphone operations, their immediate family members (or accompanying personnel) could be asked to assist with image uploads and feedback checks. Additionally, some patients experienced issues with the display of evaluation results due to network problems, but they successfully used the program after troubleshooting their network and devices. To address network obstacles, an “offline evaluation–subsequent synchronization” dual-mode approach should be developed in the future. The app should support locally storing encrypted images and perform offline analysis using lightweight CNNs, with automatic data synchronization enabled once network connectivity is restored. Regarding adverse reactions, AI-guided laxative dose reduction lowered the incidence of nausea, vomiting, and abdominal distension, with no severe adverse events reported. This benefit arose from the AI model’s ability to precisely identify optimal bowel cleanliness thresholds through real-time image analysis, thereby avoiding overmedication in nonconstipated patients under fixed-dose regimens. Mechanistically, this reduced intestinal distension and vagal nerve stimulation. Furthermore, patients in the AI-guided group had a higher medication adherence, indicating that the AI program has high usability in clinical practice and significant potential for broader application.

This research has limitations. First, this study exclusively included patients using sodium phosphate for bowel preparation, a decision driven by our research design. However, this approach may restrict the broader applicability of our findings to other laxatives (eg, polyethylene glycol). Future studies should expand the sample size and incorporate multiple laxative regimens to enhance the clinical generalizability of AI-driven bowel cleanliness assessment tools. Second, the operation of the AI bowel preparation program relies on the support of smartphones and wireless networks, which means that some individuals who cannot use smartphones, particularly certain older patients, were excluded from the study, potentially leading to selection bias.

In conclusion, this study presents the use of an AI bowel preparation program to guide patients in personalized bowel preparation, which can reduce unnecessary use of laxatives while achieving results comparable to those obtained with standard practices. Promoting this program in clinical practice could help improve the efficiency and comfort of bowel preparation for patients.

Acknowledgments

The authors would like to thank the assistance provided by Xiamen Innovision Medical Technology in the development of the AI app. Generative AI was not used in the writing of the manuscript.

Funding

This study was supported by the Key Scientific Research Project of Colleges and Universities in Henan Province (grant 23A320020).

Data Availability

The data that support the findings of this study are available from the corresponding author on reasonable request.

Authors' Contributions

All authors contributed to study conception and design. FH contributed to writing—original draft preparation. FH, SG, and JY contributed to writing—review and editing. SG and HZ contributed to methodology. FH and NW contributed to formal analysis. ZS and JX contributed to investigation. YH and YD contributed to data curation. JY contributed to funding acquisition. HZ and ZS contributed to resources. SG and HZ contributed to supervision, and all authors commented on previous versions of the manuscript. All authors read and approved the final manuscript.

Abstract

Background: Mobile health (mHealth) apps for weight and glycemic control support self-monitoring and behavior change, but engagement often declines over time. Although relapse in diet and exercise is common, little is known about how users experience relapse within digital contexts or how apps should respond.

Objective: This study aimed to explore how users of mHealth apps for weight and glycemic control experience, manage, and wish to be supported during dietary and exercise relapses.

Methods: A descriptive qualitative design was adopted. Semistructured online interviews were conducted with 26 adults who had used weight or glycemic control apps for at least 3 months and reported at least 1 relapse. Data were analyzed using inductive thematic analysis.

Results: Seven themes emerged: stress and reduced capacity as conditions surrounding relapse; cultural, temporal, and environmental misalignment; psychological disengagement and avoidance; social and relational influences; relapse as emotional disengagement rather than simply a behavioral lapse; informal relapse management and self-directed recalibration; and desire for compassionate, context-aware support. Participants described relapse in relation to stress, grief, caregiving and occupational demands, religious observances, festivals, shift work, travel, and constrained food environments. Relapse was frequently experienced as emotional disengagement, characterized by guilt, shame, identity threat, and loss of meaning, and was often accompanied by avoidance of the app or monitoring devices. Participants managed relapse through self-directed strategies such as temporal resets, goal adjustment, partial engagement, and social support, but reported few structured relapse-recovery tools within apps. They expressed a strong preference for flexible goals, context-aware modes, mood-sensitive feedback, neutral language, and gentle reentry pathways.

Conclusions: Participants' accounts suggest that relapse in mHealth contexts involves emotional responses, contextual constraints, and changing self-management capacity. Flexible goals, neutral feedback, context-sensitive support, and graded reentry are promising design targets for relapse-responsive apps, but their effects on engagement and clinical outcomes require prospective evaluation.

KEYWORDS

mobile health; dietary; weight management; glycemic control; digital health design

Introduction

The major chronic diseases, such as type 2 diabetes, cardiovascular diseases (hypertension, heart disease, and stroke), obesity, chronic obstructive pulmonary disease, and osteoarthritis, with high global prevalence, continue to be major public health challenges, and are associated with mortality risk [1-3]. Lifestyle modification, dietary regulation, and regular physical activity are a few self-management and preventive techniques that can result in improved health parameters, such as weight reduction and glycemic control [4-7]. However, adopting these behaviors in the long term could be challenging and may result in relapses, that is, returning to previous maladaptive behaviors after a period of improvement [8-10]. In weight management and diabetes self-care contexts, relapses may include neglecting or avoiding self-monitoring, reduced or absent physical activity, and adopting previous or unhealthy eating patterns [11,12].

Mobile health (mHealth), with the integration of effective and efficient technologies such as AI, has been observed to be a scalable tool for facilitating dietary tracking, physical activity monitoring, glucose level logging and monitoring, customized feedback, and tailored behavioral coaching [13,14]. However, studies [15-18] have indicated that mHealth interventions can

XSL•FO
RenderX

produce modest but significant improvements in weight and glycemic outcomes. Some of the key features of such apps include self-monitoring, goal setting, prompts, and personalized feedback, which can be related to behavior change theories such as Social Cognitive Theory and Self-Determination Theory [19].

Despite their promising benefits, sustained engagement with mHealth apps has been found to decline over time [20,21]. Attrition rates in this context are high, and discontinuation of self-monitoring is strongly associated with poorer weight and glycemic outcomes [22]. Most digital interventions, such as mHealth apps, are designed to promote adherence and behavior initiation but do not extensively focus on user experiences during relapse periods or how the app should respond effectively when lapses occur [23-25]. According to the Relapse Prevention Model, relapse is a process often influenced by high-risk situations, coping responses, and self-efficacy [26]. Furthermore, psychological and emotional factors such as guilt, shame, and reduced motivation can further aggravate disengagement following the relapse period [27].

Therefore, understanding relapses not only as a failure but also as a predictable aspect of behavior change is crucial for designing responsive mHealth apps. However, relapse-responsive features such as dynamic goal adjustment, compassionate messaging, and structured "restart" pathways are poorly addressed in intervention studies [28,29], and empirical evidence on how users experience and wish to be supported during dietary and exercise relapses in mHealth contexts is limited [30,31].

Sustained regulatory behaviors such as dietary planning, physical activity, and self-monitoring are essential for achieving long-term weight management and glycemic regulation [32,33]. mHealth apps for weight management and diabetes self-management have reflected moderate improvements in clinical and behavioral outcomes. However, their impact is usually weakened over time. Studies [15,17,34-36] focusing on mHealth apps that combine diet and physical activity monitoring with tailored feedback, goal setting, and, in some cases, professional coaching have reflected average weight losses of 1 to 2 kg at 3 to 12 months and modest glycated hemoglobin reductions. However, engagement with mHealth apps usually decreases or becomes null, reflecting that intervention content is not well aligned with the cyclical nature of behavior change and relapse.

Studies focusing on behavior change frameworks in relation to weight loss and maintenance digital interventions [37-42] identified that initial success is contributed by factors such as self-monitoring, feedback, goal setting, action planning, and shaping knowledge. However, these frameworks specify only generic messages to resume tracking but do not specify how apps should respond when users miss logs, exceed dietary targets, or stop exercising. Structured relapse-management plans, strategies to bolster autonomous motivation, and emotional self-regulation have been identified as key aspects for achieving sustained maintenance but are not effectively integrated into mHealth apps [37-39].

Furthermore, studies [43,44] have observed that digital apps can enhance awareness, knowledge, and perceived control among users in relation to weight and diabetes management but highlight the need to address complex emotional responses to lapses. It has also been observed that approaches such as reminders and feedback not only support accountability but also trigger guilt and shame among users when goals are not met, which can lead to disengagement from the app and behavior change efforts [27,45]. In relation to diabetes self-management, it was observed that patients value supportive, nonjudgmental communication from health care providers in the event of high glycemic levels [46]. Similar supportive approaches need to be translated into digital apps, but this requires careful design to avoid exacerbating feelings of failure. Some of the challenges identified by users include tracking burden, usability issues, competing life demands, and the feeling that apps do not adapt to their changing capabilities, illness episodes, or psychological factors such as mood that precipitate relapse [47-49]. Studies focusing on user-centered designs highlight the importance of autonomy support, flexible goal recalibration, and normalization of setbacks [50,51].

Research on relapse in diet and physical activity digital interventions highlights that lapses are a common phenomenon, triggered by emotional distress, social situations, environmental cues, and disruptions to routine. A few skills, such as self-efficacy, coping planning, and reframing lapses as learning opportunities, were found to be associated with effective lapse recovery and sustained maintenance of physical activity and weight loss [52]. However, most digital apps assume linear progress, providing limited scaffolding for users to navigate cyclical patterns of engagement and disengagement. Furthermore, there is a lack of research examining how individuals using weight and glycemic control apps interpret and respond to relapses in diet and exercise, how app features shape these experiences, and what forms of digital support they would find acceptable and helpful during relapse episodes.

Considering these gaps, this study aims to explore how users of mHealth apps for weight and glycemic control experience, manage, and wish to be supported during dietary and exercise relapses. Specifically, it examines the relationships among changing personal circumstances, emotional responses to app-generated feedback, and disengagement from digital self-management. By translating these experiences into proposed relapse-responsive app features and behavior change strategies, the study seeks to inform interventions that support recovery and reengagement rather than assuming uninterrupted adherence.

Methods

Study Settings and Participants

A descriptive qualitative design was adopted to gain a deeper understanding of how users of mHealth apps for weight and glycemic control experience, manage, and wish to be supported during dietary and exercise relapses. A qualitative approach was selected because the study focused on a multidimensional construct—lived experiences, perceptions, emotional responses, coping strategies, and support needs during relapse episodes—that requires in-depth interpretation of users'

XSL•FO
RenderX

perspectives. Semistructured online interviews were used to gather participants' accounts of relapse in the context of mHealth app use. Participants included adult users of mHealth apps for weight management and/or glycemic control.

Recruitment and Sampling

A purposive sampling strategy was adopted to ensure the inclusion of diverse participants in different contexts. Inclusion criteria were as follows: (1) use of a mobile app for weight management and/or glycemic control for at least 3 months and (2) self-reported experience of at least 1 noticeable relapse in diet and/or exercise during that period (eg, cessation of logging, reduced physical activity, or reversion to previous eating patterns). Variation was sought in age, gender, app type, and health goals (weight management and/or glycemic control) to capture diverse perspectives. Participants were recruited through online advertisements posted on social media platforms, digital health forums, diabetes and weight management community groups, and university mailing lists.

An initial target of 17 interviews was informed by methodological guidance on sample sizes for qualitative interview studies [53]. Recruitment continued beyond this target to ensure variation in age, gender, occupation, health goal, app type, and relapse context. During analysis, the research team reviewed new codes and themes after each batch of interviews. By approximately interview 24, no substantively new domains of experience were identified, although later interviews continued to provide contextual variation and elaboration. All eligible individuals invited to interview agreed to participate, and no participants withdrew or discontinued their interviews. Interviews continued to 26 to strengthen diversity and depth rather than to increase statistical precision. The final sample of 26 participants is therefore described as providing adequate information for the study's descriptive aims.

Reporting Guideline

This study was reported with reference to the COREQ (Consolidated Criteria for Reporting Qualitative Research) checklist. The completed checklist is provided in Checklist 1.

Research Team and Reflexivity

Interviews were conducted by the primary researcher, the corresponding author, who had no prior relationship with participants. The interviewer introduced the study as independent research examining users' experiences of relapse in mHealth apps. The corresponding author, a female associate professor, conducted the interviews. She had prior experience in multiple research projects, data collection, and the application of research methods.

The research team discussed their assumptions concerning relapse, self-management, and digital health during study design and analysis. These discussions supported reflexive awareness of how researchers' expectations could influence the interpretation of participants' accounts and the framing of themes. Reflexivity was therefore used to make the researchers' interpretive role explicit rather than to claim that researcher influence could be eliminated. During analysis, initial codes and differing interpretations were discussed with reference to the transcripts, and analytic decisions were documented in an audit trail. These procedures supported transparent interpretation and helped limit the uncritical application of preexisting assumptions to participants' experiences.

Interview Guide and Data Collection

The semistructured interview guide was developed from the study objectives and relevant literature on relapse, self-management, and user experience of digital health tools. It was reviewed by 2 academic professors in the eHealth department and piloted with 3 eligible users who were not included in the final sample. Minor revisions were made to improve the clarity and sequencing of questions.

Before each interview, participants were informed that the study concerned experiences of dietary and exercise relapse while using apps for weight management and/or glycemic control. They received information about the interview procedure, voluntary participation, confidentiality, and their rights as research participants. Written informed consent was obtained before interviewing, including consent to audio recording and permission to publish anonymized quotations and nonidentifying participant characteristics. Participants were also informed about the anticipated interview duration and their right to decline individual questions or discontinue the interview. No nonparticipants were present during the interviews; only the participant and the interviewer attended each session.

Semistructured interviews were conducted through secure online videoconferencing apps. The average interview duration ranged from 40 to 50 minutes. Each participant was interviewed once; no repeat interviews were conducted. No field notes were taken during or after the interviews. Interviews were guided by questions focusing on key components, examining how individuals using weight and glycemic control apps interpret and respond to relapses in diet and exercise, how app features shape these experiences, and what forms of digital support they would find acceptable and helpful during relapse episodes. The interviews were audio recorded and conducted in Arabic with the consent of participants.

Data Analysis

Audio-recorded interviews were transcribed, translated into English, and checked by the authors to preserve the meaning of participants' accounts. Data were analyzed using inductive thematic analysis organized around Braun and Clarke's 6 phases: familiarization, initial coding, development of candidate themes, review of themes, definition and naming of themes, and report production. NVivo (version 14; Lumivero) supported data organization, coding, and theme refinement. Codes and themes were developed through engagement with participants' accounts rather than imposed from a predefined theoretical framework.

Two researchers independently coded all transcripts. Initial codes were compared during analytic meetings, and differences were resolved through discussion and reference to the transcripts. The team maintained an audit trail documenting code development, theme refinement, and decisions about theme boundaries. Following Braun and Clarke's clarification of the diversity of thematic analysis approaches [54], this procedure is reported as an inductive thematic analysis using independent

XSL•FO
RenderX

coding and discussion-based resolution, rather than characterized as their contemporary reflexive thematic analysis approach. The 6-phase framework organized the analysis, while the reported coding procedures describe how it was implemented in this study.

Coding was nonexclusive: participants could contribute to multiple themes and subthemes. Consequently, participant counts were used descriptively and were not interpreted as prevalence estimates. The analysis focused on patterns of meaning across accounts, including differences between digital disengagement and continued health-related activity. The final sample was considered adequate for the study's descriptive aims on the basis of the breadth and contextual depth of the accounts, as described in the *Recruitment and Sampling* subsection.

Trustworthiness

Trustworthiness was addressed through procedures supporting credibility, dependability, confirmability, and transferability. Credibility was supported by a review of the interview guide by 2 academic professors, pilot interviews with 3 eligible users outside the final sample, verification of translated transcripts by the authors, participant review of interview transcripts, and the presentation of participant quotations to substantiate interpretations. Transcripts were returned to participants for review and feedback, and a small number of changes were made in response to their comments. This process supported the accuracy of the interview records used for analysis. The reporting of contrasting experiences, including continued physical activity despite withdrawal from app monitoring, also helped preserve variation within the accounts.

Dependability was supported by a documented interview-guide development process and an audit trail recording code development, theme refinement, and decisions about theme boundaries. Confirmability was supported by linking interpretations to transcript material, discussing researchers' assumptions and differing interpretations, and documenting analytic decisions. These procedures made the interpretation process more transparent; they do not imply that the findings were independent of researcher judgment.

Transferability was supported by describing the recruitment strategy, eligibility criteria, participant characteristics, health goals, and cultural, social, and occupational circumstances surrounding relapse. These contextual details enable readers to assess the relevance of the findings to other populations and settings. The purposive sample was intended to provide diverse accounts rather than statistical representativeness, and transferability beyond this Saudi Arabian sample requires attention to contextual differences.

Ethical Considerations

This study adhered to strict ethical guidelines, including voluntary participation, confidentiality, and informed consent. Ethical approval (KFU-REC-2026-FEB--ETHICS4011) was obtained from the Research Ethics Committee at King Faisal University, Saudi Arabia, before conducting the interviews. Participants were fully informed about the interview procedure and their rights before starting the interviews. Written informed consent was obtained from all participants before the interviews. The consent process included permission to use anonymized quotations and nonidentifying participant characteristics in publications. Identifying details were removed or generalized before analysis and reporting. Data were anonymized or deidentified, and access was restricted to the research team.

Results

Participants' Sociodemographic Characteristics, Health Goals, and Patterns of Relapse Triggers

As shown in Table 1, a total of 26 individuals participated in the semistructured interviews. Participants were aged between 19 and 70 years and represented a diverse group, including students, working professionals, shift workers, homemakers, and retirees. Female representation was slightly higher (n=14) than male representation (n=12). Diverse health goals were observed among the participants, with 11 participants focused primarily on weight management, 8 on type 2 diabetes management, 5 on prediabetes, 1 on polycystic ovary syndrome (PCOS)–related weight concerns, and 1 on muscle gain/bulking. Various types of relapses were observed among the participants. Work- and stress-related relapse was prominent across 5 participants, followed by cultural and celebratory contexts (n=5), digital design–induced relapse (n=4), grief- and loss-related relapse (n=3), injury- or health flare–related relapse (n=3), psychological and emotional eating (n=3), monitoring burnout or anxiety-driven relapse (n=2), structural or occupational environmental barrier–based relapse (n=2), and goal incongruence–based relapse (n=1). Analyzing the relapse types, relapse triggers were distributed across emotional (8/26, approximately 31%), contextual/cultural (5/26, 19%), structural/occupational (2/26, 8%), injury/health-related (3/26, 12%), digital design–related (4/26, 15%), and social influence factors (including peer pressure and isolation; 8% - 12%), reflecting the multidimensional nature of relapse, which is influenced by personal, social, cultural, and technological factors.

Table . Participant demographics.

Participant ID	Age group (y)	Gender	Health condition/goal	Relapse context (brief description)
P01	30 - 39	Female	Weight loss/prediabetes	Work stress–induced dietary and exercise cessation
P02	40 - 49	Male	Type 2 diabetes	Family wedding–related dietary binge and exercise lapse
P03	20 - 29	Female	PCOS[a]-related weight issues	Hormonal flare-up leading to dietary cravings and yoga cessation
P04	50 - 59	Male	Type 2 diabetes	Grief-induced comfort eating and walking avoidance
P05	30 - 39	Female	Weight/gestational diabetes history	Child exam stress causing exercise neglect
P06	20 - 29	Male	Fitness/weight (bulking)	Injury-related gym halt and macronutrient deviations
P07	60 - 69	Female	Type 2 diabetes	Arthritis flare and festive sweets overindulgence
P08	30 - 39	Male	Prediabetes/weight	Night shift disruptions and junk food binges
P09	20 - 29	Female	Weight loss	Digital disengagement following dietary lapse
P10	50 - 59	Male	Type 2 diabetes	Contextual/cultural disruption (Ramadan)
P11	30 - 39	Female	Weight loss	Injury-related activity reduction with algorithmic misalignment
P12	40 - 49	Female	Weight/prediabetes	Stress-induced emotional eating and selective nonlogging
P13	20 - 29	Male	Weight gain (muscle)	Goal incongruence and underconsumption during stress
P14	60 - 69	Female	Type 2 diabetes	Grief-related disengagement from tracking
P15	30 - 39	Male	Weight loss	Competitive burnout and leaderboard disengagement
P16	40 - 49	Female	Glycemic control	Monitoring burnout and anxiety-driven avoidance
P17	40 - 49	Male	Type 2 diabetes	Environmental/structural dietary and logging avoidance
P18	20 - 29	Female	Weight management	Psychological (“The Streak Trap”)
P19	60 - 69	Male	Prediabetes	Cultural invisibility during family festivals
P20	19 - 29	Female	Weight management	Social/binging (peer pressure and alcohol)
P21	30 - 39	Male	Weight/hypertension	Decision fatigue (exercise and dietary)
P22	30 - 39	Female	Prediabetes	Chaos-induced glucose monitoring relapse
P23	40 - 49	Male	Weight management	The “Ostrich Effect” (exercise/data avoidance)

Participant ID	Age group (y)	Gender	Health condition/goal	Relapse context (brief description)
P24	20 - 29	Female	Weight management	Emotional eating feedback loop
P25	60 - 69	Male	Type 2 diabetes	Social isolation (dietary and testing)
P26	40 - 49	Female	Prediabetes/weight	Seasonal/holiday maintenance dietary relapse

[a]PCOS: polycystic ovary syndrome.

The analysis identified 7 overlapping themes: (1) stress and reduced capacity as conditions surrounding relapse; (2) cultural, temporal, and environmental misalignment; (3) psychological disengagement and avoidance; (4) social and relational influences; (5) relapse as emotional disengagement rather than simply a behavioral lapse; (6) informal relapse management and self-directed recalibration; and (7) desire for compassionate, context-aware support (see Table S1 in Multimedia Appendix 1). The themes are presented as interpretive patterns in participants' accounts. Participant counts were used only descriptively and were not treated as prevalence estimates. Coding was nonexclusive: a participant could contribute to more than 1 theme or subtheme, and subtheme counts therefore do not sum to the total sample.

Stress and Reduced Capacity as Conditions Surrounding Relapse

Participants commonly described relapse in the context of stress, exhaustion, grief, caregiving demands, academic or occupational pressure, and reduced physical capacity. These accounts suggested that relapse was often experienced as a reduction in available emotional or cognitive resources rather than as a lack of knowledge about healthy behavior.

A software engineer described a period of intense occupational pressure:

> *A major project launch meant 14-hour days, no time for meal prep, and biryani deliveries became my savior.*

She explained that logging and exercise stopped during this period, despite her previous success with both activities. Similarly, an intensive care nurse described relapse as a consequence of limited cognitive capacity after prolonged shifts:

> *Relapse isn't always about a lack of willpower; sometimes it's about a lack of bandwidth.*

The account linked missed logging and convenience eating to exhaustion and decision fatigue rather than to a change in health goals.

Caregiving demands produced a similar disruption. A participant caring for 3 children described family emergencies and mealtimes as circumstances in which her own monitoring routine was displaced:

> *When a kid gets sick, or the toddler has a tantrum during dinner, my health routine is the first thing to go out the window.*

A school teacher also described examination periods as a time when stress eating increased and logging became uncomfortable. Together, these accounts positioned relapse within competing demands and temporary reductions in capacity.

Physical and health-related changes also altered what participants could do. Participants with an injury, arthritis flare, or PCOS described reducing exercise or changing eating patterns while their capacity was affected. One participant with a knee injury stated,

> *I didn't stop moving. I switched to gentle yoga and stretching. But because those activities didn't 'count' toward the app's metrics, they felt invisible.*

This account shows that participants did not always experience behavioral disengagement and digital disengagement as the same process.

Cultural, Temporal, and Environmental Misalignment

Participants described relapse when the routines assumed by an app did not fit religious observances, festivals, family events, seasonal schedules, shift work, travel, or constrained food environments. These accounts did not necessarily indicate rejection of health goals. Instead, participants described the app as becoming less relevant when daily routines changed.

A participant managing type 2 diabetes described Ramadan as a period when eating times shifted and glucose readings became more variable. He stated,

> *Relapse wasn't rebellion; it was misalignment.*

The app continued to provide advice based on fixed meal timing, which he experienced as inconsistent with his religious practice. He wanted the app to recognize that

> *My lived experience wasn't recognized by the digital system guiding me.*

Cultural food practices were also described as a source of difficulty. A retired participant explained that the app's database did not adequately represent homemade biryani and festival foods:

> *I felt like the app was telling me that my culture and my health were incompatible.*

He described abandoning logging after repeated uncertainty about how to record traditional meals. Another participant described family weddings and social meals as events that interrupted exercise and dietary routines. Rather than avoiding such events, he wished for an event mode that would support flexible tracking and recovery after celebrations.

XSL•FO
RenderX

Work schedules and travel created additional environmental barriers. A shift worker described night rotations, disrupted sleep, and irregular meals. A long-haul truck driver described limited food choices during a winter storm and stated that the app seemed "designed for someone with a kitchen and a routine, not for someone whose life happens in a 70-foot vehicle." These accounts indicate that relapse was sometimes associated with structural constraints, including limited access to suitable food, irregular work hours, travel, and the physical environment in which self-management occurred.

Seasonal demands also affected engagement. A teacher described school holidays and end-of-term events as periods when weight loss was unrealistic. She wanted a maintenance option because

> *When the goal becomes 'perfection or nothing', people choose 'nothing' every time the holidays roll around.*

This account illustrates how rigid goals could become difficult to sustain during predictable periods of contextual change.

Psychological Disengagement and Avoidance

Participants described a process in which an initial lapse was followed by avoidance of the app, monitoring devices, or feedback. Avoidance took several forms, including not logging, removing or hiding devices, ignoring glucose readings, selectively recording food, or postponing reengagement until behavior appeared more acceptable.

A marketing executive described opening the app after several takeout meals and then closing it without recording anything: "It wasn't forgetfulness—it was avoidance." She associated the app with failure and described the loss of the reflective pause that logging had previously created. A participant managing weight described a similar process as "The Ostrich Effect," explaining, "If I don't wear the watch, the data doesn't exist." In both accounts, avoidance reduced immediate emotional discomfort but also interrupted monitoring.

Visual feedback and streak systems were particularly salient. One participant stated that red graphs and notifications produced guilt and led her to hide the app. Another described a 75-day streak ending after one missed entry:

> *If I can't have a perfect score, why bother playing the game?*

The participant interpreted the loss of the streak as a loss of status and subsequently stopped using the app for an extended period.

Some participants described selective nonlogging rather than complete disengagement. A school teacher explained that color-coded food categories made recording certain foods uncomfortable: "Red meant wrong." She began eating foods without recording them and later stopped logging altogether because she did not want a record of "bad days." A participant using a continuous glucose monitor described the opposite pattern: repeated checking of minor fluctuations increased anxiety until she avoided the app. Thus, disengagement could follow both undermonitoring and excessive monitoring.

The findings also showed that digital disengagement did not always correspond to complete behavioral disengagement. A participant recovering from injury continued gentle activity even though the app classified her reduced-intensity exercise as insufficient. Another participant continued occasional walking after withdrawing from a competitive leaderboard. These accounts suggest that app data may not fully represent participants' physical or self-management activities during relapse periods.

Social and Relational Influences

Participants described relapse as embedded in relationships and social settings. Family meals, weddings, peer drinking, parenting responsibilities, bereavement, and social isolation all influenced whether participants could maintain routines or felt able to reengage with an app.

A university student described tracking as socially uncomfortable during evenings with friends:

> *If I pull out my phone to track a drink, I feel like a total buzzkill.*

She experienced a conflict between being healthy and maintaining her social identity. Her account suggested that the app made these identities feel incompatible during social occasions.

Family contexts could either disrupt or support reengagement. A business owner described negotiating home workouts with his wife after a wedding-related lapse. A widowed participant stated that her daughter's encouragement helped her return to glucose monitoring:

> *Human connection restarted what technology couldn't.*

Another older participant living alone described relapse as connected to loneliness and requested a check-in system that could alert a trusted person when prolonged disengagement occurred.

Participants also described social features that were not uniformly helpful. Competitive leaderboards initially motivated one participant but later became discouraging when he fell behind. He explained,

> *Relapse here wasn't about inactivity—it was discouragement.*

These accounts indicate that social accountability may support reengagement when it is experienced as relational and supportive, but may contribute to withdrawal when it is experienced as comparison or public failure.

Relapse as Emotional Disengagement

Participants frequently described relapse using emotional terms, including guilt, shame, discouragement, hopelessness, loss of meaning, identity threat, and indifference. These accounts did not imply that every participant understood relapse in the same way. Rather, they illustrate a recurring interpretation in which emotional responses shaped how a lapse was understood and whether the participant returned to the app.

XSL•FO
RenderX

A software engineer described the experience as a threat to her identity: "I'm a failure at this too." A participant with PCOS described feeling that her body had betrayed her during a flare-up. A participant managing diabetes after bereavement stated,

> *Relapse, in that period, was existential. It wasn't rebellion or ignorance. It was emotional depletion.*

These accounts framed relapse as a disruption in meaning and self-understanding, not simply as a failure to perform a health behavior.

Participants also described a difference between a behavioral lapse and an emotional withdrawal from self-management. One participant summarized this distinction as follows:

> *For me, relapse is less about food and more about losing the reflective habit that the app initially helped build.*

Another participant continued gentle physical activity after an injury but considered herself digitally unsuccessful because the app did not recognize the activity. Such accounts suggest that participants evaluated relapse through both their lived behavior and the app's representation of that behavior.

Informal Relapse Management and Self-Directed Recalibration

Participants generally described managing relapse through improvised, self-directed strategies rather than through structured recovery tools within the apps. Strategies included restarting on a chosen date, reducing goals, switching to simpler activities, recording only selected measures, using journaling or professional advice, and seeking support from family or friends.

Several participants described temporal resets, such as restarting on Monday or after a holiday. A participant experiencing social eating described a "Weekend Void" followed by an intention to "start fresh on Monday." Another participant used journaling and discussions with clinicians to manage a health-related flare-up. These strategies helped participants regain a sense of control but were not usually supported by an explicit relapse pathway in the app.

Participants also recalibrated goals when full adherence was unrealistic. Examples included using lighter activity during injury, adjusting goals during night shifts, choosing maintenance rather than weight loss during holidays, and simplifying food recording during long work shifts. A participant working in intensive care wanted an app that would reduce demands during high-capacity periods and ask for a simpler account of eating rather than exact measurements.

Partial engagement was another form of self-management. Participants sometimes measured glucose, continued some movement, or recorded selected meals while avoiding complete tracking. One participant described restarting gradually but found partial entries discouraging because the app treated them as incomplete. These accounts suggest that participants were attempting to maintain a connection with self-management, even when they could not meet the app's preferred level of monitoring.

Desire for Compassionate and Context-Aware Support

Participants consistently described a preference for support that recognized emotional states, changing circumstances, health conditions, and temporary limitations. Their suggestions included pause or crisis modes, event and festival modes, maintenance goals, injury-sensitive plans, mood tracking, neutral feedback, simplified logging, accessible interfaces, and gentle reentry pathways.

A participant experiencing work stress wanted "a pause mode for high-stress weeks" with a smaller goal, such as logging 1 meal. A participant managing type 2 diabetes during Ramadan wanted seasonal or cultural adaptation. A participant with an injury wanted to record that she was recovering so that the app could recalibrate activity expectations. These suggestions shared the assumption that support should adapt to changing capacity rather than continue to evaluate users against a fixed routine.

Participants also requested emotional and relational support. Suggestions included mood tracking, reflection prompts, grief resources, peer stories, family support, check-in buddies, and community connections. A participant experiencing emotional eating stated,

> *When the app only treats the 'what' and not the 'why', it's only doing half the job.*

An older participant living alone wanted the app to function as "a bridge to other people, not just a digital diary."

Gentle reentry was a central feature of participants' desired support. Participants described wanting fresh-start options, archived difficult periods, blind weighing, reset streaks, maintenance modes, and neutral language. One participant wished for a system that would separate logging from judgment, while another wanted to "archive" a difficult week without deleting previous progress. Overall, participants described relapse-responsive support as flexible, nonpunitive, and attentive to the circumstances in which health behaviors occur.

The overall findings indicate that participants experienced relapse as a dynamic interaction among stress, reduced capacity, contextual misalignment, psychological responses to digital feedback, and social circumstances. Participants described self-directed attempts to recover but reported few structured app features for managing relapse. Their accounts pointed to the importance of flexible goals, culturally and contextually responsive interfaces, neutral feedback, and supportive reentry. These findings are interpretive and should not be read as estimates of the frequency of these experiences among all mHealth app users.

Discussion

Principal Findings and Contribution to mHealth

The findings provide deeper insights into how users experience, interpret, and manage dietary and exercise relapse within mHealth apps for weight and glycemic control. Consistent with the Relapse Prevention Model, participants described stress, social events, health-related limitations, and contextual instability as circumstances surrounding relapse. However, their accounts also highlighted emotional disengagement, including

XSL•FO
RenderX

guilt, shame, discouragement, and identity disruption. These findings complement research on goal-discrepant feedback and mHealth engagement by illustrating how users may interpret app-generated information during periods of difficulty.

An important distinction was that digital disengagement did not always correspond to complete behavioral disengagement. Some participants continued walking, adapted their exercise, or monitored selected health indicators despite withdrawing from an app. Consequently, an absence of app entries may indicate tracking burden, discomfort with feedback, or a mismatch between app expectations and users' circumstances rather than abandonment of health goals. This finding adds a user-centered perspective to research examining disengagement from self-monitoring and declining mHealth engagement [20-22].

Participants reported limited structured support for recovering from relapse within the apps they used. Their accounts suggest a possible sequence in which an initial lapse is followed by negative self-evaluation, avoidance of feedback, and delayed reentry. However, the qualitative design does not establish mediation or causality, and these accounts should not be interpreted as evidence that specific features caused disengagement. Instead, they identify potentially important processes for investigation and highlight the need to distinguish support for behavior initiation from support for recovery and maintenance [40].

Emotional Responses and Recovery After Relapse

Participants' accounts suggest that relapse-responsive support should address the emotional meaning attributed to setbacks as well as the behaviors themselves. Broken streaks, unmet targets, and evaluative displays were sometimes interpreted as evidence of personal failure or loss of previous progress. These experiences provide context for research examining engagement following goal-discrepant feedback. Rather than treating feedback as inherently motivating, developers should consider how its language, visual presentation, and timing may be experienced by users whose capacity has temporarily declined.

A practical implication is to combine self-monitoring with supportive reflection and gradual recovery. An app could acknowledge previous progress, invite users to identify the circumstances surrounding a lapse, and support the selection of a manageable next action. For example, a user returning after a stressful week might choose to record one meal or complete a short activity rather than immediately restore all previous targets. These proposals translate participants' existing strategies of partial engagement and goal recalibration into structured support and are conceptually consistent with the role of self-efficacy and coping in weight maintenance.

Compassionate communication should not imply that health goals are unimportant. Rather, it could separate information about behavior from judgments about personal worth. Neutral wording, recognition of partial completion, and preservation of accumulated progress may make reentry more acceptable for users who experience all-or-nothing responses to missed targets. These are user-informed design proposals, however, and their effects on emotional responses, self-management, and sustained engagement require evaluation.

Relapse-Responsive Features and Behavior Change Strategies

The findings identify opportunities to translate established behavior change strategies into relapse-responsive app features. Research on digital weight-management interventions has examined self-monitoring, goal setting, feedback, and persuasive design approaches [37-40]. This study extends this discussion by considering how these strategies could be adapted when users experience stress, emotional distress, injury, or disruption to their usual routines. Table 2 summarizes the relationships between the study findings, proposed relapse-responsive app features, corresponding behavior change strategies, and priorities for evaluation.

XSL•FO
RenderX

Table . Proposed relapse-responsive app features and behavior change strategies.

Study finding	Proposed app feature	Corresponding behavior change strategy	Evaluation priority
Stress, exhaustion, and reduced capacity	Optional low-demand mode with simplified logging, fewer nonessential prompts, and smaller goals	Graded tasks, goal review, and action planning	Perceived tracking burden and maintenance of feasible self-management
Cultural, temporal, and environmental misalignment	User-selected Ramadan, celebration, travel, or shift-work settings and culturally relevant food entries	Context-specific planning and problem solving	Cultural acceptability, usability, and clinical appropriateness
Shame and avoidance following evaluative feedback	Neutral language, recognition of partial completion, and preservation of accumulated progress	Supportive feedback and reflection on setbacks	Emotional responses, avoidance, and willingness to resume monitoring
All-or-nothing responses to missed targets	Graded reentry without mandatory completion of missing records or punitive streak resets	Graded tasks and review of achievable goals	Time to reengagement and sustained self-management after a lapse
Social isolation or discouraging comparison	Optional trusted-person check-ins, noncompetitive peer support, and user-controlled sharing	Emotional and practical social support	Acceptability, perceived autonomy, privacy, and supportive contact
Injury or health-related limitations	Capacity-sensitive activity goals and temporary maintenance options within clinically appropriate boundaries	Goal adjustment and problem solving	Safety, feasibility, and recognition of adapted health-related activity

For participants experiencing reduced capacity, an optional low-demand mode could simplify food recording, reduce nonessential prompts, and support smaller, achievable goals. Goal review and graded tasks could allow users to maintain some connection with self-management without requiring full adherence immediately. Similarly, temporary maintenance goals or capacity-sensitive activity targets could recognize that weight loss or usual exercise intensity may not be feasible during every period. These proposals align with user-centered approaches to adaptive interfaces and personalized recommendations, but their effectiveness during relapse remains to be established [50].

Gentle reentry pathways could address the difficulty participants described when attempting to resume app use. Possible features include restarting without retrospectively completing missing records, retaining previous achievements after a broken streak, and allowing users to select a limited set of activities before restoring their usual routine. Such features would recognize recovery as a process rather than a single decision to resume tracking. Importantly, these proposals should complement, but not replace, clinically appropriate self-management guidance.

Social support features also require differentiation between supportive contact and competitive comparison. Participants described family encouragement and trusted-person contact as helpful, whereas leaderboards could become discouraging when they fell behind. Optional check-ins, noncompetitive peer support, and user-controlled sharing may therefore offer acceptable recovery pathways for some users. Their design should preserve choice and privacy rather than assume that increased visibility or accountability benefits everyone.

Cultural and Contextual Adaptation

Cultural and contextual misalignment was a prominent concern in participants' accounts. Religious observances, celebrations, traditional foods, shift work, travel, and constrained food environments altered the feasibility of fixed tracking expectations. These findings complement qualitative research examining the fit between digital self-management tools and users' everyday circumstances [47-49]. They suggest that personalization should extend beyond demographic characteristics to changing routines, available resources, and self-management capacity.

For example, user-selected Ramadan, celebration, travel, or shift-work settings could adjust optional reminder schedules and support context-specific planning. Culturally relevant food entries and simplified recording options could reduce difficulties associated with logging traditional meals. However, such features should accommodate individual variation rather than assume that all users within a cultural or religious group follow the same practices. The relevance of these adaptations should be established through user involvement, consistent with user-centered development approaches [50].

Adaptation should also begin with user confirmation rather than automatic interpretation of missing data as relapse. A missed entry alone cannot establish whether a person is struggling, successfully adapting their behavior, or choosing not to use the app. A neutral invitation to select a smaller goal, change a schedule, or pause optional reminders could provide support while preserving autonomy. This distinction is particularly important given participants' accounts of continued health-related activity despite reduced digital engagement.

Broader Implications and Future Evaluation

The broader implication for mHealth is that sustained self-management should not be equated with uninterrupted app interaction. Research has documented challenges in maintaining engagement and sustaining the benefits of app-based interventions [20,21,34-36]. These findings suggest that useful digital support may involve helping users navigate disruption, preserve feasible behaviors, and return after a lapse rather than prioritizing continuous tracking or perfect streaks.

XSL•FO
RenderX

Relapse-responsive features should therefore be evaluated using outcomes that distinguish digital activity from health behavior. In addition to app use, relevant outcomes could include time to reengagement, recovery after a lapse, perceived tracking burden, emotional responses to feedback, and sustained self-management. Weight and glycemic outcomes should also be examined where appropriate, given evidence linking self-monitoring adherence with weight-management outcomes. Increased interaction alone would not establish benefit if it also increased anxiety or burden [22].

Implementation must also distinguish reduced interaction demands from reduced clinically necessary care. Low-demand modes could simplify optional logging or motivational reminders, but features used in glycemic-control apps would require clinical review to ensure that essential monitoring and safety functions remain appropriate. Mood-related information and trusted-person notifications would similarly require clear consent, privacy protections, and user control. These are considerations for future development rather than outcomes assessed in this study.

Overall, the findings provide a user-informed basis for developing flexible goals, neutral feedback, contextual adaptation, optional relational support, and graded reentry pathways. Participatory development and prospective evaluation are needed to determine their acceptability, safety, and effectiveness. The study's contribution is therefore to identify how digital support might remain useful during periods of reduced capacity and disrupted routines, rather than to demonstrate that these proposed features improve engagement or clinical outcomes.

Limitations and Future Research

Several limitations should be considered. Interviews were conducted in Arabic and translated into English; subtle changes in meaning may have occurred despite author verification. The purposive sample comprised 26 adults using apps for weight and/or glycemic control in Saudi Arabia. Although participants differed in age, gender, occupation, health goals, and relapse circumstances, the study does not support statistical generalization. Recruitment through online communities and university mailing lists may also have favored individuals willing and able to discuss digital self-management.

Transferability depends on similarities between the study context and other settings, particularly concerning religious observances, food practices, family relationships, occupational schedules, and access to suitable food or activity opportunities. Retrospective accounts are also susceptible to recall and social desirability influences. The analysis involved researcher interpretation supported by independent coding, transcript-based discussion, and documented analytic decisions; these procedures do not eliminate interpretive influence. Although interview transcripts were returned to participants for feedback and a small number of changes were made in response, this process supported the accuracy of the interview records rather than establishing the validity of the researchers' thematic interpretations.

The study did not independently assess app functionality, usage logs, behavioral trajectories, or clinical outcomes. Participants' reports of limited recovery support should therefore not be interpreted as an objective assessment of all apps or proof that such features were absent. Likewise, the study does not establish causal relationships among app feedback, emotional responses, and disengagement. The proposed relapse-responsive features are user-informed design hypotheses requiring participatory development and prospective evaluation.

Conclusions

Participants described dietary and exercise relapse in mHealth contexts as involving emotional disengagement, changing capacity, contextual misalignment, and social circumstances, rather than simply failure to meet behavioral targets. Digital disengagement did not always indicate abandonment of health-related activity. These findings identify opportunities for relapse-responsive support through flexible goals, neutral feedback, culturally appropriate adaptation, optional relational support, and graded reentry. Their acceptability, safety, and effectiveness require evaluation; this study provides a user-informed basis for developing such interventions rather than evidence of their clinical benefit.

Abstract

Background: Excessive salt intake is detrimental to the kidneys. Nevertheless, salt restriction is often suboptimal in patients with chronic kidney disease (CKD). Smartphone app–based interventions might help reduce salt intake by supporting self-monitoring and behavior change at scale. However, clinical trials evaluating these interventions for salt reduction are limited, particularly in CKD populations.

Objective: This study investigated whether a hypertension management app could reduce urinary sodium excretion in patients with CKD.

Methods: This open-label, single-center, randomized clinical trial included 101 patients with CKD who had a history of hypertension and estimated 24-hour urinary sodium excretion of 100 mmol or greater. Patients in the intervention group used CureApp HT, a smartphone app designed to manage hypertension through lifestyle modifications and self-monitoring, particularly for salt restriction. The app delivered daily, individualized guidance tailored to each patient's lifestyle. Patients also received lifestyle counseling by nephrologists during outpatient visits. The control group received lifestyle counseling alone. The intervention period was 12 weeks. The primary outcome was the change in estimated 24-hour urinary sodium excretion from baseline to week 12, calculated from spot urine samples using the Tanaka method. Key secondary outcomes included office blood pressure, brachial-ankle pulse wave velocity, urinary protein-to-creatinine ratio, and plasma brain natriuretic peptide. The analysis was conducted in the intention-to-treat population, using a mixed-effects model for repeated measures.

Results: A total of 101 patients were randomly assigned to the intervention group (n=51) or the control group (n=50). The median (IQR) app engagement rate, calculated by dividing the number of days patients recorded blood pressure in the app by the total intervention period, was 96% (73%-99%). The mean (SD) baseline estimated glomerular filtration rate and 24-hour urinary sodium excretion were 38 (18) mL/min/1.73 m^2 and 145 (33) mmol, respectively. A higher proportion of patients in the intervention group reported that their salt intake behaviors had "significantly improved" or "somewhat improved" by the intervention than those in the control group (35/46, 76% vs 18/47, 38%; $P<.001$). However, the mean change in estimated 24-hour urinary sodium excretion during the intervention period did not differ significantly between groups (1.4, 95% CI −12.0 to 14.7 mmol in the intervention group vs 2.5, 95% CI −10.7 to 15.6 mmol in the control group; between-group difference −1.1, 95% CI −19.8 to 17.7 mmol; $P=.92$). Secondary outcomes were not significantly different between groups. These outcomes were not altered even in a subgroup of patients reporting improved self-reported salt intake behaviors.

Conclusions: The smartphone app did not reduce salt intake in patients with CKD, despite a substantial improvement in self-reported salt intake behaviors. Enhancing the intervention intensity may be necessary to effectively bridge the intention-behavior gap.

Introduction

Excessive salt intake is a major public health concern [1], contributing to a growing number of noncommunicable diseases, such as hypertension and cardiovascular diseases, as well as mortality [2-6]. Sodium load is also detrimental to the kidney, independent of blood pressure levels [7]. Cohort studies showed an association between higher urinary sodium excretion and an elevated risk of kidney outcomes even after adjustment for blood pressure levels [8,9]. In a meta-analysis of randomized controlled trials (RCTs), short-term low-salt diets reduced albuminuria by 36% with only a modest decrease in blood pressure levels among patients with early stages of chronic kidney disease (CKD) [10]. Salt restriction may also enhance proteinuria-lowering effects of renin-angiotensin system inhibitors and improve kidney outcomes [11,12]. Thus, limiting salt intake is an essential part of dietary therapy for patients with CKD, potentially offering kidney protection beyond blood pressure control. Accordingly, the Kidney Disease Improving Global Outcomes guideline recommends a daily sodium intake of less than 2 g for patients with hypertensive CKD [13].

In real-world clinical settings, however, salt restriction is often challenging. The average urinary sodium excretion in patients with CKD has been reported to be well above the guideline recommendation (124.6-160.9 mmol/24 h [2.9-3.7 g/24 h]) [8,14-17]. Lifestyle modifications through dietary consultation and motivational interviewing guided by health care professionals have not shown consistent long-term efficacy for salt restriction [18-22]. Notably, such time-consuming individualized therapy would be costly and difficult to scale for the growing CKD population.

Smartphone app–based interventions have emerged as promising therapeutic options for hypertension. These apps aim to facilitate behavior changes and have the potential to be delivered at scale. However, RCTs examining the efficacy of these apps are scarce [23]. A recent meta-analysis showed a moderate reduction in 24-hour urinary sodium excretion (−0.39 g, 95% CI −0.50 to −0.27) by technology-supported behavior change interventions, including smartphone apps, although patients with CKD were excluded [24]. CureApp HT is a hypertension management app that provides individualized health care advice for lifestyle modification. In the HERB Digital Hypertension 1 pivotal phase III trial, a 12-week use of CureApp HT reduced blood pressure and self-reported salt intake among hypertensive patients who had not used antihypertensive medications [25]. Since the majority of participants in this trial had normal kidney function, it remains uncertain whether CureApp HT would confer similar benefits to patients with CKD who are managed by nephrologists. Here, we evaluated the efficacy of CureApp HT in patients with CKD who were treated at a tertiary referral hospital and exhibited elevated urinary sodium excretion.

Methods

Study Design

This was an open-label, single-center, RCT examining efficacy of CureApp HT, a smartphone app for hypertension management, on urinary sodium excretion in patients with CKD. The intervention period lasted 12 weeks, followed by a 12-week post-intervention period to assess sustainability of treatment effects. A detailed schedule is shown in Figure S1 in Multimedia Appendix 1. Patients were enrolled from the nephrology outpatient department at Osaka University Hospital, Japan, between February 2023 and November 2023. This study was conducted and reported in accordance with the CONSORT eHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and Online Telehealth) checklist (Checklist 1).

Ethical Considerations

The study protocol was approved by the University of Osaka Clinical Research Review Board (approval number 22015) and registered at Japan Registry of Clinical Trials (jRCTs052220164) on February 6, 2023. All participants provided written informed consent. Participants' data were deidentified with unique identification codes and maintained in password-protected, access-restricted institutional databases. No financial or other compensation was provided to participants. The trial was conducted in accordance with the Declaration of Helsinki.

Eligibility Criteria

The eligibility criteria were (1) aged 18 years or older, (2) CKD stages G1 to G5, (3) a history of hypertension (systolic blood pressure 140 mmHg or higher and/or diastolic blood pressure 90 mmHg or higher and/or use of antihypertensive medications), and (4) an estimated 24-hour urinary sodium excretion based on the Tanaka method of 100 mmol or greater [26].

Patients were excluded if (1) they were unable to handle a smartphone due to cognitive impairment or impaired finger dexterity or (2) they already used other health care smartphone apps.

Randomization

Eligible patients were randomly assigned to the intervention group or control group in a 1:1 ratio. Randomization was performed using a computer-generated random number list with a permuted block size of 4, stratified by age (≥75 or <75 y) and estimated 24-hour urinary sodium excretion (≥170 or <170 mmol). The randomization procedure was conducted by one of the investigators who was unaware of participants' information and had no involvement in patient enrollment.

Interventions

Patients assigned to the intervention group used CureApp HT (CureApp Inc.), a smartphone app designed to facilitate hypertension management through lifestyle modifications and self-monitoring, for 12 weeks. This app was approved by the Pharmaceuticals and Medical Devices Agency as software as a medical device in Japan and was included in the national health insurance coverage on September 1, 2022. They also received lifestyle counseling by nephrologists as per the Clinical Practice Guideline for CKD 2018 issued by the Japanese Society of Nephrology [27]. This lifestyle counseling included general recommendations on salt restriction (targeting <6 g/d), moderation of alcohol consumption, and other standard dietary and behavioral advice. Patients in the control group received

XSL•FO
RenderX

lifestyle counseling during outpatient visits, typically once every 1 to 3 months, without access to the app.

To minimize the risk of cross-contamination, all patient recruitment and follow-up were conducted individually through routine outpatient visits. No group education sessions or group-based activities were provided. Patients in both the intervention and control groups were not informed of each other's group assignments. Furthermore, the app was accessed privately by patients in the intervention group on their personal smartphones.

Dose adjustment of antihypertensive medications, diuretics, oral antihyperglycemic medications, and potassium binders was not permitted throughout the intervention period, unless deemed clinically necessary by attending physicians.

Patients in the intervention group were instructed to download CureApp HT to their smartphones and activate it using prescription codes. They entered personal data, including age, sex, body weight, lifestyle behaviors, social background, and daily home blood pressure. These data were transferred to the cloud system, which generated individualized lifestyle modification programs.

CureApp HT is designed to enhance patients' awareness of hypertension and facilitate lifestyle modifications and self-management through the following 3 steps:

- Step 1 (Education): Patients acquire knowledge about hypertension and lifestyle modification methods through interactive conversations with a virtual nurse within the app.
- Step 2 (Implementation): The app provides patients with personalized action plans, including salt restriction, weight loss, exercise, improvement of sleep quality, mitigation of mental stress, and reduction in alcohol consumption.
- Step 3 (Habituation): Patients set their own behavioral goals and cultivate habits with the support of the app.

Through a specialized web application, attending physicians monitored patients' daily blood pressure levels, as entered by patients in the app, and tracked the progress of the 3 steps mentioned above.

Primary Outcome

The primary outcome was the change in estimated 24-hour urinary sodium excretion during the intervention period, measured at baseline, week 4, and week 12. The estimated 24-hour urinary sodium excretion was calculated using the Tanaka method based on spot urine samples [26]: Estimated 24-hour urinary sodium excretion (mg) = 23 × 21.98 × {[urinary Na (mEq/L)/(urinary creatinine (mg/dL)×10)] × predicted 24-hour urinary creatinine excretion (mg/day)}$^{0.392}$

Predicted 24-hour urinary creatinine excretion (mg/day) = [−2.04 × age (years)] + [14.89 × weight (kg)] + [16.14 × height (cm)] − 2244.45

Secondary Outcomes

Secondary outcomes were selected to explore the potential impact of the intervention on kidney and cardiovascular risk markers, including the changes in the following parameters during the intervention period, measured at baseline and week 12: (1) office blood pressure, (2) brachial-ankle pulse wave velocity (baPWV), (3) urinary protein-to-creatinine ratio (UPCR), (4) urinary potassium-to-creatinine ratio, (5) urinary sodium-to-potassium ratio, (6) estimated glomerular filtration rate (eGFR), (7) brain natriuretic peptide (BNP), (8) body weight, and (9) the number of antihypertensive medications.

Office blood pressure was measured using an automated oscillometric blood pressure monitor (Omron HEM-907). Patients self-measured their blood pressure after resting quietly in a seated position for 5 minutes without attendance of medical personnel. The average value of 2 measurements at 1-minute intervals was used for statistical analysis.

The baPWV was measured using a noninvasive automated device (Omron BP-203RPEIII) after patients rested for 5 minutes in a supine position. This device measured baPWV twice simultaneously on the right and left sides. The average value of these 4 measurements was used for statistical analysis.

eGFR was calculated using the Japanese standard formula: 194 × creatinine$^{-1.094}$ × age$^{-0.287}$ (if female, × 0.739) [28].

Questionnaire Survey on Salt Intake Behaviors

After the 12-week postintervention period, patients were asked to assess how much their lifestyle behaviors had improved by responding to the following question: "To what extent has your lifestyle related to (1) salt intake, (2) exercise, (3) sleep quality, (4) mental stress, and (5) alcohol consumption improved as a result of participating in this trial?." Patients selected one of the following options: "significantly improved," "somewhat improved," "not much improved," or "not improved at all." Regarding research objectives, only the salt-intake item was included in a between-group comparison in the present analysis.

Statistical Analysis

A previous observational study reported that every 40 mmol/24 h increase in urinary sodium excretion was associated with a 10% higher hazard of cardiovascular events in patients with CKD [9]. Based on this finding, we considered a 40 mmol/24 h decrease in urinary sodium excretion to be clinically relevant. According to the 2-arm pilot trial sample size calculation [29], 96 patients (48 in each group) were required to provide 90% power, with a 2-sided type I error level of .05, to detect a between-group difference of 40 mmol/24 h with a SD of 60 mmol/24 h. To account for a 5% dropout rate, we planned to recruit 100 patients.

Between-group comparisons were conducted using the Student *t* test or Mann-Whitney test for continuous variables and the chi-square test or Fisher exact test for categorical variables, as appropriate.

The primary analysis was conducted in the intention-to-treat population, defined as all randomized patients who used CureApp HT for at least one day or received at least one lifestyle counseling session. We employed a mixed-effects model for repeated measures (MMRM) with an unstructured covariance matrix to compare between-group differences in the primary and secondary outcomes. Fixed effects in the MMRM were treatment groups, categoric time, treatment-by-time interaction,

XSL•FO
RenderX

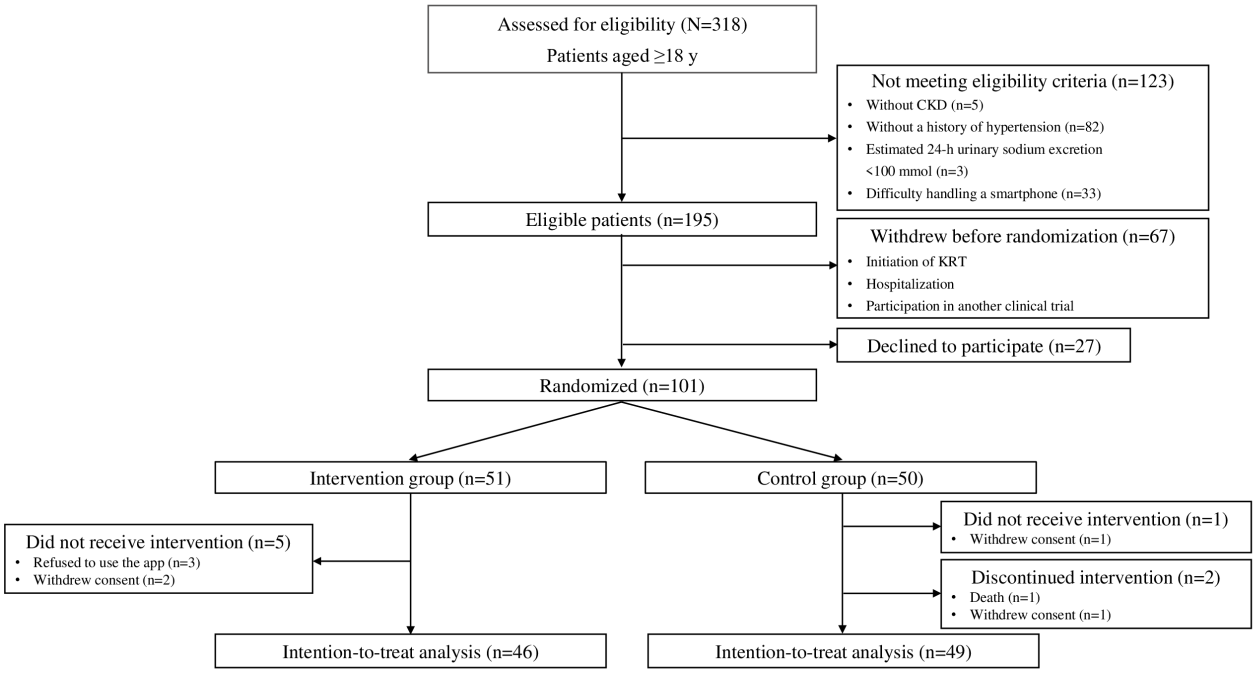
and stratification factors (age and baseline estimated 24-h urinary sodium excretion). No multiplicity adjustments for each outcome were made in this proof-of-concept study. There were no missing data on baseline estimated 24-hour urinary sodium excretion. The missing data after baseline were not imputed but were instead handled directly within the MMRM.

Prespecified subgroup analyses were performed based on baseline age (below or above the median), baseline estimated 24-hour urinary sodium excretion (below or above the median), and app engagement rates calculated by dividing the number of days patients recorded blood pressure in the app by the total intervention period (≥71.4% or <71.4%). Effect modifications were tested by incorporating treatment-by-subgroup interactions into the MMRM.

Sensitivity analyses were performed after excluding patients (1) who did not reach step 3 and (2) whose family members assisted with app usage due to patients' difficulty in operating a smartphone.

An exploratory analysis was conducted in which patients were categorized into 4 groups using the results of the questionnaire survey on salt intake behaviors ("not improved at all," "not much improved," "somewhat improved," and "significantly improved"). A linear regression model was used to evaluate the association between the self-reported behavior category and the change in estimated 24-hour urinary sodium excretion.

All statistical analyses were performed using the Stata/IC software (version 18.0; Stata Corp). A *P* value of <.05 was considered statistically significant.



Results

Patient Characteristics

A total of 101 patients were randomly assigned to the intervention group (n=51) or the control group (n=50) (Figure 1). In the intervention group, 3 patients refused to use the app and 2 patients withdrew consent before using the app, while no patients dropped out during the intervention period. In the control group, 1 patient withdrew consent before the intervention period, and 2 patients dropped out during the intervention period.

The baseline characteristics are shown in Table 1. The mean (SD) age, blood pressure, and eGFR were 66 (14) years, 131 (19)/79 (14) mmHg, and 38 (18) mL/min/1.73 m^2, respectively. Patients in the intervention group showed slightly lower systolic blood pressure and eGFR than those in the control group. The estimated 24-hour urinary sodium excretion at baseline was 145 (33) mmol and was well-balanced between groups.

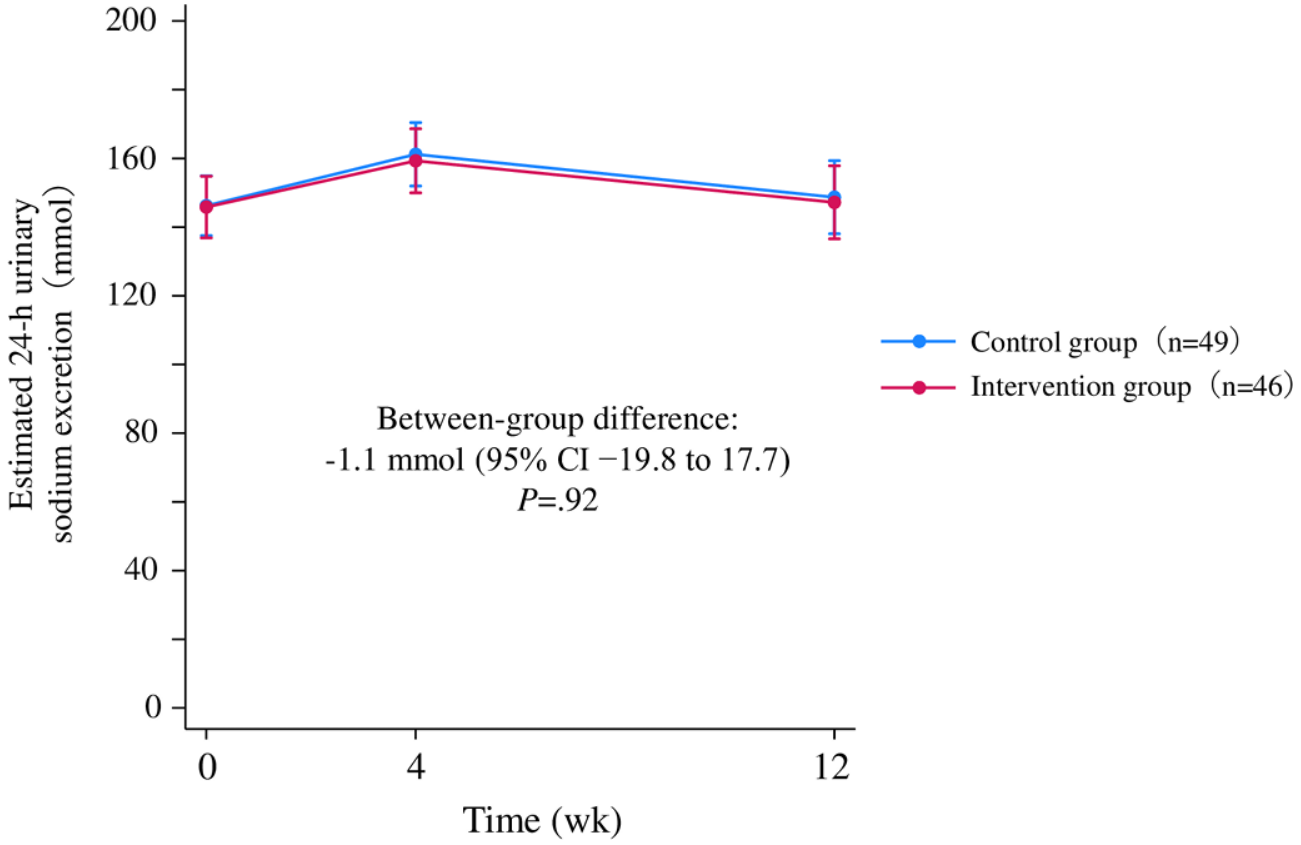
Questionnaire Survey on Salt Intake Behaviors

In the intervention group, 35 of 46 (76%) patients reported that their salt intake behavior had “significantly improved” or “somewhat improved” by the intervention, compared with 18 of 47 (38%) in the control group (χ^2_3=24.87; *P*<.001; Figure 2, Table S1 in Multimedia Appendix 1).

Figure 2. Questionnaire survey on salt intake behaviors. Self-reported salt intake behaviors were significantly improved in the intervention group compared with the control group. Patients were asked, "To what extent has your lifestyle related to salt intake improved as a result of participating in this trial?" In the intervention group, 35 of 46 (76%) patients reported that their salt intake behavior had “significantly improved” or “somewhat improved” compared with 18 of 47 (38%) in the control group (*P*<.001; χ^2_3=24.87).



Primary Outcome

The mean change in estimated 24-hour urinary sodium excretion from baseline to week 12 was 1.4 (95% CI −12.0 to 14.7) mmol in the intervention group and 2.5 (95% CI −10.7 to 15.6) mmol in the control group, with no significant between-group difference (−1.1 mmol, 95% CI −19.8 to 17.7; *P*=.92) (Figure 3, Table 2). Age, baseline estimated 24-hour urinary sodium excretion, and app engagement rates did not significantly modify the results (Table S2 in Multimedia Appendix 1).

After the 12-week postintervention period, the mean change in the estimated 24-hour urinary sodium excretion from baseline was not significantly different between the groups; 4.7 (95% CI −8.9 to 18.4) and 13.9 (95% CI 0.4-27.3) mmol in the intervention and control groups, respectively (between-group difference, −9.1 mmol, 95% CI −28.3 to 10.0; *P*=.35).

XSL•FO
RenderX

Secondary Outcomes

There were no significant between-group differences in the changes in blood pressure, baPWV, UPCR, urinary potassium-to-creatinine ratio, urinary sodium-to-potassium ratio, eGFR, BNP, body weight, and the number of antihypertensive medications during the intervention period (Table 2, Figure S2 in Multimedia Appendix 1). No adverse events related to app use were reported.

The median (IQR) app engagement rate was 96% (73%-99%). At the end of the intervention period, 35 of 46 (76%) patients who used the app at least once completed Step 1, and 22 of 46 (48%) completed both Step 1 and Step 2.

Sensitivity Analyses

The results were not substantially altered after excluding patients who did not reach Step 3 (24/46, 52%) or whose family members helped use the app (1/46, 2%) (Table S3 in Multimedia Appendix 1).

Exploratory Analysis

Participants were categorized into 4 groups according to the questionnaire survey on salt intake behaviors at week 12. There were no significant linear trends between self-reported salt intake behavior and the change in urinary sodium excretion in either the intervention or control group (Table S4 in Multimedia Appendix 1).

Discussion

Overview

In this single-center, open-label, RCT involving patients with CKD, we observed a substantial improvement in self-reported salt intake behaviors after 12 weeks of CureApp HT use. However, the app did not improve the primary outcome, estimated 24-hour urinary sodium excretion, a surrogate measure of actual salt intake. Secondary outcomes, including blood pressure, baPWV, UPCR, and BNP, also did not differ significantly between groups. Notably, these outcomes did not improve even in a subgroup of patients who reported significant improvements in salt intake behaviors, suggesting a gap between self-awareness and actual behaviors regarding dietary salt intake. Bridging this gap will be a major challenge that digital therapeutics need to address.

Principal Findings

Salt restriction is essential in the management of CKD to achieve optimal blood pressure control. Associations between urinary sodium excretion and kidney outcomes have been reported to be independent of blood pressure levels [8,9]. This suggests that mechanisms beyond blood pressure elevation may contribute to salt-induced kidney damage. Basic studies have shown that a high-salt diet accelerates kidney damage through several mechanisms, including Rac1-mediated mineralocorticoid receptor activation [7], inhibition of tissue remodeling by macula densa cells [30], and inflammation and fibrosis induced by Y-box binding protein-1 [31]. These preclinical findings imply that salt restriction may confer kidney protection even when blood pressure levels are normal. Although this concept has not been clinically tested, short-term low-salt diets significantly reduced albuminuria with only modest impacts on blood pressure levels [10,11]. Additionally, salt restriction may enhance the kidney-protective effects of renin–angiotensin system inhibitor [12]. Therefore, although our patients had well-controlled blood pressure levels, salt restriction may still be beneficial in reducing residual salt toxicity to the kidney. Thus, urinary sodium excretion is a clinically relevant outcome in this trial.

We identified a substantial discrepancy between patients' self-reported salt restriction behaviors and objectively measured urinary sodium excretion. A similar finding was reported in the HERB Digital Hypertension 1 trial, in which CureApp HT significantly improved self-reported salt intake but had minimal impact on the urinary sodium-to-creatinine ratio [25]. These findings suggest that intentions do not necessarily translate into behavioral changes, highlighting the presence of an intention-behavior gap. Psychological behavior theories, such as the Theory of Planned Behavior and Self-Determination Theory, assume that intention is the proximal determinant of behavior. However, a "gap" exists between intention and behavior [32]. There is only a modest correlation between intentions and actual behaviors [33,34]; intention accounts for only 27% of the variance in dietary habits [35], and individuals often underestimate their salt intake [36,37]. This gap is influenced by several moderators, including (1) social environment, (2) behavioral inertia, and (3) sodium palatability. The social environment plays a significant role in determining salt intake behaviors. Even when patients recognize the importance of salt restriction, it is not feasible in situations where access to fresh, low-sodium foods is limited and processed foods (including prepackaged and fast food) are prevalent. In Japan, many traditional foods, such as soy sauce and pickled vegetables, are high in salt. These social and environmental factors may impede patients' intention to adhere to a low-salt diet despite their increased awareness of salt restriction. Public health policies and social support must be implemented, in collaboration with multiple stakeholders such as the food industry, to create an environment where low-salt foods are more readily accessible [38].

Behavioral inertia is another barrier that exacerbates the intention-behavior gap. Established eating habits are a putative determinant of human salt intake [39]. A prior study found no association between the intention to change salt intake habits and the actual purchasing behavior of low-salt foods [40]. Because our patients were older, they were likely to maintain long-established dietary and cooking habits, which are inherently resistant to change, although age did not significantly modify the results in subgroup analysis. Regular face-to-face care from nephrologists may have led patients to assume that their current salt intake was already acceptable, even though their salt intake was beyond the target range. This false perception may reinforce patients' psychological resistance to behavioral modifications for salt restriction proposed by the app. Importantly, health benefits from salt restriction are not always immediately apparent. The delayed rewards of long-term health benefits obtained from salt restriction, in exchange for immediate

XSL•FO
RenderX

gratification of enjoying salty foods, further complicate maintaining salt restriction as a regular habit [40].

Finally, sodium palatability may also contribute to the intention-behavior gap among patients with CKD. Under sodium-sated conditions, humans exhibit an attraction toward low concentrations of sodium but an aversion toward high concentrations of sodium [41]. However, patients with CKD typically have a higher threshold for salty taste perception than healthy individuals [42,43], and their aversive response to high sodium concentrations may be diminished [44]. Such an altered salty taste perception, coupled with an increased tolerance for excess salt, likely enhances sodium palatability of these patients, making dietary salt restriction even more challenging.

To bridge the intention-behavior gap regarding salt restriction, it may be necessary to optimize the intensity of intervention. Greaves et al [45] reported that intervention intensity, such as the number of sessions and total contact time, was related to self-reported dietary changes. For example, in the Trials of Hypertension Prevention, which demonstrated substantial efficacy of comprehensive education and counseling on salt restriction, intensive and meticulous interventions were conducted (8 group counseling sessions and 2 individual sessions over the first 3 mo, followed by periodic group meetings and individual telephone or in-person contacts throughout the follow-up) [46]. In patients with CKD, theory-based behavioral interventions, using both face-to-face and web-based approach (e-coaching and group meetings), have shown only modest and temporary effects on salt restriction, potentially due to a relatively low intensity of these interventions [20,21]. The intensity of the smartphone-based digital intervention might be even weaker, particularly for patients with CKD who likely have a large intention-behavior gap, owing to the absence of human involvement. Therefore, enhancing intervention intensity in smartphone-based approaches, potentially by incorporating more interactive and individualized elements, may be essential to improve their effectiveness in promoting sustained salt restriction.

Limitations

This trial has several limitations, one of which is the open-label design. However, blinding was impractical given the nature of the intervention. Since the measurement of urinary sodium excretion was objective, potential bias from the open-label design was likely mitigated. Second, the sample size was modest and the trial duration was relatively short. However, given the neutral result of the primary outcome, it is unlikely that a larger and longer-term trial would have produced a positive result. Third, although the accuracy of the Tanaka method for estimating 24-hour urinary sodium excretion from a spot urine test has been validated in Japanese patients with CKD [47], its accuracy may still be inferior to that of a 24-hour urine collection. However, if dietary salt intake had been meaningfully reduced, secondary outcomes, including blood pressure, UPCR, and BNP, would likely have shown improvement. Fourth, the questionnaire survey on salt intake behaviors may have been subject to social-desirability bias, potentially leading to an overestimation of the proportion of patients reporting improvements. However, the substantial difference between the intervention and control groups suggests that the app did have some impact at least on patients' intention. Fifth, the study did not assess the potential time lag between knowledge acquisition and actual behavioral change, which may have contributed to the limited correspondence between self-reported behavior and objective outcomes. Finally, since our study included patients who were willing to use the app, the generalizability of our findings to the broader real-world population, particularly outside of Japan, is uncertain.

Conclusions

CureApp HT, a hypertension management app that provides individualized advice and self-monitoring for lifestyle modifications and salt restriction, was not effective in reducing urinary sodium excretion among patients with CKD, despite substantial improvement in self-reported salt intake behaviors. Secondary outcomes, including blood pressure, baPWV, UPCR, and BNP, also did not differ significantly between groups, further indicating that the app did not improve other cardiovascular and kidney risk markers. These results should be interpreted with caution due to the open-label design and the relatively short duration of the trial. Nonetheless, these findings suggest the presence of an intention-behavior gap for salt restriction, which might be addressed by enhancing the intensity of smartphone app–based interventions.

Abstract

Background: Behavioral and psychological symptoms of dementia (BPSD) are common and negatively impact both individuals with dementia and their families. Although nonpharmacological interventions are recommended as the first-line treatments, their use in community settings is limited by access and caregiver resources. Existing approaches are often not individualized and rely on institutional or clinician-led delivery.

Objective: We developed a caregiver-initiated and individualized multimodal mobile app. The app delivers tailored nonpharmacological interventions—such as music therapy, exercise, and reminiscence therapy—based on each user's preferences and functional abilities. This study aimed to evaluate the effectiveness of this mobile app–based intervention in reducing BPSD in community-dwelling persons living with dementia.

Methods: This study used a single-blinded randomized controlled trial design. Participants were recruited from an outpatient clinic of a tertiary hospital, a dementia care center, and 5 home care service centers. A total of 36 dyads participated, each comprising a community-dwelling person living with dementia aged 60 years or older and their primary family caregiver. The dyads were randomly allocated to either the intervention or control group. The intervention group received a caregiver-initiated, multimodal, mobile app–based individualized intervention for 4 weeks, whereas the control group continued with usual care. The primary outcomes were overall BPSD, agitated behavior, and depression. The secondary outcomes were nighttime sleep efficiency and caregiver competency in managing BPSD. Assessments were conducted at baseline, immediately after the intervention, and at a 2-week follow-up.

Results: Of the 36 randomized dyads, 33 were included in the final analysis. Although the intervention group showed greater reductions in overall BPSD, agitated behavior, and depression after the intervention, no significant group-by-time interaction effects were observed in the total sample. In the subgroup analysis of participants with clinically significant baseline BPSD, a statistically significant improvement in overall BPSD was found in favor of the intervention group (β=–12.885, 95% CI –24.530 to –1.240; *P*=.03). No significant effects were observed for either nighttime sleep efficiency or competence in the management of BPSD.

Conclusions: A mobile app–based individualized intervention may offer a flexible, caregiver-initiated approach to managing BPSD in home-care settings. While overall effects were limited, exploratory subgroup findings provided meaningful insights, indicating potential benefits for those with higher baseline symptom severity. The results highlight the need for further research on adaptive personalization and optimized intervention delivery to enhance the clinical effectiveness of digital dementia care.

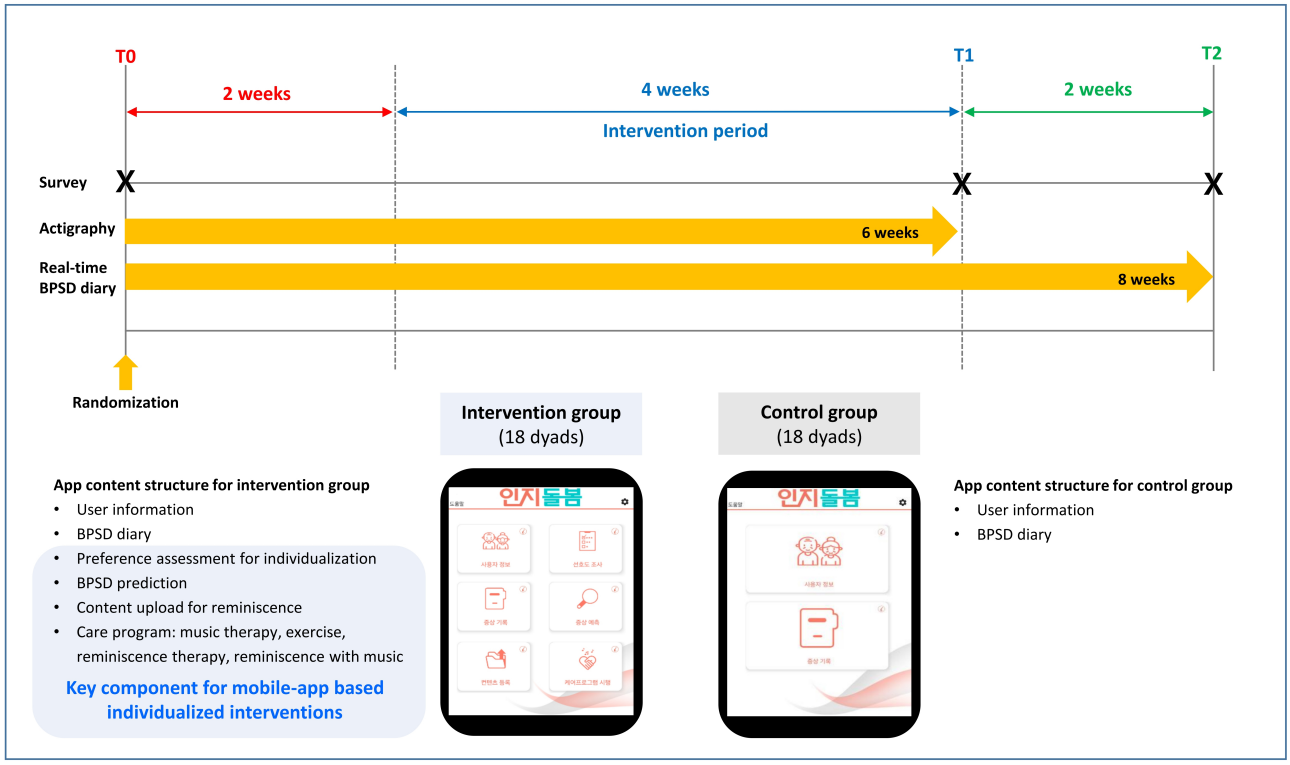
Introduction

Cognitive decline is a common symptom of dementia, with behavioral and psychological symptoms of dementia (BPSD) recognized as the core features of the condition [1]. The nature of BPSD varies depending on the type and stage of the condition; however, these symptoms can appear at any time [1]. According to recent literature, nearly 90% of persons living with dementia experience BPSD [2]. Among these, symptoms such as apathy, depression, anxiety, irritability, agitation, and aggression are commonly observed in persons living with dementia [3], and often coexist with sleep disturbances, which are highly prevalent in this population [4-6]. In particular, a person living with dementia frequently exhibits reduced nighttime sleep efficiency and disrupted rest–activity rhythms, characterized by fragmented nocturnal sleep and frequent nighttime awakenings [4,5]. These disturbances are not simply co-occurring conditions but interact bidirectionally with BPSD, jointly contributing to increased mortality [7] and decreased quality of life [8]. Furthermore, BPSD and nocturnal sleep disruptions significantly increase caregiver burden [8-11] and care costs [8]. Therefore, implementing effective interventions targeting BPSD has become critical in dementia care. Such interventions can alleviate caregiver burden at the individual level and mitigate the broader societal impact of dementia care.

Nonpharmacological interventions are recommended as a first-line strategy for managing BPSD owing to their comparable efficacy to pharmacological treatments while minimizing adverse effects [12,13]. A wide range of nonpharmacological approaches has been developed to address the cognitive, psychological, social, and environmental dimensions of dementia care [12-14]. Interventions such as music therapy, exercise, and reminiscence therapy have demonstrated effectiveness in managing BPSD [14-17] and may be applied to support their prevention and management. Despite the growing emphasis on nonpharmacological interventions for BPSD, the COVID-19 pandemic has exacerbated the exclusion of community-dwelling persons living with dementia from essential care services. In particular, access to nonpharmacological activities was restricted by global social distancing measures [18-20]. These challenges persist beyond the pandemic, particularly among family caregivers, who often face limited access to therapy, logistical challenges in scheduling sessions, insufficient funding, and poor local accessibility [21].

In light of the constraints on home-based nonpharmacological interventions during and after the pandemic, digital approaches for remote delivery have gained growing importance [22]. Digital technologies, such as virtual reality, robotics, and mobile apps, have been widely applied to deliver diverse nonpharmacological interventions for persons living with dementia. These technologies have enabled activity-based programs, exercise, interactive activities, and coaching or counseling support [23-25]. A systematic review found that reminiscence therapy delivered through mobile apps enhanced social interaction [23], and a pet robot in long-term care settings helped alleviate BPSD [24]. However, most of these digital tools have been implemented in long-term care settings or require operation by clinicians or trained staff [25]. Among these, artificial intelligence–based cognitive stimulation programs and digital reminiscence therapies have been delivered by care staff in institutional environments [26,27]. A range of apps and digital platforms enables clinicians and formal caregivers to assess, record, and manage BPSD, with limited applicability to home settings [28-30]. Although mobile apps are also used to provide family caregivers with training on disease-related information, caregiving skills, and coping strategies [31,32], adherence to nonpharmacological interventions remains low [21,33]. Moreover, existing apps rarely enable family caregivers to directly deliver these interventions in real-world home settings, highlighting a critical gap in current digital care approaches. While these interventions have shown beneficial effects on BPSD, their impact could be further enhanced through greater individualization [25,26,34]. Therefore, there is a need for enhanced digital tools to support caregiver-led interventions and tailor strategies to the diverse contexts of persons living with dementia.

To address this gap, we developed a mobile app to empower family caregivers to deliver tailored interventions in real-world home settings. The app's usability and user acceptability were evaluated during its developmental phase among persons living with dementia and their caregivers [35]. The app guides caregivers through a structured process that includes the assessment of symptoms and potential triggers and recommends tailored nonpharmacological strategies that caregivers can implement. Because BPSD management often exceeds the competence of family caregivers, the app was also designed to gradually build their skills and confidence in delivering these interventions. Building on these findings, we designed a randomized controlled trial to assess the effectiveness of this mobile app–based intervention for persons living with dementia in a community setting. We hypothesized that it would alleviate the severity and frequency of BPSD compared with usual care. The objective of this randomized controlled trial was to evaluate the effectiveness of a mobile app that delivers individualized nonpharmacological interventions for reducing BPSD. The study also examined its effects on nighttime sleep efficiency and caregiver competence.



Methods

Study Design and Setting

This was a single-blind, parallel, randomized controlled trial designed to compare mobile app–based individualized nonpharmacological interventions with usual care. Participants were recruited from the neurology outpatient clinic of a tertiary hospital, a regional dementia care center, and 5 home care service centers. Figure 1 presents an overview of the study timeline and app components for each group.

XSL•FO
RenderX

Figure 1. Study timeline and app components by group. BPSD: behavioral and psychological symptoms of dementia.

Trained research assistants visited participants to collect outcome data and baseline information according to the study timeline and provided education on app use. They remained available to answer any questions and ensure completeness while family caregivers completed self-administered paper questionnaires. Outcome assessments were conducted at baseline (T0), 4 weeks postintervention (T1), and at 2 weeks of follow-up (T2). The trial was prospectively registered with the Clinical Research Information Service (registration number: KCT0008713). The study protocol has been published previously [36].

Participants

The study sample included persons living with dementia in a community setting and their family caregivers as a dyad. Eligibility was assessed by trained research assistants. The inclusion criteria for persons living with dementia were (1) aged 60 years or older, (2) any type of dementia, (3) Korean version of the Mini-Mental State Examination score <24, (4) exhibited BPSD at least once per week, and (5) lived in Seoul or Gyeonggi-do Province with their family caregivers. The inclusion criteria for family caregivers were (1) primary caregivers of persons living with dementia, and (2) no difficulties in reading and writing Korean. The participants were enrolled between October 2023 and March 2024, based on the eligibility criteria.

Ethical Considerations

This study was approved by the institutional review board of Yonsei University Health System (IRB number 4-2023-0660). Written informed consent was obtained from both persons living with dementia and their primary family caregivers after a detailed explanation of the study objectives and procedures. In cases where persons living with dementia were unable to provide consent due to impaired decision-making capacity, consent was obtained from a surrogate decision-maker. Given the dependency and vulnerability of the study population, special ethical considerations were applied throughout the study period. To ensure confidentiality, all participants were assigned identification numbers, and access to the collected data was restricted to the research team only. A small token of appreciation was provided based on the study participation period. Participants who completed the entire study received approximately US $146 (KRW ₩ 200,000) per dyad.

Sample Size

The sample size was calculated using Cohen's power analysis (repeated measure analysis of variance within factor: α=.05, power level=0.8, effect size=0.25, groups=2, and number of measurements=3). A minimum sample size of 28 participants was required to achieve a statistical power of 0.80. As the intervention was primarily implemented by caregivers, an anticipated 30% attrition rate was applied, based on previous intervention studies with dementia caregivers [37,38]. Accordingly, 36 patient–caregiver dyads were recruited from both groups.

Randomization and Blinding

Participants were randomly assigned to the intervention and control groups in a 1:1 allocation ratio. A researcher who was not in contact with the participants created a randomization list using a computer program (STATA version 13.1; StatCorp LP). Block randomization (with a block size of 4 to assign patients to 9 groups) was used to evenly allocate the dyads to the intervention and control groups. The generated randomization list was sealed in an envelope and stored. After participants provided consent and the study commenced, group allocation was disclosed only to the researcher responsible for data

XSL•FO
RenderX

collection and mobile app training. Persons living with dementia and their caregivers were not informed of their group allocation to minimize bias. Both the intervention and control groups used the same mobile app interface and wore actigraphy devices during the study period. The only distinction was that the intervention group used both symptom diaries and individualized nonpharmacological interventions through the app, whereas the control group used only symptom diaries via the app.

Intervention

All participants were provided with a tablet device (Galaxy Tab A8; Samsung) preinstalled with a mobile app. Both the intervention and control groups were instructed to record a real-time diary of BPSD throughout the study period using the app, allowing continuous monitoring of symptoms and possible triggers.

Only the intervention group received a 4-week individualized nonpharmacological intervention program via the app. Caregivers were instructed to initiate the intervention at least once daily but could use it more frequently or flexibly according to their needs. The program included 4 types of activities: music therapy, exercise, reminiscence therapy, and reminiscence therapy with music. To enhance individualization, the trained research assistants collected information on personal backgrounds, preferences, and physical functioning at baseline. The app also integrates individualized content, such as family-uploaded photographs, videos, individualized music playlists, and tailored exercise programs. Additionally, the intervention content was updated based on caregivers' requests to reflect their changing preferences and needs. Family caregivers in the intervention group autonomously selected and initiated interventions based on the app's recommendations and observed the response of persons living with dementia during the 4-week period.

In addition, the app incorporated a machine-learning–based BPSD prediction model developed and validated in our previous studies [35,39]. The model was trained using data collected from 187 community-dwelling persons living with dementia, with data from 35 others used for external validation. Information collected included demographic data, health status, and personality traits prior to dementia onset. Actigraphy devices tracked participants' sleep and activity, and caregivers documented daily BPSD symptoms and possible triggers in a symptom diary. Multiple algorithms were tested, including logistic regression, random forest, gradient boosting machine, and support vector machine. Among these, the gradient boosting machine demonstrated the best predictive performance, with average AUC values above 0.8 for most symptoms [39]. Based on these findings, the gradient boosting model was implemented within the mobile app to provide BPSD prediction. Furthermore, we conducted an umbrella review to identify evidence-based nonpharmacological approaches with demonstrated effectiveness for each BPSD to guide the selection of appropriate interventions [14]. Based on this review, we developed evidence-based recommendations, which were integrated into the app. Thus, this app recommends tailored nonpharmacological interventions based on BPSD subtypes predicted through machine learning. Meanwhile, the control group did not receive any nonpharmacological interventions through the app and continued routine care throughout the same period.

Measurements

Primary outcomes were assessed at 3 time points based on the observation of primary family caregivers. Secondary outcomes regarding nighttime sleep efficiency and caregiver competence in managing BPSD were also collected at baseline and at the 4-week postintervention period.

Primary Outcomes

The Korean version of the Neuropsychiatric Inventory (NPI) was used to assess overall dementia-related symptoms. The total score is calculated by multiplying the frequencies and severities of the domains, with a higher score indicating more BPSD [40]. Agitated behaviors were measured using the Korean version of the Cohen-Mansfield Agitation Inventory, which consists of 29 items that assess the frequency of agitated behaviors. The total score ranges from 29 to 203, with higher scores indicating a higher frequency of agitated behavior [41]. Depressive symptoms were evaluated using the Korean version of the Cornell Scale for Depression, which contains 19 items on depressive signs and symptoms [42]. The total score on this scale ranges from 0 to 38, with a higher score indicating a more depressed status.

Secondary Outcomes

The activity monitor wGT3X-BT (ActiGraph, LLC), a validated actigraphy device for assessing circadian rhythms in persons living with dementia [43], was used in this study. Persons living with dementia were instructed to wear the wrist-worn actigraphy device as consistently as possible, particularly at night. Sleep data were collected over 2 distinct periods: during the 2 weeks prior to the intervention (baseline period) and throughout the 4-week intervention period. The initial 2-week period was used to collect the data necessary for predicting BPSD patterns and establishing baseline information. The subsequent 4-week period was used to evaluate the effects of the intervention. Nighttime sleep data from these periods were extracted and analyzed to monitor changes in sleep patterns. Sleep efficiency was operationalized as nighttime sleep efficiency, given that it serves as a core indicator of overall sleep quality in persons living with dementia [44]. Previous studies have demonstrated that insufficient nighttime sleep is closely associated with the exacerbation of BPSD [4-6,45] and increased caregiver burden [11], highlighting its clinical relevance in dementia care. Nighttime sleep efficiency was calculated for the period between 8 PM and 8 AM as the ratio of total sleep time to time in bed, consistent with the operational definitions used in previous studies [5].

Our app was designed to provide a comprehensive care framework that includes symptom assessment, prediction of BPSD, recommendation of tailored nonpharmacological strategies, and delivery of interventions. This structured process was expected to enhance caregivers' competence in managing BPSD, thereby contributing to the effectiveness and sustainability of the intervention. Accordingly, caregiver competence was assessed using the competence scale in managing BPSD [46]. This is a self-report tool for measuring

XSL•FO
RenderX

knowledge, skills, and attitudes in the management of BPSD. In addition to the 28 core items, an additional question assessed family caregivers' general competency.

Engagement Measures

As both groups completed BPSD diaries for 8 weeks, the number of diary entries was obtained from in-app logs. During the 4-week intervention period, app usage data in the intervention group were extracted from the logs, including usage frequency and mean usage time for each program. The app dose for each participant was operationalized as the number of days used, the total number of sessions, and the mean session duration. Engagement level was defined as the degree to which the persons living with dementia actively participated in the app-guided nonpharmacological intervention. It was rated by family caregivers after each session on a 5-point Likert scale ranging from very bad (1) to very good (5).

Basic Information

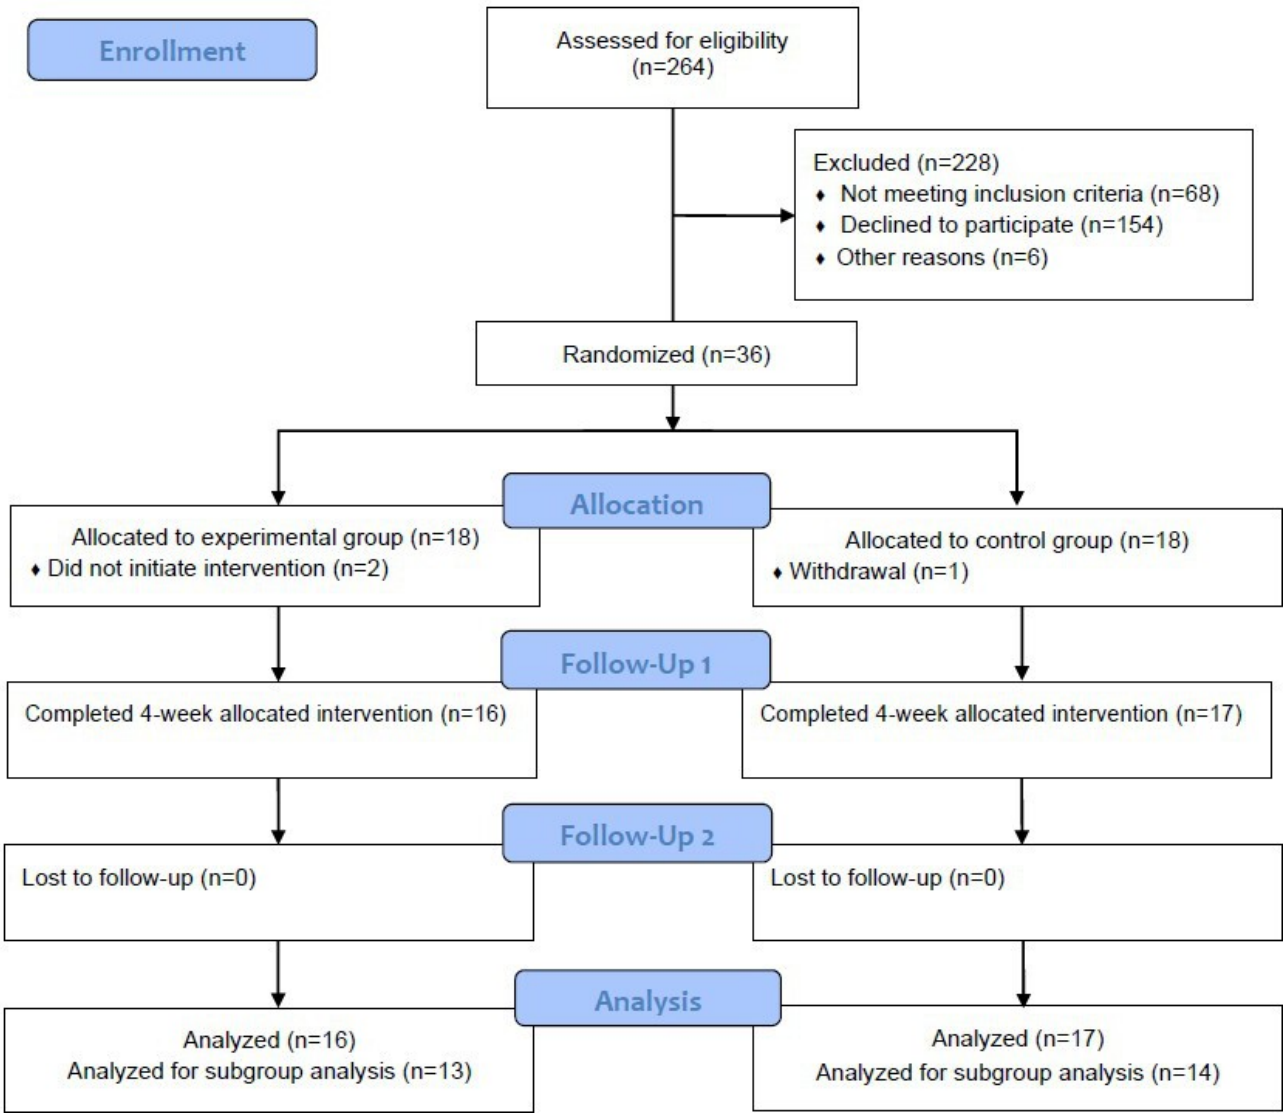
Sociodemographic variables for persons living with dementia included sex, age, years of education, marital status, and dementia diagnosis. Cognitive function was assessed with the Korean version of Mini-Mental State Examination-2, with scores below 24 out of 30 indicating cognitive impairment [47]. Activities of daily living were measured using the Korean Activities of Daily Living scale [48], a 7-item measure of basic physical functions (eg, dressing, face washing, bladder/bowel control, eating, toilet use, and mobility). Higher scores reflect greater dependence, with scores ≥8 indicating dependency. Sociodemographic variables for family caregivers included sex, age, years of education, and relationship with persons living with dementia. Family caregiver–perceived intimacy was assessed using a single Likert item ("How close would you describe your relationship with the person living with dementia?") rated on a 5-point scale from very high (1) to very low (5). For analysis, scores of 1 - 2 were categorized as high intimacy, 3 as moderate intimacy, and 4 - 5 as low intimacy. Caregiver subjective health was assessed with a single 5-point item from very healthy (1) to very unhealthy (5), and for analysis, scores of 1 or 2 were categorized as healthy, and 3 to 5 as moderate-to-unhealthy.

Statistical Analyses

All statistical analyses were performed using SPSS Statistics for Windows (version 27.0; IBM Corp., Armonk, NY). All statistical tests were 2-tailed with a significance level of 0.05. Descriptive statistics were used to summarize participants' general characteristics. Baseline homogeneity between the intervention and control groups was assessed using the Pearson chi-square test, Fisher exact test, and the independent *t* test. We applied a mixed-effects model to examine whether changes in outcomes over time differed between the intervention and control groups across the 3 measurement time points (T0, baseline; T1, postintervention; and T2, follow-up). The model included fixed effects for group, time, and their interaction (group×time). The baseline value of each outcome variable was included as a covariate to adjust for initial differences between participants. A subject-level random intercept was specified to account for within-participant correlations arising from repeated measures. Time was modeled as a categorical factor to avoid assuming linearity. In this specification, each group×time coefficient reflects the time-specific difference-in-difference, that is, the between-group difference in change from baseline. This approach enabled us to (1) incorporate all available data under the missing-at-random assumption, (2) model within-subject covariance structures to improve estimation efficiency, and (3) perform an omnibus Wald/F test of overall trajectory differences. This reduced the risk of multiplicity compared with conducting separate per-visit analyses. Furthermore, as BPSD are expected to change gradually over time, alternative covariance structures were compared. Specifically, compound symmetry and first-order autoregressive structures were evaluated, and model fit was compared using the Akaike Information Criterion and the Bayesian Information Criterion. The first-order autoregressive structure provided the better fit and was therefore adopted. Although unstructured and independent structures converged, the final Hessian was not positive definite, and therefore, they were not considered further. To improve the accuracy of inference with a relatively small sample, degrees of freedom were adjusted using the Kenward–Roger method.

In addition, due to heterogeneity in baseline BPSD, we conducted an exploratory subgroup analysis of participants with baseline NPI scores ≥11, based on a commonly used threshold for clinically significant BPSD [49]. This analysis aimed to explore whether the intervention exerted greater effects in participants with more severe baseline symptoms. Within this subgroup, the same linear mixed-effects model including group, time, and group×time was fitted to examine whether the intervention effect differed among participants with higher baseline symptom burden. This model was chosen to ensure consistency with the main analysis and to account for repeated measures while estimating time-specific differences in intervention effects within this clinically meaningful subgroup.

Results



Participant Baseline Characteristics

Participants were recruited between October 2023 and March 2024, with follow-up being completed by April 2024. As shown in Figure 2, 264 participants were assessed for eligibility across 7 institutions (a neurology outpatient clinic in a tertiary hospital, a dementia care center, and 5 home care service centers). Of these, 36 dyads were enrolled and randomly allocated to either the intervention (n=18) or the control group (n=18). One dyad from the control group withdrew consent for personal reasons before the intervention. Two dyads in the intervention group withdrew because the intervention could not be initiated, as the persons living with dementia refused to participate due to worsening BPSD. Therefore, data from 33 dyads were included in the analysis. The participants' baseline characteristics are presented in Table 1. The mean age of the participants was 82.70 (SD 7.10) years, and most of them (24/33, 72.7%) were female. A homogeneity test of the persons living with dementia showed no significant differences between the groups at baseline. As shown in Table 2, the mean age of the family caregivers was 65.03 (SD 11.28) years, and most of them (27/33, 81.8%) were

XSL•FO
RenderX

female. Family caregivers had provided care for their relatives with dementia for an average of 4.39 (SD 4.37) years, offering approximately 16.32 (SD 8.58) hours of care per day.

Effects of Mobile App–Based Individualized Interventions on Outcome Variables

Table 3 presents the changes in mean scores and group×time effects for each outcome variable, with baseline scores included as covariates in the linear mixed model analysis. Descriptive trends indicated reductions in overall BPSD, agitated behavior, and depression in both groups after the 4-week intervention. The linear mixed model analysis revealed no statistically significant group×time effects for overall BPSD (β=–8.647, 95% CI –18.737 to 1.442; *P*=.09), agitated behavior (β=–1.290, 95% CI –7.236 to 4.655; *P*=.67), or depression (β=.121, 95% CI –2.794 to 3.037; *P*=.93).

Table . Effects of the mobile app–based individualized nonpharmacological intervention on outcome variables.

Outcome variables	Intervention (n=16)	Control (n=17)	Estimate[a] (95% CI)	*P* value
Overall BPSD[b], mean (SD)				
T1[c]-T0[d]	−11.00 (18.46)	−2.35 (13.13)	−8.647 (−18.737 to 1.442)	.09
T2[e]-T0	−8.44 (20.37)	−3.76 (17.89)	−4.673 (−16.689 to 7.343)	.44
Agitated behavior, mean (SD)				
T1-T0	−1.94 (7.45)	−0.65 (7.56)	−1.290 (−7.236 to 4.655)	.67
T2-T0	−4.38 (10.26)	−3.24 (10.69)	−1.140 (−7.913 to 5.634)	.74
Depression, mean (SD)				
T1-T0	−0.94 (5.69)	−1.06 (4.41)	0.121 (−2.794 to 3.037)	.93
T2-T0	−2.13 (4.88)	−0.59 (3.26)	−1.537 (−4.832 to 1.758)	.36
Nighttime sleep efficiency (%), mean (SD)				
T1-T0	−0.57 (1.42)	−0.52 (1.95)	−0.054 (−1.271 to 1.163)	.93
Competence in managing BPSD, mean (SD)				
T1-T0	6.00 (12.78)	0.07 (12.19)	5.933 (−6.979 to 18.846)	.36

[a]All models were adjusted for baseline scores as covariates. The control group at baseline (T0) was used as the reference.

[b]BPSD: behavioral and psychological symptoms of dementia.

[c]T1: after 4 weeks.

[d].T0: baseline

[e]T2: 2-week follow-up.

At the 2-week postintervention period, overall BPSD increased in the intervention group, while the control group maintained a downward trend. This difference, however, did not reach statistical significance (β=–4.673, 95% CI –16.689 to 7.343; *P*=.44). Agitated behaviors continued to decrease in both groups, with no statistically significant interaction effect (β=–1.140, 95% CI –7.913 to 5.634; *P*=.74). Depressive symptoms increased in the control group but showed a downward trend in the intervention group. However, no statistically significant group×time effect was observed (β=–1.537, 95% CI –4.832 to 1.758; *P*=.36).

Regarding secondary outcomes, no statistically significant group×time interaction effect on nighttime sleep efficiency was observed after the intervention (β=−.054, 95% CI −1.271 to 1.163; *P*=.93). Family caregivers' level of competence in managing BPSD increased in the intervention group; however, the group×time effect was not statistically significant (β=5.933, 95% CI –6.979 to 18.846; *P*=.36). No harm was recorded during the study period in either group.

Subgroup Analysis of Outcomes

Table 4 presents a subgroup analysis among participants with baseline NPI scores ≥11, a cutoff previously identified as indicating clinically significant BPSD. Greater reductions in overall BPSD, agitated behavior, and depression were observed in the intervention group over the study period. However, the linear mixed model analysis controlling for baseline scores showed that only the group×time interaction for overall BPSD was statistically significant after the 4-week intervention (β=–12.885, 95% CI –24.530 to –1.240; *P*=.03).

Use of Behavioral and Psychological Symptoms of Dementia Diary and App-Based Individualized Nonpharmacological Interventions

During the 4-week intervention period, the frequency and intensity of use varied across participants. The total number of days the intervention was used ranged from 6 to 25, and the total number of sessions ranged from 9 to 45. The average session duration ranged from 11 to 54 minutes. On average, participants engaged with the intervention on approximately 15 days, completing about 22 sessions, with a mean session duration of around 30 minutes.

Tables 5 and 6 present the logs of the BPSD diary records and mobile app–based individualized nonpharmacological interventions. Over the 8-week study period, the total number of diary records was 1819 in the intervention group and 1324 in the control group. The mean number of records per participant was higher in the intervention group than in the control group. Music therapy was the most frequently used intervention in the intervention group, demonstrating the highest usage time (mean 38.21, SD 33.46 min) and engagement level (mean 3.84, SD 0.91). Although exercise therapy had a shorter average usage time (23.12, SD 15.37 min), it recorded the second-highest frequency of use (94/357, 26.3%). Reminiscence therapy had a relatively low usage frequency (82/357, 23.0%) and engagement (mean 3.49, SD 1.03). However, its average usage time exceeded the overall intervention mean of 31.40 (SD 28.79) min. In contrast, reminiscence therapy with music showed the lowest usage frequency (29/357, 8.1%) and shortest average usage time (12.76, SD 9.14 min); however, it received a relatively positive engagement rating (mean 3.69, SD 0.85).

Table . Summary of behavioral and psychological symptoms of dementia diary records.

	Control	Intervention
Total number of records	1324	1819
Number of records		
Mean (SD)	77.76 (35.17)	113.81 (166.42)
Range	51 - 164	42 - 735

RenderX

Table . Summary of mobile app-based nonpharmacological intervention usage.

Type of intervention[a]	Frequency, n (%)	Usage time, mean (SD)	Engagement level, mean (SD)
Total	357 (100)	31.40 (28.79)	3.71 (0.93)
Music therapy	152 (42.6)	38.21 (33.46)	3.84 (0.91)
Exercise	94 (26.3)	23.12 (15.37)	3.71 (0.84)
Reminiscence therapy	82 (23.0)	34.88 (30.90)	3.49 (1.03)
Reminiscence with music	29 (8.1)	12.76 (9.14)	3.69 (0.85)

[a]Intervention usage data were collected only for the intervention group.

Exploratory analyses were conducted to examine the relationship between intervention dose and changes in outcome variables. Participants were categorized into high-dose and low-dose groups based on the median values of usage metrics (total frequency and mean usage time). Dose-response exploratory plots are presented in Multimedia Appendix 1. Exploratory comparisons showed no significant differences in pre-post changes of outcome variables between participants with higher and lower intervention usage. This result remained consistent even among participants with baseline NPI scores ≥11.

Discussion

Principal Results

Unlike previous studies that primarily implemented clinician-led interventions or were conducted in institutional settings, this study assessed a fully caregiver-driven app-based intervention in real-world community environments. Family caregivers were able to independently monitor symptoms and deliver tailored nonpharmacological interventions at home. In this way, this study demonstrated the feasibility of a decentralized, technology-enabled dementia care model. This approach aligns with the growing demand for accessible and scalable solutions that reduce the reliance on formal care systems. No statistically significant differences were observed between the intervention and control groups in overall BPSD, agitated behavior, or depression after the intervention. However, an exploratory subgroup analysis of participants with more severe BPSD (NPI≥11) suggested a potential benefit (β=–12.885; *P*=.03). Given the pilot nature of this study, these findings should be regarded as preliminary and exploratory and not interpreted as definitive. Nevertheless, even mild reductions in BPSD can have clinical significance, as they may help reduce caregiver burden, delay institutionalization, and improve quality of life for both persons living with dementia and their families.

Comparison With Prior Work

Several factors may account for these small effects. First, regular assessment and documentation of BPSD, including symptom type, severity, and triggers, has been widely recognized as an effective strategy for managing these symptoms [29,50-54]. However, previous studies have often relied on digital databases, such as electronic medical records, which rely on retrospective documentation with limited contextual detail [55,56]. In contrast, the mobile app was used in this study to collect real-time, caregiver-reported data in the home setting. This approach allowed for more precise identification and characterization of BPSD and their triggers as they occurred. The NPI, a commonly used tool for assessing BPSD, has been adapted for daily diaries in mobile apps, minimizing recall bias and enabling users to record and monitor symptoms in real time [52,53]. This tool facilitates easier access to symptom information and enhances symptom awareness, offering therapeutic value through improved recognition and monitoring [53]. In this study, both the intervention and control groups were instructed to assess and document BPSD, including the type, frequency, and severity, using a mobile app modeled after the NPI. Moreover, family caregivers were asked to record potential triggers of BPSD, such as pain, discomfort, or environmental stressors. This approach is consistent with the Need-driven Dementia-compromised Behavior model [57], which views BPSD as an expression of unmet needs triggered by proximal factors. By regularly recording these symptoms and their potential triggers, family caregivers may be better equipped to recognize and preempt these unmet needs. This allows them to address potential issues early, before they escalate into more severe behavioral manifestations [58]. Overall, systematic documentation of BPSD and their triggers via a mobile app serves not only as a real-time monitoring tool but also as a key component of proactive, person-centered dementia care. Such an approach, therefore, aligns with dementia care frameworks, which emphasize that comprehensive assessment should guide tailored nonpharmacological strategies [54].

Second, it is important to consider the individual abilities of persons living with dementia when applying nonpharmacological interventions. Factors such as sensory function, attention span, and mobility limitations can significantly influence the appropriateness and effectiveness of the intervention [59]. To address individual needs, our study included 4 types of mobile app interventions, allowing for flexible selection according to user characteristics. We also made efforts to incorporate individual preferences into the intervention planning process, as tailoring individual preferences may assist in treatment adherence [58]. Preferences were continuously updated based on caregivers' observations of persons living with dementia's responses during the sessions. However, it is worth noting that the tailoring efforts in this study relied primarily on caregiver-reported observations of preferences rather than direct input from the persons living with dementia. To complement these efforts, the difficulty level of each activity could be adjusted according to the user's cognitive and physical function to ensure appropriate challenge and accessibility. In our app, individualized multimedia content such as photos, videos, and music reflecting users' memories

XSL•FO
RenderX

and preferences was incorporated. Future updates could further expand this feature to enhance engagement and emotional connection. This can also be achieved by analyzing and incorporating in-app records, including caregiver-entered engagement data and log data on intervention use. Furthermore, integrating external factors, including real-time data from wearable sensors, environmental monitoring, or smart home technologies, may further improve the adaptability of the intervention [60,61].

Finally, unlike traditional nonpharmacological interventions, which typically maintain a consistent intensity based on the facilitator's planned structure [15-17], our approach allowed greater flexibility. Participants initiated sessions according to their own preferences. This flexible delivery model may have led to variability in outcomes and how participants engage with the program [62,63]. Consistent with this design feature, we observed considerable variation in usage metrics, including total usage days, number of sessions, and average duration per session. These findings indicate differences in intervention fidelity, which may explain the heterogeneous use patterns observed across different components of the program, including music and reminiscence therapy. Music therapy was the most frequently used intervention in this study, likely due to its ease of use and flexible format [64]. Despite its popularity, however, it did not lead to significant reductions in BPSD. This finding echoes prior findings that family-delivered music interventions show limited effects, whereas those provided by trained professionals yield clearer benefits [33]. In contrast, reminiscence therapy in our study showed the lowest levels of usage and engagement, possibly reflecting greater usability challenges than those associated with music- or exercise-based interventions. Yet, recent evidence indicates that digital reminiscence therapy can be more effective than traditional formats [65].

Our exploratory analyses showed no significant differences between higher- and lower-usage participants, indicating that dosage alone may not drive clinical effects. A previous study reported that factors such as intervention quality, caregiver capacity, and contextual support likely play a more critical role in shaping outcomes [66]. In institutional settings, professional caregivers such as nurses can integrate cognitive stimulation activities into daily routines. By contrast, in home environments, limited expertise and resources among family caregivers may reduce intervention fidelity and impact [67]. To address this, structured support should be provided in community settings, so that caregivers can use the app independently while still receiving regular guidance from trained professionals or volunteers [58,68]. Such support, together with age-friendly interface improvements and user education, may help enhance digital competencies and promote more consistent engagement. These improvements, in turn, could increase the effectiveness of caregiver-initiated, app-based nonpharmacological interventions [66,68]. Broader contextual factors, such as differences in broadband access, digital literacy, and cultural familiarity, may also affect how interventions are used and how well they work. In particular, the fact that many caregivers in our study were older adults may have influenced their ability to consistently use the app. Therefore, tailored implementation strategies are needed for different care settings [66].

Implications for Practice and Policy

This study provides preliminary evidence on the potential of caregiver-driven, technology-enabled dementia care within the Korean context. The findings suggest that integrating structured guidance and support could enhance caregiver capacity, ensuring a more effective and sustainable implementation of nonpharmacological interventions in home settings. Given the global rise in the prevalence of dementia and reliance on informal caregivers, these exploratory results may inform future efforts to adapt and refine digital intervention frameworks.

Future Research

Building on the current findings, future studies should consider larger and more diverse samples and examine the effects of stratifying participants according to baseline BPSD severity. Moreover, the development of adaptive personalization algorithms that incorporate direct and continuous monitoring of persons living with dementia's responses may enhance intervention responsiveness and reduce caregiver burden. Such systems should also dynamically adapt to factors such as modality of use, thereby revealing intervention preferences and informing recommendations for optimal dosage. In addition, tailoring recommendations based on cognitive and physical function as well as BPSD severity may further refine the personalization of nonpharmacological interventions. Finally, evaluating the implementation of this intervention in long-term care or rural settings may extend its utility and scalability. The BPSD diary itself may also serve as a monitoring strategy that helps alleviate symptoms. Therefore, a 3-arm randomized controlled trial including (1) no diary and no intervention, (2) diary monitoring only, and (3) diary monitoring with the intervention could provide robust evidence on their individual and combined effects.

Limitations

Despite its strengths, this study had several limitations. First, the sample size was relatively small and restricted to urban community-dwelling participants in South Korea, which may limit the generalizability of the findings. While South Korea is one of the most digitally advanced countries [69], the study participants were predominantly from urban areas. As such, the observed feasibility and engagement levels may not fully reflect outcomes in populations with limited broadband access or in rural settings where digital resources are less developed. In addition, the sample size was calculated a priori based on a medium effect size. However, the wide confidence intervals raise the possibility of a type II error and suggest that the study may have been underpowered to detect smaller-than-expected effects. Accordingly, these findings should be regarded as preliminary and interpreted with caution. Second, the personalization of interventions was based on caregiver-reported observations, with limited direct input from persons living with dementia. This reliance on proxy reports may have introduced reporting bias and restricted the extent to which the intervention reflected the lived experiences and preferences of persons living with dementia themselves. Finally, nighttime sleep efficiency,

XSL•FO
RenderX

included as a secondary outcome, was already high at baseline (94%), which is comparable to or even higher than levels reported in previous studies involving persons living with dementia [44]. This suggests that participants in our study exhibited relatively preserved sleep quality at baseline. A potential ceiling effect may therefore have constrained the magnitude of observable change. As a result, the interpretation of sleep-related outcomes should take this limitation into account.

Conclusions

This study evaluated a mobile app–based individualized nonpharmacological intervention for managing BPSD in community-dwelling persons living with dementia. Although improvements were observed, they did not reach statistical significance in the overall analysis. Exploratory findings indicated potential benefits for participants with more severe baseline BPSD; however, these results should be interpreted with caution. Nevertheless, the findings highlight the potential value of empowering family caregivers to deliver flexible, person-centered care at home through digital tools. Future research should refine personalized strategies and optimize intervention delivery by using usage data. Despite its limitations, including a small sample size and variability in engagement, this study shows the potential of caregiver-driven, app-based, individualized nonpharmacological intervention for BPSD in the home and community setting. Continued efforts to integrate digital interventions within community-based care frameworks, accompanied by education and guidance for family caregivers, may contribute to the development of sustainable person-centered dementia care approaches.

Funding

This work was supported by the Basic Science Research Program through the National Research Foundation of Korea (NRF), funded by the Ministry of Education (grant number RS-2020-NR049581). MY was supported by the 2025 Kyu-Hee Lee Post-Doctoral Fellowship from Yonsei University College of Nursing. The funders had no involvement in the study design, data collection, analysis, interpretation, or the writing of the manuscript.

Data Availability

Data related to the findings reported in this manuscript may be made available by the corresponding author upon reasonable request.

Authors' Contributions

EC contributed to the conceptualization, methodology, funding acquisition, and writing of the original draft, as well as the review and editing of the manuscript. SH, EK, and JC contributed to writing the original draft and to the review and editing of the manuscript and were also involved in formal analysis and data curation. MJK contributed to writing the original draft and to the review and editing of the manuscript. MY contributed to writing the original draft and to the review and editing of the manuscript, as well as to methodology, formal analysis, and data curation. All authors read and approved the final version of the manuscript.

Abstract

Background: Continuous follow-up for patients with major depressive disorder (MDD) is essential for treatment decisions and a better prognosis. There remains limited evidence regarding the critical issue of depression variation trajectory prediction using mobile health (mHealth) measures. Moreover, the temporal dynamics of mHealth measures have not been fully modeled in previous studies, and the poor patient adherence to mHealth records poses great challenges to the dynamic feature modeling.

Objective: This study aimed to examine the contribution of mHealth measures in predicting depression variation trajectory for patients with MDD, with full consideration of the temporal dynamics of mHealth measures.

Methods: A total of 229 patients with MDD from a multiple-center, prospective cohort were included. A 12-week follow-up was conducted involving the collection of the Hamilton Depression Rating Scale (HAMD-17), along with patient-reported outcomes (Immediate Mood Scaler and Altman Self-Rating Mania Scale) via mobile devices and sleep duration through wearable wristbands. We used functional data analysis to extract dynamic features from the sparse mHealth records, rather than aggregating the data to a single scalar summary measure through collapsing over time. Subsequently, 3 machine learning models were applied to predict the depression variation trajectory classes based on the baseline characteristics and these extracted dynamic features.

Results: Based on the variation of HAMD-17 scores within 12 weeks, the participants were labeled into 4 classes through the *k*-means algorithm. The classes included stable decline (n=93), fluctuate decline (n=44), fast decline (n=60), and delayed and fluctuate (n=32), in light of the shape of depression trajectories. With both baseline features and dynamic features of the mHealth measures, accuracy rates for the overall data were 54.35%, 60.87%, and 56.52%, for the stable decline patients were 78.95%, 84.21%, and 73.68%, for the nonstable decline patients were 59.26%, 62.96%, and 70.37% based on the 3 machine learning models, respectively. The results were significantly superior to the prediction obtained without mHealth measures (with an overall accuracy below 50%) and only showed a marginal reduction in accuracy relative to the ideal prediction with assessment obtained from clinical visits. Moreover, in the construction of the most accurate prediction model, dynamic features of the Immediate Mood Scaler, the Altman Self-Rating Mania Scale, and sleep duration emerged as the most influential predictors, ranking first, third, and fourth, respectively, in terms of their relative importance.

Conclusions: Longitudinal mHealth measures show potential in depression variation trajectory monitoring for patients with MDD even under poor patient adherence. Our work provides practical help in alleviating the follow-up burden for patients with MDD and validates the effectiveness of mHealth measures in clinical applications.

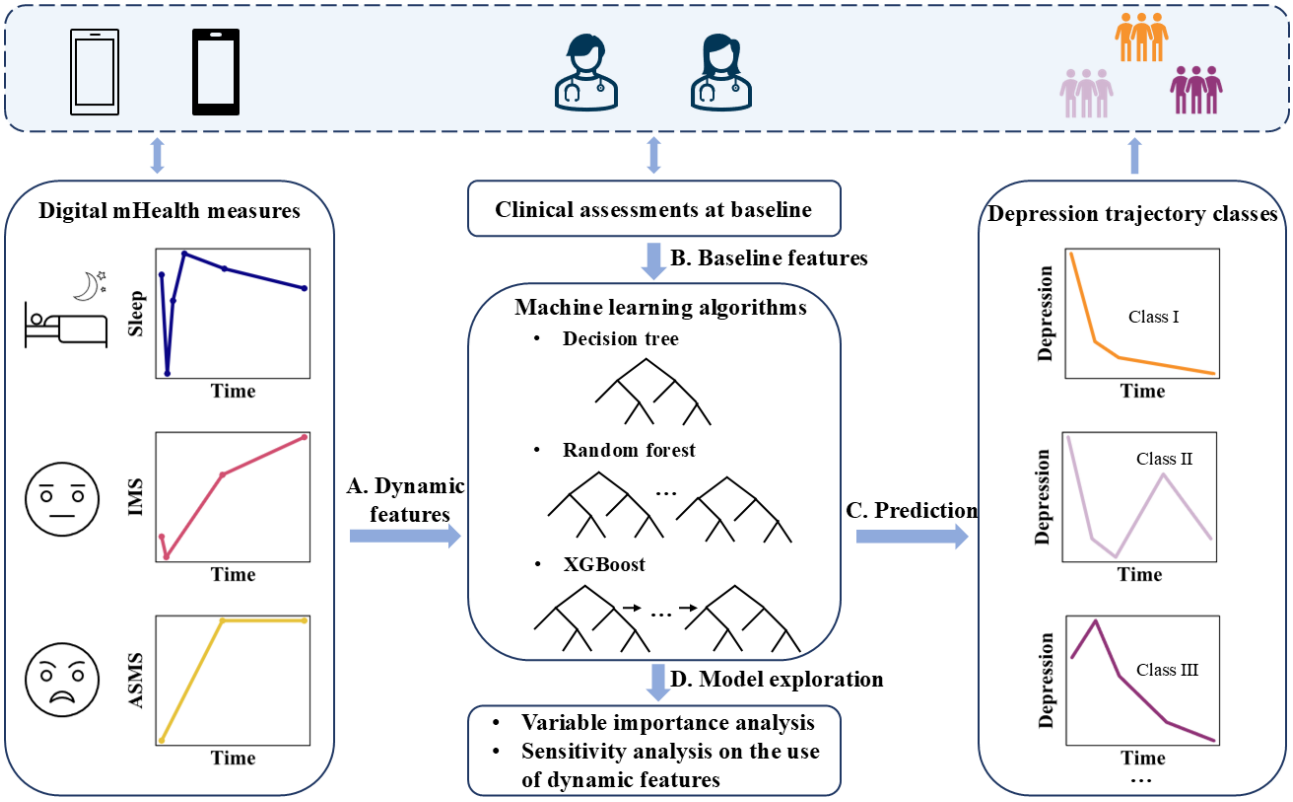
Introduction

Depression is a common mental disorder with a high lifetime prevalence, ranked as one of the most crucial causes of disease burden worldwide [1,2]. Despite the availability of evidence-based treatments, including antidepressants and psychotherapy, more than 60% of patients with major depressive disorder (MDD) exhibit inadequate response with their first treatment, often requiring either an alternative antidepressant or adjunctive treatment [3]. The early reduction of depressive symptoms observed in the first 2 - 4 weeks of antidepressant treatment has been proposed as a potential predictor of treatment success, possibly reflecting psychological resilience in patients with MDD [4], and the predictive efficacy of early response varies across antidepressants. Leveraging time-varying individual characteristics, including demographics, clinical phenotypes, and social functioning [5], holds promise for refining treatment algorithms. An important question raised in this context is how to capture the temporal dynamics of depression severity, which remains a persistent challenge in both clinical practice and research.

It is burdensome for both patients and doctors to conduct continuous and frequent face-to-face psychometric evaluations. Fortunately, with the increasing use of smartphones and wearable devices in modern life, it has become possible to achieve real-time monitoring of physical activity, sleep, and self-assessment for patients with MDD through mobile health (mHealth) technologies [6-8]. The mHealth measures obtained from smartphones and wearable devices can be summarized into 2 types, which are self-reported data (patient-reported outcomes [PROs] such as questionnaire scores) and passively collected data (digital phenotype data such as sleep data, activity data, and phone usage data) [9]. Smartphones are superior in capturing mood changes, while wearable devices are effective in daily activity records [10]. The incorporation of records from both smartphones and wearable devices is beneficial for clinical evaluation and provides a new perspective for depression monitoring [7].

For the potential of self-reported data recorded by smartphone in the depressive symptoms monitoring, Torous et al [11] examined the correlation between the Patient Health Questionnaire-9 scores recorded by smartphone and paper for the patients with MDD, demonstrating the capability of digital depressive symptom monitoring. Moreover, Goltermann et al [9] also revealed the validity of smartphone-based monitoring of depressive symptoms through the analysis of the agreement between smartphone-based and non–smartphone-based assessments. These studies highlight the effectiveness of smartphone-based self-reported data in tracking depressive symptoms.

Digital phenotype data have been widely applied in mental health studies and have shown the ability to strengthen the management of depressive symptoms [12,13]. As sleep problems occur frequently in patients with MDD [14], an increasing number of studies focused on the relationship between remote sleep records and depression symptoms [15,16]. Moreover, Lim et al [17] used sleep-wake pattern data exclusively in the prediction of mood episodes. Further, compared with other types of digital phenotype data, sleep data are easier to collect and less affected by other interfering factors [18]. These findings revealed the potential of remote sleep records in enhancing depression monitoring and prediction.



As depressive symptoms are constantly evolving and show heterogeneity over time, capturing the temporal dynamics of depression severity is essential [19]. However, given the great importance of depression dynamics, studies on the prediction of depression variation trajectory through mHealth measures were scarce. Bai et al [20] discussed the prediction of mood swings for patients with MDD using passively collected data from smartphones and wearable devices. Price et al [21] used digital phenotype data in the prediction of depression symptom variability. The definition of depression variation was still vague in existing mHealth literature and lack intuitiveness and clinical significance. And there is a growing demand for ascertaining the contribution of mHealth measures in depression variation trajectory prediction.

Additionally, fusing the temporal dynamic features of smartphone- and wearable device–based data in the prediction of depression trajectory is also crucial due to the dynamic nature of personalized behaviors [22-24]. However, the records from smartphones and wearable devices are always sparse and irregular, owing to poor study adherence and unsatisfactory patient compliance [25-27]. Patients may accidentally switch off the app or forget to report their states. The sparsity of the mHealth records poses additional challenges to the capture of dynamic features for both self-reported data and digital phenotype data, which calls for the clinical application of novel statistical methods.

The primary objective of this study is to examine the contribution of longitudinal mHealth measures in predicting depression variation trajectory for patients with MDD. By applying a functional data analysis method to the longitudinal records of sleep duration, Immediate Mood Scaler (IMS) scores, and Altman Self-Rating Mania Scale (ASMS) scores, the dynamic features of mHealth measures (including both PROs and digital phenotypes) were obtained (Figure 1A). The depression trajectory class was predicted (Figure 1C) based on the dynamic features of mHealth measures and clinical assessments at baseline (Figure 1B) through machine learning algorithms. The investigation of classification accuracy with and without the longitudinal records of PROs and digital phenotypes, as well as the variable importance analysis and sensitivity analysis (Figure 1D), enables the detection for the contribution of the dynamic features of mHealth measures in depression variation trajectory prediction for patients with MDD.

Methods

Ethical Considerations

This study used data from an epidemiological, noninterventional, cohort study conducted between February 2019 and April 2020 at 4 psychiatric hospitals or units in general hospitals in China. The study was approved by the Independent Medical Ethics Committee Board of Beijing Anding Hospital and the other 3 sites (ethical approval no. 2018-119-201917FS-2). All patients provided written informed consent to participate in the study. To ensure confidentiality, each participant was assigned an identification number. Moreover, participants received ¥100 (US $15.5) for each follow-up visit.

Participants

Study inclusion and exclusion criteria have been reported [20]. Generally, inclusion criteria for the study included outpatients (1) aged 18 - 60 years and (2) diagnosed with MDD according to the *Diagnostic and Statistical Manual of Mental Disorders* (fourth edition) criteria. Exclusion criteria included patients who had axis I primary psychiatric diagnosis other than MDD or had substance abuse. Patients in this cohort were followed up at 2, 4, 8, and 12 weeks.

Measures

Demographics and Clinical Characteristics

The participants' basic social-demographic and clinical characteristics were collected through the structured questionnaire designed for this study.

Clinical-Rated Outcomes

The Hamilton Depression Rating Scale (HAMD-17) [28] was used to measure depressive symptoms. The total HAMD-17 score ranges from 0 to 52, with a higher score indicating greater severity of depression.

The Hamilton Anxiety Scale (HAMA) [29] was used to measure anxiety symptoms. The total HAMA score ranges from 0 to 56, and a higher score indicates the severity of anxiety.

The Sheehan Disability Scale [30] was used to measure the social functional impairment due to MDD that interferes with work/school, social life/leisure activities, and family life/home responsibilities. The participants are invited to rate the extent to which each domain is impaired by their symptoms using a 10-point scale (0=not at all impaired, 1 - 3=mildly impaired, 4 - 6=moderately impaired, 7 - 9=markedly impaired, and 10=extremely impaired).

Patient-Reported Outcomes

The Chinese version of the IMS was used to assess current mood symptoms [31,32]. It is composed of 22 questions about the respondent's state of mood. Each item was rated on a 7-point scale with complementary antonyms positioned at opposite ends. A higher summed score of the 22 items reflects a higher level of severity of the patient's depressive symptoms. Upon enrollment, participants were instructed to complete the IMS scale on their smartphones on a daily basis.

The ASMS was administered as a self-assessment tool to evaluate the intensity of manic symptoms [33]. The ASMS comprises five key symptom domains: (1) elevated mood, (2) heightened self-esteem, (3) diminished need for sleep, (4) rapid

XSL•FO
RenderX

or pressured speech, and (5) psychomotor agitation. Patients rated each item by choosing from 5 response options, ranging from 0 (symptom not present) to 4 (highly severe). Participants were instructed to complete weekly administrations of the ASMS using their smartphones.

Digital Phenotype

Participants were instructed and trained to wear wristbands during sleep for sleep-related data collection during the 12-week follow-up. The data collected would first be stored locally and uploaded to our server when the user connects with the wristband using the Mood Mirror app [20]. Key sleep characteristics, particularly total sleep duration and slow-wave sleep time, were systematically extracted and incorporated into the analytical model.

Statistical Analysis

Clustering Analysis

In this paper, we mainly focused on the variation of depression severity at 5 consecutive visits within 12 weeks. Therefore, the class labels for the patients were expected to be related to the variation of depression severity. To determine the class label for each patient, the *k*-means clustering algorithm was used. The *k*-means clustering algorithm is an unsupervised learning method that can divide samples into *k* clusters based on the cluster means. We computed the difference of HAMD-17 scores between each adjacent visit (week 2 to week 0, week 4 to week 2, week 8 to week 4, and week 12 to week 8) for each patient and input these features into the clustering analysis. That means patients who had a similar changing trend of HAMD-17 score would be assigned to the same cluster. We implemented the *k*-means algorithm through the kmeans function in R statistical software, version 4.4.1. The number of clusters was selected by considering both the silhouette coefficients and the clinical significance of the clustering results. The silhouette coefficients were computed by the silhouette function of the cluster R package, version 2.1.6. After comparing the results obtained by k=2,3,4,5, we chose the cluster number as 4 and further defined the class labels as stable decline, fluctuate decline, fast decline, and delayed and fluctuate.

Feature Extraction by Functional Principal Component Analysis

Within the 12 weeks of monitoring, the median numbers of days with a record of IMS score, ASMS score, and sleep duration were 5 (IQR 4-8), 4 (IQR 3-4), and 50 (IQR 28-63), respectively. Figure S1 in Multimedia Appendix 1 shows the heatmap of the observation size for each participant in the record of IMS scores, ASMS scores, and sleep duration. It is shown that the records for all the mHealth measures were severely sparse, especially for the IMS scores and ASMS scores, due to poor patient adherence.

To extract the dynamic features of the IMS scores, ASMS scores, and sleep duration from baseline to week 12 for each patient, functional data analysis methods were used [34]. Through functional data analysis methods, the temporally dependent PROs and digital phenotype records have not to be collapsed into a single value, and the temporal dynamic information can be retained [35]. In specific, to adapt to the sparseness of the data caused by poor patient adherence, a method called principal components analysis through conditional expectation (PACE) was used [36]. The PACE approach is a commonly used functional principal component (FPC) analysis method that is designed for sparsely and irregularly observed functional data. This approach uses a local linear smoother for the estimation of the mean function and the covariance function, and then it computes the FPC scores based on conditional expectations. The PACE approach borrows the strength of the entire sample in the computation, so it can make full use of the information from the dataset. By using the fdapace R package with version 0.6.0, we implemented the PACE approach for the records of IMS score, ASMS score, and sleep duration, respectively, and the estimated first FPC scores were treated as the extracted dynamic features.

Machine Learning Models

To predict the variation trajectory class of depression severity for the patients, various machine learning methods were used, such as decision tree, random forest, and XGBoost (Extreme Gradient Boosting). In specific, a decision tree completes classification by recursively selecting the best decision rules to partition the data, and the decision paths can be summarized through a tree structure. Random forest and XGBoost are both ensemble learning methods, but with different ensemble patterns. Random forest depends on many independent decision trees, while XGBoost trains a sequence of decision trees in an iterative way. To alleviate the overfit problems for the random forest and XGBoost methods, the node size (minimum size of terminal nodes) was selected as 10 for the random forest model, and the maximum depth of a tree was set as 3 for the XGBoost model. We conducted the above machine learning methods using the rpart, randomForest, and xgboost R packages with versions 4.1.24, 4.7‐1.2, and 1.7.11.1, respectively.

Predictive Performance Assessment

To find out how the records of IMS score, ASMS score, and sleep duration contribute to the classification of depression variation, we compared the classification results obtained from different input information. In specific, we considered the prediction based on 4 types of input scenarios. Scenario 1 uses only baseline features; scenario 2 integrates baseline features with the FPC scores of the PROs and digital phenotype records; scenario 3 combines baseline features and HAMD-17 and HAMA scores assessed at week 2; scenario 4 incorporates baseline features, FPC scores of the PROs and digital phenotype records, and HAMD-17 and HAMA scores at week 2. Here, scenario 2 was our central focus, while scenario 1 was used to assess the prediction without mHealth measures. Moreover, scenarios 3 and 4 were introduced to simulate the ideal cases with assessments obtained from clinical visits. By comparing scenario 2 with scenarios 3 and 4, we can shed light on how the predictive performance in scenario 2 approaches the ideal cases.

Moreover, the performance was evaluated by the classification accuracy for the overall data, stable decline patients, and nonstable decline patients. The 95% CIs of the classification accuracy were obtained through the Wilson method based on Hmisc R package. The dataset was randomly split into a training

XSL•FO
RenderX

set (80%) and a test set (20%). Given the class imbalance, we randomly oversampled the fluctuate decline, fast decline, and delayed and fluctuate classes to make their class size 80% of the size of the stable decline. The oversampling procedure was implemented within the training set, ensuring a strict separation between the training set and test set.

Variable Importance

The importance of the considered predictive factors was assessed for the decision tree, random forest, and XGBoost to illustrate the contribution of mHealth measures in the model construction. Specifically, Gini impurity reduction [37] was used to compute variable importance for the decision tree [38] and random forest models [39], while the Gain metric [40] was used for the XGBoost model. For the implementation, the rpart package, randomForest package, and xgboost package in R were used, respectively. Moreover, we also conducted a permutation test to estimate the significance of variable importance for the random forest model through permuting the response variable 1000 times [41]. A *P* value less than .05 indicates a significant variable contribution. The rfPermute R package with version 2.5.5 was used for the computation.

Sensitivity Analysis

Further, to investigate the advantage of the functional data analysis method, we also evaluate the predictive performance when the mean values of IMS score, ASMS score, and sleep duration were used for model construction, rather than their FPC scores. The dynamic features of the PROs and digital phenotype were disrupted because the records were roughly summarized as a single value. Hence, it is hypothesized that using the FPC scores would yield a more accurate prediction.

Results

Characteristics of Participants

A total of 229 patients with MDD were included in the study (Figure 2), with 78 males (34.1%), 151 females (65.9%), and a mean age of 28.7 years. According to the variation of HAMD-17 scores, the participants were labeled as stable decline, fluctuate decline, fast decline, and delayed and fluctuate, respectively. The number of classes was selected as k=4 with the consideration of both silhouette coefficients (0.182) and clinical significance. Clinical significance refers to the capacity of the chosen clusters to distinguish 4 clinically recognizable patterns of symptom reduction over 12 weeks, categorizing the longitudinal patient responses into stable decline, fluctuate decline, fast decline, and delayed and fluctuate trajectories.

XSL•FO
RenderX

Figure 2. Flowchart illustrating participant inclusion. With 358 patients enrolled in the multiple centers, prospective cohort, 229 patients were finally included in our study. mHealth: mobile health.

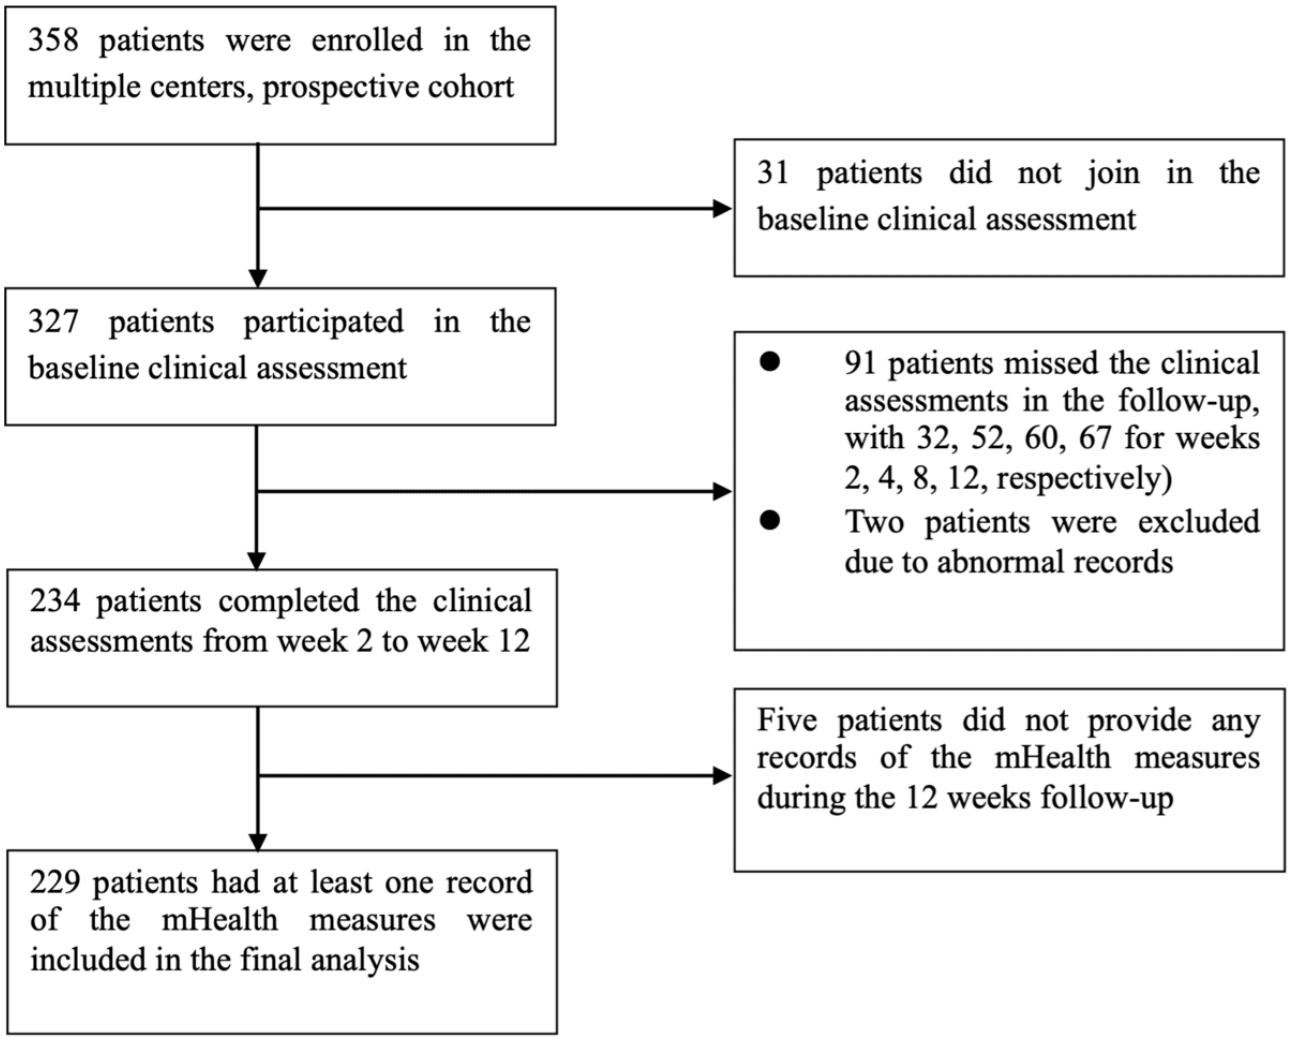

Figure 3 shows the variation of the mean HAMD-17 scores from baseline to week 12 for each class (refer to Multimedia Appendix 1 for HAMD-17 scores figures when k=2,3,5), and Figure S4 in Multimedia Appendix 1 shows that patients within the same class exhibited the same temporal trend of depression severity. In specific, the stable decline class contained 93 (40.6%) patients with MDD, who were more likely to improve steadily during the study. There were 44 (19.2%) patients with MDD in the fluctuate decline class. It is shown that the HAMD-17 scores of participants in the fluctuate decline class might go through an upward fluctuation before week 2 and begin to decrease afterwards. The fast decline class included 60 (26.2%) patients with MDD, and the HAMD-17 scores of these patients showed a rapid decline before week 2. Moreover, 32 (14%) patients with MDD were assigned to the delayed and fluctuate class. It is evident that the HAMD-17 scores of these patients showed a delayed decline and were prone to exhibit a drastic rise at week 8. The symptomatic rebound at week 8 indicates a critical clinical juncture for evaluating treatment efficacy in depression [42]. This pattern suggests a unique phenotype of therapeutic instability where early progress fails to persist. Such findings emphasize the importance of extended clinical monitoring to identify patients at risk of midstage relapse.

XSL•FO
RenderX

Figure 3. The mean HAMD-17 scores from baseline to week 12 for patients in stable decline, fluctuate decline, fast decline, and delayed and fluctuate classes. HAMD-17: Hamilton Depression Rating Scale.

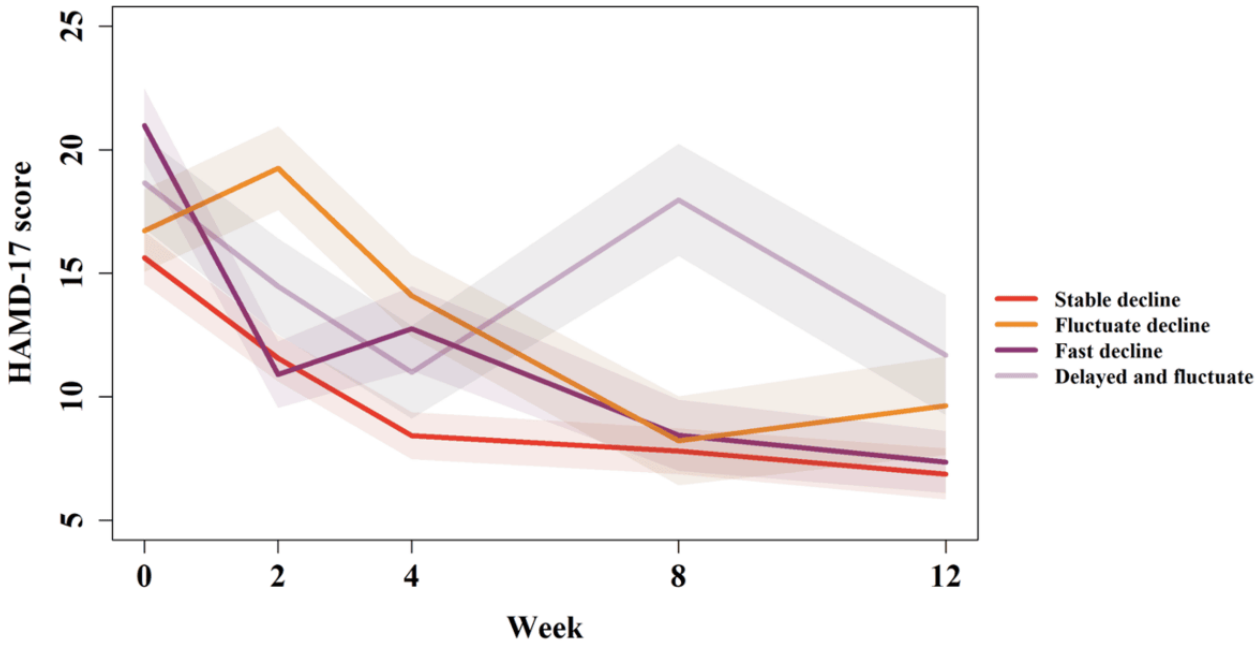

Table 1 reports the demographic and clinical characteristics of the patients with MDD in each class. It can be observed that the HAMD-17 and HAMA scores, as well as the changes in HAMD-17 scores, were significantly different among these 4 classes for each week. In addition, the average IMS scores during the follow-up were also significantly different among these 4 classes. Moreover, there was no significant difference in sex, age, BMI, and baseline Quality of Life Enjoyment and Satisfaction Questionnaire—Short Form, Sheehan Disability Scale, IMS, and ASMS scores among these 4 classes. Refer to Multimedia Appendix 1 for the figures of mean curves of IMS scores, ASMS scores, and sleep duration for each class, and for the demographic characteristics of patients in each participating center.

Prediction of Depression Variation Pattern With Digital mHealth Measures

Figure 4 and Table S2 in Multimedia Appendix 1 show the classification results obtained from various input information by different machine learning approaches. It is shown that by using baseline features and FPC scores of the PROs and digital phenotype records (scenario 2), decision tree, random forest, and XGBoost all give reasonable classification accuracy for the overall data (54.35%, 60.87%, and 56.52%), stable decline patients (78.95%, 84.21%, and 73.68%), and nonstable decline patients (59.26%, 62.96%, and 70.37%). On the other hand, when the models were constructed without dynamic features of the digital mHealth measures (scenario 1), all considered machine learning approaches show poor classification efficacy, which indicates the great importance of digital mHealth measures in the monitoring of depression variation. Further, comparing the predictive performance in scenario 2 with that in scenarios 3 and 4, though the classification accuracy was elevated, the improvement was not as obvious as that achieved by changing from scenario 1 to scenario 2. Moreover, despite a marginal reduction compared to the ideal clinical scenarios, scenario 2 offers practical advantages in terms of scalability and reduces assessment burden for continuous follow-ups.

Figure 4. Classification accuracy for the overall data, stable decline patients, and nonstable decline patients with different input information based on the machine learning algorithms: (A)decision tree, (B) random forest, and (C) XGBoost. Scenario 1: baseline features; scenario 2: baseline features and FPC scores of the PROs and digital phenotype records; scenario 3: baseline features and HAMD-17 and HAMA scores at week 2; scenario 4: baseline features, FPC scores of the PROs and digital phenotype records, and HAMD-17 and HAMA scores at week 2. FPC: functional principal component; HAMA: Hamilton Anxiety Scale; HAMD-17: Hamilton Depression Rating Scale; PRO: patient-reported outcome; XGBoost: Extreme Gradient Boosting.

Contribution of Digital mHealth Measures

Figure S5 and Table S3 in Multimedia Appendix 1 show the variable importance for decision tree, random forest, and XGBoost in the prediction of depression variation patterns using baseline features and FPC scores of the PROs and digital phenotype records (scenario 2). For both random forest and XGBoost, which yielded more accurate classification, the dynamic feature of IMS score records was of paramount importance in the model construction. Moreover, FPC scores of the ASMS score and sleep duration also played a dominant role in the modeling, closely following the baseline HAMD-17 score. Table S4 in Multimedia Appendix 1 reports the *P* values of the permutation test, which confirm the significance of the contribution of both baseline HAMD-17 score and mHealth measures. The variable importance results demonstrated the great contribution of digital mHealth measures in the prediction of depression variation.

Sensitivity Analysis

Table S5 in Multimedia Appendix 1 reports the classification results of decision tree, random forest, and XGBoost with the use of baseline features and the mean values of IMS score, ASMS score, and sleep duration, rather than the FPC scores of them (scenario 2). Compared with introducing the dynamic features of the mHealth measures, using the mean values led to inferior prediction, especially for decision trees (overall data: 54.35% vs 47.83%; stable decline: 78.95% vs 47.37%; nonstable decline: 59.26% vs 59.26%) and random forests (overall data: 60.87% vs 50.00%; stable decline: 84.21% vs 78.95%; nonstable decline: 62.96% vs 55.56%). The results implied the necessity of considering the temporal dynamics of the digital mHealth measures.

Discussion

Principal Findings

This study evaluated the contribution of digital mHealth measures, including PROs and digital phenotype, to the prediction of the variation of depression within 12 weeks for patients with MDD. Based on the variation of HAMD-17 scores at 5 visits within 12 weeks, each patient was labeled as stable decline, fluctuate decline, fast decline, or delayed and fluctuate. The study used functional data analysis methods to address the severe sparsity of PROs and digital phenotype records caused by poor patient adherence, thereby effectively extracting their dynamic features. The classification results showed that by combining the baseline features with the dynamic information of PROs and digital phenotypes, the depression variation pattern can be identified with reasonable accuracy. Overall, our study demonstrated that the dynamic features of mHealth measures extracted by the functional data analysis method can be an effective alternative to clinical visits for depression variation monitoring. The findings can alleviate the burdens for both patients and doctors.

For the detection of latent trajectory classes regarding depression severity, growth mixture modeling was widely used in the previous studies [43-45]. However, growth mixture modeling was more likely to capture the similarity in the magnitude of depression severity, rather than its changing pattern. In our study, the patients with MDD were classified into 4 classes based on *k*-means clustering through the HAMD-17 score differences. Within each class, the patients exhibited the same temporal trend of depression severity. The classes were further named based on the dynamic characteristics of the depression symptom trajectories. In specific, stable decline implies a stable improvement of depression symptoms, fluctuate decline indicates a fluctuation of depression symptoms in the early stage and an alleviation at the end, fast decline represents a high baseline severity and a rapid improvement of depression symptoms, while delayed and fluctuate means a delayed improvement and sharp variation of depression symptoms.

Our findings revealed that the dynamic features of digital mHealth measures can reflect the depression variation of patients with MDD. By recording the trajectories of IMS scores, ASMS scores, and sleep duration using the smartphone and wristband, the dynamic characteristics of depression severity can be evaluated without strong dependence on continuous tracking of HAMD-17 scores. Moreover, results from the variable

XSL•FO
RenderX

importance analysis highlighted the contribution of the mHealth measures in the depression variation prediction.

Further, the sensitivity analysis indicated that taking into account the temporal dynamics of the mHealth measures is beneficial. In our study, the dynamic features of PROs and digital phenotypes were fully characterized through a functional data analysis method, rather than aggregating the records to a single scalar summary measure (eg, mean or median) by collapsing over time. Functional data analysis is popular in the study of continuously recorded data, such as physical activity data [46] and electroencephalography data [35], which supports the use of functional data analysis methods in our research. However, classical functional data analysis methods are only suitable for densely collected data. To extract dynamic features of the sparsely collected PROs and digital phenotypes, the PACE method was applied, which is a commonly used method for the principal component analysis of sparsely and irregularly observed functional data [36]. Collectively, the benefits of using functional data analysis methods can be summarized in two aspects: (1) avoiding the loss of information related to temporal dynamics of the PROs and digital phenotype records and (2) conquering the problem of sparse observations caused by poor patient adherence without excluding any participants with a low observation size (or in other words, with a high percentage of missing observations).

Comparison With Previous Work

Previous studies have demonstrated the potential of mHealth measures in predicting symptom severity of patients with MDD [6,23,47]. To further monitor the depression stability, Bai et al [20] defined two types of variation patterns, steady and swing, based on the patient-reported Patient Health Questionnaire-9 scores. However, such PRO records cannot substitute for the gold-standard HAMD-17 scores evaluated by clinicians in the longitudinal monitoring of patients with MDD. In our study, the more credible clinician-reported scores were used for outcome labeling, and PROs were incorporated as predictive factors, underscoring the need for more sophisticated use of PRO records. Moreover, Ikäheimonen et al [48] also considered variation of depression by partitioning the participants into 4 classes: declines, increases, remains depressed, and remains nondepressed. Although their model based on smartphone behavioral data achieved an overall accuracy of 75%, the predicting efficacy for classes with state changes (declines and increases) was invalid with a precision lower than 50%. Compared with their work, we refined the depression variation labels to facilitate the detection of specific temporal patterns, and our model yielded a more robust predictive performance for patients with fluctuating clinical courses. This improvement likely stems from our application of the functional data analysis to the mHealth records, which can effectively characterize the continuous underlying transition patterns that traditional summary statistics might overlook.

The core contribution of our study lies in the methodological integration of dual temporal dynamics for depression severity and mHealth measures, and the capacity to handle extremely sparse mHealth records. First, our definition of the outcome labels effectively characterized the temporal evolution of depression severity, enabling the identification of the inherent heterogeneity in depression progression over time. Moreover, the dynamic features of mHealth measures were extracted to predict the changing patterns of depression trajectory, forming an innovative dual-dynamic framework that is more practical in real-world psychiatric monitoring. Last but not least, our study made it feasible to obtain an acceptable depression monitoring using mHealth records with great irregularity and sparsity, which significantly enhances the ecological validity of our model and mitigates the adherence-related barriers that hinder clinical application of mHealth measures.

In recent years, high-resource biological markers derived from neuroimaging [49] and electrophysiology [50] have gained prominence in predicting antidepressant response due to their insights into underlying mechanisms. Compared with these markers, low-cost mHealth measures possess the ability of high-frequency, continuous recording within a naturalistic environment, facilitating scalable real-world monitoring and the dynamic capture of longitudinal symptom variations that static biomarkers may overlook. Given the complementary strengths, the integration of high-resource biological markers with real-world mHealth data represents a promising avenue for personalized psychiatry that warrants further investigation.

Strengths and Limitations

The strengths of our study can be summarized as follows. First, this study contained a long period of continuous monitoring for a large number of patients with MDD. Second, our study overcame the missing and sparse problems that universally existed in natural observations with the use of functional data analysis methods, which also facilitated the characterization of the temporal dynamics of PROs and digital phenotype records. Third, our study effectively reduced the dependence of patient adherence and eased the heavy burden of clinical follow-up in the prediction of depression variation trajectory.

Our study still has several limitations. One limitation is that only the IMS score, ASMS score, and sleep duration were continuously monitored and were used in the prediction of depression severity. Additional collection of more indicators of PROs and digital phenotype would be beneficial [27]. The other limitation is that only HAMD-17 scores were used in the construction of the labels of depression variation, which may be insufficient. Therefore, collecting more indicators of depressive symptoms and putting them together would be advantageous for the characterization of the change of depression severity. In addition, as the entire sample was used in the *k*-means clustering analysis to ensure a robust definition of clinical phenotypic labels, an implicit data leakage was introduced into the model assessment. So, the results, which may be inclined toward optimism, should be interpreted with caution. Moreover, constrained by the limited and imbalanced sample sizes of the participating centers, the predictive performance exhibited variability across heterogeneous clinical environments. This suboptimal performance underscores the inherent challenges of model generalizability. Thus, further research is required to enhance the robustness of the model when applied to diverse clinical settings. Last, while the predicted depression variation pattern can guide further

XSL•FO
RenderX

treatment for the patient with MDD, it was not able to provide an earlier warning within 12 weeks, which is worth further research.

Conclusions

Our study demonstrated the potential of mHealth measures, as an alternative to clinical visits, in the monitoring of depression variation, even under poor patient adherence. The results suggested that dynamic features of PROs and digital phenotypes, combined with baseline clinical features, can provide clinically meaningful information for depression variation patterns. Our findings help reduce dependence on strict patient adherence and alleviate the burdens of frequent clinical follow-ups, which facilitates a more practical monitoring of depression trajectory variations.

Abstract

Background: Digital interventions offer scalable alternatives to traditional face-to-face diabetes education, but often face challenges related to inconsistent clinical effectiveness, and declining user engagement. However, whether a digital structured education program integrated with behavioral nudge tools can improve metabolic, behavioral, and psychological outcomes in adults with type 2 diabetes remains unclear.

Objective: This study aimed to evaluate the effectiveness of a digital structured education program integrated with behavioral nudge tools in improving metabolic, behavioral, and psychological outcomes among adults with type 2 diabetes.

Methods: This multicenter randomized controlled trial was conducted in the endocrinology departments of 4 hospitals in China. Adults with type 2 diabetes were randomly assigned to an intervention group receiving a digital structured education program integrated with behavioral nudge tools (n=146) or a control group receiving standard digital diabetes education (n=147). Assessments were conducted at baseline and 12-week follow-up. The primary outcome was hemoglobin A_{1c} (HbA_{1c}) at 12 weeks, adjusted for baseline HbA_{1c}, and study center. Secondary outcomes included fasting blood glucose (FBG), weight, BMI, waist circumference, blood pressure, lipid profiles, self-management behaviors, self-efficacy, and habit strength.

Results: Among 293 participants (mean age 49.19, SD 10.02 y), 287 (97.9%) completed follow-up. At 12 weeks, the intervention group demonstrated significantly greater improvements than the control group in HbA_{1c} (adjusted mean difference −0.38%, 95% CI −0.68% to −0.09%; *P*=.01), FBG (adjusted mean difference −0.75, 95% CI −1.27 to −0.44 mmol/L; *P*<.001), weight (adjusted mean difference −0.84, 95% CI −1.61 to −0.07 kg; *P*=.03), BMI (adjusted mean difference −0.38, 95% CI −0.65 to −0.11 kg/m²; *P*=.01), systolic blood pressure (adjusted mean difference −2.71, 95% CI −4.62 to −0.79 mm Hg; *P*=.01), diastolic blood pressure (adjusted mean difference −2.92, 95% CI −4.47 to −1.37 mm Hg; *P*<.001), and total cholesterol (adjusted mean difference −0.27, 95% CI −0.48 to −0.05 mmol/L; *P*=.02). The intervention was also associated with significantly greater improvements in self-management behaviors, self-efficacy, and habit strength (all *P*<.05).

Conclusions: Digital structured education integrated with behavioral nudge tools improved metabolic outcomes and strengthened psychological and behavioral determinants of self-management among adults with type 2 diabetes over a 12-week period. These findings suggest that a digital structured education program integrated with behavioral nudge tools may enhance diabetes self-management beyond standard digital diabetes education. Further studies with longer follow-up and real-world implementation are warranted to evaluate the sustainability, generalizability, and long-term clinical impact of this integrated intervention.

KEYWORDS

type 2 diabetes; digital structured education; behavioral nudges; self-management behaviors; randomized controlled trial

Introduction

Background

Type 2 diabetes is a major global public health challenge and one of the fastest-growing chronic diseases. The International Diabetes Federation estimates that 589 million adults aged 20-79 years were living with diabetes in 2024, including approximately 148 million in China, where type 2 diabetes accounts for 90%-95% of cases [1]. Diabetes contributes to more than 3.4 million deaths annually worldwide and generates nearly US $1 trillion in health care expenditures, posing substantial clinical, economic, and societal burdens [1]. In China, the high prevalence of type 2 diabetes and its complications underscores an urgent need for effective and scalable management strategies.

Optimal diabetes management requires maintained glycemic and lipid control, blood pressure regulation, and long-term adherence to self-management behaviors [2,3]. However, control rates for blood glucose, blood pressure, and lipids remain suboptimal in mainland China, partly due to limited access to structured education and insufficient long-term engagement in self-management [4,5]. Improving maintained behavior change remains a central challenge in chronic disease management. Behavior change is increasingly understood through the lens of dual-process theory, which describes maintained 2 interacting systems: a reflective system that supports deliberate, goal-directed decision-making and an automatic system that drives habitual behavior through environmental cues [6-8].

Digital health interventions have emerged as scalable tools for diabetes management, providing remote education, monitoring, and personalized feedback through mobile and web-based platforms [9,10]. Evidence indicates that digital approaches can improve glycemic control, reduce health care usage, and enhance patient empowerment, particularly in resource-limited settings [7,11-13]. However, despite their potential, existing evidence on digital interventions reveals inconsistent findings regarding efficacy, with some studies highlighting challenges in maintaining engagement and a reliance on passive features like reminders rather than comprehensive behavioral strategies [9,14].

Behavioral Nudges in Digital Diabetes Management

Behavioral nudge tools, grounded in nudge theory, represent an evolving innovation in health behavior change, subtly altering environments or choices to promote healthier decisions without limiting autonomy [15-17]. These tools have been applied in various chronic disease contexts, including obesity and cardiovascular health, showing promise in fostering habits through unconscious cues, such as default options or timely prompts [17,18]. Nevertheless, digital structured education programs integrated with behavioral nudge tools remain underexplored, particularly in China, where adoption is limited and often disconnected from structured educational frameworks.

A digital structured education program integrated with behavioral nudge tools may better address both reflective and automatic drivers of behavior by combining complementary intervention components. Digital education enhances knowledge, self-efficacy, and intentional self-management, while behavioral nudge tools target automatic processes to build habits, such as through gamified prompts or environmental cues that encourage maintained actions like physical activity or medication adherence [19-21]. By simultaneously targeting these complementary behavioral processes, such integrated programs may reduce cognitive load, facilitate maintained behavior change, and potentially achieve greater improvements than standard digital diabetes education alone.

Knowledge Gap

Despite these synergies, significant gaps persist in the integration of nudge tools with digital education for adults with type 2 diabetes. Limited high-quality evidence from multicenter randomized controlled trials evaluating digital structured education programs integrated with behavioral nudge tools, especially in diverse populations like those in China, hinders understanding of their effectiveness and cultural adaptability [22]. Additionally, there is a scarcity of studies examining how these integrated interventions affect psychological outcomes (eg, habit strength and self-efficacy) alongside metabolic ones, and how they can be scaled equitably amid varying digital literacy levels.

Study Objective

To address these gaps, we conducted a multicenter randomized controlled trial to evaluate the effectiveness of a digital structured education with behavioral nudge tools (DSE-BN) program compared with standard digital diabetes education developed by the Chinese Diabetes Association among adults with type 2 diabetes in China. Guided by dual-process theory, the DSE-BN program was designed to target both reflective and automatic behavioral processes through the integration of digital structured education and behavioral nudge tools. We hypothesized that, compared with standard digital diabetes education, the DSE-BN program would produce greater improvements in metabolic outcomes (hemoglobin A_{1c} [HbA_{1c}], fasting blood glucose [FBG], weight, BMI, blood pressure, and lipid profiles), behavioral outcomes (diabetes self-management behaviors), and psychological outcomes (self-efficacy and habit strength) among adults with type 2 diabetes in China.

Methods

Study Design and Setting

This multicenter randomized clinical trial was conducted across 3 tertiary hospitals in Hainan Province, China—Hainan Provincial People's Hospital and the First and Second Affiliated Hospitals of Hainan Medical University. To ensure adequate recruitment, 928th Hospital was added as an additional study

XSL•FO
RenderX

site after trial initiation; no other substantive changes were made to the trial design, outcomes, or analytical plan.

Participants were recruited between March and September 2024 and were randomly assigned in a 1:1 ratio to either the intervention or control group. Follow-up assessments of both benefits and harms were completed at 12 weeks, between June 2024 and December 2025. An interim analysis was conducted midway through the trial to monitor data quality, recruitment progress, and participant safety. Given the low-risk nature of the behavioral education intervention, no formal stopping rules were predefined, and the trial was completed as planned without early termination. Reporting followed the CONSORT (Consolidated Standards of Reporting Trials) checklist.

Participants

Eligible participants were adults aged 18 to 65 years with type 2 diabetes diagnosed according to the 2020 Chinese guideline for the prevention and treatment of type 2 diabetes mellitus [23], receiving lifestyle interventions alone or combined with oral agents, cognitively and communicatively intact, and able to use a smartphone with guidance. Exclusion criteria included severe diabetes-related complications, mental or cognitive disorders, mobility impairment, recent cancer treatment, or participation in other trials.

The sample size was calculated using PASS (Power Analysis and Sample Size; version 15.0; NCSS) with the tests for 2 means in a multicenter randomized design procedure, using HbA_{1c} as the primary outcome. Assuming a between-group difference of 0.3% and an SD of 0.85% [10], with a 2-sided α of .05 and 80% power, the required sample size was 227 participants. Because the PASS multicenter randomized design procedure requires specification of an intraclass correlation coefficient (ICC), and no empirical estimate of the ICC was available from previous comparable studies, an ICC of 0.10 was adopted as a conservative design assumption, following the recommendation provided in the PASS software documentation, to account for potential within-site correlation. Allowing for a 20% attrition rate, the target sample size was 284 participants. Ultimately, 293 participants were enrolled, exceeding the prespecified target sample size.

Randomization and Blinding

Participants were randomly allocated in a 1:1 ratio to the intervention or control group using a computer-generated randomization sequence created with SPSS (version 26.0; IBM Corp). Individual-level simple randomization was adopted. Neither block randomization nor stratified randomization by study center was implemented; therefore, allocation block size was not applicable. After eligible participants had been recruited at each study site, an independent researcher centrally assigned participants according to the pregenerated randomization sequence. The randomization process was independent of participant recruitment and outcome assessment, and allocation concealment was maintained throughout the allocation process, thereby minimizing the risk of selection bias across study sites.

Due to the nature of the behavioral intervention, blinding of participants and intervention nurses was not feasible. However, physicians responsible for routine clinical care and outcome assessment, as well as data analysts, were blinded to group allocation to minimize potential performance and detection bias. In addition, study center was included as a covariate in the primary statistical analyses to account for potential between-center differences.

Intervention

Intervention Implementation

Each study site was supported by at least 1 physician and 1 nurse, operating within a centrally coordinated intervention team. Physicians were responsible for clinical diagnosis and participant recruitment, while nurses delivered the intervention and managed informed consent, baseline and follow-up data collection, registration on the self-management support system (SMASS), and ongoing participant support. Study procedures and intervention delivery were coordinated centrally to ensure consistency across sites.

To standardize implementation of the intervention across study sites, all intervention personnel completed uniform, centralized training before study initiation. Training covered intervention content, delivery procedures, use of the SMASS platform, and fidelity requirements. Competency assessments were conducted following training, and only personnel meeting predefined competency criteria were authorized to deliver the intervention. Ongoing supervision and cross-site communication were used to maintain consistency of implementation throughout the study period.

Intervention Group

Participants in the intervention group received the DSE-BN program, a nurse-developed, theory-informed digital structured education program incorporating an enhanced educational workflow, shared digital support features, and behavioral nudge tools. Grounded in dual-process theory, the DSE-BN program was designed to influence both reflective and automatic behavioral processes. Reflective behavior change was targeted through structured digital education aimed at improving diabetes-related knowledge and enhancing self-efficacy via progressive goal setting, structured knowledge learning, repetition and review, timely positive feedback, experience sharing, and reminders, while automatic behavioral processes were addressed through subtle environmental modifications using behavioral nudge tools embedded in participants' everyday environments.

The DSE-BN program comprised two integrated components: (1) a theory-informed digital structured education program incorporating an enhanced educational workflow and shared digital support features and (2) behavioral nudge tools. The digital structured education component was designed to facilitate reflective behavior change through structured educational activities and enhanced educational workflow, whereas the behavioral nudge component targeted automatic behavioral processes by providing environmental cues embedded within participants' daily living environments. These 2 components were implemented simultaneously throughout the intervention period as complementary elements of a single integrated intervention.

XSL•FO

Behavioral nudge tools	✓ (Self-monitoring reminder sticker, portion-control plate, footprint exercise mat, foot-care reminder image, and medication reminder sticker)	—

[a]DSE-BN: digital structured education with behavioral nudge tools.

[b]SMASS: self-management support system.

[c]Not applicable.

Digital Structured Education

The digital structured education component incorporated structured educational content, an enhanced educational workflow, and shared digital support features delivered individually and remotely through 4 weekly modules via the SMASS platform, enabling participants to complete the program independently in their home environments using their smartphones over 4 consecutive weeks (1 session per week; 9 - 25 min per module; total education time approximately 74 min) [11,12,24]. Module content covered diabetes knowledge and self-monitoring, diet management, physical activity and foot care, and regular examinations and follow-up (Table 2). Educational materials included prerecorded videos, interactive quizzes, and learning checkpoints. Modules were completed sequentially, with progression restricted until completion of the current module.

Following completion of baseline assessments, participants commenced the DSE-BN program. Each module followed a standardized learning workflow, beginning with brief preparatory questions before video viewing. Educational videos were presented in a preset order and could not be skipped or

XSL•FO
RenderX

fast-forwarded to ensure completion of all learning content. After each module, participants completed review questions and received immediate feedback through encouraging language and supportive visual cues (eg, emojis) to reinforce knowledge acquisition and active learning.

Table . Components and delivery of the digital structured education with behavioral nudge tools (DSE-BN) program[a].

Contents of each module	Tools: design rationale and description
Module 1: knowledge about diabetes and self-monitoring	
This module introduces the importance of diabetes management and facilitates patients' self-monitoring. It covers normal blood glucose ranges, hyperglycemia, and hypoglycemia, emphasizing the significance of routine self-monitoring and accurate record-keeping. Patients are encouraged to recognize early warning signs, actively engage in managing their blood glucose levels by self-monitoring.	• Self-monitoring reminder sticker[b]: Developed as a reminder sticker to be placed in prominent household locations or near medications, serving to prompt patients while also reinforcing the blood glucose and urine monitoring components of the structured education program.
Module 2: diet management	
Building on module 1, this session highlights the role of weight management in diabetes care. Patients are introduced to different nutrients and calorie, values using visual aids such as food images. Practical exercises include evaluating and calculating daily dietary intake. Patients are encouraged to set personalized dietary goals and develop a structured meal plan tailored to their needs.	• Nudge plate[c]: A real, 3-color round plate was developed for home dietary management. The plate adopts a traffic-light scheme, divided into 1 red zone, 2 yellow zones, and 1 green zone. Rim markings correspond directly to the food classification cards used in the structured education program. The green zone is designated for low-calorie, vegetables, the yellow zones for moderate-calorie, foods such as staple grains, lean meat, eggs, poultry, and root vegetables, and the red zone for high-calorie, items such as sugary or fatty foods. Notably, the red zone is half the size of the other colored zones. By incorporating familiar traffic-light cues and linking them with the structured education cards, the plate provides an intuitive visual reminder that encourages patients to increase vegetable consumption, consume moderate portions of staple foods and lean proteins, and limit the intake of high-calorie, foods.
Module 3: physical activity and foot care	
This module reviews the dietary principles discussed previously and emphasizes the importance of regular exercise in diabetes management. Patients are guided to set achievable exercise goals and create individualized activity plans. The session also includes education on foot care, with demonstrations of foot exercises to reduce complications and encouragement to integrate these practices into daily routines. Patients are encouraged to conduct foot care and take exercise.	• Footprint exercise mat[b]: Designed as a green footprint exercise mat, with a starting point labeled “6000 steps per day.” Placed at the household entrance, it serves as a daily prompt for physical activity, creating a supportive proximal home microenvironment while reinforcing the exercise component of the structured education program. • Foot care reminder image[b]: Developed as a reminder image to be displayed at home, prompting patients to perform daily foot care and providing guidance on proper techniques, while reinforcing the foot care component of the structured education program.
Module 4: regular examinations and follow-up	
The final module revisits the key points of physical activity and foot care, then expands on the importance of regular medical examinations. Patients are educated about appropriate timing, essential laboratory tests, and screening for diabetes-related complications. Medication management is introduced, with a focus on adherence and understanding prescribed treatments. Patients are encouraged to maintain their goals and attend regular follow-up visits with health care providers.	• Medication reminder sticker[b]: Developed as a reminder sticker to be placed in the home’s drinking area, serving to prompt patients while reinforcing the medication adherence component of the structured education program.

[a]Digital structured education was delivered through the self-management support system platform as 1 session per week for 4 consecutive weeks (9-25 minutes per module; total education time approximately 74 minutes). Behavioral nudge tools were introduced at the beginning of the intervention and used continuously in participants’ home environments throughout the 12-week intervention to provide ongoing environmental cues reinforcing healthy self-management behaviors. Refer to the study by Liu et al [24] for the structured education program.

[b]China Copyright Protection Center. Copyright registration certificate for the work “Self-Management Behavior Illustrations.” Registration No. 国作登字-2024-F-00022150. Beijing: China Copyright Protection Center; 2024 [25].

[c]Nudge plate is a patent product [26].

Beyond the enhanced educational workflow described above, participants in the DSE-BN group also received the same digital support features available to the control group. These shared digital support features included a discussion area for peer interaction and professional support, automated reminders, rule-based tailored feedback, and data-driven early-warning alerts. Within the discussion area of the SMASS platform, participants could post questions or comments and interact with health care professionals and other participants, thereby facilitating peer interaction and professional support. Automated

XSL•FO
RenderX

reminders encouraged timely completion of the learning modules. Rule-based tailored feedback was generated according to participants' learning progress and self-reported metabolic indicator records uploaded through the SMASS platform and was accompanied by encouraging messages to reinforce self-management behaviors. In addition, participants' metabolic status was displayed using a traffic-light system (green, yellow, and red) to facilitate timely recognition of abnormal results and encourage appropriate self-management actions.

Behavioral Nudge Tools

The behavioral nudge component consisted of a set of environmental cueing tools (Table 2), including a self-monitoring reminder sticker, a nudge plate, a footprint exercise mat, a foot care reminder image, and a medication reminder sticker. These tools were designed to subtly encourage healthy behaviors by modifying participants' everyday environments while preserving individual autonomy.

Standardized instructional videos embedded within the SMASS platform guided participants on how to place and use each behavioral nudge tool appropriately in their homes and daily living environments according to their individual routines. These environmental cues remained in participants' home environments throughout the intervention period, providing continuous environmental cues to reinforce healthy self-management behaviors.

Intervention Fidelity

Intervention fidelity was ensured through standardized educational content, centralized training of intervention personnel, restricted module progression, automated reminders, and system-based tracking of learning activities. Engagement with the digital education component was monitored using SMASS system logs. Among the 146 participants allocated to the DSE-BN group, platform records verified that 142 participants completed all 4 educational modules, 1 participant completed 3 modules, and 3 participants completed 1 or fewer modules. Implementation of the behavioral nudge tools was confirmed through participant-submitted photographs of home-based installations reviewed by research nurses. No substantive modifications were made to the DSE-BN program during the study period.

Control Group

Participants in the control group received standard digital diabetes education delivered through the SMASS platform, with educational content developed by the study team based on educational materials from the Chinese Diabetes Association. The control program consisted of 4 weekly sessions (15 - 30 min per session; total approximately 103 min) covering diabetes basics, pharmacotherapy, glucose monitoring, complications, and lifestyle management. WeChat (Tencent Holdings Ltd) was used only for routine communication and follow-up management and was not part of the intervention delivery.

Similar to the DSE-BN group, participants completed the educational modules through the SMASS platform and had access to the same shared digital support features, including sequential learning, a discussion area for interaction with health care professionals and other participants, automated reminders, rule-based tailored feedback, and data-driven early-warning alerts throughout the intervention period. However, unlike the DSE-BN program, the control intervention did not include the enhanced educational workflow, including preparatory questions before video learning and postmodule review questions with immediate feedback, or home-based behavioral nudge tools designed to provide home-based environmental cues for behavior change.

Among the 147 participants in the control group, completion of the 4 digital education modules was tracked through the platform. Platform records indicated that 113 participants completed all 4 modules, 25 completed 3 modules, 6 completed 2 modules, and 3 completed 1 or fewer modules.

All participants in both groups continued to receive routine diabetes care, including outpatient visits, laboratory monitoring, and pharmacological treatment as prescribed by their physicians.

Outcome Measures

All metabolic, psychosocial, and behavioral outcome data were collected at baseline and at the 12-week follow-up (March 2024 to December 2025). The primary outcome was HbA_{1c} level at 12 weeks. Secondary metabolic outcomes of blood lipid profiles (total cholesterol [TC], triglycerides, high-density lipoprotein cholesterol [HDL], and low-density lipoprotein cholesterol [LDL]) were extracted from medical records at each study site. Additional secondary outcomes, including FBG, blood pressure, weight, waist circumference (WC), BMI, self-efficacy, habit strength, self-management behaviors, and other outcomes of medications, were assessed and recorded by trained research nurses using reliable and validated instruments.

Diabetes self-efficacy was assessed using the validated Chinese version of the Self-Efficacy for Diabetes (C-SED) scale [27]. The original scale was developed by Lorig and colleagues [28] in the United States and was subsequently translated and culturally adapted into Chinese by Wei et al [27]. The C-SED comprises 9 items covering 4 domains: diet, physical activity, blood glucose management, and disease control. Each item is rated on a 5-point Likert scale, ranging from 1 ("not at all confident") to 5 ("completely confident"). The mean score ranges from 1 to 5, with higher scores indicating greater diabetes self-efficacy. The Chinese version has demonstrated good reliability in previous studies, and the Cronbach α in this study was 0.87.

Habit strength was assessed using the Self-Report Habit Index (SRHI) [29,30]. The original SRHI consists of standardized descriptive statements that can be adapted to specific behavioral contexts (eg, "XXX is something I do automatically"). In this study, the SRHI was adapted to assess 5 diabetes self-management behaviors: dietary management, physical activity, blood glucose monitoring, foot care, and medication adherence. Following contextual adaptation and expert review, a 20-item questionnaire was developed, comprising 4 items for each behavior. All items were rated on a 5-point Likert scale, ranging from 1 ("strongly disagree") to 5 ("strongly agree"). Total scores range from 20 to 100, with higher scores indicating

XSL•FO
RenderX

stronger habit strength [30]. The Cronbach α in this study was 0.94.

Diabetes self-management behaviors were assessed using the validated Chinese version of the Summary of Diabetes Self-Care Activities questionnaire [31]. The questionnaire comprises 11 items across 6 domains: general diet (2 items), specific diet (2 items), physical activity (2 items), blood glucose monitoring (2 items), foot care (2 items), and medication adherence (1 item). Each item assesses the number of days per week (0 - 7 d) on which the corresponding self-management behavior was performed. Total scores range from 0 to 77, with higher scores indicating better diabetes self-management behaviors. Item 4 is reverse scored, whereas all remaining items are scored in the positive direction. The Cronbach α in this study was 0.78.

Harms were defined as severe hypoglycemia, characterized by events requiring assistance from another person or medical attention. These events were assessed systematically at the 12-week follow-up visit through structured participant interviews and review of medical records, and supplemented by nonsystematic participant self-reports during the study period. All reported events were documented and verified by site investigators.

Demographic and clinical characteristics were collected using a self-designed questionnaire. Information collected included age, sex, ethnicity, medical insurance, educational background, employment status, marital status, cohabitation group, individual monthly income, smoking status, alcohol consumption, and electronic health management. Clinical characteristics included type 2 diabetes duration, type 2 diabetes medication duration, types of medications, and diabetes-related complications.

Quality Control

To ensure consistency and methodological rigor across study sites, standardized operating procedures were used to guide participant recruitment, intervention delivery, data collection, and follow-up. All study personnel received uniform training before study initiation, and adherence to the study protocol was reinforced throughout the trial.

Intervention fidelity was supported through system-based controls embedded within the SMASS platform, including restricted module progression, automated reminders, and engagement prompts (eg, pre- and postmodule quizzes and timed pauses). Nurses monitored participants' engagement and progress on a weekly basis, provided reminders as needed, and assisted with scheduling follow-up assessments. To minimize potential contamination between study groups, intervention materials and behavioral nudge tools were accessible only to participants randomized to the intervention group, and participants in the intervention and control groups were followed up at separate time points.

Quality assurance procedures were implemented at both the site and central levels. Monthly site monitoring was conducted to assess protocol adherence and resolve implementation issues. Data accuracy and completeness were ensured through double data entry and independent expert review. Any discrepancies were resolved by consensus. When necessary, original source data were verified by contacting participants, and records were corrected accordingly.

Ethical Considerations

The trial was registered with the Chinese Clinical Trial Registry (ChiCTR2400082373) on March 27, 2024. The study protocol is available at the registry website, and deidentified study data are available from the corresponding author upon reasonable request. Ethical approval was granted by the Ethics Committee of Hainan Medical University (HYLL-2023 - 461), and the study was conducted in accordance with the Declaration of Helsinki. Before enrollment, all participants received detailed information regarding the study objectives, study procedures, potential risks and benefits, and measures to protect their privacy and confidentiality. Written informed consent was obtained from all participants before participation, and participants were informed of their right to withdraw from the study at any time without affecting their medical care.

To protect participants' privacy and confidentiality, all study data were deidentified before analysis and securely stored, with access restricted to authorized research personnel only. Participants received free access to the SMASS platform throughout the study and could consult the research team at no cost during the intervention period. Participants in the intervention group also received the behavioral nudge tools free of charge, including a self-monitoring reminder sticker, a nudge plate, a footprint exercise mat, a foot care reminder image, and a medication reminder sticker. No monetary compensation was provided for participation in the study.

Statistical Analysis

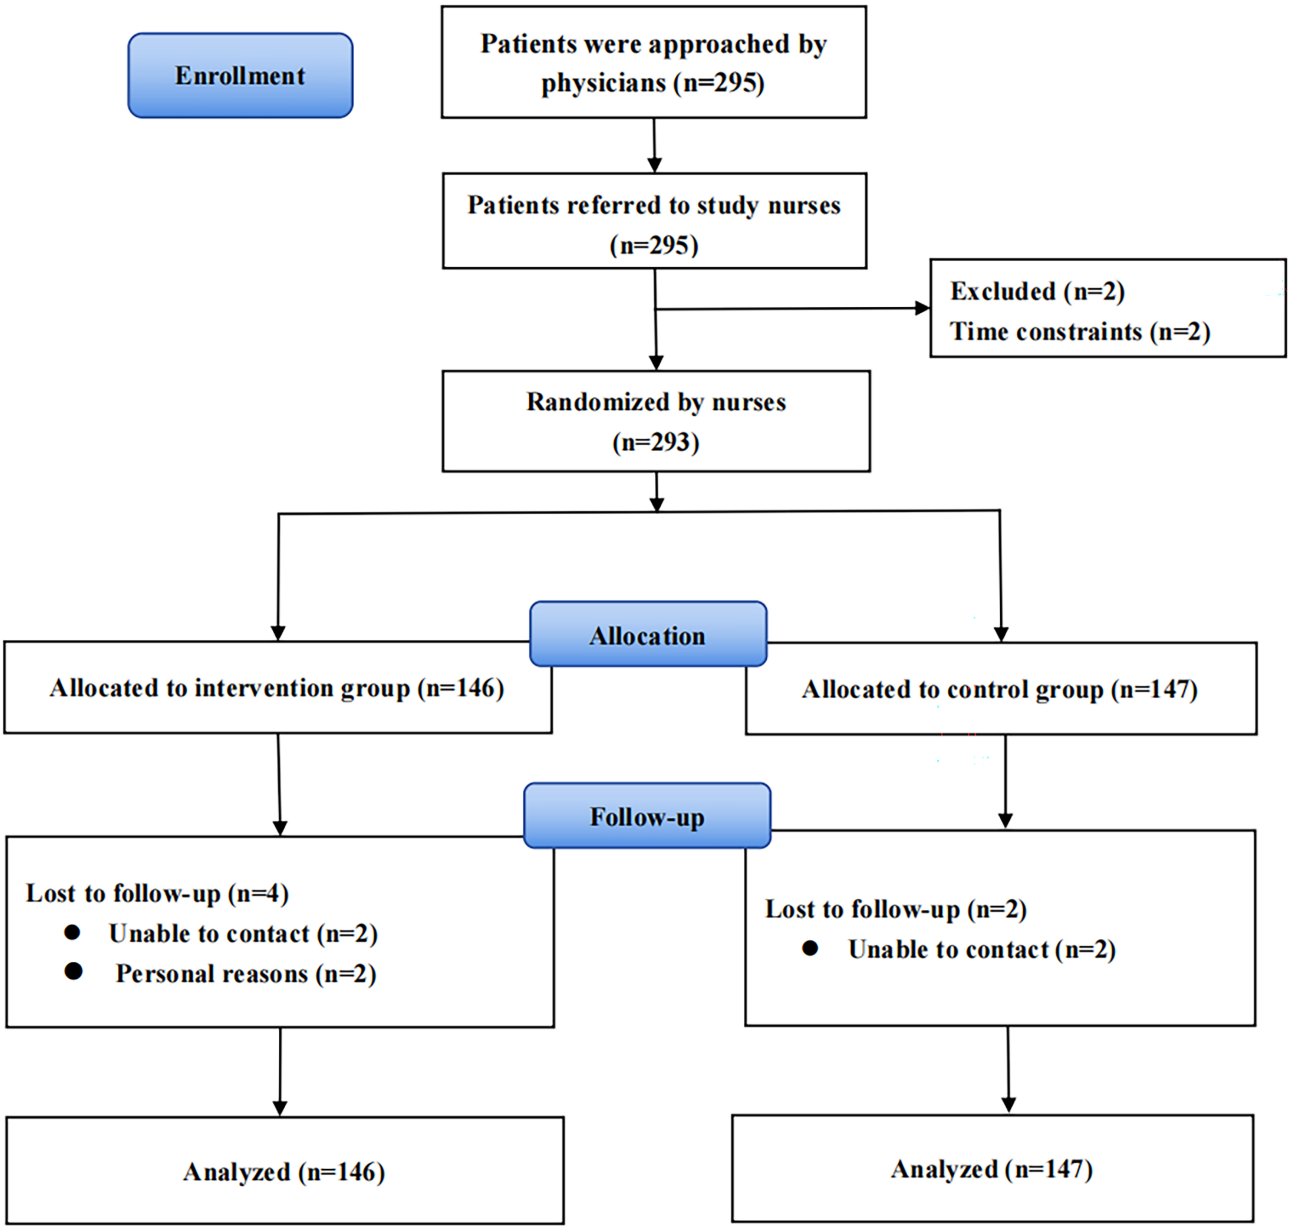
Analyses were conducted using SPSS (version 27.0) under the intention-to-treat principle. At the 12-week follow-up, outcome data were missing for 6 of the 293 (2%) participants. Missing values were observed for weight, BMI, WC, FBG, HbA_{1c}, lipid profiles, self-efficacy, diabetes self-management behaviors, and habit strength. These missing outcome data were handled using multiple imputation before the primary analyses. A total of 5 imputed datasets were generated via a Markov chain Monte Carlo approach with 10 iterations per dataset. Predictive mean matching was applied for continuous variables, and logistic regression was used for categorical variables. Final estimates were derived by pooling results across datasets according to Rubin's rules.

Baseline characteristics were summarized using means and SDs for normally distributed continuous variables or medians (IQRs) for nonnormally distributed variables, as appropriate, and numbers (percentages) for categorical variables. Between-group comparisons of baseline characteristics were conducted using independent-samples *t* tests, chi-square tests, Fisher exact tests, or Mann-Whitney *U* tests, as appropriate.

The primary analysis compared HbA_{1c} at 12 weeks between the intervention and control groups using ANCOVA, with adjustment for baseline HbA_{1c} and study center as a fixed effect. The same baseline- and center-adjusted ANCOVA approach was applied to secondary outcomes. Sensitivity analyses for both primary and secondary outcomes at 12 weeks were

XSL•FO
RenderX

conducted using ANCOVA with adjustment for baseline values only.



Between-group comparisons of other outcomes, including achievement of an HbA_{1c} reduction ≥0.5% and differences in medication use at 12 weeks, were performed using chi-square tests or Mann-Whitney *U* tests, as appropriate. Within-group comparisons of primary and secondary outcomes between baseline and 12 weeks were conducted using paired *t* tests or Wilcoxon signed-rank tests, as appropriate. All tests were 2-sided, with a *P* value <.05 considered statistically significant.

Results

Overview

A total of 295 participants met the inclusion criteria, of whom 293 (99.3%) consented and completed baseline data collection. Participants were randomized to the intervention group receiving digital structured education with nudging tools (n=146) or the control group receiving standard digital health education (n=147). Moreover, 4 participants in the intervention group and 2 in the control group were lost to follow-up, each completing fewer than 2 modules (Figure 1).

Figure 1. The study flowchart.

Baseline Characteristics

The 293 participants had a mean age of 49.19 (SD 10.02) years; 191 (65.2%) were male, and 281 (95.9%) were of Han ethnicity. Most participants were married (n=254, 86.7%), employed (n=211, 72%), and had completed at least junior high school education (n=157, 53.6%). About two-thirds (n=196, 66.9%) were covered by urban employee or urban-rural resident medical insurance. The mean duration of type 2 diabetes was 3.94 (SD 4.39) years, with a mean treatment duration of 3.36 (SD 4.32) years; 208 (71%) reported no diabetes-related complications. Overall, 184 (62.8%) had not previously used electronic devices for disease management. Baseline characteristics of the 2 groups are presented in Table 3.

Between-Group Comparisons at 12 Weeks

At follow-up, the intervention group demonstrated greater reductions in HbA_{1c} (adjusted mean difference −0.38, 95% CI −0.68 to −0.09; *P*=.01), FBG (adjusted mean difference −0.75, 95% CI −1.27 to −0.44; *P*<.001), weight (adjusted mean difference −0.84, 95% CI −1.16 to −0.07; *P*=.03), BMI (adjusted mean difference −0.38, 95% CI −0.65 to −0.11; *P*=.01), systolic blood pressure (SBP; adjusted mean difference −2.71, 95% CI −4.62 to −0.79; *P*=.01), and diastolic blood pressure (DBP; adjusted mean difference −2.92, 95% CI −4.47 to −1.37, *P*<.001), TC (adjusted mean difference −0.27, 95% CI −0.48 to −0.05; *P*=.02), compared with the control group (Table 4). Moreover, the proportion of participants with an HbA_{1c} reduction ≥0.5% was significantly higher than in the control group (70.54% vs 57.82%; χ^2_1=5.2; *P*=.02).

[a]Within-group mean differences represent changes from baseline to week 12.

[b]Adjusted between-group mean differences were estimated using ANCOVA, with baseline values and study center included as covariates.

[c]Primary outcome.

[d]HbA_{1c}: hemoglobin A_{1c}.

[e]IG: intervention group.

[f]CG: control group.

[g]FBG: fasting blood glucose.

[h]WC: waist circumference.

[i]SBP: systolic blood pressure.

[j]DBP: diastolic blood pressure.

[k]TC: total cholesterol.

[l]TG: triglycerides.

[m]HDL: high - density lipoprotein cholesterol.

[n]LDL: low - density lipoprotein cholesterol.

[o]Behaviors: diabetes self - management behaviors.

Compared with controls, the intervention group achieved greater improvements in self-management behaviors (adjusted mean difference 5.90, 95% CI 3.67 - 8.14; *P*<.001), self-efficacy (adjusted mean difference 2.90, 95% CI 1.79 - 4.01; *P*<.001), and habit strength (adjusted mean difference 6.34, 95% CI 4.32 - 8.37; *P*<.001). No significant between-group differences were observed for WC, triglycerides, HDL, or LDL (Table 4). No severe hypoglycemia occurred or nonsignificant difference was observed among medications among 2 groups (Table S1 in Multimedia Appendix 1).

XSL•FO
RenderX

Sensitivity analyses adjusting for baseline values only yielded results that were largely consistent with the primary analyses adjusted for both baseline values and study center. The direction and statistical significance of the primary and secondary outcomes remained unchanged, with the exception of weight, for which the between-group difference was attenuated and no longer statistically significant (Table S2 in Multimedia Appendix 1).

Within-Group Changes From Baseline to 12 Weeks

Both 2 groups showed significant improvements in HbA_{1c}, FBG, weight, BMI, WC, and blood lipids of TC, triglycerides, HDL, and LDL levels from baseline to 12 weeks. Blood pressure of SBP and DBP improved significantly only in the intervention group, with no significant changes observed in the control group. From baseline to follow-up, both groups demonstrated significant gains in self-management behaviors, self-efficacy, and habit strength (Table 4).

Discussion

Principal Findings

This multicenter randomized trial demonstrated that the DSE-BN program improved HbA_{1c}, FBG, weight, BMI, blood pressure, and TC compared with standard digital diabetes education. The intervention was also associated with improvements in diabetes self-management behaviors, self-efficacy, and habit strength, highlighting the potential value of an integrated digital structured education program incorporating behavioral nudge tools and complementary digital support features to simultaneously support reflective and automatic behavioral processes in diabetes self-management.

Interpretation of Findings

The observed improvements in glycemic outcomes in the intervention group, including a mean reduction of 0.38% in HbA_{1c} and decreases in FBG, are consistent with previous evidence suggesting that app-based diabetes education may support glycemic control by facilitating lifestyle modification and self-management behaviors [32]. Although the absolute HbA_{1c} reduction was modest, a significantly greater proportion of participants in the intervention group achieved an HbA_{1c} reduction of ≥0.5% compared with the control group, indicating that the intervention was capable of producing clinically meaningful improvements in a subset of participants. It is important to note that the mean HbA_{1c} reduction observed in this study falls below the 0.5% threshold commonly considered clinically meaningful at the individual level [33], and the relatively short follow-up period limits inference regarding long-term glycemic benefit. Nevertheless, modest HbA_{1c} reductions have been shown to be relevant at the population level. For example, findings from the UK Prospective Diabetes Study suggest that each 1% decrease in HbA_{1c} is associated with substantial reductions in diabetes-related complications [34]. While extrapolation should be interpreted with caution, the findings of this study suggest that even small improvements achieved through low-intensity, scalable digital interventions may have public health relevance if maintained over time.

In contrast, pharmacological agents like glucagon-like peptide-1 receptor agonists typically achieve HbA_{1c} reductions exceeding 1.2% [35]. Improvements observed in the control group are consistent with evidence that digital interventions can enhance cognitive-behavioral processes and health literacy [36,37]. Notably, although the intervention group received a more streamlined educational curriculum than the control group, it achieved superior improvements across several metabolic and behavioral outcomes. This finding may reflect the added value of the integrated intervention package, which combined digital structured education with multiple behavioral support components, including instructional videos, interactive quizzes, preparatory and postmodule review questions with immediate feedback, peer interaction, automated reminders, rule-based tailored feedback, data-driven early-warning alerts, and home-based behavioral nudge tools. Together, these integrated features may have reinforced both intentional self-management and habit formation, thereby supporting long-term engagement beyond education alone. Importantly, no significant between-group differences were observed in the use of antihyperglycemic medications at the 12-week follow-up, and no severe hypoglycemic events were reported, supporting the safety of the intervention and indicating that the observed effects were unlikely to be driven by pharmacological changes.

The design of the DSE-BN program was informed by dual-process theory, which proposes that health behaviors are influenced by both reflective and automatic behavioral processes [38]. Rather than relying on education alone, the intervention integrated digital structured education with complementary digital support features and behavioral nudge tools to reinforce healthy behaviors in participants' home environments. By simultaneously strengthening reflective processes through structured education and supporting automatic processes through home-based behavioral nudge tools and digital behavioral support, the intervention may have facilitated the transition from intentional self-management to more consistent daily habits. These behavioral changes may, in turn, have contributed to the observed improvements in weight, BMI, blood pressure, and TC through better adherence to physical activity, medication use, and healthy dietary behaviors [39]. Consistent with this interpretation, no significant between-group differences were observed in the use of antihypertensive or lipid-lowering medications at the 12-week follow-up, suggesting that these cardiometabolic benefits were also unlikely to be driven by medication changes. Although this trial evaluated the overall effectiveness of an integrated intervention package rather than the independent effects of individual components, the findings suggest that integrating behavioral nudge tools within a broader digital structured education program may provide additional benefits beyond education alone.

Psychological enhancements in self-efficacy, self-management, and habit strength echo previous research [40], with structured education addressing personal and environmental factors per social cognitive theory [41]. From the perspective of dual-process theory, the integrated intervention may have further strengthened automatic behavioral processes while reinforcing the effects of reflective learning [26,42]. This integration of reflective and automatic behavioral processes may have

XSL•FO
RenderX

facilitated the transition from conscious goal-setting to more habitual self-management behaviors, providing a theory-informed approach to promoting long-term diabetes self-management [43,44]. Future studies should investigate the neural mechanisms underlying behavioral changes following this dual-process intervention and evaluate the relative contribution of individual intervention components [45].

Consistent with American Diabetes Association and European Association for the Study of Diabetes guidelines recommending HbA_{1c} levels below 7% to mitigate complications [46], this nonpharmacological intervention serves as an adjunct for patients near targets or in combination with medications, enhancing accessibility in real-world practice.

Implications for Digital Health Practice

This multicenter randomized trial demonstrates that an integrated digital structured education program incorporating behavioral nudge tools and complementary behavioral support strategies can enhance diabetes self-management by simultaneously supporting reflective and automatic behavioral processes. The intervention was associated with improvements in HbA_{1c}, weight, BMI, blood pressure, TC, self-management behaviors, self-efficacy, and habit strength, addressing common limitations of digital interventions such as declining engagement and suboptimal adherence.

By extending support into patients' home environments, this low-cost, technology-enabled approach shows strong potential for scalable, sustainable deployment in routine diabetes care, particularly in resource-constrained settings. Its favorable safety profile and independence from pharmacological changes further support its feasibility as an adjunct to standard treatment. These findings underscore the potential value of integrated, theory-informed digital interventions that integrate reflective learning with support for automatic behavior formation, providing a scalable approach to sustainable diabetes self-management.

Study Limitations

Several limitations of this study should be acknowledged. Blinding of participants was infeasible due to the intervention's behavioral nature, which may have introduced expectation bias. Outcomes were assessed only at 12 weeks, limiting inference regarding the sustainability of intervention effects over the longer term. Accordingly, improvements observed across multiple secondary outcomes should be interpreted cautiously. This relatively short follow-up period may also partly explain the attenuation of the between-group difference in weight observed in sensitivity analyses, suggesting that weight-related outcomes—given their multifactorial determinants—may be more sensitive to model specification than glycemic and behavioral outcomes. Recruitment from a single Chinese city limited population diversity, and the educated, urban, insured sample may reduce generalizability, particularly regarding socioeconomic, rural-urban, and digital literacy disparities that could exacerbate exclusion. In addition, because this study evaluated the overall effectiveness of an integrated intervention package, it was not designed to isolate the effects of individual intervention components. Future dismantling studies are warranted to identify the active components and optimize the design of theory-informed digital behavioral interventions. Despite these limitations, the multicenter randomized design, standardized intervention delivery, and the theory-informed dual-process framework bolster internal validity. Future studies with longer follow-up and more diverse populations are warranted to confirm and extend these findings.

Conclusions

This study demonstrates that an integrated digital structured education program incorporating behavioral nudge tools can improve glycemic control, weight, BMI, blood pressure, TC, and self-management in adults with type 2 diabetes. Beyond clinical outcomes, the intervention was associated with improvements in psychological and behavioral factors, including self-efficacy and habit formation, which are critical for supporting short- to medium-term adherence in chronic disease management. These findings suggest that an integrated digital structured education program incorporating behavioral nudge tools provides a scalable, theory-informed approach that bridges intentional behavior change and habit formation, with potential to support sustainable diabetes self-management in routine care.

Acknowledgments

The authors sincerely thank all participants for their valuable contributions to this study.

Abstract

Background: Radiographic knee osteoarthritis (ROA) is associated with abnormal plantar loading and altered gait coordination. Insole-based plantar-pressure sensing offers a practical wearable approach to ROA identification, but existing methods typically use either conventional biomechanical descriptors or end-to-end temporal models. An interpretable subject-level framework that captures both local abnormalities and distributed coordination is, therefore, needed.

Objective: This study aimed to develop an interpretable subject-level framework that combines conventional biomechanical descriptors with coordination-level plantar information to identify ROA.

Methods: In secondary cross-sectional analysis, using a previously reported Pearl River Osteoarthritis Cohort plantar-pressure dataset from our group, we analyzed 92 participants (43 with ROA and 49 without ROA; mean age 63.0, SD 8.4 y). The source cohort was recruited from clinical and nearby community sources at Zhujiang Hospital of Southern Medical University, Guangzhou, China, between January 2022 and February 2023. We developed an interpretable participant-level classification framework integrating conventional biomechanical descriptors with a coordination-level Plantar Synergy Index (PSI). Participant-wise stratified split allocated 72 participants for 5-fold cross-validation, and 20 for locked independent evaluation. Feature selection used Fisher-score ranking (k=50). All point estimates are accompanied by 2000-iteration bootstrap 95% CIs, and paired model comparisons used DeLong tests. All statistical tests used α=.05. Additional analyses examined feature stability, phase-resolved PSI patterns, robustness to perturbation and design variation, and comparisons with representative end-to-end temporal baselines.

Results: The fusion model achieved the best primary classification performance on the independent test set, with an F_1-score of 0.842 (95% CI 0.615 - 1.000) and accuracy of 0.850 (95% CI 0.700 - 1.000). It also showed balanced performance across additional metrics, with area under the receiver operating characteristic curve (AUROC) of 0.818 (95% CI 0.576 - 1.000), precision of 0.800 (95% CI 0.538 - 1.000), recall of 0.889 (95% CI 0.636 - 1.000), and specificity of 0.818 (95% CI 0.571 - 1.000). DeLong testing showed that fusion outperformed PSI-only at the AUROC level (P=.02). Stable retained descriptors were dominated by biomechanical features, with a reproducible PSI component. Phase-resolved analyses suggested distributed stance-phase coordination differences. Robustness and baseline comparisons supported the stability of the framework, but the wide CIs indicate that the findings remain preliminary.

Conclusions: This study introduces an interpretable participant-level representation that integrates local biomechanical loading with multiscale interregional temporal coordination, extending plantar-pressure approaches based on summary descriptors or end-to-end models. Across evaluated settings, the framework showed competitive identification and preliminary robustness. Local biomechanical descriptors constituted the main discriminative basis, whereas PSI contributed a reproducible coordination-level component whose incremental predictive value remains to be established. This broadens plantar-pressure analysis from local loading to distributed coordination. External multicenter prospective validation is required before evaluating the framework as an imaging adjunct for functional assessment and longitudinal monitoring.

Introduction

Osteoarthritis is a chronic disease characterized by whole-joint degeneration. It causes pain, reduced activity, and functional decline, and is a major global cause of disability [1]. Knee osteoarthritis is one of the most common forms, and its burden continues to rise, highlighting the need for scalable and repeatable assessment tools that can capture functional change and support rehabilitation management and longitudinal follow-up [2].

In clinical practice, imaging—especially X-ray—is widely used to assess knee osteoarthritis, and the Kellgren-Lawrence (K-L) scale is one of the most common radiographic grading systems [3]. Here, we focus on radiographic knee osteoarthritis (ROA), using radiographic status as the reference standard for classification-oriented model development and evaluation. However, radiographic grades mainly reflect static structural changes and do not directly capture functional abnormalities during walking and daily activities. Moreover, a mismatch between imaging findings and symptoms, including pain, has been reported repeatedly [4,5]. Together, these limitations suggest that imaging alone may be insufficient for rehabilitation-oriented functional assessment, motivating the exploration of wearable functional biomarkers that reflect gait-related impairment [1].

Gait biomechanics is closely linked to the functional manifestations of knee osteoarthritis [6]. Recent studies have further linked ROA-related functional impairment to altered plantar-pressure behavior, gastrocnemius muscle-tendon-unit stiffness, and 3D gait biomechanics [7,8]. Plantar pressure is particularly informative because it reflects both load distribution and gait control, providing interpretable measures such as pressure distribution, peak pressure, and center-of-pressure progression. Wearable insole systems are especially attractive due to their portability and ease of deployment, enabling data collection in both clinical and daily-life settings [9-12]. Earlier intelligent-footwear research demonstrated daily-life monitoring of spatial and temporal plantar pressure, in-shoe conditions, center-of-pressure trajectories, and acceleration in people with diabetes [12]. Recent digital insole studies further suggest promising potential for detecting ROA-related gait signatures [13].

Current plantar-pressure modeling for knee osteoarthritis largely follows 2 paradigms, each with distinct strengths and limitations. The first relies on handcrafted biomechanical features, which are typically interpretable but often emphasize localized loading characteristics or outcome-level summaries. As a result, they may not adequately capture how plantar regions coordinate and covary over time during gait. The second applies end-to-end deep learning directly to pressure sequences, which is more flexible for temporal pattern learning but can be less stable and less interpretable in medical settings with limited sample sizes [14]. However, within plantar-pressure–based ROA identification, an important unresolved challenge is how to represent pressure signals in a way that preserves biomechanical interpretability while also capturing distributed interregional coordination beyond conventional summary descriptors.

Previous plantar-pressure studies have identified ROA-related abnormalities in anatomically meaningful foot regions, including reduced hallux loading, altered heel pressure distribution, and increased mediolateral center-of-pressure excursion [15-18]. However, most studies have relied on summary-level biomechanical descriptors and have not examined how plantar regions coordinate with one another over the gait cycle. On the same 92-participant Pearl River Osteoarthritis Cohort (PROC) cohort, previous work by our group distinguished ROA from non-ROA using handcrafted features at the window level [19] and predicted functional performance at the participant level [20], but neither incorporated interregional coordination structure. Whether coordination-level information captured from the same plantar-pressure signals provides discriminative power beyond conventional biomechanical features therefore remains an open question—one that the growing adoption of wearable-based biomechanical assessment makes increasingly timely [21].

This evidence, across both the broader literature and our own previous work, points to a specific representation gap in plantar-pressure–based ROA classification, that is, existing frameworks either provide interpretable biomechanical anchors or flexible temporal modeling, but none explicitly incorporate interregional coordination structure. In this study, we treat conventional biomechanical descriptors and interregional coordination patterns as 2 complementary components of plantar-pressure representation. Accordingly, in this secondary methodological analysis of a previously reported plantar-pressure cohort, we aimed to determine whether multiscale plantar coordination information, quantified by the Plantar Synergy Index (PSI), provides participant-level discriminatory information beyond conventional biomechanical descriptors for ROA identification. We hypothesized that combining PSI with biomechanical descriptors would improve threshold-dependent classification performance while preserving interpretability under a strict participant-wise, leakage-controlled evaluation protocol. To test this hypothesis, we developed an interpretable framework and evaluated it using a locked independent test set, feature-stability analyses, phase-resolved PSI visualization, robustness analyses, and comparisons with representative end-to-end temporal baselines.

Methods

Study Design, Data Source, and Participants

Study Design and Data Source

This study was a secondary cross-sectional analysis of a plantar-pressure dataset previously reported in related studies [19,20]. The analytic dataset was derived from the PROC and included 92 participants, comprising 43 participants with ROA and 49 participants with non-ROA. ROA was defined according to the original radiographic criterion used in the source study, namely modified K-L grade ≥2.

The source cohort was recruited from the PROC study at Zhujiang Hospital of Southern Medical University, Guangzhou, China, between January 2022 and February 2023. Participants in the source PROC cohort were recruited from osteoarthritis

XSL•FO
RenderX

outpatient clinics and nearby communities; therefore, the recruitment procedure is best characterized as nonprobability clinical or community-based recruitment rather than random population sampling. No new participant recruitment or additional plantar-pressure data collection was conducted for the secondary analysis of this study. This study used the available bilateral in-shoe plantar-pressure recordings and ROA status for participant-level ROA identification.

A participant-wise stratified split was used for model development and final evaluation, allocating 72 participants to the development set and 20 participants to the locked independent test set. The *Journal Article Reporting Standards* (JARS) participant flowchart documenting cohort flow, data completeness, and the development or test split is provided in Figure S1 in Multimedia Appendix 1.

Eligibility and Participant Characteristics

The original source cohort involved adults with knee osteoarthritis who were able to walk independently, as described in the related cohort report [20]. For the analysis of this study, inclusion required available bilateral wearable in-shoe plantar-pressure recordings, available ROA or non-ROA status, and complete demographic and anthropometric variables, including age, height, weight, and BMI.

All 92 participants in the available source dataset met these analytic inclusion requirements. Baseline demographic and anthropometric characteristics stratified by ROA status are reported in Table S1 in Multimedia Appendix 1. The ROA group was older than the non-ROA group (mean 66.6, SD 7.5 y vs mean 59.8, SD 7.9 y; Cohen d=−0.885; Mann-Whitney P<.001) and had higher BMI (mean 25.4, SD 3.6 kg/m^2 vs mean 23.7, SD 3.1 kg/m^2; Cohen d=−0.504; Welch t test P=.02). Height and weight did not differ significantly between groups. Individual-level sex distribution and K-L grade were not available in the dataset of this analysis and are therefore reported descriptively based on the available source information rather than used as adjustment covariates.

Measures and Covariates

The primary outcome was binary ROA status, defined as modified K-L grade ≥2 for the classification task of this study. The primary predictors were participant-level plantar-pressure descriptors derived from conventional biomechanical features, PSI-derived plantar coordination features, or their fusion. Detailed preprocessing, windowing, PSI construction, biomechanical feature definitions, and participant-level aggregation procedures are described in the subsections under the Methods section and Multimedia Appendices 2-4. Available demographic and anthropometric covariates included age, height, weight, and BMI.

Sample Size, Power, Precision, and Missing Data

The analytic sample size was determined by the available PROC source dataset rather than by a new prospective sample-size calculation. The final analytic sample included all 92 available participants. Given the modest sample size, especially the 20-participant locked independent test set, we emphasized estimation precision rather than relying on point estimates alone. CIs and paired area under the receiver operating characteristic curve (AUROC) comparisons were used to support precision-aware interpretation, as described in the Statistical Analysis subsection.

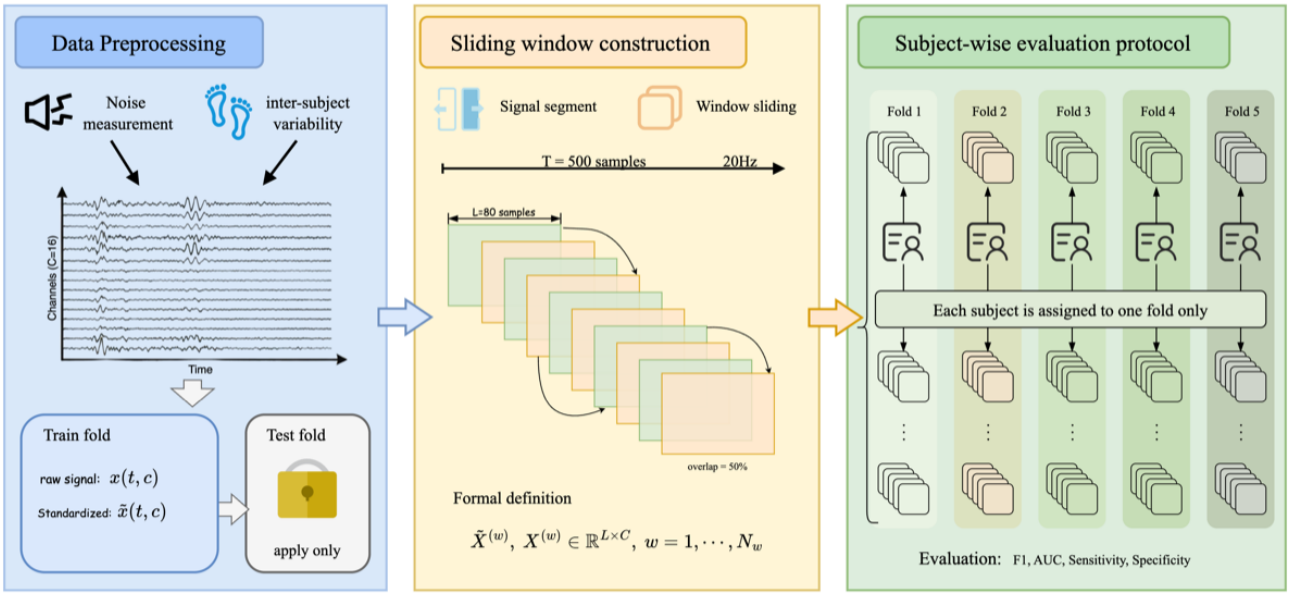
No data were missing; all 92 participants completed the full bilateral plantar-pressure acquisition, and no pressure windows were missing. The 4 demographic and anthropometric variables used in this analysis, namely age, height, weight, and BMI, were complete for all participants.

Overlap Statement With Previous Cohort Studies

This study uses the same 92-participant PROC plantar-pressure dataset previously used in related studies by our group [19,20]. It overlaps with those studies in participant cohort, wearable in-shoe pressure-sensing system, bilateral raw plantar-pressure recordings, and available clinical or radiographic source information. There is also partial authorship overlap with the previous cohort publications.

However, this study differs in analytical objective, feature representation, outcome modeling, and evaluation protocol. Previous work focused on conventional biomechanical descriptors for window-level ROA classification [19] or participant-level functional-performance prediction [20]. In contrast, this study evaluates whether multiscale PSI-derived plantar coordination descriptors provide complementary participant-level information when combined with conventional biomechanical descriptors under a strict participant-wise, leakage-controlled classification protocol. A structured comparison with previous plantar-pressure and gait-based studies is provided in Multimedia Appendix 5.

Accordingly, the contribution of this manuscript is methodological and representational. No new cohort, device, deployment setting, or longitudinal validation is claimed.



Plantar-Pressure Acquisition and Preprocessing

Plantar-pressure data were collected using a bilateral in-shoe wearable system, with 1 insole per foot. Each insole contained 8 discrete pressure sensors, yielding 16 channels sampled at 20 Hz. The detailed 16-channel sensor-to-anatomy mapping and region definitions are provided in Multimedia Appendix 2.

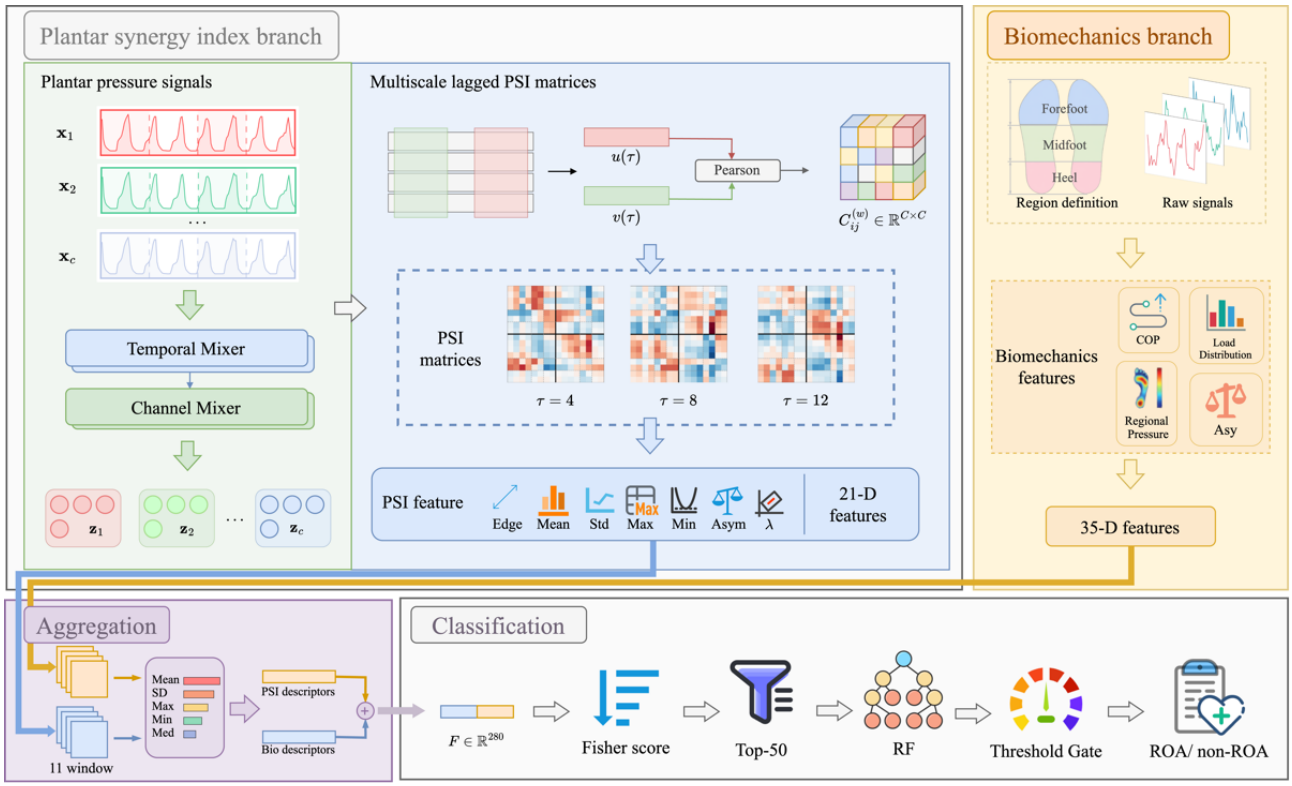
Figure 1 illustrates the leakage-controlled preprocessing and evaluation pipeline used in this study. The full workflow consisted of following 3 steps: participant-wise data splitting, construction of parallel signal representations, and sliding-window construction. All windows from the same participant were assigned to the same subset throughout, preventing repeated-participant leakage across model development and final testing and reducing optimistic bias in performance estimation [22,23]. We first performed a participant-level stratified split, yielding an independent test set of 20 participants (11 non-ROA and 9 ROA) and a development set of 72 participants. All subsequent model-development procedures were confined to the development set.

XSL•FO
RenderX

Figure 1. Leakage-controlled data preprocessing pipeline. All windows from the same participant were kept within a single subset throughout the workflow. Representation construction, preprocessing, and model development were performed without using information from the independent test set.

For each participant, a fixed-length steady-walking segment of 500 samples was retained from the original plantar-pressure recording. From this same segment, 2 signal representations were constructed for subsequent analyses—the raw plantar-pressure signal in its original scale, and a participant-wise channel-wise standardized representation. Let μc and σc denote the mean and SD of channel c computed from that participant's steady-walking signal. We first standardize each channel within a participant:

(1)x~(t,c)=x(t,c)−μcσc+



where =10-6 ensured numerical stability. The same representation-construction procedure was applied to both the development and independent test sets. After representation construction, the retained steady-walking segment was segmented into overlapping windows to capture short-term dynamics. We set the window length to L=80 samples (4 s at 20 Hz) and the stride to s=40 samples (2 s), yielding 50% overlap. This duration was chosen to span approximately 3 - 4 complete gait cycles at typical walking cadences (1.0 - 1.2 Hz), balancing within-window stability for PSI estimation against temporal resolution. This procedure produced Nw=11 windows per participant, so that all participants contributed the same number of window-level samples. Each window was denoted as X(w)∈ RL×C for w=1,…,Nw.

Window-Level Feature Extraction

We extracted 2 complementary window-level feature sets from the windowed plantar-pressure signals (ie, conventional biomechanical features and PSI-based coordination features; Figure 2). In the PSI branch, we aimed to capture distributed coordination patterns across plantar regions that may not be adequately characterized by conventional biomechanical descriptors alone. The PSI-related analyses were based on the participant-wise standardized representation. Estimating PSI directly from the window X~(w) can be sensitive to sensor noise, gait-phase misalignment, and interparticipant amplitude variation, particularly in small cohorts. To improve robustness while preserving a lightweight formulation, we introduced a mixer-style representation transform inspired by the token-channel mixing strategy of multilayer perceptron (MLP)-mixer and its time-series adaptations [24,25].

XSL•FO
RenderX

Figure 2. Two-branch plantar-pressure representation framework for subject-level ROA (radiographic knee osteoarthritis) identification. The biomechanics branch operates on raw pressure windows, whereas the PSI (Plantar Synergy Index) branch operates on the subject-wise standardized representation. Window-level features from both branches are aggregated to subject level for feature selection and final classification.

Within each development split, this transform was pretrained using only non-ROA windows from the corresponding training subset in a self-supervised one-step-ahead prediction task, consistent with predictive representation learning for sequential data [26,27]. The resulting module alternates temporal and channel mixing to produce a stable intermediate representation before PSI construction. Specifically, the transformed signal was defined as:

(2)Z(w)=M2 (M1 (X~(w))), Z(w)∈ RL×C

where M1 and M2 implement temporal mixing and channel mixing, respectively, using lightweight MLPs shared across channels and time steps to control complexity. PSI matrices were then constructed for each window over a multiscale lag set T = {4, 8, 12}, chosen to span short-to-long coordination offsets under the current sampling rate. The sensitivity of this design choice was further examined in the design-variation analyses. Each PSI matrix was defined from lag-aligned interregional correlation, motivated by the lead-lag structure commonly observed in plantar-pressure signals [28,29]. For window w, let $z_i^{(w)(t)}$ denote channel i at time t in $Z^{(w)}$. For any τ ∈ T, we formed a lead-lag aligned signal pair:

(3)ui(w)(τ)=[zi(w)(1+τ),...,zi(w)(L)],vj(w)(τ)=[zj(w)(1),...,zj(w)(L−τ)]

and defined the PSI matrix C(w)(τ)∈ RC×C as

(4)Cij(w)(τ)=corr(ui(w)(τ),vj(w)(τ)),τ∈ T

where corr(·,·) is Pearson correlation over length L-τ.

From each PSI matrix C(w)(τ), we extracted a compact set of PSI-derived summary features to characterize global coupling structure at each lag scale. These features capture complementary aspects of PSI structure, including edge density, distributional summaries (mean, SD, maximum, minimum), lagged asymmetry, and dominant spectral organization. The full definitions, mathematical formulations, and naming rules for PSI are provided in Multimedia Appendix 3. Thus, PSI features from all 3 lag scales were included in the candidate representation space before downstream feature selection.

Meanwhile, the biomechanics branch computed conventional plantar-pressure features directly from the raw pressure window X(w), providing interpretable anchors such as overall statistics, center-of-pressure (CoP), load ratios, and asymmetry indices. The complete feature list (35 features), channel mappings, region definitions, and formulas are provided in the Multimedia Appendix 2. This branch outputs window-level biomechanics feature vector fBio(w)∈ R35. For each window, the PSI and biomechanics features were concatenated to form the window-level feature vector f(w)=[fPSI(w);fBio(w)].

Participant-Level Modeling

To obtain 1 risk score per participant, we aggregated window-level features into a participant-level representation using fixed summary statistics. For a scalar window feature sequence {uk(w)}w=1Nw, we computed 5 statistics (mean, SD, maximum, minimum, and median) and stacked them as

(5)Ak,m=Statm({uk(w)}w=1Nw),m=1,…,5

Applying this aggregation to PSI features fPSI(w)∈ R21 and biomechanics features fBio(w)∈ R35 yielded F∈ R105 and G∈ R175, respectively, and the final participant-level feature vector was x=[F;G]∈ R280.

XSL•FO
RenderX

Given the limited cohort size relative to the 280-dimensional representation, the resulting feature space was prone to redundancy and overfitting. We therefore used Fisher score ranking as a simple filter-based selection step to retain the most discriminative participant-level features. For feature i, the score was defined as

(6)Fscore(i)=(μi,1−μi)2+(μi,0−μi)2(σi,1)2+(σi,0)2+

Here, μi,c and σi,c denote the class-specific mean and standard deviation for class c∈ {0,1}, μi denotes the pooled mean, and =10-6 is a small constant for numerical stability. The Fisher score quantifies between-class separability relative to within-class variance. The top-50 setting was fixed before locked independent test-set evaluation according to the development protocol. The top-k sensitivity analysis reported below was conducted to examine whether this feature count lay within a stable performance range, rather than to select the final feature count using the locked test set.

Leakage-Controlled Model Development and Evaluation

The downstream classifier was a random forest (RF), chosen for its robustness in small-sample settings and its ability to capture nonlinear feature interactions [30]. To avoid information leakage in threshold selection, the operating threshold was determined within the development set by participant-level 5-fold cross-validation. In each fold, all model-development steps, including Fisher score ranking, top-50 retention, and RF fitting, were performed using only the fold-specific training partition. Each validation participant contributed 1 aggregated participant-level feature vector and 1 corresponding RF probability as an out-of-fold estimate, ensuring that the probability used for threshold selection was generated without using that participant in representation learning, feature selection, or classifier fitting. The final threshold was selected from these pooled out-of-fold predictions to maximize the score.

After this internal development step, Fisher score ranking was reapplied once to the full development set to construct the final top-50 panel, and the RF classifier was refit on all 72 development participants using the locked feature panel and locked operating threshold before 1-time evaluation on the independent test set. Thus, cross-validation was used for internal model development rather than for reporting averaged final performance, whereas the independent test set was reserved for a single locked evaluation. Further implementation details are provided in Multimedia Appendix 4.

We additionally benchmarked the proposed fusion model against 3 representative end-to-end temporal baselines to examine how it compares with alternative modeling paradigms under the same fixed-length input, development or test split, and participant-level evaluation protocol. InceptionTime was included as a strong convolutional baseline for time-series classification [31], Medformer as a Transformer baseline whose multigranularity patching design is well-suited to medical time-series classification [32], and TodyNet as a graph-based baseline that directly models multivariate temporal dynamics through dynamic graph construction and temporal graph learning [33]. For fairness, each baseline was trained with its own tuned model-specific hyperparameter configuration, while the shared data handling and evaluation setup are summarized in Multimedia Appendix 4.

Statistical Analysis

All evaluations were performed at the participant level, with 1 ROA risk score and 1 binary decision assigned to each participant. We used the F_1-score as the primary metric:

(7)F1=2·Precision·RecallPrecision+Recall

In addition to F1, we reported AUROC, sensitivity, specificity, and precision to provide a more comprehensive characterization of discrimination performance. Given the limited test-set size (n=20), point estimates alone could overstate differences between models. We therefore computed 2000-iteration bootstrap 95% CIs for all metrics, and supplemented the bootstrap analysis with paired DeLong tests to evaluate whether observed AUROC differences were statistically distinguishable from chance. To assess whether the primary model performance could be explained primarily by available demographic and anthropometric variables, we conducted a supplementary model-level covariate sensitivity analysis. First, we trained a demographics-only RF model using age, height, weight, and BMI under the same participant-wise evaluation protocol. Second, we added these variables to the Fusion feature set before Fisher-score selection and RF classification. The complete covariate sensitivity analysis protocol is detailed in Multimedia Appendix 6.

To better understand which participant-level descriptors contributed consistently under resampling, we examined feature-selection stability across the 5 development folds. Within each fold, Fisher score ranking was applied to the training partition using the same feature-selection procedure as in the main pipeline. For each candidate feature, we summarized the number of folds in which it was retained and its mean within-fold Fisher score. For interpretation, retained features were further grouped by descriptor family, lag scale, and anatomical sensor region according to the insole topology.

To characterize robustness, we evaluated the fusion, bio-only, and PSI-only models under the following 3 perturbation categories: temporal scaling, random channel dropout, and additive Gaussian noise. Temporal scaling was tested at 0.8×, 1.0×, and 1.2× relative to the native sampling rate. Random channel dropout was evaluated at masking rates (0.0, 0.1, 0.2, and 0.3), and additive Gaussian noise was evaluated at σ=0.00, 0.01, 0.03, and 0.05 applied to the standardized signal. Design sensitivity was further examined by varying the sparsity threshold in PSI matrix construction, the lag configuration (single-scale vs multiscale), and the window length using 3 s, 4 s, and 5 s windows with 50% overlap. Phase-resolved PSI patterns were visualized by aligning trajectories to the normalized stance phase using 5% bins and pooling them at the group level within each functional module and lag setting. These perturbation and design-sensitivity analyses were used to assess the stability of the selected configuration and were not used to reselect the feature count, window length, lag configuration, sparsity threshold, classifier, or operating threshold.

Ethical Considerations

The study was approved by the Institutional Review Board (IRB) of Zhujiang Hospital, Southern Medical University, Guangzhou (IRB 2019-KY-016 - 02). All participants were enrolled from the PROC study and provided written informed consent before data collection; the original consent permitted secondary analysis of deidentified data without additional consent. Participants received financial compensation of approximately US $30 per participant. No identifiable images of individual participants appear in this manuscript or its supplementary materials.

Results

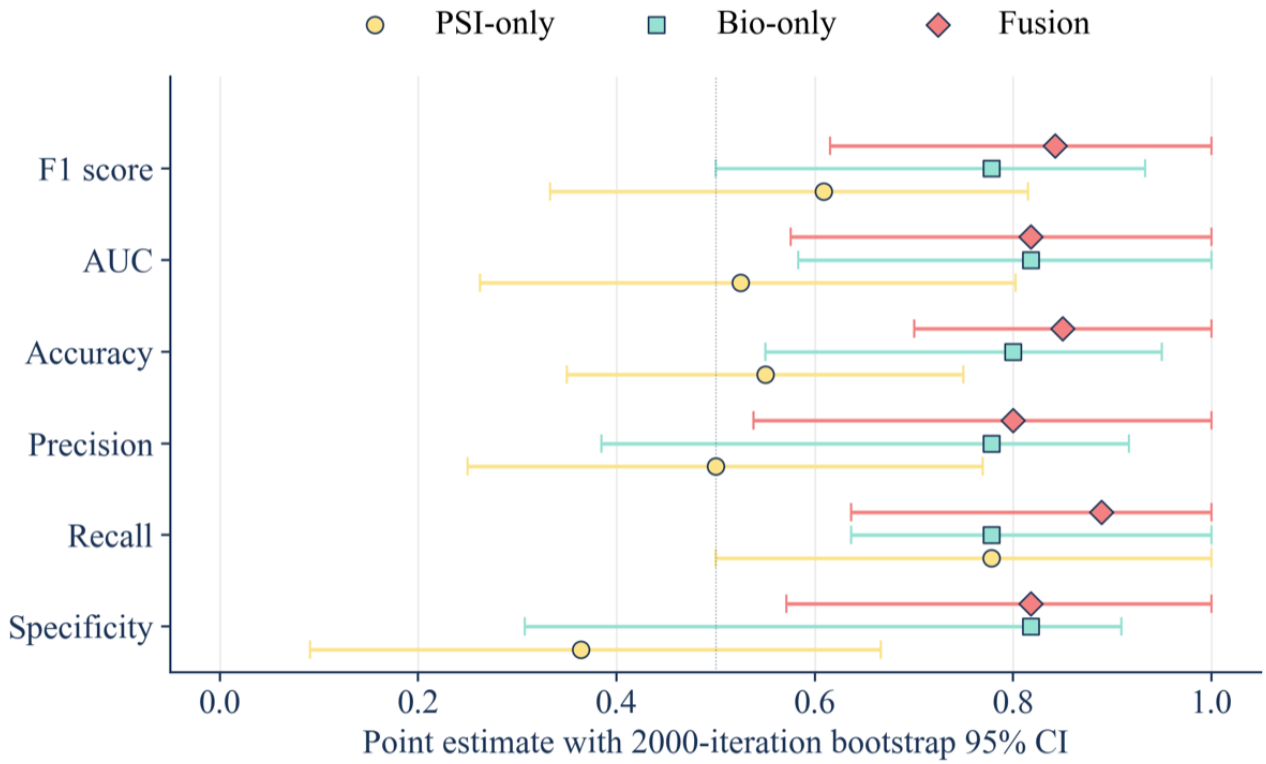
Primary Classification Performance

We first compared PSI-only, bio-only, and fusion models under the leakage-controlled development or test protocol. As summarized in Table 1, PSI-only showed limited standalone classification performance, with a low F_1-score, AUROC, accuracy, and precision despite relatively high recall. Bio-only provided a strong baseline with substantially improved discrimination and a balanced sensitivity-specificity profile. Fusion showed numerically higher F_1-scores (0.842 vs 0.778), accuracy (0.850 vs 0.800), precision (0.800 vs 0.778), and recall (0.889 vs 0.778) than bio-only, while AUROC and specificity were identical between the 2 models.

Table . Participant-level classification performance on the independent test set for PSI[a]-only, bio-only, and fusion models.

Metric	PSI-only	Bio-only	Fusion
F_1-score	0.609	0.778	0.842
AUROC[b]	0.525	0.818	0.818
Accuracy	0.550	0.800	0.850
Precision	0.500	0.778	0.800
Recall	0.778	0.778	0.889
Specificity	0.364	0.818	0.818

[a]PSI: Plantar Synergy Index.



[b]AUROC: area under the receiver operating characteristic curve.

Bootstrap 95% CIs for all metrics are shown in Figure 3. The intervals were wide and overlapping across branches; for instance, the F_1-score spanned 0.500 - 0.948 for bio-only and 0.615 - 1.000 for fusion. Paired DeLong tests showed that both fusion and bio-only outperformed PSI-only at the AUROC level (P=.02 and P=.04, respectively), whereas fusion did not differ from bio-only in AUROC (P>.99). Together, these results suggest that PSI alone is insufficient as a standalone classifier, while fusion showed a directionally favorable threshold-dependent profile relative to bio-only. Given the wide and overlapping CIs, this pattern should be interpreted cautiously as preliminary evidence that PSI may complement biomechanical descriptors rather than as definitive superiority over bio-only. The complete bootstrap confidence intervals and paired DeLong comparisons are provided in Multimedia Appendix 7.

The covariate sensitivity analysis is summarized in Multimedia Appendix 6. The demographics-only RF model performed substantially worse than the fusion model, indicating that age, height, weight, and BMI alone could not reproduce the primary plantar-pressure–based classification performance. Adding these demographic and anthropometric variables to the fusion feature set did not materially improve the F_1-score, AUROC, or specificity. Within the augmented feature space, age and BMI were retained by Fisher score ranking, whereas height and weight were not retained. These findings suggest that the fusion model was not simply a demographic proxy, although residual confounding cannot be excluded.

Figure 3. Bootstrap 95% CIs for six metrics across PSI (Plantar Synergy Index)-only, Bio-only, and Fusion (2000 iterations, n=20). Point estimates and CIs are shown for each branch–metric combination; wide and overlapping intervals reflect the limited test-set size. These intervals support cautious interpretation of between-branch differences, particularly for Fusion versus Bio-only. AUC: area under the curve.

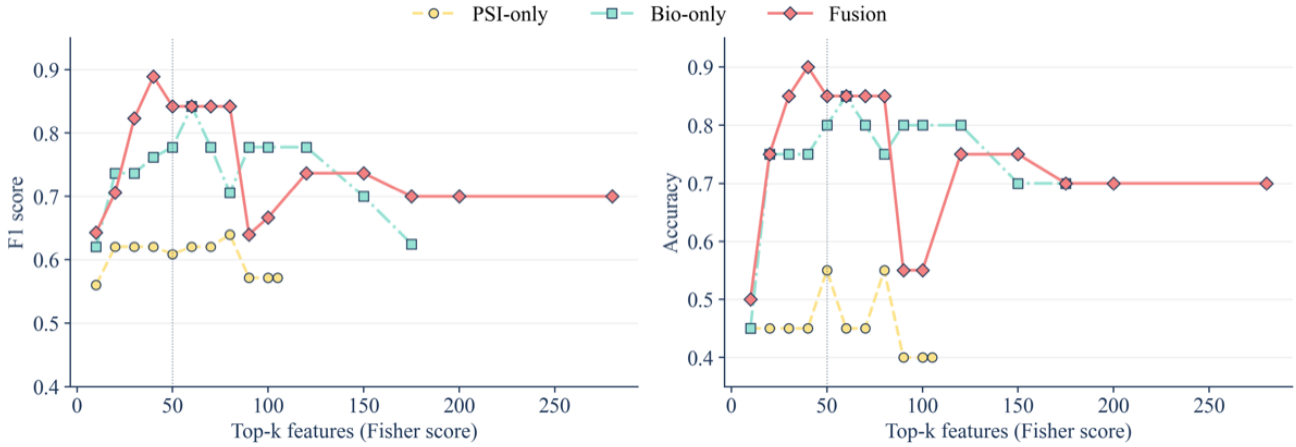
Cross-Fold Feature-Selection Stability and Representative Stable Descriptors

To examine whether the locked top-50 feature-retention setting lay within a stable performance range, we conducted a top-k scan across 15 values; results are illustrated in Figure 4. Fusion performance at k=50 (F_1-score=0.842) lay within a high-performance plateau, with similarly strong F_1-score and accuracy at neighboring k values. At smaller k values, performance was limited by an insufficient number of retained features, whereas larger panels around k>=90 - 100 showed degraded classification performance, with F_1-score dropping to 0.667 at k=100. These results suggest that k=50 was located within a relatively stable operating range rather than representing an isolated favorable point. However, this analysis was used to assess the robustness of the selected configuration and was not used for final feature-count tuning.

To evaluate whether the descriptors selected during the 5-fold development procedure were reproducible under sample variation, we analyzed feature-selection stability across the 5 development folds. In each fold, Fisher score ranking was applied to the fold-specific training partition using the same selection procedure as in the main pipeline, and the top 50 descriptors were retained. Each descriptor was then summarized by its cross-fold selection rate and mean within-fold Fisher score, and descriptors retained in at least 3 of 5 folds were regarded as stable. This cross-fold view was used for interpretation because, in the present small-sample setting, the single top-50 panel obtained from the full development set may be sensitive to sample composition, whereas repeatedly retained descriptors are more likely to reflect reproducible discriminative structure [34-36].

XSL•FO
RenderX

Figure 4. Top-k sensitivity scan for Fisher-score feature retention. Left: F_1-score across retained feature counts (k ∈ {10, ., 280}). Right: Accuracy across retained feature counts. PSI (Plantar Synergy Index)-only, Bio-only, and Fusion are shown in each panel. The analysis evaluates whether the prespecified Top-50 configuration lies within a stable performance range, rather than serving as final model tuning.



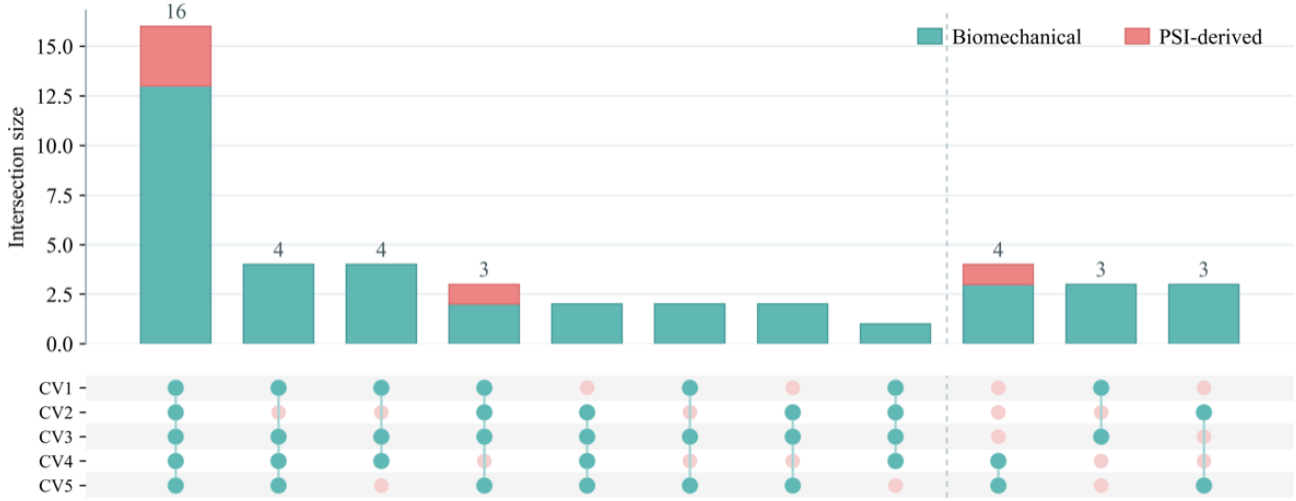


Figure 5 summarizes the cross-fold overlap structure of selected descriptors across the 5 development folds. A substantial shared overlap, together with several additional higher-overlap intersections, indicates that the retained descriptor set was not purely fold-specific but contained a reproducible core. Importantly, the higher-overlap intersections were dominated by biomechanical descriptors, supporting conventional biomechanics as the primary anchor of the stable feature set. PSI-derived descriptors appeared less frequently and in smaller numbers, but they were still recurrent across multiple higher-overlap intersections, indicating a complementary yet reproducible coordination-level contribution. Lower-overlap intersections were also present, suggesting some sensitivity of the selected panel to sample composition, although these intersections were generally smaller and more heterogeneous. Importantly, these stable descriptors were used for interpretation rather than as a fixed final feature panel. For final model construction, Fisher score ranking was reapplied once to the full development set, and the locked top-50 panel was selected from all candidate descriptors using all 72 development participants.

To further illustrate the main discriminative signals within this reproducible subset, Table 2 highlights representative descriptors that were both relatively stable across folds and highly ranked by Fisher score.

The representative examples make the reproducible structure more concrete and highlight two complementary, clinically meaningful patterns. First, the biomechanical examples are concentrated in interpretable domains, such as asymmetry, CoP, and gait timing, reinforcing conventional biomechanics as the primary anchor of the stable signal. This pattern is consistent with previous evidence that knee osteoarthritis is associated with abnormal plantar-pressure distribution, altered load redistribution, and CoP-related gait changes [6,16-18]. Second, PSI-derived descriptors were also retained among the stable high-ranking features, indicating that coordination-level information was recurrently represented alongside conventional biomechanical descriptors. Taken together, these representative descriptors indicate that ROA-related discrimination in the present cohort was anchored in clinically interpretable abnormalities of plantar loading, load redistribution, and whole-foot progression.

Figure 5. Cross-fold overlap structure of selected descriptors across the 5 development folds. Each column shows one descriptor-overlap pattern across the 5 development folds. Bar height indicates the overlap size, and stacked colors indicate the numbers of biomechanical and PSI (Plantar Synergy Index)-derived descriptors. For clarity, only a subset of lower-overlap patterns (<3 folds) is displayed. Stable retained descriptors were mainly biomechanical, with a smaller recurrent PSI-derived component.

XSL•FO

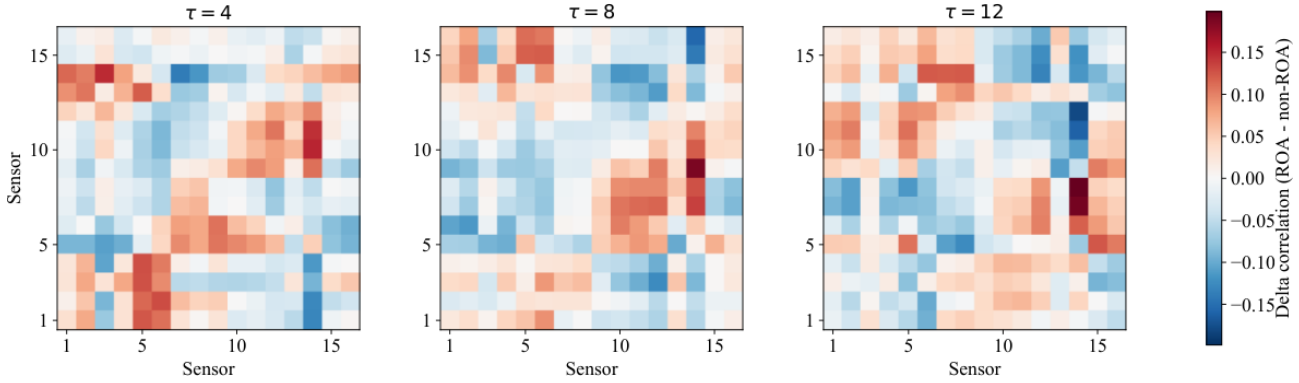
PSI-Edge-L-Min	0.6	3.11 (0.60)



[a]PSI: Plantar Synergy Index.

Phase-Resolved PSI Patterns Across Lag Scales and Functional Modules

To further interpret the coordination-level information captured by PSI, we examined whether ROA-related PSI differences showed coherent organization across lag scales, stance phase, and functional plantar modules. Because PSI was designed to characterize interregional temporal coupling rather than local pressure magnitude, the analysis was structured as a progressive visualization from sensor-pair spatial organization to phase-resolved stance dynamics, and finally to module-level difference trajectories. This design allowed us to assess whether PSI captured a distributed coordination pattern associated with ROA rather than isolated or nonspecific correlation differences.

We first visualized sensor-pair delta-correlation matrices, defined as ROA minus non-ROA, at representative lag settings. As illustrated in Figure 6, the delta-correlation matrices revealed spatially distributed group differences across multiple sensor pairs, rather than a focal abnormality confined to a single plantar region. The pattern also varied across lag settings, indicating that ROA-related PSI alterations depended on the temporal offset used to characterize interregional coupling. At shorter lags, the observed differences may reflect altered near-synchronous load sharing among plantar regions, whereas longer lags may capture delayed coordination related to forward load transfer and bilateral stance progression. These findings suggest that PSI differences were not merely a consequence of local pressure magnitude changes, but reflected lag-dependent reorganization of plantar coordination.

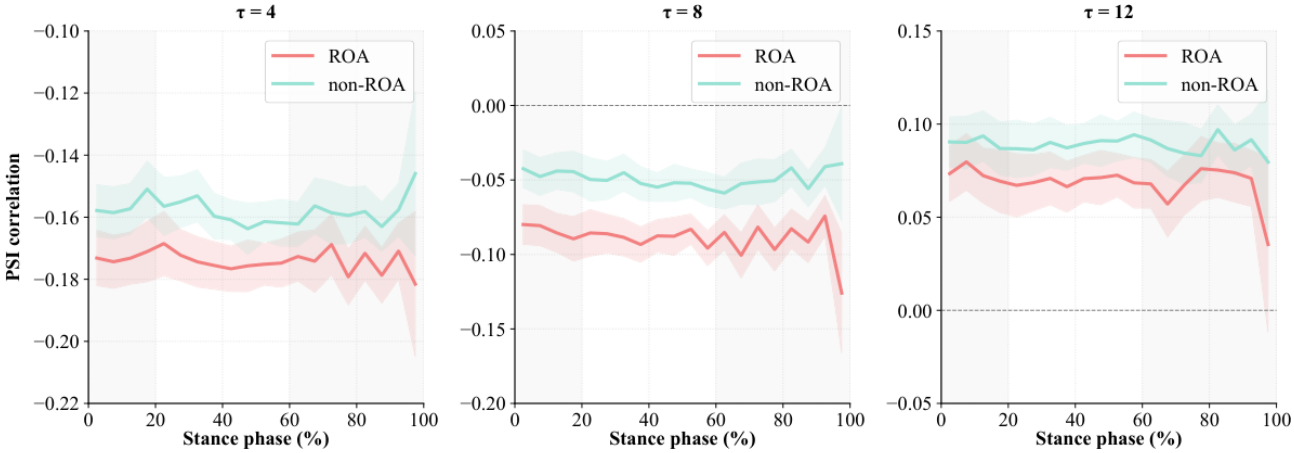
Figure 6. Sensor-pair delta-correlation heatmaps across representative lag settings. Heatmaps show the difference in lag-aligned sensor-pair correlation between ROA (radiographic knee osteoarthritis) and non-ROA groups (ROA minus non-ROA) at τ=4,8and12. Sensors 1 - 8 and 9 - 16 correspond to homologous plantar regions on the left and right feet, respectively. PSI (Plantar Synergy Index) differences were distributed across sensor pairs and varied by lag, rather than being confined to a single sensor region.

The spatially distributed and lag-dependent delta-correlation patterns in Figure 6 suggested that ROA-related PSI differences were linked to the temporal organization of plantar coordination during walking. However, the heatmap representation does not indicate when during stance these coordination differences emerged. We therefore further aligned PSI trajectories to the normalized stance phase (0% - 100%) to examine the temporal expression of the observed lag-dependent coordination changes. As illustrated in Figure 7, group-level PSI trajectories differed between ROA and non-ROA across all examined lag settings. Across broad portions of stance, the ROA curves remained lower than the non-ROA curves, suggesting reduced or less coherent interregional plantar coordination in the ROA group. From a gait-phase perspective, this reduction was not limited to initial contact or early loading, but extended across mid-stance and late stance, where controlled CoP progression, forward load transfer, and preparation for push-off become increasingly important. The magnitude and temporal expression of this separation varied with lag scale; shorter lags emphasized more immediate interregional coupling, whereas longer lags showed

XSL•FO
RenderX

greater fluctuation near late stance and push-off. These lag-dependent patterns suggest that the proposed PSI may capture ROA-related compensatory changes in plantar load redistribution, particularly during forward load transfer and propulsion, when coordinated forefoot and heel-to-midfoot interactions become biomechanically important.

Figure 7. Phase-resolved PSI (Plantar Synergy Index) patterns for ROA (radiographic knee osteoarthritis) and non-ROA groups across lag scales. Stance phase was normalized to 0% - 100% and summarized in 5% bins. Curves represent group-level PSI summaries pooled across modules within each phase bin; shaded bands indicate 95% CIs. PSI differences emerged primarily in mid-to-late stance, consistent with altered load redistribution and propulsion-phase coordination in ROA.



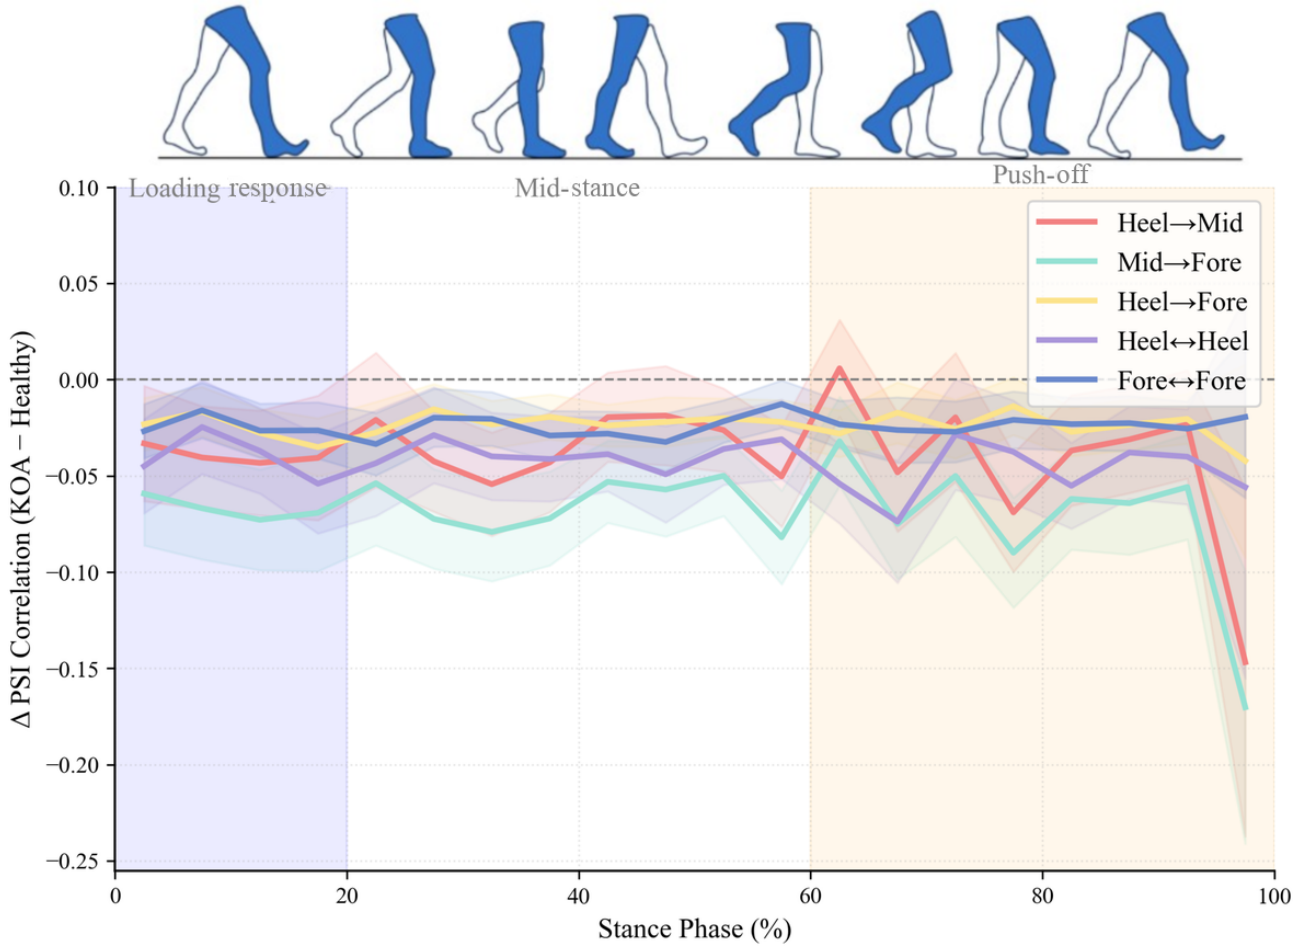


Figure 8 further shows phase-resolved PSI difference trajectories at a representative lag (τ=0.4s), where the vertical axis represents ΔPSI=PSIROA-PSInon-ROA. Across most of stance, the major module-level trajectories remained below zero, indicating that PSI was generally lower in ROA than in non-ROA for these interregion couplings. The persistence of negative differences across broad stance intervals suggests that ROA-related coordination changes were not restricted to a single gait event, but were expressed throughout stance-phase load transfer. This group difference persisted across broad portions of stance and was especially evident in forefoot-related and heel-to-mid couplings, while larger fluctuations near late stance and push-off suggested greater between-participant heterogeneity when forward load transfer and propulsion became dominant [6,16,17].

XSL•FO
RenderX

Figure 8. Phase-resolved PSI (Plantar Synergy Index) difference trajectories at the representative lag τ=0.4 s. Curves show ΔPSI=PSIROA-PSInon-ROA for different inter-region functional modules across the normalized stance phase. Shaded background regions indicate major stance sub-phases. Cross-module PSI differences persisted across multiple stance-phase bins, indicating distributed inter-regional coupling changes rather than isolated within-module effects. ROA: radiographic knee osteoarthritis.

Taken together, Figures 6-8 indicate a coherent progression of PSI evidence: ROA-related differences were spatially distributed across sensor pairs, temporally expressed across the normalized stance phase, and functionally organized across interregion plantar modules. Importantly, these phase-resolved analyses were intended to characterize the organization of PSI differences, rather than to imply that all stance bins, lag scales, or modules contributed equally to the final classifier. The final retained descriptors were still determined by the participant-level feature-selection procedure.

Robustness to Perturbation and Design Variation

We further examined whether PSI-related information remained useful under perturbation and design variation. Across temporal scaling, channel dropout, and Gaussian noise, fusion generally maintained the highest or among the highest participant-level F_1-scores among the 3 models (Table 3). Performance was strongest at the native and mildly stretched temporal scales (1.0× and 1.2×, both F_1-score=0.842), with only a modest reduction under compression (F_1-score=0.824 at 0.8×). Under channel dropout and Gaussian noise, fusion also maintained a generally favorable profile relative to both PSI-only and bio-only models. These perturbation analyses suggest preliminary robustness of the combined representation under moderate signal variation, although the small locked test set limits strong comparative claims.

XSL•FO
RenderX

Table . Robustness of PSI-only, bio-only, and fusion models under temporal and signal perturbations. Reported values are subject-level F_1-scores on the independent test set.

Setting and level	PSI[a]-only	Bio-only	Fusion
Temporal scaling			
0.8×	0.593	0.778	0.824
1.0×	0.609	0.778	0.842
1.2×	0.571	0.824	0.842
Channel dropout			
0.0	0.609	0.778	0.842
0.1	0.588	0.762	0.824
0.2	0.615	0.727	0.818
0.3	0.571	0.692	0.762
Gaussian noise			
0.00	0.609	0.778	0.842
0.01	0.600	0.778	0.824
0.03	0.571	0.727	0.800
0.05	0.556	0.667	0.818

[a]PSI: Plantar Synergy Index.

As shown in Table 4, across design variations, fusion showed F_1-scores values within a relatively narrow range over sparsity thresholds (F_1-score=0.824 - 0.842) and lag settings (F_1-score=0.818 - 0.842), while showing greater sensitivity to window length (F_1-score=0.761 - 0.842). The 4-second window (80 samples at 20 Hz, spanning approximately 3 - 4 complete gait cycles at typical walking cadences of 1.0 - 1.2 Hz) showed the numerically highest F_1-score among the examined window lengths. Shorter 3-second windows, covering only 1 - 2 gait cycles, may have yielded less reliable correlation estimates for PSI matrix construction because the reduced sample size per window limited the statistical stability of the lag-aligned Pearson correlations. Conversely, 5-second windows, although providing more samples per correlation estimate, may have smoothed phase-specific coordination changes across stance subphases, reducing the ability to resolve temporally localized PSI differences between ROA and non-ROA groups. The 4-second window therefore appeared to provide a suitable balance between within-window statistical stability for correlation-based PSI estimation and temporal resolution across stance subphases.

Within the lag analysis, the multiscale configuration (T={4, 8, 12}, corresponding to 0.20, 0.40, and 0.60 s at 20 Hz) showed the numerically highest performance among the examined lag settings (F_1-score=0.842), compared with each single-scale alternative. A single lag may not simultaneously capture rapid intrafoot pressure propagation between adjacent sensors and slower cross-region coordination reorganization spanning multiple functional modules. The multiscale design therefore provided a broader candidate coordination space—spanning short-to-intermediate coupling timescales relevant to mid-to-late stance gait dynamics—from which downstream Fisher score selection could retain informative lag-specific descriptors across all 3 scales. This exploratory pattern is consistent with the idea that the multiscale design may capture complementary coupling timescales, but it requires confirmation in larger independent cohorts. Overall, these exploratory perturbation and design-sensitivity analyses suggest that the selected configuration was not uniquely dependent on a single perturbation or design setting. These findings should be interpreted as preliminary robustness checks rather than as independent optimization or validation of the model design.

Benchmarking Against Representative Convolutional Neural Network, Transformer, and Graph-Based Baselines

Table 5 shows that fusion achieved the strongest overall participant-level performance among the evaluated models. Among the baselines, InceptionTime [31] was the strongest competitor and showed a relatively balanced classification profile, but remained below fusion in accuracy, F_1-score, AUROC, precision, and recall, while matching the best specificity. Medformer [32] achieved high recall comparable with fusion, but with lower AUROC, lower precision, and markedly reduced specificity, indicating a more false-positive−prone decision profile. TodyNet [33] showed perfect recall but near-zero specificity, yielding the weakest overall discrimination and suggesting a strong bias toward positive predictions under the present data scale.

Overall, these results suggest that, under the current data scale and evaluation setting, fusion showed a directionally favorable threshold-dependent profile relative to the evaluated end-to-end baselines. Relative to InceptionTime, the strongest baseline, fusion showed numerically higher accuracy, F_1-score, AUROC, precision, and recall while matching specificity, but these differences should be interpreted cautiously given the small locked test set. Medformer preserved high recall but at the cost of lower specificity and lower overall discrimination, whereas TodyNet showed a marked false-positive tendency with poor ranking quality. Together, these comparisons suggest that the proposed representation-based framework remained competitive with representative end-to-end baselines in this proof-of-concept evaluation.

Table . Participant-level comparison between the proposed fusion model and representative end-to-end baselines on the independent test set. All models used the same participant-wise development/test split, fixed-length input, and participant-level evaluation protocol.

Model	Accuracy	F_1-score	AUROC[a]	Precision	Recall	Specificity
InceptionTime	0.800	0.778	0.802	0.778	0.778	0.818
Medformer	0.700	0.727	0.707	0.615	0.889	0.545
TodyNet	0.450	0.621	0.485	0.450	1.000	0.000
Fusion	0.850	0.842	0.818	0.800	0.889	0.818

Discussion

Principal Results

This study addressed a key representation gap in plantar-pressure–based ROA identification by introducing a coordination-aware framework that integrates local biomechanical loading with multiscale interregional temporal information. The combined framework achieved competitive participant-level ROA identification, but it did not show consistent superiority over bio-only across performance metrics. The biomechanics branch made the strongest individual contribution, whereas PSI showed limited standalone discrimination. However, PSI captured complementary coordination patterns that were not represented by conventional biomechanical descriptors, and a reproducible PSI component

XSL•FO
RenderX

was retained within the combined representation. Robustness and design-sensitivity analyses provided preliminary evidence that the findings were not confined to a single evaluated configuration. Accordingly, the principal innovation of this study is representational and methodological rather than cohort- or device-based; it explicitly combines interpretable local loading descriptors with multiscale interregional temporal coordination under a participant-level, leakage-controlled evaluation protocol.

The branch-wise findings help explain the primary source of discrimination. The strong contribution of the biomechanics branch is consistent with previous evidence that ROA-related plantar-pressure abnormalities occur in anatomically meaningful regions, particularly the hallux and heel, and are also reflected in CoP stability and variability [17,18]. This interpretation is further supported by recent studies associating ROA-related functional impairment with altered plantar-pressure behavior, gastrocnemius muscle-tendon-unit stiffness, and 3D gait biomechanics [7,8]. These patterns are biomechanically plausible because structural degeneration, pain-related gait adaptation, and altered neuromuscular control at the knee may be associated with compensatory load redistribution and changes in stance progression [6-8,15-18]. Experimental modulation of tibialis anterior activity has also been shown to alter plantar pressure and gastrocnemius activity during gait, supporting the sensitivity of plantar loading to neuromuscular modulation [37]. The findings of this study therefore reinforce the importance of anatomically grounded loading descriptors for participant-level ROA identification.

The phase-resolved and fold-wise analyses help clarify what PSI may contribute beyond these local loading descriptors. The observed PSI differences were distributed across multiple functional modules and lag settings rather than being confined to isolated local extrema. In addition, a core group of PSI descriptors was repeatedly retained across the development folds, supporting the reproducibility of these selected patterns within the present dataset in accordance with established feature-stability principles [34,35]. Although PSI is not a direct measure of joint kinematics or electromyographic muscle activity, its distributed temporal patterns are compatible with studies reporting altered kinematic synergy, muscle synergy, and muscle-activation patterns in individuals with KOA during walking [38-40]. PSI may therefore provide an interpretable coordination-level description of bilateral load transfer and whole-foot progression. However, feature stability and phase-resolved interpretability do not by themselves establish incremental predictive value beyond the biomechanics branch. Given the limited standalone discrimination of PSI and the absence of consistent superiority of fusion over bio-only, the findings of this study should not be interpreted as definitive evidence of additional predictive or clinical value.

Comparisons with the end-to-end baselines place these findings in a broader modeling context. The evaluated models represented complementary learning paradigms but exhibited different operating profiles: InceptionTime was the strongest and most balanced competitor, Medformer favored sensitivity over specificity, and TodyNet showed lower specificity and a higher false-positive tendency in the present locked test set. The value of the proposed framework therefore lies less in definitive performance superiority over every alternative than in combining competitive participant-level identification with an explicit and interpretable organization of plantar-pressure information before classification. The robustness and design-sensitivity analyses further suggested that the main findings were not entirely dependent on a single analytical configuration, although these analyses remain internal and exploratory. Together with the structured comparison in Multimedia Appendix 5, these results support the positioning of the framework as a representational and methodological contribution rather than a cohort- or device-based advance.

To provide a screening-context interpretation of the locked-test operating characteristics, we translated sensitivity and specificity into positive predictive value and negative predictive value across assumed community ROA prevalence levels in Multimedia Appendix 8 [41]. This supplementary analysis illustrates how disease prevalence could affect the potential rule-in and rule-out value of the framework. It should not, however, be interpreted as evidence of clinical deployment readiness because the underlying operating characteristics were estimated from a small internal test set rather than from a representative prospective screening population.

Limitations

Several limitations should be acknowledged. The sample size was modest, and all participants were drawn from a single previously reported cohort, limiting the precision and external generalizability of the performance estimates. Although the locked test set was separated from model development, it remained part of the same source cohort and therefore represents an internal held-out proof-of-concept evaluation rather than external validation. Contemporary prediction-model guidance emphasizes that independent validation should be adequately powered to estimate performance with sufficient precision [14,42]. The findings of this study should consequently be interpreted as preliminary and require confirmation in larger independent cohorts.

Important clinical and demographic factors, including age, BMI, and affected-side heterogeneity, may influence plantar-pressure patterns [15]. The supplementary covariate sensitivity analysis indicated that the available demographic variables alone did not reproduce the performance of the fusion model and that their inclusion did not materially improve its performance (Multimedia Appendix 6). Nevertheless, this analysis cannot exclude residual confounding or establish the independent and interactive effects of age and BMI in the present modest sample. These questions will require larger, more carefully stratified cohorts with richer clinical covariate information. Furthermore, to our knowledge, no publicly available dataset combined confirmed ROA labels with suitable in-shoe plantar-pressure recordings for direct external validation. Available public resources lacked either ROA annotations or compatible pressure measurements, precluding cross-dataset benchmarking [43,44]. Multicenter efforts to establish open datasets with imaging-grade clinical labels and standardized plantar-pressure recordings would substantially strengthen future evaluation.

XSL•FO
RenderX

This study also focused on binary ROA identification rather than disease-severity stratification or longitudinal progression. PSI depends on sensor layout, signal quality, and preprocessing choices, which may affect the validity and comparability of plantar-pressure measurements [10]; its transferability across devices and clinical settings therefore remains uncertain. Recent Soft Science studies demonstrate advances in biocompatible piezoelectric, gel-based, and electrospun flexible pressure sensors for walking, human-motion, gait, and continuous health monitoring [45-47]. These developments strengthen the technological basis for wearable plantar sensing, but they also underscore the need to verify signal stability, durability, environmental resilience, and cross-platform calibration before clinical translation [45-47]. In addition, the proposed coordination-level interpretation was not directly validated using concurrent joint-kinematic, electromyographic, or other neuromuscular measurements. Future studies should validate the framework prospectively in larger multicenter cohorts, evaluate its robustness across sensor platforms and patient subgroups, examine its association with direct biomechanical and neuromuscular measurements, and extend it toward severity modeling and longitudinal prediction.

Conclusions

This study introduces an interpretable participant-level representation that integrates local biomechanical loading with multiscale interregional temporal coordination, extending plantar-pressure approaches centered primarily on summary descriptors or less interpretable end-to-end models. Complementary evaluations provided convergent evidence of competitive participant-level ROA identification and preliminary robustness across the evaluated settings, while showing that local biomechanical descriptors constituted the main discriminative basis and that PSI offered a reproducible coordination-level component whose incremental predictive value remains to be established. By broadening plantar-pressure analysis from local loading to distributed gait coordination, the framework provides a methodological basis for more interpretable functional characterization of ROA. If prospectively validated in external multicenter cohorts, it could warrant further evaluation as an adjunct to imaging for functional assessment and longitudinal monitoring. Prospective multicenter validation is required before clinical translation.

Acknowledgments

We thank all participants for their valuable contributions. Hongbo Yao and LS are co-corresponding authors.

The authors declare the use of generative AI (GenAI) tools during manuscript preparation and the July 2026 revision. According to the GAIDeT taxonomy (2025), the following tasks were delegated to GenAI tools under full human supervision: literature search and systematization, proofreading and editing, reformatting, quality assessment, identification of limitations, recommendations, and publication support. The GenAI tools used were ChatGPT 5.5 Thinking (OpenAI; accessed July 2026) and DeepSeek V4 Pro (DeepSeek; accessed July 2026).

Specifically, the tools assisted with language editing; condensation and restructuring of manuscript text; refinement of the Abstract, Discussion, and Conclusions; checking reporting consistency and whether claims had adequate citation support; identifying limitations; recommending manuscript revisions; and preparing draft responses to reviewers. The tools were not used to formulate the research questions or hypotheses, design the study, collect or analyze data, generate code, create figures, or independently interpret the results or determine the scientific conclusions.

The authors critically reviewed and revised all AI-assisted outputs and independently verified factual statements, references, calculations, statistical interpretations, and journal requirements. Responsibility for the final manuscript lies entirely with the authors. GenAI tools are not listed as authors and do not bear responsibility for the final outcomes. This declaration was submitted collectively by all authors.

Abstract

Background: Prenatal depression and anxiety have emerged as pressing global public health challenges. In the digital era, excessive smartphone use may exert complex effects on maternal mental health. Prior research has predominantly focused on adolescents, whereas evidence among pregnant women, particularly regarding total weekly use and use during critical circadian windows, such as after waking and before bedtime, remains limited. Furthermore, the mediating role of sleep quality in these associations has yet to be systematically examined.

Objective: This study aimed to investigate the associations of smartphone addiction and time-specific smartphone use with prenatal depression and anxiety, and to assess the mediating role of sleep quality in these associations.

Methods: This cross-sectional observational study enrolled 537 pregnant women. Smartphone use characteristics, sleep quality, and prenatal depression and anxiety were assessed using the Smartphone Addiction Scale-Short Version (SAS-SV), objective total weekly smartphone use recorded by the device, and self-reported duration of smartphone use after waking and duration of bedtime smartphone use; the Pittsburgh Sleep Quality Index (PSQI), the Patient Health Questionnaire-9 (PHQ-9), and the Generalized Anxiety Disorder-7 (GAD-7), respectively. Binary logistic regression was used to estimate associations, restricted cubic spline (RCS) models were used to explore nonlinear patterns, and exploratory mediation analyses were used to examine whether sleep quality statistically accounted for part of the observed associations.

Results: The prevalence of moderate-to-severe prenatal depression and anxiety was 8.8% (47/537) and 5.8% (31/537), respectively. After adjusting for covariates, smartphone addiction was associated with higher odds of depression (odds ratio [OR] 3.461, 95% CI 1.771 - 7.100) and anxiety (OR 7.738, 95% CI 3.064 - 23.172). Duration of smartphone use after waking ≥61 minutes and duration of bedtime smartphone use ≥91 minutes were also associated with higher odds of affective disorders. RCS analyses further revealed distinct nonlinear patterns across different exposure dimensions: duration of smartphone use after waking displayed U-shaped and J-shaped associations with depression and anxiety, respectively, while total weekly use displayed a U-shaped association with anxiety. Exploratory mediation analyses showed that the indirect pathways through sleep quality were statistically significant for the associations of bedtime smartphone use, weekly smartphone use, and smartphone addiction with prenatal depression, with mediation proportions of 44.89% (0.0065/0.0145), 31.30% (0.0056/0.0183), and 31.48% (0.0415/0.1315), respectively. The corresponding proportions in the anxiety models were 35.83% (0.0044/0.0123), 27.05% (0.0039/0.0144), and 22.73% (0.0271/0.1187).

Conclusions: Smartphone addiction and excessive smartphone use after waking and before bedtime were associated with higher odds of prenatal depression and anxiety. Sleep quality may statistically account for part of these associations, but longitudinal studies are needed to establish temporal ordering and causal pathways.

Introduction

Pregnancy represents a critically vulnerable period in a woman's life course, both physiologically and psychologically [1-3]. During this period, women not only endure physiological challenges such as dramatic hormonal fluctuations and early pregnancy symptoms, but also face multiple psychosocial stressors, including shifts in social roles, restructuring of family relationships, and concerns about fetal well-being [4,5]. Although pregnancy is generally regarded as a positive life event, it is frequently accompanied by significant affective disturbances. A systematic review reported that the global average prevalence of prenatal depression is approximately 28.5%, which is substantially higher than that of postpartum depression [6]. In mainland China, a systematic review encompassing 271 studies and 369,477 women found that the average prevalence of prenatal anxiety reached 17.4% [7]. These common prenatal affective disorders, if left unaddressed, can substantially increase the risk of adverse obstetric outcomes, such as preterm birth, low birth weight, and preeclampsia [8,9].

In the digital era, smartphones have become an integral extension of daily life. For pregnant women, smartphones serve as important tools for accessing health information and maintaining social support. Healthy smartphone use can, to some extent, alleviate the sense of isolation and uncertainty brought about by the temporary disruption of social roles [10]. Conversely, the fragmented entertainment offered by smartphones can easily trigger overuse, blurring the self-perceived boundary between functional use and pathological dependence [11]. Against this backdrop, the positive mental health effects of smartphone use may be reversed, turning it into a potential risk factor that jeopardizes maternal prenatal mental health [12].

Smartphone addiction, also referred to as problematic smartphone use, is defined as excessive dependence on smartphones, characterized by core features of behavioral addiction such as withdrawal anxiety, increased tolerance, and impaired social functioning [13,14]. In recent years, the adverse effects of smartphone addiction on mental health have been widely documented across diverse populations. Large-scale studies among adolescents, in particular, have demonstrated significant positive associations of problematic smartphone use with depressive and anxiety symptoms as well as sleep disturbance [15-17]. Moreover, several longitudinal studies have shown that baseline levels of smartphone addiction prospectively predict the worsening of anxiety symptoms and the continued deterioration of sleep quality during follow-up, suggesting that smartphone addiction may not merely be a consequence of psychological distress but a potential cause that precipitates or exacerbates affective disorders [18,19].

Although previous research has established negative associations between smartphone addiction and mental health in adolescents [20,21], studies examining the association between smartphone addiction and prenatal affective disorders among pregnant women, a population characterized by marked physiological and psychological fluctuations, remain scarce. In addition, few studies have distinguished total smartphone use time from use during specific periods. This distinction may be theoretically relevant: circadian rhythm disruption plays a key role in the onset, recurrence, and treatment response of mood disorders, and the central role of circadian rhythms in emotional regulation is widely recognized [22,23]. Screen exposure during different circadian phases may influence emotional states through distinct neurobiological pathways. Specifically, bedtime screen exposure is closely associated with reduced sleep quality [24], whereas screen exposure after waking may have different effects on the daytime stress regulation system [25]. Compared with absolute usage duration, whether screen exposure during key circadian windows, such as bedtime and after waking, is associated with prenatal depressive and anxiety symptoms has yet to be systematically investigated.

In recent years, studies on adolescents have shown that smartphone use is associated with reduced sleep quality and emotional problems [20,26,27]. Experimental studies have further found that nighttime blue light exposure can prolong sleep latency and cause a circadian phase shift by suppressing melatonin secretion [28], while the cognitive and emotional arousal triggered by immersive screen exposure may also interfere with sleep onset and maintenance [29]. It is worth noting that sleep quality in pregnant women undergoes a physiological deterioration as pregnancy progresses, with the prevalence of sleep disturbances rising significantly from the first trimester to the third trimester [30]. This vulnerability may stem from the combined effects of hormonal fluctuations, increased nocturia, and physical discomfort [31]. Furthermore, poor sleep quality is associated with an increased risk of prenatal depression and anxiety [32,33], and its neural mechanisms may involve the effects of sleep deprivation on prefrontal cortex function and amygdala reactivity [34,35]. Based on this prior evidence and biological plausibility, it is reasonable to infer that sleep quality may mediate the relationship between smartphone use and prenatal affective disorders. However, current research on this topic remains scarce, particularly studies that comprehensively assess multiple dimensions, such as smartphone use at specific time points and smartphone addiction.

To address this research gap, this study aims to investigate the associations between smartphone addiction and usage during specific time periods and prenatal depression and anxiety, and to explore the mediating effect of sleep quality on these associations, to provide evidence-based support for the development of digital health guidelines and clinical intervention strategies during pregnancy.

Methods

Study Population

This study used a cross-sectional design and was conducted in the obstetrics outpatient clinic and inpatient ward of Hunan Provincial Maternal and Child Health Hospital. Participants were recruited using convenience sampling. The survey was administered by uniformly trained interviewers, who explained the study's purpose and procedures to eligible pregnant women while they were waiting to give birth in the admission area or in the ward. After obtaining informed consent, the interviewers provided one-on-one guidance to help participants scan a QR code to complete the electronic questionnaire, which was filled out and submitted on the spot. Investigators provided necessary explanations and assistance but did not interfere with the respondents' answers. Inclusion criteria were as follows: (1) permanent residents of Changsha, (2) all prenatal checkups completed at the study hospital, (3) age ≥18 years, (4) singleton pregnancy. Exclusion criteria were (1) severe cognitive impairment or mental illness preventing effective communication or understanding of the questionnaire content, and (2) presence of legally reportable infectious diseases such as HIV, syphilis, or hepatitis B. Participants who met all inclusion criteria and none of the exclusion criteria were formally enrolled in the study after signing the informed consent form.

All data in this study were collected by having participants scan a QR code to complete a structured questionnaire. All key research variables in the questionnaire were marked as required fields; participants could not submit the questionnaire unless they had completed all required items. Consequently, none of the variables analyzed in this study had missing values, and all 537 cases ultimately included in the analysis were valid questionnaires.

Ethical Considerations

The study protocol, encompassing participant recruitment procedures, informed consent procedures, data collection, and quality control methods, was reviewed and approved by the Ethics Committee of the Xiangya School of Public Health, Central South University (approval number: XYGW-2024 - 19) and the Ethics Committee of the Hunan Provincial Maternal and Child Health Care Hospital (approval number: 2023-S189). After fully understanding the study's objectives, procedures, potential risks, and benefits, all participants voluntarily signed a paper informed consent form and were informed of their right to withdraw from the study at any time without condition. No remuneration or compensation was provided to any participant in this study.

Exposure Measurement

Smartphone addiction tendency was assessed using the Smartphone Addiction Scale-Short Version (SAS-SV). The scale consists of 10 items rated on a 6-point Likert scale (1="strongly disagree" to 6="strongly agree"), yielding a total score ranging from 10 to 60, with higher scores indicating a greater risk of smartphone addiction. According to the developers' recommendation, a cut-off score of 33 was adopted to define a high risk of addiction for females. The SAS-SV has demonstrated good psychometric properties, with an internal consistency Cronbach α coefficient of 0.91 [36]. The scale has been widely applied and validated in Chinese populations and is suitable for the rapid screening of smartphone dependence among adults [37].

Time-specific smartphone use was assessed using self-developed items, including duration of bedtime smartphone use and duration of smartphone use after waking. Bedtime smartphone use was defined as the cumulative duration of smartphone use from the moment participants lay down in bed with the intention to sleep until they actually fell asleep. Smartphone use after waking was defined as the cumulative duration of use from the moment participants awoke in the morning until they got out of bed. Both definitions were clearly stated in the questionnaire and were verbally explained in a standardized manner by trained investigators before questionnaire completion. Investigators specifically emphasized that the reported duration should only include time spent actively using the phone while lying in bed, rather than the total time spent in bed including nonuse states. Meanwhile, participants were instructed to recall their typical usage patterns over the past week rather than relying on a single day's experience. Both measures were specific to nighttime sleep periods and did not include daytime naps, and were recorded in minutes. Weekly smartphone use was obtained by asking participants to check the average daily usage duration of all applications over the past week through the screen time management feature built into their smartphone system settings (corresponding to "Screen Time" or "Healthy Phone Usage Time" or "App Management Time" in Android and Apple iOS systems, respectively), and was recorded in hours. According to the current distribution of data and previous studies on smartphone use duration, we classified participants into 4 consecutive groups as follows: (1) duration at bedtime [25]: 0 - 30 minutes, 31 - 60 minutes, 61 - 90 minutes, and ≥91 minutes; (2) duration after waking [38]: 0 - 1 minutes, 2 - 10 minutes, 11 - 60 minutes, and ≥61 minutes; (3) duration of total week [39,40]: 0 - 14 hours/week, 15 - 28 hours/week, 29 - 49 hours/week, and ≥50 hours/week.

Participants' sleep quality over the past month was assessed using the Pittsburgh Sleep Quality Index (PSQI). Developed by Buysse et al [41], the PSQI comprises 7 dimensions: subjective sleep quality, sleep latency, sleep duration, habitual sleep efficiency, sleep disturbances, use of sleep medication, and daytime dysfunction. The total score, ranging from 0 to 21, is calculated as the sum of all component scores. Based on the threshold established by previous studies, a total score of ≥7 was defined as poor sleep quality in this study [42,43].

Outcome Measurement

Depressive symptoms over the past 2 weeks were assessed using the Patient Health Questionnaire-9 (PHQ-9). Developed by Kroenke et al [44] based on the DSM-IV diagnostic criteria for depression, the PHQ-9 comprises nine items. Each item asks respondents to rate the frequency of each symptom over the past 2 weeks on a 4-point Likert scale (0="not at all" to 3="nearly every day"), yielding a total score ranging from 0 to 27, with higher scores indicating more severe depressive

XSL•FO
RenderX

symptoms. The PHQ-9 has demonstrated good reliability and validity among Chinese pregnant women [45]. As prior research has shown that moderate-to-severe depressive symptoms may lead to more adverse outcomes, a cut-off score of ≥10 was adopted in this study to define moderate-to-severe depressive symptoms, in line with previous studies [46,47]. Hereafter, the term "prenatal depression" refers to moderate-to-severe prenatal depressive symptoms.

Anxiety symptoms were measured using the Generalized Anxiety Disorder-7 (GAD-7). Developed by Spitzer et al [48], the GAD-7 is designed for rapid screening of generalized anxiety symptoms over the past 2 weeks. The scale consists of 7 self-reported items, each requiring respondents to rate the frequency of anxiety symptoms over the past 2 weeks on a 4-point Likert scale (0="not at all" to 3="nearly every day"), with total scores ranging from 0 to 21, higher scores reflecting more severe anxiety symptoms. Given that moderate-to-severe anxiety symptoms may be associated with more detrimental effects, a cut-off score of ≥10 was used to define moderate-to-severe anxiety, consistent with previous research [49,50]. Hereafter, the term "prenatal anxiety" refers to moderate-to-severe prenatal anxiety symptoms.

Covariates

Based on previous studies [12,51-55], the following variables that may influence smartphone use and prenatal mental health outcomes were included as covariates in the analyses, covering 3 domains: sociodemographic characteristics, behavioral and lifestyle factors, and health and pregnancy-related characteristics. Sociodemographic characteristics included maternal age (years), maternal educational attainment (junior high school or below, high school or vocational high school, and college or above), and paternal educational attainment (junior high school or below, high school or vocational high school, and college or above). Behavioral and lifestyle factors included prepregnancy smoking status within the 6 months before pregnancy (yes or no), prepregnancy alcohol consumption within the 6 months before pregnancy (yes or no), frequency of physical exercise during pregnancy (<once per week, 1 - 3 times per week, 4 - 6 times per week, and ≥ once per day), and frequency of social media posting on platforms such as WeChat (Tencent) and Xiaohongshu (Xingyin Information Technology Ltd.) during pregnancy (less than once every 6 months, 2 - 5 times per year, 1 - 2 times per month, 3 - 4 times per month, and several times per week). Health- and pregnancy-related characteristics included gestational age (weeks), prepregnancy BMI (kg/m^2), gestational weight gain (kg), gestational diabetes mellitus (yes or no), abortus (times), and gravida (times).

Statistical Analysis

Descriptive statistics were computed for the dataset, with continuous variables presented as means and SD and categorical variables expressed as counts and percentages. Between-group comparisons were performed using independent-samples *t* tests for continuous variables and chi-square tests for categorical variables. Pearson correlation coefficients were used to assess the bivariate associations among total weekly smartphone use duration, duration of smartphone use after waking, duration of bedtime smartphone use, SAS-SV score, PHQ-9 score, and GAD-7 score.

Subsequently, binary logistic regression models were fitted separately for each smartphone-use dimension and outcome. Two models were constructed to verify the robustness of the associations: Model 1 was a crude model that assessed the initial associations without adjusting for any covariates; Model 2 was a fully adjusted model that included maternal age, maternal educational attainment, paternal educational attainment, prepregnancy BMI, gestational weight gain, gestational age, gestational diabetes mellitus, gravida, abortus, prepregnancy smoking status, prepregnancy alcohol consumption, frequency of physical exercise during pregnancy, and frequency of social media posting during pregnancy as covariates. Results were expressed as odds ratios (ORs) with their 95% CIs.

To further explore potential nonlinear dose-response relationships between smartphone use, sleep quality, and prenatal affective disorders, restricted cubic spline (RCS) functions were fitted on the basis of the above logistic regression models. Following previous studies, 4 knots were placed at the fifth, 35th, 65th, and 95th percentiles, and the median of each independent variable was set as the reference value [56-58]. Finally, mediation models were established to exploratorily examine the indirect pathways of sleep quality in the associations between multidimensional smartphone use and prenatal affective disorders. In our mediation analysis, we clearly distinguished between the total effect, the direct effect, and the indirect effect based on the effect decomposition framework. We used the continuous scores of the PHQ-9 and GAD-7 as outcome variables to preserve the informational integrity of the original scales and enhance the statistical power for detecting indirect effects. Point estimates for direct and indirect effects were obtained using linear regression models, and their 95% CIs were estimated via 1000 Monte Carlo simulations; the mediation proportion was calculated by dividing the indirect effect by the total effect. All models were adjusted for all abovementioned covariates. In addition, to examine the impact of outcome definition on the stability of mediation results, we conducted a sensitivity analysis based on a binary outcome (PHQ-9 and GAD-7 score ≥10). Given the cross-sectional design of this study, the results of the mediation analysis should be interpreted as an exploratory decomposition of association pathways rather than evidence of causal mechanisms.

Given the limited number of events for moderate-to-severe depression (n=47) and anxiety (n=31), two sensitivity analyses were conducted to assess the robustness of the main findings. First, Firth penalized maximum likelihood estimation was applied to refit all models to reduce small-sample bias in rare-events logistic regression [59]. Second, the threshold for the PHQ-9 and GAD-7 outcomes was lowered from ≥10 to ≥5 (ie, including those with mild and above depression and anxiety symptoms) to evaluate whether the observed associations were sensitive to the choice of the cutoff for symptom severity.

Data analyses were performed using SPSS 26.0 (IBM Corp) and R 4.4.1 (R Foundation for Statistical Computing). The primary R packages used included *dplyr*, *rms*, *mediation*, and

XSL•FO
RenderX

ggplot2. The significance level was set at α=.05, and *P*<.05 was considered statistically significant.

Results

Baseline Characteristics of Participants

Table 1 presents the baseline characteristics of the study participants. A total of 537 pregnant women were included, with a mean age of 31.7 (4.0) years. Moderate-to-severe prenatal depression and anxiety were present in 47 (8.8%) and 31 (5.8%) participants, respectively. The mean SAS-SV score (SD) in the moderate-to-severe depression group was 36.4 (9.4), significantly higher than that in the nonmoderate-to-severe depression group (30.8, SD 8.9). The moderate-to-severe depression group also had longer weekly screen time and significantly longer durations of smartphone use after waking and before bedtime compared with the nonmoderate-to-severe depression group (*P*=.02 and *P*=.002, respectively). In addition, the PSQI score in the moderate-to-severe depression group was significantly higher than that in the nonmoderate-to-severe depression group (*P*<.001). The pattern of differences between the moderate-to-severe anxiety group and the nonmoderate-to-severe anxiety group was generally similar. The overall detection rate of sleep disturbance was 46.2% (n=248), and the detection rates in both the moderate-to-severe depression group and the moderate-to-severe anxiety group were significantly higher than those in their respective control groups (*P*=.003 and *P*=.008, respectively).

The Correlation between Different Dimensions of Smartphone Use and Prenatal Affective Disorders

To preliminarily explore the bivariate associations between multidimensional smartphone use characteristics during pregnancy (SAS-SV total score, weekly smartphone use, bedtime smartphone use, and smartphone use after waking) and prenatal affective disorders (PHQ-9 and GAD-7 total scores), Pearson correlation analysis was performed, with the results presented in Figure 1. The correlation matrix showed that both

XSL•FO
RenderX

the SAS-SV total score and all dimensions of smartphone use duration were significantly positively correlated with PHQ-9 and GAD-7 total scores (P<.05), providing preliminary evidence that excessive digital media exposure was related to prenatal affective disorders.

Figure 1. Correlation between different dimensions of smartphone use and prenatal affective disorders. These values are Pearson correlation coefficients (r). The dash "-" on the diagonal indicates that self-correlations were not computed (not applicable). *: P value <.05; **: P value <.01; ***: P value <.001. The Associations of Different Smartphone Use Dimensions and Sleep Quality With Prenatal Affective Disorders

The results of the independent associations between various dimensions of smartphone use and prenatal affective disorders are detailed in Table 2. Smartphone addiction was associated with higher odds of both outcomes in the crude and adjusted models. In the fully adjusted model, the OR was 3.461 (95% CI 1.771 - 7.100) for prenatal depression and 7.738 (95% CI 3.064 - 23.172) for prenatal anxiety. For bedtime use, compared with 0 - 30 minutes, use of ≥91 minutes was associated with higher odds of depression (OR 3.716, 95% CI 1.467 - 10.377) and anxiety (OR 5.141, 95% CI 1.568 - 20.808). For use after waking, ≥61 minutes was associated with higher odds of depression (OR 4.758, 95% CI 1.736 - 13.773) and anxiety (OR 10.902, 95% CI 2.606 - 58.482). Weekly use showed a nonmonotonic categorical pattern: compared with 0 - 14 hours/week, the 29-49 hours/week group had lower odds of depression (OR 0.378, 95% CI 0.119 - 1.012) and anxiety (OR 0.221, 95% CI 0.033 - 0.868), whereas the ≥50 hours/week group demonstrated elevated odds estimates for both outcomes (depression OR 1.687, 95% CI 0.795 - 3.597; anxiety OR 1.979, 95% CI 0.830 - 4.795). Sensitivity analyses using Firth penalized maximum likelihood estimation and an alternative threshold (PHQ-9 and GAD-7 score ≥5) yielded results consistent with the main findings in terms of direction, supporting the robustness of our results (Tables S1 and S2 in Multimedia Appendix 1).

RCS analyses showed that bedtime smartphone use and SAS-SV score had monotonic positive associations with both outcomes, without statistically significant evidence of nonlinearity. Smartphone use after waking showed a U-shaped association with depression (P for nonlinearity=.01) and a J-shaped association with anxiety (P for nonlinearity=.009). Weekly smartphone use showed a U-shaped association with anxiety (P for nonlinearity=.01), whereas its nonlinear association with depression was not statistically significant (Figures 2 and 3).

[a]Continuous exposure variables were SAS-SV total score, weekly smartphone use, smartphone use after waking, and bedtime smartphone use. For continuous exposures, ORs represent the change in odds per 1-point increase in SAS-SV total score, per 14-hour increase in weekly smartphone use, and per 30-minute increase in smartphone use after waking and bedtime smartphone use. A total SAS-SV score of 33 or higher is defined as smartphone addiction. Categorical smartphone use variables used the first category as the reference (Ref).

XSL•FO
RenderX

Furthermore, the independent association between sleep quality and prenatal affective disorders was evaluated, with the results shown in Table 3. In the fully adjusted model, when the PSQI score was analyzed as a continuous variable, each 1-point increase in the score was associated with significantly higher odds of prenatal depression (OR 1.243, 95% CI 1.130 - 1.373) and anxiety (OR 1.220, 95% CI 1.087 - 1.374). The analysis using a categorical variable yielded consistent results: pregnant women with sleep disturbance (PSQI ≥7) had 2.732 times the odds of depression (OR 2.732, 95% CI 1.389 - 5.592) and 2.702 times the odds of anxiety (OR 2.702, 95% CI 1.174 - 6.657) compared with those with normal sleep. RCS analyses revealed that the PSQI score was positively associated with both prenatal depression and anxiety, although the nonlinear trends did not reach statistical significance (Figure 2E and Figure 3E).

Mediating Effect Analysis

In this study, sleep quality was examined as a potential mediator in the associations between multidimensional smartphone use and prenatal affective disorders (Figures 4 and 5). Exploratory mediation analyses showed that the indirect pathways via sleep quality were statistically significant for the associations of bedtime smartphone use, weekly smartphone use, and smartphone addiction with prenatal depression, with mediation proportions of 44.89% (0.0065/0.0145; *P*<.001; Figure 4C), 31.30% (0.0056/0.0183; *P*=.04; Figure 4D), and 31.48% (0.0415/0.1315; *P*<.001; Figure 4A), respectively. Similar indirect patterns were observed in the anxiety models, with corresponding mediation proportions of 35.83% (0.0044/0.0123; *P*<.001; Figure 5C), 27.05% (0.0039/0.0144; *P*=.04; Figure 5D), and 22.73% (0.0271/0.1187; *P*<.001; Figure 5 B1). However, the indirect pathways from smartphone use after waking to depression and anxiety through sleep quality did not reach statistical significance (*P*=.12; Figure 4B and Figure 5B). Sensitivity mediation analyses using binary outcomes (PHQ-9 or GAD-7≥10) showed that the direction of indirect effects across pathways remained consistent with the main analysis, supporting the robustness of our mediation findings (Figures S1 and S2 in Multimedia Appendix 1).

Discussion

Principal Findings

This study systematically explored the associations of multidimensional smartphone use characteristics with prenatal depression and anxiety, and quantitatively validated the mediating role of sleep quality in these associations. The results showed that smartphone addiction and excessive use after waking and before bedtime were significantly associated with higher odds of prenatal affective disorders, and these associations remained robust after adjustment for multidimensional covariates. RCS analyses further revealed distinct dose–response relationships across different exposure dimensions: smartphone use after waking showed U-shaped and J-shaped associations with prenatal depression and anxiety, respectively; bedtime smartphone use and SAS-SV score showed monotonic positive associations. In addition, sleep quality partially mediated the associations of bedtime use, total weekly use, and smartphone addiction with prenatal depression and anxiety, with the mediation proportions varying across models.

The observed positive associations between smartphone addiction and prenatal depression and anxiety are consistent with findings from adolescents and college students [60-62]. In a meta-analysis encompassing 17 studies and 24,019 college students, Tang et al [63] reported that the pooled OR for the association between problematic smartphone use and depressive symptoms was 2.40 (95% CI 2.19 - 2.63), which is lower than the estimate found in this study among pregnant women. This discrepancy suggests that pregnant women may be more susceptible to the adverse mental health effects of smartphone addiction. The potential mechanisms may involve 2 levels. From a neuroendocrine perspective, the dramatic fluctuations in pregnancy-related hormones such as estradiol, progesterone, and cortisol have already rendered the hypothalamic-pituitary-adrenal axis and the emotional regulation circuits of the limbic system in a fragile state of equilibrium; the withdrawal symptoms accompanying smartphone addiction may constitute an additional stress load that further disrupts an emotional homeostasis already operating at a compensatory margin [64,65]. From a sociobehavioral perspective, individuals with addiction tendencies tend to allocate a large amount of time to virtual social environments, thereby encroaching on the time budget that could otherwise be devoted to seeking family emotional support, offline health care visits, and self-care behaviors in the real world, consequently exacerbating the sense of social isolation that is characteristic of the prenatal period [66].

Notably, the associations of time-specific exposure demonstrated marked heterogeneity in this study. In the logistic regression analyses, bedtime smartphone use exceeding 91 minutes and smartphone use after waking exceeding 61 minutes were both significantly associated with higher odds of prenatal depression and anxiety. Previous studies have confirmed that bedtime and nocturnal smartphone use are associated with increased blue light exposure, which in turn has been linked to suppression of melatonin secretion and circadian phase delay [67-69]. However, the underlying mechanisms of digital exposure during the period after waking remain unclear. One possible explanation is that exposure to information on smartphones immediately after waking, such as work notifications and social media updates, may be associated with additional morning psychosocial stressors, which could in turn be related to fluctuations in daytime emotional states. Previous literature has suggested an association between smartphone use and alterations in neuroendocrine function, such as the cortisol awakening response [70]; however, as this study did not directly measure cortisol or other biomarkers, such pathways remain to be verified in future research. Therefore, the mechanisms linking smartphone use after waking to prenatal affective disorders should be interpreted with caution.

In this study, pregnant women with either very low or very high levels of smartphone use exhibited relatively higher odds of depression and anxiety, whereas those with a weekly use duration of 29 - 49 hours had relatively lower effect estimates. This nonlinear pattern is similar to the U-shaped trend previously observed in the association between social media use and mental health [20]. From a clinical perspective, the use duration within this range may reflect pregnant women's active needs for accessing pregnancy-related health information and maintaining social connections, rather than pathological overreliance [10]. Previous studies have suggested that daily smartphone use exceeding 4 hours is significantly associated with prenatal anxiety [12], which appears to contrast with the findings of this study. This discrepancy may indicate that the relationship between smartphone duration and mental health is moderated by multiple factors such as purpose of use, content, and individual susceptibility, rather than being a simple linear accumulation. In addition, the wide CIs for this point estimate and the inability to completely rule out residual confounding warrant a cautious interpretation of the findings.

The RCS analyses further revealed differences in nonlinear patterns across exposure dimensions. The dose-response relationship for duration of smartphone use after waking could not be adequately described by a simple monotonic linear function, with curves showing J-shaped and U-shaped patterns for anxiety and depression, respectively. The association between weekly total use duration and anxiety exhibited a U-shaped curve, whereas its nonlinear trend with depression was not statistically significant, suggesting that the between-group differences observed in Table 2 may partly arise from fluctuations introduced by the categorization strategy. Both duration of bedtime smartphone use and smartphone addiction score showed monotonically increasing associations with depression and anxiety, suggesting that higher exposure levels or greater addiction severity may be associated with higher odds of these outcomes. Thus, the adverse mental health correlates of smartphone use are not solely dependent on cumulative screen time but exhibit notable time-specific differences. Compared with focusing only on total weekly use duration, precise identification of and intervention on screen exposure during critical circadian windows may hold greater clinical value.

Exploratory mediation analyses further indicated that sleep quality partially accounted for the associations between multidimensional smartphone use and prenatal affective

XSL•FO
RenderX

disorders, which is consistent with the mechanisms previously observed in nonpregnant populations [20,26,27]. Previous studies have demonstrated that excessive use of electronic devices such as smartphones is associated with increased blue light exposure, which in turn has been shown to suppress the normal secretory rhythm of pineal melatonin, prolong sleep onset latency, and delay circadian phase [67-69]. In addition, research has suggested that cognitive and emotional arousal triggered by immersive screen exposure before bedtime may interfere with sleep initiation and maintenance [29]. For pregnant women who already experience physiological sleep fragmentation, these effects may be further amplified. Previous research has also indicated that sleep deprivation is associated with impaired prefrontal cortex function and increased amygdala reactivity, which may weaken prefrontal-amygdala connectivity and contribute to emotion dysregulation [34,71]; insufficient sleep may also be associated with higher odds of depression and anxiety through activation of the sympathetic nervous system and inflammatory signaling pathways [72,73]. In this study, the mediation proportions of sleep quality in the associations of bedtime use, weekly use, and smartphone addiction with prenatal depression were 44.89% (0.0065/0.0145), 31.30% (0.0056/0.0183), and 31.48% (0.0415/0.1315), respectively; for prenatal anxiety, the corresponding proportions were 35.83% (0.0044/0.0123), 27.05% (0.0039/0.0144), and 22.73% (0.0271/0.1187). These findings suggest that sleep quality may represent a relevant pathway in these associations. Notably, the indirect pathways through sleep quality for smartphone use after waking were not statistically significant for either depression or anxiety. The specificity of these patterns suggests that the associations between digital device use at different times of day and prenatal mental health may operate through distinct biobehavioral pathways.

The association between prolonged and time-specific smartphone use and higher odds of prenatal affective disorders underscores the urgency of digital health management during pregnancy as an important public health issue. In this study, RCS analyses revealed a nonlinear association between smartphone use after waking and prenatal affective disorders, and identified a U-shaped pattern in the relationship between weekly smartphone use and affective disorders. This finding is consistent with the U-shaped association between social media use and mental health observed by Singh et al [74] in adolescent populations, suggesting that moderate smartphone use may be associated with lower emotional distress, whereas excessive use may be related to poorer mental health. These findings provide preliminary evidence for the development of prenatal digital health guidelines. These findings suggest that prenatal mental health interventions should not simply advocate a blanket reduction in smartphone use, but should instead shift toward more precise risk-stratification strategies, such as prioritizing screening for smartphone addiction tendencies and targeting screen exposure behaviors during high-risk periods, specifically after waking and before bedtime. Furthermore, the mediation proportion of sleep quality suggests that improving sleep may be a key intervention target for interrupting the pathway linking digital exposure to affective disorders. Cognitive behavioral interventions targeting bedtime smartphone use behavior may achieve the dual benefits of improving sleep and stabilizing mood simultaneously.

This study has several limitations. First, the study was conducted at the Hunan Provincial Maternal and Child Health Care Hospital, and the study population was limited to permanent residents who completed their entire prenatal care at that hospital; nearly 90 percent (475/537) of them held a college degree or higher, which may have influenced smartphone usage patterns: pregnant women with higher educational attainment may be more inclined to use smartphones to access prenatal health information, but they may also face a higher cognitive load from work-related information processing. Their smartphone usage behavior may reflect a dual characteristic of both health promotion and overreliance, which in turn limits the generalizability of this study's conclusions to pregnant women with lower educational levels or those in rural areas. Second, the cross-sectional design limits our ability to infer causality; although the pathways in the mediation analysis were established based on evidence from previous longitudinal studies and biological plausibility, we cannot rule out the possibility of reverse pathways. Pregnant women may increase their smartphone use, particularly during periods of nighttime wakefulness, to pass the time or alleviate distress due to preexisting poor sleep quality or symptoms of depression and anxiety. This reverse causality may violate the temporal sequence assumption of the mediation model and could introduce bias into the estimates of indirect effects.

Furthermore, assessments of smartphone usage duration during specific time periods, smartphone addiction, and sleep quality relied on self-report questionnaires, which may introduce recall bias. In this study, total weekly usage duration was objectively recorded using the screen time feature built into the smartphone operating system; however, for usage durations after waking and before bedtime, self-reporting was used as an alternative because the existing operating system could not export data for specific time periods separately. This inconsistency in measurement methods may have some impact on the comparability of the results. Additionally, although we adjusted for several key covariates in our models, some theoretically important confounders (such as caffeine intake, dietary habits, sleep patterns, and occupation type) were not included in the analysis; their omission may lead to residual confounding, which could affect the precision of the effect estimates. Although this study included gestational diabetes mellitus as a covariate to control for the potential impact of common pregnancy complications, other unmeasured complications and lifestyle factors may still constitute residual confounding. However, given that the primary objective of this study was to explore the direction of the association and dose-response trends between smartphone usage patterns and prenatal affective disorders, the impact of these omissions on the directionality and statistical significance of the core conclusions is likely limited; nevertheless, more comprehensive covariate control would help yield more accurate effect estimates. Given the limited sample size in the anxiety group, the CIs for some estimates are relatively wide, indicating limited precision; therefore, the results should be interpreted with caution. Future large-scale, multicenter, prospective longitudinal cohort studies

XSL•FO
RenderX

are needed to integrate objective data on screen time tracking and sleep monitoring, comprehensively collect the aforementioned covariates, and explore mediating mechanisms within a longitudinal research framework to further validate the findings of this study.

Conclusion

The results of this study indicate that smartphone addiction and excessive smartphone use after waking and before bedtime were significantly associated with elevated odds of prenatal depression and anxiety, and distinct dose-response patterns exist across different exposure-outcome combinations. Additionally, exploratory mediation analyses indicated that sleep quality may statistically account for part of these associations. Future longitudinal studies are needed to establish temporal precedence and to test the directional assumptions underlying the mediation model.

Acknowledgments

The authors express their gratitude to all the participants and staff involved in this study. Their efforts and contributions are vital to the success of the research.

Funding

The study was funded through grants from Hunan Province Health Research Project (grant number 20255507, 20254300), the Natural Science Foundation of Hunan Province (2025JJ80661), the National Clinical Key Specialty Cultivation Project (Nursing Key Specialty), and the National Natural Science Foundation of China (Grant No. 42407585).

Data Availability

The datasets generated and analyzed during this study are not publicly available due to their containing sensitive information about participants' social media use and mental health, and to protect participant confidentiality as stipulated by the ethics approval. However, deidentified data underlying the findings presented in this study are available from the corresponding author (MYW) upon reasonable request. Requestors will need to submit a methodologically sound proposal and sign a data access agreement.

Abstract

Background: Chronic disease and comorbid mental health problems disproportionately affect rural and underserved populations. Digital self-management programs are potentially scalable, but evaluations often focus on narrow outcomes.

Objective: This study examined 12-month longitudinal changes in psychological and multidomain outcomes among Pictou County Patient Empowerment Program participants and explored co-occurring changes and psychological moderators.

Methods: This single-arm prospective interventional study enrolled 182 community-dwelling adults with ≥1 chronic condition in Pictou County, Nova Scotia, between October 2023 and August 2025 through community-based outreach. Median age was 60 (IQR 51 - 68) years, 155 of 182 (85.2%) participants were women, and the median number of chronic conditions was 3 (IQR 1 - 3). The initial 6-month digital intervention delivered brief daily modules targeting physical activity, nutrition, stress regulation, sleep, habit formation, and social connection, followed by a 6-month lower-intensity maintenance period during which monthly group videoconference sessions continued to be offered. Outcomes were assessed at baseline, 6 months, and 12 months. Primary outcomes were illness perceptions (Brief Illness Perception Questionnaire), perceived stress (10-item Perceived Stress Scale [PSS-10]), disease-related worry (10-item Questionnaire on Distress in Cancer Patients), life satisfaction (Satisfaction With Life Scale), and mental well-being (World Health Organization-Five Well-Being Index [WHO-5]). Secondary outcomes assessed the physical, behavioral, and psychosocial domains. Generalized estimating equations estimated population-averaged longitudinal changes, adjusted for age, sex, relationship status, comorbidity burden, and baseline depression or anxiety medication use. Exploratory models examined co-occurring changes and moderation. Tests were 2-sided with α=.05.

Results: Across outcomes and follow-up assessments, completion ranged from 58.2% (95% CI 51.0%-65.2%; 106/182) to 65.4% (95% CI 58.2% - 71.9%; 119/182). At 12 months, illness perceptions decreased (β=−7.3, 95% CI −9.7 to −4.9), perceived stress decreased (β=−2.4, 95% CI −3.5 to −1.3), disease-related worry decreased (β=−6.3, 95% CI −7.8 to −4.7), life satisfaction increased (β=2.5, 95% CI 1.4 - 3.5), and mental well-being increased (β=10.4, 95% CI 7.2 - 13.5; all P<.001). Secondary outcomes improved across fatigue, sleep, diet quality, sedentary behavior, spiritual well-being, mental health–related quality of life, weight, and BMI. Exploratory analyses showed that improvements in fatigue, sleep quality, and illness perceptions co-occurred with greater well-being and life satisfaction and lower perceived stress and disease-related worry at both follow-up assessment points. Clinically meaningful stress improvement (≥4-point PSS-10 reduction) was achieved by 36.4% (95% CI 27.3%-45.6%, 39/107) and 43.4% (95% CI 34.0%-52.8%, 46/106) participants at 6 and 12 months, respectively. At 12 months, 43.5% (95% CI 34.2%-52.9%, 47/108) participants reported clinically meaningful improvement in mental well-being (≥10-point WHO-5 increase).

Conclusions: Participation in this low-bandwidth, home-based digital self-management program was associated with sustained psychological, physical, and behavioral improvements among rural adults with chronic conditions. These multidomain findings support randomized controlled evaluation of scalable digital self-management approaches as adjuncts to rural chronic disease care.

Introduction

Chronic disease represents a growing public health challenge. In 2021, approximately 45% of Canadians were living with at least 1 major chronic condition, and 1 in 12 had 3 or more comorbid chronic diseases [1]. Globally, chronic diseases account for an estimated 75% of non–pandemic-related deaths and are projected to generate cumulative health care costs exceeding US $47 trillion by 2030 [2,3]. Chronic disease frequently co-occurs with adverse mental health outcomes, including depression, anxiety, and psychological distress, contributing to reduced quality of life, symptom exacerbation, and higher risk of downstream morbidity and mortality [4,5].

Rural populations may be particularly vulnerable to this clustering of physical and mental health burden. Compared with urban populations, rural residents experience a higher prevalence of chronic disease [6] and face substantial barriers to accessing specialized care, including mental health services. Even among individuals prescribed pharmacological treatment for mental health conditions, access to follow-up and supportive services declines across urban, rural-adjacent, and rural-nonadjacent settings [7]. These disparities underscore the need for accessible, scalable approaches to chronic disease management that extend beyond disease-specific biomedical care.

Effective self-management is a central component of chronic disease care. Clinical practice guidelines increasingly emphasize self-management education and support as core elements of long-term disease control [8]. Evidence from systematic reviews and meta-analyses demonstrates that self-management programs improve quality of life, self-efficacy, and depressive symptoms [9]; that interventions incorporating psychotherapeutic components yield superior physiological outcomes [10]; and that multicomponent approaches targeting multiple behaviors simultaneously are more effective than single-behavior interventions [11]. Despite this evidence, many chronic disease programs omit outcomes and supports that patients identify as important, including stress regulation, emotional well-being, and social connection [12]. Social support in particular influences self-management both directly and indirectly through empowerment and psychological resilience [13]. Even in the context of emerging pharmacotherapies for obesity-related and cardiometabolic conditions, experts increasingly emphasize the need for integrated psychosocial and behavioral support to sustain benefits and mitigate adverse psychological effects [14].

Although many chronic diseases are preventable or modifiable, health systems remain largely organized around reactive, episodic care, prioritizing treatment of acute disease escalation rather than sustained self-management and prevention. Models such as the Expanded Chronic Care Model emphasize proactive support, patient activation, and community-based resources, yet scalable implementations of these principles remain limited, particularly for populations living with multimorbidity and in rural settings. As a result, many individuals experience fragmented care that addresses downstream symptoms without adequately targeting upstream behavioral and psychosocial processes that shape chronic disease trajectories over time.

Digital health interventions offer a promising and scalable approach to address these gaps [15,16]. Importantly, digital self-management programs can extend behavioral and psychosocial support beyond traditional clinical encounters by embedding brief, scalable guidance into patients' daily routines, enabling continuous engagement with health behaviors between health care visits. Such interventions can extend care beyond traditional clinical encounters; support continuity and personalization; and incorporate outcomes that matter to patients, including sleep, physical activity, and psychosocial well-being [15,17]. By addressing shared behavioral and psychosocial risk factors across conditions, digital self-management programs have the potential to activate patients in their own care, support daily decision-making, and improve adherence and longer-term outcomes.

While digital interventions for chronic disease have demonstrated benefits for mental health outcomes, the mechanisms through which these improvements occur remain poorly understood. Meta-analyses of digital interventions for depression suggest that change occurs through multiple indirect pathways, including cognitive, behavioral, self-related, physiological, and mindfulness-related processes [18,19]. However, most individual studies are narrow in scope, mechanistic insights outside depression are limited, and few evaluations examine multidomain change over extended periods. Mechanistic understanding is particularly sparse in rural populations and in digital interventions addressing chronic disease more broadly. Identifying co-occurring changes across psychological, physical, behavioral, and social domains, as well as factors that modify response, is essential for optimizing intervention design and implementation.

To address these gaps, the Pictou County Patient Empowerment Program (PictouCountyPEP) was developed as a 6-month, comprehensive digital self-management program for adults living with chronic conditions in a rural setting [20]. A prior digital health evaluation established the feasibility, usability, and sustained mental health benefits of this low-bandwidth delivery model in rural adults with chronic disease [20]. The present study extends this work by evaluating longer-term change across psychological, physical, behavioral, and social domains and by examining whether improvements occur in theoretically coherent patterns relevant to chronic disease self-management.

The program builds on an empowerment-based intervention model previously evaluated in cancer populations [21,22] and was adapted to remove cancer-specific content while retaining the core behavioral and psychosocial components. Rather than targeting a single symptom or disease-specific pathway, the program was designed to influence modifiable upstream processes related to stress regulation, coping, self-efficacy, health behaviors, and social connection that are expected to covary with psychological distress and chronic disease burden

XSL•FO
RenderX

over time. Chronic diseases frequently cluster and progress through shared upstream processes, including stress dysregulation, physical inactivity, sleep disruption, social isolation, and reduced self-efficacy. Interventions that target these shared processes may be preventive in orientation, with potential to attenuate escalation and accumulation of multimorbidity, even when not designed to prevent specific diagnoses.

The primary objective of this study was to quantify longitudinal changes in psychological outcomes over 12 months following participation in PictouCountyPEP. Concurrent changes in physical, behavioral, and social outcomes were examined to contextualize psychological change. Secondary objectives were to characterize changes across physical, behavioral, and social outcomes; examine whether changes in selected candidate factors were associated with changes in psychological outcomes; and explore whether baseline psychological characteristics modified longitudinal change. These analyses were exploratory and hypothesis-generating and were intended to identify candidate pathways for evaluation in future controlled studies rather than establish causal mechanisms.

Understanding longitudinal psychosocial, physical, and behavioral changes associated with participation in a comprehensive digital self-management program can inform clinical decision-making in rural primary care, support health system planning for chronic disease management, and guide adaptation for populations at higher risk of multimorbidity. Identifying potential psychological pathways of change may further inform the optimization, personalization, and scale-up of digital empowerment interventions in rural and underserved regions.

Methods

Study Design

This study reports outcomes from the PictouCountyPEP, a single-arm, prospective, 6-month digital behavioral intervention delivered to adults living with chronic health conditions in Pictou County, Nova Scotia, Canada (October 2023 – August 2025). The study was designed as a pragmatic, real-world evaluation of feasibility, engagement, and longitudinal change under community delivery conditions rather than as a controlled efficacy trial; accordingly, observed changes over time cannot be attributed solely to the intervention.

Setting

Pictou County is a predominantly rural region with approximately 44,000 residents and limited access to specialty health services [23].

Participant Inclusion and Exclusion Criteria

Adults aged 18 years or older residing in Pictou County and living with 1 or more self-reported chronic conditions were eligible to participate. Eligibility was not restricted to a prespecified list of chronic disease diagnoses; the program was intentionally designed for adults living with chronic conditions across diagnostic categories and for those with multimorbidity. Eligibility required the ability to safely engage in low- to moderate-intensity physical activity, assessed using the Physical Activity Readiness Questionnaire for Everyone (PAR-Q+) [24], English proficiency, and access to the internet and email. No specific chronic disease categories were otherwise excluded; however, individuals with a current or recent cancer diagnosis were excluded because the intervention model has been evaluated separately in cancer populations in prior trials [21,22].

Recruitment and Sampling Procedures

Recruitment occurred through community-based outreach, including local media, social media, flyers, and partner organizations [20]. Eligible participants were enrolled consecutively as they presented for participation during the recruitment period.

Ethical Considerations

Participants provided electronic informed consent via the REDCap eConsent framework. No financial compensation for study participation was provided. Data were collected and managed in accordance with Nova Scotia Health privacy policies and the requirements of Canada's Personal Information Protection and Electronic Documents Act (PIPEDA). No images identifying individual participants are included in the manuscript or supplementary materials. The study was approved by the Nova Scotia Health Research Ethics Board (REB 1029744) prior to participant enrollment and was registered on ClinicalTrials.gov (NCT06064110).

Data Collection and Assessment Schedule

Self-reported surveys were administered using REDCap [25]. Participants completed assessments at baseline, 6 months, and 12 months.

Intervention

PictouCountyPEP is a home-based, multicomponent digital intervention designed to support self-management and mental well-being among adults living with chronic health conditions. The intervention was adapted from previously evaluated patient empowerment program models and modified to remove all cancer-specific education. The full protocol has been published previously [20].

The program delivered daily automated emails over a 26-week period, linking participants to brief instructional videos hosted by authors GI and RDHR. The videos were approximately 4 to 6 minutes in duration and accessible asynchronously via a public video-hosting platform. The content addressed 6 behavioral domains: aerobic physical activity, strength training or yoga, relaxation and stress management, dietary guidance, habit formation, and relationship and social connection skills. The content was modular, allowing flexible engagement according to individual needs and symptom burden.

Exercise guidance aligned with the national physical activity recommendations, encouraging 150 to 300 minutes per week of moderate-intensity aerobic activity and strength or flexibility training at least twice weekly. The content emphasized pacing, gradual progression, and symptom monitoring, with encouragement to tailor activities in consultation with health care providers. Dietary guidance promoted a predominantly plant-based pattern with reduced intake of ultra-processed foods,

XSL•FO
RenderX

consistent with Canada's Food Guide [26]. The stress management content incorporated mindfulness-based practices, breathing techniques, and cognitive strategies. The relationship modules focused on communication, boundary setting, and social connection, while the habit formation content emphasized small, sustainable behavioral changes.

The intervention was designed for low-bandwidth delivery and mobile accessibility to minimize barriers related to internet speed, device availability, or digital literacy. No specialized applications, wearable devices, or synchronous participation was required. Engagement was encouraged through daily reminders and weekly compliance surveys. Optional components included a peer support option, monthly live group videoconference sessions, and occasional in-person community events. These components were offered to enhance social connection and accountability but were not required or standardized. The intervention was delivered under real-world conditions to maximize external validity and inform future scale-up. Given the single-arm interventional design, this study follows the TREND (Transparent Reporting of Evaluations with Nonrandomized Designs) guidelines for nonrandomized evaluations of behavioral interventions [27]. The daily digital intervention content was delivered during the initial 6 months. During months 7 to 12, participants entered a lower-intensity maintenance period in which monthly group videoconference sessions continued to be offered, but daily intervention emails were no longer delivered. The 12-month assessment therefore reflects outcomes following the initial 6-month daily intervention and the subsequent 6-month lower-intensity maintenance period.

Because the intervention content was delivered asynchronously and participants could engage flexibly with individual components, standardized individual-level measures of total intervention exposure or module completion were not available for the present analysis; consequently, a formal dose-response analysis was not conducted.

Outcomes and Measures

Primary and Secondary Outcomes and Measures

Primary outcomes were prespecified psychological measures reflecting illness perceptions, well-being, perceived stress, life satisfaction, and disease-related worry. Participants completed validated self-report measures assessing psychological, physical, behavioral, and social outcomes. All multi-item composite scales were scored using complete item-level data. References for all measures and cut points can be found in the Multimedia Appendix 1.

Primary Psychological Measures

Illness perceptions were assessed using the 9-item Brief Illness Perception Questionnaire (B-IPQ), which measures the perceived consequences, timeline, personal control, treatment control, symptom identity, concern, emotional response, and illness coherence related to chronic illness [28]. Each item is rated on a 0 to 10 numeric scale, with 3 items being reverse-coded. Higher scores indicate more threatening or negative illness perceptions. A total score was derived by summing all items, and an improvement of ≥7 was considered clinically meaningful [29].

Psychological well-being was measured using the World Health Organization-Five Well-Being Index (WHO-5), a 5-item instrument assessing positive mood, vitality, and general interest in daily life over the preceding 2 weeks [30]. Raw scores (range 0 - 25) were multiplied by 4 to yield a total score ranging from 0 to 100, with higher scores indicating better well-being. Scores below 50 were used to indicate poor well-being in binary analyses [31].

Perceived stress was assessed using the 10-item Perceived Stress Scale (PSS-10), which measures the extent to which situations in one's life are appraised as stressful, unpredictable, and uncontrollable during the past month [32]. Items are rated from 0 ("never") to 4 ("very often"), with 4 items being reverse-coded. The items were summed to produce a total score ranging from 0 to 40, with higher scores indicating greater perceived stress. Scores ≥20 were used to classify high perceived stress, consistent with prior studies [33].

Life satisfaction was measured using the Satisfaction With Life Scale (SWLS), a 5-item instrument assessing global cognitive judgments of satisfaction with one's life [34]. Items are rated from 1 ("strongly disagree") to 7 ("strongly agree") and summed to yield total scores ranging from 5 to 35, with higher scores indicating greater life satisfaction. For responder analyses, an improvement of ≥5 points was used as an interpretive threshold informed by the scale author's score categories [35].

Disease-related worry was assessed using the 10-item Questionnaire on Distress in Cancer Patients (QSC-R10), which measures illness-related fears and concerns relevant to individuals living with chronic conditions [36]. Each item assesses whether a concern applies and the degree of distress it causes, rated from 0 to 5. Items were summed to produce total scores ranging from 0 to 50, with higher scores indicating greater disease-related worry. A cut point of>14 was used to classify clinically relevant need for psychosocial support in exploratory analyses [36].

Secondary Physical, Psychosocial, and Behavioral Measures

BMI was derived from self-reported weight and height. BMI (kg/m^2) was calculated as weight (kg) divided by height (m) squared. Outcomes included continuous change in weight (lb) and BMI, as well as categorical indicators of clinically meaningful weight loss (≥3%), consistent with previous trials and recommended guidelines [37,38].

Health-related quality of life was assessed using the 12-item Short Form Health Survey (SF-12), yielding norm-based Physical Component Summary (PCS) and Mental Component Summary (MCS) scores standardized to a mean of 50 and SD of 10 in the general population [39,40]. Higher scores indicate better health-related quality of life. Score changes of ≥3 points were considered clinically meaningful, in line with previous research [41].

Fatigue was assessed using the 13-item Functional Assessment of Chronic Illness Therapy—Fatigue scale (FACIT-F) [42],

XSL•FO
RenderX

which evaluates fatigue severity and its impact on daily functioning. Items are rated from 0 ("not at all") to 4 ("very much") and summed after reverse scoring, such that higher scores indicate less fatigue. A change in score of ≥3 points was used to define clinically meaningful improvement [43].

Sleep quality was measured using the Pittsburgh Sleep Quality Index (PSQI), which yields a global score ranging from 0 to 21, with higher scores indicating poorer sleep quality [44]. A global score >5 was used to identify poor sleep [44].

Sedentary behavior was assessed using the adult Sedentary Behavior Questionnaire (SBQ), which captures time spent in common sedentary activities during weekdays and weekends [45]. Reported hours were converted to total daily sedentary time, with values exceeding 24 hours being truncated. Daily weekday and weekend hours were summed to obtain weekly sedentary hours. High sedentary behavior was defined as ≥8 hours per day (equivalent to ≥56 hours per week), consistent with prior studies [46].

Perceived social support was measured using the 19-item Medical Outcomes Study Social Support Survey (MOS-SSS), yielding emotional and informational, tangible, affectionate, positive interaction, and overall support scores [47]. Items are rated from 1 to 5 and averaged according to scoring guidelines, with higher scores indicating greater perceived support.

Diet quality was assessed using the Rapid Eating Assessment for Participants—Shortened version (REAP-S), a 13-item measure of dietary habits over the past week [48]. Items are scored from 1 to 3, yielding total scores ranging from 13 to 39, with higher scores indicating healthier dietary patterns.

Spiritual well-being was measured using the 12-item Functional Assessment of Chronic Illness Therapy—Spiritual Well-Being scale (FACIT-SP-12), which assesses meaning, peace, and faith [49]. Items are scored from 0 to 4 (reversed where scoring instructions indicate) and summed to yield total scores ranging from 0 to 48, with higher scores indicating greater spiritual well-being.

Alcohol consumption was assessed using self-reported drinking and binge drinking frequency over the preceding 6 months. Binge drinking was defined as consuming 5 or more drinks containing any kind of alcohol within a 2-hour period [50]. Original categorical responses were converted into continuous frequency scores to retain variability and maximize statistical power, with values ranging from 0 (none) to 9 (daily) [51].

Cannabis use was assessed using self-reported frequency of use over the preceding 6 months and self-identification as a regular user. Categorical frequency responses were converted into a continuous score ranging from 0 (no use) to 4 (8 or more uses), using the same rationale applied to alcohol frequency scoring [51].

Measurement Reliability

Internal consistency of all multi-item scales was assessed at baseline using Cronbach α with 95% CI to characterize measurement reliability in the study population prior to intervention exposure (Table S1 in Multimedia Appendix 1).

Covariates

Covariates included age, sex, relationship status, comorbidity burden measured by the Charlson Comorbidity Index, and use of medication for depression or anxiety at baseline. These variables were selected a priori based on theoretical relevance and prior evidence from related patient empowerment program trials identifying their associations with mental health outcomes and intervention response [20-22].

Sample Size, Power, and Precision

This phase 2 interventional study enrolled 182 participants to evaluate feasibility, engagement, and longitudinal changes across a broad set of health outcomes. The sample size was determined pragmatically based on anticipated recruitment capacity within the study region and time frame rather than a formal a priori power calculation, consistent with the study's phase 2 implementation-focused objectives.

Statistical Analysis

All participants who consented and completed baseline assessments were included in the analytic cohort. Primary longitudinal analyses incorporated all available observed outcome data from participants who contributed data at the relevant assessment time points.

Longitudinal changes in psychosocial, physical, and behavioral outcomes were examined using generalized estimating equations (GEEs), which estimate population-averaged effects while accounting for within-participant correlation across repeated measurements. Continuous outcomes were modeled using an identity link with Gaussian working variance, and binary outcomes defined using established clinical thresholds (Multimedia Appendix 1) were modeled using a logit link with binomial working variance. An exchangeable working correlation structure was specified for all models, reflecting the limited number of equally spaced follow-up assessments, and robust (sandwich) SEs were used for inference to ensure valid estimation under potential misspecification of the working correlation. GEEs were selected to estimate population-averaged effects aligned with the study objective of evaluating overall program-associated change rather than subject-specific trajectories.

Time was modeled as a categorical variable (baseline, 6 months, and 12 months). All models were adjusted a priori for baseline age, sex, relationship status, comorbidity burden (Charlson Comorbidity Index), and use of medication for depression or anxiety. Model-based estimated marginal means and corresponding SEs were derived at each time point, and pairwise contrasts were used to estimate differences between baseline and follow-up assessments, with 95% CI reported. Primary inference for continuous outcomes was based on time indicator coefficients from these models, representing adjusted population-averaged mean differences from baseline.

Exploratory interaction models were estimated for psychological outcomes only, by including baseline characteristics interacted with time, to examine whether baseline factors modified trajectories of psychological change. These analyses were

XSL•FO
RenderX

prespecified as exploratory and interpreted as hypothesis-generating.

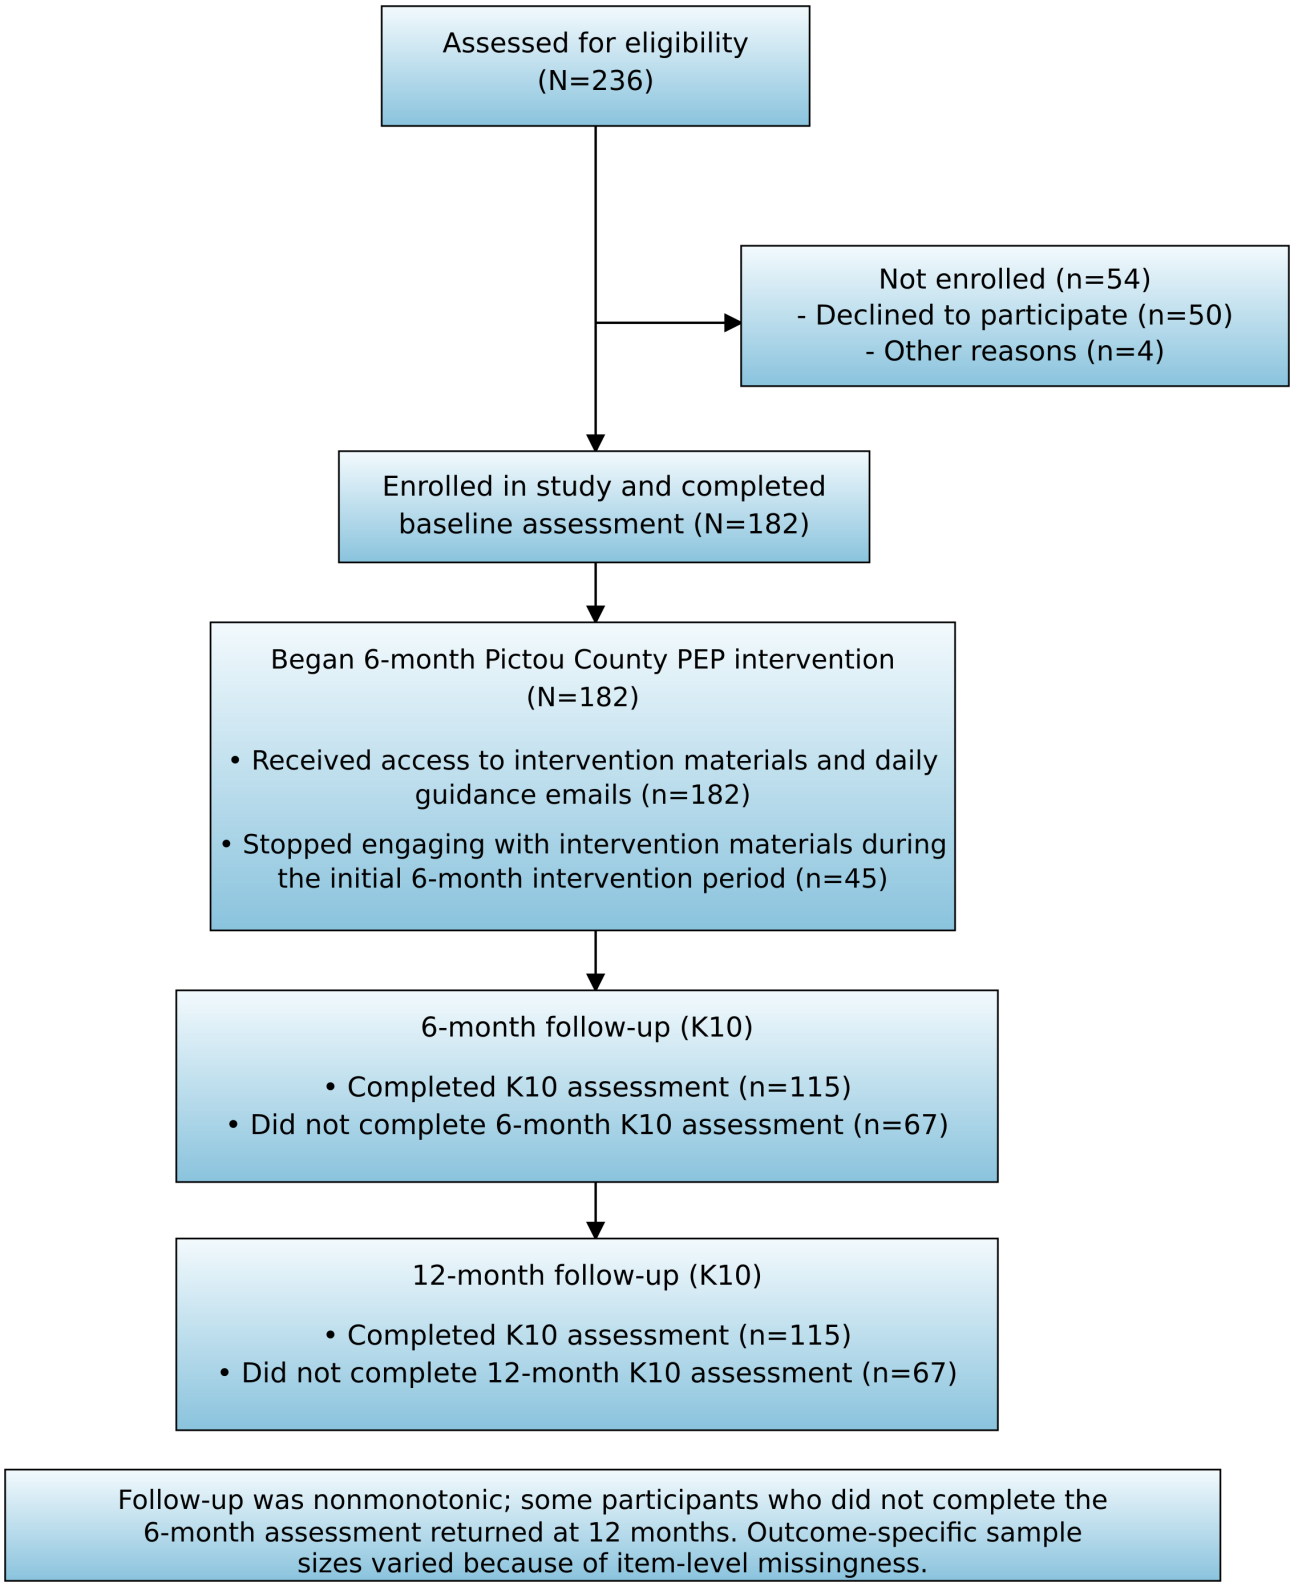
Exploratory analyses examined associations between within-participant changes in selected candidate factors and changes in psychological outcomes. These analyses were intended to identify patterns of co-occurring change and generate hypotheses regarding potential pathways rather than to test formal statistical mediation or establish causal mechanisms. Residualized change scores from baseline to follow-up were calculated, and linear regression models were fitted to assess associations between changes in physical, psychosocial, and substance use measures and changes in psychological well-being (WHO-5), perceived stress (PSS-10), life satisfaction (SWLS), and disease-related worry (QSC-R10). Models were adjusted for baseline outcome values and prespecified covariates. Results are interpreted as exploratory associations between longitudinal changes rather than as estimates of mediation or causal effects.

Clinically meaningful improvement was further examined using responder analyses based on established thresholds. Two responder definitions were applied: magnitude-based change, defined as achieving a prespecified minimally important difference regardless of baseline status, and categorical improvement, defined as movement from a clinically worse category at baseline to a more favorable category at follow-up, restricted to participants eligible to improve. Responder proportions at 6 and 12 months were calculated with 95% CI. Exploratory univariate logistic regression models were used to examine associations between baseline characteristics and responder status.

Missing Data and Sensitivity Analyses

Missing follow-up data were evaluated using several complementary approaches. In unadjusted comparisons, participants with incomplete follow-up had significantly lower baseline well-being (WHO-5; *P*=.03) and life satisfaction (SWLS; *P*=.01) than participants with complete follow-up, whereas no statistically significant differences were observed for age, sex, comorbidity burden, relationship status, baseline depression/anxiety medication use, illness perceptions (B-IPQ), perceived stress (PSS-10), or disease-related worry (QSC-R10) (Table S2 in Multimedia Appendix 1). Complete follow-up was defined as completion of assessments at baseline, 6 months, and 12 months; follow-up was nonmonotonic, with some participants missing the 6-month assessment but returning at 12 months. Missingness was further evaluated using logistic regression models for incomplete follow-up, including all prespecified covariates and primary psychological outcomes as predictors. None of the included variables was statistically significantly associated with incomplete follow-up in the multivariable model. Primary analyses used covariate-adjusted GEE models and included all available observed outcome data, regardless of follow-up status. To evaluate the robustness of findings to incomplete follow-up, sensitivity analyses were conducted using both complete case analyses and analyses using stabilized inverse probability weights for attrition. Findings were highly consistent across the primary, complete case, and weighted analyses, indicating that the principal results were not materially altered by the analytic approach to incomplete follow-up.

All analyses were conducted using R software (version 4.5.1; R Foundation for Statistical Computing) [52]. Statistical tests were 2-sided, with a significance level of α=.05. Given the number of outcomes assessed, no formal adjustment for multiple comparisons was applied; results for secondary and exploratory analyses are therefore interpreted with emphasis on effect sizes, CI, and consistency of findings rather than statistical significance alone, and these findings are considered hypothesis-generating rather than confirmatory. Full model–based estimated marginal means and associated SEs for continuous outcomes are provided in Multimedia Appendix 1.



Results

Participants and Baseline Characteristics

A total of 182 individuals enrolled and completed the baseline assessment. Across outcomes and follow-up assessments, outcome-specific completion ranged from 106 of 182 (58.2%) participants to 119 of 182 (65.4%) participants (Figure 1; Table S4 in Multimedia Appendix 1). Baseline characteristics are shown in Table 1. Participants had a median age of 60 (IQR 51 - 68) years; of the 182 participants, 155 (85.2%) were women, and 89 (48.9%) resided in the Municipality of Pictou County. The median number of diagnosed chronic conditions was 3 (IQR 1 - 3), and the median age-adjusted Charlson Comorbidity Index was 2 (IQR 1 - 3). The baseline symptom burden was substantial: of 182 participants, 52.7% (n=96) screened positive for low well-being (WHO-5<50), 41.2% (n=75) screened positive for high perceived stress (PSS-10≥20), and 48.4% (n=88) screened positive for psychological distress. Additional baseline sociodemographic, clinical, and health care use characteristics are reported in Table S3 in Multimedia Appendix 1. The follow-up status for each outcome is reported in Table S4 Multimedia Appendix 1.

Primary Outcomes: Longitudinal Changes in Psychological Outcomes

In adjusted population-averaged GEE models, all primary psychological outcomes improved from baseline to 6 months, with effects sustained or larger at 12 months (Table 2; Figure 2). Illness perceptions (B-IPQ) decreased at 6 months (β=−5.1, 95% CI −7.3 to −3.0; *P*<.001) and 12 months (β=−7.3, 95% CI −9.7 to −4.9; *P*<.001). Perceived stress (PSS-10) declined at 6 months (β=−2.2, 95% CI −3.2 to −1.2; *P*<.001) and 12 months (β=−2.4, 95% CI −3.5 to −1.3; *P*<.001), and disease-related worry (QSC-R10) decreased at 6 months (β=−3.7, 95% CI −5.2 to −2.3; *P*<.001) and 12 months (β=−6.3, 95% CI −7.8 to −4.7; *P*<.001). Life satisfaction (SWLS) increased at 6 months (β=1.5, 95% CI 0.5-2.6; *P*=.004) and 12 months (β=2.5, 95% CI 1.4-3.5; *P*<.001). Well-being (WHO-5) increased at 6 months (β=10.1, 95% CI 7.2-13.0; *P*<.001) and 12 months (β=10.4, 95% CI 7.2-13.5; *P*<.001). Mental health–related quality of life (SF-12 MCS) improved at 6 months (β=3.5, 95% CI 1.8-5.2; *P*<.001) and 12 months (β=4.3, 95% CI 2.4-6.2; *P*<.001).

Figure 2. Adjusted marginal means (95% CI) at baseline (0 months), 6 months, and 12 months for continuous outcomes. Marginal means were estimated from adjusted population-averaged generalized estimating equation models including age, sex, comorbidity burden, relationship status, and baseline use of medication for depression or anxiety. Lower scores represent improvement for B-IPQ, PSS-10, QSC-R10, SBQ, PSQI, BMI, weight, and substance use frequency measures, whereas higher scores represent improvement for the positively scored measures. B-IPQ: Brief Illness Perception Questionnaire; FACIT-F: Functional Assessment of Chronic Illness Therapy—Fatigue scale; FACIT-SP-12: Functional Assessment of Chronic Illness Therapy—Spiritual Well-Being scale; MOS-SSS: Medical Outcomes Study Social Support Survey; PSQI: Pittsburgh Sleep Quality Index; PSS-10: Perceived Stress Scale; QSC-R10: Questionnaire on Distress in Cancer Patients; REAP-S: Rapid Eating Assessment for Participants—Shortened; SBQ: Sedentary Behavior Questionnaire; SF-12 MCS: 12-item Short Form Health Survey Mental Component Summary; SF-12 PCS: 12-item Short Form Health Survey Physical Component Summary; SWLS: Satisfaction With Life Scale; WHO-5: World Health Organization-Five Well-Being Index.

Secondary Outcomes: Multidomain Health Changes

Several secondary outcomes improved over follow-up (Table 2; Figure 2). Fatigue (FACIT-F) improved at 6 months (β=3.6, 95% CI 2.0-5.2; *P*<.001) and 12 months (β=5.0, 95% CI 3.3-6.8; *P*<.001), and sleep quality (PSQI) improved at 6 months (β=−1.8, 95% CI −2.4 to −1.2; *P*<.001) and 12 months (β=−2.2, 95% CI −2.8 to −1.5; *P*<.001). Diet quality (REAP-S) improved at 6 months (β=3.0, 95% CI 2.4-3.7; *P*<.001) and 12 months (β=2.6, 95% CI 2.0-3.3; *P*<.001), and sedentary behavior (SBQ) decreased at 6 months (β=−5.7, 95% CI −10.0 to −1.4; *P*=.01) and 12 months (β=−8.7, 95% CI −13.2 to −4.2; *P*<.001). Spiritual well-being (FACIT-SP-12) improved at 6 months (β=2.9, 95% CI 1.8-4.0; *P*<.001) and 12 months (β=4.6, 95% CI 3.0-6.2; *P*<.001). Perceived social support (MOS-SSS) increased at 6 months (β=0.2, 95% CI 0.1-0.3; *P*<.001) but was not clearly different from baseline at 12 months (β=0.1, 95% CI −0.01 to 0.21; *P*=.08). Physical health–related quality of life (SF-12 PCS) improved at 6 months (β=1.8, 95% CI 0.3-3.3; *P*=.02) with a larger improvement at 12 months (β=2.9, 95% CI 1.0-4.9; *P*=.003). Weight and BMI decreased at both follow-ups (weight, 6 months: β=−7.2 lb, 95% CI −10.4 to −4.0, *P*<.001; 12 months: β=−10.3 lb, 95% CI −15.2 to −5.4, *P*<.001; BMI, 6 months: β=−1.2, 95% CI −1.8 to −0.7, *P*<.001; 12 months: β=−1.7, 95% CI −2.5 to −0.9, *P*<.001). Alcohol frequency decreased at 6 months (Drink score β=−0.5, 95% CI −0.8 to −0.2; *P*=.002) and 12 months (β=−0.6, 95% CI −0.9 to −0.4; *P*<.001). Binge drinking frequency showed a small reduction at 6 months (β=−0.21, 95% CI −0.42 to 0.00; *P*=.047) but was not clearly different from baseline at 12 months (β=−0.03, 95% CI −0.31 to 0.26; *P*=.90), and cannabis use frequency did not show a clear change at either follow-up (6 months: β=−0.13, 95% CI −0.27 to 0.01; *P*=.06; 12 months: β=−0.12, 95% CI −0.27 to 0.02; *P*=.09). Model-estimated

RenderX

marginal means and full contrasts for all continuous outcomes are provided in Tables S5 and S6 in Multimedia Appendix 1.

Binary Clinical Threshold Outcomes

Relative to baseline, the odds of low well-being (WHO-5<50) were lower at 6 months (odds ratio [OR] 0.17, 95% CI 0.11-0.26; *P*<.001) and 12 months (OR 0.15, 95% CI 0.10-0.24; *P*<.001) (Table 3). The odds of high perceived stress (PSS-10≥20) were lower at 6 months (OR 0.31, 95% CI 0.21-0.48; *P*<.001) and 12 months (OR 0.20, 95% CI 0.13-0.33; *P*<.001). The odds of clinically elevated disease-related worry (QSC-R10>14) decreased at 6 months (OR 0.39, 95% CI 0.26-0.57; *P*<.001) and 12 months (OR 0.24, 95% CI 0.15-0.37; *P*<.001). Poor sleep (PSQI>5) decreased at 6 months (OR 0.45, 95% CI 0.30-0.68; *P*<.001) and 12 months (OR 0.33, 95% CI 0.21-0.52; *P*<.001), and high sedentary behavior (≥8 hours/day; ≥56 hours/week) decreased at 6 months (OR 0.59, 95% CI 0.39-0.89; *P*=.01) and 12 months (OR 0.43, 95% CI 0.28-0.65; *P*<.001). Obesity prevalence (BMI≥30) did not change at 6 months (OR 0.88, 95% CI 0.72-1.07; *P*=.20) or 12 months (OR 0.88, 95% CI 0.67-1.15; *P*=.30).

Table . Adjusted odds ratios (ORs) for meeting clinical threshold outcomes at 6 and 12 months vs baseline (GEE[a] models[b]).

Outcome (threshold)	OR (vs baseline), 6 months	95% CI	*P* value	OR (vs baseline), 12 months	95% CI	*P* value
Low well-being (WHO-5[c]<50)	0.17	0.11-0.26	<.001	0.15	0.10-0.24	<.001
High perceived stress (PSS-10[d]≥20)	0.31	0.21-0.48	<.001	0.20	0.13-0.33	<.001
Clinically elevated worry (QSC-R10[e]>14)	0.39	0.26-0.57	<.001	0.24	0.15-0.37	<.001
Obesity (BMI≥30)	0.88	0.72-1.07	.20	0.88	0.67-1.15	.30
Poor sleep (PSQI[f]>5)	0.45	0.30-0.68	<.001	0.33	0.21-0.52	<.001
High sedentary time (SBQ[g]≥56 hours/week)	0.59	0.39-0.89	.011	0.43	0.28-0.65	<.001

[a]GEE: generalized estimating equation.

[b]ORs represent adjusted odds ratios relative to baseline. Models were adjusted for age, sex, comorbidity burden, relationship status, and psychotropic medication use.

[c]WHO-5: World Health Organization-Five Well-Being Index.

[d]PSS-10: Perceived Stress Scale.

[e]QSC-R10: Questionnaire on Distress in Cancer Patients.

[f]PSQI: Pittsburgh Sleep Quality Index.

[g]SBQ: Sedentary Behavior Questionnaire.

Responder analyses showed clinically meaningful improvement across multiple domains (Table S7 in Multimedia Appendix 1). At 6 and 12 months, respectively, 39 of 107 (36.4%, 95% CI 27.3%-45.6%) and 46 of 106 (43.4%, 95% CI 34.0%-52.8%) participants achieved a ≥4-point reduction in perceived stress (PSS-10), while 53 of 108 (49.1%, 95% CI 39.6%-58.5%) and 47 of 108 (43.5%, 95% CI 34.2%-52.9%) achieved a ≥10-point improvement in mental well-being (WHO-5). At 12 months, clinically meaningful improvements were also observed for illness perceptions (B-IPQ; 54/108, 50.0%, 95% CI 40.6%-59.4%), disease-related worry (QSC-R10; 56/111, 50.5%, 95% CI 41.1%-59.8%), fatigue (FACIT-F; 62/109, 56.9%, 95% CI 47.6%-66.2%), physical health–related quality of life (SF-12 PCS; 60/111, 54.1%, 95% CI 44.8%-63.3%), mental health–related quality of life (SF-12 MCS; 53/111, 47.7%, 95% CI 38.5%-57.0%), and ≥3% weight loss (52/115, 45.2%, 95% CI 36.1%-54.3%).

Exploratory Analyses: Co-Occurring Changes in Candidate Factors and Psychological Outcomes

Exploratory adjusted models examined associations between changes in prespecified candidate factors and changes in psychological outcomes (Table 4). Improvements in fatigue were consistently associated with improvements in well-being, life satisfaction, perceived stress, and disease-related worry. From baseline to 6 months, improvement in FACIT-F scores was associated with improvement in WHO-5 (β=0.9, 95% CI 0.6 to 1.2; *P*<.001), SWLS (β=0.3, 95% CI 0.2-0.4; *P*<.001), PSS-10 (β=−0.4, 95% CI −0.5 to −0.3; *P*<.001), and QSC-R10 (β=−0.6, 95% CI −0.8 to −0.5; *P*<.001) scores.

[k]MOS-SSS: Medical Outcomes Study Social Support Survey.

[l]SBQ: Sedentary Behavior Questionnaire.

[m]REAP-S: Rapid Eating Assessment for Participants—Shortened.

[n]FACIT-SP-12: Functional Assessment of Chronic Illness Therapy—Spiritual Well-Being scale.

[o]B-IPQ: Brief Illness Perception Questionnaire.

Improvements in sleep quality were similarly associated with improvements across psychological outcomes. From baseline to 6 months, improvement in PSQI scores was associated with improvement in WHO-5 (β=−2.2, 95% CI −3.1 to −1.3; *P*<.001), SWLS (β=−0.8, 95% CI −1.2 to −0.5; *P*<.001), PSS-10 (β=0.8, 95% CI 0.4 to 1.1; *P*<.001), and QSC-R10 (β=1.4, 95% CI 0.9 to 1.8; *P*<.001).

More favorable illness perceptions were also associated with improvements across psychological outcomes. From baseline to 6 months, improvement in B-IPQ scores was associated with improvement in WHO-5 (β=−0.6, 95% CI −0.8 to −0.4; *P*<.001), SWLS (β=−0.2, 95% CI −0.3 to −0.1; *P*<.001), PSS-10 (β=0.3, 95% CI 0.2-0.3; *P*<.001), and QSC-R10 (β=0.4, 95% CI 0.3-0.5; *P*<.001). Similar patterns of association were observed at 12 months (Table 4). Additional exploratory associations between changes in candidate factors and psychological outcomes are reported in Tables S8 and S9 in Multimedia Appendix 1.

Exploratory Analyses: Moderators of Psychological Trajectories

Exploratory moderation analyses assessed whether baseline characteristics modified trajectories of psychological change (Table 5). Higher baseline perceived stress was associated with larger reductions in perceived stress at 12 months (time × baseline PSS-10: β=−0.4, 95% CI −0.6 to −0.3; *P*<.001) and greater improvement in well-being (time × baseline PSS-10 for WHO-5: β=0.6, 95% CI 0.2-1.1; *P*=.007). Higher baseline well-being was associated with smaller improvement in well-being (time × baseline WHO-5: β=−0.2, 95% CI −0.3 to −0.1; *P*<.001), and higher baseline life satisfaction was associated with smaller gains in life satisfaction (time × baseline SWLS: β=−0.4, 95% CI −0.5 to −0.2; *P*<.001). Baseline illness perceptions did not modify trajectories of well-being (time × baseline B-IPQ: β=0.13, 95% CI −0.10 to 0.37; *P*=.30) or perceived stress (time × baseline B-IPQ for PSS-10: β=−0.06, 95% CI −0.15 to 0.04; *P*=.20). Full interaction outputs are provided in Table S10 in Multimedia Appendix 1.

[d]B-IPQ: Brief Illness Perception Questionnaire.

[e]SWLS: Satisfaction With Life Scale.

Discussion

Principal Findings

This secondary analysis of PictouCountyPEP found sustained improvements across multiple psychological, behavioral, and physical health domains over 12 months in rural adults living with chronic conditions. Improvements were observed across all primary psychological outcomes and were accompanied by favorable changes in fatigue, sleep, diet quality, sedentary behavior, spiritual well-being, and mental health–related quality of life. Exploratory analyses further suggested that psychological improvements co-occurred with changes in fatigue, sleep, illness perceptions, social support, and spiritual well-being, pointing to plausible multidomain pathways through which digital self-management interventions may influence well-being over time.

Exploratory analyses further showed that improvements in several candidate factors, notably fatigue, sleep quality, illness perceptions, social support, and spiritual well-being, were associated with improvements in psychological outcomes. These patterns of co-occurring improvement may help identify candidate multidomain pathways for future investigation but should not be interpreted as evidence of statistical mediation or causal mechanisms. Establishing whether these factors mediate intervention-related psychological outcomes will require an appropriate temporal and causal analytic framework, ideally within a controlled study designed prospectively to test these pathways.

Social support and binge drinking frequency were less clearly improved at 12 months, and improvements in diet quality were somewhat attenuated, but the overall pattern remained favorable. Binary threshold and responder analyses were broadly concordant with the continuous outcome models. Obesity status was the main exception: although the odds of meeting the binary obesity threshold did not change, continuous BMI and weight outcomes improved, as did responder analyses based on clinically meaningful weight loss. Program engagement, adherence, and acceptability have been reported elsewhere and are therefore not repeated here [20].

These findings contribute to the growing literature on digital health interventions for chronic disease self-management in community settings [53]. Importantly, this study evaluated the program under real-world delivery conditions rather than within a tightly controlled clinical trial environment. Participants accessed the intervention remotely using their own devices, engagement occurred asynchronously, and optional components were used flexibly. These characteristics provide context for interpreting the observed outcomes and for future evaluation of feasibility, accessibility, and acceptability in routine community settings [53]. Such implementation-oriented evidence is particularly relevant for digital health interventions intended to reach geographically dispersed populations [20,53].

The sustained psychological improvements observed at 12 months contrast with several recent systematic reviews and meta-analyses of digital interventions, which commonly report attenuation of mental health effects over time. For example, digital behavioral activation interventions have shown reductions in depressive symptoms at shorter follow-up, but no significant

XSL•FO
RenderX

pooled benefit at 12 months; pooled anxiety outcomes were not significantly improved at the assessed follow-up points [54]. Digital peer support interventions have similarly demonstrated weaker mental health effects with longer follow-up [55], and digital exercise interventions have shown improvements at the end of the intervention that are not consistently maintained at later follow-up [56]. By contrast, psychological improvements in PictouCountyPEP remained evident at 12 months, during the lower-intensity maintenance period. Although direct comparisons across interventions and follow-up designs should be made cautiously, these findings suggest that comprehensive, multicomponent approaches warrant further evaluation for their potential to support longer-term psychological benefits. These findings complement evidence that interventions targeting multiple health behaviors can support chronic disease management [11] and indicate a need to evaluate their longer-term psychological outcomes.

The durability of effects may also reflect intervention design choices intended to reduce common barriers to digital engagement in rural settings, including low-bandwidth delivery, brief daily content, and minimal onboarding requirements [57]. Although engagement mechanisms were not directly tested in the present study, this microdose format may support habit formation and continued participation among individuals managing fluctuating symptoms and competing life demands [58]. These findings are also relevant to the well-described mismatch between health care systems historically oriented toward acute, reactive care and the proactive, ongoing support required for effective chronic disease self-management [59,60]. Many determinants most closely linked to symptom burden and progression unfold between clinical encounters, including sleep disruption, fatigue, stress, dietary patterns, social connection, and illness perceptions [60]. In this context, PictouCountyPEP may function as a low-burden adjunct that supports daily self-regulation and patient capability in routine living, complementing rather than replacing biomedical care.

Exploratory moderation analyses addressed an important question for digital self-management programs: for whom do these interventions appear to work best? Participants with higher baseline perceived stress experienced larger reductions in stress and greater improvements in well-being over 12 months, whereas those with higher baseline well-being or life satisfaction showed smaller gains in those same domains. This pattern suggests that the program may confer greater benefit among individuals with greater baseline psychological need. We found no consistent evidence that demographic characteristics substantially altered psychological trajectories, although these exploratory analyses may have been underpowered to detect smaller subgroup differences.

The exploratory mechanistic analyses point to several plausible pathways through which psychological improvement may occur. One pathway may involve modification of upstream cognitive processes, including illness perceptions that shape coping and behavioral responses, consistent with Leventhal's common-sense model of self-regulation [61]. Another may reflect increased engagement in meaningful, reinforced daily activities supported by social connection and sustained routines, aligning with behavioral activation frameworks [62]. More broadly, the observed pattern is consistent with interdependent changes across energy, sleep, cognition, and social resources that collectively support psychological recovery [61-63]. These findings extend earlier work on Prostate Cancer Patient Empowerment Program (PC-PEP), in which self-efficacy and illness perceptions explained improvements in psychological distress [64]. However, these analyses are exploratory and should not be interpreted as evidence of causal mediation. Future studies should formally test these candidate pathways using longitudinal mediation models or experimental designs.

Although this study was not designed to assess disease incidence, the improvements observed across stress, sleep, diet quality, sedentary behavior, and social support are relevant to secondary prevention in chronic disease. These domains represent potentially modifiable targets relevant to chronic disease self-management and health [60,65]. Future controlled studies with longer follow-up should examine whether these changes translate into downstream clinical outcomes, multimorbidity accumulation, or health service use.

Beyond the observed health improvements, PictouCountyPEP builds on a digital delivery model already implemented in PC-PEP across Canada and internationally. The program delivers core content through automated email prompts and brief asynchronous video modules, limiting the need for clinicians to deliver individual sessions. An international phase 4 implementation trial of PC-PEP reported similar follow-up completion across rural and urban participants, high program acceptability, and sustained improvements in mental health [66]. This implementation experience supports the scalability of the delivery model and provides a foundation for extending it to rural chronic disease self-management. Broader implementation of PictouCountyPEP should build on this experience while accounting for local digital access, staffing arrangements, and integration with existing services [57,67].

From a health system perspective, scalable self-management programs that can be delivered at low cost and without reliance on specialized personnel are of increasing interest, particularly in rural and resource-constrained settings [66,68]. An economic evaluation within the PC-PEP randomized controlled trial estimated program delivery costs of CAD $200.07 (CAD $1=US $0.73 as of August 29, 2025) per participant and found that early delivery improved outcomes while lowering overall health care costs [68]. These findings provide an economic rationale for broader implementation of the delivery model. A formal cost-effectiveness analysis of PictouCountyPEP from the health care system perspective is currently underway to assess downstream resource use and longer-term value. These findings also have implications for how digital self-management programs could be integrated into chronic disease care pathways. In many health systems, patients with multimorbidity receive episodic clinical care but limited ongoing behavioral or psychosocial support between visits [59,60]. Digital empowerment programs may complement traditional care by providing continuous, low-intensity behavioral guidance that patients can access independently. For primary care teams serving rural populations, such programs could function as an adjunct resource that reinforces lifestyle recommendations, supports stress regulation, and promotes patient activation

XSL•FO
RenderX

without substantially increasing clinical workload. Work is currently underway in collaboration with Nova Scotia Health to explore potential implementation pathways for the program within existing care structures. Together with the ongoing cost-effectiveness analysis, these efforts aim to determine whether digitally delivered self-management programs can offer a sustainable and cost-efficient complement to traditional chronic disease care models.

Nursing and Primary Care Implications

Although PictouCountyPEP was not designed as a nurse-delivered intervention, its asynchronous, home-based structure has potential implications for nursing and primary care practice in rural settings. Nurse-led remote digital approaches have been used to support adults with chronic conditions through health education, remote support, monitoring, and other forms of digitally enabled care [69]. More broadly, digital interventions are increasingly being evaluated as adjuncts to chronic disease self-management, although their effectiveness varies across conditions, intervention components, and self-care domains [65]. Rather than requiring nurses to deliver the intervention content directly, a program of this type could provide a standardized adjunct to health education and self-management support, with nurses and other primary care professionals potentially identifying appropriate patients, reinforcing individualized self-management goals, recognizing emerging needs during routine encounters, and directing patients to additional clinical or community services when required. This model may be particularly relevant in settings where clinical time and access to specialized chronic disease services are constrained because the core educational and behavioral content is delivered outside the clinical encounter and does not require continuous clinician involvement [69].

These implementation questions are particularly relevant in the present rural context: at baseline, 19 of 182 (10.4%) participants reported receiving primary care from another provider such as a nurse practitioner, while 46 of 182 (25.3%) participants reported having no regular primary care provider (Table S3 in Multimedia Appendix 1). Importantly, however, these potential nursing and primary care roles were not evaluated in the present study. Future implementation research should examine how referral to digital self-management programs can be incorporated into rural primary care and nursing workflows, including which patients are most appropriate for referral, whether some patients require additional adherence or digital navigation support, and whether integration can extend self-management support without increasing clinical workload.

Limitations

This study has several limitations. First, the study was conducted in a single, predominantly rural region, and the sample was predominantly female (85.2%) and White (96.2%), limiting generalizability to men and more ethnoculturally diverse populations. Eligibility also required English proficiency and access to the internet and email; consequently, the findings cannot be assumed to generalize to non–English-speaking populations or to individuals experiencing greater barriers to digital access or with lower digital health literacy. Although the intervention was intentionally designed for low-bandwidth delivery and did not require specialized applications, wearable devices, or synchronous participation, these design features do not eliminate potential digital access or digital literacy barriers. Generalizability to other rural regions may also depend on local sociodemographic characteristics, health care access, digital infrastructure, and community resources [57,67]. Similarly, the findings should not be assumed to apply directly to urban populations, where health service availability, referral pathways, and opportunities for in-person chronic disease support may differ. Evaluation in more diverse populations and geographic settings is therefore needed. Second, the single-arm design precludes causal attribution of the observed longitudinal changes to PictouCountyPEP. Without a concurrent control group, changes associated with natural disease trajectories, secular or time effects, regression to the mean, unmeasured co-interventions, and residual confounding cannot be separated from changes occurring during program participation. Although covariate adjustment and sensitivity analyses strengthen the assessment of longitudinal associations, they do not overcome this design limitation. Future randomized controlled trials should evaluate the efficacy of PictouCountyPEP relative to an appropriate comparator and determine whether the observed multidomain changes are attributable to the intervention. Third, all outcomes were self-reported and may therefore be subject to recall, reporting, and social desirability biases. The study also did not assess longer-term clinical or health service outcomes, such as hospitalization or mortality; consequently, the observed changes in patient-reported outcomes should not be interpreted as evidence of effects on these outcomes. Fourth, participants with incomplete follow-up had lower baseline well-being and life satisfaction, raising the possibility of attrition-related bias. However, none of the included variables was significantly associated with incomplete follow-up in the adjusted model, and the primary findings were consistent in complete case and weighted sensitivity analyses. Fifth, because multiple outcomes and exploratory analyses were examined without formal adjustment for multiple comparisons, some statistically significant findings may reflect chance. Accordingly, secondary and exploratory findings should be interpreted with caution, with emphasis on consistency and effect size rather than statistical significance alone. Finally, responder analyses were only possible for measures with available thresholds for meaningful change; for some outcomes, such thresholds remain poorly defined in general chronic disease populations. Future research should prioritize the development and validation of clinically meaningful benchmarks across relevant outcomes in chronic disease settings. Notwithstanding these limitations, strengths of the study include its comprehensive multidomain scope, use of validated instruments, prospective longitudinal design, and analytic approach incorporating all available observed outcome data, supported by complete case and inverse probability–weighted sensitivity analyses.

Conclusion

PictouCountyPEP is a digitally delivered self-management program associated with sustained improvements across multiple psychological, behavioral, and physical health domains in rural adults living with chronic conditions. These findings suggest that low-burden, multicomponent digital interventions may

XSL•FO
RenderX

support sustained improvements in mental well-being alongside favorable changes in related behavioral and psychosocial outcomes. The program's low-bandwidth, asynchronous delivery model highlights its potential scalability and relevance for rural and underserved populations, where access to ongoing behavioral and psychosocial support is limited. By addressing shared, upstream determinants of chronic disease across conditions, digitally delivered self-management programs may complement traditional care by extending support into patients' daily lives without increasing clinical workload. Future research should evaluate long-term clinical and health system outcomes, including health service use and cost-effectiveness, and prospectively test the candidate pathways suggested by these exploratory analyses to inform intervention optimization and implementation at scale.

Abstract

Background: Smartphone-delivered travel-record and health-code systems were deployed across China during the COVID-19 pandemic to classify risk based on travel history and regulate access to venues and travel. The geographic classification rule is a key design choice for these systems. A city-boundary rule (city-cut) is administratively convenient but may group areas with different mobility patterns under one risk label, whereas a fixed-radius rule (radius-cut) offers greater spatial precision but may exclude more distant areas connected by routine travel. Whether a classification rule aligns with observed mobility is a design question distinct from evaluating a deployed system's epidemiological effects.

Objective: This study examined whether observed mobility in Shanghai supported a city-cut or a radius-cut geographic design for a mobile health travel-record system and whether mobility-derived communities corresponded to administrative districts.

Methods: We conducted a retrospective observational analysis of 1.44 billion deidentified China Unicom mobility records collected for two 46-day periods in 2019 and 2020. The analytical unit was the daily origin-area movement proportion. We calculated within-Shanghai, confirmed external-city, and nonadjacent-district movement proportions; for each origin area, we paired them by calendar day. We constructed grid-level transition matrices, used spectral clustering followed by k-means++, and checked the groupings across repeated initializations and selected dates.

Results: Across 46 daily city-average observations in 2019, the intracity proportion was 97.2% (95% *t* CI 97.1% - 97.3%). Nonadjacent-district movement was 13.7% (95% *t* CI 13.5% - 13.9%), compared with 2.8% (95% *t* CI 2.7% - 2.9%) for confirmed external-city movement. A paired, 2-tailed Newey-West heteroskedasticity- and autocorrelation-consistent (HAC) *t* test (α=.05) gave a mean difference of 10.9 (95% HAC CI 10.7 - 11.1; *P*<.001) percentage points. At the Chongming border, the corresponding difference was –3.1 (95% HAC CI –4.1 to –2.1; *P*<.001) percentage points.

Conclusions: This study moves the question from postdeployment evaluation to predeployment design, treating geographic calibration as an upstream mobile health decision. It differs from prior work that assessed uptake, privacy, or epidemiological outcomes after fielding, and from mobility research that treated movement data as a predictor, an outcome, or a model input rather than as a criterion for choosing a boundary rule. The contribution is threefold: it formulates a boundary-fit question that can be answered before a system is built; it provides a reproducible, auditable workflow (daily origin-area proportions, a paired HAC-based comparison, and a mobility-clustering check) that agencies and developers can rerun on their own data; and it demonstrates the workflow from end to end in a large municipality. Practically, a city-level unit is a defensible starting reference where movement is predominantly internal, whereas border areas warrant separate local assessment. Agencies should document where a boundary fits local movement and where exceptions may be needed. Decisions about restrictions also require epidemiological evidence and assessment of proportionality, public acceptability, and social costs.

Introduction

During the COVID-19 pandemic in mainland China, health-code and travel-record systems used smartphone-delivered information to regulate access to venues and travel [1-3]. These systems made the choice of geographic unit consequential: a city-level risk label could affect people whose recorded travel history included that city. Location-based digital health tools also raised concerns about privacy, consent, and governance [1,4-9]. A central design question is the spatial scale at which a travel-history system should assign a risk label. An administrative city boundary is simple to communicate and implement, whereas a fixed-radius rule is geographically narrower [1-3]. The best fit depends partly on how people move across and within the relevant boundaries. A broad label can encompass places with different movement patterns, while a narrow label can divide locations connected by routine travel. The design task is therefore to make the geographic assumption explicit and assess its consistency with observed connectivity before using it to classify travel histories.

We examine this question using mobility data from Shanghai, China. Shanghai is a large and internally heterogeneous municipality with 16 districts [10]. The city provides a useful comparison between a city boundary and a fixed-radius rule: residents may live far from an index location within Shanghai, while some locations just beyond the municipal boundary may be geographically close. This setting makes it necessary to distinguish geographic distance from membership in the same administrative unit. Examining the city as a whole, alongside areas near its municipal boundary, can reveal whether an aggregate pattern obscures local differences. The internal district structure also provides an administrative reference against which to consider functional mobility regions. We evaluate both designs against observed mobility without assuming that either applies universally.

First, we ask whether observed movement within Shanghai is more frequent than confirmed movement to other cities, including for border-origin areas. Second, we ask whether movement between nonadjacent Shanghai districts is substantial and more frequent than confirmed external-city movement, including for border-origin areas. We refer to these as the intracity and nonadjacent-district comparisons. The first concerns how much recorded movement remains within the proposed city unit. The second concerns connectivity across more widely separated parts of that unit, which is relevant to whether a geographically narrow label would capture the scale of routine movement. Border-origin areas are especially informative because proximity to another jurisdiction may weaken the fit of a uniform municipal label. Both comparisons describe mobility; neither tests infection transmission nor intervention effectiveness. These questions connect work on digital public-health systems with research on mobility and epidemic spread [11].

Location-based digital public-health tools, including digital contact tracing, geofenced quarantine monitoring, and travel-record systems, became prominent components of COVID-19 governance [12-14]. Mobile health (mHealth) scholarship identifies client registration, tracking of vital events, and data collection as core application types [15]. A scoping review distinguishes contact tracing and location-based risk assessment from population-level outbreak detection and mobility tracking [14]. This distinction helps locate the present question within digital public health: the geographic rule used to summarize a travel history should be evaluated in relation to that function, without treating it as a measure of individual contact or infection. Prior evaluations have examined adoption and epidemiological outcomes after deployment [7,16-19], while work on health-code systems has emphasized their operational and governance implications [1-3,6,20,21]. Studies in this literature show that design and governance shape how digital systems operate [6,8,9], but seldom test the geographic unit that determines who will be flagged before the system is deployed. Selecting the boundary before deployment differs from estimating whether a deployed tool changed infection outcomes. The question is whether a proposed spatial boundary fits observed mobility at the scale the system is intended to manage.

Large-scale mobile-phone datasets have been used to characterize human mobility during the COVID-19 pandemic, study the effects of movement restrictions, and inform public-health action [11,22-31]. Related research has examined spatial connectivity and the role of movement in infectious-disease models [32-36]. Work on the public-health use of mobile-phone data also emphasizes the need to match data and analysis to the decision being supported, while addressing access, coordination, and privacy constraints [26]. For a travel-record system, the relevant design question is whether the chosen unit captures observed connections within its boundary and distinguishes them from connections across it. This application requires an explicit link between a mobility measure and the geographic classification decision it is intended to inform. These studies generally treat mobility as a predictor, an outcome, or a model input rather than as evidence for choosing the geographic boundary of a digital travel-record system.

Network studies also show that interaction data can delineate functional regions that may differ from administrative borders [37,38]. Such functional regions summarize interaction patterns and provide a way to examine whether administrative divisions align with those patterns [37,38]. Alignment would support their use as an operational reference, whereas divergence would identify places where classification or coordination may require closer attention. Neither outcome alone establishes an appropriate restriction because a mobility partition and a public-health decision serve different purposes. Community-detection and spectral-clustering methods [39-42] can inform boundary design: mobility-based clustering can be compared with official geography, while aggregate movement shares can measure movement within and across a proposed

XSL•FO
RenderX

unit. Mobility evidence cannot resolve legal, ethical, or epidemiological questions, but it can make the assumptions behind a geographic rule explicit.

To examine this design question, we use deidentified, aggregated Shanghai mobile-phone mobility records. We evaluate city-cut and radius-cut designs using daily intracity, confirmed external-city, border-origin, nonadjacent-district, and center-bound movement proportions. We also apply a prespecified spectral clustering procedure to assess how closely the resulting communities correspond to district boundaries. This approach evaluates geographic calibration before deployment and complements postdeployment evaluations of digital interventions. The study objectives are to assess whether within-city and nonadjacent-district mobility patterns in municipal-border areas support the use of a city-level geographic unit and to examine the correspondence between mobility-derived communities and administrative districts.

Methods

Study Context and Setting

This study evaluates the geographic design of China's antipandemic travel-record card system in the Shanghai setting. The record card was a smartphone-based travel-history credential that displayed cities visited during the previous 14 days and could trigger restrictions when a listed city was classified as medium or high risk. Figure 1 illustrates the card interface used to communicate these city-level risk labels. Shanghai was selected because it is a large, highly connected municipality bordered by several major neighboring cities, making it a useful case for comparing city-cut and radius-cut risk classification. Figure 2 shows Shanghai's district structure and surrounding cities, which define the geographic context for the mobility analysis.

Research Design

This was a retrospective observational secondary-data study. It involved no intervention allocation, randomization, or follow-up of individual participants. All conditions were naturally observed; the investigators did not manipulate mobility conditions or assign individuals or geographic areas to groups. The design comprised repeated daily observations during 2 prespecified 46-day windows in 2019 and 2020, as well as comparisons across naturally occurring geographic origin areas and movement categories.

Data Collection Procedures

China Unicom processed and deidentified the supplied operator records before author access was granted. The authors received aggregated records for the prespecified 2019 and 2020 study windows and applied the documented visit, movement, and daily origin-area aggregation procedures.

Inclusion and Exclusion

No participants were recruited. The provider preprocessed and deidentified the records before they were accessed by the authors. All supplied records within the study windows were used; the authors did not apply individual-level inclusion or exclusion criteria.

Unit of Analysis and Data Characteristics

The unit of analysis was a daily origin-area movement proportion, not an individual participant. The study used deidentified, aggregated movement records and did not collect

XSL•FO
RenderX

participant characteristics. The data did not contain individual names, phone numbers, device identifiers, or individual-level trajectories.

Sampling Procedures

The dataset was supplied by China Unicom for the specified study windows in Shanghai. It is an operator-based data source rather than a probability sample of Shanghai residents. All obtained records were retained after provider deidentification and the documented movement-construction procedures.

Sample Size, Power, and Precision

No a priori power analysis was performed because the analysis used all supplied aggregate records. Precision is reported using 2-tailed 95% *t* CIs for the mean of daily origin-area proportions across 46 days, based on day-to-day variation, with heteroskedasticity- and autocorrelation-consistent (HAC) intervals used as a serial-correlation-robustness analysis.

Measures and Covariates

The prespecified mobility measures were intracity movement, confirmed external-city movement, nonadjacent-district movement, center-bound movement, and border-origin status. Administrative-district, center-area, and municipal-border labels were assigned through the grid crosswalk. No participant-level covariates were available or analyzed.

Data Quality and Missing Data

No unavailable origin or destination codes were used in the analysis. State 9999 represented confirmed external-city journeys rather than missing geography, and no imputation was performed.

We obtained proprietary, deidentified, aggregated mobile-phone signaling records from China Unicom, a major Chinese mobile service provider. The data provide a large operator-based mobility dataset, but we do not assume that China Unicom subscribers represent the overall Shanghai population. This potential coverage bias is addressed as a study limitation.

China Unicom's deidentified mobile-phone signaling records capture device connections to base stations, which were used to reconstruct aggregated daily visits and movement segments. The dataset covers all records supplied for Shanghai from October 10 to November 24, 2019, and the corresponding dates in 2020. The movement-location records used in the analysis did not include records with missing origin or destination codes. Confirmed movements outside Shanghai were instead represented by the external-city state (9999).

Based on suggestions from location-tracking experts at China Unicom, we used the following settings:

The map of Shanghai was divided into 2213 grid units of 2 km × 2 km. If a device remained continuously in a grid for more than 30 minutes, we counted this as a visit to that grid. This 30-minute threshold was used to exclude brief pass-through observations, such as travel by car or train, without a substantive stay. When a device had 2 consecutive visits (eg, grid A followed by grid B), we counted this as a movement from grid A to grid B. If a device left Shanghai and remained in another city for more than 30 minutes, we used its last observed grid in Shanghai (eg, grid A) and counted this as a movement from grid A to another city. This counting procedure was repeated for each calendar day.

If a device stayed in 1 grid (eg, grid A) throughout a calendar day, we counted this as local movement within grid A.

In total, the supplied dataset contained 1.44 billion observed movement segments. The main text reports the 2019 baseline results, and Multimedia Appendix 1 reports the parallel 2020 analysis.

Data preprocessing followed a clean-append-merge workflow implemented in Stata (StataCorp LLC). Outbound Shanghai journeys were aggregated by day and origin grid and coded with the confirmed external-city destination state (9999); inbound journeys were aggregated by day and destination grid and coded with the confirmed external-city origin state (9999). These records were appended to within-Shanghai grid-to-grid movements. The 30-minute active-population file was merged by day and origin grid, and movement probability was calculated as prob = wnumpop30, where wnum is the movement count and pop30 is the corresponding 30-minute active population. Each movement record carried an origin and a destination grid identifier (s_{fnid} and e_{fnid}), where *fnid* is the numeric code of a 2-km grid cell. The reserved value 9999 denotes the external-city state rather than a Shanghai grid. For inbound records originating outside Shanghai (s_{fnid}=9999), the external-state denominator was set using the archived population-scaling rule; outbound records leaving Shanghai (e_{fnid}=9999) retained the 30-minute active-population denominator of their Shanghai origin grid. For reproducibility, the fixed external-city denominator used for inbound records (s_{fnid}=9999) was constructed by scaling the total Shanghai grid active population by the ratio of the population outside Shanghai to the Shanghai population; the formula, parameter values, and reference date are provided in Multimedia Appendix 1. Finally, origin and destination grids were merged with the grid-to-administrative-region crosswalk and the center-area, border-band, and external-city labels.

Visit histories were processed for each calendar day. A stay of more than 30 minutes in a 2 km × 2 km grid was treated as a visit. Two consecutive visits generated 1 directed movement segment. A day with no grid change was counted as a local movement. A device observed to leave Shanghai and remain in another city for more than 30 minutes was recorded from its last Shanghai grid to a confirmed external-city state; this coding did not denote missing data.

Statistical Analysis

We defined 4 movement types: intra was movement within Shanghai, including local movement; inter was movement to the confirmed external-city state; intra ld was movement between nonadjacent Shanghai districts; and intra tc was movement toward one of the 7 central districts (Changning, Hongkou, Huangpu, Jing'an, Putuo, Xuhui, and Yangpu).

The analytical unit was the daily origin-area proportion. For every district, border-origin area, and city-average series, we reconstructed 46 calendar-day proportions and reported their

XSL•FO
RenderX

mean with a conventional 2-tailed 95% *t* CI, calculated from the same 46 daily proportions. As a robustness analysis for possible serial correlation across consecutive days, we also calculated Newey-West HAC intervals from an intercept-only model with lag 3, selected by the conventional rule 4(N100)29 for *N*=46 [43]. The HAC results were substantively consistent with the conventional 95% *t* CIs. Hypothesis comparisons used a paired, 2-tailed Newey-West HAC *t* test of the 46 daily differences, d_t=Intra ld_t-$Inter_t$, with null mean (d_t)=0 and α=.05. Movement segments were not treated as independent observations. Inference was based on the 46 ordered daily proportions; the HAC analysis allowed heteroskedasticity and autocorrelation through lag 3.

For a daily proportion series, the conventional interval was calculated as x− ± t0.975,45s46, where x- is the mean of the 46 daily proportions and s is their SD. It is therefore a conventional descriptive interval based on day-to-day variation, not an individual-movement sampling interval. The Newey-West HAC covariance estimator adjusts the estimated uncertainty for heteroskedasticity and autocovariances through lag 3, reducing reliance on independence of adjacent daily proportions; it was reported as a robustness analysis rather than as proof that all temporal dependence had been removed [43,44].

City-border areas were defined as grids within Shanghai's boundary districts that were within 8 km, equivalent to four 2-km grid units, of the municipal boundary. This definition is used consistently throughout the main analysis and in Multimedia Appendix 1. We then repeated the movement-proportion calculations for movements originating within these border areas.

The intracity long-distance metric is an operational measure of nonadjacent-district connectivity, not proof of a direct, nonstop trip. Because visits are recorded only after a stay of more than 30 minutes, a segment may include short, unrecorded pass-through travel, including through central areas. Conversely, a stay of more than 30 minutes in an intermediate grid splits a journey into separate segments.

Cluster Analysis

We explored whether the tested mobility-clustering specification produced an administratively interpretable subcity partition. This was an exploratory analysis: it assessed the correspondence of a specified clustering procedure to district geography, rather than adjudicating among all possible subcity classifications.

We used a spectral Markov-chain clustering approach [41,42]. The primary input was the October 10, 2019, Shanghai grid-level transition dataset, with 2213 Shanghai grid states plus the confirmed external-city state (9999). We summed repeated origin-destination edges, constructed a sparse off-diagonal transition matrix from observed probabilities, and assigned the residual probability to each diagonal stay entry. States with no observed off-diagonal movement were removed, and the reduced row-stochastic matrix was rebuilt before eigendecomposition. We computed 8 eigenvectors using eigs(T2,8,'largestabs') and clustered the real-valued second eigenvector. The primary specification used *k*=16. In an audited reimplementation, k-means++ initialization, Lloyd iterations (maximum 1000), 100 restarts per seeded fit, and 50 fixed seeds (5000 initializations) were used. We also examined a 46-day transition-probability average and selected daily matrices across the 2019 and 2020 windows. Repeated fits were stable to initialization, but the tested specifications showed only partial and spatially heterogeneous correspondence with districts; they did not exactly reproduce the district partition and do not rule out other subcity classifications.

Ethical Considerations

This study used secondary, deidentified, and aggregated mobile-phone signaling records provided by China Unicom under data-use and privacy restrictions. The authors did not recruit participants; interact with individuals; or access names, phone numbers, device identifiers, or individual-level trajectories. An institutional ethics review was not required for this secondary analysis because the dataset available to the authors had been deidentified before analysis, and all results are reported only as aggregated district-level, border-area, or grid-cluster summaries. No additional informed consent was obtained for this secondary analysis, and no compensation was provided because there was no participant recruitment or direct participation. The article, figures, and supplementary materials do not contain identifiable individual/user information.

Results

Unit of Analysis and Participant Flow

No participants were recruited or followed. The analytical flow comprised provider-supplied, deidentified movement records, daily origin-area aggregation, construction of 46 daily proportions for each series, and summary and paired comparison of those proportions.

Recruitment

The study used secondary deidentified aggregate data and involved no recruitment, enrollment, or participant compensation.

Statistics and Data Analysis

The exact inferential procedure, analytical unit, number of daily observations, pairing, sidedness, conventional 95% *t* CIs, and HAC robustness analysis are reported in the *Statistical Analysis* subsection. Tables 1 and 2 present the reconstructed means and conventional 95% *t* CIs.

Table . Movement proportions by Shanghai origin district, 2019.[a]

District	Intra[b] (%), mean (95% CI)	Inter[c] (%), mean (95% CI)	Intra ld[d] (%), mean (95% CI)	Intra tc[e] (%), mean (95% CI)
Baoshan	98.2 (98.2 - 98.3)	1.8 (1.7 - 1.8)	14.8 (14.5 - 15.1)	15.2 (14.8 - 15.7)
Changning	98.0 (97.8 - 98.1)	2.0 (1.9 - 2.2)	24.3 (24.1 - 24.5)	18.6 (18.5 - 18.8)
Chongming	93.7 (93.6 - 93.8)	6.3 (6.2 - 6.4)	11.2 (10.8 - 11.5)	3.9 (3.7 - 4.0)
Fengxian	99.0 (99.0 - 99.1)	1.0 (0.9 - 1.0)	4.7 (4.6 - 4.8)	3.3 (3.2 - 3.4)
Hongkou	98.5 (98.3 - 98.7)	1.5 (1.3 - 1.7)	15.1 (14.7 - 15.4)	19.3 (18.9 - 19.7)
Huangpu	98.5 (98.4 - 98.6)	1.5 (1.4 - 1.6)	23.4 (23.2 - 23.6)	18.0 (17.8 - 18.2)
Jiading	95.0 (94.9 - 95.0)	5.0 (5.0 - 5.1)	10.7 (10.6 - 10.8)	11.4 (11.2 - 11.7)
Jing'an	98.5 (98.4 - 98.6)	1.5 (1.4 - 1.6)	19.5 (19.3-19.7)	19.0 (18.7 - 19.2)
Jinshan	94.7 (94.6 - 94.8)	5.3 (5.2 - 5.4)	9.9 (9.7 - 10.1)	3.5 (3.3 - 3.6)
Minhang	97.6 (97.5 - 97.8)	2.4 (2.2 - 2.5)	10.7 (10.4 - 10.9)	13.1 (12.8 - 13.4)
Pudong	98.1 (98.0 - 98.1)	1.9 (1.9 - 2.0)	10.1 (9.9 - 10.2)	11.0 (10.7 - 11.2)
Putuo	96.4 (96.1 - 96.6)	3.6 (3.4 - 3.9)	21.5 (21.1 - 21.8)	18.6 (18.3 - 19.0)
Qingpu	91.8 (91.4 - 92.2)	8.2 (7.8 - 8.6)	13.3 (13.1 - 13.4)	8.2 (8.1 - 8.3)
Songjiang	98.2 (98.1 - 98.2)	1.8 (1.8 - 1.9)	11.4 (11.2 - 11.6)	7.1 (6.9 - 7.2)
Xuhui	98.7 (98.6 - 98.7)	1.3 (1.3 - 1.4)	17.2 (17.0 - 17.5)	19.0 (18.6 - 19.4)
Yangpu	99.0 (98.9 - 99.1)	1.0 (0.9 - 1.1)	18.1 (17.8 - 18.5)	18.8 (18.4 - 19.1)
City average	97.2 (97.1 - 97.3)	2.8 (2.7 - 2.9)	13.7 (13.5 - 13.9)	12.6 (12.4 - 12.9)

[a]Values are means (conventional 95% *t* CIs) of 46 daily origin-area proportions. Corresponding Newey-West heteroskedasticity- and autocorrelation-consistent CIs, which allow for serial correlation across days, were evaluated as a robustness analysis.

[b]Intra: movements within Shanghai, including local movements.

[c]Inter: confirmed movements to the external-city state.

[d]Intra ld: movements between nonadjacent Shanghai districts.

[e]Intra tc: movements toward the 7 central districts.

Table . Movement proportions by Shanghai municipal-border origin area, 2019.[a]

Area	Intra[b] (%), mean (95% CI)	Inter[c] (%), mean (95% CI)	Intra ld[d] (%), mean (95% CI)	Intra tc[e] (%), mean (95% CI)
Baoshan city border	92.0 (91.9 - 92.1)	8.0 (7.9 - 8.1)	10.7 (10.6 - 10.9)	5.3 (5.2 - 5.5)
Chongming city border	84.6 (84.3 - 84.9)	15.4 (15.1 - 15.7)	12.3 (11.9 - 12.7)	4.2 (4.0 - 4.5)
Jiading city border	91.4 (91.3 - 91.5)	8.6 (8.5 - 8.7)	10.3 (10.2 - 10.4)	8.9 (8.8 - 9.0)
Jinshan city border	93.3 (93.2 - 93.4)	6.7 (6.6 - 6.8)	11.4 (11.2 - 11.6)	4.1 (3.9 - 4.2)
Qingpu city border	90.7 (90.5 - 90.8)	9.3 (9.2 - 9.5)	10.3 (10.1 - 10.4)	5.8 (5.7 - 5.8)
City average	91.0 (90.9 - 91.1)	9.0 (8.9 - 9.1)	10.8 (10.6 - 11.0)	6.1 (6.0 - 6.2)

[a]Values are means (conventional 95% *t* CIs) of 46 daily origin-area proportions. Corresponding Newey-West heteroskedasticity- and autocorrelation-consistent CIs, which allow for serial correlation across days, were evaluated as a robustness analysis.

[b]Intra: movements within Shanghai, including local movements.

[c]Inter: confirmed movements to the external-city state.

[d]Intra ld: movements between nonadjacent Shanghai districts.

[e]Intra tc: movements toward the 7 central districts.

Ancillary Analyses

Ancillary analyses applied the same daily proportion workflow to a parallel 2020 window and examined the 46-day average and selected daily transition matrices. These analyses were used to assess the robustness of descriptive mobility and clustering patterns across dates.

Adverse Events

This secondary analysis involved no interventions, participant recruitment, or participant-facing study procedures.

XSL•FO
RenderX

Table 1 reports mean daily mobility proportions for each origin district, and Table 2 reports the same quantities for movements originating in the 8-km municipal border band. Parentheses contain conventional 95% *t* CIs, based on 46 daily proportions rather than SDs. HAC intervals using the same daily series were examined as a serial-correlation-robustness analysis. The long-distance measure captures nonadjacent-district connectivity at the grid-day resolution and should not be interpreted as evidence that every movement was nonstop.

Across the 16 districts in 2019, intracity movement proportions exceeded 90%; the city average was 97.2% (conventional 95% *t* CI 97.1% - 97.3%). The city-average intracity long-distance proportion was 13.7% (conventional 95% *t* CI 13.5% - 13.9%), compared with 2.8% (conventional 95% *t* CI 2.7% - 2.9%) for confirmed external-city movement.

For district-origin series, the paired mean difference between intracity long-distance and external-city movement was positive in every district and at the city average. The city-average difference was 10.9 (95% HAC CI 10.7 - 11.1; 2-tailed paired HAC *t* test $P<.001$) percentage points. The 2019 border-origin results were also positive except in Chongming, where external-city movement was more frequent than nonadjacent-district movement. The corresponding 2020 city-border average was not different from 0 (mean difference –0.1 percentage points, 95% HAC CI –0.3 to 0.1; $P=.52$), with negative differences in Chongming and Jiading. These exceptions qualify the citywide pattern and motivate local assessment near municipal boundaries.

The border-origin analysis is interpreted with deliberate caution. Chongming is geographically distinct, and its border-origin series had more confirmed external-city movement than nonadjacent-district movement in 2019. Therefore, border-area results do not support a uniform inference for every municipal edge.

Taken together, the movement results provide mobility-based evidence relevant to city-cut classification in Shanghai, while identifying boundary-area exceptions. They do not, by themselves, establish legal, ethical, social, epidemiological, or intervention-effectiveness legitimacy.

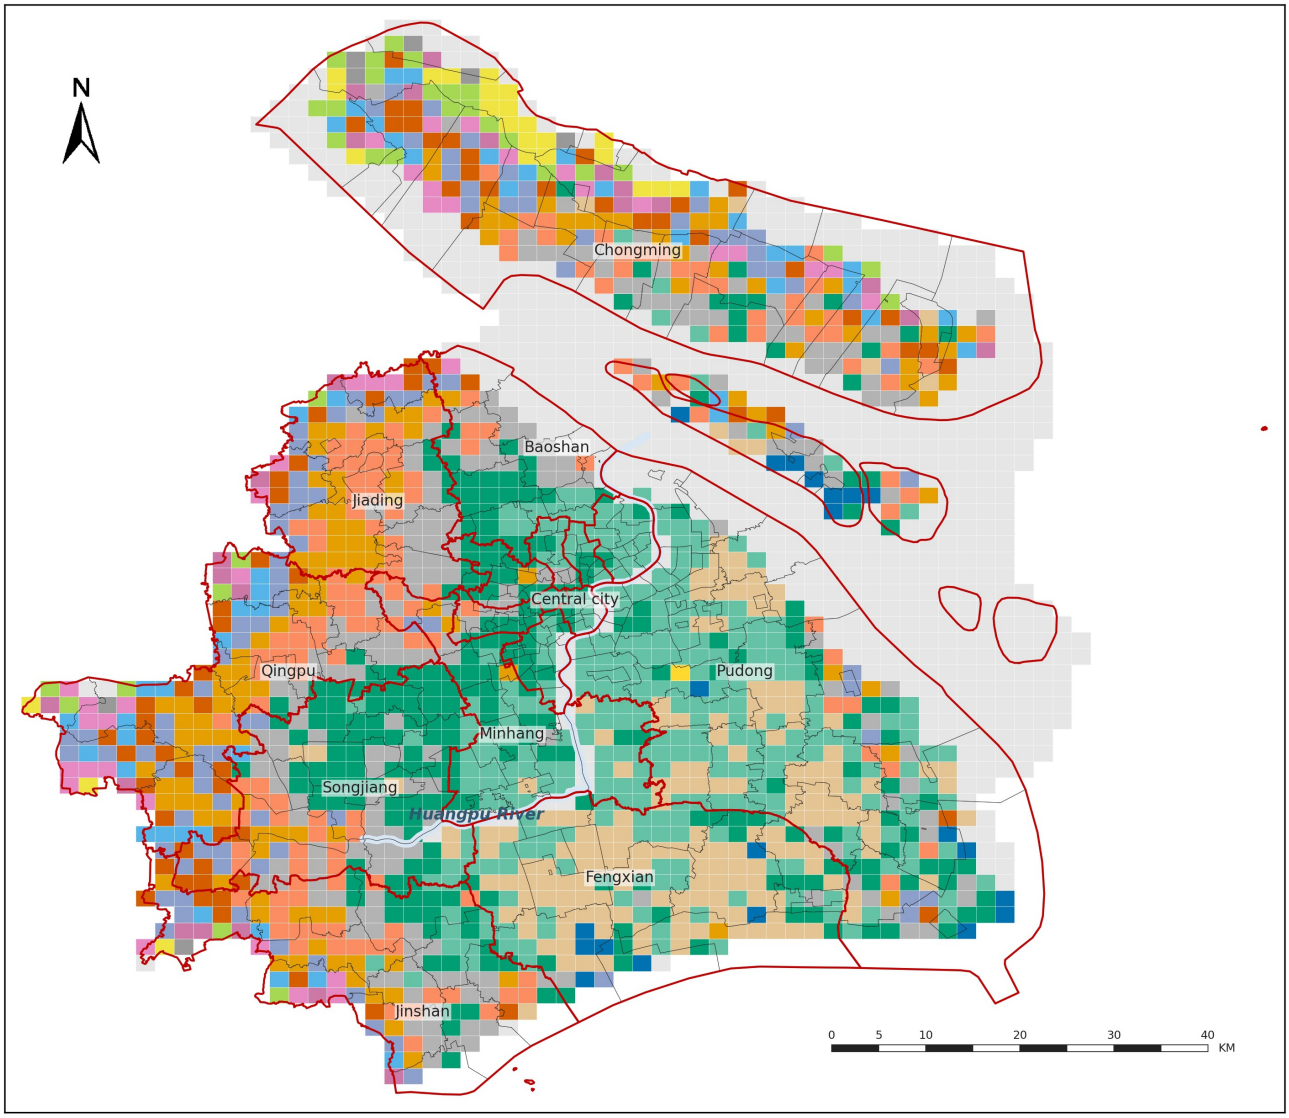
The same workflow was applied to the 2020 data; Multimedia Appendix 1 provides the 2020 point estimates and conventional 95% *t* CIs. The corresponding HAC analysis produced substantively consistent conclusions.

Mobility Communities and District Geography

Figure 3 presents the 16-cluster spectral partition for the October 10, 2019, transition matrix. Colors identify mobility communities, and district boundaries are overlaid for comparison. The map shows partial geographic correspondence in several peripheral areas but no exact one-to-one recovery of all district boundaries. Repeated-initialization and selected-date checks produced stable partitions, but this tested procedure does not identify a unique optimal subcity partition. The corresponding 46-day average map is provided in Figure S1 in Multimedia Appendix 1.

The corresponding 46-day average partitions for 2019 and 2020 are presented in Figures S1 and S2 in Multimedia Appendix 1.

The clustering results are exploratory evidence of functional connectivity rather than a ready-made policy boundary. They are most informative when used to compare the tested mobility partition with existing administrative geography.



The single-day map shows broad, spatially coherent mobility regions, including partial correspondence with district geography in peripheral areas. In the 46-day average map (Figure S1 in Multimedia Appendix 1), several western areas remain visibly separated by district geography, whereas Fengxian and Pudong form a more integrated cross-district community, and the central urban area is more internally connected. These visual patterns identify places where cross-district coordination may be relevant; they do not confirm direct routes or infection transmission.

Some peripheral areas, including parts of Songjiang and Chongming, form more spatially concentrated blocks than the central city. Other blocks combine grids from multiple districts. This heterogeneity is consistent with districts being a practical first-order administrative reference in some settings, rather than a uniquely optimal or perfectly self-contained mobility partition.

The tested spectral-clustering specifications did not reproduce existing districts or simple district groupings as an exact map. This result does not rule out other subcity classifications, which would require purpose-built objectives, geographic constraints, and independent validation before policy use.

Discussion

Principal Findings

This study examined whether daily mobility patterns provide evidence relevant to the city-cut geographic design of a digital travel-record system. In 2019, movement within Shanghai was common across all origin districts, and the city-average nonadjacent-district movement proportion exceeded the confirmed external-city movement by 10.9 (95% HAC CI 10.7 - 11.1) percentage points. The 2020 analysis showed a similar district-level pattern, although border-origin comparisons were heterogeneous. These estimates concern observed mobility connectivity, not infection transmission or the effectiveness of a travel-restriction policy. The clustering analysis complements rather than overturns the city-level result. Under the reported spectral/Fiedler-vector/k-means specification, repeated fits produced stable mobility communities with partial and spatially heterogeneous correspondence to district geography. The 46-day average map retains some western district-oriented separation while showing tighter Fengxian-Pudong and central-area communities (Figure S1 in Multimedia Appendix 1). The clusters did not exactly reproduce the district map, but that finding neither rules out district-based management nor excludes other data-driven subcity classifications.

Comparison With Prior Work

Prior mobility research has used digital-trace data to characterize movement, model spatial transmission, or evaluate how restrictions changed mobility [11,22-24,27-36]. Our study differs by using observed mobility to examine an upstream system-design choice: the geographic unit used to flag travel histories. This distinction is important because a boundary rule determines the spatial scope of a digital intervention before effects on transmission or uptake can be measured. Network and community-detection studies show that interaction data can reveal functional regions that sometimes diverge from official boundaries [37,38]. Building on that work, we use grid-level transition probabilities to compare a city boundary with a radius-based alternative and to assess whether a tested subcity clustering procedure corresponds to administratively usable districts. The contribution is an empirical, reproducible boundary-calibration workflow rather than a model of disease spread or a claim that mobility alone determines a policy's

XSL•FO
RenderX

value. The results should not be read as evidence that mobility connectivity causes rapid transmission, that city-cut policies reduce infections, or that city-wide restrictions are proportionate. Those questions require linked epidemiological, behavioral, legal, and equity evidence [6,16-19]. The present study instead documents a mobility pattern that policymakers could consider alongside those other forms of evidence when defining geographic risk units.

Location-based mHealth tools were widely deployed during the COVID-19 pandemic, and evaluations of these systems have examined uptake, privacy practices, and epidemiological outcomes [7-9,16-19]. Our analysis contributes earlier in the design sequence by making the geographic classification rule empirically inspectable. It shows how aggregate mobility data can be used to test whether a proposed administrative boundary is broadly consistent with the movement scale the tool is intended to manage. For Shanghai, high within-city mobility and substantial nonadjacent-district movement provide a mobility-based rationale for considering a city-level unit, with clear caution for some border-origin areas. At a subcity scale, districts offer an administratively available first-order reference, but central and corridor-like connections may need cross-district coordination. This interpretation is deliberately narrower than a claim of policy effectiveness or broad legitimacy.

Real-World Implications

The most direct real-world application of this workflow is at the point where a location-based mHealth system is specified rather than after it has been fielded. Travel-record and health-code systems require a geographic unit before a single record can be classified, and that unit determines who will be flagged [1-3,20,21]. The analysis reported here shows that this choice can be treated as an explicit, testable parameter: daily origin-area movement proportions and a paired HAC comparison give a documented and reproducible basis for adopting or rejecting a candidate boundary. Development teams can therefore record the mobility assumptions behind a geographic rule in the same way they record data retention or consent settings, producing an auditable design trail that reviewers, regulators, and the public can inspect [8,9]. For public-health agencies, the results support treating a city-level boundary as a first-order operational reference in settings where observed movement is predominantly internal. In Shanghai in 2019, the city-average intracity proportion was 97.2% (95% *t* CI 97.1% - 97.3%) and nonadjacent-district movement exceeded confirmed external-city movement by 10.9 (95% HAC CI 10.7 - 11.1) percentage points, so the movement that a city-level rule is intended to govern occurred largely inside the boundary that the rule would draw. Agencies elsewhere can apply the same daily proportion construction to test whether that condition holds locally before adopting a comparable rule and can repeat the test as travel patterns change, rather than importing a boundary convention from another jurisdiction.

The border-origin results carry a more specific operational message. Comparisons for the 8-km municipal border band were heterogeneous, and Chongming showed a negative difference, meaning that confirmed external-city movement exceeded nonadjacent-district movement for that origin area. A uniform city label would misdescribe the movement of such areas. Practical responses include treating designated border zones as separate classification units, applying a lower-intensity label within them, or coordinating classification with the adjacent jurisdiction. The clustering results point the same way at a finer scale: mobility communities showed only partial correspondence with district geography, so central and corridor-like areas may warrant cross-district coordination even where a city-level unit is retained [37,38].

More importantly, the workflow is not specific to Shanghai, to a single operator's data, or to COVID-19. It requires only aggregated origin-destination counts, an activity denominator, and a candidate boundary, inputs that are available to operators and statistical agencies in many settings [25,26]. It can be applied to other administrative units, to other hazards for which movement-based risk labeling is proposed, and to periodic recalibration as travel patterns shift. Where comparable data cannot be obtained, the same reasoning can still be used qualitatively to state, and later test, the mobility assumption on which a proposed boundary depends. At last, these implications should be read within the study's evidentiary limits. The analysis describes observed mobility. It does not measure infections, evaluate whether a city-cut rule reduced transmission, or establish that any restriction was legally authorized, ethically proportionate, or publicly acceptable [16-19]. Mobility evidence is one input among several, and this workflow is offered as a way to make that one input explicit and checkable, not as a decision procedure for policy.

Strengths and Limitations

This study's strengths are the large deidentified operator dataset, the reconstruction of daily origin-area proportions, the parallel 2019 and 2020 analyses, and transparent operational definitions for the movement measures. The grid-level records allow movement to be examined across Shanghai while retaining the spatial detail needed to distinguish district and municipal-border patterns. Applying the same geographic definitions and daily aggregation procedures in both years provides a consistent basis for comparing the 2 study periods. The district-level and border-origin comparisons help reveal local differences that would be obscured by a citywide average, while the clustering analysis provides a complementary view of how observed connectivity relates to administrative geography. Documenting the visit threshold, movement categories, and transition-matrix construction makes the analytical choices explicit and supports the assessment of the approach in settings with comparable data.

Despite these strengths, several limitations should be acknowledged. First, reliance on 1 mobile service provider may introduce bias if its users differ from the broader population, despite China Unicom's substantial market share [35]. Second, the visit definition requires a stay of more than 30 minutes in a 2 km × 2 km grid. This threshold reduces pass-through noise but may miss shorter epidemiologically relevant encounters. Third, the nonadjacent-district metric captures connectivity at the resolution of recorded visits and may include unobserved pass-through travel. Fourth, this study provides a mobility-based empirical justification for city-cut classification, but it does not evaluate epidemiological effectiveness, legal authority, ethical

XSL•FO
RenderX

proportionality, public acceptability, or the social costs of restrictions. Future research should combine mobility data with epidemiological and policy-outcome data to assess these broader dimensions.

Conclusions

This study introduces a mobility-based approach to an upstream design choice in location-based mHealth: how to define the geographic unit used for travel-risk classification. Unlike studies that assess transmission or intervention outcomes after deployment, it uses daily grid-to-grid mobility to assess whether a proposed boundary is consistent with observed movement. In Shanghai, the results support considering a city-level unit as a mobility-based reference while identifying border-area and subcity exceptions that require local assessment. The approach can inform more transparent geographic calibration of digital public-health tools, but it does not establish infection effects, legal legitimacy, or the overall appropriateness of any restriction policy. The innovation of this work lies in relocating the analytic question from postdeployment evaluation to predeployment design. It differs from existing studies in 2 respects. Evaluations of deployed location-based mHealth tools have assessed uptake, privacy practices, and epidemiological outcomes [7-9,16-19], and prior mobility research has treated movement data as a predictor, an outcome, or a model input rather than as a criterion for choosing a boundary rule [11,22-24,27-36]. This study contributes to the field a reproducible and auditable calibration workflow, combining daily origin-area movement proportions with paired HAC inference and transition-matrix clustering that can be applied to any candidate geographic unit in any setting with comparable aggregated mobility data. In real-world terms, the findings indicate that where observed movement is predominantly internal, a city-level unit is a defensible starting reference for travel-risk classification, while border-origin areas such as Chongming require separate local assessment before a uniform city label is applied, and areas whose mobility communities span administrative lines may require cross-district coordination. For developers and public-health agencies, the practical implication is that a boundary rule can be stated, tested, and documented before deployment rather than justified retrospectively.

Generative AI Use

The authors declare the use of generative AI (GenAI) in the research and writing process. According to the Generative AI Delegation Taxonomy (GAIDeT; 2025), GenAI tools were used under full human supervision for code generation, algorithm development for data analysis, visualization, reproducibility testing, text generation, proofreading and editing, reformatting, and publication support. The GenAI tool used was OpenAI Codex (GPT-5). The authors retain full responsibility for the final manuscript. GenAI tools are not listed as authors and do not bear responsibility for the final outcomes. The declaration was submitted under the collective responsibility of the authors.

The original data-processing and analytical code was developed manually by the authors. GenAI was subsequently used to assist with auxiliary code generation and the reproduction and verification of selected prespecified analyses, including the recalculation of summary estimates and CIs, sensitivity checks, figure and table preparation, language editing, and the preparation of draft responses. The tool had access only to deidentified, aggregated mobility files; no identifiable individual-level data were provided. The authors independently reviewed and verified all AI-assisted code and outputs and retained responsibility for the research design, data processing, statistical analysis, interpretation, and the final manuscript.

Funding

This research was supported by the Strategic Topic Fund (Grant No. STG2/P-705/24-R) of the Research Grants Council of Hong Kong, the HKU-100 Scholar Fund of The University of Hong Kong, and the Startup Research Grant of Liaoning University.

Data Availability

The data used in this study were obtained from China Unicom and are subject to data use agreements and privacy restrictions. Therefore, the data are not publicly available. Aggregated results supporting the findings of this study are included in the paper and supplementary materials. Researchers interested in accessing similar data may contact China Unicom directly, subject to its data access policies and approval procedures.

All mobility results are reported as aggregated district-level, border-area, or grid-cluster summaries. Analytical definitions, preprocessing steps, and construction of the transition matrix are described in the *Methods* section and Multimedia Appendix 1 to support reproducibility.

Conflicts of Interest

None declared.

Multimedia Appendix 1
This appendix reports the parallel 2020 analysis using the same 46-day daily proportion construction and conventional 95% *t* CIs. Corresponding heteroskedasticity- and autocorrelation-consistent analyses are reported as robustness checks.

Abstract

Background: Enhanced recovery after surgery (ERAS) guidelines recommend early postoperative mobilization to reduce complications, but adherence is often suboptimal, highlighting the need for effective tools to monitor and encourage movement. The Mindray enhanced patient monitoring (ePM)/electrophysiology (ep) pod, capable of tracking activity, vital signs, sleep, and pain, offers high-precision postoperative monitoring and is well-suited for research on activity feedback.

Objective: The study aims to assess whether wearable device-based (ePM/ep pod) activity feedback could reduce postoperative complications within 30 days of colorectal cancer (CRC) surgery.

Methods: We conducted an open-label, evaluator-blind, randomized controlled trial involving patients aged ≥18 years scheduled for CRC surgery. Patients were randomized to a feedback group or a control group. Both groups were set the same target activity time postoperatively based on ERAS guidelines. The feedback group received real-time visual feedback of movement time daily through the ePM/ep pod device, while the control group did not receive feedback. The primary outcome was the comprehensive complication index (CCI) within postoperative 30 days. Secondary outcomes included daily activity time, pain Numeric Rating Scale scores for rest and movement during the first 3 postoperative days, length of stay, percentage of reaching the scheduled mobilization target, 30-day postoperative mortality rate, and the times of first exhaust and defecation.

Results: Two hundred thirty-nine patients were recruited between February 2023 and September 2023, with 216 randomized (n=108 for each group). There was no significant difference in CCI within 30 postoperative days between the control group (median CCI 0, range 0 - 20.90) and the activity feedback group (median CCI 0, range 0 - 12.20). The estimated mean difference was −0.59 (95% CI −3.56 to 2.38; *P*=.66). Sensitivity analysis excluding patients with low device compliance did not alter these findings. No significant differences between groups were found in daily activity time, length of hospital stay, or pain scores. Post hoc analysis revealed significant negative correlations between 30-day CCI and activity on the second day after operation (*r*=−0.166) and the third day after operation (POD3) (*r*=−0.264; *P*<.05 for both). Linear regression indicated that POD3 activity significantly reduced CCI (β=−.025; 95% CI −0.045 to −0.006; *P*=.01), with peak CCI reduction at 215 minutes of activity.

Conclusions: In the context of ERAS, this study found no evidence that activity stimulation based on feedback from the wearable device (ePM/ep pod) could reduce 30-day postoperative CCI in patients undergoing CRC surgery. However, the ePM/ep pod could accurately record daily activity duration, which may be negatively correlated with CCI on POD3.

Introduction

Colorectal cancer (CRC) is the second most common cancer in China and ranks third globally in mortality rate [1,2], which is an urgent health problem. Surgery is the first-line treatment of CRC. Unfortunately, 50% of patients undergoing surgery develop postoperative complications [3], leading to increased medical expenses, longer hospital stays, and delay of postoperative recovery [4]. Previous studies have shown that postoperative complications are an independent risk factor related to poor 5-year survival and the increased overall recurrence rate [5-7].

Enhanced recovery after surgery (ERAS) is committed to reducing surgical trauma and stress, decreasing postoperative morbidity, and accelerating postoperative recovery of patients [8-10]. ERAS guidelines emphasize the importance of early mobilization after surgery [11], which can reduce adverse outcomes such as pulmonary complications, decreased skeletal muscle strength, thromboembolism, and insulin resistance [12]. It was confirmed that ERAS was safe and effective in patients undergoing CRC surgery [13,14], and early mobilization after operation was the key to the success of ERAS [15]. However, more than half of the patients did not mobilize as recommended in the ERAS guidelines [16], which meant a reliable measurement tool was needed to not only accurately monitor the postoperative activity of patients, but also to increase their enthusiasm for mobilization. One of the possibilities is to use a wearable device [17,18].

The development of wearable devices allows objective measurements of, for example, activity steps or activity time, which can be used as a feedback tool to urge patients to achieve their intended mobilization goals [17-19]. A study found it was safe to use an activity tracker with feedback after gynecological operations and may increase patients' physical activity [20]. Several wearable devices (such as Apple Watch, Fitbit, and Garmin) that provide combined automatic and visual feedback have been identified as effective tools for cancer survivors to raise awareness of self-activity, stimulate behavior change, and improve physical activity [21,22]. However, the clinical effect on recovery or promoting movement after operation of the wearable devices has not been sufficiently evaluated in patients with CRC. The enhanced patient monitoring (ePM)/electrophysiology (ep) pod developed by Mindray supports activity time statistics, continuous vital sign monitoring, sleep monitoring, pain scores, and trend recording, has a high accuracy of postoperative activity monitoring [23], and is suitable for related research.

The present study aims to determine whether the activity incentive feedback based on a wearable device (ePM/ep pod) could reduce postoperative complications of patients with CRC within 30 days after their operations. We hypothesized that postoperative complications would be reduced in the activity feedback group compared to the usual postoperative care group.

Methods

Study Design and Patients

It was an open-label, evaluator-blind, randomized controlled study with 2 parallel groups.

Patients aged ≥18 years and scheduled for CRC surgery were included. The exclusion criteria were patients who (1) had American Society of Anesthesiologists (ASA) grade >III, (2) had preoperative immobility or inability to walk unaided affected by neural, muscular, or skeletal diseases, (3) had participated in other clinical studies in the past 3 months, (4) had planned reoperation within 30 days after the initial operation, and (5) had expected to be transferred to the intensive care unit after their operations.

Ethical Considerations

The Ethics Committee of the First Affiliated Hospital of the Air Force Military Medical University approved this randomized controlled trial (approval no. KY20222299-F-1), and the study protocol was registered with the Chinese Clinical Trial Registry (ChiCTR2300068107) on July 2, 2023. All procedures complied with the Declaration of Helsinki and institutional regulations (The Ethics Committee of the First Affiliated Hospital of the Air Force Military Medical University, Medical Ethics Committee Charter) [24]. Written informed consent was obtained from all participants prior to enrollment, which included detailed explanation of the study and their right to withdraw at any time. Upon registration, each patient was assigned a unique study number, and all subsequent data analyses were performed using a deidentified dataset to ensure participant privacy and confidentiality. No financial compensation was provided for participation.

Interventions

All patients in the trial were randomly assigned (1:1) to a feedback group or a control group. Both groups were set the same target activity time postoperatively and thus performed activities for 2 hours on the first day after operation (POD1), 4 hours on the second day after operation (POD2), and 6 hours on the third day after operation (POD3), according to the ERAS guidelines and our ERAS pathway for CRC [10]. All patients were fitted with a wireless wearable device that continuously recorded their daily ambulation durations (ePM 12M monitor placed at the bedside or ep pod monitor placed on their wrist or blood pressure pod monitor placed on their upper arm).

In the feedback group, patients received real-time visual feedback of the movement time every day through the display of the ePM. According to the wards' routine care based on ERAS guidelines, patients were reminded to engage in activities combined with ePM/ep pod feedback to meet predefined daily step goals and also informed about the gap between the active time and the target time.

In the control group, patients' movement time was set to not appear on the display of the ePM. Patients were not given feedback, and they were only encouraged to carry out activities according to the current care standards based on ERAS guidelines.

XSL•FO
RenderX

Prevention and Handling of Adverse Events

If the following incidents occur, activity supervision should be suspended immediately: participants experience pain intensity >4 (from 0 to -10), electrocardiogram abnormalities (signs of arrhythmia or acute ischemia), indoor air oxygen saturation <88%, systolic blood pressure <90 mmHg, symptoms of standing intolerance (ie, dizziness, nausea, and blurred vision), exercise weakness (ie, difficulty standing), etc. In the next scheduled mobilization, if the participant is considered to be in stable physical condition after clinical evaluation, a new mobilization attempt will be conducted. If serious adverse events such as falling out of bed or falling occur, in addition to suspending activity supervision, the competent physician should also be asked to evaluate the patient's injury and terminate the study if necessary. The researcher should immediately fill out the serious adverse event report and report it to the hospital ethics committee.

Randomization and Blinding

Patients were randomized using block random groups (sized blocks of 2 and 4) generated by specialized staff. All random assignments were made and sealed to an envelope by intervention staff using Statistical Analysis Software. The randomization process was performed by an independent anesthesiologist at the end of the surgical procedure, separated from the ward's nursing staff and outcome assessors to reduce potential bias.

It was impractical to blind the intervention staff in view of the intervening measure, but contrary to the outcome evaluators. To ensure blinding during outcome assessments in the surgical ward, a schedule was established to stagger the intervention and evaluation implementation. Ward staff were informed about the activity monitoring study but were not provided with any specific hypothetical details to prevent potential bias from influencing the study results. Given the intervention characteristics, blinding the patients was also deemed to be unfeasible. To minimize performance bias, patients were informed that we were evaluating 2 mobilization schemes on the understanding that neither scheme was expected to confer any potential advantage.

Data Collection

Preoperative baseline data were collected before an operation as follows: demographic data; preoperative medication and abdominal surgery history, and preoperative radiotherapy and chemotherapy history; vital signs; available preoperative examinations; and preoperative physical activity ability assessed by the International Physical Activity Questionnaire (IPAQ) [25]. Operation-related data collected on the day of surgery included surgical duration, intraoperative bleeding, site, type, and catheter placement status. Postoperative data were collected after each operation as follows: complications according to the Clavien-Dindo classification during hospitalization and 1 week, 2 weeks, and 1 month after the operation; the wearable device ep pod record of the activity time; digital pain Numeric Rating Scale (NRS) scores of rest and exercise; length of hospitalization; time of first exhaust and defecation; and opioids consumption; when discharged from hospital, patients in the intervention group were asked about concerns for feedback on activity time and whether they would supplement activities.

Outcome Measurement

Primary Outcome

The primary outcome was the comprehensive complication index (CCI) [26] within 30 days after surgery. The CCI measured the overall complication calculated for each patient, ranging from 0 (no complication) to 100 (death), including any minor complications instead of focusing on specific ones. It was thus an objective measure with comprehensive and accurate evaluation [27-29]. When calculating CCI, all postoperative complications were evaluated and classified based on the Clavien-Dindo classification, then converted into a weighted continuous scale including quantity and severity. Finally, the CCI value was evaluated using the CCI calculator available [30].

Secondary Outcomes

Daily activity time was set from 12 AM to 11:59 PM based on the data uploaded by ePM/ep pod until the 4th day or until discharge, whichever came first. The patient's compliance was considered to be low [31] on the condition that the patient wore it for less than 8 hours between 8 AM and 8 PM. The degree of pain for rest and exercise in the first 3 days after operation was scored by the NRS [32]. NRS used 0 - 10 points to represent different degrees of pain scored by patients according to their subjective feelings, 0 for no pain and 10 for severe pain. The length of stay was set as the actual length of stay after a patient's operation. The percentage of reaching the scheduled mobilization target was calculated. The patient's activity was considered to be not up to standard if the daily activity time after their operation did not reach the target time. The mortality rate of 30 days after operation was also counted. The first exhaust and defecating times were subject to the patient's own assessment, meaning that an obvious feeling of exhaust or defecation was reported.

Sample Size Calculation

The sample size calculation was based on the primary outcome measured by the CCI 30 days after operation. CCI represents the measurement data that follows a normal distribution, as detailed in the previous trials on postoperative complications [33,34]. The average postoperative CCI of CRC was 10 (SD 5). Assuming that the visual feedback of the movement time could reduce CCI by 25%, the average CCI of the feedback group was set to 7.5 (SD 5) [35]. Based on the above effect size, Power Analysis and Sample Size 2015 Software was used to calculate that a minimum of 172 patients (n=86 per group) would provide 90% power to detect a 25% decrease of CCI and an α of .05 (2-sided test), assuming the feedback group was more favorable compared to the control group [35]. To compensate for a potential 20% dropout rate, 216 patients were required to be included (n=108 per group).

Statistical Analysis

We followed the intention-to-treat principle analyzing all random patients in the baseline analysis. The analysis results of the study were based on the modified intention-to-treat

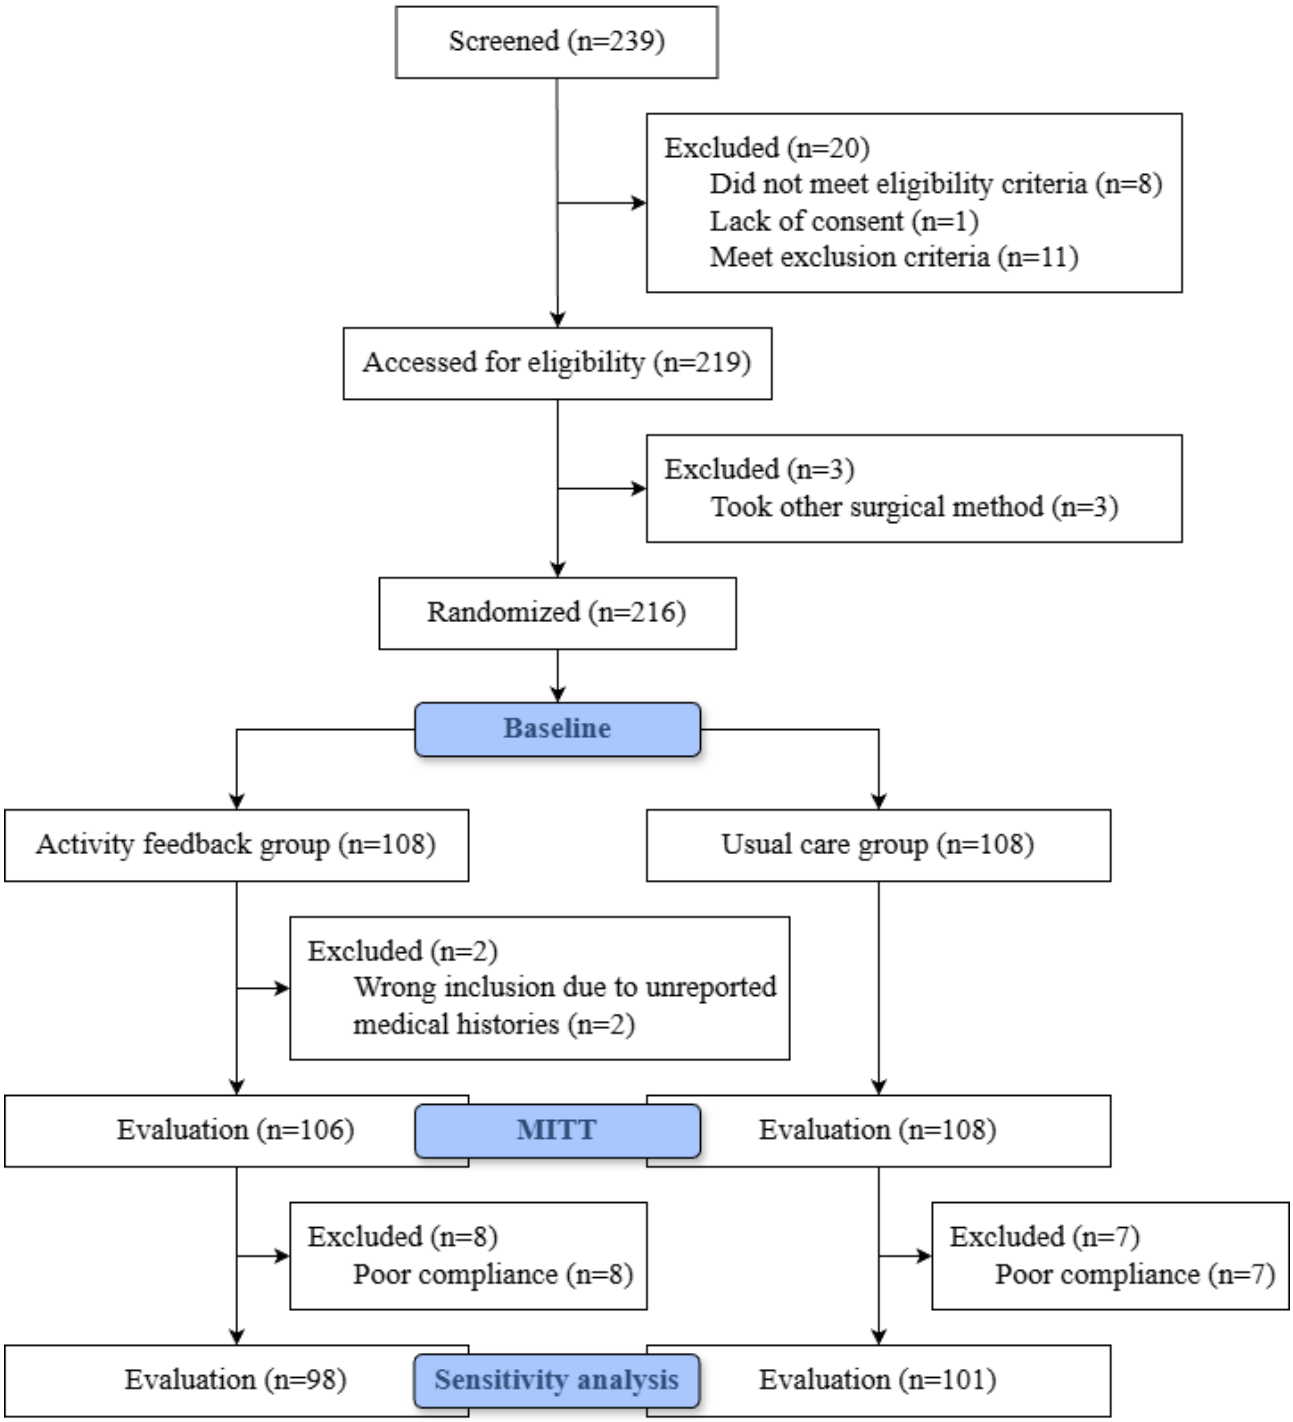
XSL•FO
RenderX

(MITT) set. Statistical analyses were performed using SPSS version 23.0. The 2-sided significance level was set at a *P* value <.05.

Continuous variables with independent access to mean and SD were initially subjected to the Kolmogorov-Smirnov test to assess their normality. Otherwise, the Shapiro-Wilk test was chosen. The Levene test was used for the analysis of homogeneity of variance. Data with skewed distributions are reported as medians with IQR, while data adhering to a normal distribution are given as means with SD. Categorical variables are expressed as frequencies, percentages, and ratios. For baseline comparisons, normally distributed continuous variables with comparable variance were analyzed using Student *t* test. In contrast, continuous variables with skewed distributions or uneven variance were analyzed with the Mann-Whitney *U* test. Categorical variables were compared using either the chi-square or Fisher exact tests.

The impact of the primary outcome CCI within 30 days after an operation was analyzed using the Student *t* test or the Mann-Whitney *U* test. Except for the MITT analysis, subjects with low device compliance (wearing ePM/ep pod for less than 8 h from 8 AM to 8 PM) were excluded for sensitivity analysis of the primary outcome. In addition, subgroup analyses (preselected age, ASA, preoperative chemoradiotherapy, surgical site, and preoperative mobility) were carried out. Simultaneously, we examined the interaction between the treatment effect and these 5 subgroup variables. In addition, we statistically described the distribution of postoperative complications at all levels in the 2 groups and performed a chi-square test between the groups. As a post hoc analysis, the Spearman/point-biserial correlation coefficient was used to determine the correlation between CCI and the postoperative movement time. In the preliminary analysis, the linear regression model showed a good fitting effect. Based on this result, we conducted a linear regression analysis to assess the relationship between the movement time of POD3 (for patients discharged on POD3, the activity time on POD2 was used to fill in the data) and CCI, adjusted for potential factors such as age, ASA, sex, preoperative chemoradiotherapy, and BMI, all factors which could influence postoperative recovery.

In analyses of secondary outcomes, the Mann-Whitney *U* or Student *t* tests were used to analyze the other measurement data except for repeated measurements. The chi-square test was used to analyze the percentage of patients who achieved the predetermined mobilization goal. Binary logistic regression analysis was used to determine the determinants of patient cohorts to achieve mobilization goals. The regression model considered the following variables: age, sex, ASA grade, surgical site, and the IPAQ [25]. Repeated measurement of the NRS pain score, using a generalized linear mixed model with multinomial distribution, was used for within-group comparisons.



Results

A total of CRC 239 patients were recruited between February 2023 and September 2023. Of these, 216 were randomized, 108 into usual care and 108 with activity feedback. Two patients who met the exclusion criteria were inadvertently enrolled due to unreported medical histories and were subsequently excluded from the MITT analysis (Figure 1). Patients in each randomized group had similar baseline and perioperative characteristics (Table 1).

As shown in Table 2, no significant differences were found in CCI within 30 postoperative days between the control group, with a median CCI of 0 (range, 0 - 20.90), and the activity feedback group, with a median CCI of 0 (range, 0 - 12.20). The estimated mean difference between the 2 groups was −0.59 (95% CI −3.56 to 2.38; *P*=.66). Removing 15 patients with low device compliance as a sensitivity analysis, the estimated mean difference was −0.98 (95% CI −4.07 to 2.10; *P*=.54). The subgroup analysis results revealed no significant interaction between the two groups on CCI within 30 days and all the subgroup variables (Figure 2 and Checklist 1).

The rate of no complications accounted for 58.3% (63/108) of patients in the usual care group and 60.4% (64/106) in the activity feedback group, while severe complications accounted for 4.6% (5/108) and 3.8% (4/106), respectively (Table 2). Both groups had the highest proportion of grade 2 complications. In addition, the incidence of urinary retention was the highest (15/108, 13.9% in the usual care group and 11/106, 10.4% in the activity feedback group) among the operative complications. The incidence rates of complications of infectious, respiratory system, and cardiovascular systems were 6.5% (7/108) vs 9.4% (11/106), 5.5% (6/108) vs 2.8% (3/106), and 1.9% (1/108) vs 1.8% (2/106), respectively, in the usual care group and in the activity feedback group (Table 3). On the analysis of specific complications, by the Fisher exact test, the incidence rate for pneumonia in the routine care group was 4.6% (5/108) and that in the activity feedback group was 1.9% (2/106), *P*=.45; the incidence rate for ileus in the routine care group was 0.9% (1/108) and that in the activity feedback group was 3.8% (4/106), *P*=.21, which indicated that the intervention had no significant effect on the incidence of these specific complications.

Table . Type of complications 30 days after operation.

Other gastrointestinal complications[b]	6 (5.6)	7 (6.6)

[a]Other infections: including leukocytosis (white blood cells) >12 and temperature >38°C, shingles.

[b]Other gastrointestinal complications, including diarrhea, constipation, and gastroparesis.

As shown in Table 4, the 2 groups had no significant difference in daily activity time. Similarly, there was no difference in the rate of reaching the target between groups. The usual care and activity feedback groups demonstrated no significant difference in the length of postoperative hospital stay, with a median of 4 days for both groups (*P*=.99), in the first exhaust time (37.13, IQR 22.73-58.77 h vs 38.29, IQR 22.15-57.49 h, respectively, in the usual care group and in the activity feedback group; *P*=.89), and in the first defecating time (44.50, IQR 24.04-68.88 h vs 44.13, IQR 25.81-67.44 h; *P*=.91, respectively, in the usual care group and in the activity feedback group; Table 5). The results of the generalized linear mixed model (Table 6) revealed that the NRS scores of rest and activity showed a declining trend over time, with a significant time effect that was independent of the patient groups (*P*<.001). Moreover, there were no significant interactions between the intervention and the NRS scores at rest (*P*=.54) or during movement (*P*=.89).

In post hoc analysis, there was a significant negative correlation between CCI within the 30th postoperative day and the activity duration on POD2 (r=−0.166; *P*=.02) and POD3 (r=−0.264; *P*=.002). A linear regression analysis showed that the movement time of POD3 was negatively correlated with CCI within the 30th postoperative day, and the standardized β was −.025 (95% CI −.045 to −.006; *P*=.01). Additionally, the longer the activity time of POD3 before 215 minutes, the faster the CCI decreased; however, beyond 215 minutes, the rate of the decline slowed (Figure 3).

Discussion

Principal Findings

In this study, the activity incentive feedback based on a wearable device (ePM/ep pod) did not reduce the CCI of patients with CRC within postoperative 30 days. The differences between groups in terms of daily activity time, length of postoperative hospital stay, intestinal function recovery, and NRS pain scores were also not significant.

There may be the following reasons for the lack of difference in CCI and daily activity durations between the 2 groups. First, this study was conducted in a surgical ward with relatively deepening ERAS guidelines, where preoperative education and routine activity supervision may have facilitated effective postoperative activities even in the absence of the feedback from wearable devices. Second, all the subjects in the present study received the same activity encouragement by medical staff according to the routine care and were set the same daily activity target; therefore, patients in the control group with high compliance might obtain activity feedback through other means. Third, laparoscopy accounted for more than 95% of CRC surgery in the present study, which was similar to the type of surgery used in another study that yielded negative results regarding the hypothesis that early postoperative activity could reduce complications [15]. Future studies should investigate whether such incentive feedback would be effective for patients experiencing more intense surgical stimulation or possessing less ERAS education. Previous studies using step count feedback for mobility-enhancing showed conflicting

The assessment of early postoperative activity achievement in patients with CRC directly reflects the practical outcomes of the intervention strategies employed in this study. The activity compliance rate of patients with CRC on POD1 was 37.4% (in the usual care group) and 43.8% (in the activity monitoring feedback group), which was much lower than expected, indicating that even with the feedback mechanism, there was only a marginal improvement in patients' adherence to the activity targets. Based on the current 6 hours recommended by ERAS guidelines, this study set a less active target of 2 hours for POD 0. In addition, the maximum activity time on POD1 was 310 minutes, which was much lower than the 6 hours recommended by ERAS guidelines. The relatively low compliance rates suggest that factors beyond the provision of activity feedback may be at play in influencing patients' postoperative behavior, such as the intensity and appropriateness of the activity targets set. The insights gained from analyzing the achievement of early postoperative activity not only provide a deeper understanding of the limitations of the feedback intervention but also highlight the need for more tailored and patient-centered approaches to enhance postoperative mobilization. The postoperative activity time was measured by an electronic parameter objectively recorded by a wearable device, and the measurement method may be different from the

XSL•FO
RenderX

considerations of previous guidelines. This may be the reason why the postoperative activity time was inconsistent with most previous studies.

Previous studies [37,38] have found patients undergoing major visceral (abdominal) surgery may not be able to achieve the mobilization goals in the early postoperative period. An observational pilot study [39] pointed out that only 50% of patients undergoing major visceral surgery could walk until POD2. The cumulative duration of postoperative activity per day ranged from 15 to 155 minutes, and only 40% of patients were satisfied with activity or physical exercise. There is a discrepancy between ERAS goals and clinical practice. Another study [40] reported that only a few patients (23.5%) achieved the mobilization goal of 6 hours (ERAS guidelines) of activity on the first day after CRC surgery. Ramírez et al [41] set the early activity goal for patients with CRC as sitting for at least 6 hours on the first postoperative day. However, the achievement rate was only 44.6%. In general, the mobilization goals described in most studies were either unclearly defined, imprecisely measured, or inaccurately monitored.

In addition, the early activity goals in ERAS did not differentiate between disease types, and radical abdominal tumor surgery is far more invasive than other simple abdominal organ partial removal. Patients with tumors were often elderly and had comorbidities, which can limit physical fitness and motivation. A study by Reed et al [42] on activity tracking after bariatric surgery found a significant negative correlation between age and the steps on POD1. Our study presented similar findings in that age was an independent factor affecting the achievement of activity on POD1. The older the patients were, the lower the possibility of reaching the activity goal. Furthermore, age negatively affected activity duration on POD2 and POD3. All patients with CRC in the present study were 61 years on average, and 42% had preoperative comorbidities, which may also be the reason for the low level of postoperative activity. Also, regression analysis showed that the activity duration of patients with colon cancer on POD2 was significantly longer than that of patients with rectal cancer, being 26.42 minutes longer. Patients with colon cancer were 2.28 times more likely than those with rectal cancer to meet the activity standard on POD2. It can be seen that the mobility of patients with colon cancer on POD2 was higher than that of patients with rectal cancer. We speculate that the reason for this finding may be that colon cancer basically does not receive radiotherapy, the proportion of preoperative chemotherapy may be lower than for rectal cancer, and the proportion of temporary ileostomy of colon cancer being much lower than that for rectal cancer. Our finding also suggests the target of early activity recommended by current ERAS guidelines (6 h in POD1) may be too high for these patients. A further increase in activity did not increase the benefit when activity levels reached a certain level. Considering our result of the regression analysis, 215 minutes might be considered as the target for activity time on POD3 to decrease CCI in patients with CRC.

In addition, several studies [43-45] have reported that early postoperative mobilization (within 24 h) was associated with fewer postoperative complications, fewer major complications, faster intestinal function recovery, and shorter hospital stays. The regression analysis in this study found that patients with high levels of physical activity before surgery were about 27 minutes more active the next day compared to patients with moderate levels of physical activity before surgery, and about 37 minutes more active than patients with low levels of physical activity before surgery. Therefore, perhaps by exploring the extent of postoperative activity decline caused by different surgical trauma, the approximate postoperative activity amount of the patient can be inferred and then combined with the preoperative activity level of the patient, a personalized postoperative activity plan can be formulated.

Limitations

This study had some limitations. First, the 216 patients were all admitted to one hospital; therefore, the conclusion still needs to be verified in more hospitals where ERAS guidelines are less practiced. The low proportion of ASA 3 patients in this study may limit our comprehensive assessment of the benefits of patients with high comorbidities from feedback from postoperative activities. Future research may consider including more ASA3 patients to better understand the response of this special population to postoperative activity feedback intervention. Second, since it was not possible to blind the patients in this study, the 2 groups of patients may have influenced each other. Due to practical difficulties such as high patient mobility and limited follow-up time, this study failed to collect information about the views of patients and clinicians with the wearable device and how motivated they felt by wearing this. In the future, the study can be expanded to multiple wards to achieve cluster randomization, which may reduce bias. Future research can also be combined with qualitative items to provide a more comprehensive understanding of patient and clinician experiences and perceptions of wearable devices. Third, as 96% of patients in this study underwent laparoscopic surgery, the results may not be generalized to open surgery or other types of surgery. Although our inclusion criteria were broad, we excluded patients who had difficulty with preoperative activity or were in a poor physical condition. These patients may benefit from the incentive of activity feedback. A final limitation was there may be a difference between self-reported preoperative mobility assessed by IPAQ, which was not designed for hospital patients, but for assessing physical activity in daily life, and actual quantitative mobility.

Conclusions

In the context of ERAS, this randomized controlled trial did not find evidence that activity stimulation based on feedback from ePM/ep pod wearable devices could reduce 30-day postoperative CCI in patients who underwent CRC surgery. However, ePM/ep pod could accurately record daily activity duration, which may be negatively correlated with CCI on POD3.

Abstract

Background: Despite the high prevalence of type 2 diabetes mellitus in China, few patients are achieving adequate management targets. While digital behavior change interventions (DBCIs) are promising solutions, sustained long-term user engagement with these new technologies remains challenging.

Objective: The objectives of this study were to (1) describe the long-term user engagement with the SMARTDiabetes app, (2) explore the associations between user engagement and trial effectiveness, and (3) identify main influencing factors of user engagement.

Methods: A mixed methods process evaluation was conducted alongside the 2-year SMARTDiabetes trial to assess long-term user engagement with the DBCI, investigate its association with trial effectiveness, and explore its influencing factors. Quantitative data included clinical outcomes and app usage data; qualitative data included an expert review of the DBCI and semistructured interviews with key stakeholders. Findings were synthesized using Michie's conceptual framework for engagement with DBCIs.

Results: A total of 1038 participants were included in the quantitative analyses, and 12 in-depth interviews were conducted in June 2020. The mean proportion of monthly active users was 46.4% (SD 7.8%), with a gradual decline from 56.3% at the start (April 2018) to 42.2% at the end of trial (July 2019). The proportion of sustained active users was 32.9% (342/1038), with rural users showing a significantly higher rate than urban users (38.3% vs 27.3%; P<.001). We found a strong link between user engagement and the effectiveness in achieving primary health outcome (risk ratio 1.37, 95% CI 1.21 - 1,55; P<.001) and a clear dose-response relationship between the level of app interactions and degree of improvement in the health outcome. Key drivers of user engagement included 6 behavior change techniques (ie, reward, feedback, reminders, goal setting, self-monitoring, and social support features), 4 implementation facilitators (credibility features, professional support, guidance, and ease of use), and 5 contextual contributors (younger age, better education, greater smartphone literacy, closer patient-doctor relationship, and stronger primary health care facilities commitment).

Conclusions: Long-term, sustained engagement with a mobile app intervention for type 2 diabetes mellitus self-management is achievable in the primary health care setting in China. Higher engagement is associated with better health outcomes. The influencing factors identified in the SMARTDiabetes study provide valuable insights for developing targeted strategies to enhance user engagement with DBCIs and improve overall program effectiveness.

Introduction

China has the largest number of patients with type 2 diabetes mellitus (T2DM) globally. The Chinese government has launched a series of health reforms since 2009, aiming to improve the management of diabetes by strengthening primary health care (PHC) [1]. In China, PHC facilities are typically the first point of contact for patients with the national health system, and individuals with T2DM receive most of their health care services at these facilities. PHC facilities are organized into 2 tiers, with grassroots-level facilities managed under the supervision of center-level facilities. In urban areas, community health stations are managed by community health centers, whereas in rural areas, village clinics are managed by township health centers [1]. Despite the reforms, the rates of awareness (36.7%), treatment (32.9%), and control (50.1%) of diabetes remained low [2]. The study projected that the suboptimal management of diabetes in China will lead to a rapid increase in economic burden, with the total costs rising from US $250.2 billion in 2020 to US $460.4 billion by 2030 [3]. These findings underscore the urgent need for better and innovative T2DM management strategies.

To address this challenge, we developed a multifaceted digital behavior change intervention (DBCI) and evaluated it in a 24-month cluster randomized controlled trial in 80 PHC facilities (40 rural villages and 40 urban communities) in Shijiazhuang City, Hebei Province, China [4,5]. The SMARTDiabetes intervention was underpinned by a mobile health (mHealth) system comprising three integrated components: (1) an app for patients and lay family members, also known as family health promoters (FHPs), who were invited to assist patients in managing their health conditions; (2) an app for PHC providers, which provided e-clinical decision support and access to a daily e-log containing data entered by patients; and (3) a web-based dashboard for local health administrators or governors, which generated real-time data-monitoring reports of key performance indicators (Figure S1 in Multimedia Appendix 1). The primary clinical outcome was the difference in proportion of patients achieving at least 2 American Diabetes Association "ABC" management targets ([A] glycated hemoglobin [HbA_{1c}] <7.0%, [B] blood pressure (BP) <140/80 mm Hg, and [C] low-density lipoprotein cholesterol <2.6 mmol/L) at 24 months. Overall, the SMARTDiabetes intervention significantly improved the primary outcome (intervention group: 35.9% vs usual care: 29.9%; *P*=.03). However, we observed significant heterogeneity in the primary outcome between rural and urban settings; the same intervention was significantly more effective in rural areas than in urban areas (rural—intervention group: 42.6% vs usual care: 31.0%; urban—intervention group: 27.9% vs usual care: 28.6% [*P*=.02 for heterogeneity]) [5].

Engagement with DBCIs, defined by (1) the extent (eg, amount, frequency, duration, and depth) of usage and (2) a subjective experience characterized by attention, interest, and affect [6], is logically a precondition for effectiveness [7-11]. Many studies on diabetes self-management apps have shown a positive association between user engagement and intervention effectiveness [12-15]. However, in practice, low clinical uptake, poor user engagement, and sustaining long-term participation are common challenges for these DBCIs [16-18]. The SMARTDiabetes trial is the longest (2 years) mobile app intervention for improving T2DM self-management with a rigorous research design (clustered randomized controlled trial) and a decent sample size (about 2000 patients) in the real-world PHC setting. Therefore, evaluating the long-term user engagement and understanding its influencing factors are crucial for optimizing the DBCIs design and implementation. These insights can help develop targeted strategies to enhance user engagement and improve overall program effectiveness [11,19].

In this study, we adopted a mixed methods multidimensional approach to assess both the subjective and objective measures of user engagement [6,11]. The aims of this study were to (1) describe the long-term user engagement with the SMARTDiabetes app, (2) explore the associations between user engagement and trial effectiveness (ie, the "ABC" biomarkers predetermined as the primary and secondary trial outcomes), and (3) identify main influencing factors of user engagement.

Methods

Study Design

In this mixed methods process evaluation, we conducted a descriptive analysis of user engagement with the SMARTDiabetes app over 2 years and a post-hoc analysis of its association with the trial effectiveness. In addition, to identify main influencing factors with the user engagement and trial effectiveness, we conducted a rapid theory-informed expert review of the DBCI tools, followed by 12 semistructured interviews to key stakeholders (ie, selected PHC providers, patients, and their FHPs in the intervention arm) conducted in June 2020, and concluded with a synthesis of evidence to explain the significant geographic heterogeneity in trial effectiveness observed in our previous publication (see Figure S2 in Multimedia Appendix 1 for timeline for data collection) [5]. The mixed methods study conformed with the GRAMMS (Good Reporting of A Mixed Methods Study) checklist [20].

Setting and Participants

The study recruitment was conducted at 80 PHC facilities (40 rural and 40 urban) in Shijiazhuang city, China, from August 2017 to December 2017. A full description of selection criteria for PHC facilities has previously been published [5]. PHC providers invited participants from the diabetes management list within the routine registration system for screening. This list included all identified patients with diabetes within the service range of the PHC facilities. The recruitment inclusion criteria were adults who (1) were diagnosed with T2DM, (2) were aged 40 years or older, (3) had a HbA_{1c} level of 7.0% or higher, (4) had access to the internet via a smartphone (confirmed verbally), either independently or through a designated family member, and (5) provided informed consent. Patients were excluded if they (1) had severe physical or psychological injury or illness, (2) were unable to attend the site visit or consciously answer questions, (3) were women in the process of or planning for pregnancy or breastfeeding, or (4) participated in any other clinical trial within the previous 6 months.

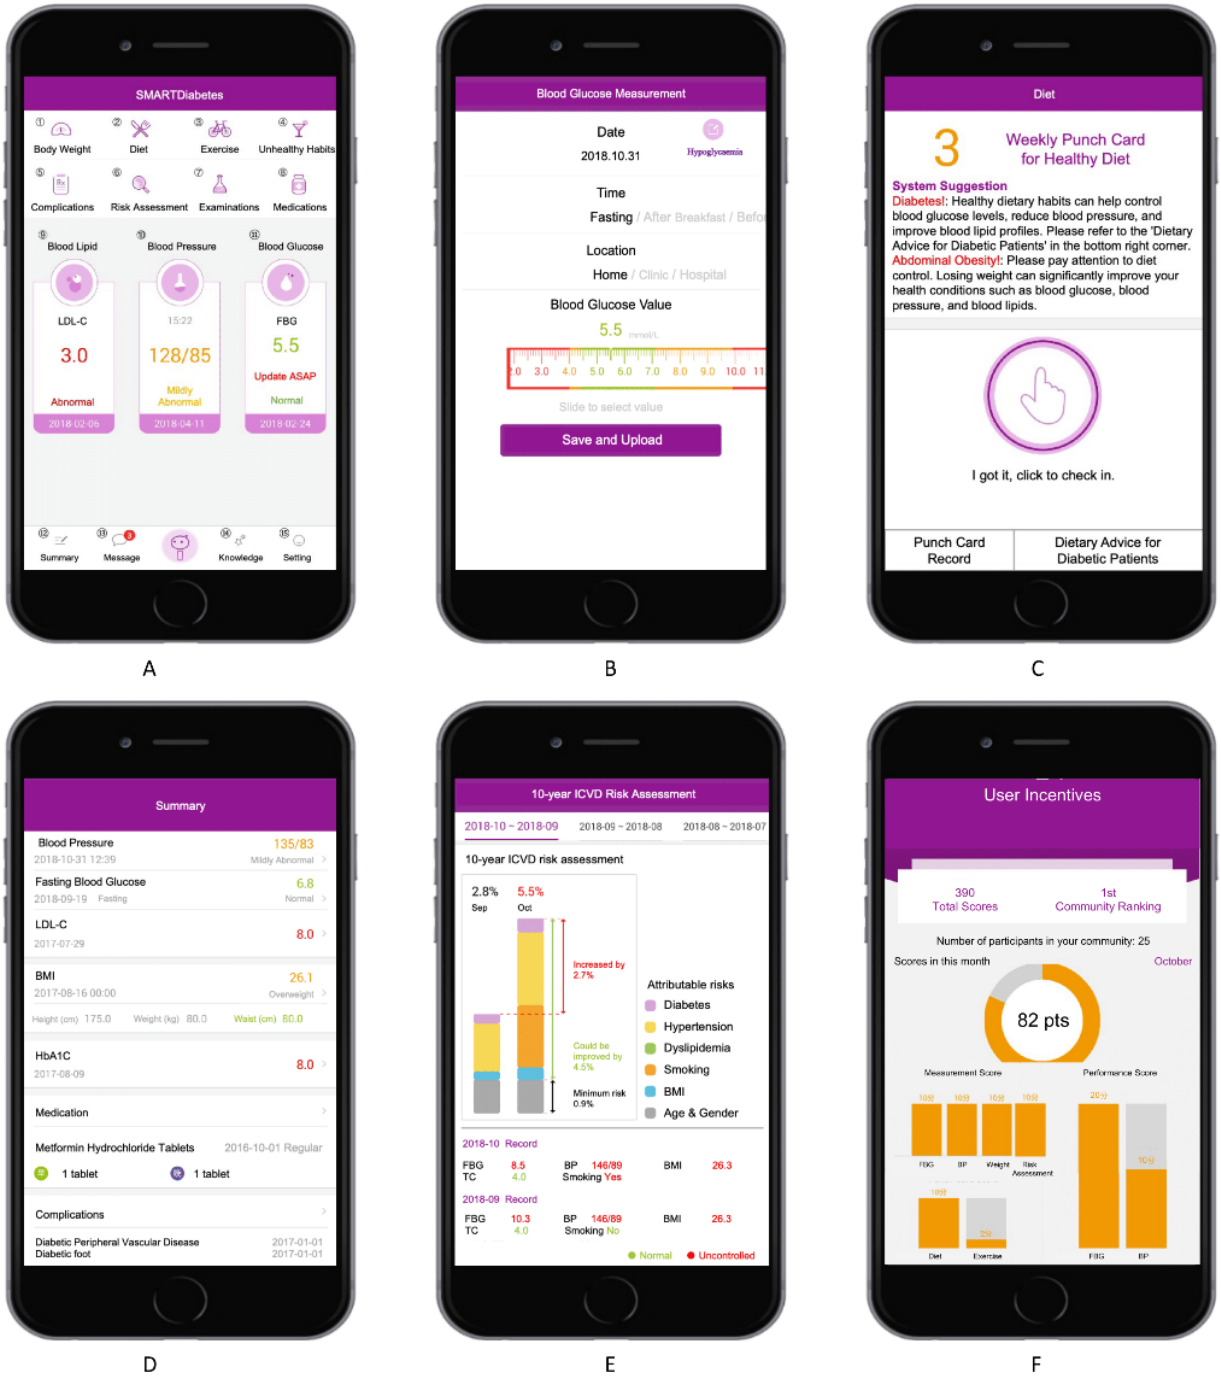
SMARTDiabetes Intervention



Based on a previous mixed methods study that systematically explored major barriers to and facilitators of PHC management of T2DM in China [21], our team developed the SMARTDiabetes app adopting a user-centered design approach [4,5]. In brief, the SMARTDiabetes app incorporates recommendations from Chinese national and international guidelines to support disease self-monitoring, adoption of healthier lifestyles, better medication adherence, and prevention of diabetes complications [4]. As illustrated in Figure 1, a total of 15 functions are displayed on the main landing page (Figure 1A). Four functions, "Blood glucose," "Blood pressure," "Blood lipid," and "Body weight" (Figure 1B), are for disease self-monitoring, where users can upload their latest data to receive immediate in-app feedback with result interpretation, improvement suggestions (goal setting), and relevant healthy literacy materials. The next 2 functions, "Diet" and "Exercise" (Figure 1C), are assisted by a digital punch card (*Da Ka*—clocking registration) system, which sends reminders for consuming healthier diets and engaging in appropriate physical activities. A further 5 functions, "Unhealthy lifestyles," "Health status summaries," "Physical examinations and lab tests," "Medications," and "Diabetes complications" (Figure 1D), serve as a medical record, enabling the tracking of unhealthy practices, medication adherence, and disease progression. The 12th function—"iCVD risk assessments" (Figure 1E) shows onset probabilities of ischemic cardiovascular diseases (iCVDs) including stroke within the following 10-year period, accompanied by a forecasted, monthly adjusted risk progression curve, on the basis of users' latest self-monitored data entry. This risk forecast model was constructed by the research team, using the risk assessment tools of Wu and colleagues [22]. The final 3 functions include 2 administrative functions ("Settings" and "Messages") and 1 preloaded health literacy function ("Knowledge and skills bank").

The reward program (Figure 1F) allows users to earn and accumulate reward points by interacting with the 6 core app functions (ie, "Blood glucose self-monitoring," "Blood pressure self-monitoring," "Body weight," "Diet punch card," "Exercise punch card," and "iCVD risk assessment quiz"). Users can earn up to 100 points per month (see detailed scoreboard in Table S1 in Multimedia Appendix 1) and redeem their points for small gifts of little monetary value, such as soap, towels, or laundry powder, from their respective PHC providers in the communities.

Before the trial commenced, the research team conducted a comprehensive training session for the 40 PHC providers in the intervention arm, covering downloading, installing, and using both the patient and provider versions of the SMARTDiabetes app. Subsequently, PHC providers organized training sessions for their enrolled patients and the patients' FHPs. To facilitate and standardize these sessions, a PowerPoint slide deck and an instruction brochure were developed (Figure S2 in Multimedia Appendix 1).

XSL•FO
RenderX

Figure 1. Main functions of the SMARTDiabetes app.

User Engagement Metrics

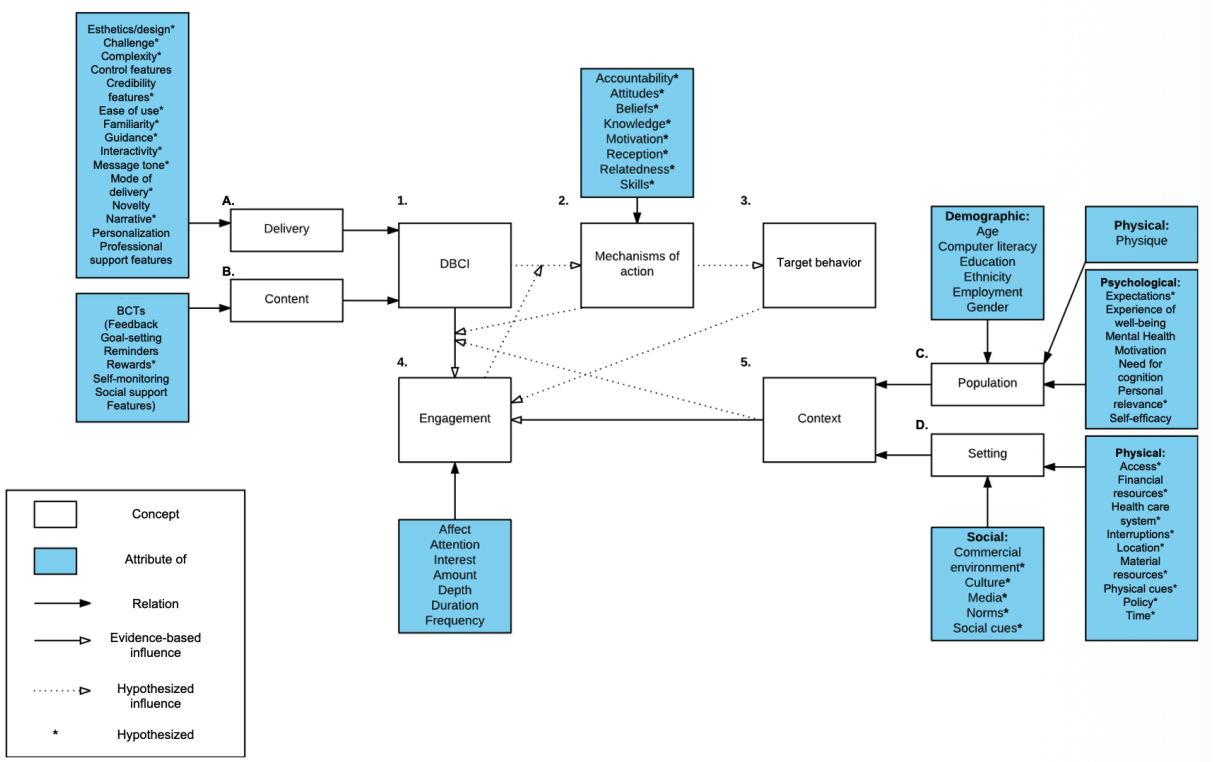
Deidentified app usage data collected between April 2018 and July 2019, including log-in frequencies and app functions click-through counts, were extracted by the service provider (Beihang University) and sent to the research team for secondary data analysis. In addition, a series of autogenerated key performance indicators (eg, BP control rates and fasting blood glucose [FBG] self-monitoring rates), in the form of cluster-level aggregated monthly reports, were presented on the SMARTDiabetes website. The research team documented these key performance indicators at the end of each month.

User engagement was evaluated using the following four metrics. (1) The proportion of monthly active users (MAUs), defined as participants who logged into the app at least once in a certain month, which was calculated by dividing the number of MAUs by the total number of participants in the intervention arm. Sustained active users were defined as participants who maintained MAU status for at least 12 months within the 16-month assessment period (April 2018 to July 2019), while others were categorized as “inactive users.” (2) The proportion of users with FHP involvement, which was calculated by dividing the number of patients who reported receiving FHPs’ assistance in app use by the total number of participants in the

XSL•FO
RenderX

intervention arm. (3) The total click-through counts per month, which was calculated by adding the number of clicks by each function. (4) The proportion of users who adhered to the recommended FBG self-monitoring frequencies per the SMARTDiabetes app's algorithm (see the algorithm in Table S2 in Multimedia Appendix 1).

The first 2 metrics were derived from app usage data, the third metric was obtained from the final trial assessment questionnaire, and the fourth metric was a cluster-level performance indicator retrieved from the SMARTDiabetes website. Descriptive analysis was conducted using SAS software (version 9.4 or above; SAS Institute). Means and SDs were reported for continuous variables with normal distribution; medians and IQRs were reported when the data were skewed. Proportions were reported for categorical variables.



Association Between User Engagement Levels and Trial Effectiveness

In a post hoc analysis, associations with the primary outcome at 24 months were analyzed for the following subgroups: (1) sustained active users versus inactive users, (2) users with versus without FHP involvement in app use assistance, and (3) click-through registration levels, with users grouped into quartiles based on the total number of clicks on app functions during the same period.

An inverse propensity score weighted analysis was conducted to compare the trial effectiveness across subgroups with different engagement levels. Propensity scores were developed to control for the differences in baseline demographics, medical history, and laboratory characteristics across subgroups. Propensity scores were generated by a logit regression model with covariates of age, sex, locality, HBA_{1c}, FBG, systolic BP, diastolic BP, low-density lipoprotein cholesterol, education levels, duration of diabetes category, and diabetic complications. A log-binomial regression model with generalized estimation equation and adjustment for community clustering and the weighted inverse propensity score was then developed. The associations were presented as the relative risk (RR) with its 95% CIs. All analyses were performed with SAS software (version 9.4 or above; SAS Institute).

To better understand the geographic heterogeneity in trial effectiveness observed in our primary results study [5], we conducted additional subgroup analyses by locality to understand their differences in PHC facilities characteristics (Figure 2D), population baseline characteristics (Figure 2C), and engagement patterns (Figures 2-4). Two-tailed *t* tests were conducted for continuous variables with normal distribution, Wilcoxon signed-rank tests were conducted for continuous variables without a normal distribution, and chi-square tests were conducted for categorical variables.

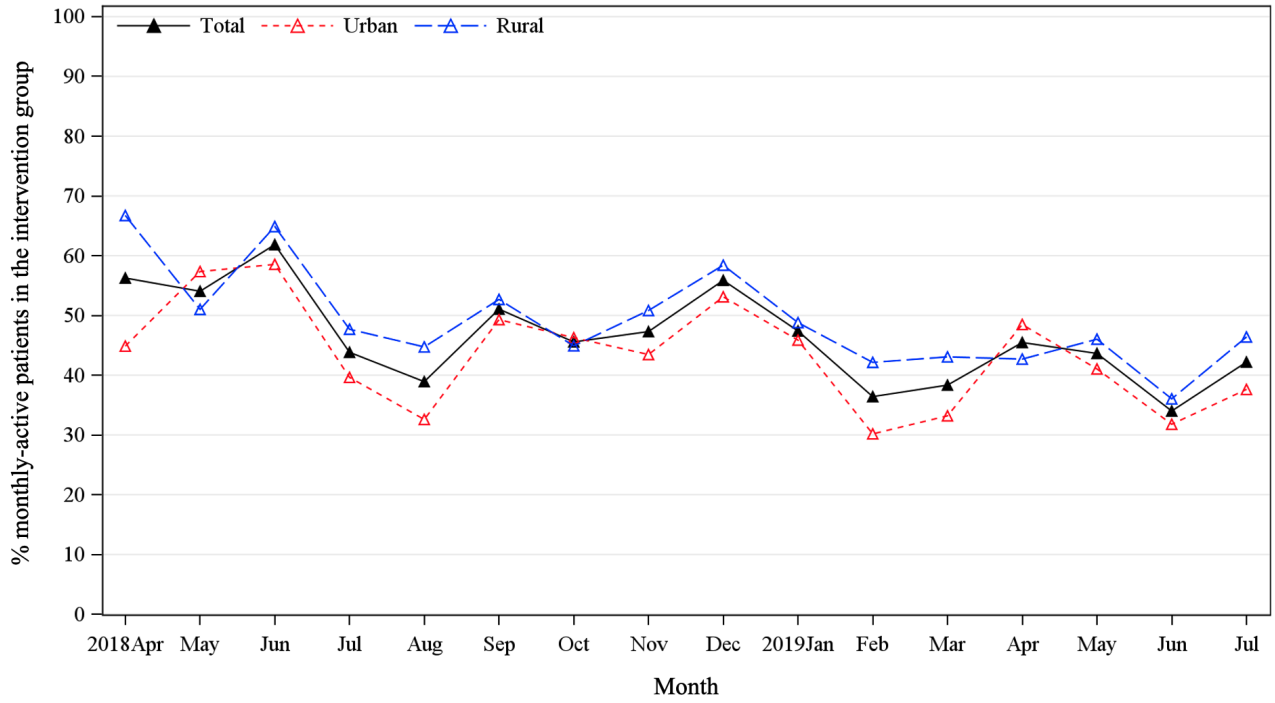
Figure 3. The proportion of monthly active users.



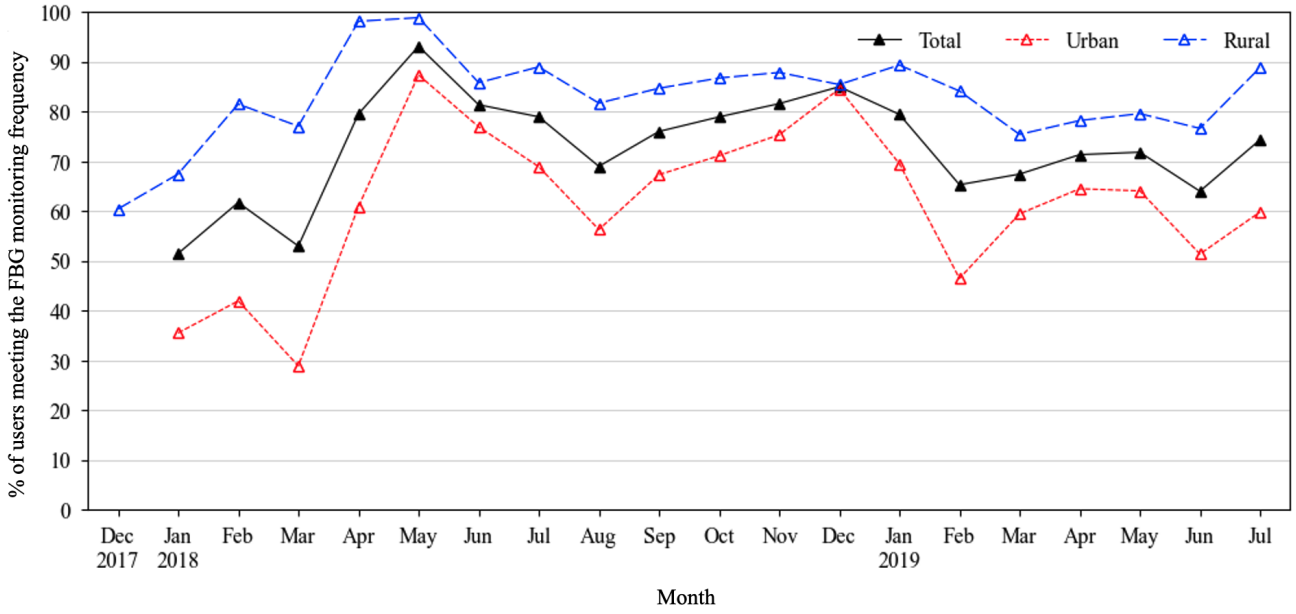


Figure 4. The proportion of users meeting the FBG monitoring frequency. FBG: fasting blood glucose.

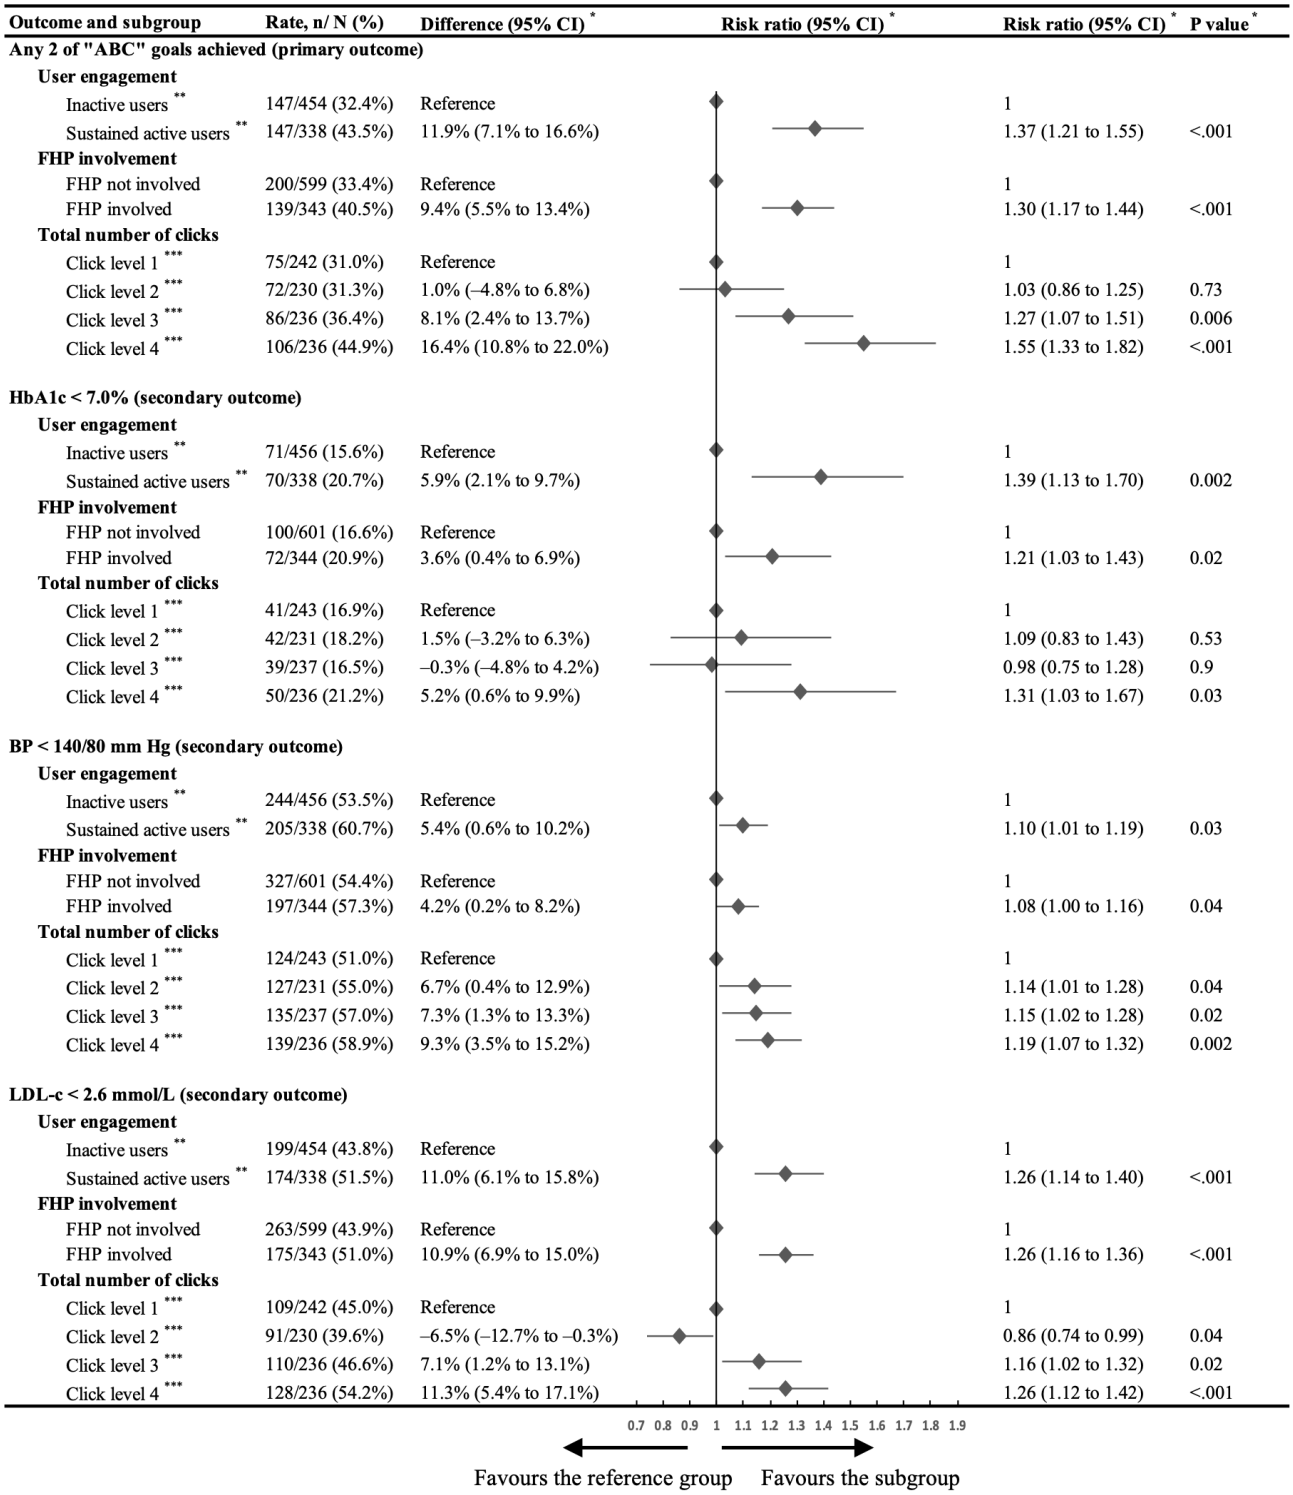
Influencing Factors of User Engagement

After the trial, 2 qualitative activities were undertaken to explore the influencing factors for user engagement and trial effectiveness.



1. An expert review of the DBCI including app features (DBCI content, Figure 2B) and trial implementation activities (DBCI delivery, Figure 2A) based on the conceptual DBCI engagement framework by Michie and colleagues [6]. This framework conceptualizes the potential direct and indirect influences on engagement, as well as the relationships between engagement and the effectiveness of the interventions. The behavior change techniques (BCTs) adopted by our DBCI were identified against the internationally recognized Behavior Change Technique Taxonomy (V1) [23]. Two researchers (XT and PZ) independently conducted the review. With the majority in agreement, a small amount of disagreement was resolved by discussion and a consensus was reached.
2. In-depth interviews. Interviews with key stakeholders, including selected PHC providers, patients, and FHPs in both urban and rural settings, were conducted in June 2020 to deepen our understandings of factors contributing to user engagement with the app. Semistructured, user-type specific interview guides were developed by our multidisciplinary research team, piloted with a few participants, and then revised (see posttrial interview guides in Multimedia Appendix 1). Face-to-face, one-on-one in-depth interviews,

XSL•FO
RenderX

each lasting approximately 1 hour, were conducted in Mandarin Chinese by 2 team members (XT and PZ) in designated private areas. The interviews were audio-recorded and transcribed verbatim. Iterative thematic analysis was conducted by generating codes, forming themes, and further categorizing into 3 domains— DBCI content (Figure 2B), DBCI delivery (Figure 2A), and context (Figures 2-5)—based on the conceptual framework for engagement with DBCIs by Michie and colleagues [6]. During coding, the researchers were blinded to the overall trial outcomes. All analyses were performed with Nvivo12 (QSR International).

XSL•FO
RenderX

Figure 5. Forest plot of the effects of user engagement on main clinical outcomes. BP: blood pressure; FHP: family health promoter; HbA_{1c}: glycated hemoglobin; LDL-c: low-density lipoprotein cholesterol.

*: Inverse PS weighted model: log-binomial model with GEE and with adjustment of cluster with inverse propensity score weighted. Propensity Score was calculated according to differences in baseline sociodemographic characteristics, medical history and lab test results between subgroup users (in the intervention arm). Propensity scores were generated by a logit regression model with covariates of age, sex, locality, HBA1c, FBG, SBP, DBP, LDL-c, education levels, duration of diabetes category, and diabetic complications.

**: Sustained active users are defined as users who logged in the app for at least 12 months (at least once per month) or above, where inactive users are defined as users who logged in the app for less than 12 months.

***: The click levels are divided by quartiles of the total number of clicks of App functions No. 1-15 (Table 1) from July 2019 to April 2018. Level 1 (0–10 clicks, n = 243), Level 2 (11–75 clicks, n=231), Level 3 (76–315 clicks, n=237), and Level 4 (>315 clicks, n=236).

Triangulation and Synthesis of Quantitative and Qualitative Findings

All findings were integrated by matching the quantitative and qualitative results against the attributes and concepts—DBCI content, DBCI delivery, and context—of Michie's conceptual framework (Figure 2) in a joint display for further comparisons and metainferences [6].

Ethical Considerations

The SMARTDiabetes study was approved by the Peking University Health Sciences Institutional Review Board, Beijing, China, (IRB00001052-15062), and The University of Sydney Human Research Ethics Committee, Sydney, Australia (project no. 2016/105). The trial was registered at ClinicalTrials.gov (registration record NCT02726100, March 22, 2016). All participants provided written informed consent to the collection of individual-level trial assessment data and app usage data at the beginning of the trial. All interviewed participants provided verbal consent prior to interviews. All data were deidentified to ensure privacy and confidentiality. Participants were not financially compensated for taking part in the trial; however, all participants received free health examinations at baseline, midterm, and study completion.

Results

User Engagement

A total of 1038 participants from 40 clusters (20 rural villages and 20 urban communities) were assigned to the intervention arm. The mean MAUs proportion during the 16-month assessment period was 46.4% (SD 7.8%), with a gradual decline from 56.3% at the beginning (April 2018) to 42.2% at the end of follow-up (July 2019) (Figure 3). The proportion of sustained active users was 32.9% (342/1038 participants), with rural users showing a significantly higher rate than urban users (rural: 207/541 participants, 38.3% vs urban: 135/497 participants, 27.3%; $P<.001$).

After the initial period of training, installation, and familiarizing with the app, by May 2018, most users had been actively entering their FBG data into the app, with 98.9% (491/495) of rural and 87.4% (473/541) of urban users meeting the app-recommended monitoring frequencies (Figure 4). Throughout the entire trial period, the mean proportion of users meeting the recommended FBG-monitoring frequencies was 72.5% (SD 16.5%), with rural users outperforming their urban counterparts (rural 82.9%, SD 2.0% vs urban 61.6%, SD 3.6%; $P<.001$).

Table 1 summarized the monthly click-through rates per person for each of the 15 functions of the SMARTDiabetes app. The median total clicks per person per month was 3.9, with rural participants using more (rural 4.9 vs urban 3.5; $P=.32$). The most commonly used app functions were the 2 reminders "Diet punch card" and "Exercise punch card," followed by the 2 self-monitoring ones "Blood glucose" and "Blood pressure," all of which were incentivized functions.

[a]*Directly or indirectly incentivized functions.

[b] iCVD: ischemic cardiovascular diseases.

Associations Between App Engagement and Effectiveness

As shown in Figure 5, sustained active users and users with FHP involvement achieved significantly better results in primary outcome and all 3 secondary outcomes. Users with the fewest clicks (click level 1) had a 31.0% success rate in achieving any 2 of the "ABC" goals. This rate remained unchanged at 31.3% in click level 2 (RR 1.03, 95% CI 0.86-1.25; *P*=.73). However, click level 3 users showed a statistically significant improvement, with a 36.4% success rate (RR 1.27, 95% CI 1.07-1.51; *P*=.006), and those in click level 4 achieved an even higher 44.9% success rate (RR 1.55, 95% CI 1.33-1.82; *P*<.001). This gradient in health outcomes across the different levels of user engagement, as measured by the total number of clicks on the SMARTDiabetes app functions, was also evident in achieving each individual "ABC" goal at 24 months.

Rural-Urban Heterogeneity

Table 2 showed the disparities between rural and urban settings. Rural PHC facilities had fewer health care resources but were 100% (20/20) government-owned compared with 65% (13/20) of urban ones and were more distant from tertiary hospitals (13.3 km vs 1.9 km; *P*<.001). Rural participants were younger (*P*<.001) but had lower educational levels. Despite these differences, rural participants demonstrated higher engagement across all levels: a larger proportion of sustained active users (38.3% vs 27.2%; *P*<.001), greater FHP involvement (48.6% vs 21.5%; *P*<.001), more frequent interaction with the app (4.9 clicks per person per month vs 3.5; *P*=.32), and higher rates of self-monitoring FBG (82.9% vs 61.6%; *P*<.001).

[d]FHP: family health promoter.

[e]FBG: fasting blood glucose.

Influencing Factors of User Engagement

The rapid expert review of the SMARTDiabetes app features (DBCI content) suggested that 6 main features, corresponding to previously proven effective BCTs [23], were very likely to have contributed to the success of the trial. These features included (1) the incentive system (Reward), (2) real-time feedback on individual result interpretation and suggestions for improvement (Feedback), (3) in-app reminder messages and healthy lifestyle punch card (Reminders), (4) setting goals and targets (Goal setting), (5) self-monitoring tools (Self-monitoring), and (6) support from FHPs (Social support

XSL•FO
RenderX

features). The review of the SMARTDiabetes trial implementation activities (DBCI delivery) revealed several factors that have been proven effective [6], including partnerships with the local authorities (Credibility features), ongoing professional support from PHC providers (Professional support features), and a step-by-step, illustrative app instruction brochure (Guidance) (see Figure S3 in Multimedia Appendix 1 for the brochure). However, the complex installation process and frequent software updates were identified as major barriers to adoption and sustained engagement (Ease of use).

Twelve stakeholders (2 PHC providers, 7 patients, and 3 FHPs) were interviewed. The thematic analysis confirmed that rewards of nominal gifts, automated reminders, patient involvement in regular chronic disease self-monitoring, and adequate support from both FHPs and PHC providers were the most highly valued features of the SMARTDiabetes app. These features were perceived by the key stakeholders to be most influential in contributing to our app engagement. Furthermore, several key barriers to engagement were also identified in the interviews. First, a few patient users reported reluctance to involve their FHPs as it was perceived to lay an excessive burden to the FHPs, and this was more likely to occur if the FHPs had a busy daily life schedule or they lived far apart from the patient users. Technical difficulties related to the app installation and version updates were cited by several key stakeholders as a major barrier. Also, older participants, those with low literacy, and those inexperienced in smartphone use were the least likely to be active users. Qualitative findings also showed that in rural areas, the patient-doctor relationship is more personal and community-focused, PHC facilities are more committed to government initiatives, and FHPs are actively involved in patient care, whereas in urban areas, patients could bypass PHC facilities in favor of accessible tertiary hospitals.

Synthesis of Findings

Based on the conceptual framework of DBCI engagement by Michie and colleagues [6,23], our team constructed this program logic to suggest potential influences and pathways contributing to user engagement and trial effectiveness, according to (1) DBCI content, (2) DBCI delivery, and (3) context. Table 3 shows the joint display of synthesized mixed methods findings where key quantitative findings were juxtaposed with illustrative interview quotes.

XSL•FO
RenderX

Table . Summary of the quantitative and qualitative findings.

Concept	Attribute	SMARTDiabetes features	Dose/fidelity	Quantitative evidence of effectiveness	Qualitative evidence of effectiveness
DBCI[a] Content	Rewards	• Users accumulate reward points by using certain functions in the app (Table S1 in Multimedia Appendix 1). Each user can earn a maximum of 100 points per month. These points can then be redeemed for nominal gifts (valued 5 - 30 CNY[b]), distributed by their PHC[c] providers. The reward system was launched in April 2018 and had been active throughout the rest of the trial.	• In total, app users generated 982,005 reward points, with 93.2% (915,571/982,005) redeemed. In total, 97.0% (1006/1038) users have received gifts.	• The incentivized app functions were more commonly accessed than those without (Table 1). • After the introduction of the reward system in April 2018, there was a significant increase in the number of active users (Figure S4 in Multimedia Appendix 1). The rate of users meeting the recommended FBG[d]-monitoring frequencies increased from 77% to 99% in rural sites; and from 27% to 87% in urban sites in the following 2 months (Figure S3 in Multimedia Appendix 1).	• "I am delighted to have earned the top-ranked reward points in my group" (Patient user, urban). • "The monetary value of the reward isn't important. The gift serves as motivation for making positive changes" (Patient user, urban). • "The monetary value of the gift doesn't matter. As long as they get something, it should be effective [to motivate patient engagement" (PHC provider, urban). • "Patients will be happy even if they get the smallest gift, but they need to be able to redeem the gifts more frequently" (PHC provider, rural).
DBCI Content	Feedback	• The app provided real-time feedback based on user inputs after users self-recorded their FBG readings.	• The mean proportion of users meeting the recommended FBG self-monitoring and uploading frequencies was 72.5% (SD 16.5%).	N/A[e]	N/A

XSL•FO
RenderX

Concept	Attribute	SMARTDiabetes features	Dose/fidelity	Quantitative evidence of effectiveness	Qualitative evidence of effectiveness
DBCI Content	Reminders	• Users received in-app messages reminders to encourage self-monitoring of FBG and BP[f], along with alerts for potential risks of unhealthy practices. The messages were categorized into 4 genres: urgent, serious, self-management, and system notifications. The "Diet" and "Exercise" functions set reminders to adhere to a healthy diet and daily exercise through a digital register.	• In total, 57.7% (291/504) urgent messages, 14.3% (42,625/298,873) serious messages, 6.4% (35,103/550,912) self-management messages, and 15.1% (1565/10,341) system notifications were read by the users. A total of 58,581 click-throughs to the "Diet" function and 55,126 to the "Exercise" function (Table 1).	N/A	• "The app sends reminders if you forget to measure your FBG or BP. When you receive the warning messages, it serves as a reminder, which is helpful, especially for elderly users who may forget at times. The "Diet" Da Ka (punch card) register advises me daily to consume less flour and starch, which I find beneficial. I'm particularly keen on the "Exercise" feature, where I can record my daily physical activity" (Patient user, urban).
DBCI Content	Goal setting	• On the app's main display screen, the latest FBG, BP, and LDL-c[g] data were shown with a visually memorable color grading scheme: good results were marked in green, moderate ones in yellow, and poor ones in red (Figure 1A). The "ABC" goals were set to achieve FPG[h] level below 7.0 mmol/L; BP readings below 140/80 mm Hg; and LDL-c levels below 100 mg/dL or 2.6 mmol/L.	• Each time at login, users could review their 3 "ABC" goals displayed upfront on main screen.	N/A	N/A
	Self-monitoring	• The app encourages users to self-monitor and upload their FBG and BP readings.	• Throughout the trial, the mean frequency of FBG measurements was 1.50 (SD 0.39) times per month per person and BP levels were 1.45 (SD 0.39) times per month per person.	N/A	

XSL•FO
RenderX

Concept	Attribute	SMARTDiabetes features	Dose/fidelity	Quantitative evidence of effectiveness	Qualitative evidence of effectiveness
					• "I monitored my BP and FBG levels more frequently after using the app" (Patient user, urban). • "I used the BP and FBG functions the most (to upload and record BP and FBG levels)" (Patient user, urban).
DBCI Content	Social support features	• Family members played an active role in assisting patients with diabetes management.	• In the intervention arm, 36.4% (344/945) of participant users reported having a family member who was able to assist them with the app (Table 2—Proportion of users with FHP[i] involvement). • The majority of FHPs were the patients' adult children (78.8%), followed by their spouses (14.2%). Most FHPs were living together with the patient users (71.5%) (Table S3 in Multimedia Appendix 1).	• FHP involvement was associated with better primary clinical outcomes (40.5% vs 33.4%; RR[j] 1.30, 95% CI 1.17-1.44; *P*<.001), as well as better secondary clinical outcomes, including HbA_{1c}[k] (20.9% vs 16.6%; *P*=.02), BP (57.3% vs 54.4%; *P*=.04), and LDL-c (51.0% vs 43.9%, *P*<.001) (Figure 5). • Of the various support and assistance provided by the patient users' FHPs, reminding of medication uptake (66.0%), dietary control (64.8%), and exercise (57.3%) were the most common. This was closely followed by accompanying patient users to seek medical treatment when needed (50.3%) (Table S3 in Multimedia Appendix 1).	• Facilitators: "FHPs supervise the patients. Sometimes they buy medicine for them" (PHC provider, rural). • "My wife supported me in using this app. She learned how to use it first and then taught me. I am not good at using smartphones, and I tend to forget how to use the app" (Patient user, urban). • "I reminded the patient to take the medication" (FHP user, rural). • Barriers: "My children are busy, so I don't want to bother them" (Patient user, urban). • "FHPs are busy" (PHC provider, rural). • "My children come home about once per year" (Patient user, rural).
DBCI Delivery	Credibility features		• At each app login	N/A	N/A

XSL•FO
RenderX

Concept	Attribute	SMARTDiabetes features	Dose/fidelity	Quantitative evidence of effectiveness	Qualitative evidence of effectiveness
		• The app and the brochure (Figure S3 in Multimedia Appendix 1) displayed main local health authority's (our study partners') logos (the Hebei Medical University and Shijiazhuang Center for Disease Control and Prevention).			
	Professional support	• An initial app induction about downloading, installation, and key functions was followed by continuous support from pretrained PHC providers.	• PHC providers in the intervention arm were trained to download, install, update, and skillfully use every function of the app ("train the trainer").	N/A	• "The app made my communication with my doctor more frequent and more convenient. Our relationship became closer" (Patient user, urban). • "I tend to forget how to use the app. I need help from the doctor so that I can continue to use the app" (Patient user, urban). • "I gathered all patients and FHPs in my clinic and talked with them about the app. If they can't make it, I went to organise other teaching chances at another time" (PHC provider, rural).
DBCI Delivery	Guidance	• A detailed, easy-to-understand instruction brochure (app operation manual), accompanied by a set of picture-based illustrative PowerPoint slides, was developed (Figure S1 in Multimedia Appendix 1).	• Written app operation instruction materials were adequately distributed to all participating PHC providers, which further facilitated their patient user training.	N/A	N/A
	Ease of use		• App retraining had to be repeated every time there were major updates.	N/A	

XSL•FO
RenderX

Concept	Attribute	SMARTDiabetes features	Dose/fidelity	Quantitative evidence of effectiveness	Qualitative evidence of effectiveness
		• The app installation and updating process was perceived NOT to be easy to follow. Users were initially instructed to scan a QR code, which then directed them to go through a few steps to gain the system access permission before they could download.			• "Upgrading is challenging for patients as they need to download first and then find the file and obtain permission to access the app...It's too complicated when the upgrades are very frequent" (PHC provider, urban). • "I don't understand the "iCVD risk" function as it is too complicated" (FHP user, rural).
Context	Population	• Older people, those with low education literacy, and those with low smartphone experiences were the least likely to engage with the app.	N/A	• The mean age of the patient users in the intervention arm was 61.4 years (SD 7.1), with 62.8% (652/1038) aged 60 years or older. Close to half (758/1038, 73.0%) of the patient users did not complete the Chinese 9-year compulsory education (ie, not completing senior high school).	• "I feel that older people may struggle to use the app due to lower education levels, making it difficult for them to learn new skills. This is why patients in rural areas often rely more on their FHPs, while urban patients may not face the same challenges" (PHC provider, urban). • "I am old, and it's hard for me to accept new things. Our generation has only recently started using smartphones. We need to take it slowly" (Patient user, urban).
Context	Setting (rural vs urban)		N/A	• Refer to Table 2	

XSL•FO
RenderX

Concept	Attribute	SMARTDiabetes features	Dose/fidelity	Quantitative evidence of effectiveness	Qualitative evidence of effectiveness
		• While the SMARTDiabetes intervention demonstrated significant improvement in the proportion of participants achieving at least 2 American Diabetes Association "ABC" management targets compared with usual care (intervention group: 35.9% vs usual care: 29.9%; *P*=.025), we observed significant heterogeneity in the primary outcome between rural (intervention group: 42.6% vs usual care: 31.0%) and urban (intervention group: 27.9% vs usual care: 28.6%) settings (*P*=.02 for heterogeneity).			

XSL•FO
RenderX

Concept	Attribute	SMARTDiabetes features	Dose/fidelity	Quantitative evidence of effectiveness	Qualitative evidence of effectiveness
					• Closer patient-doctor relationship in rural areas: In rural areas, the patient-doctor relationship often resembles that of close-knit neighborhoods, characterized by familiarity and reciprocity. In contrast, in urban areas, personal contact is often more distant, with the patient-doctor relationship largely shaped by the PHC provider's professional expertise and communication skills. • Stronger commitment of PHC facilities in rural areas: Government-owned or public-funded PHC facilities tend to show greater commitment to government-endorsed initiatives, while private-owned facilities, more common in urban areas, often prioritize profit-driven activities. • Bypassing the PHC facilities in urban areas: In urban areas, where tertiary hospitals are much closer, patients often bypass PHC facilities, opting instead to seek health care directly at nearby hospitals without needing a referral. This practice potentially undermines the effectiveness of PHC providers in delivering continuous care to patients with chronic conditions. • More FHP involvement in the

XSL•FO
RenderX

Concept	Attribute	SMARTDiabetes features	Dose/fidelity	Quantitative evidence of effectiveness	Qualitative evidence of effectiveness
					rural areas: FHPs, primarily patients' children and spouses, played a vital role in patient care. They assisted with app use, including reminding patients to take medications, supporting dietary management, encouraging regular exercise, and often accompanying patients' hospital visits for scheduled medical appointments. While both rural and urban patients reported reluctance to ask for help from FHPs, rural patients generally found it easier due to their closer proximity to family members.

Discussion

Principal Findings

The SMARTDiabetes trial was the first long-term (over 1 year) mobile app intervention for T2DM self-management conducted in a real-world PHC setting. Throughout the whole trial period, 46.4% of participants were MAUs and 32.9% (342/1038) were sustained active users. We observed a dose-response relationship between user engagement and trial effectiveness. Specifically, sustained engagement with the app, involvement of family members, and frequent interaction with app functions were associated with improved clinical outcomes. Key drivers of user engagement and trial effectiveness included 6 known BCTs underpinning the 15 app functions (ie, reward, feedback, reminders, goal setting, self-monitoring, and social support features), 4 implementation facilitators (credibility features, professional support, guidance, and ease of use), and 5 contextual contributors (younger age, better education, greater smartphone literacy, closer patient-doctor relationship, and stronger PHC facilities commitment).

We observed a modest yet effective level of engagement with the SMARTDiabetes app, with half of the participants logging in at least once per month, leading to significant improvement in achieving at least 2 ADA "ABC" management targets [5]. Effective engagement with DBCI is empirically defined as the level of interaction necessary to achieve the intended health outcomes [11]. It involves both "microengagement," which refers to the intensity and consistency of app use, and "macroengagement," which pertains to the alignment with and commitment to the broader intervention goals. Both forms of engagement are closely intertwined, and while each is important, neither alone is sufficient for achieving effective outcomes. Previous DBCIs for diabetes primarily focused on patients and doctors only [12-15]. However, the SMARTDiabetes mHealth

XSL•FO
RenderX

system, consisting of 2 apps and 1 website, fostered stronger connections among patients, family members, PHC providers, and local governors (Figure S1 in Multimedia Appendix 1). It enabled remote family members to stay informed about their loved ones' health and facilitated lay FHPs in delivering evidence-based, guideline-informed care (eg, FHPs helped remind patients to take medications, supported dietary management, encouraged regular exercise, and accompanied patients to medical appointments; Table S3 in Multimedia Appendix 1). The system also encouraged patients to actively engage with their doctors through in-app messages, phone calls, and face-to-face interactions during training and the gift redemption process, addressing a key barrier to diabetes management at the PHC level in China [21]. Additionally, it provided governors with real-time access to validated health statistics and powerful data visualization tools, enabling them to track changes, make informed comparisons, and drive performance-based improvements in the quality of care. These macrolevel improvements in engagement were hard to measure yet indispensable to the trial's overall success.

Comparing engagement levels across DBCI studies is challenging and often inconclusive due to the heterogeneity in intervention types, implementation duration, delivery modes, population demographics, study settings, intended behavioral objectives, and measures of engagement [24]. Standardized checklists to describe engagement with DBCIs will assist with comparing engagement across studies. The observed nonengagement rate (170/1038, 16.4%) in our study compares favorably with previous studies, which reported nonengagement rates of 50.2% (101/201) [14] and 57.2% (16,958/29,643) [25]. The SMARTDiabetes trial's user engagement compared favorably at 6, 9, and 12 months to 3 similar studies conducted in real-world settings with large populations—the Cornerstones4Care study reported a 30.5% engagement rate in 6 months [25], the National Health Service Digital Diabetes Prevention Programme study had a 36.5% engagement rate in 9 months [26], and the myDESMOND study showed a 17.6% engagement rate in 12 months [27].

The decline in app engagement over time has been commonly reported in mHealth interventions [18,28]. We also noticed a gradual decline in engagement in our study, with the proportion of MAUs decreasing by 25.0%, from 56.3% to 42.2% over 16 months, resulting in a retention rate of 75.0%. In comparison, the Cornerstones4Care study reported a 71.4% (9051/12,685) retention rate over 6 months [25], the National Health Service Digital Diabetes Prevention Programme study showed a 54.2% (667/1230) retention rate over 9 months [26], and the myDESMOND study had a 31.3% (1676/5360) retention rate over 12 months [27].

Previous research has demonstrated a strong link between user engagement with DBCIs and their effectiveness in achieving intended health outcomes [9,29]. The dose-response relationship between the total number of app clicks and improvements in the primary outcome suggests that DBCIs require a minimum threshold of engagement—an optimal dose—to achieve intended outcomes [6]. Beyond this threshold, the intensity of engagement has a positive correlation with the extent of outcome improvements. However, due to the complexity of engagement, defining the optimal dose is challenging, as some individuals may require a longer period of interaction with the app than others [30]. It is also plausible that the individuals who are more motivated and successful in achieving behavioral change tend to engage more, or that those who engage more differ systematically from those who are less engaged [29]. Assessing the extent to which engagement influences behavioral and health-related outcomes is challenging, as it may be confounded by factors such as increased motivation and self-regulation skills [11]. Future research should investigate these potential confounders to draw more definitive conclusions.

The design of app features (ie, DBCI content) plays a crucial role in user engagement, and 6 effective BCTs were repeatedly associated with higher engagement levels [6,9]. In our study, we found that incentive features (ie, "rewards") [11] were highly effective both in boosting engagement at the initial adoption phase (ie, "trigger") and in sustaining long-term use. Our findings also suggest that the impact of rewards is believed to rely less on their monetary value and more on their distribution frequencies (instant positive reinforcement). The most frequently used functions were the diet and exercise punch cards, both of which integrated key aspects of gamification and loyalty. Gamification is a promising strategy for enhancing user engagement [31], and the commercial sector has excelled in implementing these concepts. For instance, Duolingo has used game elements such as leaderboard, level system, and badges to motivate users, achieving a staggering 100 million MAUs [32]. Academia can benefit from studying these successful models to improve the design of DBCIs.

One important lesson we learned was that the SMARTDiabetes app was not user-friendly when it came to downloading, installing, and updating. The app was unavailable on public app markets, requiring users to scan a QR code and download it via a third-party website. After downloading, users had to manually grant permissions for the app and complete the installation process. Moreover, with every update, users were forced to repeat the entire procedure. This cumbersome process likely contributed to a significant loss of active users [17]. Future mobile app interventions should focus on integrating the installation and updating processes with commonly used app stores.

Finally, context matters in implementation science research [33]. Our previous study showed that the same mHealth intervention package—using identical intervention tools and delivery strategies—was significantly more effective in rural settings than in urban settings [5]. The quantitative findings of this process evaluation showed that rural participants demonstrated higher engagement with the SMARTDiabetes program, reflected in a higher proportion of sustained active users (38.3% vs 27.2%; $P<.001$), more frequent app interactions (4.9 clicks per person per month vs 3.5; $P=.32$), and a higher rate of FBG self-monitoring (82.9% vs 61.6%; $P<.001$). Our qualitative findings indicated that higher engagement in rural settings was attributed to 3 main factors: closer and more reciprocal patient-doctor relationships, stronger commitment from PHC facilities, and greater involvement from the family members (Table 3). Together, these factors created a more

XSL•FO
RenderX

supportive environment for patients' sustained participation in the SMARTDiabetes program.

Strengths and Limitations

The strength of this study is its mixed methods design to capture multifaceted engagement with DBCIs. Study limitations include the following: First, the study's geographical scope was limited to Northern China, potentially constraining the generalizability of its findings to this specific health system context. However, this region's PHC infrastructure and services, based on the National Essential Public Health Service Programme, are representative of many areas across China. Consequently, we posit that these findings offer valuable insights applicable to other regions. Second, the total number of interviews conducted was less than anticipated, due to the difficulties of face-to-face interaction during the COVID outbreaks. Consequently, the views expressed by limited participants may not be representative of the total study population. Third, since the study was conducted a few years ago, there may have been changes over time. However, the expected impact of such changes is likely minimal, given that the core policies and regulations for diabetes and hypertension management have remained unchanged since 2009.

Conclusions

Long-term, sustained engagement with a mobile app intervention for T2DM self-management is achievable in the PHC setting in China. Our study reveals a dose-response relationship between user engagement with DBCIs and their effectiveness in achieving intended health outcomes. Specifically, DBCIs require a minimum level of engagement to be effective. The factors influencing engagement identified in the SMARTDiabetes study provide valuable insights for developing targeted strategies to enhance user engagement and improve overall program effectiveness.

Acknowledgments

The authors are grateful to Professors Linong Ji and Junfeng Xu for their contributions to the development of their mHealth intervention. The authors thank Xian Li, Fengzhuo Chen, Qiang Li, and Laurent Billot for their assistance in developing the statistical analysis plan and for checking the SAS program. The authors also extend their thanks to the patients, their relatives, and the doctors who participated in this study.

Funding

This study is supported by the Australian National Health and Medical Research Council and Global Alliance for Chronic Diseases (ID 1094712).

Data Availability

Anonymized individual-level data and datasets generated or analyzed during this study, together with the data dictionary and study protocol, are available for researchers who provide a methodologically sound proposal. Proposals should be directed to Professor Puhong Zhang (zpuhong@georgeinstitute.org.cn) and Professor David Peiris (dpeiris@georgeinstitute.org). The data will be available beginning 3 months after publication of this paper, with no end date. Any cross-border transfer of individual data must obtain official approval following legal procedures, in accordance with relevant regulations.

Authors' Contributions

XT, PZ, and DP conceived and designed the study. XT, YM, and YZ were pivotal in project management and trial implementation. XT and PZ were responsible for data collection. XT, HS, and PZ were responsible for quantitative data analyses. XT, LM, and PZ were responsible for qualitative data analyses. XT completed the draft of this paper. PZ, DP, and LM made substantial edits to the draft. YM and YZ provided critical suggestions for the draft. All coauthors approved the submission of this paper.

Conflicts of Interest

None declared.

Abstract

Background: Insomnia is a prevalent sleep disorder characterized by difficulty initiating or maintaining sleep and is associated with substantial health and economic burdens. Although cognitive behavioral therapy (CBT) is recommended as the first-line treatment, pharmacotherapy remains widely used despite adverse effects and significant indirect costs related to impaired productivity and workplace safety. Digital therapeutics delivering CBT through mobile platforms have emerged as scalable alternatives to improve access and outcomes. Somzz is a commercially available, domestically developed digital therapeutic that delivers CBT-based interventions for insomnia via a mobile app.

Objective: This study evaluated the cost-effectiveness of Somzz compared with conventional insomnia treatment combining CBT and pharmacotherapy from both health care system and societal perspectives in South Korea.

Methods: A decision-analytic model integrating a short-term decision tree with a Markov model was developed to compare costs and outcomes of digital CBT via Somzz versus conventional care in 2023. The model simulated a 27-week time horizon (three treatment cycles) and applied an annual discount rate of 4.5%. Clinical inputs, including remission probabilities and health utility values, were derived from a published randomized clinical trial comparing digital CBT delivered via Somzz with sleep hygiene education. Additional inputs, including health care resource use and unit costs, were obtained from published literature and national sources. Health outcomes were measured in quality-adjusted life years (QALYs). The cost analysis included direct medical costs and indirect costs related to absenteeism, productivity loss, and workplace accidents attributable to insomnia. Incremental cost-effectiveness ratios (ICERs) were estimated in 2023 South Korean Won (KRW). Deterministic one-way and probabilistic sensitivity analyses were conducted to assess uncertainty.

Results: From a health care system perspective, digital CBT via Somzz resulted in modestly higher costs and improved health outcomes compared with standard care. Over approximately 6.5 months, Somzz generated an additional 0.0092 QALYs per patient at an incremental cost of KRW 79,691 (US $61.87), yielding an ICER of KRW 8,719,727 (US $990,883) per QALY gained. This estimate was well below the Korean willingness-to-pay threshold of KRW 30,000,000 (US $23,192.91) per QALY. From a societal perspective, digital CBT was cost-saving, producing a negative ICER due to reductions in health care utilization, workplace accidents, and productivity losses associated with higher remission rates. Sensitivity analyses identified intervention

XSL•FO
RenderX

costs and remission probabilities as key drivers; however, digital CBT remained cost-effective across all scenarios under willingness-to-pay thresholds of KRW 30,000,000 and KRW 15,000,000 per QALY.

Conclusions: Digital CBT for insomnia offers favorable clinical and economic value in South Korea. Using Korean clinical trial data and locally relevant societal cost inputs, this study provides policy-relevant evidence supporting early integration of digital CBT into routine insomnia care, employer health strategies, and national digital health policy.

Introduction

Problem

Insomnia is a prevalent sleep disorder among adults, characterized by difficulty initiating or maintaining sleep or early morning awakening despite adequate opportunity for sleep, resulting in poor sleep quality and daytime dysfunction [1-3]. Evidence suggests that the global prevalence of insomnia has increased, particularly during the COVID-19 pandemic, with marked rises among health care workers and individuals infected with COVID-19 [4,5]. Insomnia is associated with numerous adverse health outcomes, including a higher risk of psychiatric disorders and diminished health-related quality of life [6-8]. Furthermore, insomnia may lead to decreased work productivity and a higher risk of motor vehicle accidents [9,10]. Consequently, insomnia imposes substantial health and economic burdens, including direct costs related to health care use and medication use, as well as indirect costs from absenteeism and reduced workplace productivity [6,11].

Several treatment guidelines recommend cognitive behavioral therapy (CBT) as a first-line treatment for chronic insomnia [2,12-14]. Pharmacotherapy-centered management, despite its widespread use, is associated with adverse events, limited long-term effects, and continued health care use, while often failing to restore daily functioning and work performance [15,16]. Nevertheless, pharmacotherapy remains the most commonly used treatment in the United States and other countries, including Korea [17-19]. A survey of Korean physicians reported that pharmacotherapy was chosen by 57.14% of patients, followed by sleep hygiene education (37.11%), whereas only 1.18% received CBT [17]. This discrepancy persists despite strong evidence that CBT provides durable benefits that can be maintained for more than 1 year after treatment completion, in contrast to the short-term symptom control typically observed with pharmacotherapy [20]. As a result, indirect societal costs, such as productivity loss and accident-related costs, frequently exceed direct medical expenditures in insomnia [6,21,22].

Review of Relevant Scholarship

Digital cognitive behavioral therapy for insomnia (dCBT-I) has emerged as a scalable solution that can overcome access barriers through the widespread availability of smartphones, tablets, and computers. Recent randomized controlled trials have demonstrated that dCBT-I not only reduces insomnia symptoms but also improves functional health, psychological well-being, and sleep-related quality of life over time [23]. Digital platforms can allow CBT to reach a wide population [24-26]. Meta-analytic evidence robustly supports the efficacy and broader benefits of digital CBT for insomnia. A 2022 meta-analysis demonstrated large short-term improvements in insomnia severity and moderate reductions in depressive symptoms that persisted long-term [27], while another meta-analysis focusing on occupational outcomes found significant decreases in lost productivity (presenteeism) and work-related rumination among working adults [28].

Building on this clinical evidence, recent economic evaluations have also matured: a 2023 systematic review and meta-analysis reported that dCBT-I consistently achieves favorable cost-utility and cost-effectiveness, particularly when societal costs such as productivity losses are considered [29]. Complementary findings from randomized controlled trials show that guided internet-delivered CBT-I can yield measurable quality-adjusted life years (QALY) gains and, from a societal perspective, has a high probability of dominating control conditions [30]. In addition, simulation modeling using a Markov framework in the United States found that fully automated digital CBT programs (eg, Sleepio) may not only be cost-effective but potentially cost-beneficial compared with no treatment, clinician-delivered CBT, and pharmacotherapy [31]. However, to date, no cost-effectiveness analysis of dCBT-I has been conducted using Korean clinical trial data and Korean-specific cost inputs. Given the strong influence of country-specific health care system structures and current treatment patterns on economic outcomes in insomnia, reliance on evidence generated in Western settings with limited consideration of societal costs may substantially misrepresent the value of digital CBT-I in the Korean context [29-32]. This study addresses an important evidence gap by incorporating Korean randomized clinical trial data and locally relevant cost inputs to evaluate the cost-effectiveness of a domestically developed digital CBT-I from both health care system and societal perspectives.

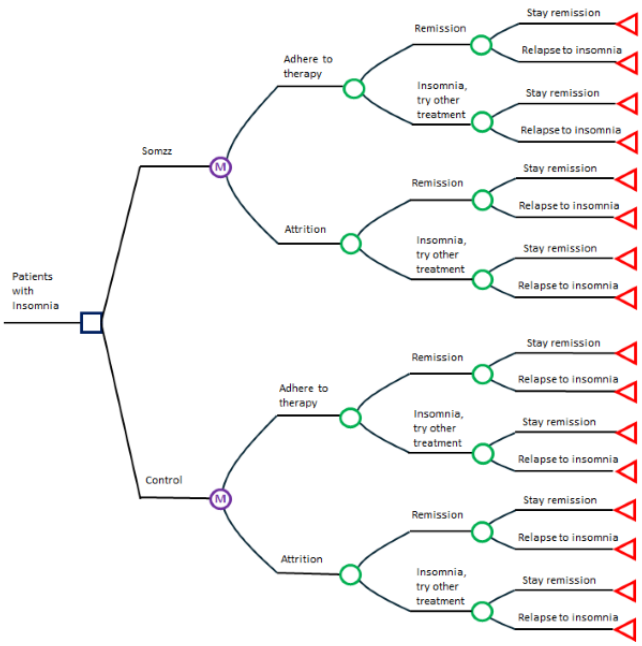
Hypothesis, Aims, and Objectives

Somzz (AIMNEXT Inc) is the first domestically developed digital therapeutic in Korea designed to deliver CBT for insomnia (CBT-I) [33]. The fully automated mobile app incorporates core CBT-I components, including stimulus control, sleep restriction, sleep hygiene education, relaxation training, cognitive therapy, and relapse prevention, while providing

XSL•FO
RenderX

personalized, real-time feedback based on users' sleep diary data and behavioral patterns. By targeting the psychological, behavioral, and cognitive factors that maintain chronic insomnia, Somzz offers a scalable alternative to clinician-delivered CBT-I.

Based on its demonstrated clinical efficacy and the substantial societal burden of untreated insomnia, we hypothesized that digital CBT-I delivered through Somzz would represent a cost-effective strategy compared with conventional care involving CBT and pharmacotherapy. In particular, we anticipated that Somzz would improve health outcomes while reducing overall costs when broader societal impacts, such as productivity losses and accident-related costs, are taken into account.



The analysis aimed to evaluate the cost-effectiveness of Somzz compared to standard care from both health care system and societal perspectives by using clinical outcomes from a Korean randomized controlled trial (RCT) and integrating real-world Korean wage, service use, and epidemiological data. We also aimed to examine the robustness of these findings through deterministic and probabilistic sensitivity analyses.

Methods

Conditions and Design

This study is a secondary analysis of a parent single-blind RCT (trial registration: KCT0007292; registered retrospectively on 2022-05-17) to assess the safety and efficacy of a digital therapeutic, Somzz [33]. This study is to compare the costs and outcomes of Somzz versus conventional care in 2023, and thus, we constructed a static decision tree model combined with a Markov model with a 27-week (3 treatment cycles over 9 weeks), which aligns with previous insomnia cost-effectiveness studies [31]. A Markov model represents disease progression by simulating transitions between mutually exclusive health states over discrete time cycles, assuming that future transitions depend only on the current state and not the path taken to reach it [34]. In our model, patients transitioned through health states of adherence, attrition, remission, relapse, and persistence of insomnia (Figure 1).

Figure 1. A basic description of the structure of the decision analytic Markov model.

We adopted the health care system and societal perspectives according to the economic evaluation guidelines in Korea [35]. This dual approach allowed us to assess the economic implications of a health care intervention more thoroughly by capturing the direct financial impact on the health care system and broader economic and societal effects. A discount of 4.5% was applied as per Korean guidelines [35]. We referred to the Consolidated Health Economic Evaluation Reporting Standards (CHEERS) guidelines [36] to conduct the overall cost-effectiveness analysis (Supplementary Table S1 in Multimedia Appendix 1).

Inclusion and Exclusion Criteria

In the aforementioned parent trial, participants were eligible if they were (1) ≥19 years old, (2) had a diagnosis of chronic insomnia, and (3) were able to participate in scheduled visits and assessments. Exclusion criteria in the original trial included: (1) severe psychiatric or neurological conditions, (2) participation in other sleep-related interventions, and (3) medical contraindications to CBT-I or study procedures [33]. This study included only participants from the original trial dataset; no additional inclusion or exclusion criteria were applied.

Participant Characteristics

The parent RCT enrolled 98 adults (Somzz: 49; control: 49). Key characteristics were (1) age: adults 19 years and older (details reported in original trial [33]), (2) employment: 51% engaged in paid work (Somzz: 22/49; control: 28/49), and (3) baseline insomnia severity: clinically significant chronic insomnia. Participants were similar between groups due to randomization [33].

XSL•FO
RenderX

Sampling Procedures

In the aforementioned parental randomized controlled trial, participants were recruited through multiple clinical centers via advertisements and clinician referrals [33]. Sampling followed consecutive enrollment of eligible patients [33]. The sample for this cost-effectiveness study comprises all randomized participants with complete outcome data in the parental trial [33].

Sample Size, Power, and Precision

The sample size was determined in the parent clinical trial based on detecting meaningful differences in insomnia severity (Insomnia Severity Index [ISI] scores) [33]. For the current economic evaluation, all available trial participants were included; therefore, no additional power analysis was required. Precision was improved through probabilistic sensitivity analyses using distributions for all parameters.

Measures and Covariates

Intervention and Comparator

The intervention is the digital CBT, Somzz, for insomnia treatment, and the comparator is CBT or pharmacotherapy without Somzz. As aforementioned, underpinning this study was a multicenter, single-blind, RCT (trial registration: KCT0007292) to assess the safety and efficacy of Somzz [33]. This study evaluates the cost-effectiveness of the Somzz using the collected and published information from the aforementioned parent clinical trial [33].

Outcomes

Outcomes included direct efficacy indicators related to insomnia treatment indicators (probabilities of remission, maintaining remission, attrition) and quality-adjusted-life-years. The direct efficacy values were extracted from the parent clinical trial [33]; (1) remission was defined as an ISI score of 7 or lower, indicating the absence of clinically significant insomnia; (2) the attrition; and (3) the probability of maintaining remission, which were measured during the follow-up at 18 weeks after device withdrawal. The minimum value of the attrition rate was the lower limit of the 95% CI, assuming that the attrition rate followed a normal distribution in the population. The maximum value was determined by applying values obtained from the literature [37], considering the possibility of an underestimated dropout rate in the clinical trial. QALYs were used as a health outcome measure in the analysis. QALYs were derived from the parent clinical trial [33], which measured QALY with the Short Form 6 Dimensions (SF-6D) Health State Short Form (a subset of 6 items from the Short Form Health Survey Version 1) [38]. The SF-6D includes 6 dimensions, each with 2 to 5 levels, and is capable of generating 7500 different health states. Brazier algorithm was used to calculate utility values [39]. The SF-6D was reported to show superior sensitivity to changes in mild-to-moderate physical and mental health conditions compared to the EQ-5D-3L [40,41].

Direct Medical Costs

We defined direct medical costs related to insomnia as expenses incurred from visits to clinics, hospitals, or pharmacies, specifically for insomnia treatment. The base case value for the treatment group was determined as the sum of 2 consultation fees, the cost of CBT software, and medication expenses. The minimum value for the treatment group was calculated as the 2 consultation fees, assuming no costs for CBT software or medication. The upper limit value for the treatment group was calculated by increasing the CBT software cost up to 200,000 KRW (US $155.28) with 2 consultations and related medications. The primary value for the control group included only medication costs, which were adjusted for adherence rates of 14% for prescription medications and 2% for over-the-counter medications. The minimum value of medication costs was calculated as the mean prescription medication cost subtracted from the SD. The maximum value was derived by adding the SD to the mean prescription medication cost. Medical expenses unrelated to insomnia treatment were classified as indirect medical costs.

Indirect Costs

Indirect costs were calculated as the sum of absenteeism, productivity loss, and workplace accident costs. Absenteeism and productivity losses caused by insomnia were monetized as part of absenteeism costs. We converted the number of days absent from work (cost of absenteeism) and the degree of productivity decline (cost of reduced work productivity) due to insomnia into a monetary cost for wage workers participating in the clinical trial [33]. Insomnia increases the likelihood of workplace accidents; therefore, the associated costs were estimated by multiplying the probability of insomnia-related accidents by the average cost per workplace accident. Insomnia can cause workplace accidents; therefore, we calculated the cost of insomnia-related accidents by multiplying the probability of an accident occurring because of insomnia by the average cost of an accident.

Data Collection

All clinical and quality-of-life data were collected prospectively during the parent RCT at 6 scheduled visits (screening, baseline, 1 week, 2 weeks, 4 weeks, and 18 weeks) [33]. Economic variables were derived from Korean national databases, trial-reported work impairment, and published literature. All data were de-identified before secondary analysis.

Quality of Measurements

Clinical outcomes (eg, ISI) were collected in the parent clinical trial by trained personnel following standardized protocols [33]. Economic parameters used validated national datasets. No missing data were reported in the parent clinical trial; no new missingness occurred in the secondary dataset.

Instrumentation

The instrumentation for this study included the Somzz dCBT-I mobile app, which delivers standardized CBT modules for insomnia through a smartphone-based digital platform, and the SF-6D survey instrument, a validated and widely used tool for measuring health-related utility values. All instruments were used in their original, validated formats, and no modifications were made to any components or measures.

XSL•FO
RenderX

Masking

The parent clinical trial used a single-blind design in which outcome assessors were blinded to treatment assignment. Participants were aware of their intervention due to the nature of the digital therapeutic. The economic evaluation was fully blinded to group identifiers [33].

Psychometrics

The SF-6D utilities were derived from SF-36 responses, and the psychometric properties of the Korean SF-36 support its use in Korean populations. In a Korean general population study (N=600), the SF-36 demonstrated acceptable internal consistency and test–retest reliability, with reliability coefficients ranging from 0.54 to 0.80 across domains [38,39,42]. In addition, the Korean Health Insurance Review and Assessment Service economic evaluation guideline allows the use of multi-attribute utility instruments, including SF-6D–derived utilities, in the Korean health technology assessment context [35]. Utility scoring used validated country-neutral algorithms. Attrition and remission measurements followed established ISI-based definitions [33].

Data Diagnostics

We evaluated plausibility ranges for all parameters, checked for outliers in cost distributions, and verified internal model consistency. The attrition rate distribution was modeled using normal assumptions based on trial data. Costs from claims databases were cross-validated with external Korean sources.

Analytic Strategy

Base-Case Analysis

The base-case analysis estimated the incremental cost-effectiveness ratio (ICER) by comparing the costs and health outcomes of digital CBT with those of treatment as usual. Health outcomes were measured in QALYs, and the analysis incorporated both direct medical costs and indirect societal costs to comprehensively assess the economic impact of the intervention.

Sensitivity Analysis

We ensured the robustness of our findings by varying several key assumptions, including the frequency of clinic visits, the need for additional consultations and educational sessions, and incremental health care expenditures related to insomnia. We also varied the financial impact of absenteeism, presenteeism, and workplace accidents resulting from insomnia. For absenteeism and presenteeism, we alternatively used data from the Work Productivity and Activity Impairment, which provides average, maximum, and minimum values for these factors [43]. We established the minimum cost of workplace accidents as zero with a scenario of no accident occurrence and the maximum cost as the highest individual accident cost recorded in the Industrial Accident Insurance Statistics [44] to account for the most severe financial impact observed.

Ethical Considerations

The trial was approved by the institutional review boards (IRBs) of all participating centers and conducted in accordance with the Declaration of Helsinki and Good Clinical Practice guidelines [33]. This study is a secondary analysis using existing data with primary consent, and the original consent or IRB approval covers secondary analysis without additional consent. Furthermore, ethical approval for the cost-effectiveness study was obtained from the Institutional Review Board of Yonsei University (approval number 202111-HR-2636-01). A waiver of informed consent for the use of retrospective data was also granted by the Institutional Review Board of Yonsei University. No financial incentives were provided in the parental clinical trial [33]. All data were deidentified before analysis. This study involved secondary analysis of anonymized clinical trial data already covered under the original IRB approval [33]. No images or supplementary materials in this article contain identifiable information about individual participants or users. All figures and tables present aggregated or schematic data only. Therefore, no additional consent for the use of identifiable images was required. If any materials containing identifiable information were to be included in the future, we would obtain explicit written consent from those individuals and upload the corresponding consent documentation in accordance with journal guidelines.

Results

Participant Flow

Overview

In the parental clinical trial, a total of 98 adults with chronic insomnia were enrolled and randomized in a 1:1 ratio to the Somzz group (n=49) or the control (sleep hygiene education [SHE]) group (n=49). All participants initiated the assigned intervention, and all participants had 6 scheduled visits (screening, baseline, 1 week, 2 weeks, 4 weeks, and 18 weeks as post intervention) over 6-9 months. The attrition rate in the Somzz group was 12% (6/49), whereas the SHE group showed comparable retention (5/49, 10%) over the 4-month follow-up period. Outcome analyses were conducted according to the intention-to-treat principle [33].

Recruitment

Participants were recruited from 3 university-affiliated hospitals through outpatient clinics and study advertisements. Eligible individuals were screened by research staff and invited to participate between baseline and randomization. After informed consent, participants completed baseline assessments and were randomly assigned to the Somzz or SHE condition using a single-blind allocation procedure [33].

Baseline Characteristics

At baseline, the 2 groups were comparable in demographic and clinical characteristics. Participants were adults with chronic insomnia and demonstrated similar insomnia severity, sleep diary metrics, and mental health profiles prior to randomization. No meaningful group differences were observed at baseline, supporting the validity of the randomization process [33].

Primary Outcomes

Outcomes included direct efficacy indicators related to insomnia treatment indicators (probabilities of remission, maintaining remission, and attrition) and quality-adjusted-life-years. The

XSL•FO
RenderX

direct efficacy values were extracted from the parent clinical trial [33]; (1) remission was 51% (22/43) of the digital CBT group and 14% (6/44) of the control group post intervention; (2) the attrition rate was 12% (6/49) for the in the digital CBT group and 10% (5/49) in the control group; (3) the probability of maintaining remission was 35% (15/43) of the treatment group and 11% (5/44) of the control group. For indirect medical costs, we compared medical claims from individuals diagnosed with insomnia to those without an insomnia diagnosis and determined that excess health expenditure caused by insomnia would amount to 553,625 KRW (US $429.83) over 9 weeks (Table 1).

Indirect costs were calculated as the sum of absenteeism, productivity loss, and workplace accident costs. In a parent clinical study, 54% were "individuals employed in paid work," and they reported being absent from work because of insomnia-related issues for 3.11 hours per week on average before starting treatment [33]. Therefore, we calculated the cost of absenteeism due to insomnia per one 9-week treatment cycle as follows: 9 weeks × 3.11h/week × 19,806 KRW (US $15.38) (hourly wage) × 54% (employment rate) ≒ 33,312 KRW (US $25.87). The parent clinical trial participants reported a 55% decline in productivity caused by insomnia [33]. Therefore, the indirect cost of lost productivity for one 9-week treatment cycle was approximated as follows: 45 days (5 days of work per week for the 9-week treatment period) × 55% (productivity loss due to insomnia) × 157,260 KRW (US $122.10)/day (daily wage) × 54% (employment rate) ≒ 2,101,347 KRW (US $1631.49) (Table 1). The probability of an insomnia-related workplace accident was assumed to be 1% [11]. According to the Ministry of Employment and Labor's Industrial Accident Insurance Statistics in Korea, the total amount of industrial accident insurance benefits in 2020 was 6.00 trillion KRW paid across 350,000 beneficiaries, resulting in an average of 17 million KRW per person [44]. Thus, the estimated accident cost per person is 85 million KRW annually and approximately 79,562 KRW (US $61.77) for a 9-week period [45,46] (Table 1).

Statistics and Data Analysis

Cost-Effectiveness of Digital CBT

Table 2 presents scenarios detailing the simulated health utility (QALYs) and cost outcomes for the baseline model. All scenarios, except Scenario 4, were analyzed by including only direct medical costs. Costs and QALYs increased for patients who implemented the digital CBT solution. The model predicted that the use of digital software to treat insomnia would produce 0.3701 QALYs and 101,729 KRW (US $78.98) of expected costs compared with 0.3609 QALYs and 22,038 KRW generated by treatment as usual without the aid of digital software over 6.5 months. Introducing the digital insomnia solution would increase costs by 79,691 KRW (US $61.87) and QALYs by 0.0091. The ICER associated with insomnia treatment using digital software was 8,719,727 KRW (US $6770.00) per QALY gained, which is well below the hypothetical threshold value in Korea of 30,000,000 KRW (US $23,292)/QALY gained.

Table 2. Cost-effectiveness analysis of digital cognitive behavioral therapy (Somzz) for chronic insomnia among Korean adults relative to the control group by base case and scenario.

Strategy	Cost, KRW (US $)	Effectiveness (QALYs)[a]	Incremental cost, KRW (US $)	Incremental effectiveness (QALYs)	ICER[b], KRW /QALYs (US $/QALYs)
Base case: 2 clinic visits					
Control group	22,038 (17.11)	0.3609	—[c]	—	—
Treatment group (Somzz)	101,729 (78.98)	0.3701	79,691 (61.88)	0.0091	8,719,727 (6,770.87)
Scenario 1: 3 clinic visits					
Control group	22,038 (17.11)	0.3609	—	—	—
Treatment group (Somzz)	113,859 (88.40)	0.3701	91,821 (71.30)	0.0091	10,046,980 (7,801.48)
Scenario 2: 2 clinic visits + educational and consultant fees					
Control group	22,038 (17.11)	0.3609	—	—	—
Treatment group (Somzz)	131,729 (102.27)	0.3701	109,691 (85.18)	0.0091	12,002,298 (9,319.78)
Scenario 3: 3 clinic visits + educational and consultant fees					
Control group	22,038 (17.11)	0.3609	—	—	—
Treatment group (Somzz)	143,859 (111.69)	0.3701	121,821 (94.59)	0.0091	13,329,551 (10,350.40)
Scenario 4: all costs included[d]					
Control group	7,679,657 (596.49)	0.3609	—	—	—
Treatment group (Somzz)	6,777,978 (526.42)	0.3701	–901,678 (–700.15)	0.0091	–98,660,780 (76,610.10)

[a]QALYs: quality-adjusted life years.

[b]ICER: incremental cost-effectiveness ratio.

[c]Not available.

[d]Direct medical costs related to insomnia + (educational and consultation fees) + direct medical costs unrelated to insomnia + indirect costs.

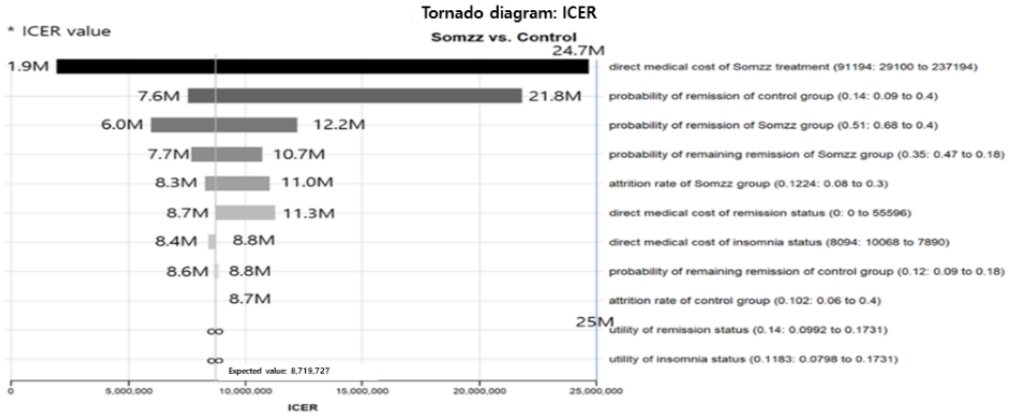
Compared to the control group, the ICER for insomnia treatment using the digital intervention, assuming all possible indirect costs, yielded a lower cost of 901,678 KRW (US $700.06) and higher QALYs of 0.0091. This negative ICER arises from combining the reduced total costs and increased health utility. Digital CBT reduces insomnia-related indirect costs, such as health care expenses and lost workplace productivity, through higher effectiveness and remission rates. These cost reductions surpass the direct costs associated with digital CBT (Table 2).

Sensitivity Analysis

We conducted a one-way deterministic and probabilistic sensitivity analysis to test the robustness of our findings. Figure 2 shows a tornado diagram of the results of this analysis. The direct costs of the digital CBT group, which ranged from 29,100 to 237,194 KRW (US $22.59 to US $184.16), had the largest impact on the ICER, followed by the probability of remission in the control group. These parameters had the greatest impact in all scenarios (Multimedia Appendices 2-4). The Monte Carlo simulation results indicated that digital CBT is the optimal cost-effective strategy with a probability of 67.4%, represented as an ICE scatterplot in Figure 3.

XSL•FO
RenderX

Figure 2. Tornado diagram for incremental cost-effectiveness ratio. ICER: incremental cost-effectiveness ratio.



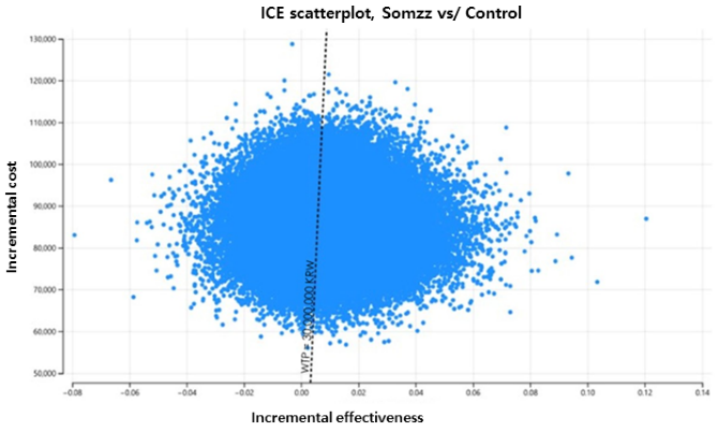


Figure 3. Probabilistic sensitivity analysis results: incremental cost-effectiveness scatterplot (estimates based on the 95% CI).

For Scenarios 1-3, digital CBT was the most cost-effective strategy, with probabilities of 66.9%, 65.1%, and 63.9%, respectively (Multimedia Appendices 5-7). Furthermore, digital CBT was identified as the most cost-effective strategy at a willingness-to-pay threshold of 15,000,000 KRW (US $11,647.5), with probabilities of 58.8%, 57.8%, 53.5%, and 51.3% for the base case and Scenarios 1-3, respectively (Multimedia Appendix 8).

Discussion

Support of Original Hypotheses

We combined a decision tree and the Markov model to assess the cost-effectiveness of digital CBT for adults seeking treatment for insomnia in South Korea. While several prior studies have evaluated the cost-effectiveness of digital CBT for insomnia, most were conducted in Western health care systems [29-32]. In contrast, this study evaluates a regulated, commercially available digital therapeutic using Korean randomized trial data and explicitly incorporates societal costs that are highly relevant to the Korean labor and health care context. From a health care perspective, digital CBT slightly increased health care costs while improving health outcomes compared with standard care. In contrast, from a societal perspective, digital CBT was cost-beneficial, yielding a negative ICER. Accordingly, the digital therapeutic evaluated in this study was highly cost-effective for functional outcomes in insomnia treatment at a willingness-to-pay threshold of 30,000,000 KRW (US $23,295) per QALY gained and remained cost-effective at a lower threshold of 15,000,000 KRW (US $11,647.5) per QALY gained. These findings underscore that incorporating broader societal costs meaningfully changes the economic value of insomnia treatment interventions. Reduced health care use, lower risks of workplace accidents, and improved work productivity associated with insomnia remission were key drivers of cost-effectiveness. Both deterministic and probabilistic sensitivity analyses confirmed the robustness of these results.

Similarity of Results and Interpretation

These results align with those of previous studies that found guided digital CBT to be cost-effective [30-32]. One strength of our study was the inclusion of indirect costs. We considered reductions in health care expenditure as effective insomnia treatment can lead to fewer medical visits, less need for medication, and lower overall health care use [21,22]. Furthermore, we accounted for a decreased risk of workplace accidents. Insomnia impairs cognitive and physical functioning, which increases the likelihood of errors and accidents at work [50,51]. Treating insomnia can mitigate this risk, thereby leading to safer work environments. Our analysis also included improved workplace productivity. Insomnia negatively affects concentration, efficiency, and overall job performance [52,53]. Therefore, effective treatment can enhance productivity by improving employees' sleep quality and daytime functioning. By capturing these indirect costs, our analysis demonstrates the broader economic benefits of insomnia treatment beyond

XSL•FO
RenderX

immediate improvements in individual health. Insomnia is linked to 7.2% of all costly workplace accidents and errors, and accounts for 23.7% of the total costs associated with these incidents [11]. Not including these additional costs could underestimate the total economic burden of insomnia and potential costs saved through the application of effective treatment. In contrast, including costs related to workplace accidents and errors could reveal higher overall costs, and thus, a greater potential for cost savings through insomnia treatment.

The demand for effective insomnia treatment is substantial, with 20%-30% of the population experiencing insomnia symptoms [1-3]. However, several factors hinder traditional clinician-delivered CBT, including the availability of trained therapists and the need for patients to attend scheduled sessions, which many people can find challenging. Patients often face difficulties in taking time off work and securing childcare or older adult care to attend in-person therapy sessions. These logistical challenges limit the reach and effectiveness of clinician-delivered CBT [54].

Digital CBT delivery offers a promising solution to these accessibility issues by enabling instant and unlimited access to CBT resources, thereby allowing patients to engage with therapy at any time and from any location, effectively eliminating waiting times. This flexibility is crucial for patients who may be unable to attend regular appointments because of their busy schedules [54]. Digital platforms can make CBT more widely available, ensuring that more individuals who require treatment can access it promptly and conveniently. This approach not only expands the reach of effective insomnia treatment but also aligns with the high demand for such interventions, ultimately helping bridge the gap between the recommended use of CBT and its actual accessibility and use.

Generalizability

The generalizability of this study's findings should be interpreted in the context of the Korean population and health care system. Participants were digitally literate adults recruited from university hospitals [33], which may not fully represent individuals with limited technology access or older adults who may engage differently with mobile health interventions. Nonetheless, given Korea's high smartphone penetration rate and increasing familiarity with digital health tools, Somzz has strong potential for scalable implementation across the broader adult population.

Economic estimates in this model reflect Korean wage levels, health care use patterns, and societal cost structures. Although absolute cost differences may vary in other countries, the primary mechanisms driving cost-effectiveness, such as higher remission rates, reduced health care use, and improved productivity, are likely applicable to other high-income settings with similar burdens of insomnia and labor market characteristics. Because Somzz was developed within the Korean cultural and linguistic environment, differences in cultural attitudes toward sleep, mental health, and digital therapeutics may influence usability and adherence in other populations. Additionally, real-world engagement with digital CBT-I may vary outside a controlled trial setting, which could influence long-term effectiveness and economic outcomes.

Overall, while these findings are most directly applicable to technologically advanced health care systems with strong digital readiness, they provide valuable insights for other countries considering digital CBT-I adoption. Extrapolation should be undertaken cautiously with attention to cultural, economic, and infrastructural differences.

Implications

This study provides novel evidence by incorporating indirect societal costs, including productivity loss and workplace accidents, into the economic evaluation of digital CBT, dimensions that are rarely captured in prior analyses. Importantly, by focusing on a digital therapeutic that meets regulatory standards and is designed for real-world implementation, this study extends prior digital CBT economic evaluations toward policy-relevant evidence for reimbursable digital therapeutics. By using Korean clinical trial data [33] and locally relevant economic parameters rather than relying on Western-based assumptions, the study offers population-specific insights that more accurately reflect real-world conditions. This comprehensive approach strengthens the relevance of our findings for clinicians, policymakers, and employers by demonstrating the broader economic and workplace impact of digital CBT and informing decision-making for large-scale adoption within the Korean health care and occupational health systems.

One limitation of this study was the relatively short follow-up period. Although a period of 6.5 months is approximately the same or longer than that used in all previous studies on the cost-effectiveness of CBT for insomnia, it may not be sufficient to fully capture the long-term economic benefits of treatment. Simulating costs over a longer period, such as 12 or 24 months, could more effectively demonstrate potential long-term cost reductions for employers. A longer time horizon may allow for a more significant accumulation of treatment benefits, suggesting that our current results may be conservative.

Another limitation is the sample size. Economic evaluations conducted in parallel with clinical trials often face power issues because cost variables typically have a higher variance and require larger sample sizes than clinical outcomes to achieve statistical significance. Considering these challenges, we adopted a probabilistic decision-making approach to account for the uncertainty and variability in cost and utility estimates. This approach helped us perform a more robust analysis despite the limitations of the sample size and follow-up duration in this study.

Finally, the parent clinical trial from which outcome data were extracted [33] was not structured to compare traditional and digital CBT directly, primarily because of practical constraints (eg, despite having insomnia symptoms, only a small proportion of patients actively seek pharmacotherapy in the real world). This approach mimics real-world scenarios in which patients often receive a combination of treatments rather than a single isolated therapy.

This study did not involve direct patient or stakeholder engagement. However, the societal burden and impact of insomnia were incorporated into the analytical framework. No

direct involvement from patients, service recipients, the general public, or other stakeholders influenced the approach or findings of this study.

Conclusions

The results of this study suggest the significant potential of early integration of digital CBT into insomnia treatment to improve health care outcomes and generate substantial cost-effectiveness. These findings underscore the importance of incorporating such technology as a valuable enhancement to routine medical practice, thereby ultimately enhancing overall insomnia care. Beyond demonstrating cost-effectiveness, this study contributes to the growing evidence base supporting digital therapeutics by illustrating how locally grounded economic evaluations can inform reimbursement, employer adoption, and national digital health policy. Given these promising results, future research should focus on expanding access to digital CBT and assessing its effectiveness on a population-wide scale. Understanding the effectiveness of digital CBT in real-world settings, in which factors such as varying levels of access, patient engagement, and implementation challenges can influence outcomes, is crucial.

Abstract

Background: Metamemory training (MMT) offers a potential nonpharmacological approach to enhance cognitive function in individuals with mild cognitive impairment (MCI). While digital cognitive training improves accessibility, the effectiveness of mobile app–based MMT has not been evaluated in a randomized clinical trial.

Objective: We aimed to evaluate the efficacy and safety of a mobile app–based MMT program, ET-101 (Cogthera), compared to a sham device control group in individuals with MCI.

Methods: This multicenter, randomized controlled trial enrolled participants with MCI, recruited from 7 medical centers, and randomly assigned them to the ET-101 or control group (1:1 ratio). The intervention lasted 12 weeks, with a 12-week follow-up. The ET-101 group received metamemory-based multimemory strategy training and real-time feedback. Assessments of cognition, the daily activities of living, and the quality of life were conducted at baseline, week 12, and week 24. The primary outcome was the proportion of participants who showed cognitive improvement as assessed by the Alzheimer's Disease Assessment Scale-Cognitive Subscale (ADAS-Cog)-14 at weeks 12 and 24. Secondary outcomes included changes in the scores of scales assessing cognition, daily activities, and quality of life. Safety analysis assessed adverse events and their relation to digital therapeutics.

Results: In the full analysis set, 49 participants were included in the ET-101 group and 50 in the control group. At week 24, the proportion of responders who maintained or improved their ADAS-Cog-14 scores was significantly higher in the ET-101 group than in the control group (P=.002). Additionally, the ET-101 group showed a significant improvement in ADAS-Cog-14

XSL•FO
RenderX

scores at week 24 compared to baseline levels (estimates=–2.53; t_{265}=–3.05; Bonferroni-adjusted *P*=.003). A subdomain analysis revealed significant improvements in the memory (estimates=–2.50; t_{264}=–4.03; Bonferroni-adjusted *P*<.001) and language (estimates=–0.807; t_{290}=–3.68; Bonferroni-adjusted *P*<.001) domains at week 24 in the ET-101 group compared to the control group. In the safety analysis, 6 adverse events occurred in the ET-101 group and 4 in the control group, but none were related to the interventions. The attrition rate in the ET-101 group was 22.4% (11/49).

Conclusions: ET-101 significantly improved cognitive function compared to the sham device, with effects observed not only in the memory domain but also in the language domain, indicating a transfer effect. Therefore, ET-101 has the potential to provide effective MMT to a broader population with MCI by overcoming location and personnel limitations through a mobile app–based platform.

cognitive decline; cognitive training; digital therapeutics; mild cognitive impairment; mobile app–based cognitive training

Introduction

Background

With the global population aging rapidly, the number of people affected by dementia is estimated to reach 153 million by 2050 [1]. Increasing evidence shows that timely diagnosis and treatment can slow the rate of cognitive deterioration, significantly reducing the burden on caregivers and social care systems [1]. As a result, effective interventions for mild cognitive impairment (MCI), which is at high risk of progressing, have become a priority in geriatric care [2].

Notably, anti–amyloid monoclonal antibody treatments, which have recently attracted attention in the management of MCI, may be appropriate only for patients who meet several eligibility criteria. Moreover, this treatment is associated with adverse effects that could limit continued use in some cases [3]. In contrast, cognitive training represents a relatively safe intervention with greater generalizability and applicability in the treatment of MCI, and it can also be used in combination with pharmacotherapy or as a stand-alone treatment option for patients who are unable to undergo or continue pharmacological therapy. According to a meta-analysis, cognitive training significantly improves memory function [4]. Moreover, magnetic resonance imaging–based studies have demonstrated that cognitive training improves cerebral blood flow and brain network connectivity, confirming the biological effects of cognitive interventions [5]. However, while cognitive training, as used in previous studies, improved older adults' performance on practiced tasks, the studies did not consider the participants' ability to self-perceive and regulate cognitive strategies during cognitively demanding tasks [6]. In addition, previous studies indicate that one of the key challenges in cognitive training for MCI is the lack of sustained effects once the training period ends [7,8]. These studies address the need for future interventions that aim to address and overcome this limitation and thereby enhance the real-life applicability of the learned strategies [7,8].

To address the limitations of previous methods of cognitive training, Flavell's concept of "metamemory" can be beneficial [9]. Metamemory refers to one's awareness of one's own memory, including the contents and processes of their memory system [6,9]. Metamemory training (MMT) takes into account the concepts of meta-knowledge, meta-monitoring, and meta-judgement [10]. Meta-knowledge addresses how aging affects memory abilities, enabling older adults to learn strategies to deal with age-related cognitive decline [10]. In the meta-monitoring and meta-judgment components, older adults assess their own performance, enabling them to regulate their memorization ability by independently adjusting effective memory strategies according to the demands of the task at hand [10]. According to previous studies, MMT not only shows positive effects on everyday memory performance in older populations but also improves global cognitive functions while significantly reducing the frequency of memory-related discomfort in daily life [11-14].

Conventionally, the main limitation of cognitive interventions for MCI is their reliance on face-to-face interactions with professionals, which hampers the accessibility and continuity of training [15]. However, digitalization is ideal for facilitating the migration of care from clinics to patients' homes, thereby overcoming constraints related to time and space. According to previous studies that evaluated the feasibility of digital cognitive therapy for MCI, patients adhered more to digital therapy compared to paper-and-pencil training. Additionally, in terms of effectiveness, a review of studies on computerized cognitive training for MCI found that its effect on cognitive function was not inferior to that of conventional cognitive interventions [15].

Objectives

Thus, metamemory-based digital cognitive training can be expected to enhance the benefits of cognitive training in individuals with MCI by addressing the limitations of previous cognitive interventions. Based on this concept, ET-101 (Cogthera)—a mobile app–based MMT program—was developed. In this randomized clinical trial, we aimed to evaluate the efficacy and safety of ET-101 in older individuals with MCI compared to a control group using a sham device. To evaluate both the immediate and sustained effects of ET-101, we assessed its efficacy compared to sham controls at 2 time points that is, at 12 weeks, immediately after completion of the intervention, and 24 weeks, corresponding to a 12-week follow-up after the end of the intervention. This study aimed to evaluate the

XSL•FO
RenderX

following hypotheses: first, for the primary outcome, we compared responder proportions (defined as participants showing maintenance or improvement in Alzheimer's Disease Assessment Scale-cognitive Cognitive Subscale [ADAS-Cog]-14 scores) between the ET-101 and sham control groups, hypothesizing that the responder rate would be higher in the ET-101 group. Second, regarding secondary outcomes, we assessed changes from baseline to 12- and 24-week follow-ups in validated measures of cognitive function, activities of daily living (ADL), and quality of life, hypothesizing that greater improvements would be observed in the ET-101 group versus the sham control group. Finally, exploratory analyses were conducted to determine whether improvements on ADAS-Cog-14 were predominantly observed in the memory, language, or praxis domains to identify which specific cognitive functions were most responsive to ET-101.

Methods

Study Design and Participants

This was a multicenter, 24-week parallel, randomized, sham device–controlled study of ET-101. The participants were recruited through memory clinics of 7 medical centers in the Republic of Korea. The participants were recruited from June to December 2023. Participants who met the following inclusion criteria were included in the study: (1) individuals aged 55-85 years; (2) patients diagnosed with amnestic MCI by trained psychiatrists or neurologists according to Petersen's criteria, characterized by cognitive complaints and objective memory impairment determined by either the Consortium to Establish a Registry for Alzheimer's Disease Neuropsychological Assessment Battery (CERAD-NP) or the Seoul Neuropsychological Screening Battery (SNSB) verbal learning test [16,17]. Memory impairment was defined as a *z* score of –1 or lower on at least one of the following subtests: an immediate word recall test, a delayed word recall test, or a delayed word recognition part of the verbal learning test in CERAD-NP or SNSB, while maintaining essentially normal functional activities; (3) a Mini Mental State Examination (MMSE) score of 27 or lower [18]; (4) not meeting the diagnostic criteria for dementia; (5) a global Clinical Dementia Rating score of 0.5 [19]; (6) taking a stable dose for at least 12 weeks prior to randomization if prescribed acetylcholinesterase inhibitors or memantine; (7) having a study partner who spends more than 8 hours per week with the participant and agrees to assist with the participant's follow-up and clinical evaluations; (8) possession of a personal smartphone and no difficulties using mobile apps; (9) the ability to make phone calls to a study partner independently using the smartphone; (10) no difficulties reading or writing in Korean; and (11) adequate vision and hearing for participating in the clinical trial.

Participants were excluded from the study if any of the following exclusion criteria were met: (1) a history of transient ischemic attack, stroke, or seizure within the past 12 months; (2) a history of severe psychiatric disorders or currently showing unstable psychiatric symptoms; (3) active suicidal intent as assessed by the Columbia-Suicide Severity Rating Scale or a history of treatment for suicidal behavior within the past 5 years [20]; (4) unstable findings upon a physical examination, neurological examination, in vital signs, or the presence of an ongoing unstable physical illness; (5) substance dependence within the past 2 years; (6) the use of prohibited medications as outlined in Table S1 in Multimedia Appendix 1; (7) scheduled to undergo surgery requiring general anesthesia; or (8) participation in any form of cognitive intervention within the past 3 months. Neurologic and psychiatric history, including past substance dependency, current symptoms, physical status, and neurological function, was assessed through clinical interviews conducted by trained psychiatrists and neurologists.

A statistician, independent of the clinical team, carried out the block randomization task, assigning participants to either the study group or the control group at a 1:1 ratio. Throughout the trial, psychiatrists, neurologists, and outcome raters were blinded to the treatment assignment.

The intervention and control groups adhered to an identical visit schedule. Participants completed 5 visits (0-4): screening (visit 0) included screening for study eligibility; week 0 (visit 1, baseline) included baseline demographic data collection and clinical assessments of cognition, function, and quality of life, along with randomization; week 6 (visit 2) investigated compliance with the study protocol and the occurrence of adverse events (AEs); week 12 (visit 3, at the end of the 12-week treatment period) reassessed the same variables from visit 1 and visit 2; and week 24 (visit 4, follow-up assessment 12 weeks after treatment completion) reassessed the same variables from visit 3.

Sample Size Calculation

Sample size was calculated based on a 2-sample proportion test. Delayed recall has been shown to have the highest predictive accuracy (95.2%) in differentiating dementia from MCI [21]. In a previous study, the proportion of participants showing an improvement on delayed recall was 82.8% in the intervention group and 45.16% in the control group [12]. With a 2-sided α of .05 and power of 0.90, and assuming a 1:1 allocation ratio, the minimum sample size per group was determined to be 32 participants. Anticipating a dropout rate of 35%, we intended to enroll 50 participants per group.

Intervention

Study Group: ET-101

Study group participants used ET-101, a mobile app–based MMT program incorporating multimemory strategies. ET-101 is based on an MMT program developed by Youn and colleagues [22] and was produced by Emocog Inc. We previously introduced offline and smart speaker–based versions of this MMT program, and their effectiveness has been well validated [12,14].

Real-time metamemory teaching is a primary feature of ET-101. The training agent of ET-101 interacts with users through voice-based, 2-way communication to enhance metamemory, including meta-knowledge, meta-monitoring, and meta-judgment. Regarding meta-knowledge, on the first day, the agent begins the training by asking users questions about their long-term memory encoding and the memory strategies

XSL•FO
RenderX

they currently use in daily life. Additionally, during the training sessions, the agent introduces multimemory strategies that can enhance long-term memory and explains how these strategies can improve memory performance. This helps users gain objective insight into their cognitive levels and understand how to compensate for cognitive deficits. Regarding meta-monitoring and meta-judgment, the agent explains the daily trends in users' memory spans based on their training results. The agent identifies users' strong and weak memory strategies, helping them recognize their cognitive strengths and weaknesses. Additionally, at the end of the training, the agent provides guidance on how to apply the learned strategies to daily life, facilitating the generalization of memory strategy use. Throughout the metamemory process, the agent provides personalized feedback, adjusts difficulty levels, and modifies training tasks based on users' responses and training results.

ET-101 includes cognitive exercises specifically designed to incorporate memory strategies focusing on attention, imagination, and associations. According to the memory formation process and neuroscience findings, these strategies have been shown to effectively address issues with memory encoding and retrieval commonly observed in older people with cognitive decline [23,24]. Furthermore, attention, imagination, and association processes are known to strengthen related brain regions, including the prefrontal cortex, hippocampus, parahippocampus, precuneus, and the cingulum that connects these areas [23,25]. Attention training includes exercises that enhance trainees' selective focus on stimuli to be memorized, as well as tasks aimed at improving the processing speed and increasing working memory. Imagination training facilitates the transition to long-term memory by linking spatial-temporal memory and visual imagery associated with the objects to be memorized. In association training, 2 or more pieces of information that need to be remembered are connected and assigned mutual meaning, thereby strengthening the semantic cue to aid in long-term memory formation. The detailed content of each activity can be found in Table S2 in Multimedia Appendix 1, and example screenshots are available in Multimedia Appendix 2.

The study group engaged in a 12-week training program using ET-101. The program was structured to involve 2 sessions each day, 7 days a week, lasting approximately 15 minutes per session. The initial session includes 3 representative cognitive exercises, with 1 session each for attention, imagination, and association. In the later session, 4 additional exercises are conducted, selected from 9 available options, excluding the 3 exercises from the initial session, based on a personalized algorithm (Table S3 in Multimedia Appendix 1). A push alarm was provided daily to encourage training.

Control Group: Sham Device

The control group used a sham device over a 12-week period, which featured cognitive assessments and gamification elements but did not include any cognitive training. In the sham device, on the first day, users are asked the same questions as in ET-101 about their long-term memory encoding and the memory strategies they currently use in daily life, presented in a conversational interaction format with the agent. From the second day onward, it offered a gamification element to encourage daily log-ins, in this case displaying a flower that gradually grows. No content related to cognitive training was provided. The guidelines for program usage frequency were identical to those followed by the study group.

Measures

The efficacy of digital therapeutics was evaluated in terms of cognition, ADL, and quality of life. The scales listed below were assessed by a trained psychologist in a face-to-face manner.

Alzheimer's Disease Assessment Scale-Cognitive Subscale-14

ADAS-Cog-14 was used to assess the severity of cognitive dysfunction [26]. ADAS-Cog-14 consists of the following 14 tasks: (1) word recall, (2) commands, (3) constructional praxis, (4) delayed word recall, (5) naming, (6) ideational praxis, (7) orientation, (8) word recognition, (9) maze, (10) number cancellation, (11) remembering instructions, (12) comprehension, (13) word-finding difficulty, and (14) spoken language ability. The total ADAS-Cog-14 score ranges from 0 to 90 points, calculated by summing the number of errors made on each task. A score of 0 indicates no impairment, while a score of 90 reflects the maximum level of impairment. ADAS-Cog subdomains were grouped into 3 domains: memory, language, and praxis [27]. The composite score range for each subdomain is as follows: memory (0-40), language (0-25), and praxis (0-15), with lower scores indicating less impairment.

Korean Mini Mental State Examination, 2nd Edition

MMSE is a brief neuropsychological test that provides an overview of the cognitive function in individuals with cognitive decline [28]. In this study, we used the latest revised version, the Korean Mini Mental State Examination, 2nd Edition (K-MMSE-II), whose validity has already been established [18]. It tests 5 areas of cognitive function: orientation, registration, attention and calculation, recall, and language. The scale ranges from 0 to 30 points, where higher scores indicate less impairment.

Clinical Dementia Rating-Sum of Boxes

Clinical Dementia Rating-Sum of Boxes (CDR-SB) is used to assess the stage of severity in Alzheimer dementia or MCI [29]. The score is determined through interviews with patients and informants, evaluating cognitive functioning across 6 domains: memory, orientation, judgment and problem-solving, community affairs, home and hobbies, and personal care. Each domain is scored from 0 to 3, and the CDR-SB outcome is calculated by summing the scores across all domains, resulting in a total score ranging from 0 to 18. Higher scores indicate greater impairment.

Alzheimer's Disease Composite Score

Alzheimer's Disease Composite Score (ADCOMS) is a tool developed to measure clinical progression and treatment effects in patients with cognitive decline [30]. ADCOMS comprises a total of 12 items, specifically 4 items from ADAS-Cog, 2 items from the MMSE, and all 6 items from CDR-SB. The total score is calculated by applying predetermined weights to each item. Total ADCOMS values range from 0 to 1.97, with higher scores indicating greater impairment.

XSL•FO
RenderX

Digit Symbol Coding

Digit Symbol Coding (DSC) is designed to assess frontal and executive functions [16]. Participants are shown symbols corresponding to numbers from 1 to 9 and are asked to draw the appropriate symbol in 133 blank spaces. Each correctly drawn symbol is awarded 1 point, resulting in a total score ranging from 0 to 133 points. Higher scores indicate better cognitive function.

Clinician Interview–Based Impression of Severity and Clinician Interview–Based Impression of Change Plus Caregiver Input

The Clinician Interview–Based Impression tool is used to assess the severity of cognitive function through semistructured interviews with patients and their caregivers [31]. The Clinician Interview–Based Impression of Severity (CIBIS) is specifically designed to assess baseline severity. Clinicians evaluate responses across 4 domains—general condition, mental or cognitive state, behavior, and ADL—on a scale of 1 to 7 points, where higher scores indicate greater severity. Clinician Interview–Based Impression of Change Plus Caregiver Input (CIBIC-Plus) is used during follow-up to evaluate whether there has been an improvement or decline compared to the baseline level. It assesses 3 aspects: cognition, behavior, and function. Based on these evaluations, the clinician rates the patient's overall condition on a 7-point Likert scale, where 1 indicates very much improved and 7 indicates marked worsening.

Alzheimer's Disease Cooperative Study-Mild Cognitive Impairment-Activities of Daily Living

The Alzheimer's Disease Cooperative Study-Mild Cognitive Impairment-Activities of Daily Living (ADCS-MCI-ADL) assesses the ability of patients to perform ADL through a structured questionnaire administered to the patient and caregiver by a qualified rater [32]. The scale evaluates both basic and instrumental ADL, with the 24-item version used in this study. Scores range from 0 to 69, with higher scores indicating better ability to independently manage daily living activities, while lower scores reflect a higher degree of dependency when performing such tasks.

EQ-5D-3L and EQ-5D-Visual Analogue Scale

EQ-5D is a tool used to measure health-related quality of life, assessing the 5 dimensions of mobility, self-care, usual activities, pain or discomfort, and anxiety or depression [33]. EQ-5D-3L evaluates each of these dimensions on 3 levels: no problems, some problems, and extreme problems. The responses are then converted into an index score by applying weighted values to each item and summing them, resulting in a score ranging from 0 (death) to 1 (perfect health). In addition, EQ-5D-Visual Analogue Scale (EQ-5D-VAS) captures the respondent's overall assessment of their health on a scale ranging from 0 (worst health imaginable) to 100 (best health imaginable). In this study, both EQ-5D-3L and EQ-5D-VAS were administered to assess the quality of life of patients with MCI as well as the quality of life of their study partners who live with them.

Safety Measures

The occurrence of AEs was monitored actively and systematically, following the Consolidated Standards of Reporting Trials (CONSORT) Harms guideline [34]. AEs were assessed weekly by investigators through telephone contact. Additionally, participants were allowed to report AEs spontaneously at any time during the trial. AEs that involve death, life-threatening conditions, hospitalization or prolonged hospitalization, persistent or significant disability or functional impairment, congenital anomalies or birth defects, or other medically important conditions were classified as serious adverse events (SAEs). Furthermore, the relationship between these AEs and the digital therapeutic device used in this trial was evaluated using a 5-level categorical scale ranging from "Definitely not related" to "Definitely related."

Outcomes

For the primary outcome, participants were categorized as responders or nonresponders based on whether their ADAS-Cog-14 scores were maintained or improved, and the proportion of responders was compared between the ET-101 and sham control groups at weeks 12 and 24. For the secondary outcomes, changes from baseline to 12 and 24 weeks were compared between groups using the following assessments: cognitive function (ADAS-Cog-14, K-MMSE-II, CDR-SB, ADCOMS, and DSC), ADL (CIBIS, CIBIC-Plus, and ADCS-MCI-ADL), and quality of life (EQ-5D-3L and EQ-5D-VAS). For the exploratory analysis, group comparisons of the change scores of the ADAS-Cog-14 subdomains were conducted, including the memory, language, and praxis subdomains. For the safety analysis, the proportions of total AEs, SAEs, and events deemed related to the digital therapeutic intervention were compared between groups.

Statistical Analysis

All statistical analyses were conducted on the full analysis set population, which included all randomized participants who received at least 1 session of the assigned study treatment. This approach is consistent with the modified intention-to-treat concept used in many previous clinical trials [35-37]. Baseline characteristics were compared between the intervention and control groups using an independent 2-tailed *t* test for continuous variables and either a chi-square test or Fisher exact test for categorical variables. The primary outcome, the proportion of responders and nonresponders between the ET-101 group and the control group, was compared by means of a chi-square test. In this study, nonresponder imputation (NRI) was applied, classifying trial dropouts as nonresponders. NRI is a method of handling missing data by assigning all missing cases as nonresponders, thereby preventing treatment benefits from being overestimated. This approach is widely recognized and has been extensively adopted in clinical trials that investigate drug efficacy across various areas [38,39]. In this study, based on NRI, responders were defined as participants who completed the study through week 24 and whose ADAS-Cog-14 score was either maintained or decreased compared to the baseline level, indicating preserved or improved cognitive function [40]. In contrast, nonresponders included those who either failed to

XSL•FO
RenderX

complete the study through week 24 or whose ADAS-Cog-14 score increased compared to the baseline level.

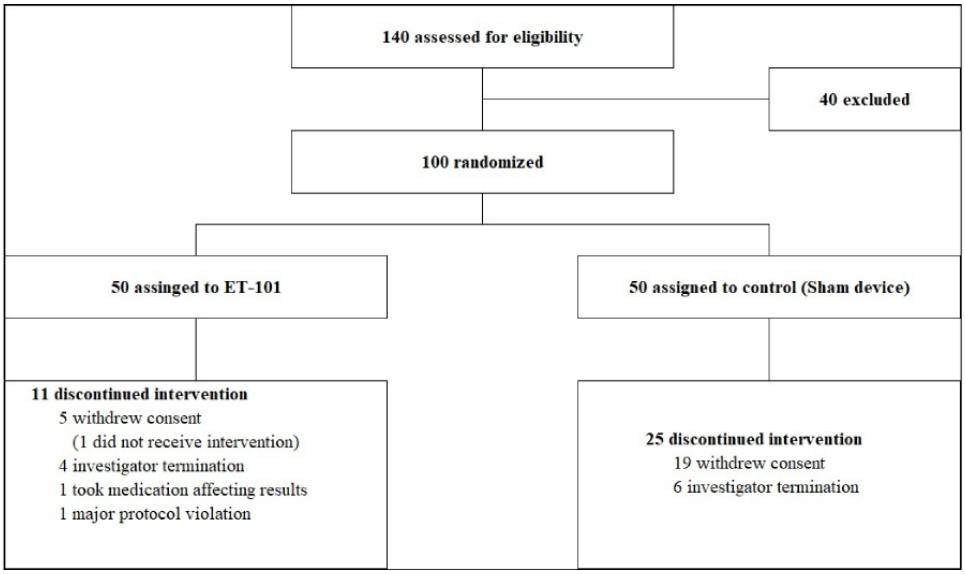
Secondary outcomes, in this case, clinical measures of cognition, ADL, and quality of life, were assessed by analyzing the changes from baseline to week 12 and week 24. Missing data in clinical scales due to trial dropouts were replaced using conditional mean imputation via a regression analysis. For the regression analysis used in imputation, the ADAS-Cog-14, K-MMSE-II, and CDR-SB scores at baseline, as well as the visit and visit-specific values of each clinical measure, were considered. Conditional mean imputation through a regression analysis was conducted using Python (version 3.9.20; Python Software Foundation). Independent *t* tests were used to evaluate whether the score changes differed significantly between the 2 groups. Additionally, a linear mixed model analysis was conducted to examine the treatment-time interaction for each clinical assessment. In this model, treatment, time (indicating baseline, week 12, and week 24), treatment-time interaction, and the baseline score of each scale were included as fixed effects. If a significant difference in the treatment-time interaction between the ET-101 and control groups was found in the linear mixed model, a post hoc analysis was performed to identify the specific time points at which the treatment-time interaction was significant. As a sensitivity analysis, to confirm that the imputation of missing data did not affect the results, the same linear mixed model analysis and post hoc analysis were performed without missing value imputation for variables where a significant treatment-time interaction was found in secondary outcomes.

As an exploratory analysis, the linear mixed model was applied to assess which subdomains of ADAS-Cog-14 (memory, language, and praxis) showed significant treatment-time interaction. If a significant treatment-time interaction was present, a post hoc analysis was conducted to determine the specific time points at which this interaction was significant. As a safety analysis, independent *t* tests were performed for continuous variables, while chi-square tests or Fisher exact tests were used for categorical variables.

All statistical tests were 2-tailed, and *P* scores of <.05 were considered statistically significant. For the post hoc analysis of the linear mixed model, Bonferroni-adjusted *P* scores were reported, with values <.05 indicating statistical significance. All statistical analyses were performed using the *lmerTest* package for the linear mixed model in R software (version 4.4.2; The R Foundation for Statistical Computing).

Ethical Considerations

All participants provided written, informed consent to participate, and their study partners were asked to provide separate written, informed consent. The study was conducted following the Declaration of Helsinki and was approved by the institutional review boards (IRBs) at each of the 7 participating medical centers (Gachon University Gil Medical Center IRB: GCIRB2023-048; Konkuk University Medical Center IRB: 2023-02-017; The Catholic University of Korea, Yeouido St. Mary's Hospital IRB: SC23DDDS0007; Severance Hospital IRB: 10-2023-68; The Catholic University of Korea, Eunpyeong St. Mary's Hospital IRB: PC23DDDS0021; Kangwon National University Hospital IRB: 2023-02-001; SMG-SNU Boramae Medical Center IRB: 1-2023-0005). All participants were anonymized by assigning randomly generated identification numbers. All participants received a compensation of KRW 100,000 (US $68.22) per visit, and study partners were provided with KRW 50,000 (US $34.11) per visit. The study consisted of 5 visits for those who completed the entire study. The reporting of this trial follows the CONSORT statement (Multimedia Appendix 3).



Results

Overview

A total of 140 participants were screened, of whom 40 were excluded based on the inclusion and exclusion criteria (Figure 1). The remaining 100 participants were randomized at a 1:1 ratio. During the clinical trial period, 11 (22.4%) participants in the ET-101 group and 25 (50%) participants in the control group did not complete the study. In the ET-101 group, 1 participant did not use the digital therapeutic device at all after randomization. Therefore, the analysis was conducted on a total of 99 participants in the full analysis set. The dropout rate from the beginning of the training to week 12 was 3 (6%) participants in the ET-101 group and 8 (16%) participants in the sham control group. From week 12 to week 24, the dropout rate was 8 (16%) participants in the ET-101 group and 17 (34%) participants in the sham control group. The adherence rate, defined as the proportion of completed sessions during the 12-week intervention period, was higher in the ET-101 group (mean 83.2%, SD 24.4%) compared to the sham control group (mean 63.8%, SD 31.4%). Daily usage, measured by the number of days participants accessed the program out of the total 84 scheduled training days (12 weeks × 7 days), was also higher in the ET-101 group (mean 69.7, SD 20.2 days) than in the sham control group (mean 53.3, SD 25.8 days). The baseline demographic and clinical characteristics are summarized in Table 1. There were no statistically significant differences in baseline characteristics between the 2 groups.

Primary Outcome

As shown in Table 2, the proportion of responders and nonresponders did not differ significantly between the ET-101 group and the control group at week 12 (*P*=.47). However, at visit 4, the proportion of responders was significantly higher in the ET-101 group (n=29, 59.2% responders) compared to the sham device group (n=14, 28% responders; *P*=.002).

XSL•FO

24 weeks			.002
Responder	29 (59.2)	14 (28)	
Nonresponder	20 (40.8)	36 (72)	

Secondary Outcome

The changes in clinical measures from baseline to weeks 12 and 24 are presented in Table 3. For ADAS-Cog-14, the change in scores from baseline to week 12 was compared between the ET-101 and control groups, showing no statistically significant differences (change difference=1.42; *P*=.13). However, at week 24, the change in scores from baseline showed a statistically significant improvement in the ET-101 group compared to the control group (change difference=–2.55; *P*=.02). These findings remained consistent even when examining the treatment-time interaction effect in a linear mixed model that adjusted for baseline ADAS-Cog-14 scores ($F_{2,\ 194}$=7.45; *P*<.001). In the post hoc analysis conducted to identify the specific time points associated with the significant treatment-time interaction, no significant differences were observed between the 2 groups at baseline (estimates=0.022; t_{265}=0.026; Bonferroni-adjusted *P*=.98) or week 12 (estimates=1.44; t_{265}=1.74; Bonferroni-adjusted *P*=.08). However, at week 24, cognitive improvement as measured by ADAS-Cog-14 was statistically significant in the ET-101 group compared to the control group (estimates=–2.53; t_{265}=–3.05; Bonferroni-adjusted *P*=.003; Figure 2). For the other clinical measures, no statistically significant differences were observed.

Figure 2. Comparison of adjusted mean change of Alzheimer's Disease Assessment Scale-Cognitive Subscale-14 (ADAS-Cog-14) between ET-101 and the control group using a linear mixed model. Lower scores represent better performance. ADAS-Cog-14 scores adjusted for baseline differences.

Sensitivity Analysis

Even when the linear mixed model was used without applying conditional mean imputation for missing data, the treatment-time interaction remained statistically significant in ADAS-Cog-14 ($F_{2,\ 176}$=3.91; *P*=.02). In the post hoc analysis, no statistically significant differences were observed at baseline (estimates=0.018; t_{232}=0.021; Bonferroni-adjusted *P*=.98) or at week 12 (estimates=1.53; t_{235}=1.69; Bonferroni-adjusted *P*=.09). At week 24, the Bonferroni-adjusted *P* value was .05, indicating a trend toward greater improvement in ADAS-Cog-14 scores in the ET-101 group compared to those of the control group (estimates=–2.13; t_{244}=–1.96).

Exploratory Analysis

The results of the linear mixed model and post hoc analysis for the subdomains of ADAS-Cog-14 are presented in Table S4 in Multimedia Appendix 1. Among the subdomains of ADAS-Cog-14, the treatment-time interaction in the memory domain was statistically significant ($F_{2,\ 194}$=11.2; *P*<.001). In the post hoc analysis, ET-101 showed a statistically significant improvement in the memory domain compared to the control group at week 24 (estimates=–2.50; t_{264}=–4.03; Bonferroni-adjusted *P*<.001).

The treatment-time interaction was also found to be statistically significant for the language domain ($F_{2,\ 194}$=3.99; *P*=.02). In the post hoc analysis, ET-101 demonstrated a statistically significant improvement compared to the control group at week 24 (estimates=–0.807; t_{290}=–3.68; Bonferroni-adjusted *P*<.001). For the praxis subdomain, representing executive function, the treatment-time interaction was not statistically significant ($F_{2,\ 194}$=0.497; *P*=.67).

Safety Analysis

In the ET-101 group, 6 AEs occurred, while 4 AEs were reported in the control group, with no statistically significant difference in AE incidence between the groups (*P*=.53; Table 4). Among the AEs in the ET-101 group, 2 were classified as SAEs due to prolonged hospitalization (non-ST elevation myocardial infarction and herniated disc disease of the lumbar spine); however, the incidence of SAEs also did not differ significantly between the 2 groups (*P*=.47). All reported AEs were determined to be definitely not related to ET-101.

Discussion

Principal Findings

This study investigated the efficacy and safety of ET-101 in patients with MCI compared to a sham device control group. We found that the ET-101 group showed significantly greater improvement in the ADAS-Cog-14 score in 24 weeks compared to the control group. Furthermore, no AEs related to the use of ET-101 were observed. Among the various types of digital cognitive training, to the best of our knowledge, this study is the first to investigate the effects of MMT using multimemory strategies in the form of a mobile app.

ET-101, a metamemory-based multistrategic cognitive training program, showed improvement in global cognitive function as well as memory function. In the primary outcome, the responder rate at 24 weeks was significantly higher in the ET-101 group. Additionally, in the secondary outcomes, the ADAS-Cog-14 score showed a statistically significant improvement in the ET-101 group compared to the control group at 24 weeks. According to a meta-analysis that included trials on computerized cognitive training for individuals with MCI, independently delivered digital cognitive training programs, such as ET-101, demonstrated a significant effect on verbal episodic memory, with a standardized mean difference of 0.21 (95% CI 0.04-0.38). This is consistent with the observed memory improvement in this study [41]. ET-101 demonstrated cognitive improvement comparable to that observed with donepezil in terms of ADAS-Cog score changes, suggesting that ET-101 may have a similar cognitive improvement effect [42]. One of the most well-known protective factors against memory decline in MCI is cognitive reserve, which refers to the ability to use cognitive processes and brain networks adaptively to compensate for deterioration [43]. In MCI, there is not only a reduction in the hippocampal volume but also a weakening of the connectivity among key brain regions involved in memory function, such as the frontal, temporal, and parietal lobes [44]. With ET-101, MMT enables individuals to monitor their own memory function objectively and select the most efficient memory strategies tailored to their needs, facilitating the frontal lobe [14]. Additionally, efficient memory strategies, including attention, imagination, and association, enhance the connectivity of brain regions related to cognitive reserve [23,24]. Biological evidence also supports the cognitive reserve–enhancing effects of metamemory. A previous study of MMT found reduced mean diffusivity in the left superior longitudinal fasciculus and corona radiata, which link the frontal, temporal, and parietal lobes [14], suggesting that ET-101 may contribute to enhancing cognitive reserve, which in turn could support improvements in memory function.

Another characteristic of ET-101's cognitive function improvement is that it has a transfer effect on the language domain. In the subdomain analysis of ADAS-Cog-14, the ET-101 group showed a significantly greater improvement in the language domain compared to the control group at 24 weeks. Meta-analyses of several studies of cognitive training in patients with MCI have not shown significant improvements in the language domain [41]. Earlier work has suggested that cognitive training gains typically reflect the training content and that insufficient training on other cognitive domains may therefore make improvements beyond the memory domain less observable [41]. However, MMT-based multistrategic cognitive training, on which ET-101 is based, has consistently demonstrated functional improvements not only in memory but also in the language domain across multiple studies [11,12,14]. One possible explanation for this transfer effect is that the metamemory and memory strategies of ET-101 repeatedly strengthen the connection between episodic memory and semantic memory. MMT helps individuals select compensatory strategies to address their cognitive deficits, and ET-101, in particular, repeatedly trains strategies such as imagination and association, facilitating the connection between episodic and semantic memory [45]. This is especially relevant to lexical production, which is impaired in MCI and requires effortful semantic memory processing, such as in fluency and naming tasks [46]. Notably, naming and semantic fluency have been identified in the literature as strong predictors of the conversion from MCI to Alzheimer dementia, and ET-101 appears to

XSL•FO
RenderX

reinforce cognitive functions that are closely associated with this deterioration [21]. Additional long-term studies are needed to investigate the effects of ET-101 on the rate of conversion from MCI to Alzheimer dementia and to assess its long-term efficacy further.

The observed improvement in the memory and language domains following ET-101 training is closely linked to the memory strategies embedded in the program, which are known to support memory formation. ET-101 primarily incorporates 3 core memory strategies: attention, imagination, and association. First, attention serves as an initial step in memory formation by facilitating selective encoding. Numerous neuroimaging studies have demonstrated that attention enhances memory by activating interactions between the hippocampus and fronto-parietal regions within the dorsal attention network [47-49]. This activation is thought to strengthen neocortical representations, thereby supporting long-term memory storage [50]. Clinically, studies have shown that increased activation of the dorsal attention network is positively correlated with the accuracy and strength of memory recall [51]. Next, imagination shares common neural circuits with episodic memory, involving the hippocampus, medial prefrontal cortex, and anterolateral temporal cortex—regions that are closely associated with memory consolidation [52,53]. Hippocampal replay facilitates the reconstruction of sensory experiences by integrating visual, sensory, and semantic information [52]. This process allows imagination to contribute to memory formation and strengthening, even in the absence of direct sensory input [52]. Regarding association, it has been suggested that newly learned words can facilitate the recall of previously acquired information through retroactive facilitation [54]. Notably, neural evidence indicates that while preexisting semantic relationships are primarily represented within the neocortex, unrelated word pairs can be bound by the hippocampus through associative processes, along with their episodic list context and novelty [54]. Taken together, findings from previous studies suggest that the strategies used in ET-101—attention, imagination, and association—effectively activate the hippocampus and related regions, thereby potentially compensating for the memory deficits observed in individuals with MCI.

However, ET-101 did not show a significant difference compared to the control group on the praxis subdomain, ADL, or quality of life measures. There was no statistically significant difference between the ET-101 and control groups in ADL assessments using CIBIC-Plus and ADCS-MCI-ADL, or in quality-of-life assessments for patients with MCI and their study partners using EQ-5D. Additionally, the praxis domain of ADAS-Cog-14 did not show a significant difference between the groups up to 24 weeks. These findings appear to be related to the characteristics of MCI and the measured scales. MCI involves cognitive decline, but the functional impairment at this stage is not severe enough to warrant a diagnosis of overt dementia [55,56]. Given that those with MCI typically manage daily activities well, ADL and quality-of-life scales may have a ceiling effect, reducing their sensitivity to detect meaningful changes [57]. Therefore, to observe subtle changes in ADL among individuals with MCI, this study used the ADCS-MCI-ADL scale, which is sensitive to detecting changes in ADL among individuals with MCI [32]. In prior pharmacological trials, reported improvements in ADCS-MCI-ADL included participants with both MCI and mild Alzheimer disease [3,58]. However, such improvements in ADCS-MCI-ADL have typically been observed over longer durations, such as 18-month follow-up periods, whereas the 24-week follow-up in our study may not have been long enough to detect meaningful changes [3,58]. This suggests that longer-term follow-up may be necessary to capture significant improvements in ADL or quality of life associated with ET-101. Similarly, in ADAS-Cog-14, the praxis domain has been shown to be less effective in distinguishing different stages of cognitive decline compared to the memory and language domains, and it appears to exhibit a ceiling effect in MCI [26]. Given recent efforts to develop more sensitive scales for detecting changes in ADL, quality of life, and cognitive function in MCI, future studies using these updated tools will be essential for accurately evaluating the effects of ET-101.

The improvement in cognitive function with ET-101 followed a delayed pattern, with significant effects emerging at the 24-week follow-up. While no group differences were observed immediately after the 12-week training period in either the primary or secondary outcomes, the ET-101 group showed significantly greater responder rates and ADAS-Cog-14 improvements at 24 weeks. These findings suggest that the cognitive benefits of ET-101 may not be immediate but instead become evident and persist after the intervention ends. This pattern contrasts with traditional cognitive training, which often shows immediate but short-lived effects. For example, the Advanced Cognitive Training for Independent and Vital Elderly trial reported improvements immediately after memory training, but these effects were not maintained at the 1-year follow-up [7]. In a study of computerized cognitive training that included follow-up data, the initially significant improvements in attention and memory observed immediately after the intervention were no longer present at the 3-month follow-up [8]. Previous meta-analyses have suggested that the effects of memory strategy training tend to be short-lived [59]. Moreover, most studies have not evaluated maintenance effects, resulting in limited evidence on whether training-induced improvements observed during the intervention are sustained in real-life situations [15]. In contrast, ET-101 showed significant gains after the training ended. This delayed onset and sustained improvement align with findings from strategy-based training programs, such as those including memory education, skill practice, and cognitive restructuring of memory-related beliefs [60-62]. Similar to ET-101, these studies did not show immediate cognitive improvements posttraining but demonstrated significant effects during follow-up assessments [60-62]. Such outcomes suggest that benefits emerge gradually as participants apply learned strategies in real-world contexts [61-63]. From a neurobiological perspective, memory consolidation involves synaptic consolidation, which includes short-term molecular processes such as protein synthesis and synaptic potentiation occurring within minutes to hours after memory formation, followed by systems consolidation, during which the interaction between the hippocampus and neocortex is gradually strengthened [64,65]. System consolidation can take several months to years in humans, and sufficient time may

XSL•FO
RenderX

be required to detect changes in memory ensembles and their associated engram networks, which could explain the delayed onset of cognitive improvement observed in this study [65]. However, alternative explanations cannot be excluded. The cognitive improvement observed at the 24-week follow-up may also be partially influenced by practice effects in cognitive testing or by reduced psychological distress after the completion of trial participation, leading to more apparent posttrial improvements. Moreover, the underlying mechanisms of the delayed and lasting cognitive effects remain unclear, and further longitudinal follow-up and functional neuroimaging studies are warranted to elucidate the temporal dynamics of training-induced neural plasticity. Future meta-analyses and systematic reviews should also investigate the characteristics of cognitive training protocols associated with either immediate or delayed effects to clarify the factors that determine these distinct temporal response patterns.

The cognitive improvement effect of ET-101 was observed in the ADAS-Cog-14 case, but not on other cognitive function assessment scales. In the secondary outcomes, the measures K-MMSE-II, CDR-SB, ADCOMS, and DSC did not show a statistically significant treatment-time interaction. These findings may be related to the sensitivity of cognitive function assessment scales. Previous studies comparing ADAS-Cog-14 with other cognitive measures have shown that ADAS-Cog can detect cognitive changes in MCI significantly more sensitively compared to MMSE and CDR-SB [66,67]. Notably, this study used the 14-item version of ADAS-Cog, which has been specifically reported to be highly sensitive for MCI assessment [26]. Therefore, the observed improvement in ADAS-Cog-14, but not on other scales, is likely due to differences in the sensitivity of these assessments in MCI, with ADAS-Cog-14 being more capable of detecting subtle cognitive changes.

Limitations

One limitation of this study is the relatively high number of dropouts during the trial. During the 12-week training period, 3 (6%) participants in the ET-101 group and 8 (16%) participants in the sham control group dropped out, values that fall within or below the typical range of dropout rates (30%-40%) reported in previous digital intervention studies [68,69]. However, between week 12 and week 24—after the intervention had ended—additional dropouts occurred in both groups: 8 (16%) participants in the ET-101 group and 17 (34%) in the sham control group. This increase may reflect reduced motivation to continue participation in the absence of active training. As these attrition rates necessitated an imputation strategy for missing data, the interpretation of the results should be approached with caution. In particular, the NRI method may overpenalize attrition and potentially bias the treatment effect estimates downward, especially when the reasons for dropout differ between groups. Therefore, to minimize the impact of the imputation used in this study, we conducted analyses to verify whether the results remained consistent across different statistical approaches. These included a comparison of the proportion of participants showing maintenance or improvement in cognitive function between the ET-101 and sham control groups based on NRI, as well as analyses of continuous cognitive scores using both independent *t* tests and linear mixed models. Furthermore, to minimize the impact of the imputation as conducted here, we used the same linear mixed model without imputation for missing data. Across these multiple analytic approaches, we consistently observed that ET-101 produced significantly better maintenance or improvement of cognitive function compared to sham controls at the 24-week follow-up.

Additionally, certain clinical variables, in this case CDR-SB and EQ-5D-VAS, had *P* values close to .05 in baseline comparisons, indicating that the 2 groups were not entirely homogeneous in terms of certain variables. To address this, we incorporated each scale's baseline score as a fixed effect in the linear mixed model when analyzing secondary outcomes. This approach allowed us to confirm that the treatment-time interaction remained statistically significant even after adjusting for these differences.

Third, although participants were not explicitly informed of their group assignment, differences in content between the ET-101 and sham control groups may have caused some participants to infer their allocation based on the app experience. This is a common issue in studies evaluating the efficacy of software-based interventions, where a sham condition must be provided without including the active training components. As such, there is a potential risk of performance and expectation bias between groups, which must be taken into consideration when interpreting the results.

Fourth, this study included only participants who were able to own and operate a smartphone, which may have led to the inclusion of a relatively more tech-savvy population. However, this inclusion criterion was necessary because ET-101 is designed to be used independently without additional assistance during the training process, targeting individuals with basic smartphone literacy. In particular, in the context of Korea, epidemiological data from 2023 show that approximately 95% of individuals aged 60 years and older own a personal mobile phone [70]. Therefore, this inclusion criterion does not substantially deviate from the characteristics of the older adult population in Korea.

Conclusions

Metamemory-based multistrategic cognitive training, ET-101, was found to improve cognitive function compared to a sham device control group. This effect was observed in both the targeted domain of memory and in the language domain, indicating a transfer effect. Additionally, the cognitive improvement became pronounced at 24 weeks, suggesting that ET-101 has a sustained effect beyond the training period. These findings indicate that ET-101 has the potential to provide effective MMT to a broader population with MCI, overcoming location and personnel limitations via its mobile app–based platform.

Abstract

Background: Accurate limb circumference measurement is essential for the diagnosis and management of lymphedema, facilitating the objective evaluation of treatment outcomes and early detection of disease progression. Although manual tape measurements are inexpensive and widely used, they are limited by interobserver variability and low reproducibility. Advanced modalities such as computed tomography and magnetic resonance imaging provide high precision but are costly and impractical for routine or home-based use. To overcome these limitations, we developed and validated a novel 3D measurement system that integrates a marker-based bodysuit (ZOZOSUIT2) with a smartphone app, enabling fast, accurate, and reproducible limb circumference assessment.

Objective: This study aimed to evaluate the accuracy, repeatability, and time efficiency of the 3D measurement bodysuit and smartphone system compared with those of manual tape measurements in patients with upper and lower limb lymphedema.

Methods: This prospective study included 26 patients (n=10 with upper limb lymphedema and n=16 with lower limb lymphedema). Using the ZOZOSUIT2, which contains approximately 20,000 dot markers, 12 full-body photographs were captured with a smartphone, and a 3D model was automatically generated. Circumference values were extracted at 10 standardized points on the upper limb (from the wrist to the top of the upper arm) and 9 on the lower limb (from the ankle to the base of the thigh). Each measurement was repeated 3 times to assess repeatability. Manual tape measurements were used as the reference standard. For each measurement point, the repeatability (intrameasurement variation) and the mean absolute error between the 2 methods were calculated. Measurement time was also recorded for both methods and compared statistically using the Wilcoxon signed-rank test.

Results: Across all measurement points, the median repeatability of the bodysuit smartphone system ranged from 2.2 to 6.4 mm, indicating high reproducibility. When compared with manual measurements, the median of the mean absolute error for upper limb points ranged from 6.7 to 20.5 mm, and for lower limb points ranged from 5.5 to 15.9 mm. Relatively larger discrepancies were observed at the wrist (median 19.8, IQR 15.5-24.1 mm), 5 cm proximal to the wrist (median 20.5, IQR 8.5-28.1 mm), and the base of the thigh (median 15.9, IQR 10.2-25.9 mm). Mean measurement time was significantly shorter with the bodysuit smartphone system (88.2, SD 16.0 seconds) than with manual tape measurement (293.8, SD 58.5 seconds; $P<.001$).

Conclusions: The bodysuit smartphone system enables rapid, precise, and highly reproducible limb circumference assessment in patients with lymphedema. Despite minor differences at anatomical sites with complex contours, such as the wrist and the

Introduction

Lymphedema is a chronic condition characterized by the abnormal accumulation of lymphatic fluid in the interstitial tissues, often resulting in swelling, discomfort, and functional impairments [1]. Accurate measurement of limb circumference is critical for both the diagnosis and monitoring of lymphedema, as well as for evaluating the effectiveness of conservative therapies or surgical interventions [2]. Early detection through precise measurement is particularly important to mitigate disease progression and optimize therapeutic outcomes [3].

Various methods for limb circumference measurement have been developed, each with distinct advantages and limitations. Manual circumference measurement using a tape measure is widely used because of its simplicity and low cost. However, it is inherently prone to interobserver and intraobserver variability and provides limited data points, restricting its utility in comprehensive assessment [4]. Advanced imaging techniques such as computed tomography and magnetic resonance imaging offer high accuracy and detailed data; however, their high cost, limited accessibility, and invasive nature make them unsuitable for routine or home-based monitoring [5,6]. These limitations underscore the need for a measurement method that is accurate, noninvasive, cost-effective, and user-friendly.

In recent years, technological advancements have facilitated the use of 3D scanning and smartphone-based tools for health monitoring. These innovations have made it possible to obtain detailed and accurate measurements with minimal invasiveness, providing new opportunities for disease management in both clinical and home settings [7,8]. However, there remains a lack of practical solutions that combine accuracy, user-friendliness, and cost-effectiveness, particularly for conditions such as lymphedema that require frequent and precise monitoring. To address this challenge, we have developed a novel approach using a 3D measurement bodysuit (ZOZOSUIT2; ZOZO Inc) and a smartphone [9]. With a standard smartphone camera, participants could generate a 3D virtual representation of their bodies in a few minutes. The primary objective of this study was to validate the accuracy and reliability of this newly developed method for measuring limb circumference in patients with lymphedema.

Methods

Study Design and Participants

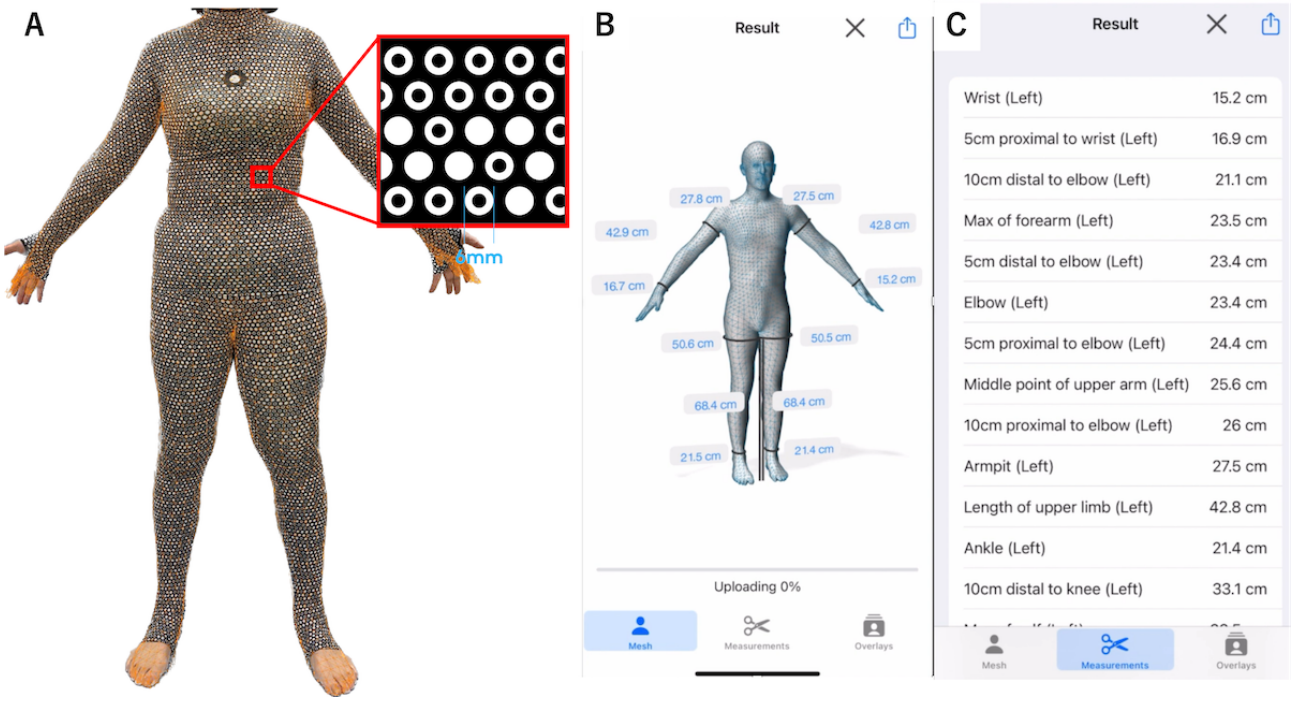
This was a prospective, multicenter observational study conducted to validate the accuracy and reliability of limb circumference measurements using a 3D measurement bodysuit (ZOZOSUIT2) and a smartphone. Consecutive patients diagnosed with upper or lower limb lymphedema who visited the Cancer Institute Hospital between November 2021 and February 2023 were screened for eligibility. Patients were identified from the outpatient clinic records and were approached in person during their regular visits. Participants who met the inclusion criteria and provided written informed consent were enrolled. Those who declined participation or were unable to wear the designated bodysuit due to size incompatibility were excluded.

Ethical Considerations

This study was reviewed and approved by the institutional review board of the Japanese Foundation for Cancer Research (2021-GA-1050) on April 5, 2022. All participants provided written informed consent before enrollment after receiving a full explanation of the study objectives and procedures. All collected data were anonymized before analysis to protect participant privacy and confidentiality. No financial or other compensation was provided to participants for their involvement in the study. This study was conducted and reported in accordance with the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) guidelines [10].

Data Collection and Manual Measurement

Patient characteristics and clinical data were obtained, including age, sex, BMI, and clinical stages based on the International Society of Lymphology (ISL) classification. Manual circumference measurements were performed using a standard measuring tape for comparison. For the upper limbs, circumferences were measured at the following 10 predefined points: top of the upper arm, 10 cm proximal to the elbow, midpoint of the upper arm, 5 cm proximal to the elbow, the elbow, 5 cm distal to the elbow, maximum point of the forearm, 10 cm proximal to the wrist, 5 cm proximal to the wrist, and the wrist. For the lower limbs, circumferences were measured at the following 9 predefined points: base of the thigh, 20 cm proximal to the knee, 10 cm proximal to the knee, the knee, just below the knee, 5 cm distal to the knee, maximum point of the lower leg, 10 cm distal to the knee, and the ankle.



To ensure consistency between methods, manual tape measurements were performed in a standing position, matching the posture used for the bodysuit smartphone measurements. In addition to circumference measurements, the time required to complete manual measurements for both upper and lower limbs was recorded. Measurement time was defined as the total duration from placement of the measuring tape at the first predefined point to completion of the final measurement.

RenderX

Measurement System and Procedure

The ZOZOSUIT2 is a bodysuit embedded with approximately 20,000 dot markers, enabling high-accuracy 3D measurement through a smartphone camera (Figure 1). Participants wore the ZOZOSUIT2, and 12 photographs were taken from different angles using a smartphone (iPhone 14; Apple Inc) according to the manufacturer's protocol.

Figure 1. Workflow of the 3D measurement system using the ZOZOSUIT2 and smartphone app. (A) The ZOZOSUIT2 is a bodysuit embedded with approximately 20,000 dot markers, enabling high-accuracy 3D measurement through a smartphone camera. (B) The application analyzes the 12 images to extract the 2D position of each visible marker and the participant's silhouette, and the 3D virtual human body model is displayed in the app. (C) The images were then processed by proprietary software to generate a 3D model of the participant's body, from which limb circumferences were automatically extracted at multiple points.

The participants were instructed to adopt a posture with their arms and lower limbs slightly spread out. The smartphone running the fitting app was placed on a phone stand at a height of 70 cm and positioned 1.5 m away from the participant. The app used audio prompts to guide the participant. Participants were instructed to turn clockwise by 30° every 6 seconds. Participants actively rotated their own body position without the use of a revolving platform. The app automatically captured a new image at the end of each interval. At the end of the whole process, the app had acquired 12 images of the participant. The app analyzed the 12 images to extract the 2D position of each visible marker and the participant's silhouette. Finally, a 3D virtual human body model was displayed in the app. These images were processed by proprietary software to generate a 3D model of the participant's body, from which limb circumferences were automatically extracted at multiple points (Figure 1). The measurement time was recorded.

Statistical Analyses

To assess the reproducibility of the bodysuit smartphone system, 3 consecutive measurements were performed for each participant under identical conditions. Repeatability for each measurement point was defined as the mean of the absolute differences between paired measurements (scan 1 vs scan 2, scan 2 vs scan 3, and scan 1 vs scan 3) across all participants. The limb circumference measurements obtained with the ZOZOSUIT2 and smartphone were compared to those obtained through manual measurements using a tape measure. The mean absolute error for each measurement point was calculated to evaluate accuracy.

Measurement times were recorded for both the bodysuit smartphone method and manual measurements. The start time was defined as the point at which the measurement process began (putting on the bodysuit or preparing the tape measure), and the end time was when all measurements were completed. Statistical comparisons of measurement times were performed between the 2 methods.

All statistical analyses were conducted using Google Sheets (Google LLC). Built-in spreadsheet functions were used to calculate descriptive statistics (mean, SD), and paired *t* tests (2-tailed) were performed to compare measurement times between the bodysuit smartphone and manual methods. Statistical significance was set at $P<.05$. The data were cross-checked using Microsoft Excel (version 16.106.2; Microsoft Corp) to verify calculation consistency.

Results

Patient Characteristics

Our study included 26 patients, consisting of 10 with upper limb lymphedema and 16 with lower limb lymphedema. We performed a total of 78 measurements using the bodysuit smartphone method. Table 1 shows the demographics of patients with upper limb lymphedema. The mean age was 56.1 (SD 15.2;

XSL•FO
RenderX

range 30-79) years. All patients were female. The mean BMI was 22.6 (SD 2.3; range 17.9-25.9) kg/m^2. The causative disease of lymphedema was breast cancer in all patients. Of 10 patients, lymphedema severity was stage I in 3 (30%), stage IIa in 2 (20%), and stage IIb in 5 (50%), based on the ISL classification.

Table 1. Demographics of patients with upper limb lymphedema (N=10).

Parameter	Value
Age (years), average (SD; range)	56.1 (15.2; 30-79)
Sex, n (%)	
Female	10 (100)
Physical parameters, average (SD; range)	
Height (cm)	155.2 (5.8; 146-163)
Weight (kg)	54.8 (8.4; 43.0-68.8)
BMI (kg/m^2)	22.6 (2.3; 17.9-25.9)
Cause of disease, n (%)	
Breast cancer	10 (100)
International Society of Lymphology stage, n (%)	
I	3 (30)
IIa	2 (20)
IIb	5 (50)

Table 2 shows the demographics of patients with lower limb lymphedema. The mean age was 60.9 (SD 11.2; range 43-76) years. All patients were female. The mean BMI was 21.8 (SD 2.8; range 16.5-28.1) kg/m^2. Of 16 patients, the causative disease of lymphedema was cervical cancer in 9 (56%), uterine cancer in 5 (31%), and ovarian cancer in 2 (13%). Lymphedema severity was stage I in 2 (13%), stage IIa in 5 (31%), and stage IIb in 9 (56%), based on the ISL classification.

Table 2. Demographics of patients with lower limb lymphedema (N=16).

Parameter	Value
Age (years), average (SD: range)	60.9 (11.2; 43-76)
Sex, n (%)	
Female	10 (100)
Physical parameters, average (SD: range)	
Height (cm)	157.8 (5.4; 148-167)
Weight (kg)	54.2 (6.4; 45.6-65.5)
BMI (kg/m^2)	21.8 (2.8; 16.5-28.1)

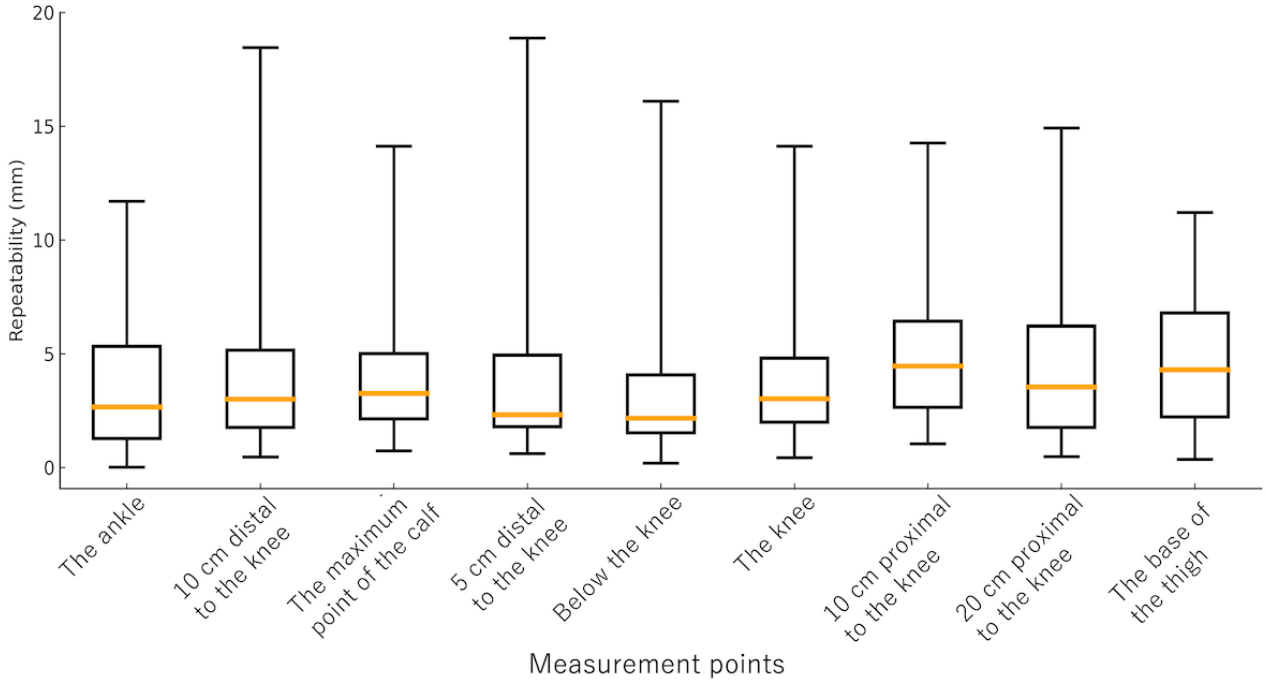
Repeatability of Limb Circumference Measurements

The median repeatability of limb circumference measurements obtained using the bodysuit smartphone system ranged from 2.2 to 6.4 mm across all measurement points for both the upper and lower limbs. Specifically, the median repeatability values for the upper limbs were as follows: the wrist, 3.8 (IQR 1.5-5.2) mm; 5 cm proximal to the wrist, 4.4 (IQR 3.0-5.4) mm; 10 cm distal to the elbow, 3.5 (IQR 2.8-4.8) mm; the maximum point of the forearm, 4.0 (IQR 2.2-5.1) mm; 5 cm distal to the elbow, 3.3 (IQR 2.2-4.6) mm; the elbow, 3.9 (IQR 3.2-5.8) mm; 5 cm

XSL•FO
RenderX

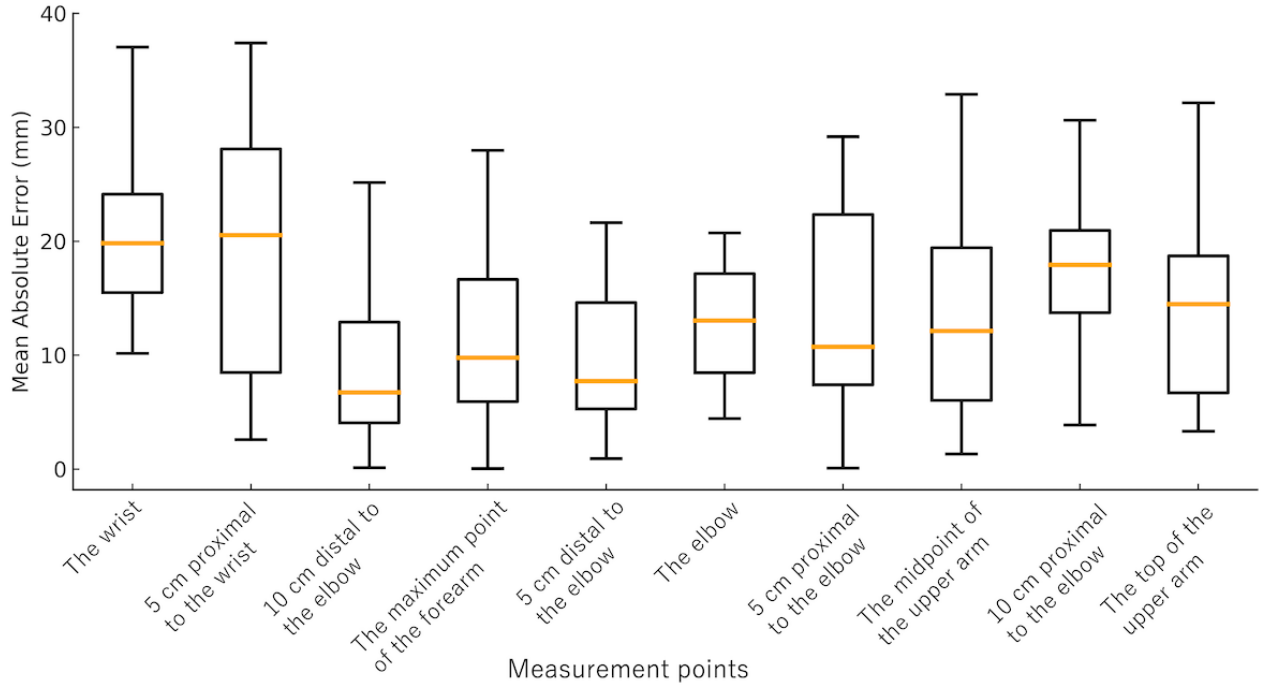


proximal to the elbow, 4.1 (IQR 2.2-5.3) mm; the midpoint of the upper arm, 4.6 (IQR 2.8-6.9) mm; 10 cm proximal to the elbow, 6.4 (IQR 2.7-7.7) mm; and the top of the upper arm, 6.4 (IQR 3.6-6.9) mm (Figure 2). For the lower limbs, the median values were as follows: the ankle, 2.7 (IQR 1.3-5.3) mm; 10 cm distal to the knee, 3.0 (IQR 1.8-5.2) mm; the maximum point of the lower leg, 3.3 (IQR 2.1-5.0) mm; 5 cm distal to the knee, 2.3 (IQR 1.8-4.9) mm; just below the knee, 2.2 (IQR 1.5-4.1) mm; the knee, 3.0 (IQR 2.0-4.8) mm; 10 cm proximal to the knee, 4.5 (IQR 2.6-6.4) mm; 20 cm proximal to the knee, 3.5 (IQR 1.8-6.2) mm; and the base of the thigh, 4.3 (IQR 2.2-6.8) mm (Figure 3). All repeatability values were below 10 mm, indicating a high level of reproducibility and confirming the system's reliability for both upper and lower limb measurements.

Figure 2. Repeatability of measurements at each upper limb point. Box-and-whisker plots show the repeatability of circumference measurements at 10 predefined upper limb points obtained using the 3D measurement bodysuit smartphone system. Each box represents the IQR, the orange line indicates the median, and the whiskers show the full range. Measurement points include the wrist, 5 cm proximal to the wrist, 10 cm distal to the elbow, the maximum point of the forearm, 5 cm distal to the elbow, the elbow, 5 cm proximal to the elbow, the midpoint of the upper arm, 10 cm proximal to the elbow, and the top of the upper arm.

XSL•FO
RenderX

Figure 3. Repeatability of measurements at each lower limb point. Box-and-whisker plots show the repeatability of circumference measurements at 9 predefined lower limb points obtained using the 3D measurement bodysuit smartphone system. Each box represents the IQR, the orange line indicates the median, and the whiskers show the full range. Measurement points include the ankle, 10 cm distal to the knee, the maximum point of the calf, 5 cm distal to the knee, just below the knee, the knee, 10 cm proximal to the knee, 20 cm proximal to the knee, and the base of the thigh.



Comparison Between the Bodysuit Smartphone Method and Manual Measurements

The mean absolute error between manual measurements and those obtained using the bodysuit smartphone system for the upper limb is shown in Figure 4. The median of the mean absolute error values across all upper limb measurement points ranged from 6.7 to 20.5 mm. Specifically, the median of the mean absolute error values were as follows: the wrist, 19.8 (IQR 15.5-24.1) mm; 5 cm proximal to the wrist, 20.5 (IQR 8.5-28.1) mm; 10 cm distal to the elbow, 6.7 (IQR 4.1-12.9) mm; the maximum point of the forearm, 9.8 (IQR 5.9-16.7) mm; 5 cm distal to the elbow, 7.7 (IQR 5.3-14.6) mm; the elbow, 13.0 (IQR 8.5-17.2) mm; 5 cm proximal to the elbow, 10.8 (IQR 7.4-22.4) mm; the midpoint of the upper arm, 12.1 (IQR 6.0-19.4) mm; 10 cm proximal to the elbow, 17.9 (IQR 13.7-21.0) mm; and the top of the upper arm, 14.5 (IQR 6.7-18.7) mm.

XSL•FO
RenderX

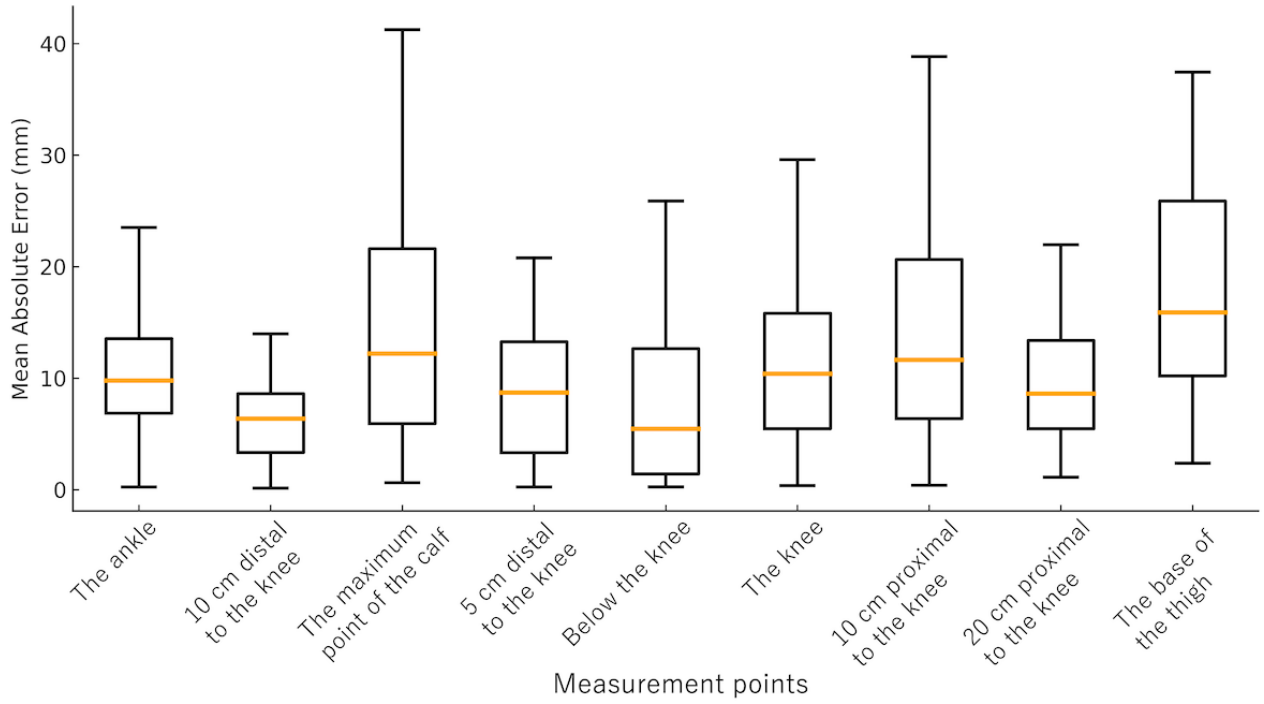


Figure 4. Mean absolute error between manual and bodysuit smartphone measurements at each upper limb point. Box-and-whisker plots illustrate the mean absolute error between manual and digital measurements across 10 measurement points on the upper limb (the wrist, 5 cm proximal to the wrist, 10 cm distal to the elbow, the maximum point of the forearm, 5 cm distal to the elbow, the elbow, 5 cm proximal to the elbow, the midpoint of the upper arm, 10 cm proximal to the elbow, and the top of the upper arm). The boxes represent the IQR, the central line indicates the median, and the whiskers denote the range excluding outliers. The overall median of the mean absolute error ranged from 6.7 to 20.5 mm, with higher variability observed in the proximal regions.

The mean absolute error between manual measurements and those obtained using the bodysuit smartphone system for the lower limb is shown in Figure 5. The median of the mean absolute error values ranged from 5.5 to 15.9 mm across all measurement points. Specifically, the median of the mean absolute error values were as follows: the ankle, 9.8 (IQR 6.9-13.6) mm; 10 cm distal to the knee, 6.4 (IQR 3.3-8.6) mm; the maximum point of the calf, 12.2 (IQR 5.9-21.6) mm; 5 cm distal to the knee, 8.7 (IQR 3.3-13.3) mm; just below the knee, 5.5 (IQR 1.4-12.7) mm; the knee, 10.4 (IQR 5.5-15.8) mm; 10 cm proximal to the knee, 11.6 (IQR 6.4-20.7) mm; 20 cm proximal to the knee, 8.6 (IQR 5.5-13.4) mm; and the base of the thigh, 15.9 (IQR 10.2-25.9) mm.

XSL•FO
RenderX

Figure 5. Mean absolute error between manual and bodysuit smartphone measurements at each lower limb point. Box-and-whisker plots illustrate the mean absolute error between manual and digital measurements across 9 measurement points on the lower limb (the ankle, 10 cm distal to the knee, the maximum point of the calf, 5 cm distal to the knee, just below the knee, the knee, 10 cm proximal to the knee, 20 cm proximal to the knee, and the base of the thigh). The boxes indicate the IQR, the central line shows the median, and the whiskers represent the range. The overall median of the mean absolute error ranged from 5.5 to 15.9 mm, with slightly larger deviations observed at the base of the thigh.

Furthermore, compared to the manual measurement group, the bodysuit smartphone method group demonstrated significantly shorter mean measurement times (88.2, SD 16.0 vs 293.8, SD 58.5 seconds; $P<.001$). The variability in measurement time was also considerably lower in the bodysuit smartphone method group than in the manual measurement group, indicating a more consistent measurement process.

Discussion

This study aimed to validate the accuracy and reliability of a novel limb circumference measurement system using a 3D measurement bodysuit and a smartphone compared to the conventional manual measuring tape method. The findings demonstrate that the bodysuit smartphone system is not only highly accurate and reproducible but also significantly more time-efficient than manual methods, indicating its potential as a valuable tool for lymphedema management.

The median of the mean absolute error across all measurement points for the 3D measurement bodysuit smartphone system was less than 10 mm. This level of accuracy is within clinically acceptable thresholds for lymphedema monitoring, where errors of less than 10 mm are generally considered sufficient to detect changes in limb circumference and disease progression [11]. Furthermore, the reproducibility of this method suggests transformative potential for the way limb circumference measurements are made. Unlike traditional manual measurements, which require the assistance of health care professionals or trained individuals, this method enables patients to perform measurements independently at home. This autonomy could significantly reduce the burden on health care systems by minimizing the need for clinic visits, thereby conserving medical resources and streamlining patient care [7]. The implications of these findings highlight the potential of the 3D measurement bodysuit smartphone system to revolutionize lymphedema management through improved accessibility and efficiency.

When comparing the mean absolute error between manual measurements and those obtained using the 3D measurement bodysuit smartphone system, the errors at most measurement points were less than 20 mm. This level of accuracy is considered clinically acceptable and comparable to manual measurements. However, in the upper limb, relatively larger errors were observed at the wrist and 5 cm proximal to the wrist, with median of the mean absolute errors of 19.8 (IQR 15.5-24.1) mm and 20.5 (IQR 8.5-28.1) mm, respectively.

In the lower limb, the base of the thigh also showed a relatively larger deviation, with median of the mean absolute errors of 15.9 (IQR 10.2-25.9) mm. These differences are likely attributable to the difficulty of obtaining consistent manual measurements at these anatomical sites rather than limitations of the bodysuit smartphone system itself. The thigh base includes a large and deformable soft tissue volume, which makes it challenging to define and reproduce an identical measurement level with a tape measure, particularly in the standing position. At the wrist, bony prominences such as the radial and ulnar styloid processes can interfere with stable tape placement. Considering the high repeatability of the bodysuit based method, it may offer greater reproducibility and reduce variability caused by individual measurers, thus contributing to the standardization of limb circumference measurement. These features highlight the potential of this method to provide consistent and reliable

XSL•FO
RenderX

data for both clinical practice and research settings. In addition, posture may also influence limb circumference measurement because gravity affects lymphatic fluid distribution. In our study, both manual and bodysuit smartphone measurements were performed in a standing position to minimize posture-related discrepancies. This standardized posture helped ensure that any differences between the 2 methods were due to measurement technique rather than variation in limb fluid distribution.

In addition to its accuracy, the 3D measurement bodysuit smartphone system demonstrated significantly shorter measurement times than manual methods. The bodysuit based method required an average of 88.2 (SD 16.0) seconds, whereas manual measurements took 293.8 (SD 58.5) seconds on average. This time efficiency has important implications for clinical workflows, particularly in high-volume lymphedema clinics. By reducing the time needed for circumference measurements, health care providers can focus more on other critical aspects of patient care such as treatment planning and counseling. This efficiency underscores the potential of this system to streamline lymphedema management in both clinical and home settings.

Advanced imaging modalities such as magnetic resonance imaging and computed tomography are capable of providing detailed anatomical and volumetric data, making them highly accurate tools for lymphedema assessment. However, their high cost, limited accessibility, and the need for specialized facilities and personnel render them impractical for routine use or home-based monitoring. The 3D measurement bodysuit smartphone system offers a noninvasive, portable, and cost-effective alternative that bridges the gap between these advanced imaging techniques and traditional manual methods. Additionally, devices such as the Perometer (Pero-System GmbH), which use infrared light to measure limb volume, have been established as reliable tools in clinical settings. While the Perometer is less labor intensive and provides high precision, its reliance on bulky, fixed equipment and higher costs limit its applicability for home use or resource-limited environments [12,13]. In contrast, the bodysuit smartphone system leverages widely available smartphone technology, thereby providing greater accessibility and usability. Its portability and ease of use make it particularly suitable for frequent or remote monitoring, empowering patients and reducing the burden on health care providers. This combination of practicality and accuracy positions it as a promising alternative for routine lymphedema management.

The implications of these findings are significant. Early detection and timely intervention are crucial for preventing lymphedema progression, and the 3D measurement bodysuit smartphone system enables frequent and accurate monitoring, empowering patients to take an active role in their care. By facilitating self-monitoring at home, this method reduces the need for frequent clinic visits, thereby alleviating the burden on both patients and health care providers. Its portability makes it a practical option for diverse clinical settings, including those in remote or underserved areas. Furthermore, the potential to integrate this technology into telemedicine platforms enhances its utility, allowing clinicians to remotely monitor patient progress and provide timely interventions when necessary [8]. These findings align with previous reports emphasizing the need for reproducible, patient-centered measurement systems in chronic disease monitoring and further extend this concept to lymphedema care [14].

While this study has several strengths, including its prospective design and the inclusion of a diverse cohort of patients with upper and lower limb lymphedema, it is not without limitations. The relatively small sample size and the fact that the study was conducted at only 2 centers may limit the generalizability of the findings. Larger, multicenter studies are needed to confirm the results and assess the applicability of the 3D measurement bodysuit smartphone system across different populations and clinical settings. Additionally, the greater measurement errors observed at specific points, such as the base of the thigh and the wrist, suggest potential limitations in the system's ability to accurately assess regions with complex anatomical contours or limited marker visibility. Future improvements to the technology should focus on addressing these challenges to further enhance its accuracy and reliability.

In conclusion, the 3D measurement bodysuit smartphone system represents a significant advancement in the field of lymphedema management. Its high accuracy, excellent reproducibility, and time efficiency make it a promising alternative to conventional manual methods. By providing access to accurate and user-friendly measurement tools, this system has the potential to transform lymphedema care by empowering patients to actively monitor their condition and enabling clinicians to deliver more efficient and personalized care. Future research should focus on addressing the system's limitations, validating its use in broader and more diverse populations, and exploring its integration into telemedicine and advanced data analytics platforms.

Acknowledgments

The authors thank all patients who participated in this study and the clinical staff who supported data collection. The authors also thank ZOZO, Inc, for technical support with the measurement device. Generative artificial intelligence tools (ChatGPT; version 5.0; OpenAI) were used only for language refinement and grammar checking after the scientific content was finalized by the authors. The authors reviewed and verified all outputs for accuracy.

Abstract

Background: Mobile health (mHealth) apps are increasingly incorporated into diabetes self-management education and support (DSMES) programs to improve access to behavioral and clinical support. Although digital DSMES interventions have demonstrated benefits for self-management and glycemic control, considerable variability exists in app use, and less is known about whether preintervention technology attitudes are associated with subsequent app use and related outcomes.

Objective: This study examined whether baseline technology attitudes are associated with app use and whether app use is associated with diabetes self-care and hemoglobin A_{1c} (HbA_{1c}) among adults participating in a digital DSMES intervention.

Methods: We conducted a secondary analysis of the Living Healthier with Diabetes randomized controlled trial (RCT) in Texas (2020-2022). The RCT included 3 study arms: virtual DSMES, smartphone app–based DSMES, and a combined intervention. Analyses were restricted to the 2 intervention arms with app access. Baseline technology attitude was assessed using a 4-item composite scale. App use was measured using 2 indices: a primary app use index derived from days per week, minutes per day, and overall 3-month usage, and a feature-use index summing use across 10 app functions. Outcomes included HbA_{1c} and diabetes self-care. Multivariable linear regression and linear mixed-effects models were used to evaluate associations after adjustment for intervention arm, age, gender, past month financial situation, and baseline outcome values.

Results: Of the 189 participants enrolled in the primary trial, 129 randomized to the intervention arms with smartphone app access were included. Follow-up HbA_{1c} and diabetes self-care data were available for 116 (89.9%) and 114 (88.4%) participants at 3 months and 117 (90.7%) and 116 (89.9%) participants at 6 months, respectively. More positive baseline technology attitudes

XSL•FO
RenderX

were associated with greater app use at both 3 months (β=0.64, 95% CI 0.29 to 0.99; *P*<.001) and 6 months (β=0.78, 95% CI 0.39 to 1.17; *P*<.001) but were not associated with feature use. App use was not associated with HbA_{1c} at 3 months but was associated with lower HbA_{1c} at 6 months (β=−0.04, 95% CI −0.074 to −0.013; *P*=.005) and in longitudinal models (β=−0.04, 95% CI −0.074 to −0.006; *P*=.02). Greater app use was associated with higher self-care at 3 months (β=0.56, 95% CI 0.29 to 0.82; *P*<.001) and 6 months (β=0.38, 95% CI 0.14 to 0.62; *P*=.002) and remained associated with self-care in longitudinal analyses (β=0.44, 95% CI 0.21 to 0.68; *P*<.001). App and feature use did not change significantly between 3 and 6 months (*P*=.14 and *P*=.11, respectively).

Conclusions: These findings suggest that preintervention technology attitudes are associated with greater app use within digital DSMES programs and that greater use of the app may represent an important pathway linking mHealth interventions with behavioral and clinical outcomes in adults with type 2 diabetes.

Introduction

The number of people with diabetes (diagnosed and undiagnosed) in the United States surpassed 40 million as of recent estimates [1], with an increase in the age-adjusted prevalence rates (diagnosed and undiagnosed) for adults from 11.2% (2001-2004) to 13.5% (2021-2023). When considering diagnosed diabetes among adults during 2021-2023, the most recent data reveal marked geographic variations [1]. For example, higher rates were identified in nonmetropolitan areas as compared to metropolitan areas (10% vs 8.3%), for those with less than 100% of the federal poverty level (FPL) as compared to those at 500% or more of the FPL (13% vs 5.5%), and for those with less than a high school education vs those with more than high school (13.3 vs 7%) [1]. Beyond its rising prevalence, type 2 diabetes mellitus (T2D) is a complex, chronic illness that, when inadequately managed, confers substantial microvascular and macrovascular complications, which impair health-related quality of life and contribute to excess morbidity and mortality [2]. The economic burden is substantial; recent analyses provide estimates of the growing economic costs for diagnosed diabetes at US $412.9 billion in 2022 alone, of which US $306.6 billion was attributed to direct medical costs while another US $106.3 billion was attributed to indirect costs [3,4]. This represents a major financial burden to the US economy and to the millions of Americans impacted by this major public health issue. As such, there are several opportunities for potential interventions aimed at specific aspects of diabetes-related self-care.

Diabetes self-management education and support (DSMES) is a foundational component of type 2 diabetes care, facilitating the knowledge, skills, and behaviors required for effective self-management [5,6]. Evidence from a network meta-analysis of 108 randomized trials involving 17,735 participants demonstrated that DSMES significantly improves glycemic outcomes, reducing hemoglobin A_{1c} (HbA_{1c}) by an average of 0.61% compared with usual care [7]. Additional benefits include improvements in diabetes knowledge, self-efficacy, and weight-related outcomes, with effects sustained beyond the intervention period in some studies [8]. Despite its established effectiveness, DSMES remains substantially underused [9]. Referral, participation, and completion rates remain low, with disparities observed among individuals with lower income, lower educational attainment, and historically underserved populations [10,11].

Additionally, national evidence suggests that individuals experiencing lower socioeconomic status (SES) or who are Black or Hispanic may experience gaps in access to the internet at home [12]. The authors suggest that this link between lower access and potential for lags in access to health promotion may further worsen existing disparities [12]. Therefore, action must be taken to increase access and ameliorate both existing and potentially further disparities into the future as this cohort ages into adulthood [12,13]. Regardless of age, there is increased recognition of internet access as a social determinant of health [13,14], especially with more services being delivered through telehealth and patient portals that require access to the internet [14]. As such, this is a critical resource that warrants further investigation and widespread recognition to eliminate persistent disparities. These barriers have prompted increasing interest in alternative delivery approaches. In particular, digital and mobile health (mHealth)–based DSMES models have emerged as strategies that extend access to evidence-based DSMES beyond traditional in-person settings [15,16].

In 2018, a global review identified over 1000 apps focused on diabetes management alone [17]. The use of mHealth apps for T2D management has garnered significant research attention in recent years, with studies examining both clinical outcomes and self-management behaviors. Smartphone apps pose an alternative option that can help people with T2D improve HbA_{1c} levels by optimizing insulin management [18]. The proliferation of mHealth apps designed for T2D management has prompted researchers to evaluate their clinical effectiveness and impact on patient self-management. People living with T2D who use diabetes management apps demonstrated modest improvements in glycemic control and enhanced self-care behaviors [19-22]. Key factors linked to better outcomes included sustained app use, app features that support active self-monitoring, and

XSL•FO
RenderX

integration of feedback mechanisms [19-23]. A recent scoping review concluded that mobile apps for people living with diabetes allowed for convenient user experiences and contributed to improved blood glucose levels, with significant HbA_{1c} reductions [24]. Mobile apps have demonstrated potential for clinically meaningful reductions in HbA_{1c} levels, though results vary based on participants, intervention duration, and app use frequency [24].

While mobile apps offer an additional avenue for providing health-related interventions, technology attitudes may be associated with adoption and sustained use of mHealth apps, particularly in chronic disease self-management. A systematic review has demonstrated that attrition rates in mHealth interventions for chronic disease average approximately 43%, with real-world engagement often far lower [25]. Individual orientation toward technology has been described through related constructs such as personal innovativeness in IT and technology readiness. Personal innovativeness refers to an individual's willingness to try new information technologies [26], while technology readiness reflects a person's propensity to embrace and use new technologies [27]. These concepts provide a basis for considering technology attitudes as a person's general orientation toward new technologies. Prior research has linked technology readiness with technology adoption and use [28].

Although diabetes mobile apps and digital DSMES programs have been associated with improvements in self-care and HbA_{1c}, app use remains uneven and is influenced by multiple patient and implementation factors [23,29,30]. Moreover, even among those who initially adopt a diabetes app, a discrepancy has been observed between early uptake and sustained long-term use, with many individuals substantially reducing or discontinuing engagement over time [25,31]. Such variability in app use may help explain differences in behavioral and clinical outcomes observed across participants. Despite evidence that more positive attitudes toward technology are associated with willingness to use digital health tools, less is known about whether baseline technology attitudes predict subsequent app use within DSMES programs [32,33]. Consequently, an important gap remains in understanding whether preintervention technology attitudes are associated with subsequent app use within DSMES programs and whether app use is associated with diabetes self-management behaviors and glycemic outcomes.

To address these gaps, we used data from the Living Healthier with Diabetes trial, a 3-arm randomized controlled DSMES trial conducted in Texas to examine patterns of app use over time and their associations with outcomes [34]. Specifically, we aimed to (1) examine differences in sociodemographic factors between groups with high and low attitudes toward technology at baseline, (2) examine whether baseline technology attitudes were associated with app use at 3 and 6 months, (3) evaluate the association between app use and diabetes self-care and HbA_{1c}, and (4) assess whether app use declined between 3 and 6 months. We hypothesized that more positive baseline technology attitudes would be associated with greater app use at follow-up. We further expected that higher levels of app use would be associated with better self-care behaviors, given the proximal role of behavior change in DSMES, and with lower HbA_{1c}. Finally, given the structured support embedded within the intervention (eg, blood glucose tracking, health coaching), we expected that app use would not decline between 3- and 6-month assessments.

Methods

Study Design and Setting

We conducted a secondary analysis of data from a 3-arm randomized controlled trial (RCT) designed to assess the relative effectiveness of DSMES interventions in adults with T2D in Texas [34]. Participants were recruited and enrolled between November 2020 and March 2022. The three arms of the intervention were (1) a virtual asynchronous DSMES program with individualized follow-up support, called Virtual Making Moves With Diabetes (vMMWD); (2) a technology-based education and support delivered through a smartphone app (TBES); and (3) a combined modality where participants received vMMWD followed by TBES. Participants completed a web-based survey on sociodemographic, behavioral, and health data and HbA_{1c} assessment at 3 time points: baseline, 3 months, and 6 months. Details of the study design, participant recruitment, and primary findings related to HbA_{1c} outcomes have been previously reported [34].

Ory et al [34] evaluated the effectiveness of the 3 intervention approaches and reported significant improvements across all intervention arms. The present secondary analysis focused on technology attitudes, app use, and diabetes-related outcomes among participants with access to the smartphone app. We therefore restricted the sample to participants in the TBES-only and combined arms. Specifically, we examined whether baseline technology attitude was associated with app use at 3- and 6-month follow-up assessments and whether app use was associated with better self-care behaviors and glycemic outcomes. The combined arm provided app use data during the TBES exposure period, which occurred after the vMMWD component was completed.

Participants

The inclusion criteria for the trial were being aged ≥25 years, self-reporting as T2D, having baseline HbA_{1c} ≥7.5%, living in Texas, having a smartphone with internet access, and being able to read and speak English. Pregnant individuals and individuals who previously had conditions known to invalidate HbA_{1c} values (eg, liver failure, kidney dialysis, or organ transplant) were excluded from participation. Participants were recruited through community partnerships, provider referrals, social media, and radio ads [34].

Of the 189 participants enrolled in the trial, those assigned to the vMMWD-only arm (n=60) were excluded because participants in this arm did not have access to the mobile app. Our analytic sample at baseline (N=129) included participants from the TBES-only (n=68) and combined arms (n=61). Analyses were conducted using available case data.

XSL•FO
RenderX

Intervention

Participants randomized to TBES were given access to a smartphone app designed to support diabetes self-management [34]. The intervention was delivered over 3 months; however, participants continued to have access to the app thereafter and used the app at their own pace. The app included features for tracking blood glucose, meals, physical activity, and medications, as well as medication reminders, health coaching, and access to diabetes-related information (Table S1 in Multimedia Appendix 1). Participants could also communicate through the app with a diabetes coach, who provided text-based support several times per week, including encouragement, recipe ideas, and support related to blood glucose and other health tracking. Participants in the combined arm received both interventions sequentially, completing the vMMWD DSMES program before receiving access to the TBES mobile app. Compared to TBES, vMMWD included more structured education and counseling support through 8 hours of online diabetes education and periodic 1:1 virtual education and counseling with a clinical diabetes educator (eg, a registered nurse or registered dietitian nutritionist).

Variables

Primary Exposure: App Use

App use was assessed using an index score based on 3 self-reported items representing the intensity and frequency of app use over the past 3 months. App use was assessed at the 3- and 6-month follow-up surveys. The three items were (1) the number of times participants used the app for diabetes management over the preceding 3 months (10-point scale, 1 [never] to 10 [all the time]), (2) days per week of app use (0 to 7 days per week), and (3) average minutes per day of app use (7-point ordinal scale, 1 through 7 corresponded to 0-10 minutes, 11-20 minutes, 21-30 minutes, 31-40 minutes, 41-50 minutes, 51-60 minutes, and more than 60 minutes per day, respectively). Due to the heterogeneity of these scales, we rescaled each component to a common 0-10 metric using the transformation:

where X is the original observed value, X_{min} is the lowest possible value of the scale, X_{range} denotes the span of possible values of the scale (calculated as the maximum minus the minimum), and n sets the upper limit of the rescaled scale (here, n=10). The app use variable was created by summing the 3 rescaled components. Scores on the app use index ranged from 0 to 30, with higher values indicating more overall use of the app (Table S2 in Multimedia Appendix 1).

Secondary Exposure: Feature Use

Additionally, at 3- and 6-month follow-up assessments, participants rated the frequency with which they used 10 specific app features over the preceding 3 months. Responses were captured using a 10-point scale ranging from 1 (never) to 10 (all the time). The assessed features are summarized in Table S1 in Multimedia Appendix 1. To capture the overall use of the features in the app, a feature use index was calculated as the sum of responses across the 10 features. Possible scores ranged from 10 to 100, where a score of 10 indicates no reported feature use, and higher scores reflect more frequent use of individual features, broader use across multiple features, or both.

Baseline Technology Attitude

In this study, technology attitude refers to a person's general orientation toward new technologies. We assessed baseline technology attitude using 4 items. Study participants indicated their level of agreement with the following items on a 5-point Likert scale ranging from 1 (strongly agree) to 5 (strongly disagree): (1) I usually try new technologies before others do, (2) I generally avoid using new equipment or technology, (3) I enjoy using new equipment or technology, and (4) my friends come to me to learn about new technologies. The 3 positively worded items (1, 3, and 4) were reverse-coded so that higher scores across all 4 items reflected a more positive attitude toward technology (Table S3 in Multimedia Appendix 1). Baseline technology attitude score was computed by summing responses across the 4 items; scores therefore ranged from 4 to 20, with higher scores indicating a more positive attitude toward technology. The 4 items were adapted for this study. Internal consistency of the technology attitude measure was acceptable (Cronbach α=0.798).

Outcomes

The primary clinical outcome was HbA_{1c}. Given the statewide reach of the trial and restrictions on routine health care access during the COVID-19 pandemic, we chose a home-based testing approach using self-administered A_{1c}Now+ kits (PTS Diagnostics). This method has been used in previous diabetes self-management research [35]. Study personnel provided standardized testing instructions to supplement the manufacturer's instructions. Participants assessed their HbA_{1c} at baseline, 3 months, and 6 months and reported their results to the study team. HbA_{1c} was treated as a continuous outcome with possible values ranging from 4% to 14%. Higher scores represent poorer glycemic control.

Diabetes self-care was the secondary outcome and was measured using a 9-item modified Summary of Diabetes Self-Care Activities [36]. Items included assessing diet, physical activity, blood glucose monitoring, and foot care in the past 7 days using a scale ranging from 0 to 7 (Table S4 in Multimedia Appendix 1). The items were harmonized and summed up, creating a possible score ranging from 0 to 63. Higher scores represent greater performance of diabetes self-care activities. Cronbach α at baseline, 3 months, and 6 months were 0.81, 0.75, and 0.79, respectively.

Covariates

Additional variables considered important were selected based on existing literature [34], including intervention arm (TBES-only vs combined), age (years), gender (male or female), and self-reported financial situation over the past month (categorized as having money left over, just enough, or not enough). Race or ethnicity (non-Hispanic White, Hispanic, or other) and marital status (married or partnered, or other) were also collected and are reported to describe the study sample.

XSL•FO
RenderX

Ethical Considerations

The RCT was approved by the Texas A&M Institutional Review Board (IRB; #2019-0804D) and registered at ClinicalTrials.gov (NCT06370494). All participants provided written informed consent before enrollment, and participation was voluntary. Participants could withdraw from the study at any time without a penalty. Study data were deidentified and deposited in the Texas A&M institutional data repository, with access restricted to members of the study team. Participants could receive up to US $375 in compensation based on completion of study assessments. This secondary analysis used deidentified data collected under the original study approval.

Sample Size

The RCT used an a priori sample-size calculation based on its primary outcome, HbA_{1c}. Assuming a moderate effect size (Cohen *d*=0.5), 34 participants with baseline and postintervention measurements were required to provide 80% power at a 2-sided α=.05 [34]. The present study is a secondary analysis restricted to participants in the 2 intervention arms with access to the mobile app, with 129 participants available at baseline. Because this analysis used the available sample from the primary trial, no new prospective sample-size calculation was performed. For transparency, we conducted a sensitivity analysis for the multivariable linear regression models using the analytic sample available for each model (n=106-113). At 80% power and a 2-sided α=.05, the minimum detectable effect size for the focal predictor (Cohen f^2) ranged from 0.074 to 0.080 across the primary regression models. At 90% power, the corresponding minimum detectable effect size ranged from 0.099 to 0.107. These values indicate the analysis was sensitive to small-to-medium standardized effects.

Statistical Analysis

Baseline characteristics of participants were summarized using means with SDs for continuous variables and frequencies with percentages for categorical variables. Median splits of baseline technology attitude and app use at 3-month follow-up were used to separately stratify the participants' characteristics at baseline. Group differences were compared using a 2-sided Welch *t* test for continuous variables and Pearson chi-square test for categorical variables.

Separate multivariable linear regression models were fitted to investigate the association between baseline technology attitude and app use at 3- and 6-month follow-ups. Two outcomes were considered: app use and feature use. All models were adjusted for the intervention arm, age, gender, and the participant's baseline past-month financial situation.

Multivariable linear regression models were then used to investigate the cross-sectional associations between app use and health and behavioral outcomes at each of the follow-up time points. The primary predictor was app use measured at 3 and 6 months, and outcomes included HbA_{1c} and self-care assessed at the respective time points. The models were adjusted for baseline values of the respective outcome variables, intervention arm, age, gender, and past month's financial situation. The same model specifications were subsequently applied using feature use as an alternate predictor. The regression analyses used complete cases for each model. To assess the potential impact of missing data, we conducted sensitivity analyses using multiple imputation by chained equations (50 imputed datasets) with the *mice* package in R (R Foundation). Estimates were pooled using Rubin rules. These analyses yielded comparable estimates for the primary app-use associations.

Linear mixed-effects models with random participant intercepts were used to evaluate the association between app use and outcomes (HbA_{1c} and self-care) over time. In these models, app use at 3 months was included as a predictor of longitudinal outcomes measured at 3 and 6 months. Models were adjusted for baseline values of outcomes, intervention arm, age, gender, and past month's financial situation. The same model specifications were then applied using feature use as an alternate predictor.

To assess whether use of the app was sustained during the 3- to 6-month assessments, paired *t* tests were performed on the app use and on the feature use. Within-subject differences were calculated as 6-month minus 3-month, and the mean changes were reported with a 95% CI.

We assessed model assumptions by visually examining residual plots for linearity, homoscedasticity, and normality. Multicollinearity was assessed using variance inflation factor (VIF) and tolerance values (VIF range 1.00-1.47; tolerance range 0.68-1.00). Influential observations were assessed using Cook distance, with all values below 1 (maximum 0.37). All statistical analyses were conducted in R software, version 4.5.2. A 2-sided α of .05 was used as the threshold for statistical significance.

Results

Participant Characteristics

Figure 1 illustrates the participant selection process and data availability for the secondary analysis. At baseline, the analytic sample included 129 participants with access to the mobile app. Follow-up data were available for 116 (89.9%) participants for HbA_{1c} and 114 (88.4%) for self-care at 3 months and for 117 (90.7%) and 116 (89.9%), respectively, at 6 months.

Table 1 shows baseline characteristics stratified by median split of baseline technology attitude. Participants with an above-median technology attitude were younger (mean 49.2, SD 11.8) compared with those at or below the median (mean 53.5, SD 9.6; *P*=.03). No other significant differences were observed across attitude groups for gender, race and ethnicity, marital status, financial situation, baseline HbA_{1c}, or baseline self-care (all *P*>.05).

Baseline characteristics of participants with available app use data at 3 months (n=116) stratified by median split of 3-month app use are presented in Table S1 in Multimedia Appendix 2. A significantly greater proportion of participants in the combined arm fell into the lower app use group (36/58, 62.1%) compared to the proportion in the app-only arm (*P*=.02). Baseline technology attitude was higher among those with above-median app use (mean 14.6, SD 3.2) compared to those

XSL•FO
RenderX

at or below the median (mean 13.3, SD 3.7; *P*=.04). No other significant differences were observed.

Association of Baseline Technology Attitude With App Use

Higher baseline technology attitude was significantly associated with greater app use at both 3 months (β=0.64, 95% CI 0.29 to 0.99; *P*<.001) and 6 months (β=0.78, 95% CI 0.39 to 1.17; *P*<.001; Table S2 in Multimedia Appendix 2). Participants randomized to the combined arm had significantly lower app use at 3 months compared with participants randomized to the app-only arm (β=–2.90, 95% CI –5.17 to –0.62; *P*=.01). On the other hand, higher baseline technology attitude was not significantly associated with feature use at 3 months (β=0.72, 95% CI –0.23 to 1.67; *P*=.14) or 6 months (β=0.67, 95% CI –0.35 to 1.68; *P*=.20) after adjustment for covariates (Table S3 in Multimedia Appendix 2).

Association of App Use With HbA1c

The complete-case cross-sectional regression models for HbA_{1c} included 112 participants at 3 months and 113 at 6 months. At 3 months, app use was not associated with HbA_{1c} following adjustment (β=–0.04, 95% CI –0.08 to 0.00; *P*=.08; Table 2). However, at 6-month follow-up, higher app use was associated with lower HbA_{1c} (β=–0.04, 95% CI –0.074 to –0.013; *P*=.005; Table 2). In the longitudinal analysis, app use was associated with lower Hb A_{1c} (β=–0.04, 95% CI –0.074 to –0.006; *P*=.02; Table 3). Time was not significantly associated with HbA_{1c} across follow-up (*P*=.18).

Table 2. Multivariable linear regression analyses examining the association of app use with HbA_{1c}[a]. Analyses were restricted to participants with complete data on all variables included in each regression model.

Association of App Use With Diabetes Self-Care

For self-care, the complete-case cross-sectional regression models included 108 participants at 3 months and 111 at 6 months. Greater app use was associated with better self-care at 3 months (β=0.56, 95% CI 0.29 to 0.82; *P*<.001; Table 4). Similarly, at 6 months, app use continued to show an association with self-care (β=0.38, 95% CI 0.14 to 0.62; *P*=.002; Table 4). In longitudinal analysis, app use was associated with higher self-care across follow-up (β=0.44, 95% CI 0.21 to 0.68; *P*<.001; Table 5). The main effect of time was not significantly associated with self-care changes (*P*=.79).

Table 4. Multivariable linear regression analyses examining the association of app use with diabetes self-care. Analyses were restricted to participants with complete data on all variables included in each regression model.

Association of Feature Use and Outcomes

Feature use was not associated with HbA_{1c} at 3 months (β=0.00, 95% CI –0.02 to 0.02; *P*=.82). At 6 months, feature use was associated with lower HbA_{1c} (β=–0.01, 95% CI –0.03 to 0.00; *P*=.02; Table S4 in Multimedia Appendix 2). In the longitudinal model, the association between feature use at 3 months and HbA_{1c} across follow-up did not reach statistical significance (Table S5 in Multimedia Appendix 2). Turning to self-care, feature use was associated with self-care at both 3 months (β=0.18, 95% CI 0.07 to 0.29; *P*=.002) and 6 months (β=0.16, 95% CI 0.06 to 0.27; *P*=.002; Table S6 in Multimedia Appendix 2). The association remained statistically significant in the longitudinal analysis (β=0.14, 95% CI 0.04 to 0.23; *P*=.005; Table S7 in Multimedia Appendix 2).

Change in App Use Between 3- and 6-Month Follow-Up

Paired *t* tests showed no significant decline in use between the 3- and 6-month assessments. App use was not significantly different between 3 months (mean 9.13, SD 6.48) and 6 months (mean 8.49, SD 7.13), with a mean change of –0.64 (SD 4.52, 95% CI –1.49 to 0.21; *P*=.14). Similarly, feature use was not significantly different between 3 months (mean 24.45, SD 16.49) and 6 months (mean 27, SD 18.77), with a mean change of 2.55 (SD 16.45, 95% CI –0.56 to 5.65; *P*=.11; Tables S8 in Multimedia Appendix 2).

Sensitivity Analysis

Sensitivity analyses using multiple imputation yielded estimates comparable to the complete-case analyses. The association between app use and HbA_{1c} at 6 months remained statistically significant, whereas the association at 3 months remained nonsignificant. Positive associations between app use and self-care were maintained at both follow-up assessments (Table S9 in Multimedia Appendix 2).

Discussion

Principal Results and Interpretations

This study examined the association between baseline technology attitude, app use, and diabetes outcomes within a digital DSMES intervention. Baseline technology attitude was associated with greater app use at both 3 and 6 months, with stronger estimates observed at 6 months. No clear association was observed with feature use. Higher app use, in turn, was associated with better diabetes self-care at both 3 and 6 months. In contrast, the association between app use and HbA_{1c} at 3 months was not statistically significant, but higher app use was associated with lower HbA_{1c} at 6 months. In longitudinal analyses, app use at 3 months remained associated with both self-care and HbA_{1c} across follow-up. Finally, app use did not decline significantly between 3 and 6 months.

In this study, higher baseline technology attitude was associated with greater app use at both 3 and 6 months, independent of age, gender, financial situation, and intervention arm. The larger estimate at 6 months suggests that technology attitudes may remain relevant as participants transition from early exposure to longer-term app use. This finding is consistent with previous research showing that individuals with greater personal innovativeness toward new technologies used a health promotion app more frequently [37]. Similar findings have been reported among adults with T2D, where participants who continued using a diabetes management app had more positive baseline attitudes toward technology, and more positive attitudes were associated with greater frequency and intensity of app use among noninsulin users [38]. In contrast, baseline technology attitude was not associated with feature use. This divergence suggests that general attitudes toward technology may shape willingness to incorporate an app into self-management routines, whereas use of individual features may depend on perceived relevance, usability, and personal need. Similar heterogeneity in module use has been reported in real-world diabetes app studies, where most users used only a single app component, a pattern the authors attributed to the highly heterogeneous self-management needs of patients with diabetes [32].

The pattern of findings for HbA_{1c} suggests that the association between mHealth app use and glycemic control may differ across follow-up assessments. Although app use was not associated with HbA_{1c} at 3 months, higher use was associated with lower HbA_{1c} at 6 months, and 3-month use was associated

XSL•FO
RenderX

with HbA_{1c} in the longitudinal analysis. This temporal pattern is consistent with evidence indicating that clinically meaningful glycemic improvements often require sustained exposure to digital self-management interventions. Studies of diabetes apps and digital therapeutics have reported greater HbA_{1c} reductions among participants with higher levels of app use, including dose-response patterns across engagement groups [39] and stronger clinical effects after 6 months of continued use [40]. However, findings across the mHealth literature are not entirely consistent. Vehi et al [41] observed improvements in glycemic outcomes regardless of use frequency, suggesting that frequency alone may not fully explain clinical benefit. Collectively, these findings suggest that the association between app use and glycemic outcomes may extend beyond frequency of use alone and may involve the quality, consistency, and behavioral context of use.

The clinical significance of these findings warrants consideration. Although the adjusted association between app use and HbA_{1c} at 6 months was modest (β=−0.04 per point), the observed IQR of the app-use index (1.43-14.19) corresponds to an estimated 0.51 percentage-point lower HbA_{1c} at the higher level of app use, based on the fitted regression model. This magnitude is comparable to the pooled HbA_{1c} improvement of approximately 0.2-0.4 percentage points reported across intervention categories in a systematic review and meta-analysis of randomized trials of mHealth-delivered DSMES, which the authors characterized as clinically relevant [16]. However, unlike intervention effects reported in randomized trials, our estimate reflects an observational association between self-reported app use and HbA_{1c}. Thus, the observed association may be clinically relevant across meaningful differences in app use, but its causal interpretation remains uncertain.

Greater app use demonstrated a consistent association with diabetes self-care at both 3 and 6 months and remained significant in longitudinal analyses. This finding is consistent with prior mHealth research showing that diabetes app users report higher levels of self-management behaviors than nonusers [21]. The feature-use findings further support this interpretation, as greater use of app features was also associated with higher self-care scores. Prior research suggests that diabetes apps support self-management through functions such as blood glucose monitoring, dietary recording, medication management and reminders, physical activity tracking, and tailored education or real-time feedback, which are intended to reinforce adherence to self-care regimens [42,43]. Real-world evidence from the myDiabetes app similarly suggests that use of digital education and self-monitoring functions can support structured diabetes education and ongoing self-management activities [44]. Taken together, these findings suggest that digital DSMES apps may support self-care by facilitating ongoing self-monitoring, feedback, and behavioral reinforcement.

App and feature use did not significantly decline between the 3- and 6-month assessments. This finding contrasts with the pattern reported in mHealth interventions, where app use declines commonly after an initial adoption period. Large-scale evaluations of digital diabetes prevention programs have documented progressive reductions in use over time, with many participants disengaging from intervention features within the first several months of enrollment [45]. The stability observed in the present study may reflect the structured nature of DSMES delivery and the continued support provided within the intervention. Similar observations have been reported in studies showing that sustained retention and continued app use are associated with more favorable long-term glycemic outcomes [46].

Significance and Strengths

This study contributes to digital DSMES literature in 3 ways. First, previous research linking technology attitudes to mHealth use has been conducted within acceptance-based frameworks, which primarily model behavioral intention rather than directly measured usage [47,48]. In this study, we assessed technology attitude before exposure to the app and then examined its association with reported app use at 3 and 6 months. This allowed us to evaluate whether baseline disposition toward technology was associated with subsequent app use. Second, many mHealth studies characterize app use using single measures, such as logins or time-based indicators [49,50]. We assessed app use using an app-use index capturing frequency, regularity, and duration, alongside a separate index of use across specific app features. This provided complementary measures of how participants used the app. Third, app use is not often evaluated over time in mHealth research. In a systematic review, only one-third of studies assessed change in engagement over time [50]. By measuring app and feature use at 3 and 6 months within a randomized DSMES trial, our study adds temporal depth to a literature that often relies on a single time point.

Limitations

This study has several limitations. App use was determined using self-report, rather than objective app-use logging data, which, while common in community-based research, may be subject to recall and social desirability biases. Despite this, self-reported app use can capture dimensions of engagement that may not be fully captured by objective usage metrics alone [51]. Additionally, diabetes self-care was self-reported and may therefore be subject to recall and social desirability bias. HbA_{1c} was measured using self-administered home testing kits, with participants reporting their results to the study team. This approach may be less precise than laboratory-based measurement [52] and may introduce reporting errors.

The feature-use index combines frequency of use across 10 app features into a single score. Similar scores could therefore represent different patterns of use, such as frequent use of a small number of features or less frequent use across several features. The index should be interpreted as a measure of overall feature use and does not distinguish the breadth and frequency of feature use. Residual confounding is also possible because some potentially relevant factors were not measured and so were not included in the adjusted models. These include medication regimen or insulin use, digital literacy, and other factors that could be related to both app use and study outcomes. Additionally, participants in the combined arm received structured DSMES before app access. Although the regression models adjusted for the intervention arm, differences in prior structured DSMES exposure, self-management knowledge, and

XSL•FO
RenderX

confidence between the intervention arms could still have contributed to the observed associations.

Restricting the analysis to the 2 intervention arms with app access was necessary because app use was only defined for participants assigned to receive the mobile app. Because app access was determined by randomized treatment assignment, this restriction is less likely to introduce collider bias through self-selection into app use. Nevertheless, trial eligibility required smartphone and internet access, and the analyses relied on available follow-up data. These factors may introduce selection bias and limit the generalizability of the findings to populations with lower digital access or different patterns of follow-up participation. Lastly, recruitment and data collection for the parent trial occurred during the COVID-19 pandemic [34]. The pandemic may have influenced participants' willingness to enroll in a digital DSMES intervention as well as their technology attitudes, access to digital resources, and patterns of app engagement. Consequently, the observed associations may not fully reflect technology use and engagement under usual, nonpandemic conditions.

Research and Policy Implications

Future mHealth research should move beyond evaluating app use through single, isolated metrics such as login counts or session duration [50]. Our parallel analysis of app and feature use indices demonstrated that each may capture distinct dimensions of participant interaction with digital interventions; for example, baseline technology attitude was associated with the app use index but not feature use. Researchers should adopt multidimensional, longitudinal approaches to better understand how technology attitudes influence different patterns of app use and how these patterns relate to behavioral and clinical outcomes over time [50].

From a policy perspective, the absence of a significant decline in app use between 3 and 6 months suggests that engagement with digital DSMES may be sustained over short-term follow-up. However, the present study did not assess costs, cost-effectiveness, health care use, reimbursement, or implementation economics. Future studies should examine the resources required to assess technology-related factors and support digital DSMES uptake, including whether such implementation strategies are cost-effective and whether reimbursement approaches can facilitate equitable access.

Conclusions

This study provides new evidence on the relationship between technology attitudes, app use, and diabetes outcomes within a digital DSMES intervention. More positive baseline technology attitudes were associated with greater app use, while higher app use was associated with better diabetes self-care and lower HbA_{1c} over follow-up. App use did not significantly decline between 3 and 6 months, contrasting with the declining use patterns commonly reported in mHealth interventions. These findings suggest that technology attitudes may influence how individuals interact with digital DSMES programs and highlight the importance of considering technology-related factors when designing, implementing, and evaluating mHealth interventions for adults with type 2 diabetes.

Acknowledgments

The authors sincerely thank Blue Cross and Blue Shield of Texas for their generous support of this research. We express our deepest gratitude to Carrie Byington, MD, and Nancy Dickey, MD, for their vital leadership, guidance, and support at the Texas A&M Health Science Center throughout this joint effort. Additionally, the authors wish to thank Keri Carpenter, MPH, and Wendy Creighton, BSN, for their invaluable contributions to program development and fieldwork coordination.

Funding

This research was supported by a grant from Blue Cross and Blue Shield of Texas to establish the Texas A&M University Health Science Center Rural Health Moonshot Initiative. The funder had no role in the design of the study, data collection, data analysis, interpretation of the results, or preparation of this paper.

Data Availability

The datasets generated or analyzed during this study are not publicly available due to restrictions enforced by Blue Cross Blue Shield of Texas. Requests to access the datasets should be directed to the Texas A&M point of contact for all data (Mr Jim Colson, MS, Texas A&M Associate Vice President, Digital Health, jim.colson@tamu.edu).

Generative AI Use

The authors declare that generative AI was not used in the preparation of this manuscript.

Abstract

Background: Digital interventions provide a scalable approach to promote healthy lifestyles, but at-scale evidence of their effects and effect modifiers is limited—even scarcer for habit-based digital interventions, although habits are promising lifestyle intervention targets.

Objective: We conducted a 1-group pre-post effect and effect modification assessment of a web-based app designed to support the formation of health-promoting lifestyle habits by exploring the relationship between objective app use and subjective changes in behavioral outcomes.

Methods: Three-month app access was offered to a subsample of the population-based Healthy Finland survey participants aged 20-74 years via SMS text messaging or mail. The app provided personalized behavioral suggestions that translated evidence-based lifestyle guidelines into simple, repeatable actions (“habits”). Users could browse and select these habits, and report and monitor their performances. The assessment used app log data, questionnaires collected through the app at baseline and at 45 and 90 days, and background information obtained from the national population register and the Healthy Finland Survey. Linear mixed effects models explored the (1) associations between app use and changes in self-reported diet quality (Healthy Diet Index), physical activity (metabolic equivalent of task hours per week), and BMI, and (2) modification of these associations by baseline characteristics related to sociodemographics, health, lifestyle, and e-service use. App use measures comprised the percentage of app use days (ie, days with logins/days of follow-up×100) and the number of reported habit performances (total, diet-related, physical activity–related, and BMI-related).

Results: Of 6975 invitees, 1282 (18.4%) accepted the invitation and 382 (5.5%; mean age 51, SD 15 y; women: n=263, 69%) completed the data collection required for the assessment. Over 90 days, the median percentage of app use days was 5.9% (IQR 3.3% - 11%), and the total number of reported habit performances was 22 (IQR 3 - 68.5). A higher percentage of use days (by 10 percentage points) was associated with a 3.09 (95% CI 0.79 - 5.39) metabolic equivalent of task hours per week greater increase in physical activity and a 1-unit higher logarithmic number of reported performances with a 0.51 (95% CI 0.07 - 0.95) Healthy Diet Index point greater improvement in diet quality. Other associations between app use and outcomes were nonsignificant. Greater physical activity and a more positive attitude to e-services at baseline appeared to enhance the effect of app use on physical activity (*P* values <.05). The app received a median acceptability rating of 2.9 (IQR 2.4 - 3.3, scale: 1 - 4) and a median overall score of 7 (IQR 5 - 8, scale: 0 - 10).

Conclusions: An inexpensive, low-intensity digital support for healthy habits could foster small beneficial lifestyle changes, but effects require user engagement and may depend on the individual. The findings warrant confirmation in more robust study designs and call for further research for identifying those most likely to benefit from such digital support.

Introduction

Digital lifestyle interventions are considered a relatively inexpensive and scalable way to support the adoption and maintenance of healthy lifestyle behaviors. They enable a delivery independent of time, place, and health professionals and provide a promising avenue to increase the availability and accessibility of health services without additional burden on the health care system. Emerging evidence also suggests that digital lifestyle interventions can save societal and health care costs [1,2]. They thus appear to be an attractive solution for aging societies that face an increasing need for care while under pressure to reduce health care expenses.

While literature reviews have drawn varying conclusions on the overall effectiveness of digital lifestyle interventions, they have demonstrated that diverse digital tools have the potential to improve health behaviors and other health outcomes among various adult populations [3-10]. For example, a recent umbrella review and meta-meta-analysis of 47 systematic reviews covering more than 500 unique randomized controlled trials (RCTs) and more than 200,000 participants found grade A–level evidence that digital lifestyle interventions (mobile apps, web-based, SMS text messaging, or mixed) yield, on average, small to medium favorable effects on dietary outcomes (fruit, vegetable, and energy intake), physical activity (total, moderate to vigorous, and steps per day), and body weight when used predominantly as stand-alone treatments [4].

However, lifestyle change can be promoted in a multitude of ways. Habit-based approaches focus on the repetition of a specific behavior in a consistent context [11,12]. These approaches promote the formation of habitual behaviors that occur automatically as a response to specific contextual cues—even without conscious deliberation, motivation, or awareness [11-13]. Supporting habit formation has the potential to result in lasting lifestyle change, which sustains even when motivation drops [12]. An umbrella review with meta-meta-analyses of behavior change interventions across behavioral domains found habits to be the most potential targets of individual-level interventions, compared with knowledge, beliefs, attitudes, skills, and emotions [14]. For weight loss, nondigital habit-based lifestyle interventions have yielded evidence of short-term effectiveness compared to no treatment or usual care among individuals with overweight or obesity [15].

Nevertheless, the habit-based approach has not yet been widely adopted in digital lifestyle interventions. Furthermore, the few digital solutions that have used a habit-based approach have mainly been studied in specific population groups or in small-scale trials. Examples include the HabitWalk app for increased brisk walking that was tested in a 15-week microrandomized trial among inactive adults [16] and the Top Tips app for weight loss that was piloted in a 3-month RCT among adults with overweight or obesity [17]. Another example was the BitHabit app that was developed for the prevention of type 2 diabetes (T2D) and tested in a 12-month RCT among adults with T2D risk factors [18,19]. While the HabitWalk study demonstrated that the repetition of a target behavior in response to a specific cue is positively associated with habit strength [16], both the Top Tips and BitHabit apps showed the greatest effects among study participants who engaged with the apps more frequently [17,20]. These results indicate that habit-based lifestyle apps may be beneficial as long as they are used and highlight the importance of incorporating use metrics in their effect assessments. Sustained engagement remains a key challenge in digital lifestyle interventions [3,4,16,17,21,22]. The learnings of habit-based and other lifestyle apps suggest that personalization could enhance engagement [17,23,24].

Overall, limited evidence exists of the effects of digital lifestyle interventions—habit-based and other—among the general adult population and thus the potential of these interventions to promote public health at scale. Similarly, evidence of individual factors that may modify the effects of digital lifestyle interventions is limited and inconclusive [3,4,7,23,25]. Studying such effect modifiers is a prerequisite for identifying population groups that could benefit from exclusively digital interventions and groups that would need other types of support, such as in-person counseling.

This study addresses the knowledge gaps mentioned earlier regarding the effects and effect modifiers of digital lifestyle interventions intended to support the formation of health-promoting habits among the general adult population. Simultaneously, the study serves as a real-world example of scaling up a habit-based lifestyle app originally developed for individuals at risk of lifestyle-related chronic noncommunicable diseases to a more heterogeneous adult population. The study used a quasi-experimental pre-post design and deployed the app as a stand-alone support for self-directed habit formation. The overall aim was to conduct an exploratory assessment of the effects of the app use on behavioral outcomes and to identify groups most likely to benefit from using the app. The specific aims were to examine (1) associations between objectively measured app use and changes in self-reported diet quality, physical activity, and BMI over 3 months; (2) the modification of these associations by the baseline characteristics of the participants; and (3) the participants' experiences (ie, acceptability and overall evaluation) of the app.

Methods

Study Design

This study followed a quasi-experimental 1-group pretest-posttest design in which the participants were followed up for 3 months via the app using continuous app log data and questionnaires conducted at baseline, midway through (approximately 45 days since the baseline), and at the end of the follow-up (approximately 90 days since the baseline). The effects and effect modifiers of the app were examined based on an exploratory analysis of the relationship between objectively measured app use and changes in self-reported behavioral

XSL•FO
RenderX

outcomes. Owing to the correlational nature of the assessment, the reporting of the study follows the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) guideline for cohort studies [26,27] (for a completed checklist, see Checklist 1).

Ethical Considerations

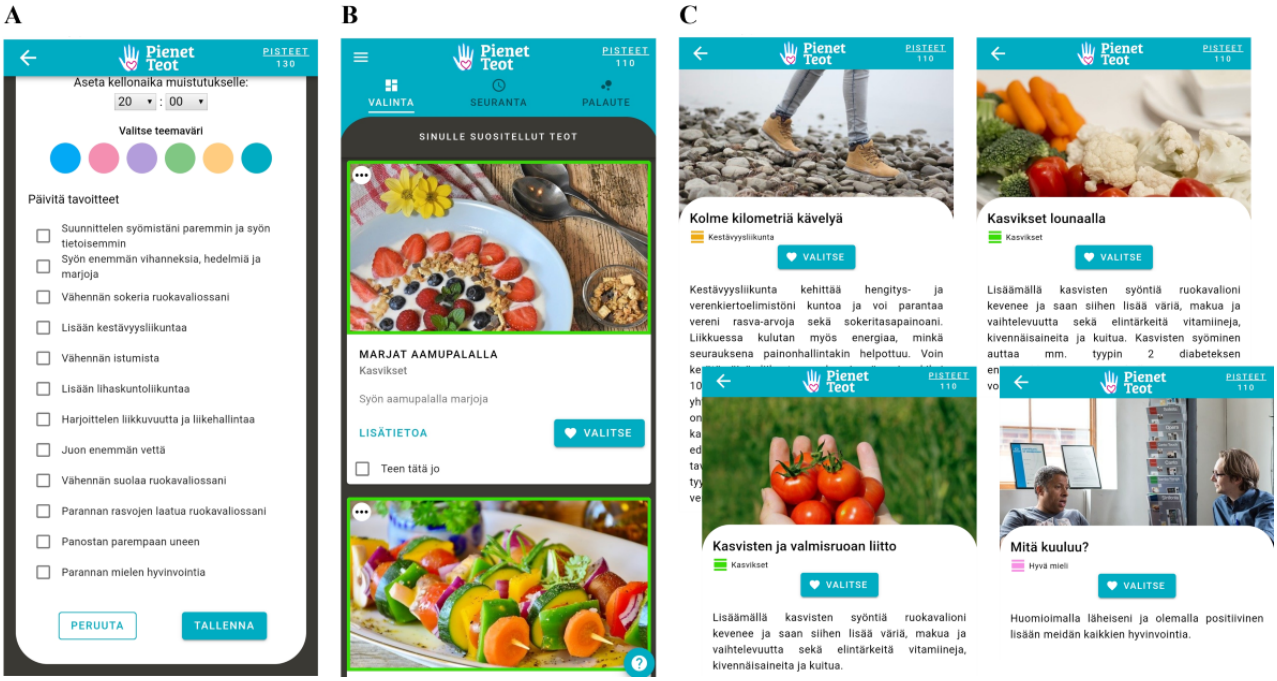
The research plan of the study was approved by the Institutional Review Board of the Finnish Institute for Health and Welfare (THL/5335/6.02.01/2022). The study participants gave their informed consent to participate. Participation was free of charge, and participants were not compensated.

Participant Recruitment

This study was a substudy of a population-based health survey, Healthy Finland, that targeted a randomly selected and nationally representative sample of adults in Finland [28]. Participants of the Healthy Finland survey were eligible for this study if they (1) spoke Finnish fluently, (2) were aged 20 to 74 years, (3) had completed the questionnaire of the Healthy Finland survey between September and the end of the year 2022, and (4) were not randomly selected for an additional health examination component of the Healthy Finland survey. The latter criterion was to avoid influencing the health examination results and to avoid burdening the participants excessively. Participation in this study also required access to the internet via a smartphone, tablet, or computer.

Among the eligible population (N=10,207), individuals with a known phone number (n=4978, 48.8%) were sent a personal invitation to participate in this study in February 2023 via SMS text message. From the remaining eligible population, 2000 individuals (19.6% of the 10,207 eligible people) were sampled based on 5-year age groups to receive the invitation via letter. The sample size was determined for the assessment of the uptake of the app [29,30] and estimated to be sufficient to detect small effects based on logistic regression with a statistical power of 0.8 and a type I error of 0.05, assuming that 10% to 15% of the invitees would choose to participate. The invitation was valid until the beginning of March 2023. The invitation directed the participant to a website of the Finnish Institute for Health and Welfare, which provided information on the study and the app, a link to the app, and instructions on how to start using the app. Of the 6975 invitees (excluding 3 who asked for their data to be removed), 1282 (18.4%) accepted the invitation, agreed to the terms of the app, and registered for the app with their phone number and a user ID that was featured in the invitation [29,30].

The App



The app used in this study was web-based and closed (ie, not open access) and could be used with a smartphone, tablet, or computer with no need to download the app on the device. The app was based on the BitHabit app that was developed in a T2D prevention study, Stop Diabetes (StopDia) [18,19,31], which involved the authors of this study and/or their affiliated research institutes. The BitHabit app was designed to support the adoption of lifestyle habits that promote health and aid the prevention of T2D and other lifestyle-related chronic diseases [19,20]. The BitHabit app was built on the principles of habit formation [32-34] and self-determination [35,36] theories. Habit formation approaches promote the repetition of a target behavior in the presence of consistent contextual cues until the cues begin to trigger the behavior automatically [32-34]. Self-determination theory emphasizes the role of autonomous motivation, perceived competence, and a sense of community in lifestyle changes and fosters the fulfillment of basic psychological needs—the perception of autonomy, the sense of control or self-efficacy, and the feeling of relatedness with peers or significant others [35,36]. After the StopDia study, the BitHabit app was updated by improving its visual appearance and by adding features for personalization (habit suggestions based on a background questionnaire) and for social support (a researcher-moderated discussion forum). This updated version was used in this study and is referred to as “the app” because the BitHabit brand has been out-licensed.

The app used in this study provided an “online store” or “library” of approximately 300 behavioral suggestions that translated lifestyle guidelines [37-41] into concrete actions. These actions were simple, specific, contextualized, and easily repeatable, and they were presented with a brief description of how they promote health. The actions were tied to and could be triggered by daily life activities, which made them optimal for habit formation [19]. The actions were organized into 19 habit categories related to eating and drinking (10 categories: mindful eating, meal pattern, vegetarian and fish courses, fruits and vegetables, grain products, dietary fats, sugar, salt, alcohol, and drinking water), physical activity (5 categories: aerobic exercise, muscle strengthening exercise, mobility and balance activities, stretching one’s legs, and everyday physical activity), sleep, positive mood, daily life management, and smoking.

On their first login to the app, the participants of this study gave their informed consent and completed a brief questionnaire on personal characteristics (eg, age, sex, and employment or study situation), health behavior (dietary habits, alcohol consumption, physical activity, sleep, and smoking), perceived stress, and well-being goals. On the basis of the participant’s responses to the questionnaire, the app determined the habit categories with the greatest potential for improvement and suggested the categories accordingly. After this, the participant could enter the app to browse the habit library; to inspect, select, and report actions; and to monitor and reflect on the actions performed. In addition, the app allowed setting reminders, enabled modifying the reported well-being goals, provided summary data on actions performed by other users, featured a researcher-moderated forum for discussion and questions, and provided information on health-promoting lifestyles. If the participant did not use the app for over a week, they automatically received up to 3 SMS text message reminders with 1-week intervals. No adjustments were made to the content or functionalities of the app during the study follow-up. Figure 1 illustrates the visual appearance and functionalities of the app.

Measures

Participant Characteristics

The participants' age and sex (male or female, as assigned at birth) were retrieved from the Finnish National Population Register. Information on socioeconomic status, health, lifestyles, and the use of e-services was obtained from the questionnaire of the Healthy Finland survey, which the participants had completed a median of 148 (range 47 - 231) days before the baseline of this study.

Information on socioeconomic status comprised education (years of full-time schooling, including primary and comprehensive school), household income (euros per month before taxes) as a 5-category variable, and principal life situation (employed or studying, on family leave or a stay-at-home parent, retired, unemployed, or other). Health-related information comprised perceived health status (poor or fairly poor vs average, fairly good, or good) and perceived cognitive function (average of 3 items: the working of memory, ability to learn new things, and ability to concentrate). Lifestyle-related information comprised getting enough sleep (rarely or hardly ever vs almost always, often, or unsure) and daily smoking or use of other tobacco products. Information on the use of e-services comprised perceived competence (low or no vs moderate, high, or very high); perceived barriers and concerns (average of 6 items related to diverse challenges in using e-services); and perceived benefits (average of 6 items related to diverse benefits of electronic social and health care services). The scoring of the variables reflecting perceived cognitive function, barriers or concerns, and benefits of e-services followed principles used in related research [42,43] and ranged from 1 to 5, with greater values reflecting better cognitive function, greater barriers or concerns, and greater perceived benefits. For original questionnaire items, see Multimedia Appendix 1.

App Use

Data on the use of the app accumulated automatically throughout the study via log files that included time-stamped user interactions with the app. App log data were considered from completion of the baseline questionnaire to the completion of the questionnaire at the end of the follow-up or, if not completed, 90 days since the baseline. The app use metrics used in the effects assessment were the percentage of use days, the total number of reported habit performances, and the number of reported habit performances targeting each primary outcome (diet quality, physical activity, and BMI; Table 1). Similar use metrics that are based on logins and activities performed have been found to be positively associated with favorable changes in behavioral and anthropometric outcomes in digital lifestyle interventions [44], including the StopDia study [45]. Reported performances related to eating or drinking were considered to target diet quality, performances related to physical activity or sedentary behavior were considered to target total physical activity, and performances related to eating, drinking, physical activity, or sedentary behavior were considered to target BMI. In addition, to describe the overall app use over the follow-up, we computed the percentage of active users per week, the number of use days, the number of habit categories with reported performances, and the number of specific habits with reported performances (Table 1).

XSL•FO
RenderX

Table . Use metrics derived from the app log files.

Use metric	Definition
Active users (% per week)	Users with ≥1 login/all users×100
Use days	Number of days with logins
% Use days	Number of days with logins/number of follow-up days×100
N categories with performances	Number of habit categories with reported performances
N habits with performances	Number of specific habits with reported performances
N performances[a]	Number of reported habit performances
Total	Total
Targeting diet quality	Related to eating or drinking
Targeting physical activity	Related to physical activity or sedentary behavior
Targeting BMI	Related to eating, drinking, physical activity, or sedentary behavior

[a]A specific habit could be marked as performed a maximum of once per day.

Primary Outcomes

The primary outcomes comprised self-reported diet quality, total physical activity, and BMI. These data were collected with questionnaires via the app at the start of the follow-up (defined as the completion of the baseline questionnaire), midway through the follow-up (approximately 45 days since the baseline), and at the end of the follow-up (approximately 90 days since the baseline). Total physical activity and BMI were additionally measured in the questionnaire of the Healthy Finland survey that was completed pre-baseline [28], and for comparability, we used the same questionnaire items (Multimedia Appendix 1).

Diet quality was measured with the Healthy Diet Index (HDI) [46], which reflects adherence to the Nordic and Finnish food-based dietary guidelines on a scale ranging from 0 (lowest diet quality) to 100 (highest diet quality). The HDI builds on a food frequency questionnaire that covers 7 dietary domains (meal pattern; grains; fruit and vegetables; fats; fish and meat; dairy; and snacks and treats, including beverages) [46]. Total physical activity covered weekly hours of low-, moderate-, and high-intensity physical exertion. To capture potential changes in both the amount and intensity of total physical activity per week, the time spent at each intensity level was weighted with its approximate metabolic equivalent of task (MET): 2.5 for low-intensity, 5 for moderate-intensity, and 10 for high-intensity exertion. The cutoffs were determined based on the description of each intensity level in the questionnaire items, corresponding MET values reported in the literature [47,48], and consultation with an expert on sports science. The weighted estimates were totaled to reach total MET hours per week. With this weighting, 12.5 MET hours per week met the current recommendation for adults to accumulate at least 2.5 hours of moderate-intensity or 1.25 hours of high-intensity aerobic physical activity per week, or an equivalent combination of both [49,50]. BMI (kg/m^2) was computed based on self-reported height and weight. While self-reported BMI is generally lower than measured BMI due to the underestimation of weight and overestimation of height, self-reported BMI tends to correlate with measured BMI over 90% and is considered a valid measure across a range of sociodemographic groups [51-53].

App Use Experience

User experiences were collected with a questionnaire via the app at the end of the follow-up. Questionnaire items reflected the acceptability and overall evaluation of the app (for original questionnaire items, see Multimedia Appendix 1). The mean acceptance of the app was computed by averaging the ratings (scale: 1 - 4, higher value indicating greater acceptance) the participants gave to 7 questionnaire items that reflected the 7 component constructs of the Theoretical Framework of Acceptability [54]. These constructs comprise affective attitude (how the participant feels about taking part in the intervention), burden (the perceived amount of effort that is required to participate in the intervention), perceived effectiveness (the extent to which the intervention is perceived as likely to achieve its purpose), opportunity costs (the extent to which benefits, profits, or values must be given up to engage in the intervention), intervention coherence (the extent to which the participant understands the intervention and how the intervention works), self-efficacy (the participant's confidence that they can perform the behaviors required to participate in the intervention), and ethicality (the extent to which the intervention has a good fit with the participant's value system) [54].

The overall evaluation of the app was computed by averaging the ratings (scale: 0 - 10, higher value indicating a more positive evaluation) the participants gave to 4 questionnaire items that asked them to evaluate the behavioral suggestions that the app offered, the app as a whole, the likelihood to use the app in the future, and the likelihood to recommend the app to a friend or a colleague. The latter item was also used to compute the net promoter score by categorizing the participants into detractors (rating ≤6), passively satisfied (rating=7 - 8), and promoters (rating ≥9), and then subtracting the percentage of detractors from the percentage of promoters [55].

Statistical Analyses

The effects assessment included participants who completed the baseline questionnaire and at least one questionnaire thereafter; that is, the questionnaire midway through and/or at

XSL•FO
RenderX

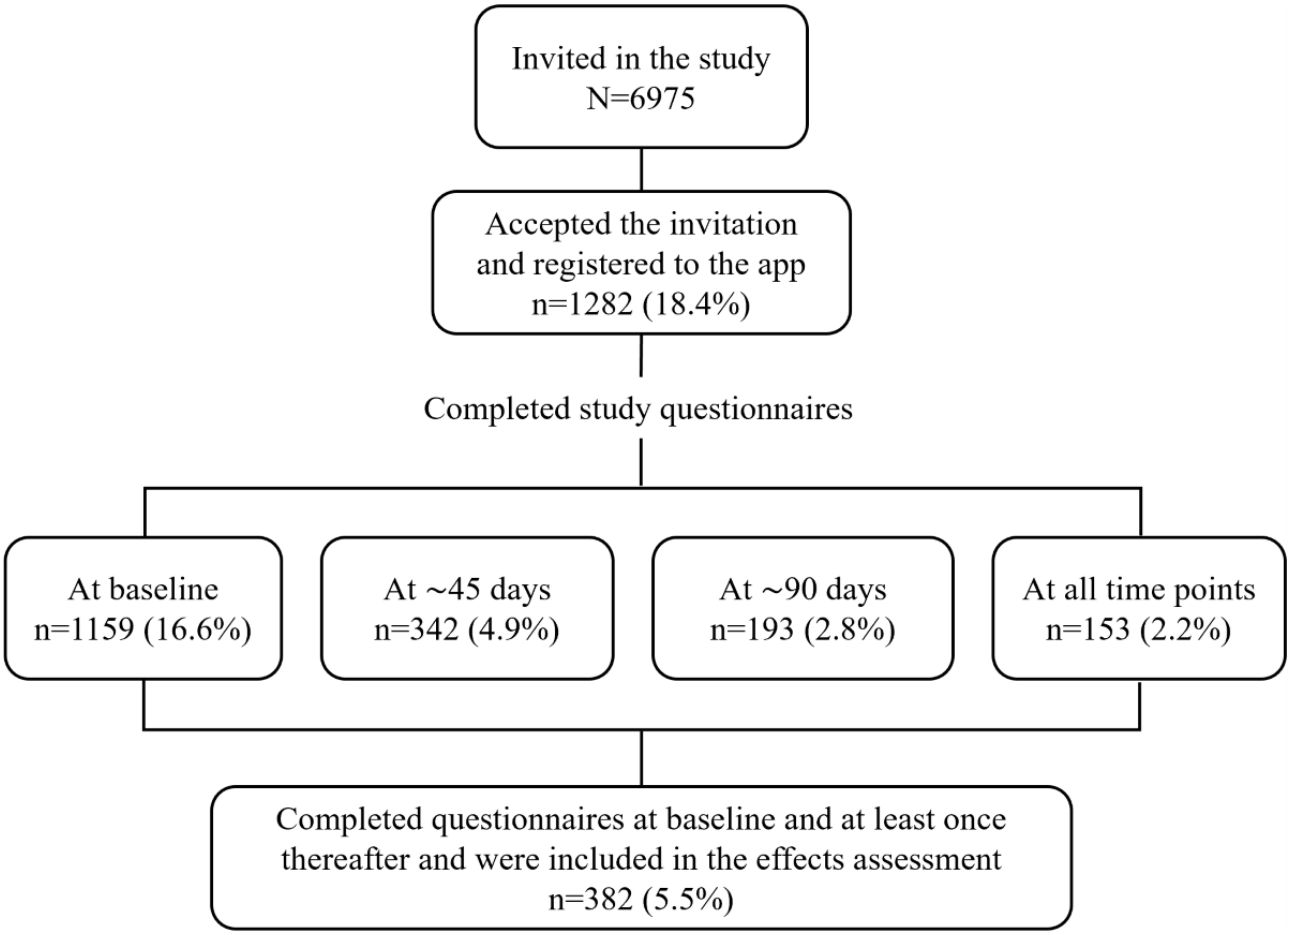
the end of the follow-up. We call these participants the "completers" of the study. Linear mixed effects models were used to estimate (1) the associations between app use and the slopes of the primary outcomes (diet quality, total physical activity, and BMI), that is, the interaction of elapsed time and an app use metric; and (2) the modification of these associations by the participants' baseline characteristics. The app use metrics were evaluated at the time of the completion of each questionnaire. The models related to diet quality and BMI were fitted with individual-level random intercepts and slopes. The models related to total physical activity were fitted with individual-level random intercepts only, as the inclusion of random slopes resulted in model convergence issues.

Separate models were fitted for each outcome–app use metric pair. The app use metrics reflecting the number of reported performances were log-transformed. The model coefficients corresponding to the log-transformed numbers of performances thus reflect the expected difference in the outcome corresponding to a 2.7-fold increase in the number of performances. All models were adjusted for the following baseline characteristics potentially influencing the app use and its effects [20,23,25,29]: age, sex, education, perceived health status, BMI, perceived cognitive function, diet quality, and total physical activity, as well as the competence, barriers or concerns, and perceived benefits of using e-services. Effect modification by the baseline characteristics was assessed by estimating the 3-way interaction parameters between each characteristic, app use metric, and elapsed time. The 3-way interaction reflected how the characteristic changed the association between the use metric and the slope of the outcome.

Regarding total physical activity, values >112 hours per week (ie, on average <8 hours per day for sedentary activities and rest) were excluded as implausible. Regarding diet quality and BMI, no implausible values were detected. To assess the sensitivity against large changes in the primary outcomes due to possible misreporting, the main models were fitted also by removing individuals with the largest changes reported between 2 successive measurements. The changes between successive measurements were standardized (ie, by subtracting the mean and dividing by the SD), and the sensitivity analyses were conducted by first removing individuals with the largest standardized change >5, and then those with the largest standardized change >3.

Analyses were performed with the R software (version 4.5.0; R Foundation for Statistical Computing [56]), using the package *lme4* [57] to fit the linear mixed effects models. Statistical significance was assessed with a likelihood ratio test, with a predetermined α level of .05. Data points with missing values were excluded from the analyses, and the data were assumed to be missing at random and that loss to follow-up was noninformative. As the analyses were of an exploratory nature, corrections for an increased type I error rate were not applied.

Results



Participant Characteristics

Of the 1282 individuals who accepted the study invitation and registered for the app (18.4% of invitees), 1159 (16.6%) completed the baseline questionnaire and 382 (5.5%) completed at least one questionnaire thereafter ("the completers"; Figure 2). The reasons for noncompletion are not available.

Among the completers, the proportion of men was 31% (119/382), age ranged from 20 to 74 (mean 51.3, SD 15.4) years, and the duration of full-time education ranged from 3 to 25 (mean 14.9, SD 3.4) years (Table 2). Most completers (280/382, 73%) belonged to the 3 higher income categories (household gross income approximately €2916 - €4580, or US $2953-US $4639, per month or more), and the majority were either employed or studying (218/382, 57%) or retired (134/382, 35%). A minority reported poor perceived health status (27/382, 7%), insufficient sleep (80/382, 21%), daily use of tobacco products (25/382, 7%), or poor competence to use e-services (7/382, 2%). On a scale ranging from 1 (poorer) to 5 (greater), the completers perceived their cognitive function to be on average 4.0 (SD 0.7), the extent to which they experienced barriers or concerns related to using e-services was on average 2.2 (SD 0.7), and the extent to which they perceived a benefit from e-services was on average 3.95 (SD 0.7).

Compared to the noncompleters (n=777), the completers had, on average, fewer years of education (14.9 vs 15.5 years; *P*=.004) and better diet quality (HDI 54.4 vs 52.5; *P*=.005; Table 2). The completers also differed from the noncompleters in their principal life situation (*P*=.03), with a greater proportion being retired (35% vs 27%) and a smaller proportion being employed or studying (57% vs 64%).

App Use

Among the completers, the percentage of active app users dropped from 97.6% (373/382) at the beginning of the follow-up to 29.1% (111/382) by the 6th week of the follow-up and to 19.9% (76/382) by the 13th week of the follow-up (Figure 3).

Figure 3. Percentage of active app users (≥1 login) per week over the 90-day follow-up.

Over the entire follow-up, the completers used the app on a median of 5.5 (IQR 3 - 10) days (Table 3). This equaled a median of 6% (IQR 3% - 11%) of the follow-up days. The completers reported performances in altogether 14 (74%) of the 19 habit categories. These 14 categories were related to physical activity (aerobic exercise, muscle strengthening exercise, mobility and balance activities, and stretching one's legs), eating and drinking (alcohol, mindful eating, drinking water, sugar, fruits and vegetables, dietary fats, salt, and meal pattern), sleep, and positive mood. The median number of habit categories with reported performances was 2 (IQR 1 - 3), while the median number of specific habits with reported performances was 5 (IQR 2 - 7). The median number of total reported performances was 22 (IQR 3 - 68.5). Across the app use metrics examined, the app use was significantly more frequent among the completers than among the noncompleters (*P* values <.001).

Targeting BMI	13 (2 - 49)	0 (0 - 1)	<.001

[a]Mann-Whitney *U* test.

Effect of App Use on Changes in Primary Outcomes

The completers' mean diet quality was 54.4 (SD 11) HDI points out of 100 at baseline, rose by 1.7 points to 56.1 (SD 10.8) by the midpoint of the follow-up, and dropped by 1.5 points to 54.6 (SD 9.8) by the end of the follow-up (Table S1 in Multimedia Appendix 1). The median total physical activity was 30 (IQR 15 - 50) MET hours per week at baseline, decreased by 1.25 units to 28.75 (IQR 17.5 - 50) by the midpoint, and returned to 30 (IQR 17.5 - 48.75) by the end of the follow-up. The mean BMI was 27.6 (SD 5.3) kg/m^2 at baseline, decreased by 0.1 units to 27.5 (SD 5.2) kg/m^2 by the midpoint, and returned to 27.6 (SD 5.7) kg/m^2 by the end of the follow-up.

When estimating the effect of app use on changes in the primary outcomes over the 90-day follow-up, the results differed depending on the app use metric and the outcome. A higher percentage of app use days (by 10 percentage points) was associated with a 3.09 (95% CI 0.79 - 5.39) MET hours per week greater change in total physical activity (Table 4). The percentage of use days was, however, not significantly associated with changes in diet quality or BMI. In contrast, a 1-unit higher logarithmic number of total reported habit performances (ie, 2.7-fold higher on the absolute scale) was associated with a 0.51 (95% CI 0.07-0.95) point greater change in diet quality. The total number of reported performances was, however, not significantly associated with changes in total physical activity or BMI. No significant associations were found between the number of reported performances targeting each outcome and the changes observed in the respective outcomes. For unadjusted effect estimates, see Table S2 in Multimedia Appendix 1.

Table . Effect of app use on changes in primary outcomes.

App use metric	Primary outcomes[a]					
	HDI (n=368)		TPA (n=362)		BMI (n=368)	
	β (95% CI)	*P* value	β (95% CI)	*P* value	β (95% CI)	*P* value
% Use days	.58 (–0.07 to 1.22)	.08	3.09 (0.79 to 5.39)	.01	.00 (–0.09 to 0.08)	.95
N performances[b]						
Total	.51 (0.07 to 0.95)	.02	1.30 (–0.30 to 2.89)	.11	–0.01 (–0.07 to 0.04)	.64
Targeting the outcome	.16 (–0.34 to 0.65)	.54	.62 (–1.02 to 2.2)	.47	–0.03 (–0.08 to 0.03)	.40

[a]Parameter estimates (β), 95% CI, and significance (*P*) of the effect of app use on Healthy Diet Index (HDI), total physical activity (TPA), and BMI. The estimates describe how changes in the outcomes over 90 days differ corresponding to a unit difference in the app use metric.

[b]Log-transformed.

The results remained predominantly robust in sensitivity analyses (Table S3 in Multimedia Appendix 1). The most notable changes were a slight attenuation of the estimated effect of the percentage of use days on physical activity (β=2.33, 95% CI 0.20-4.44; *P*=.03) and a slight strengthening of the estimated effect of the total number of performances on physical activity (β=1.71, 95% CI 0.29-3.10; *P*=.02) when removing individuals with the largest standardized change >3. In addition, the effect estimate for each app use metric on BMI was slightly stronger under the sensitivity analyses.

Effect Modification by Baseline Characteristics

Greater physical activity at baseline appeared to enhance the effect of the app use on total physical activity regardless of the app use metric used: the percentage of app use days (β=.13, 95% CI 0.06-0.2), the total number of reported performances

XSL•FO
RenderX

(β=.05, 95% CI 0.01-0.10), or the number of reported performances targeting physical activity (β=.05, 95% CI 0.00-0.09; Tables S4-S6 in Multimedia Appendix 1). This would mean that, in increasing movement, individuals who are physically more active at baseline benefit from using the app more than individuals who are physically less active.

Additionally, a greater extent to which the participants perceived to benefit from using e-services at baseline appeared to enhance the effect of the percentage of app use days (β=4.34, 95% CI 1.11-7.60) and the number of reported performances targeting physical activity (β=2.13, 95% CI 0.10-4.13) on total physical activity (Tables S4 and S6 in Multimedia Appendix 1). This would mean that, in increasing movement, individuals with more positive attitudes toward e-services at baseline benefit from using the app more than individuals with less positive attitudes. No baseline characteristic was found to modify the effect of the app use on diet quality or BMI (Tables S4-S6 in Multimedia Appendix 1).

App Use Experience

The participants who completed the user experience questionnaire at the end of the study gave the app a median overall acceptability score of 2.9 (IQR 2.4 - 3.3) on a scale ranging from 1 to 4, where a higher value indicated greater acceptance (Table 5). The participants gave both the app and the behaviors the app suggested a median overall score of 7 (IQRs 5 - 8 and 6 - 8, respectively) on a scale ranging from 0 to 10. Both the median likelihood to use the app in the future and to recommend the app to others was 5 (IQR 1 - 8).

Table . App use experiences at the end of the study (n=199).

User experience metric	Values
Acceptability (scale: 1 - 4[a]), median (IQR)	
Affective attitude	3 (2-3)
Burden	3 (2-3)
Perceived effectiveness	3 (2-3)
Opportunity costs	3 (2-4)
Intervention coherence	3 (2 - 3.5)
Self-efficacy	3 (2-3)
Ethicality	3 (3-4)
Mean of all acceptability domains	2.86 (2.43 - 3.29)
Overall evaluation (scale: 0 - 10), median (IQR)	
The behaviors the app suggested	7 (6-8)
The app as a whole	7 (5-8)
Likelihood to use the app in the future	5 (1-8)
Likelihood to recommend the app to a friend or colleague	5 (1-8)
Promoters (rating 9 - 10), n (%)	30 (15)
Passively satisfied (rating 7 - 8), n (%)	43 (22)
Detractors (rating 0 - 6), n (%)	126 (63)
Net promoter score (% promoters−% detractors)	–48

[a]Measures informed by the Theoretical Framework of Acceptability [54].

Discussion

Principal Findings

We assessed the effects and effect modifiers of the use of a habit-based healthy lifestyle app on self-reported diet quality, total physical activity, and BMI in a subsample of population-based health survey participants in Finland. The assessment was exploratory and correlational in nature, building on a quasi-experimental 1-group pre-post intervention. Over 3 months, the study participants used the app on a median of 5.9% (IQR 3%-11%) of days and reported a median of 22 (IQR 3-68.5) total habit performances. The percentage of use days was associated with increased physical activity, and the number of reported performances was associated with improved diet. Some evidence also suggested that greater baseline physical activity and a positive attitude toward e-services could enhance the app use effect on physical activity. Overall, the app was accepted and received moderate ratings. However, the likelihood at which the participants considered using the app in the future and recommending the app to others indicated that there is room to improve the app. The study contributes to the scant evidence base of the effects and factors that influence the effects of digital lifestyle interventions that use a habit-based approach, in a broadly recruited sample of adults. Moreover, the work provides a real-world example of scaling up a digital lifestyle intervention previously studied among individuals at risk of chronic diseases to a more heterogeneous audience.

RenderX

Comparison With Prior Research

App Use

With a median of 5.5 (IQR 3 - 10) objectively measured app use days (5.9%, IQR 3% - 11% of the follow-up period) and 22 (IQR 3 - 68.5) self-reported habit performances accumulated during the 3-month follow-up, many study participants were unlikely to succeed in forming new habits, particularly because the habit performances were divided into a median of 5 diverse behaviors. The minor changes observed in self-reported diet quality, physical activity, and BMI seem hence credible. While limited evidence exists of the time and number of repetitions needed to reach habit automaticity, a median of 66 (IQR 39-102) days was reported in a pioneering study that tracked the habit formation process among university students who performed a self-selected health-promoting action once per day in response to a stable cue [34]. The time needed for the habit strength to peak varies substantially, however, as the trajectory of habit formation is highly idiographic and often nonlinear [16]. Between-participant variation has been reported to range from 18 to 254 days [34,58]. Despite this variability, prior habit formation interventions have adopted a 3-month duration, considering it a sufficient period for a habit to develop—at least with daily repetition of the target behavior [15,17].

The overall low app use in this study suggests that the app was insufficiently engaging for many participants and may have failed to support them in repeating the selected behaviors. A voluntary habit-based behavior change requires sustained motivation and self-control to repeat the target behavior sufficiently for a habit to form [12]. To achieve this, people should be supported particularly during the early phases of their habit formation attempts because at this point, the emerging habit strengthens most quickly, but people are most likely to give the change attempt up if unsatisfied with initial experiences [12]. Common ways to support the continuation of the habit formation process include emphasizing the importance of the new behavior and training people in the skills needed to act in the chosen setting, for example, by making detailed action plans for the intended behavior and coping plans to overcome unintended behaviors [12]. Ideally, the support would be responsive to initial experiences and, as needed, assist in refining the set goals and methods chosen to pursue them [12].

The percentage of active app users dropped more quickly, and the app use frequency remained lower overall in this study than in the 12-month T2D prevention trial, StopDia, in which the BitHabit app was used by adults at risk of developing T2D [18,19]. During the first 6 months of StopDia, the percentage of active app users remained above 50%, the app was used on a median of 23 (IQR 12 - 42) days, and the users reported a median of 263 (IQR 60 - 703) habit performances [19]. In comparison, the Top Tips habit-based weight loss app reached an average of 25 (SD 44) logins and 10 (SD 21) completed tips during a 3-month pilot trial among individuals with overweight or obesity [17]. These differences in app use might be explained by the different target populations of the studies. While our study targeted the general adult population, the individuals who volunteered to participate tended to be healthier and have healthier lifestyles than those who did not [29,30]. The participants may hence have lacked a need or motivation to change their lifestyles. In contrast, the participants of StopDia were recruited via a T2D risk-screening website based on their risk scores (the Finnish Diabetes Risk Score ≥12 points [59]). The screening may have raised the participants' risk awareness and motivation to manage the risk by improving their lifestyles.

Supporting the interpretation related to risk awareness and motivation for lifestyle modification, digital physical activity interventions have been found to yield greater effects among at-risk and sick individuals than among healthy populations [7]. The interpretation also receives support from the Theoretical Domains Framework, an integrative framework that synthesized 33 theories and 128 theoretical constructs related to behavior change into 14 theoretical domains that facilitate explaining and predicting behavior [60,61]. According to the Theoretical Domains Framework, key determinants of behavior include knowledge, such as the awareness of personal susceptibility to develop a health condition and the severity of the condition, and beliefs about consequences, such as expectations related to the benefits of changing versus the risks of not changing behavior [61]. These determinants can influence other determinants, such as intentions (ie, conscious decisions to act), goals (eg, goal setting and prioritizing), and behavioral regulation (eg, action planning and self-monitoring) [61-64]. All these determinants reflect psychological capability and reflective motivation, which belong to the necessary conditions of behavior according to the COM-B (capability, opportunity, motivation—behavior) system [65].

Despite the generally low intervention engagement observed in this study, the variability in app use was substantial, particularly in the number of reported habit performances. The top quartile reported more than 68.5 total performances, which is a considerable effort. Similar variability was observed in StopDia [19,20], in which 11% of participants used the BitHabit app approximately twice per week and the most active 4% nearly daily throughout the 1-year intervention, reporting a median of 1433 and 4516 total performances, respectively [20]. These observations highlight the value of this study and the need for continued research efforts to identify the characteristics of the population segment that will find inexpensively scalable lifestyle apps intended for self-directed well-being and health promotion engaging and beneficial. Advancements in this research space will facilitate the allocation of more resource-intensive health services to individuals who need them most. As one size does not fit all and no single intervention will solve the public health challenges societies face, we need various tools to serve various preferences and needs, together with knowledge on the types of individuals who benefit from each tool.

Effect of App Use on Changes in Primary Outcomes

The exploratory, quasi-experimental effects assessment was performed with 2 types of app use metrics that reflected participants' engagement with the app: the percentage of app use days and the number of reported habit performances. Each metric had its pros and cons. The percentage of use days was a fully objective measure that was directly based on app logins and reflected the frequency with which the users visited the app. However, it did not reveal how the app was used during these

XSL•FO
RenderX

visits. Habit performances, in contrast, reflected concrete actions taken for habit formation. They, however, were self-reported and could be scheduled in advance or recorded retrospectively, which made them subject to recall bias.

The associations observed between the app use and changes in the primary outcomes varied depending on the app use metric and the outcome. Together, however, the findings support an interpretation that improvements in diet quality and total physical activity were connected with the app use. Diet quality was statistically significantly associated with the total number of performances, and physical activity was associated with the percentage of app use days. In addition, the estimates for the associations of diet quality with the percentage of app use days and physical activity with the total number of performances were, albeit not statistically significant, in line with a favorable app use effect. These results suggest that an active use of a habit-promoting digital tool could facilitate small favorable changes in lifestyle habits. In contrast, no evidence was found for an association between BMI and app use. This might be due to the short duration of the follow-up and the fact that not all dietary or physical activity–related changes in behavior influence energy balance and thus body weight.

Interestingly, we observed no significant associations between changes in the primary outcomes and the number of reported habit performances specifically targeting each outcome. The only exception was a sensitivity analysis that found the performances related to BMI were associated with reduced BMI. While the number of actions that specifically advance an outcome could be considered a probable and precise predictor of improved outcomes, actions that are not directly related to the outcome can also contribute to its improvement. For example, actions that enhance mood or sleep can facilitate the repetition of diet-related habit performances, resulting in improved diet quality. This pathway could explain why we found evidence of an association between diet quality and the total number of habit performances, but not with diet-related performances.

Our results provide support for prior evidence that the effectiveness of a lifestyle app depends on its use. The StopDia trial demonstrated that a higher BitHabit user engagement—measured as at or above the median of 501 self-reported habit performances over the intervention year [18] or the number of monthly use days during intervention months 2 to 12 [20]—was associated with improvements in T2D risk factor levels, including diet quality, physical activity, and BMI. The greater the use was, the greater the benefits observed. While participants with sustained use once or twice per week showed small beneficial changes compared to those who terminated the use, participants with nearly daily use throughout the study showed the most beneficial changes [20].

Similarly, the habit-based Top Tips weight loss app that was piloted in a 3-month trial among adults with overweight or obesity was found most beneficial among active users [17]. Participants with the greatest changes in eating-related self-regulatory skills, weight, and adherence to target behaviors logged into the app and recorded their weight on average 2 to 3 times more and achieved the tips more often than participants with smaller changes in the outcomes [17]. Relatedly, a 4-week feasibility trial of an app that promoted vegetable intake with goal setting, self-monitoring, and feedback found the app use days and the frequency of recording vegetable intake via the app positively associated with increased vegetable intake among young adults [21].

The scientific evidence concerning the relationship between use and outcomes is not entirely consistent, however. Two systematic reviews examined this association in exclusively digital lifestyle interventions among adults [44,66]. One of them found a weak positive overall association between use and physical activity based on a meta-analysis of 11 studies and observed that the direction of the association was consistently positive for use metrics that reflected activities completed or logins [44]. The other review found mixed associations between use and dietary intake based on a narrative synthesis of 5 studies [66]. The inconsistency in the findings might be explained by, inter alia, differences in the digital lifestyle interventions and their target behaviors [66].

Effect Modification by Baseline Characteristics

We found some evidence that, in increasing movement, the use of the app might favor individuals who are physically more active and who have positive attitudes toward e-services. These characteristics also predicted the uptake of the app among the individuals who were invited to participate in this study [29,30]. The odds of uptake, though, were increased by a wide variety of individual characteristics, including middle age, female sex, higher education, higher income, better health, a healthier lifestyle (considering diet, physical activity, sleep, and smoking), as well as higher competence, fewer barriers, and greater perceived benefits of using e-services [29,30]. Hence, the study sample was not representative of the general adult population, which may have influenced the results of the effect modification analysis. In comparison, studies on the BitHabit app have found older age [20,22] and better diet quality [20] to predict greater engagement with the app.

Regarding lifestyle apps in general, a systematic review on factors influencing app adherence also reported that a positive attitude toward technology positively influences adherence to physical activity apps [23]. In contrast, this review found evidence of the positive influence of female gender on adherence to nutrition apps and of healthy weight on adherence to physical activity apps [23]. Another systematic review found overall mixed evidence of factors that influence the effectiveness of digital lifestyle interventions [25]. The review comprised 9 studies that examined inequality in effectiveness among adults with no medical conditions other than overweight or obesity. In these studies, greater effects were observed in participants with younger age (n=2 studies), older age (n=1), female gender (n=3), male gender (n=3), higher education (n=1), professional or managerial or executive job (n=1), and residence in the capital region (n=1) [25].

In sum, our preliminary, exploratory findings on the effect modifiers of the use of a habit-based app targeted at the general adult population—together with the evidence mentioned earlier of other digital lifestyle interventions—demonstrate the multitude of factors that may influence effects. The

XSL•FO
RenderX

inconsistency in existing evidence warrants further efforts to identify groups that are and are not likely to benefit from digital lifestyle interventions. The inconsistency in findings across studies may be due to the heterogeneity of examined interventions, including but not limited to their target behaviors, theoretical underpinnings, approaches to support behavior change, components, content, intended use, target populations, evaluation context, and mode of delivery. Considering these characteristics could hence be meaningful in future studies that compare the effect modifiers of digital lifestyle interventions.

App Use Experience

The participants gave the app and the behaviors it suggested a median rating of 7 out of 10. Only 15% (30/199) were ready to promote the app to their friends or colleagues. The ratings indicate that the app failed to fully satisfy the needs of most participants. This might be because the behaviors included in the app library were rather general or because the app's approach to personalization did not meet the users' preferences. The personalization meant that the app determined and suggested habit categories with the greatest potential for improvement based on the user's self-reported demographics, health behavior, perceived stress, and well-being goals. Digital lifestyle interventions have used varying approaches to personalization, but it remains unclear what type and level of personalization works and for whom [5]. For example, some may prefer a system-driven approach in which the digital tool determines the personalization, thus reducing the cognitive effort required from the user [5]. Some, in contrast, may prefer a user-driven approach that allows the user to control the personalization and thus provides a greater sense of autonomy [5]. For an increased degree of user-driven personalization, the app could, for example, allow and guide users to plan their own target habits and the contextual cues that are supposed to trigger their performance. This way, the pursued habits would better fit the individual's lifestyle and daily routines and could thus strengthen their motivation and commitment to repeat the behaviors until they become automatic. These factors are considered crucial for the formation and maintenance of new habits [12,15,16].

Strengths and Limitations

The strengths of the study include a behavioral theory–based digital lifestyle intervention, a web-based app that had been updated based on the learnings of a prior RCT among adults at risk of T2D [18]. In this study, the app was offered to a large group of adults sampled from the participants of a population-based health survey. As such, the study served as an attempt to scale the intervention up to a broader and more heterogeneous population. The study was rolled out in a realistic setting in which the app was simply made available for self-directed promotion of well-being and health, with no additional professional or peer support provided to boost its use. The assessments of the app use effect and effect modification incorporated participants' objectively measured engagement with the app—a key determinant of effectiveness—and considered a wide variety of participant characteristics potentially influencing the effects. The work thus contributes to the scant evidence base on the effect modifiers of exclusively digital lifestyle interventions.

The results of the study must, however, be interpreted in the context of its limitations, particularly the lack of a control arm that precluded the assessment of causal effects and the reliance on self-reported data, both of which increase the uncertainty of our findings. To reduce the potential bias caused by self-reported data, we used measures that were validated (eg, the HDI), theory-based (the acceptability measures), and/or used in prior research (eg, the physical activity and BMI measurements); removed implausible responses from the data; and conducted sensitivity analyses that excluded the participants who reported the largest changes in the primary outcomes.

Further limitations include a multiplicity of analyses and outcomes, which increases the risk of type I error, and low participation and high attrition rates, which reduce the representativeness of our study sample to the general adult population and the statistical power to detect small effects. While the individuals to whom the app was offered represented a subsample of a population-based health survey that targeted a nationally representative random sample of adults [28], this subsample only included individuals who had chosen to participate in the survey by a certain date. Of these, 18% (1282/6975) accepted the offer and registered for the app. Of those registered, 30% (n=382) completed the measurements required for the effects assessment of this study. These individuals tended to be better off in terms of socioeconomic status, health, lifestyles, and e-service use. Our findings may thus have limited relevance to the broader adult population of Finland. Reaching and engaging more vulnerable population groups would likely require more tailored approaches.

The high attrition rate may cause bias if individuals who benefited from the app were more likely to complete the study questionnaires, leading to overoptimistic effect estimates. We compared the baseline characteristics of the completers and noncompleters of the study. The comparison showed that the completers had, on average, slightly fewer years of education and better diet quality and that they were more often retired than the noncompleters. The low participation and high attrition rate were not unusual, however, as they are widely reported challenges in digital lifestyle interventions [3,4,16,17,21], particularly when conducted among unselected target groups that may lack perceived need and motivation for lifestyle change [7,22]. In this study, the invitees had additionally recently participated in the population-based health survey, which may have reduced their motivation and resources to participate in this study as well. The findings of this study should therefore be considered preliminary, exploratory evidence that encourages further research in more robust study designs among more diverse and representative study populations with sufficient statistical power to detect small effects.

Implications for Future Research

The findings of this study imply that for the development of more widely engaging habit-based digital lifestyle interventions, cocreation with the target group would be crucial. In addition, expert consensus supports a user-centered and iterative development that uses mixed methods and in-depth qualitative

XSL•FO
RenderX

research to progressively refine the intervention to meet users' context and needs [67]. Such work could also deepen our understanding of the relationship between the engagement with and the effects of the app [66], for example, by facilitating the characterization of "effective engagement"—which may not simply mean "more engagement"—to achieve the intended outcomes [67].

Conclusions

This exploratory, correlational study suggests that an inexpensive, low-intensity digital support for healthy habits could foster small beneficial lifestyle changes if it succeeds in sustaining the user's engagement. However, effects may depend on the individual. Identifying those most likely to benefit from such exclusively digital interventions calls for deeper insight into the modifiers of user engagement and effects.

Acknowledgments

We are grateful to Dr Hilkka Liedes (VTT Technical Research Centre of Finland) and Adjunct Professor Jouni Lahti (Finnish Institute for Health and Welfare, THL) for advice on data analysis and to the Healthy Finland research group, particularly Adjunct Professor Annamari Lundqvist (THL) for collaboration.

Abstract

Background: Childhood obesity remains a major public health challenge. Mobile health (mHealth) interventions offer a scalable approach to support behavior change, but their effectiveness may depend on participant adherence. While both caregiver and child adherence are important, few studies have jointly examined caregiver app-use adherence and child behavioral adherence within digital obesity interventions.

Objective: This study aimed to evaluate the independent and joint associations of caregiver app-use adherence and child behavioral adherence with obesity-related outcomes in a school-based mHealth intervention.

Methods: We conducted a secondary analysis of 684 child-caregiver dyads in the intervention arm of the diet, exercise, and cardiovascular health—children cluster-randomized trial, implemented across 3 socioeconomically diverse regions in China. Caregiver app-use adherence was measured using app-recorded app-use frequency and total usage duration. Child behavioral adherence was assessed through weekly behavior monitoring scores covering diet, screen time, and physical activity. Linear mixed models estimated associations between adherence levels and changes in anthropometric and physical fitness outcomes over 9 months.

Results: Higher caregiver app-use frequency and duration were both significantly associated with reductions in children's obesity-related indicators, such as BMI (β=−0.19; *P*=.005), BMI *z*-score (β=−0.08; *P*=.006), and body fat percentage (BFP) (β=−0.70; *P*=.005) for frequency. Greater child behavioral adherence was associated with lower BFP (β=−0.63; *P*=.01) and better physical fitness, including shorter shuttle run time (β=−3.63; *P*<.001) and longer standing long jump distance (β=2.88; *P*=.005). App-use frequency and duration showed a significant interaction for rope-skipping performance (*P*=.05). In joint adherence analyses, children in the high caregiver-high child adherence group showed the most favorable changes, including lower BMI (β=−0.22; *P*=.02), lower BFP (β=−1.18 percentage points; *P*=.001), and 7.45 additional rope-skipping repetitions (*P*=.003), compared with the low caregiver-low child adherence group.

Conclusions: In this secondary analysis of an mHealth app-assisted childhood obesity intervention, higher caregiver app-use adherence and child behavioral adherence were associated with more favorable changes in weight status and physical fitness. These findings underscore the importance of coengagement in digital health programs and highlight the potential of app-supported, family-engaged strategies for childhood obesity prevention.

KEYWORDS

child; obesity; mobile health; intervention; adherence

Introduction

Childhood overweight and obesity have become critical global public health challenges. According to the World Health Organization (WHO), the prevalence of overweight and obesity among children and adolescents aged 5‐19 years has risen sharply from 4% in 1975 to 20% in 2022 [1]. In China, the obesity rate among primary and middle school students increased from 0.1% in 1985 to 9.6% in 2019, a 75.6-fold increase [2]. Childhood obesity is associated with adverse physical and psychological health consequences during childhood and elevates the risk of hypertension, type 2 diabetes, and certain cancers in adulthood [3]. Effective prevention in early life is therefore essential to curbing the obesity epidemic and reducing long-term health impacts and economic burdens.

Although numerous intervention studies on childhood obesity have been conducted worldwide, their results have been inconsistent, even when similar strategies were used [4,5]. One key but often overlooked factor related to intervention outcomes is participant adherence, defined as the extent to which participants comply with the study protocol [6]. Poor adherence can reduce the delivered intervention dose and complicate the interpretation of intervention findings. However, adherence remains underreported in obesity intervention research: a systematic review found that only 37% of high-quality studies included adherence data [7]. In addition, when reported, adherence was mostly used to assess feasibility rather than to quantitatively examine its association with intervention outcomes [8]. This gap limits understanding of how adherence is related to intervention outcomes and hinders the identification of scalable, evidence-informed strategies.

The emergence of mobile health (mHealth) technologies offers new opportunities to deliver, monitor, and tailor obesity interventions in real time [9,10]. Smartphone apps enable continuous health education, behavior tracking, and personalized feedback, potentially enhancing engagement and sustainability. This digital approach also helps address a longstanding challenge in intervention research: the repeated and simultaneous measurement of adherence. In childhood obesity interventions, adherence involves both intervention implementers, such as caregivers or teachers, and intervention participants, namely children themselves [11]. However, traditional methods have struggled to capture this process; caregiver adherence is often understudied due to measurement challenges and incomplete data [12]. Likewise, child adherence is frequently reported as a behavioral outcome rather than being examined as a process indicator related to intervention outcomes. Consequently, evidence on how caregiver app-use adherence and child behavioral adherence are jointly associated with obesity-related outcomes remains scarce. The automated data capture capabilities of mHealth platforms now allow caregiver app use and child behavioral adherence to be measured repeatedly, facilitating analysis of their independent and joint associations with health outcomes.

To address these gaps, we leveraged a mobile app-supported, multicomponent childhood obesity intervention. The app automatically recorded caregiver app-use data, while children's behavioral adherence was tracked weekly through structured monitoring. This secondary analysis of the intervention arm of the diet, exercise, and cardiovascular health—children (DECIDE-Children) cluster randomized trial aimed to evaluate how caregiver app-use adherence and child behavioral adherence, individually and jointly, were associated with obesity-related outcomes.

Methods

Study Design and Secondary Analysis Sample

This study was a secondary analysis of the intervention arm of the DECIDE-Children trial conducted in 3 socioeconomically diverse regions of China: Beijing, Changzhi (Shanxi Province), and Urumqi (Xinjiang Province). A total of 24 schools (8 schools per region) with Grade 4 students were randomly assigned (1:1) to the intervention or control group after baseline assessments. The 9-month multifaceted intervention (from September 2018 to June 2019) targeted both children and their environments by promoting a healthy diet and physical activity and by engaging schools and families to support children's behavioral changes, with family involvement strengthened through the "Eat Wisely, Move Happily" smartphone app. Details of the trial protocol have been published [13]. The reporting of this study followed the CONSORT-EHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and Online Telehealth) guidelines; the completed checklist is provided in Checklist 1.

The primary effectiveness analysis of the DECIDE-Children trial has been published previously [14]. Compared with the control group, the intervention group had a significantly greater reduction in BMI from baseline to the end of the trial, with a mean between-group difference in BMI change of −0.46 (95% CI −0.67 to −0.25; $P<.001$). The prevalence of obesity decreased by 27.0% relative to baseline in the intervention group, compared with 5.6% in the control group. The intervention also improved other adiposity outcomes, dietary, sedentary, and physical activity behaviors, and obesity-related knowledge, although no significant changes were observed in moderate-to-vigorous physical activity, physical fitness, or blood pressure. The present study focused on 684 child-caregiver dyads in the intervention arm to examine how caregiver app use and child behavioral adherence were associated with obesity-related outcomes within the intervention group.

Ethical Considerations

The original trial was approved by the Peking University Institutional Review Board (IRB00001052-18021). Written informed consent was obtained from the parents or legal guardians of all participating children before enrollment. Participation was voluntary, and participants were free to withdraw from the study at any time. The original ethics

XSL•FO
RenderX

approval covered secondary analyses of the collected data; therefore, no additional informed consent was required for the present secondary analysis. To protect participant privacy and confidentiality, the database used for analysis contained no directly identifiable information, and coded identifiers were used instead.

Intervention

The intervention was designed based on a social-ecological framework and implemented at school, family, and individual levels. At the school level, the intervention included establishing school policies to support obesity prevention and providing health education lectures and training for teachers. Teachers then delivered health education sessions to students during regular school health education classes. The core messages focused on healthy eating and physical activity, including avoiding overeating and sugar-sweetened beverages, reducing high-energy foods and sedentary time, and increasing physical activity.

At the family level, caregivers received health education materials and were encouraged to support children's behavioral changes at home, particularly by improving the home food environment and supporting physical activity outside of school. Family involvement was strengthened through a mobile app, which was installed on caregivers' smartphones to avoid increasing children's screen time. Through the app, caregivers could receive information on obesity prevention, record their children's weekly dietary and physical activity behaviors, and view their children's assessment and feedback information.

At the individual student level, the intervention included health education sessions, reinforcement of in-school physical activity, and regular monitoring of weight and height. Physical education teachers encouraged students to engage in moderate-to-vigorous physical activity during school, and trained project staff or trained teachers measured children's weight and height regularly according to standardized procedures. These data were entered into the intervention system and used to generate feedback on children's weight status and weight-management progress.

The mobile app supported the intervention through 4 main modules: information diffusion, behavior monitoring, weight management, and assessment and feedback. In the behavior-monitoring module, caregivers were asked to observe and/or inquire about their child's weekly diet, screen time, and physical activity behaviors and report this information in the app, preferably together with the child. In the assessment and feedback module, the app automatically generated feedback based on children's weight-monitoring data and behavior-monitoring records. Caregivers and students could access these assessment results and feedback through the app, which was intended to help families understand their children's weight-management status and reinforce targeted behavior changes during the 9-month intervention.

Adherence Measurement via Mobile App

Caregiver App-Use Adherence

The mobile app included 4 main modules: information diffusion, behavior monitoring, weight management, and assessment and feedback (Table S1 in Multimedia Appendix 1). Caregiver app use referred to app-recorded use of the "Eat Wisely, Move Happily" mobile app and was used to measure caregiver adherence to the app-based components of the intervention. When caregivers used any function of the app, the background system automatically recorded the student ID, the app-use event, and the usage duration. App-use frequency was defined as the total number of app-use events recorded across all modules, and app-use duration was defined as the cumulative time spent using the app. In the present analysis, these 2 app-recorded indicators were used to quantify caregiver app-use adherence.

Child Behavioral Adherence

Child behavioral adherence was defined as the extent to which children followed the targeted weekly diet, screen time, and physical activity recommendations. It was assessed through the behavior-monitoring module. According to the intervention protocol, caregivers were asked to complete the behavior-monitoring questionnaire once per week, for a total of 35 time points during the intervention. Caregivers were instructed to observe and/or inquire about their child's dietary and physical activity behaviors during the preceding week. The questionnaire was pushed through the app every Sunday at 8:00 PM, when caregivers were generally more available and could review the child's behaviors from the preceding week together with the child.

The behavior score included 7 components aligned with the intervention goals: drinking sugary beverages, eating Western fast food, eating fried food, eating unhealthy snacks, overeating, screen time of more than 1 hour, and at-home exercise. Overeating was explained to caregivers during the health education component as eating beyond satiety or eating noticeably more than the child's usual amount. Scores were assigned according to the weekly frequency of each behavior (Table S2 in Multimedia Appendix 1). For each item, 5 points indicated meeting the recommended standard, and lower scores indicated poorer adherence to the recommended behavior. The maximum weekly score was 35 points, with higher scores indicating better behavioral adherence by the child. Missing behavior-monitoring data accounted for approximately 10% of data each month and were imputed using a 2-step approach, as described in a previously published analysis of the same intervention data [15].

Outcome Measures

Obesity-related outcomes included adiposity indicators and physical fitness measures. Adiposity indicators included changes in BMI, BMI *z*-score, waist circumference (WC), and body fat percentage (BFP) from baseline to the 9-month follow-up. Height was measured using a stadiometer (Huateng GMCS-1; Beijing Xindong Huateng Sports Equipment Co, Ltd), and weight was measured using a lever scale (Wujin RGT-140). BMI was calculated as weight in kilograms divided by height in meters squared. The BMI *z*-score was calculated according to the WHO growth reference using each child's age and sex [16]. WC was measured using a MyoTape, and BFP was assessed using a body composition analyzer (Tanita MC-780 MA). Physical fitness measures included the 50 m × 8 shuttle run, standing long jump, and 1-minute rope skipping, which

XSL•FO
RenderX

were assessed by trained outcome assessors according to standardized procedures. All outcomes were measured at baseline and after the 9-month intervention.

Statistical Analyses

Descriptive Analysis

Baseline characteristics of students and their caregivers were summarized. Continuous variables were presented as means with SDs for normally distributed data, whereas categorical variables were reported as frequencies and percentages.

Association Between Caregivers' and Children's Adherence and Obesity-Related Outcomes

Caregiver app-use adherence was measured using two app-recorded indicators: (1) app-use frequency, defined as the total number of app-use events recorded when caregivers used any function of the app, and (2) app-use duration, defined as the cumulative time spent using the app. Child behavioral adherence was calculated as the average weekly score for diet, screen time, and physical activity behaviors reported through the behavior-monitoring module. Each adherence indicator was classified in two ways: (1) binary classification using the median (low vs high); (2) quartile classification (Q1: ≥ upper quartile, Q2: median to < upper quartile, Q3: lower quartile to < median, Q4: < lower quartile).

Linear mixed-effects models were used to evaluate the associations between adherence levels and changes in obesity-related outcomes, including BMI, BMI *z*-score, WC, BFP, 50 m × 8 shuttle-run time, standing long-jump distance, and 1-minute rope-skipping performance. All models were adjusted for child's age, gender, parental age, parental BMI, parental education level, and the corresponding baseline measure of each outcome. A random intercept for class was included to account for within-class clustering. For quartile-based analyses, trend tests were conducted by treating the quartile variable as an ordinal predictor.

To examine the relative importance of app-use frequency and app-use duration, participants were categorized into 4 subgroups based on median splits of both app-use frequency and app-use duration: high frequency and high duration, high frequency and low duration, low frequency and high duration, and low frequency and low duration. This 2×2 classification allowed us to compare different app-use patterns. A formal interaction term between app-use frequency and app-use duration was included in the model to assess whether their joint association with outcomes differed from their individual associations.

Joint Associations of Caregiver and Child Adherence and Trend Analyses

To investigate joint associations, three joint adherence variables were constructed by combining caregiver and child adherence indicators: (1) app-use duration × child behavioral adherence, (2) app-use frequency × child behavioral adherence, and (3) combined app-use pattern × child behavioral adherence. Each joint variable was categorized into 3 groups: both low adherence, mixed adherence, and both high adherences. The "both low adherence" group served as the reference group. Linear mixed-effects models were used to assess the associations between joint adherence groups and changes in obesity-related outcomes. Covariates and random effects were consistent with the previous models. Trend tests were conducted by treating the joint adherence groups as an ordinal variable. To assess potential variation in associations, interaction terms between caregiver and child adherence were included in the models.

Sensitivity Analyses

To examine the robustness of the findings, sensitivity analyses were conducted by excluding students who were primarily cared for by grandparents, as caregiver type may be related to app-use patterns, behavior monitoring, and response to the intervention.

The results were considered statistically significant at a 2-sided $P<.05$. Statistical analyses were carried out using R software (version 4.1.2; creators: John Chambers and colleagues; location: Jersey City, NJ, USA).

Results

Baseline Characteristics

A total of 684 students and their caregivers were included in the analysis. Baseline characteristics are presented in Table 1. Among the students, 343 were boys and 341 were girls. In addition, 627/683 (91.8%) students were of Han ethnicity. Most students were only children (408/678, 60.2%). The mean (SD) BMI and BMI *z*-score were 18.54 (3.70) and 0.70 (1.44), respectively. At baseline, 158 (23.1%) students had obesity, and 266 (38.9%) students had overweight or obesity.

[a]There is a missing value, so the synthesis is not 684, and the missing value appears to be missing at random.

[b]"High" means a college degree or above, and "low" means less than a college degree.

[c]BFP: body fat percentage.

Among caregivers, the mean ages of mothers and fathers were 37.87 (SD 4.24) and 39.88 (SD 4.74) years, respectively. The prevalences of obesity or overweight were 5.8% (n=38) and 24.7% (n=162) among mothers and 11.0% (n=70) and 57.2% (n=364) among fathers. Most primary caregivers were mothers (n=508, 74.3%), whose education levels were slightly higher than those of fathers (higher education: n=397, 59.8% vs n=362, 54.4%). Additionally, 84.2% (n=555) of mothers were employed.

Association Between Caregiver App-Use Adherence and Obesity-Related Outcomes

Caregiver app-use adherence was quantified using 2 app-recorded measures: app-use frequency and app-use duration. For app-use frequency, the corresponding median values were Q1, 32 (IQR 2 - 44) events; Q2, 57 (IQR 45 - 66) events; Q3, 81 (IQR 67 - 103) events; and Q4, 133 (IQR 104 - 529) events. For app-use duration, the quartile ranges were Q1, 17.40 (IQR 1.04 - 24.58) minutes; Q2, 31.10 (IQR 24.59 - 37.64) minutes; Q3, 46.60 (IQR 37.65 - 58.77) minutes; and Q4, 82.20 (IQR 58.78 - 240.04) minutes.

In the dichotomized analysis (Table 2), higher app-use frequency was associated with more favorable changes in BMI (β=−0.19, 95% CI −0.32 to −0.06; *P*=.005), BMI *z*-score (β=−0.08, 95% CI −0.13 to −0.02; *P*=.006), BFP (β=−0.70, 95% CI −1.19 to −0.21; *P*=.005), and rope-skipping performance (β=5.66, 95% CI 2.01-9.30; *P*=.002). Higher app-use duration was associated with lower BMI (β=−0.15, 95% CI −0.28 to −0.01; *P*=.03), BMI *z*-score (β=−0.06, 95% CI −0.12 to −0.01; *P*=.02), BFP (β=−0.51, 95% CI −1.01 to −0.02; *P*=.04), and better rope skipping performance (β=4.99, 95% CI 1.32-8.65; *P*=.008). No significant associations were found for WC, shuttle run time, or standing long jump distance.

△WC[b]	−0.34 (−0.84 to 0.16)	.19	−0.33 (−0.84 to 0.17)	.18	−0.36 (−0.86 to 0.15)	.17
△BFP[c]	−0.70 (−1.19 to −0.21)	.005	−0.51 (−1.01 to −0.02)	.04	−0.63 (−1.13 to −0.14)	.01
△shuttle run time	−0.66 (−2.72 to 1.40)	.53	−0.28 (−2.35 to 1.79)	.79	−3.63 −5.66 to −1.60)	<.001
△ standing long jump	−0.01 (−2.06 to 2.04)	≥.99	0.28 (−1.79 to 2.34)	.79	2.88 (0.85 to 4.91)	.005
△1-minute rope jumping	5.66 (2.01 to 9.30)	.002	4.99 (1.32 to 8.65)	.008	4.06 (0.45 to 7.67)	.03

[a]△ indicates the change from baseline to the end of the intervention, calculated as the postintervention value minus the baseline value.

[b]WC: waist circumference.

[c]BFP: body fat percentage.

Caregiver adherence measures refer to app-recorded app-use frequency and total usage duration. Child adherence refers to the average weekly caregiver-child behavior-monitoring score for diet, screen time, and at-home exercise. *P* values were estimated from linear mixed-effects models adjusted for age, gender, parental age, parental BMI, parental education level, and the baseline value of each outcome, with class as a random effect.

In the quartile-based analysis (Table S3 in Multimedia Appendix 1), a higher app-use frequency was significantly associated with more favorable changes in BMI, BMI *z*-score, WC, BFP, and rope-skipping performance (*P* for trend =.01, .01, .02, .01, and .009, respectively). Higher app-use duration was also significantly associated with more favorable changes in BMI, BMI *z*-score, WC, and rope-skipping performance (*P* for trend=.02, .01, .03, and .004, respectively), whereas the association with BFP was not statistically significant (*P* for trend =.08).

Association Between Child Adherence and Obesity-Related Outcomes

For child behavioral adherence scores, quartile ranges were Q1, 29.0 (IQR 22.25 - 29.95); Q2, 30.80 (IQR 29.96 - 31.54); Q3, 32.40 (IQR 31.55 - 33.14); and Q4, 34.10 (IQR 33.15 - 35). In the dichotomized analysis (Table 2), higher child behavioral adherence was associated with lower BFP (β=−0.63, 95% CI −1.13 to −0.14; *P*=.01), shorter shuttle-run time (β=−3.63, 95% CI −5.66 to −1.60; *P*<.001), longer standing long-jump distance (β=2.88, 95% CI 0.85-4.91; *P*=.005), and greater rope-skipping counts (β=4.06, 95% CI 0.45-7.67; *P*=.03). No statistically significant associations were observed between child behavioral adherence and BMI, BMI *z*-score, or WC.

Further analyses using quartile-based child adherence groups also revealed a dose-response relationship for several outcomes (Table S4 in Multimedia Appendix 1). Compared with children in the lowest quartile, those in the highest quartile of behavioral adherence had more favorable changes in BFP (β=−0.78, 95% CI −1.49 to −0.08; *P* for trend =.009), shuttle run time (β=−4.17, 95% CI −7.05 to −1.28; *P* for trend =.008), standing long jump distance (β=4.07, 95% CI 1.20-6.93; *P* for trend =.004), and rope-skipping counts (β=6.14, 95% CI 1.04-11.25; *P* for trend =.010). No significant trends were observed for BMI, BMI *z*-score, or WC.

Comparison of App-Use Patterns: Frequency Vs Duration

As shown in Table 3, children whose caregivers belonged to group 4 (high frequency and high duration) showed the most favorable changes in several obesity-related outcomes, including BMI (β=−0.21, 95% CI −0.36 to −0.06; *P*<.01), BMI *z*-score (β=−0.09, 95% CI −0.15 to −0.03; *P*<.05), and BFP (β=−0.76, 95% CI −1.32 to −0.21; *P*<.01), compared with the reference group (low frequency and low duration). Favorable changes in physical fitness, particularly rope skipping, were also observed across multiple groups with higher app-use frequency or duration.

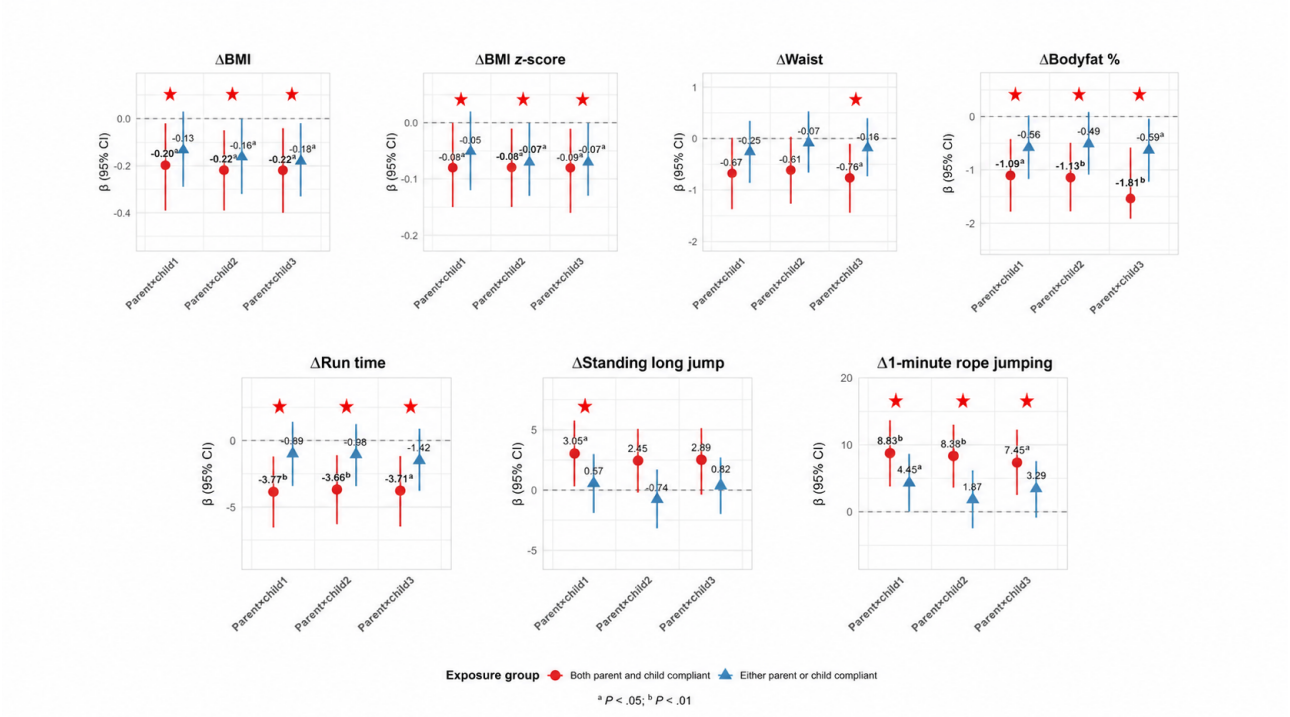
[h]BFP: body fat percentage.

To further compare app-use frequency and duration patterns, we compared group 2 (high frequency and low duration) with Group 3 (low frequency and high duration). No statistically significant differences were found across the health indicators. Although the interaction term between app-use frequency and duration was not significant for most outcomes, it was significant for rope-skipping performance (*P*=.048), suggesting a possible joint association of frequent and prolonged app use with this physical fitness outcome.



Joint Associations of Caregiver and Child Adherence and Trend Analyses

To explore the combined association of caregiver app-use adherence and child behavioral adherence, we constructed three joint adherence variables: app-use duration × child behavioral adherence, app-use frequency × child behavioral adherence, and combined app-use pattern × child behavioral adherence. Each joint variable was categorized into three groups: both low adherence, mixed adherence, and both high adherences.

As shown in Figure 1 and Table S5 in Multimedia Appendix 1, children in both high-adherence groups showed the most favorable outcomes across several obesity-related and physical-fitness indicators. Compared with the both low-adherence group, the both high-adherence group had more favorable changes in BMI (eg, app-use pattern × child adherence: β=−0.22, 95% CI −0.40 to −0.04; *P*=.02), BMI *z*-score (β=−0.08, 95% CI −0.16 to −0.01; *P*=.03), and BFP (β=−1.18, 95% CI −1.85 to −0.51; *P*=.001). Physical fitness measures also showed favorable changes; for example, the both high adherence group had a shorter shuttle run time (β=−3.71, 95% CI −6.50 to −0.93; *P*=.009) and more rope-skipping repetitions (β=7.45, 95% CI 2.50 to 12.40; *P*=.003) in the app-use pattern × child adherence model.

XSL•FO
RenderX

Figure 1. Joint associations of caregiver app use and child behavioral adherence with obesity-related outcomes.

The figure shows adjusted β coefficients and 95% CIs for the joint associations of caregiver app use and child behavioral adherence with seven obesity-related outcomes. Three caregiver app-use indicators were examined: app-use duration, app-use frequency, and combined high-frequency or high-duration app use. For each indicator, participants were classified into 3 groups: both low adherence (reference), mixed adherence, and both high adherence. Blue triangles indicate mixed adherence, and red circles indicate high adherence. Red stars indicate significant trends across adherence groups (*P* for trend<.05).

Trend analyses demonstrated significant dose–response relationships for most outcomes, indicating that higher levels of joint caregiver–child adherence were associated with progressively greater improvements in both adiposity and physical fitness indicators. Significant interaction effects between caregiver and child adherence were observed for BMI and standing long jump performance, suggesting that the association of one adherence component with these outcomes may vary according to the level of the other adherence component.

Sensitivity Analysis

To assess the robustness of the findings, we conducted sensitivity analyses by excluding participants who were primarily cared for by grandparents. The results, as shown in Table S6 in Multimedia Appendix 1, were largely consistent with the main analyses, supporting the stability of our conclusions.

Discussion

Principal Findings

To our knowledge, this was the first study to simultaneously examine caregiver app-use adherence, child behavioral adherence, and their joint associations with obesity-related outcomes in a multicomponent, app-supported childhood obesity intervention. Caregiver app-use adherence was associated mainly with adiposity-related outcomes: higher app-use frequency and longer app-use duration were consistently associated with more favorable changes in BMI, BMI *z*-score, and BFP, with graded patterns across adherence levels. Child behavioral adherence was more strongly associated with physical fitness indicators. However, given the large number of statistical comparisons performed, these statistically significant associations should be interpreted as exploratory and hypothesis-generating rather than confirmatory. This caution is particularly important for interaction analyses. The statistically significant interaction between app-use frequency and duration for rope-skipping performance suggests that both dimensions of app use may be relevant to this physical fitness outcome, but this finding requires confirmation in future studies. Similarly, the observed interaction terms between caregiver and child adherence suggest that their joint associations may differ from either component alone, although these findings should also be regarded as exploratory. Children with both high caregiver app-use adherence and high child behavioral adherence tended to show more favorable outcomes across several indicators, suggesting the potential importance of family coadherence in digital childhood obesity interventions.

Comparison With Prior Work

Participant adherence has been widely recognized as a key factor related to the effectiveness of obesity interventions. Previous studies have adopted various metrics to assess adherence and have generally reported more favorable outcomes among more adherent participants. One study used caregivers' questionnaire completion as a measure of adherence and found that children of caregivers who complied experienced greater weight loss [17]. Another study grouped participants according to the

XSL•FO
RenderX

number of educational sessions attended and found that participants in the adherent group (attended ≥3 sessions) showed significantly greater improvements in obesity-related indicators compared with those with lower attendance [18]. In interventions using interactive voice response technology, higher engagement, measured by the number of completed calls, was associated with reductions in child weight, BMI, and BMI *z*-scores [19,20]. Our findings provide additional evidence that caregiver app-use adherence and child behavioral adherence were both associated with more favorable obesity-related outcomes. These results support the importance of considering engagement and adherence in the design and implementation of childhood obesity interventions.

Both app-use frequency and app-use duration appear to be important components of digital intervention dose. Our findings suggest that these two dimensions were jointly associated with obesity-related outcomes. Although childhood obesity interventions often require substantial cumulative contact time, such as the suggested 26 hours in the first intervention year [21], the challenge lies in delivering this dose in formats acceptable to families. Evidence indicates that brief but frequent interactions may be more feasible and potentially more effective than longer, infrequent sessions. A dietary education study replaced traditional intensive dietary counseling with short, frequent telephone contacts, an approach that elicited positive participant feedback and meaningful lifestyle improvements [22]. Given increasing time constraints in modern family life, adherence becomes a central barrier. Transitioning from long-format counseling to high-frequency, short-duration digital touchpoints may improve adherence while preserving intervention dose, offering a scalable and family-centered strategy for real-world childhood obesity interventions.

The sensitivity analysis excluding children primarily cared for by grandparents showed generally similar associations, suggesting that the main findings were unlikely to be driven solely by this relatively small caregiver subgroup. One possible explanation is that grandparents caring for primary school-aged children may still have sufficient familiarity with smartphones to participate in app-based intervention activities. Nevertheless, caregiver heterogeneity should be considered in future mHealth interventions. Parents and grandparents may differ in smartphone familiarity, app-use habits, and digital health literacy, which could influence intervention engagement and behavior monitoring. Prior reviews have shown that older adults' use of eHealth or health technologies can be affected by self-efficacy, knowledge, support, technology usability, and socioeconomic factors [23,24]. Future mHealth interventions may therefore need tailored support for caregivers with different levels of technological familiarity.

The joint high-adherence pattern in both caregivers and children was associated with the most favorable changes in obesity-related and physical fitness outcomes, highlighting the importance of engaging both parties in digital health interventions. The different patterns observed for caregiver and child adherence are consistent with the design of our multicomponent intervention. The intervention app was primarily designed for caregivers to receive nutritional guidance. This may explain why caregiver app-use adherence was more strongly associated with weight-related indicators, such as BMI and BFP. By providing actionable dietary advice and tools for home environment modification, the app supported caregivers—who often influence food purchasing, meal preparation, and children's eating opportunities—in implementing healthier eating practices for their children. This interpretation is consistent with evidence that parent or family involvement and parent-targeted dietary support are important components of childhood obesity interventions [25,26]. In contrast, children's behavioral adherence was more strongly associated with physical fitness improvements. This aligns with the student-level component of our intervention, which integrated enhanced, structured physical activity into the school curriculum. Higher child behavioral adherence may reflect more consistent practice of recommended dietary, screen time, and physical activity behaviors [27]. Overall, our results suggest that childhood obesity interventions may benefit from supporting both caregiver involvement and children's adherence to targeted health behaviors. Future interventions should incorporate strategies that help caregivers create supportive home environments while encouraging children to practice and sustain healthy dietary and physical activity behaviors.

Strengths and Limitations

The main strength of this study lies in the richness and objectivity of its process evaluation data and the objective recording of caregiver app use. Caregiver app-use data were automatically recorded by the mobile app, providing objective, time-stamped information on app-use frequency and duration. Children's health behaviors were repeatedly and systematically collected through the caregiver-child behavior-monitoring module, allowing us to examine children's behavioral adherence over the intervention period. Compared with studies relying solely on qualitative process evaluation or retrospective end-of-study self-reports, the repeated app-based data collection in this study provided more detailed quantitative information for adherence analysis [28]. Moreover, we considered adherence from both the perspectives of the intervention implementers (caregivers) and the intervention subjects (children). By simultaneously evaluating caregiver app-use adherence and children's behavioral adherence, we were able to examine the interplay between the 2 and better understand how selected adherence-related processes were associated with intervention outcomes.

Several limitations should be acknowledged. First, the baseline prevalence of obesity and overweight or obesity in our analytical sample was relatively high compared with national estimates for Chinese children of similar age. This should be interpreted cautiously because the present analysis was based on a trial-based regional sample rather than a nationally representative sample. Previous Chinese surveillance studies have reported substantial geographic, urban-rural, sex, and socioeconomic variation in childhood overweight and obesity, with some school populations showing prevalence estimates higher than national averages [29]. Second, although intervention fidelity encompasses multiple components—including adherence, dose, quality of delivery, participant responsiveness, and program differentiation [30], the present analysis focused on the dose of caregiver app-use

XSL•FO
