Volume 14 (2026) ISSN 2291-5222 Editor in Chief: Lorraine Buis, PhD, MSI

Contents

Viewpoints

Systematic and Collaborative Approach to Learning and Educational Content Development (SCALED) for Health Apps: An Experience-Informed Conceptual Framework (e83442)
Qi Ong, Anita Pienkowska, Emina Obarcanin, Anne-Claire Stona, Andy Khong, Josip Car, Andy Ho. 23

Intensive, Repeated Self-Report Measures: Should We Be Concerned About Changes in Data Quality Over Time? (e68735)
Arthur Stone, Stefan Schneider, Meynard Toledo, Raymond Hernandez. 35

A Beginner's Guide to Applying Large Language Models in Behavioral Interventions (e79302)
Nirali Shah, Lorraine Buis, Derek Papierski, Alexis Castellanos, Marvin Mlakha, Susan Murphy. 44

Reviews

Applications and Current Landscape of Digital Health Technologies in the Continuity of Care for Liver Transplant Candidates and Recipients: Scoping Review (e106470)
Wanqi Shi, Jiao Sun, Jiahao Li, Yuanyuan Li, Feiyan Yuan, Ruiya Li, Zijing Chu. 54

Reporting Gaps in mHealth Intervention Studies for Adults With Diabetes: Systematic Review (e95863)
Xin Yue, Jiacheng Shen, Junke Peng, Xiaoting Huang, Mingyue Hu, Xing Hu. 76

Stakeholder Perspectives on Digital Health Technologies in Poststroke Self-Management and Rehabilitation: Systematic Review Based on the NASSS Framework (e95197)
Jing Zhao, Jie Zhao, Xiaohan Liu, Yongxin Cao, Xuan Wang, Yanhong Dong, Hong Chang. 96

The Representation of Different Populations in Studies Assessing the Validity of Consumer Wearable Photoplethysmography-Based Measurements: Scoping Review (e87324)
Rebecca Schipper, Fatime Oumar Djibrillah, Meyke Roosink, Laura Winkens, Arlene John, Eric Hazebroek, Annemieke Witteveen, Agnes Berendsen. 112

Effects of Self-Guided Digital Mindfulness Interventions on the Mental Health of Health Care Workers: Systematic Review and Meta-Analysis of Randomized Controlled Trials (e74272)
Natsu Sasaki, Akiomi Inoue, Mako Iida, Kazuhiro Watanabe, Yuka Kobayashi, Asuka Sakuraya, Hisashi Eguchi, Kanami Tsuno, Yu Komase, Yasumasa Otsuka, Mai Iwanaga, Reiko Inoue, Kazuto Kuribayashi, Ayako Hino, Hiroki Asaoka, Satoru Kanamori, Yuta Inagawa, Takenori Yamauchi, Hiroki Ikeda, Go Muto, Rika Kato, Takuro Okuyama, Naomichi Tani, Noriko Kojimahara, Takeshi Ebara, Akihito Shimazu, Akizumi Tsutsumi, Norito Kawakami, Kotaro Imamura. 137

Just-in-Time Adaptive Interventions to Reduce Sedentary Behavior and Promote Physical Activity in Patients With Chronic Disease: Scoping Review (e81378)
Junchen Guo, Furong Chen, Chan Chen, Yunyun Dai, Xianghua Xu, Yongyi Chen, Mengying Huang. 162

Patient-Reported and Technology-Assisted Monitoring in Orthotic Management of Adolescents With Idiopathic Scoliosis: Scoping Review (e88880)
Anna Mathew, Kamila Sykorova, Nenad Pavel, Marianne Johnsen, Minna Pikkarainen, Sadeeq Ali, Mette Kvammen, Parisa Gazerani. 188

Barriers and Enablers to Integrating Patient-Generated Health Data in Shared Decision-Making From Health Care Professional and Patient Perspectives: Scoping Review (e85197)
Pavithren V S Pakianathan, Devender Kumar, Jayathissa Prabath, Rada Hussein, Josef Niebauer, Albrecht Schmidt, Jan Smeddinck. 230

Patient-Facing AI-Enabled Digital Health Technologies and Quality of Life in Cancer: Systematic Review and Exploratory Meta-Analysis (e94793)
Anica Ilic, Lene Juvet, Patrick Cairns, Kristen Thornton, Hanne Lie. 253

Conceptualization From the Sensors to Suicide-Related Outcomes: Scoping Review Based on Layered Hierarchical Sensemaking Framework (e98616)
Sohee Kim, Jinyeong Kim, Wai Chien, Tzu Luk, Yu Zhang, Zhen Tan, Eunju Park, Heejung Kim. 268

Mobile Health in Home-Based Palliative Care: Realist Review of Contextual Factors and Mechanisms Influencing Outcomes (e80321)
Nuhamin Gebre, Oladayo Afolabi, Nahla Gafer, Kennedy Nkhoma, Nicola Ayers, Charlotte Hanlon, Richard Harding. 291

Engagement of Users in Digital Health Applications: Scoping Review (e66002)
Melek Aktas, Linda Cambon, Olivier Aromatario. 327

Heart Rate Monitors for the Estimation of Physical Activity in Patients With Cardiovascular Disease: Systematic Review (e79995)
Paulien Vermunicht, Christophe Buyck, Sebastiaan Naessens, Wendy Hens, Emeline Van Craenenbroeck, Kris Laukens, Lien Desteghe, Hein Heidbuchel. 340

mHealth Technologies for the Care of Children With Congenital Heart Disease: Scoping Review (e83385)
Mingzhu Wang, Qiuyin Pan, Shengrong Tan, Yuanchun Kong, Zhengling Dai, Jiao Cai, Duoqin Bi, Jiali Zhou. 384

Effects of Remote, Virtual, or Hybrid Cardiac Rehabilitation Supported by mHealth in Patients With Heart Failure: Systematic Review and Meta-Analysis (e90422)
Kaidong Shao, Chunqiu Liu, Tianshu Li, Huiyan Qu, Hua Zhou. 395

Mechanisms of Engagement With Mobile Health Apps for Adults With Long-Term Conditions: Overview of Systematic Reviews (e88382)
Jeni Baykoca, Goretti Hurtado Barbeito, Christina Pearce, Madison Milne-Ives, Joanna Hudson, Sam Norton, Rona Moss-Morris. 411

Perceptions of Adults Aged 50 Years and Older Regarding the Use of Wearable mHealth Technologies to Promote Physical Activity: Systematic Review and Meta-Ethnography (e67157)
Beatriz Rodríguez-Martín, Diego González-Arroyo, Susana Priego-Jiménez, María Lopez-González, María Medrano-Echeverría, Marta Ruiz-Grao, Celia Álvarez-Bueno. 430

Patient Acceptance and Barriers to IoT Usage in Health Care: Systematic Literature Review (e81260)
Zaenal Arifin, Putu Handayani. 469

Machine Learning Frameworks for Wearable-Based Stress Modeling in Naturalistic Settings: Scoping Review (e76632)
Shifali Sharma, Aswin Janakiraman, Lujie Chen. 494

Wearable Devices for Monitoring and Management of Comorbid Obstructive Sleep Apnea and Hypertension: Scoping Review (e84506)
Hongyi Wang, Anran Cheng, Yusheng Li, Haining Zhang, Shun Fan, Rong Shen, Wei Zhang, Huanan Li, Jingui Wang. 521

Effectiveness of Mobile Health Interventions in Pediatric Cancer: Systematic Review and Meta-Analysis of Randomized Controlled Trials (e86836)
Huilu Yao, Yiting Wen, Hongxiu Wang, Ying Xiao, Meiling Deng, Wei Yang, Yuqin Li, Xiaorong Mao. 538

Effectiveness of mHealth-Based Nutritional Interventions on Iron Status of Pregnant Women: Systematic Review of Randomized Controlled Trials (e81001)
Saba Belay, Afework Bezabih, Wim Petegem, Christophe Matthys. 561

mHealth-Based Gamification Interventions to Promote Health Among Older Adults: Scoping Review (e82368)
Xi Chen, Yishu Zhu, Dian Jiang, Jundan Huang, Qi Xie, Yishi Chen, Jing Chang, Weiping Huang, Hongting Ning, Hui Feng. 582

Effectiveness of Text Messaging Interventions on BMI Among Adults With Prediabetes: Systematic Review and Meta-Analysis (e78521)
Arkers Wong, Shun Choi, Tiffany Cheng, Chelsea Cheng, Ivy Kwong, Cheuk Fong, Chi Wong, Ka Chan. 597

Evaluating Effectiveness of mHealth Interventions for Rehabilitation in Patients With Head and Neck Cancer: Systematic Review and Meta-Analysis of Randomized Controlled Trials (e78109)
Yang Xiao, Qiuyu Zhou, Feiruo Hong, Yuwei Lin, Enhong Li, Xuefen Yu. 609

Wearable Devices for Remote Monitoring of Chronic Diseases: Systematic Review (e74071)
Masresha Tegegne, Sharareh Niakan Kalhori, Paulo Haas, Viktor Sobotta, Joana Warnecke, Thomas Deserno. 630

Video-Based Motion Capture Smartphone Apps for Testing Human Motor Performance Skills: Scoping Review (e65474)
Clara Zoeller, Claudia Niessner, Manuel Fleps, Thorsten Klein, Anke Hanssen-Doose, Alexander Burchartz, Alexander Woll, Thorsten Stein. .
6 5 2

Digital Health Interventions in Children and Adolescents With Type 1 Diabetes Mellitus and Their Impact on Clinical and Behavioral Outcomes: Scoping Review (e79338)
Eirena Beh, Jiaying Lin, Geraldyn Leong, Pei Loh, Ee Poh, Daniel Chan. 666

Examining the Use of Consumer Wearable Devices and Digital Tools for Stress Measurement in College Students: Scoping Review of Methods (e64144)
Aarti Sathyanarayana, Ohida Amin, Jennie An, Jukka Onnela. 682

Mental Health Apps Implemented in the Workplace: Scoping Review of Trends and Gaps in Evaluation Research (e57046)
Sheila Addanki, Luciana Macedo, Joy MacDermid, Sandra Moll. 728

Exploiting Unsupervised Free-Living Data for Cardiorespiratory Fitness Estimation: Systematic Review and Meta-Analysis (e69996)
Alexios Dosis, Aron Syversen, Mikolaj Kowal, Daniel Grant, Jim Tiernan, David Wong, David Jayne. 750

Digital Health Interventions to Support Chronic Disease Management: Systematic Scoping Review (e63742)
Abdullah Al Mahmud, Shane Joachim, Prem Jayaraman, Caitlin Learmonth, Shivani Tyagi, Abdur Forkan, Muhammad Shuakat, Nilmini Wickramasinghe, Jack Wheeler, Stephanie Best, Alison Trainer. 774

Mobile Apps to Improve Health Parameters in Healthy Adults: Systematic Review (e66881)
Gaia Leuzzi, Mirko Job, Carola Cosentino, Riccardo Testa, Aldo Scafoglieri, Marco Testa. 800

Advancements in Wearable Sensor Technologies for Health Monitoring in Terms of Clinical Applications, Rehabilitation, and Disease Risk Assessment: Systematic Review (e76084)
Bonsang Gu, Hyeon Kim, HyunBin Kim, Jun-Il Yoo. . . . 815

Evaluating the Effectiveness of Digital Interventions for Stress Management in Pregnant Women: Systematic Review and Meta-Analysis (e66267)
Jeung-Im Kim, Joo Lee, So-Hee Park. . . . 830

Calorie-Counting Apps for Monitoring and Managing Calorie Intake in Adults Living With Weight-Related Chronic Diseases: Decade-Long Scoping Review (2013-2024) (e64139)
Kaylee Dugas, Marie-Andrée Giroux, Abdelatif Guerroudj, Jazna Leger, Asal Rouhafzay, Ghazal Rouhafzay, Jalila Jbilou. . . . 852

Key Features of Engagement Strategies in Nutrition Apps for Adults: Scoping Review (e82276)
Maria Vasiloglou, Zoë van der Heijden, Eric Scuccimarra, Alberto Conde Freniche, Desiree Lucassen, Nienke de Vlieger, Frédéric Ronga, Elske Brouwer-Brolsma, Tamara Bucher. . . . 880

Cost-Effectiveness of Virtual Emergency Care Models: Systematic Review (e82143)
Ravi Shankar, Linda Wang, Soon Ho, Mei Liew, Satya Kumar Gollamudi, Tze Wong, Serene Wong. . . . 892

Application of Mobile Health Technologies to Prevent Unintentional Childhood Injuries: Scoping Review (e94038)
Huan Wang, Fengjiao Pu, Dongjun Jing, Hangcheng Liu, Miao Li, Xixi Li. . . . 914

Mechanical Contact Conditions in Wearable Reflectance Photoplethysmography: Scoping Review (e99333)
Chenxi Yang, Jiahang Xie, Zifei He, Jianqing Li, Chengyu Liu. . . . 926

Continuous Temperature Monitoring via Wearable Devices for Fever or Infection Management in Acute Care Hospitals: Scoping Review of Clinical Implementation and Data Analytics (e89773)
Yuwei Liu, Qimeng Zhao, Ka Li, Dawn Dowding. . . . 950

Effectiveness of Wrist-Worn Wearable–Guided Cardiac Rehabilitation Delivered Through Fully Remote or Hybrid Programs in Patients With Cardiovascular Disease: Systematic Review and Meta-Analysis of Randomized Controlled Trials (e101306)
Jun Choi, So Lee, Kyung Seo, Sang Lee, Hyo Lee, Dongbin Heo, Hyun Ryu, Jong Kim, Jeong Kwon, Bo Kim, Michael Lee. . . . 971

Measuring Perceived Stress in Healthy Adults in Daily Life: Scoping Review of Smartphone-Based Self-Assessment (e94204)
Toon Colman, Tom Van Daele, Bert Bonroy, Jean-Marie Aerts, Glen Debard, Jasper Gielen, Romy Sels, Catharina Van Oost, Maria Faurholt-Jepsen, Nele De Witte. . . . 997

Distinguishing Common Digital Phenotyping and Self-Report Parameters for Monitoring and Predicting Depression: Scoping Review (e70840)
Lisa Busshart, Milica Petrovic, Rebeka Amin, Ulrich Hegerl. . . . 1043

New Insights and Effectiveness of Digital Interventions for Health Anxiety: Systematic Review and Meta-Analysis (e91108)
Jing Xu, Jifeng Shen, Guanghui Huang, Jue Wang. . . . 1139

Mobile Health Apps for Individuals Who Are Blind or Have Low Vision: Systematic Review of Evidence, Accessibility, and App Quality (e85809)
Carlos Mora, Ester Solé, Pere Llorens-Vernet, Jordi Miró. . . . 1460

Abstract

Mobile health (mHealth) apps are widely used for noncommunicable disease prevention and self-management. However, their effectiveness and safety are undermined by substantial variation in content quality. Existing guiding frameworks primarily focus on user interface, functionality, and intervention delivery, with limited emphasis on content creation. In this viewpoint, we introduce Systematic and Collaborative Approach to Learning and Educational Content Development (SCALED), a conceptual framework designed to guide a systematic, collaborative, and evidence-based approach to mHealth educational content development, intended for app developers, researchers, health care providers, and the wider mHealth community. Developed and refined across 3 phases, the SCALED framework consists of 11 components organized into 3 sequential stages: planning and conceptualization, development of textual content, and finalization into delivery format. We discuss the rationale behind each component and illustrate its applicability through 2 mHealth use cases. The framework integrates real-world experience from the development of 3 mHealth apps, qualitative findings from 2 studies, and insights from key stakeholders. By offering a structured and replicable methodology for content development, SCALED addresses a critical gap in current mHealth frameworks and provides a practical guide to improve content veracity, with potential for adaptation across a range of medical conditions.

(JMIR Mhealth Uhealth 2026;14:e83442) doi:10.2196/83442

KEYWORDS

patient education; mHealth; mobile health; health information; conceptual framework; health apps

Introduction

Mobile health (mHealth) apps have emerged as a promising tool for disease prevention and management, providing accessible, scalable, and personalized health care interventions. Defined by the World Health Organization as "medical and public health practice supported by mobile devices, such as mobile phones, patient monitoring devices, personal digital assistants, and other wireless devices" [1], mHealth apps are widely tested for patient education, remote monitoring, behavioral interventions, and personalized care [2].

As of 2024, it was estimated that more than 35,000 mHealth apps were available on both the Apple App Store and the Google Play Store [3,4]. Despite their ubiquity and growing adoption, the effect of these apps across various health outcomes remains inconsistent [2,5,6]. Evidence from systematic reviews indicates that most mHealth apps lacked clinical credibility [7], were developed without health care professionals' (HCPs) involvement [8], and did not report theory or conceptual framework underpinning the development of educational materials [9]. Moreover, a scoping review found that 67 of 80 identified safety concerns with consumer-facing mHealth apps were related to the information quality, such as incorrect or incomplete information, variation in content quality, and inappropriate response to consumer needs [10].

These gaps could have a negative impact on their uptake, posing grave concerns for patient safety. Without adequate quality control measures and regulation for apps entering the market

XSL•FO
RenderX

[11], health care providers and organizations may become more cautious and reserved about prescribing or recommending mHealth apps to patients [12]. From the user's perspective, exposure to low-quality or misleading content may result in inappropriate lifestyle choices or self-management decisions, introducing potential clinical harms [13]. Given the dynamic and rapidly expanding mHealth landscape, it is imperative to establish and promote good practices in the design and development of educational content to ensure its effectiveness, safety, and trustworthiness.

mHealth Frameworks and Instruments

A growing number of frameworks have been proposed for mHealth apps. These frameworks primarily focus on aspects related to technical and functional design [14,15], usability and user-centeredness [16,17], as well as risk and trustworthiness [13,18]. In parallel, many instruments and tools developed for mHealth apps are intended for quality assessment and rating purposes [19,20]. Notable examples include the Mobile App Rating Scale (MARS) [21], which is a multidimensional instrument for assessing app quality across domains such as engagement, functionality, aesthetics, and information quality, and the THESIS tool, which was developed to assess the risks and benefits of health apps across a broader set of dimensions [22]. Although most included criteria are related to the veracity of content, such considerations are often addressed in a generic sense only [19]. A systematic review of mHealth assessment frameworks synthesized evaluation criteria into 7 overarching categories, one of which pertains to information and content. Key elements in this category are credibility, accuracy, quality, and quantity of information [20]. This reflects the recognition of content quality, alongside technical design, usability, and data privacy, as a key factor in how mHealth apps are evaluated and ultimately used.

The importance of content veracity in mHealth has also been formally acknowledged. The CONSORT (Consolidated Standards of Reporting Trials)-eHealth checklist, which extends reporting standards for randomized controlled trials of web-based and mHealth interventions, explicitly recommends reporting on quality assurance measures taken to ensure accuracy and quality of information in eHealth interventions [23]. While tools for evaluating readability and quality of consumer-facing health information such as Flesch-Kincaid and DISCERN do exist [24,25], there remains a critical gap: the lack of standardized methodologies for developing mHealth educational materials that are evidence-based, clinically accurate, and theory-informed. In response, some articles have outlined multistage content development processes involving initial drafting, multiple rounds of edits, professional editing, and final reviews by clinical experts [26,27]. These offer useful starting points for shaping best practices in mHealth content development, but fall short of offering a structured, stepwise approach.

To address this gap, we propose a Systematic and Collaborative Approach to Learning and Educational Content Development (SCALED), a framework informed by real-world experience in developing 3 mHealth apps, qualitative insights from end-users, and iterative input from a multidisciplinary team. By integrating educational and behavioral change theories, clinical guidelines, and user-centered design principles, SCALED aims to provide a comprehensive guide for improving content credibility and accessibility. In this viewpoint, we describe the framework's conceptual foundation, its application in 3 use cases, and its implications for mHealth research and practice.

The SCALED Framework

Conceptualization of the Framework

SCALED was conceptualized and developed in 3 phases. First, an initial framework informed by the development of a comprehensive mHealth education program was evaluated and improved in a co-design study with patients (GLOW) [28]. Second, application in 2 use cases (WellFeet and CADENCE D-PHA) to demonstrate its usability in practice and refine for improvement [29,30]. Third, finalization of the framework through discussion and consensus building with stakeholders involved in content creation. A glossary of key terms is provided in Textbox 1.

Textbox 1. Glossary of Terms.

Theme: broad, overarching topic that serves as a unifying thread for organizing curriculum content and learning experiences.

Module: self-contained units of educational content designed to address specific learning objectives within a theme.

Bite-size: small, manageable portions of content intended to facilitate focused learning and reduce cognitive load.

Conversational agent (chatbot): "Computer programs that use text, speech, and other input modalities to enable communication with users" [14].

Action-oriented: learning or intervention content designed to prompt users to perform specific behaviors, tasks, or decision-making steps that reinforce learning objectives.

Research Context

The experience of developing a diabetes education app (GLOW, Nanyang Technological University Singapore) and findings from a qualitative co-design study with patients with lived experiences of diabetes guided the conceptualization of the initial mHealth content development framework [28]. GLOW was designed to provide users with verified health information on general knowledge related to Type 2 diabetes mellitus, including complications, foot health, medication, and blood glucose monitoring, and lifestyle behaviors including exercise, diet, and sleep. It consisted of 10 modules, comprising 63 units with learning cards, quizzes, mini-challenges, and rules-based action-oriented, frequently asked questions (FAQ) chatbot conversations. The content was guided by 172 knowledge-based, 54 skills-based, and 106 attitude-based learning objectives.

XSL•FO
RenderX

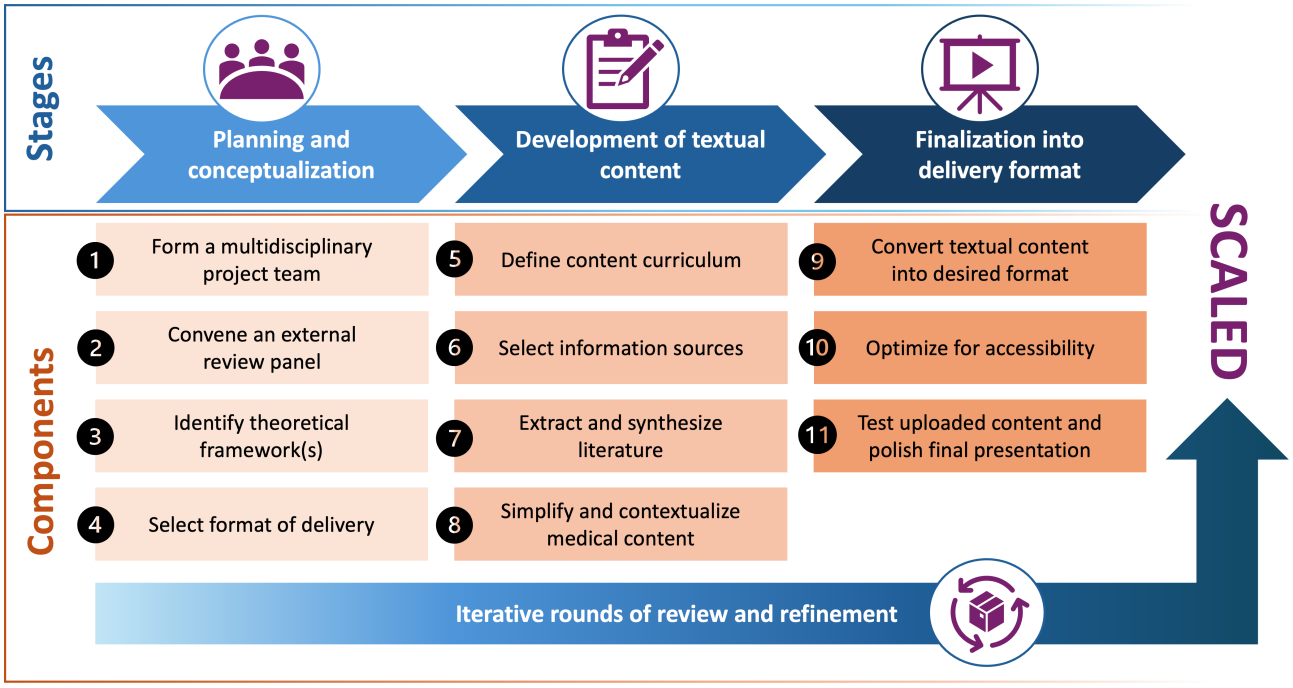
Additionally, 232 audio recordings of the text, 711 static images, and 55 motion graphics were integrated to complement the textual content of the modules. Although patients were not directly involved, GLOW app content was co-created with lay professionals. These educational modules underwent review by HCPs, including endocrinologists, nurses, podiatrists, and dieticians, from a major tertiary hospital in Singapore. This process served as the basis for the initial structure of the SCALED framework.

We subsequently applied the initial framework to two use cases: (1) WellFeet, a multilingual diabetes foot care education app for individuals at risk of diabetic foot ulcers [29], and (2) CADENCE D-PHA (digital personal health assistant) app, a multicomponent mobile health app for improving medication adherence in adults with hyperlipidemia [30].

WellFeet content consists of 4 themes, 21 topics, and 54 bite-sized videos in English, Chinese, and Malay, accompanied by quiz questions and rules-based chatbot conversations. They were guided by 21 general, 54 knowledge-based, 40 skill-based, and 38 attitude-based learning objectives. Bite-sized animations with a voice-over and a synthetically generated artificial intelligence (AI) avatar-presenter were accompanied by quiz questions, polls, reflections, and rules-based action-oriented FAQ chatbot conversations framed by a personalized and adaptive learning experience. The content was reviewed by project co-investigators and HCPs from multiple major health care institutions in Singapore. The app was tested in a single-arm, pre-post mixed-methods feasibility study [29].

CADENCE D-PHA's content (phase 1) comprises 5 themes, 13 topics, and 63 bite-sized videos accompanied by quiz questions and rules-based chatbot conversations. They were guided by 40 knowledge-based, 35 skill-based, and 20 attitude-based learning objectives. Bite-sized videos are animations with a voice-over and video recordings of HCPs and patients, accompanied by quiz questions, polls, free-text responses, and reflections. Similar to WellFeet, the education content is supported by rules-based, action-oriented FAQ chatbot conversations. Moreover, the content was reviewed by project co-investigators, collaborating HCPs from multiple tertiary and primary health care institutions in Singapore, as well as patient advocates. Phase 2 content is being developed and progressively rolled out with app updates. CADENCE D-PHA is currently being tested in an ongoing multicenter randomized controlled trial.

The framework was modified to meet the needs of each individual project, with components added or omitted as appropriate, considering factors such as target user groups, team composition, technological infrastructure, available funding, and project timeline. Applying the initial framework to these 2 use cases allowed us to assess the framework's overall applicability and refine its components. Across the 3 use cases, several cross-cutting insights emerged that informed the refinement of the SCALED framework. First, the nature of deliverables differed across projects, ranging from text-based modules to multilingual videos and interactive chatbot features. Second, variations in available resources, including team composition and funding, shaped how specific components were operationalized, particularly in decisions related to outsourcing multimedia production. Third, differing technological requirements, such as the integration of conversational agents, multimedia elements, and adaptive features, introduced additional complexity in translating textual content into user-facing formats. Despite these differences, early-stage components such as team composition, theoretical grounding, and curriculum definition remained consistently critical, while challenges frequently arose at the interface between content creation and delivery. These cross-case insights highlight the importance of a structured yet adaptable framework and inform the final configuration of the SCALED components.



SCALED Pillars

Drawing on real-world experience of developing 3 mHealth apps, 2 studies with end-users, and iterative discussions within the research team, the final SCALED framework (Figure 1) consists of eleven components embedded within 3 sequential stages. The framework moves from planning and conceptualization, to the development of textual content, and finally to its translation into delivery formats, reflecting the practical workflow observed across our 3 app development cases. The first stage establishes the conceptual, theoretical, and collaborative foundations of the intervention. The second focuses on generating, synthesizing, and tailoring the educational content, whereas the third addresses its conversion into accessible, polished, and implementation-ready materials.

The eleven components within SCALED were core recurring needs identified from our empirical experience, and they do not constitute an exhaustive taxonomy of all conceivable content-development activities. Although presented as a structured sequence, the components are not intended to function as rigid requirements to be applied identically in every context. Instead, they are core yet adaptable elements that may be modified, emphasized, or omitted depending on the intervention aims, target users, technological infrastructure, and available resources. Together, these components provide a structured pathway for developing mHealth educational content from initial conception to final deployment.

Figure 1. The Systematic and Collaborative Approach to Learning and Educational Content Development (SCALED) framework.

Planning and Conceptualization

Form a Multidisciplinary Project Team

The creation of content in mHealth apps necessitates a multidisciplinary team to ensure clinical accuracy, behavioral and cultural relevance, and user-centered delivery. Team members from diverse professional backgrounds often bring differing expectations around project management, role responsibilities, content delivery, and even use distinct "language" (using different terminologies and methodologies), which can pose communication challenges [31]. However, the benefits of this diversity offset the potential difficulties, as varied backgrounds enable team members to complement one another's knowledge and skills, ultimately enhancing the quality of the project.

HCPs contribute clinical expertise to ensure content alignment with clinical practice guidelines. Their involvement in mHealth development has been recommended to mitigate safety concerns [10]. Psychologists and behavioral scientists incorporate principles of behavior change to enhance the chances of healthy lifestyle modification. Learning designers provide input on content structure, educational framework, and delivery format to improve comprehension and accessibility. Although clearly defined roles should be established prior to initiating content development, in practice, many tasks require a flexible approach and a diverse set of competencies. For instance, content writers will often have responsibilities beyond script writing, such as adapting materials into animation-ready formats and coordinating the logistical aspects of video production. Depending on the scope and organizational capacity, specialized expertise may be acquired through external collaborators such as animators for creating visually engaging educational materials.

In all 3 cases, textual content was produced by a multidisciplinary team with capabilities to assess clinical information, conceptualize copywriting approaches, write relatable content, and perform project management duties. Given the multinational composition of the team, we made a deliberate effort to ensure our patient-centered message considered a balanced cultural power dynamic, avoiding dominance of any single cultural viewpoint. Multimedia components (eg, static graphics, animations, and short video recordings) were produced in-house by the project team in GLOW, drawing on existing expertise within the team and allowing close alignment with the pedagogical objectives. In contrast, for WellFeet and CADENCE D-PHA, a multimedia production unit was contracted to ensure professional quality, specialized technical skills, and efficient turnaround. The choice between in-house development and external contracting was guided by the availability of internal expertise, the complexity of the materials required, and project resources.

Convene an External Review Panel

It is important to engage stakeholders early in the process [32]. An external expert review panel is essential to ensure that consumer-facing health education materials are medically accurate, up-to-date, aligned with local (or regional) clinical practice and relevant to patients. In addition to the development phase, the review process should be repeated periodically as guidelines and patient needs evolve. The panel should include not just physicians, but also HCPs who are involved in the continuum of care, such as pharmacists, nurses, health psychologists, dietitians, and exercise physiologists. This allows every aspect of (chronic) disease management to be comprehensively reviewed from different perspectives.

It is equally important to actively involve a patient representative or advocate to ensure user-centered design [33]. Participatory action research (PAR) together with patient and public involvement (PPI) are increasingly recognized for their role in enhancing the quality and appropriateness of research [34]. In the context of mHealth, PAR and PPI could help identify

XSL•FO
RenderX

end-user priorities, select pertinent health education topics, ensure linguistic and cultural appropriateness, and inform user-centered delivery formats. It is also recommended to involve individuals with lived experience of the condition to strengthen the impact of PAR and PPI [35].

In all 3 use cases, the content was reviewed by collaborators from partner health care institutions. For CADENCE D-PHA, we established a formal review panel independent of the content-writing team. It comprised primary care physicians, cardiologists, clinical pharmacists, health psychologists, dietitians, and patient advocates with lived experience of hyperlipidemia and cardiovascular disease (CVD). In the case of GLOW, we conducted a co-design study with a group of patients and caregivers with diverse socioeconomic and cultural backgrounds.

Identify Theoretical Framework

Establishing the theoretical underpinnings of an intervention is a fundamental step in the development of complex programs [32]. Despite this, most mHealth apps lacked a theoretical grounding in their development, including an educational component [8,9] and behavior changes. Identifying and selecting appropriate behavioral theory is essential for supporting the adoption of healthy behaviors, while educational frameworks guide a structured and outcomes-driven approach to learning. With a plethora of behavioral theories and health promotion strategies [36,37], selecting those most relevant to the intervention's goals and the target population's needs is critical to maximizing the effectiveness of mHealth interventions.

In our use cases, we selected the health belief model and the transtheoretical model because both were well-aligned with the educational and behavioral aims of the interventions [38,39]. The health belief model was useful for structuring content around risk perception, perceived benefits and barriers, and cues to action, whereas the Transtheoretical Model supported the stepwise tailoring of content to users' readiness for behavior change. For instance, themes and topics in CADENCE D-PHA were systematically organized according to the core constructs of the health belief model. The content was designed to address the increased risk of developing CVD among patients with hyperlipidemia (perceived susceptibility), the impact of untreated hyperlipidemia and CVD on quality of life (perceived severity), misbeliefs and misconceptions about adverse effects of statins (perceived barriers), and the benefits of statin therapy in CVD prevention (perceived benefits).

However, theory selection within SCALED is not intended to be prescriptive. Rather, the framework encourages developers to identify and justify theoretical approaches that best fit the intervention goals, target behaviors, and characteristics of the intended user group. The theories used in our projects are therefore illustrative examples of how behavioral and educational frameworks can be applied within SCALED, rather than mandatory theoretical foundations of the framework.

Select Format of Delivery

The choice of instructional design and delivery format can influence user outcomes by engaging different learning styles and improving memory retention [40-42]. Compared to static images and text, animations have been shown to enhance procedural skills acquisition [43], with a positive impact on knowledge, attitudes, and cognitive engagement [44]. Conversational agents are also emerging as an innovative tool for patient education [14]. Nonetheless, the selection of delivery formats must balance the intervention's goals with practical considerations, such as funding availability and access to skilled, experienced personnel.

Across our use cases, we progressively expanded the range of formats to support engagement and learning. Beginning with text, audio, and static images in GLOW, we subsequently incorporated animations in WellFeet. These animated videos were accompanied by an AI-generated avatar-presenter that delivered the scripts. In CADENCE D-PHA, we further included transcribed videos featuring HCPs and patients, as well as audio recordings for mindfulness and meditation practice. Conversational agents in the form of rules-based chatbots remained largely consistent across 3 mHealth apps, with adaptations in their placement within the overall learning sequence to suit the specific context of each intervention. The chatbots were designed to engage users in action-oriented conversations with branching logics, enabling some degrees of personalization of content based on users' responses.

Development of Textual Content

Define Content Curriculum

Learning objectives serve as a compass for educational content developers [45]. As content creation is iterative and often collaborative, a clearly defined curriculum acts as a blueprint to ensure logical flow, alignment with intervention goals, and consistency across contributors. Topics identified through clinical expertise and literature review can be organized into thematic groups to shape the learning outcomes that reflect the overarching goals of the intervention. Learning objectives and topics can be evaluated for completeness and quality using tools such as the DISCERN instrument [25]. Feedback from an external review panel further allows content writers to prioritize practical, relevant content and remove concepts that are overly theoretical or clinically complex.

In all 3 cases, we used Bloom's taxonomy to structure learning progression and scaffold educational content by organizing it across two key dimensions: cognitive complexity and behavioral focus [46]. This involved guiding users from foundational knowledge acquisition (eg, recalling the symptoms of diabetes) to higher-order thinking skills such as creating and evaluating action-oriented goals. Complementing this, we adapted the competency-based education model to further categorize learning outcomes into knowledge, skills, and attitudes, ensuring a competency-driven approach with a strong emphasis on building efficacy in self-care skills and behaviors [47,48]. This scaffolding informed the development of learning objectives and encouraged deeper reflection on the complexity of targeted behaviors and their component tasks. It also supported more realistic decision-making about the cognitive and behavioral demands placed on users, ensuring an appropriate balance between expectation, ambition, and feasibility.

XSL•FO
RenderX

Select Information Sources

An evidence-based approach to content creation is critical to ensuring users receive health information that is up-to-date and clinically accurate. In line with principles of evidence-based medicine [49], information sources should be systematically identified and appraised. Primary sources should include an informed integration of guidelines from international or regional professional bodies, health agencies, and local clinical practice protocols. This is because although widely accepted international guidelines are useful, they might not serve the needs of certain populations or align with local standards. For instance, the recommendations for management of hyperlipidemia are known to differ between guidelines from Singapore's Agency for Care Effectiveness [48], the European Society of Cardiology [50], and the American Heart Association/American College of Cardiology [51]. Research publications, such as randomized controlled trials and systematic reviews, should be referenced with caution as individual studies may yield conflicting conclusions, vary in methodological robustness, and lack clear recommendations for real-world patient care [52,53]. Local clinical practice protocol that integrates evidence from high-quality studies with expert consensus could render them more appropriate to inform patient education. If additional information on resources such as community care support and services is needed [54], websites of health authorities, organizations, and institutions such as the World Health Organization, the UK's National Health Service, and the Centers for Disease Control and Prevention could be invaluable [48,55,56]. Once compiled, these guidelines serve as a repository to inform the entire content writing process. For each project, we systematically documented all sources used in content development, both for internal transparency and to provide users with credible references for further reading. This practice also aligns with the requirements of Google Play, which mandates the inclusion of references prior to publishing mHealth apps [57].

Extract and Synthesize Medical Literature

After creating a repository of information sources, the next step involves extracting information for the proposed topics and distilling key findings. Synthesis goes beyond merely compiling information. Given the variability in clinical guidelines and emerging evidence, it is essential to critically appraise recommendations and study findings, reconciling differences when necessary. It also involves integrating insights across multiple sources to present a balanced, contextually relevant perspective. This ensures that content remains aligned with best practices while being adaptable to specific context.

To minimize discrepancies among content writers and ensure consistency of outputs, we developed a structured template for content extraction and synthesis. This template was applied uniformly across all topics, detailing the topic description, learning outcomes, sources of evidence, raw information extracted, lay-adapted content, and the content review process. This standardizes the internal process of how and from where clinical recommendations, evidence summaries, and practical applications are documented, ensuring uniformity in tone, depth, and language. Apart from strengthening the overall coherence, the template also streamlines the review process, enabling the review panel to identify any misinterpretation of clinical recommendations by comparing the lay-adapted content with the original references and raw information extracted.

Simplify and Contextualize Medical Content

Translating complex medical information into accessible and relatable language is essential for effective health promotion [58]. Achieving this requires both simplification and contextualization. Simplification improves readability, which is a key determinant of health information accessibility, especially for people with low health literacy [59]. However, research indicates that the content of many mHealth apps was written at reading-grade levels that exceed recommended standards [60,61].

Adapting medical content into lay language involves not only enhancing readability by replacing medical jargon with simpler terms or simplifying sentence structure [59,62], but also adopting strategies to improve understandability and actionability [63], minimize linguistic stigma [64], and improve cultural sensitivity through enhancement of appropriateness and representativeness [65,66]. For example, recommendations such as the Mediterranean diet or olive oil use may hold little relevance for patients in Asia, as they do not align with local dietary norms.

For all use cases, we developed a copywriting guide with suggestions for simplified, actionable, and empathetic language. For WellFeet and CADENCE D-PHA, we adapted content into a conversational tone to suit the video scripts. We also used copywriting techniques, such as analogies and metaphors, to clarify complex ideas. When medical terms were necessary, they were supported by a built-in glossary, allowing users to click on highlighted terms for plain-language definitions. In CADENCE D-PHA, we also provided a short video introducing and explaining medical terminologies that were commonly used, such as low-density lipoprotein cholesterol, unsaturated fats, statins, and cardiovascular disease.

Finalization Into Delivery Format

Convert Textual Content into Desired Format

Design principles differ across instructional formats, with videos requiring their own specific approach [67]. Adapting text-based content for video involves more than converting it into a script. It also calls for additional guidance and materials, especially since animators usually do not have a medical background and may need support in visualizing some of the medical concepts accurately. An iterative process of providing input, reviewing storyboards, and refining video drafts is essential to ensure clarity, accuracy, and effective communication.

For both WellFeet and CADENCE D-PHA, we collaborated closely with the appointed multimedia units, not only to guide the creative process in choosing color schemes, typography, and voice-overs, but also to ensure the visual content accurately reflected the intended message. Providing carefully selected reference images was essential for ensuring accurate depiction of anatomical structures and biological processes, such as cholesterol deposition and plaque formation in arteries. All

XSL•FO
RenderX

videos underwent additional rounds of review by the content development team to verify accuracy, ensure consistency, and maintain alignment with the educational goals before being finalized and uploaded. After receiving the storyboards from animators, we optimized the characters and images. The attire, skin tone, and facial expression of animated characters were revised to better align with local context and reflect the diversity of the local population. By incorporating these considerations, mHealth apps could deliver inclusive, equitable, and accessible content to a broad range of users.

Optimize for Accessibility

Optimizing mHealth app content for better accessibility ensures that users with varying levels of digital literacy can effectively engage with the materials. Beyond app functionalities such as implementing adjustable font sizes or using a larger font as the default [68], content designers should consider including alternative text descriptions for images, high-contrast color schemes, and scalable fonts to accommodate users with visual impairments. For quizzes with text response in CADENCE D-PHA, we integrated a dictation tool to enable voice input, reducing the reliance on typing for individuals with fine motor impairments, visual disabilities, or cognitive difficulties such as dyslexia. For videos, we provided subtitles and transcripts to support individuals with hearing difficulties or impairments. This could also cater to users of a reading-based learning style. Voice-over texts were carefully refined for appropriate speed, tone, and accent suited for the target population.

Test Uploaded Content and Polish Final Presentation

Pilot testing of the final content is essential to optimize content delivery and ensure fitting with user interface before rolling out the mHealth app. The layout of content can impact visual perception and usability, often requiring refinement due to misalignment between content design and software development, which are frequently managed by separate teams. Factors such as user settings (eg, dark vs light themes and adjustable font sizes) can further influence how content is displayed and received. At this stage, established app evaluation and usability frameworks may also be used as complementary quality-assurance tools to assess broader aspects of app usability and overall quality beyond content development alone. In all 3 use cases, we observed such misalignments and addressed them during the refinement phase. For seamless presentation and usability, pilot testing of the app and its content should be conducted with end users and other stakeholders. Usability testing should gather feedback on navigation, content comprehension, visual compatibility, and overall user satisfaction. At this stage, established app evaluation and usability frameworks may also be used as complementary quality-assurance tools to assess broader aspects of app usability and overall quality beyond content development alone. Importantly, this feedback loop must be maintained continuously throughout the content development process to identify and address issues arising at every stage, ensuring that the final product meets user needs and delivers a polished, engaging experience.

Discussion

SCALED is a conceptual framework that integrates insights from real-world experience of developing mHealth apps, findings from 2 studies with end-users, and adaptations based on stakeholders' input. With eleven components grouped into 3 sequential stages, the framework offers a practical guide for mHealth content development. Unlike existing frameworks that primarily focus on app usability and intervention design, SCALED provides a structured approach to producing mHealth content that is evidence-based, clinically accurate, theoretically grounded, and user-centered. This is particularly important given that many mHealth apps currently on the market lack health care professional involvement and fail to integrate behavioral science principles, potentially limiting their effectiveness in promoting sustained behavior change.

Concerns about the content quality and safety of mHealth apps are not new. Previous research has attempted to overcome this challenge by proposing various tools and frameworks to establish standards for evaluating the content, effectiveness, and usability of mHealth apps [69]. A range of frameworks has also emerged to guide specific aspects of mHealth, such as smartphone-delivered conversational agents [14], behavior intervention technology design [70], user-centered technology design [17,33], and data security and privacy [71,72]. In parallel, broader frameworks such as the Medical Research Council framework and the Behavioral Intervention Technology model provide high-level guidance on the development and evaluation of complex interventions and on aligning clinical aims with behavior change strategies and technological features [32,70]. SCALED is intended to complement, rather than supersede, these frameworks by addressing a more specific but underdeveloped aspect of mHealth intervention design: the systematic development of educational content. This directly tackles the root cause of variability in content quality.

SCALED may have broad implications for stakeholders in mHealth apps. For developers, it provides a structured methodology to create clinically accurate, theoretically grounded, and user-centered educational content, which could help build user trust and support regulatory compliance [73]. This could be highly relevant in commercial settings, where a multidisciplinary team of HCPs might not be readily available within the organizations. In such cases, SCALED's recommendation to engage an external review panel could ensure content credibility and alignment with clinical standards. Users could benefit from more reliable, accessible, and evidence-based health information, enhancing their health literacy and informed decision-making [74]. Health care providers could use SCALED as a reference to appraise the rigor of the mHealth content development process and to assess their appropriateness before recommending them to patients. Additionally, for health systems actors and policymakers, the framework could serve as a foundation for establishing quality standards and guiding endorsement of digital health tools. By promoting a more consistent and transparent approach to content development, SCALED may ultimately support improvements in the effectiveness, credibility, and uptake of mHealth apps across different levels of the digital health ecosystem.

XSL•FO
RenderX

A key strength of the SCALED framework is its empirical foundation, having been refined based on real-world lessons from 3 mHealth apps, making it more practical and applicable than purely theoretical frameworks. Additionally, SCALED benefited from iterative feedback loops involving key stakeholders, including patients, HCPs, and content designers. Furthermore, its high-level structure provides a flexible foundation, allowing room for modification and customization of the more intricate steps in developing content across different formats and disease contexts.

A few limitations should be acknowledged. One major limitation is its untested generalizability, as the framework is based on a limited number of education-focused mHealth apps targeting chronic disease management, which may limit its direct applicability to other contexts. For instance, interventions in acute care settings, mental health, or those incorporating highly adaptive or real-time decision-making may require additional considerations beyond those captured in SCALED. Similarly, while the framework is designed to be flexible, its implementation in low-resource settings or by commercial developers without access to multidisciplinary academic teams may present practical challenges. SCALED is currently most directly applicable to interventions with a strong educational component, particularly those involving structured or rule-based content and human-reviewed materials. Its applicability to systems that rely heavily on generative AI may be limited, thus requiring further adaptation to address issues such as dynamic content generation, validation, and real-time personalization.

Another limitation of the framework is that it does not take into account regulatory checkpoints or alignments, as digital health policies vary globally. While SCALED does not address formal requirements set by regulatory bodies such as the United States Food and Drug Administration and CE (Conformité Européene) marking processes in Europe, it may serve as a complementary, preregulatory quality assurance approach by supporting the development of evidence-based and transparent educational content. It is worth noting that the framework was designed to serve as an initial step in response to the urgent need for improved quality of content in mHealth apps. Future iterations could be strengthened by having stronger engagement of target user groups and incorporating findings from systematic reviews, qualitative research, and structured stakeholder consensus methods, such as a Delphi study, to enhance framework comprehensiveness and applicability.

Conclusions

The SCALED framework offers a systematic, collaborative, and evidence-based approach to mHealth content development, addressing a critical gap in existing mHealth offerings. By ensuring alignment with clinical guidelines, theoretical frameworks, behavioral science principles, and user-centered design, SCALED demonstrates a practical and stepwise approach to improving the quality of educational content and safety of mHealth apps. Future work may focus on assessing its usability across diverse development settings, evaluating its influence on content quality and user learning, and exploring its potential for adaptation in different health contexts and digital ecosystems.

Acknowledgments

The authors specifically thank Dr Daniel Ek Kwang Chew, Dr Huiling Liew, Prof Bernhard Otto Boehm, Dr Daniel Muhammad Mahadzir, Dr Victor Jin Xue Goh, Ms Sui Jing Lim, and Mr Josh Jialong Quah for their contributions to the Glow and WellFeet app content development process. The authors are grateful to all members of the content review panels, content writers, animators, and project team members of GLOW, WellFeet, and CADENCE D-PHA apps, as well as patients who participated in the qualitative studies. We used a generative artificial intelligence (AI) tool (ChatGPT-5.2; OpenAI) solely for language refinement and grammar checks to improve the clarity and readability of the manuscript. No generative AI tools were used to generate any scientific content or figures.

Funding

This article is based on work supported by the Joint Platform 3 under the Cardiovascular Disease National Collaborative Enterprise (CADENCE) National Clinical Translational Program (MOH-001277-01). Development of WellFeet was supported by the Singapore Ministry of Health's National Medical Research Council under Health Services Research Grant (HSRG-DB17Nov002). Development of GLOW was supported by the Singapore Ministry of Health (MOH/NIC/CDM2/2018). The funders had no role in the conceptualization, development, or writing of this viewpoint.

Data Availability

This manuscript is a viewpoint, and thus no primary data were used.

Authors' Contributions

QCO, AP, EO, and AHYH conceived this viewpoint. QCO, AP, EO, AS, JC, and AHYH contributed to the methodology. All authors contributed to project administration. QCO and AP wrote the first draft of the manuscript. EO, AS, AWHK, JC, and AHYH critically reviewed and revised the manuscript for important intellectual content. AWHK, JC, and AHYH supervised this work. All authors approved the final manuscript.

Abstract

Intensive, repeated self-report measures are an important tool for behavioral and medical researchers and practitioners who are concerned with the dynamic interplay among variables at a granular level. Many mobile health applications rely on accurate measurement of immediate states and environments for both assessment and intervention delivery. Techniques for capturing repeated momentary assessments yield data with several salutary qualities: recall bias is minimized relative to assessments that rely on much longer recall periods; measurements are taken in individuals' everyday environments; and dense, repeated measures allow a new window into the processes transpiring between individuals and their environments. In this paper, we highlight several features of repeatedly completing momentary assessments that may change the nature or quality of the data collected over time. Several lines of inquiry are discussed that call into question the presumption that there is invariance in how people complete repeated assessments over time. A result of this possibility could be a reduction in data quality. We present 4 phenomena, with selected results, that may induce noninvariance in repeated measures: the amount of time required to complete assessments, the rate of missing data, the degree of careless responding, and the presence of several components of reactivity. In each of these areas, we found evidence that changes could occur over time, and we consider how data might be affected by such changes. Our conclusion is that researchers should be aware that changes can occur over time and that these changes may affect data quality.

KEYWORDS

ecological momentary assessment; EMA; repeated measurements; invariance; self-report

Introduction

Repeated self-report measures are central to intensive longitudinal methods that use momentary assessments, including ecological momentary assessment (EMA) [1,2], the experience sampling method [3], and ambulatory assessment methods [4]. Methodological strategies derived from momentary assessment studies form the backbone of optimal mobile health (mHealth) data acquisition for participant monitoring, in-the-moment treatment delivery (eg, just-in-time adaptive interventions), and real-time feedback on behavior and thoughts. As such, there is considerable value in recognizing the strengths and the potential limitations of these methods.

The advantages of repeated measures over static measures are numerous: they provide the opportunity to track trajectories of outcomes over time, enable exploration of lagged associations that may confer near-causal status, and reduce problems associated with retrospection [2,5-7]. Repeated-measures study designs are also part and parcel of many mHealth practices. Moreover, constructs often measured using momentary methods are pertinent for mHealth researchers; they include internal states (eg, pain intensity and quality, emotions, fatigue, perceived stress, symptoms, and cognitive status) and external (often observable) behaviors (eg, daily activities, social engagement, consumption, substance use, exogenous events, and location). Real-time self-reports may also be linked to ambulatory measures of physiological function (eg, heart rate, blood pressure, cortisol levels, and blood glucose) and to data

XSL•FO
RenderX

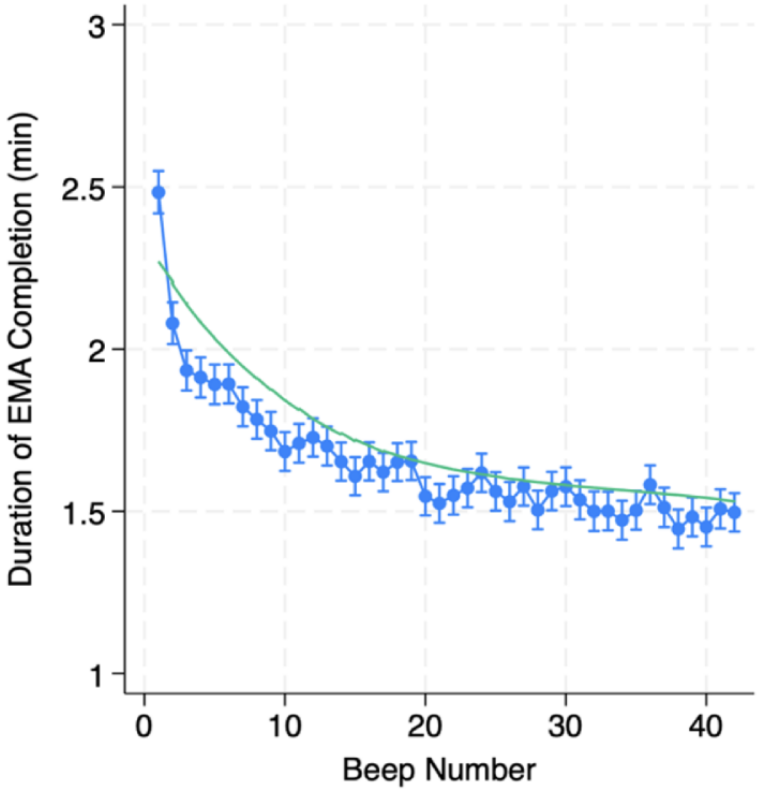
routinely collected by smartphones (eg, location, step counts, and time taken to respond to questions) to provide insights into the dynamics of these variables. Finally, intensive, repeated measures are indispensable tools for monitoring populations, evaluating treatments in medical research, analyzing economic patterns, and addressing behavioral science questions. Many review and position papers [6,8-11] are available for the interested reader.

A generally unspoken belief about repeated self-report measures is that repeated assessments conducted throughout a study—regardless of the study duration or the momentary measurement frequency—are thought to be invariant regarding how questions are interpreted, how response scales are construed, and how internal reference standards are applied to ratings. All of these are important considerations for achieving reliable and valid data. That is, we assume that the quality and integrity of responses to all assessments are not affected by repeated measurement processes. However, if this assumption of invariance does not hold, it becomes challenging to disentangle true within-person changes from shifts in measurement quality over time. For example, observed within-person patterns could be erroneously attributed to genuine change when they instead reflect evolving interpretations of questions or changes in response scale use, thereby compromising the validity of inferences about within-person dynamics and processes.

Our primary intention in this viewpoint is to highlight several features of repeated momentary assessments that we think deserve attention, given the possibility that they are associated with changes in momentary data quality. We present selected results to illustrate the point. Because the findings presented later have been reported previously, it is reasonable to assume that they may be present in at least some repeated momentary studies and, importantly, *may* systematically impact data quality and warrant further research. In the same spirit, we do not argue that the features presented are ubiquitous in EMA studies.

We now describe how intensive longitudinal momentary measurements may be distorted by repeatedly asking the same or similar questions over many repetitions. Theoretically, these distortions may be particularly germane when assessments occur many times a day, with only hours between assessments [12], but they may also occur at longer intervals. There is already substantial evidence that responses are not invariant over time, given that repeated measures can create practice effects, a phenomenon supported by abundant research on memory and performance [13-15]. Practice effects could be salutary, leading to faster and more accurate responses [16], or pernicious, leading to unwanted measurement effects such as increased bias and error [17]. In either case, the key point is that repeated exposure to the content can change how questions are answered. To date, evidence on the *adverse* consequences of repeated assessments as they pertain to EMA has been available in a piecemeal fashion spanning several content domains, making it difficult to fully appreciate the scope and importance of the issue.

Response Times Decrease for EMA Question Completion Over Repeated Measures



Overview

Although perhaps not well known to EMA researchers, studies examining the time taken to complete an EMA assessment have reported decreases in response time (time it takes individuals to complete questions) over repeated measures, consistent with the practice effects mentioned previously [18-20]. Response time reductions are likely due to respondents' increasing familiarity with the task, with the wording and meaning of questions, and with the response options over repeated assessments [21]. These decrements can be striking, with reductions of more than 50%. Aggregated response times usually follow a negative exponential pattern, with the steepest decrements occurring early during repeated measures.

To illustrate this pattern of response times over time in an EMA study, data from the Understanding American Study conducted at University of Southern California are shown in Figure 1. A total of 22,531 prompts were recorded from 706 community-dwelling adults, and up to 42 prompts were completed per week. Average response time is plotted for each prompt, revealing a dramatic drop across the first 9 prompts followed by a modest decline over the remaining prompts. Over the course of a week, there was a 32% decline in response times. The magnitude of the decrease in survey completion time is influenced by multiple factors, including the burden of the interview, incentives for completion, and the composition of the participant sample.

XSL•FO
RenderX

Figure 1. Response times over prompts. EMA: ecological momentary assessment.

Implications

We conclude that the time to complete assessments may decrease over repeated measures. We speculate that if such changes are associated with, or caused by, any of the factors discussed later, data quality may change over repeated measures. For example, increasing missingness and carelessness over time may generate faster response times and, consequently, compromise data quality. Given this possibility, we suggest that researchers examine the response time changes over the course of repeated measures, though we also acknowledge that response time may or may not be associated with validity.

Rate of Data Missingness May Increase Over Repeated Measures

Overview

One plausible explanation for faster survey completion with repeated measures is that individuals gradually disengage from the study procedures and, therefore, spend less time completing assessments. At the start of a study, participants may be motivated to complete all questions and generate optimal answers but may lose interest and become less invested as they repeatedly answer the same questions [22]. When this happens, participants may show increasing noncompliance with the study protocol and may miss assessments when prompted, a concern that has previously been acknowledged by EMA researchers [23].

To assess the magnitude of change in missed EMA prompts over time, we examined many EMA studies with a wide range of samples and variety of assessment schedules. Some studies showed a drop in compliance rates over time, across both shorter and longer studies, and with various frequencies of EMA prompting. Therefore, we suggest that repeated measures can induce *some level* of missingness in EMA studies.

We now turn to the question of whether changes in missing data are serious contenders for inducing bias and how such missingness may affect data quality. If shifts in missingness over time are minimal or if compliance rates remain high overall despite an increase in missed assessments, there is likely little cause of concern. However, in the presence of substantial increases in missingness, missing data can introduce a range of problems, including reduced statistical power, unrepresentative momentary samples (or changes in sample representation), and potential distortions of longitudinal effects. Increasing rates of missing values imply that missing values do not occur completely at random, and researchers may wish to routinely incorporate study day (or prompt number) as an auxiliary variable or covariate in statistical analyses to reduce potential bias due to systematic missingness patterns (ie, to increase the plausibility of the assumption that data are missing at random. Although statistical methods (eg, multilevel multiple imputation [24]) can help account for missing-at-random mechanisms, it is not possible to fully protect against potential patterns that are missing not at random, and only a few studies have developed or evaluated missing data methods specifically for intensive longitudinal contexts, such as EMA data [25].

Implications

Repeated measures may create bias when missingness increases to substantial levels over the course of a study, and we suggest that missingness over time be considered in intensive repeated-measures studies. Unfortunately, the precise proportion

XSL•FO
RenderX

of missingness that would signal caution depends on the cause of this missingness (eg, simple burden or a change in activities that encourage missingness, such as more exercise). Our recommendation is to implement as many safeguards as possible to encourage the most complete data throughout an entire study. This could entail a variety of methodological maneuvers: creating EMA designs that reduce respondent burden related to questionnaire length, daily sampling frequency and scheduling, and study duration; incentive structures that encourage high compliance (eg, payment being contingent on prespecified completion rules from the investigators); and implementing procedures for monitoring compliance over time and providing appropriate feedback to encourage compliance (eg, real-time or daily signaling to the research team about missed prompts). Further research would be welcome to determine which of these strategies are most effective, so that efforts to reduce missingness could be implemented efficiently.

Frequency of Careless Responding Over Time

Overview

Careless responding (or insufficient effort responding) is defined as respondents providing answers without regard to the content of the questions, and it can occur when they do not read an item or do not pay attention to what the item is asking [26,27]. Careless responding can also occur as a more subtle form of participant disengagement compared with the overt noncompliance discussed previously, in which a respondent misses prompts entirely. To reduce the burden associated with repeated assessments, respondents may minimize the effort expended by doing the least possible to satisfy study requirements [22]. Careless responding can present as invariable responses (eg, *straight-lining*, in which the same answer is given to every question) or as inconsistent or random responses. A recent small study interviewed individuals at the close of a many-month EMA study to better understand the burden and other issues that could affect data quality [28]. The authors found that respondents tried to counter the burden by responding quickly and that repeated measures over time led to more neutral responses.

Many studies have shown the detrimental effects that careless responding can have on measurement accuracy and reliability [26]. Careless responding can occur when respondents are asked to complete long questionnaires. For instance, toward the end of lengthy questionnaires with dozens or hundreds of items, respondents often give more random, uniform, and fast responses, suggesting that their motivation has waned over time [29,30]. An intuitive extrapolation of these findings is that the repetitive nature of completing brief surveys may similarly lead to more careless responding. Ganzach and Bulmash [31] documented less variable and less complex patterns of self-reporting over the course of daily repeated measures on affect and stress. These findings demonstrated that increased carelessness could occur over repeated measures [32]. Whether decreases in survey completion time can be attributed to increases in extremely fast responses (an indicator of carelessness) has also been shown to occur. In another EMA study, the frequency of speed responding increased from 3% to 8% across 49 assessments over 7 days [33]. Again, we are not saying that all studies, or even most studies, show this pattern—only that it can occur in repeated-measures studies. Another method for assessing changes in carelessness over time is by comparing self-report ratings with objective assessments of the same concept. With increased carelessness, associations over repeated measures would be predicted to decrease because of the increased measurement error. One study found a decreasing association between self-reported and objectively measured time spent on social media in adolescents, which could have been generated through carelessness [34].

Implications

Available evidence shows instances of increasing carelessness over densely repeated measures. We recommend future work to examine possible changes in careless responding over time. The addition of attention check questions might also improve engagement and reduce carelessness [28]. A fruitful direction for future research could be the development of advanced statistical models, including machine learning techniques, to detect careless responding in datasets in which EMA self-reports can be compared with objective measures. Furthermore, the longitudinal aspect of intensive repeated-measures data may prove a fertile ground for extending carelessness detection approaches, for instance, by examining shifts in within-person parameters (eg, variability, autocorrelation, and outliers) over time.

Reactivity to Question Content May Increase Over Repeated Measures

Overview

Reactivity, or reactive arrangements, has been recognized since the 1930s, when workers at a manufacturing facility in Hawthorne, New Jersey, altered their behavior in response to their actions being observed by scientists [35], even though an alternative interpretation has been offered [36]. Here, we restrict our inquiry to reactivity associated with repeated measures in intensive momentary designs, namely, the repeated answering of the same or similar questions many times. This section is divided into 3 subparts: reactivity producing a change in a targeted behavior or cognition, reactivity producing a change in the reporting of a behavior or cognition (but without corresponding change in the targeted phenomenon), and specific reactivity processes associated with changes in question meaning or scale recalibration. These are not exclusive designations, and it is possible that studies exhibit blends of these types of reactivity.

Reactivity in Behavior, Cognition, and Emotion

This type of reactivity is defined as a change in actual behavior, cognition, and emotion over time due to repeated responses. In fact, some interventions have intentionally incorporated this type of reactivity to induce desired outcomes, such as the use of self-monitoring to affect physical activity behaviors [37,38]. Despite its potential utility in intervention contexts, this phenomenon poses a threat to the internal validity of an observational study as it signifies that measurement is not

XSL•FO
RenderX

invariant over time. For example, repeated assessments may cause participants to become more conscious of their behaviors, which may, in turn, trigger self-regulatory mechanisms [39]. The same process may happen with behaviors and emotions. Unfortunately, very few studies are available on whether and how this phenomenon unfolds in EMA studies over time (eg, potential for cumulative effects) [40].

Reactivity in Reporting

A second type of reactivity is defined by respondents altering the way they *report* behaviors, cognitions, and emotions, independent of whether those behaviors or states have actually changed over time (the previous type of reactivity). In repeated-measures studies, this phenomenon could manifest as a shift in the validity of the reported variables over repeated assessments. For example, reports of affect might be accurate at the onset of a study but gradually shift to become inaccurate or less reliable later; the converse might also be true, as discussed later [18]. A problem for reporting reactivity is that most studies cannot distinguish between real change and reporting change because doing so requires objective measurement of the variable of interest, which is very uncommon in the constructs being measured in EMA. This requirement presents a challenge for the assessment of internal states, where changes over time may indicate actual change, reporting change, or a combination of both.

Reactivity Processes

The third section on reactivity discusses several ways that actual levels of, or reports of, behavior, cognition, and emotion might change over time through specific psychological processes that may be inherent in repeated measures.

Initial elevation is defined as higher levels of a variable when measured early in a study compared with levels observed at later measurements when there is no apparent reason for a shift in levels over time [41-43]. Although recognized for many years, a paper by Shrout et al [43] has renewed interest in the phenomenon. They found an initial elevation effect for momentary negative states and for momentary internal states in 4 studies with repeated measures, with small to medium effect sizes. Furthermore, Anvari et al [44] (2023) studied several thousand college students and reported a strong initial elevation bias. Thus, initial elevation has been observed, although there is some competing evidence [45] consistently. Biasing of overall levels of variables can result from such effects, for example, by producing (apparently) incorrect downward trajectories in variables over time.

Another facet of reactivity that has not received much attention is that the *meaning of questions* may evolve over repeated administrations of questions [46]. Following up on previous work by Windle [47] (1994), Knowles et al [48] (1996) explicitly explored the possibility that the interpretation of questions changes over time. Results indicated that over multiple exposures to items, individuals gained knowledge about the construct being studied (an anxiety questionnaire). Moreover, they observed shifts in question meaning within a single test administration. Later interpretations of anxiety items demonstrated that a higher standard for endorsing anxiety was evident; if all else remained constant, this would result in diminished reported anxiety later in the study. The upshot of such shifts in question meaning over repeated measures over time is clear: what we learn at the beginning of a study might not be comparable with what we learn later.

Another aspect of question meaning is *responsescale recalibration*, defined as a shift in how participants use question response options that occurs as a reaction to events experienced throughout the study [46]. Exposures to events that elicit very intense emotions or other strong reactions (eg, pain of childbirth or trauma) may alter the way individuals interpret a rating scale. Such recalibration could result in a stimulus that was once rated at a certain intensity to later receive a lower intensity rating because the upper end of the scale was redefined by the extreme emotion or reaction. Alternatively, recalibration could be induced in certain treatment modalities intended to reduce reported symptomatology through cognitive and social manipulations [49]. Therefore, recalibration could have a major impact on interpreting results over time.

Implications

It is fundamental to know if repeatedly measuring a variable creates any of the reactivity processes, given that they would be a threat to internal validity. If there is a high likelihood for reactivity, we recommend preliminary investigations to assess the potential magnitude of these effects and to incorporate design strategies to mitigate them, while acknowledging the extra financial and investigator burden inherent in this recommendation. More broadly, if empirical evidence suggests that reactivity is likely (eg, respondents having access to feedback that has been previously shown to induce reactivity), steps could be taken to eliminate the reactivity-inducing aspect of the protocol.

An existing barrier to the application of this approach is that we simply do not have an adequate way to identify reactivity-inducing circumstances. Of particular importance is the possibility that processes and events with the potential of shifting means or recalibrating scales are not routinely measured in longitudinal studies; we therefore recommend routine collection of such data to signal possible distortion. In addition, experimental manipulations of item administration (eg, item order) have been recommended as useful methods to detect possible biases from measurement reactivity [19]. Advancing methodologies to statistically control for these shifts is also recommended; however, some efforts to accomplish this have not resulted in reduced bias, such as using the *then-test* to control for shifts from pretest to posttest [49].

Conclusions

The aim of this viewpoint was to consider the possibility that studies using intensive repeated self-report measures could distort interpretations of data collected over time. We found evidence supporting the potential for all factors considered: response times can be considerably reduced, missing data rates can increase, carelessness rates can rise, and reactive effects (including reference standards and question meaning) may manifest over repeated measures. Response time reductions

XSL•FO
RenderX

alone may or may not impact data quality, as practice effects could be positive or negative. However, when reduced response times lead to increases in missingness, carelessness, and reactivity, there is the potential for compromised data quality. Heightened awareness of these possibilities is warranted for researchers using repeated assessments. We also offered suggestions for monitoring and reducing these possible effects.

We view this discussion as a supplement to prior papers that suggested *guidelines* for conducting, reporting, and analyzing EMA studies. Those papers have guidelines that could be helpful for examining some threats to validity across repeated measures, although not with an eye toward invariance over time. As early as 2002, an EMA guidelines publication [50] indicated the need for comprehensive reporting of procedures and enumerated ways of calculating prompt compliance, which are useful for understanding the threats to validity discussed here. The early set of guidelines did not mention tracking the duration of prompt completion or methods for assessing careless responding. A guidance document [51] included the recommendation to record prompt duration; these data would be pertinent for evaluating the issues raised in this paper. However, their suggestions did not mention tracking careless responding. Overall, these recommendations are positive developments for the field that should result in more robust EMA studies.

In summary, we believe a cautious position is warranted regarding the possibility that repeated questionnaire measurements affect how questions are answered. It is plausible that some results from repeated-measures studies have been affected by the processes discussed previously. This paper calls for research directed at understanding whether reactivity distorts data collected through intensive repeated measures. A speculative extension of this conclusion concerns repeated measures taken at longer intervals, such as every week or month: such longitudinal data may also be susceptible to the biases reported here, with potentially far-reaching implications.

Abstract

Digital behavioral interventions are increasingly used to support chronic disease self-management, yet many systems rely on predetermined content that limits personalization and sustained engagement. Large language models (LLMs) offer new opportunities to deliver conversational behavioral support. However, integrating LLMs into behavioral interventions requires careful architectural, methodological, and ethical planning, which may be challenging for researchers without formal training in artificial intelligence. This viewpoint provides a structured introduction to LLMs tailored to behavioral science. We describe foundational concepts in natural language processing and transformer-based architectures, outline the core components of LLM-based systems, including prompting strategies, context management, retrieval-augmented generation, and guardrails, and illustrate these principles through our experience integrating a proprietary LLM into a mobile self-management intervention for individuals with systemic sclerosis. Building on this case example, we propose a phased design workflow to guide early-stage development and responsible implementation, along with a decision framework to help researchers navigate scientific and logistical trade-offs between proprietary models and other alternatives. The considerations presented here are informed by formative implementation efforts and are intended to support early-stage design decisions for LLM-based behavioral interventions. As these interventions continue to evolve, rigorous evaluation and interdisciplinary collaboration will be important to ensure that these systems improve personalization and scalability while maintaining safety and scientific rigor.

Introduction

Behavioral interventions are treatment approaches designed to help individuals change behavior and develop skills to manage their chronic health conditions [1]. These interventions typically involve an interactive process between the individual and a health care provider and draw on evidence-based behavior change strategies, such as education, identification of patterns, motivation, goal setting, self-monitoring, evaluation, and reinforcement [1,2]. Despite evidence supporting their effectiveness in improving health outcomes [3-5], behavioral interventions are inconsistently implemented in primary care settings due to a shortage of trained providers, limited access, implementation costs, and insurance coverage constraints [6-8]. These challenges hinder scalability, personalization, and sustained engagement, thereby limiting the broader impact of behavioral interventions [9].

While digital technologies, including SMS text messaging, mobile health (mHealth), and web-based platforms, have been increasingly adopted for disease management [10,11], many systems rely on predetermined content or predefined if-then rules that do not adapt to changes in user behavior, engagement patterns, or contextual factors over time [12-14]. Digital interventions with limited tailoring or personalization are associated with lower engagement and ultimately reduced effectiveness in supporting sustained behavior change and disease management [12,15]. These limitations underscore the

XSL•FO
RenderX

need for digital behavioral interventions that are both scalable and responsive to individual needs as they evolve.

Natural Language Processing and Large Language Models

Artificial Intelligence (AI) refers to technologies that simulate human intelligence, including learning, reasoning, and decision-making [16]. Within this landscape, natural language processing (NLP) plays a central role in enabling machines to analyze and generate human language [17]. Historically, NLP relied on rule-based systems that used predefined grammars and pattern matching to classify text [17,18]. While effective for well-defined tasks, these systems struggled with the nuance of human conversations and were limited in their ability to generalize across different conversational contexts. For example, in the statement, "I'm exhausted, so I didn't go for a walk today," a rule-based system might flag the keywords "didn't go" and simply classify the statement as an instance of nonadherence. Subsequent statistical models, such as recurrent neural networks, improved on this by processing text sequentially, one word at a time [19]. However, these models often suffered from the "vanishing gradient" problem, where the mathematical influence of earlier words weakened by the time the model reached the end of a long or complex sentence [20]. In the example statement "I'm exhausted, so I didn't go for a walk today," the recurrent neural network model might lose the semantic link between "exhausted" and "didn't go," resulting in a fragmented analysis that overlooks the underlying cause of the missed physical activity. Within the context of a behavioral intervention, understanding the underlying factors of nonadherence, such as low motivation, emotional burnout, lifestyle demands, or symptoms (eg, pain or fatigue), is crucial for delivering appropriate behavioral support, yet such nuance is difficult to capture using fixed rules or narrowly trained models.

Recent advances in NLP center on transformer architectures, which use self-attention mechanisms to process all words in a sequence simultaneously, allowing the model to weigh the relevance of each word relative to every other word in the message, thus preserving the causal and contextual information central to behavioral interventions [21]. Thus, in the example stated earlier, "I'm exhausted, so I didn't go for a walk today," the transformer-based model is able to capture the relationship between "exhausted" and "didn't go for a walk," preserving the understanding that the individual did not go for a walk because they were exhausted. Training transformer architecture models on massive datasets has given rise to large language models (LLMs) with emergent capabilities [22]. A defining feature of LLMs is "in-context learning," which allows the model to adapt its interpretation and performance via specific instructions or examples through a technique called "prompting." This includes "zero-shot prompting" (following instructions without examples) and "few-shot prompting" (guided by a small number of task-relevant examples) [22]. This flexibility allows LLMs to be adapted to specific clinical contexts through instruction rather than requiring the model to be built or retrained from scratch. While this can be highly beneficial in behavioral health settings, applying LLMs to interventions requires careful design and oversight because model outputs are generated probabilistically and may occasionally produce inaccurate, misleading, or clinically inappropriate responses if not properly constrained. Therefore, responsible integration of AI systems, including the use of grounding strategies, guardrails, and systematic evaluation, is essential when using LLMs for health-related interventions.

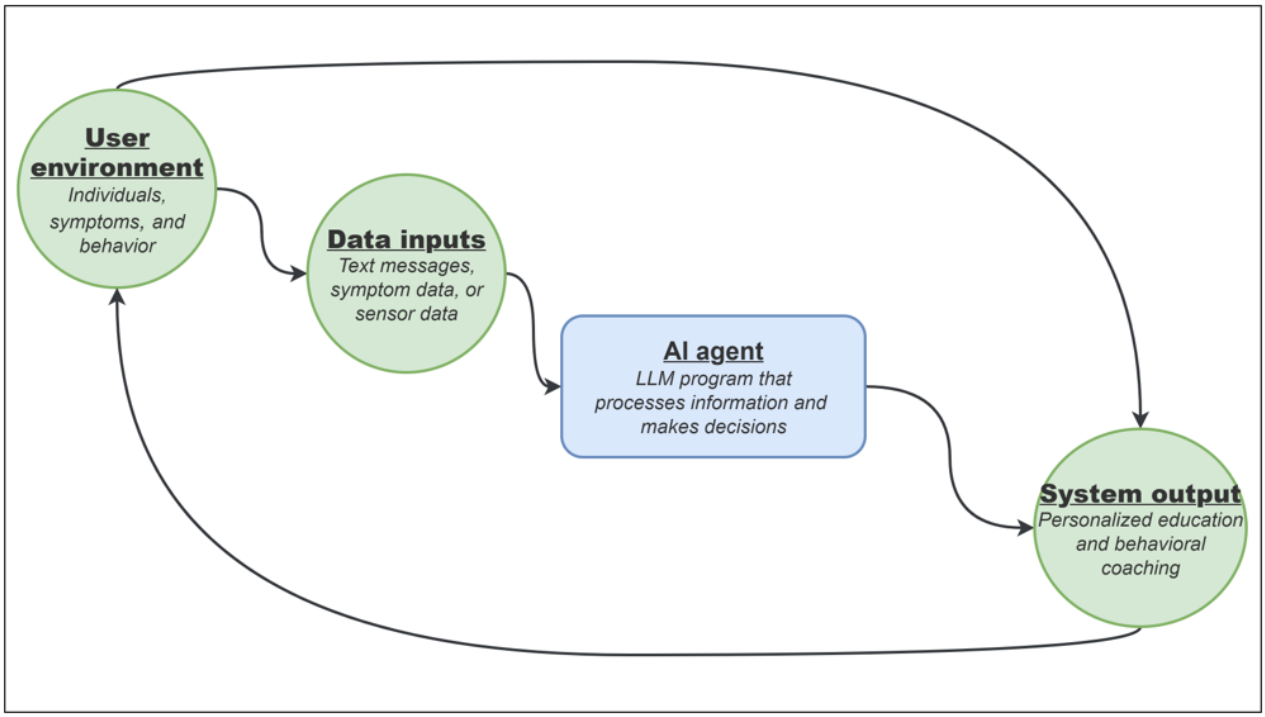
Although LLMs are increasingly adopted in behavioral and nonpharmacological treatments [23], few resources provide practical guidance on the foundational concepts and their responsible integration into interventions. This viewpoint paper aims to bridge this gap by providing a perspective-driven, practice-informed, structured introduction to core concepts, informed by our firsthand experience integrating LLMs into an mHealth intervention for individuals with systemic sclerosis (SSc) called resilience-building energy management to enhance well-being (RENEW) [24].

RENEW Intervention

The RENEW intervention is a 12-week mHealth, peer-supported fatigue self-management intervention developed for individuals with SSc [24]. The original intervention was grounded in a positive psychology framework and paired participants with trained peer health coaches who provided individualized guidance to support behavior change across domains, such as physical activity, activity pacing, relaxation techniques, adaptive thinking, self-care, nutrition, and sleep, through structured, real-time video-based coaching sessions [24]. The health coaches were trained in motivational interviewing and followed a manualized protocol with ongoing supervision to support intervention fidelity. Although the original RENEW intervention demonstrated clinical benefit [24], sustaining a peer-delivered coaching model presented challenges related to personalization, scalability, cost, and long-term availability of trained coaches. These constraints motivated the integration of LLM-based systems into the RENEW platform through the RENEW-AI and RENEW via Artificial Language (RENEWAL) projects.

RENEW-AI and RENEWAL Projects

In this paper, we describe key lessons learned from integrating an LLM into the RENEW intervention and iteratively refining it to deliver behavioral coaching content aligned with our program goals. This work was carried out in 2 phases: the RENEW-AI and RENEWAL projects. In RENEW-AI, we incorporated a chat-based interface within the RENEW mobile app that used a proprietary LLM (ie, GPT-4o; OpenAI) to provide disease-related education and behavioral health coaching consistent with the principles of the original peer-led RENEW program. In this initial iteration, responses of the AI health coach were shaped through text-based prompts such that the chat-based health coach reflected the tone, scope, and boundaries of peer health coaching provided in the original RENEW intervention. We emphasized concepts of motivational interviewing, empathy, encouragement, goal reflection, and self-management strategies, while explicitly excluding medical advice, diagnosis, or treatment recommendations.



XSL•FO
RenderX

Building on this foundation, the RENEWAL project extends the system architecture with a curated, evidence-based knowledge base of disease-specific materials. This approach allowed us to ground the model's responses in program-specific content, ensuring that conversational outputs were clinically accurate. In addition to providing standardized education, the RENEWAL framework delivers personalized behavioral health coaching tailored to individuals' reported symptoms. Specifically, the system adapts behavioral goals based on the participants' reported symptoms at baseline. To ensure safety, the system is governed by guardrails that prevent the LLM from engaging in clinical decision-making or medical diagnosis.

Overview of LLM Systems

An LLM-based behavioral intervention typically consists of a user environment, data inputs, the AI agent, and system outputs (Figure 1).

Figure 1. Overview of a large language model (LLM)–based behavioral intervention. This closed loop illustrates the dynamic interaction between the user, data inputs, the artificial intelligence (AI) agent, its underlying LLM, and system outputs.

User Environment

The user environment refers to the real-world context in which an individual interacts with the LLM system [25]. The environment includes contextual factors (eg, time of day, social setting, and symptoms) and behavioral factors (eg, physical activity, daily routines, and medication adherence) that influence both health status and device use patterns. In the RENEW-AI and RENEWAL projects, the user environment includes individuals living with SSc and their lived experience of the disease, including fluctuating symptoms and behaviors, which influence their interaction patterns with the AI health coach.

Data Inputs

Data inputs refer to the information collected from the user environment that the LLM system processes to generate system outputs [25]. The inputs may be structured (eg, survey responses) or unstructured (eg, text messages). In cases where passive data streams (eg, wearable sensor data) are incorporated, a preprocessing or translation layer is required for the LLMs to convert raw time-series data into structured features or text-based summaries that can be interpreted by the model as conversational context.

In RENEW-AI, primary data inputs consist of text messages entered by individuals with SSc through the chat functionality of the RENEW mobile app. In RENEWAL, additional input includes user-reported symptoms collected using survey data, which the system uses to provide disease-specific education and personalized health coaching.

AI Agent

An AI agent is an interactive system that receives data input, processes information, and generates output in response to user interactions [25].

In both RENEW-AI and RENEWAL, the LLM agent is a conversational health coach integrated into the RENEW mobile app. The function of the agent is determined by its underlying LLM program, components of which are described in the following subsection.

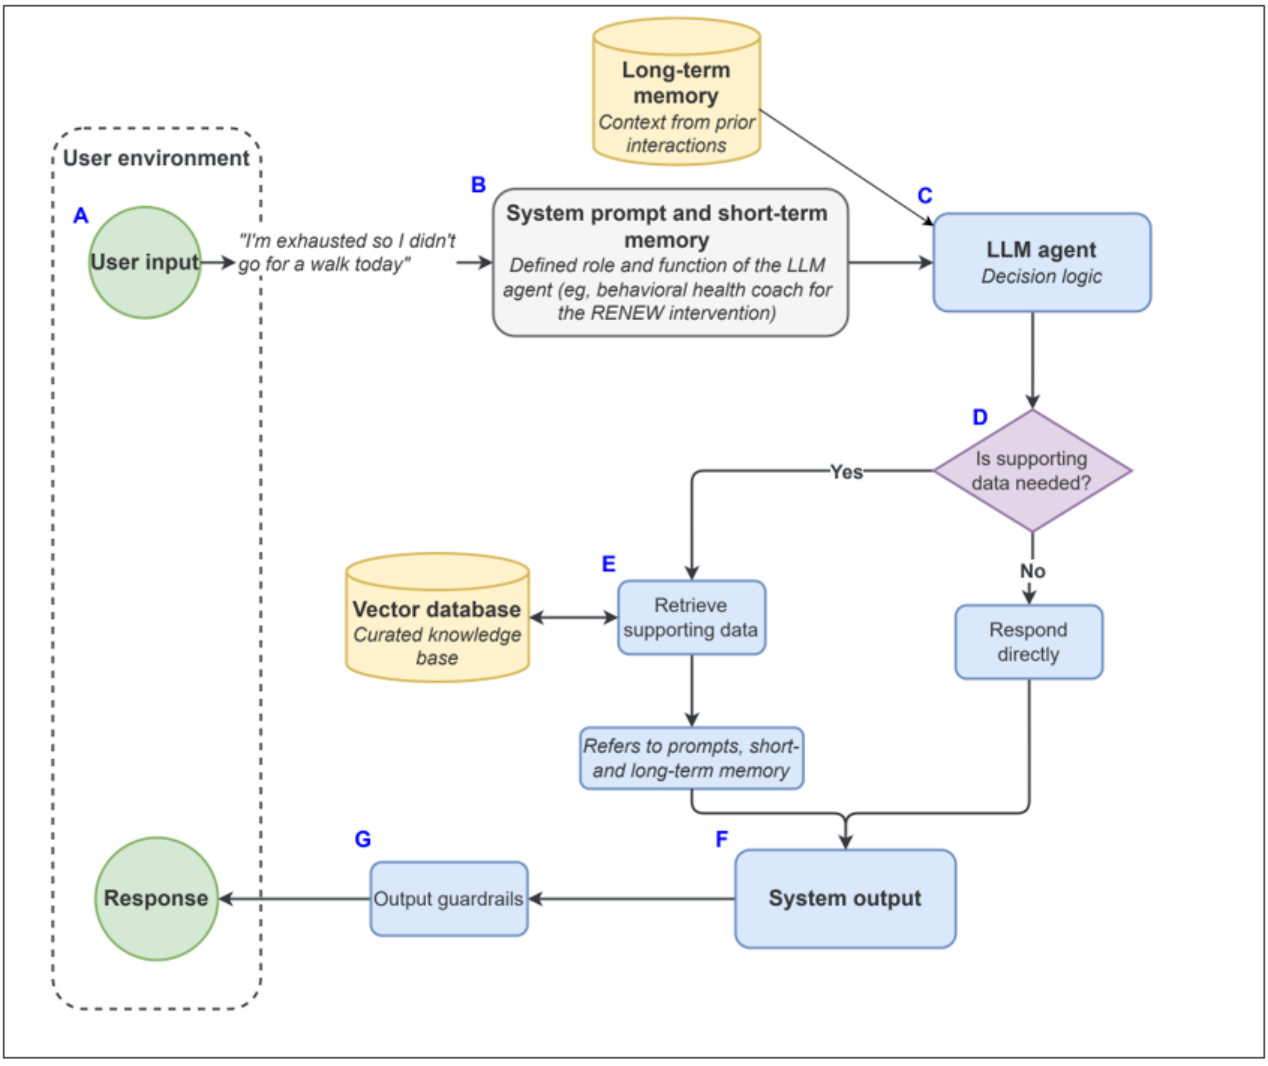
System Output

System output refers to the responses generated by the LLM agent and delivered to the user [25]. In LLM-based systems, system outputs are typically conversational text messages.

In both RENEW-AI and RENEWAL, system outputs include health coaching text responses designed to support reflection,

XSL•FO
RenderX

reinforce self-efficacy, and guide self-management behaviors. The system outputs of the LLM agent influence the user environment by shaping users' perceptions, motivation, and actions, thereby completing a feedback loop in which subsequent interactions generate new data inputs for the system.



LLM Agent and Programs

Overview

The operational architecture of an LLM-based behavioral intervention is driven by the LLM agent, the system's decision-making logic, and its underlying program, which provides the computational framework to generate natural language. While the agent serves as the system's "reasoning" layer, the underlying LLM program generates language by estimating the probability of the next unit of text (token) based on the preceding user context [21,26].

To describe the role of LLM agents and their underlying programs, we present the architectural configuration adopted in the RENEW-AI and RENEWAL projects. This configuration serves as a reproducible template for the design and implementation of future LLM-based behavioral interventions. As shown in Figure 2, the system workflow progresses through a series of components, from user input (A) to system output and guardrails (F-G).

Figure 2. Architectural workflow of the large language model–based behavioral intervention. Labeled components (A-F) correspond to key stages in the system, including (A) user input, (B) memory integration, (C) large language model (LLM) agent, (D) decision-making, (E) retrieval-augmented generation, (F) system output, and (G) output guardrails. RENEW: Resilience-Building Energy Management to Enhance Well-being.

User Input

This process is initiated within the user environment when a user provides input (eg, "I'm exhausted so I didn't go for a walk today"). This input serves as the primary data source for ongoing processing by the LLM system.

Prompting and Memory Integration

The user input is combined with system-level instructions and contextual information.

System-level instructions are given through a process called "prompting." Prompting refers to the specification of instructions, roles, tone, boundaries, and output expectations provided to an LLM [27,28]. Prompting can be done either

XSL•FO
RenderX

using instructions alone (zero-shot prompting) or using a combination of instructions and examples of input-output pairs (few-shot prompting). This approach allows the model to respond in a consistent manner without modifying the model's underlying parameters [22]. For behavioral interventions, prompt design may include the LLM's role (eg, behavioral health coach using motivational interviewing principles), interaction style (eg, empathic and reflective), and explicit boundaries (eg, avoiding medical advice or diagnosis). In the RENEW-AI and RENEWAL projects, the system prompts defined the model as a supportive peer health coach that used motivational interviewing techniques and reflective listening. The prompts also included explicit instructions to avoid making medical diagnosis or treatment recommendations.

Contextual information is provided to the system using short-term memory (current conversation history) and long-term memory (user summaries from prior interactions). The context window in an LLM system refers to the model's working memory, that is, the total volume of information the model can consider at a given time during a conversation. This typically includes data inputs, prompt instructions, context from the current conversation, and context from accumulated conversation history. Information that exceeds the context window is no longer available to the model's immediate processing unless it is explicitly reintroduced or stored through system-level mechanisms. For behavioral interventions, the standard context window (short-term memory) may be insufficient. Consequently, LLM systems may incorporate long-term memory mechanisms, such as external databases to store past interactions, allowing the agent to selectively retrieve and use relevant historical context in conversations [26]. While user summaries can improve contextual continuity in conversations, overreliance on user summaries may introduce the risk of information degradation over time. Repeated summarization of prior interactions may lead to loss of nuance, emotional context, or specific behavioral details, which are often critical in behavioral health settings. Therefore, systems incorporating long-term memory should consider strategies to preserve important contextual information, such as periodic reference to current interaction data or structured storage of key variables [26].

In the RENEWAL project, the model's context window includes the system prompt (defining the health coach's role and persona), the current session's conversation history (short-term memory), and retrieval-augmented generation (RAG)–retrieved documents (disease-specific information pulled from a curated knowledge base). This is supplemented by long-term memory in the form of user summaries, which are a running update of the user's history, health goals, symptoms, and recurring topics. This summary is stored in the database and included in the context window for future sessions.

LLM Agent and Decision-Making

The user input integrated with system-level prompts and contextual memory is processed by a large neural network (the LLM agent), which uses its transformer architecture to generate contextually relevant text responses [21]. At this stage, the system determines whether additional supporting information is required to generate an appropriate response.

In the RENEW-AI and RENEWAL projects, rather than training a model from scratch, we used a proprietary GPT model available through our university (University of Michigan; UM). While the full architectural background of these models is not yet disclosed, it is known that the GPT family is built upon transformer-based systems described above. To integrate UM-GPT4o into our intervention, we accessed it through application programming interfaces (APIs), which act as a secure data bridge between the mobile app or mHealth intervention and the institutional AI platform. Using a proprietary model via API allowed our study participants to have bidirectional conversations with our LLM-based health coach while substantially reducing the technical complexity, development time, and computational cost for our project. Because the base model's internal weights were fixed, we focused on safety, clinical relevance, and narrowing the model's general capabilities to the specific goals of our intervention through refinement of instructional prompts, grounding data, and output guardrails.

RAG and the Vector Database

RAG is an architectural approach that supplements an LLM's internal knowledge with an external library or curated knowledge base [29]. This mechanism allows the system to ground its responses in verified intervention materials, thus maintaining clinical accuracy and mitigating the risk of hallucinations (when a model produces factually incorrect information). When the LLM agent receives data input from the user and determines that additional supporting information is needed, it initiates a multistep retrieval process. First, the system converts the user's text into a numerical representation called an embedding. This embedding is then used to perform a similarity search within a vector database containing the preindexed RENEW program materials and user summaries. The system then retrieves the most relevant "chunks" of text, often referred to as the "top-k" units, and appends them to the prompt. This grounding process increases the likelihood that responses are informed by established clinical protocols and historical user context rather than general probabilistic patterns. However, RAG does not fully eliminate hallucinations, as models may still misinterpret retrieved information or fail to appropriately incorporate provided context. Therefore, RAG can be viewed as a mitigation strategy that improves response reliability but does not replace the need for additional safeguards, such as prompt constraints and output guardrails.

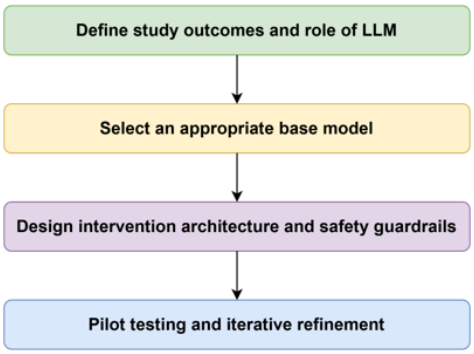
System Output

Based on the user input and integrated context (prompt, memory, and optional retrieved content), the LLM generates a response or system output. In the RENEW framework, the system output was intended to support reflection, reinforce self-efficacy, and guide behavioral decision-making.

Output Guardrails

The output guardrails refer to mechanisms designed to constrain the system's response to ensure safety, clinical appropriateness, and adherence to ethical boundaries. Because LLMs generate

XSL•FO
RenderX



responses probabilistically, they are prone to hallucinations, but using guardrails at the levels of data input, system prompts, and output can help reduce the risk of hallucinations.

In the RENEW framework, data inputs are scanned for indicators of self-harm (guardrails at the level of data input). If high-risk language is detected, the system directs the user to appropriate professional resources or emergency services. At the prompt level, safety is maintained through prompts (ie, role-definition and RAG-grounding). Finally, at the output level, system responses are flagged if clinical recommendations fall outside RENEW's scope (eg, specific dosage recommendations or diagnostic statements). Together, this ensures that the system output remains ethically sound and clinically safe. The system output completes the feedback loop by providing a grounded, supportive coaching response, which influences the user's behavior and thereby the user's next interaction with the LLM.

A Practical Design Workflow for LLM-Based Behavioral Interventions

Building on our experience with the RENEW-AI and RENEWAL projects, we propose a 4-phase design workflow to guide the development of LLM-based behavioral interventions (Figure 3).

Figure 3. Design workflow for large language model (LLM)–integrated behavioral interventions.

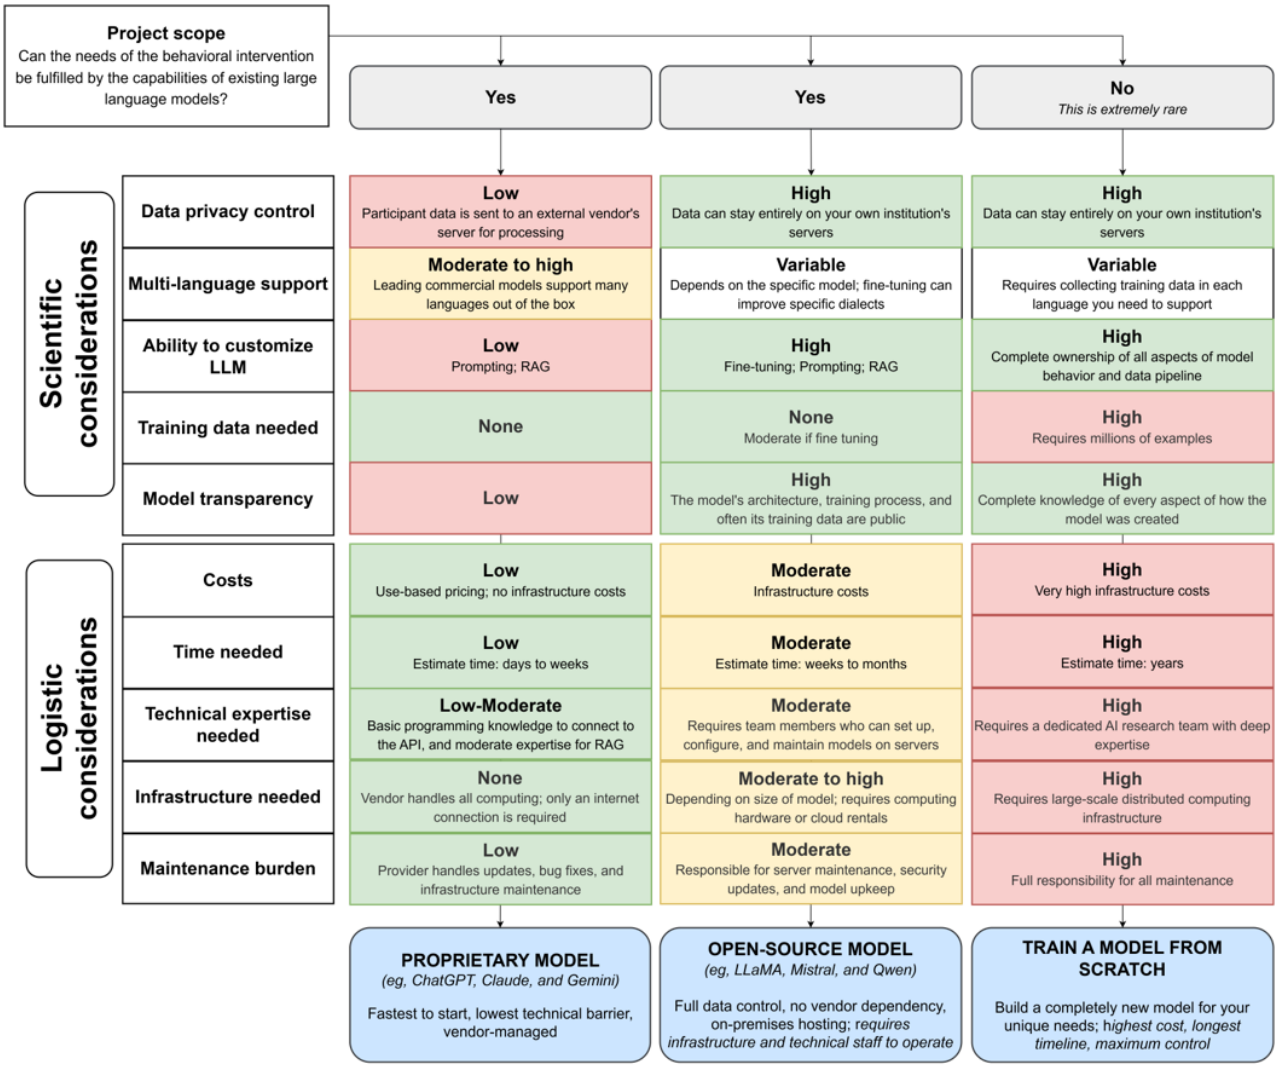
At the time of writing, our work reflects early implementation efforts, including system design, pilot testing, and initial participant engagement, rather than completed efficacy trials. Accordingly, we present this workflow as a structured approach to early-stage development and responsible integration.

Define Study Outcomes and the Role of LLM

The first step in integrating an LLM into a behavioral intervention is to clarify its intended behavioral role. Researchers should define the specific function of the model, such as providing reflective coaching, delivering structured education, reinforcing goal setting, or supporting motivational processes. Equally important is explicitly stating what the model is not intended to do, including offering medical diagnoses or treatment recommendations. In parallel, researchers should define the study's primary and secondary outcomes and articulate how LLM integration is hypothesized to influence those outcomes. These may include direct clinical outcomes, such as, fatigue severity, physical activity, and causal mechanisms (eg, engagement, self-efficacy, or adherence).

Selection of an Appropriate Base Model

Once the LLM's role and outcomes are clearly defined, researchers can determine the appropriate technical strategy. This includes selecting the appropriate LLM for the behavioral intervention. As described earlier, our team adapted a proprietary LLM to function as a digital health coach for individuals with SSc [24]. One of the most consequential decisions in this process was selecting the type of LLM to use.



For our project, we began by asking, "Can the needs of our behavioral intervention be fulfilled by the capabilities of existing LLMs?" From there, we reflected on a series of scientific and logistical considerations. Scientifically, we considered issues such as data privacy, control over participant interaction data, the language and tone required for the intervention, the specific role the LLM was expected to play, the extent to which the model would need to be customized, training data needed to refine the model's response, and finally, implications for transparency and reproducibility of our scientific methods. Logistically, we considered practical constraints including cost and available research funding, development timelines, access to technical expertise, infrastructure requirements, and our capacity to host and maintain an LLM-based intervention over time. Together, these considerations shaped our decision-making process and informed how we ultimately integrated UM-GPT4o into the RENEW platform.

As shown in Figure 4, integrating LLMs into behavioral interventions typically involves choosing among 3 approaches: using a proprietary model (eg, GPT-4o and Google Gemini), fine-tuning and hosting an open-source model (eg, Llama and Mistral), or training a foundational model from scratch. The appropriate choice depends on the intervention's goals, privacy requirements, available expertise, and resource constraints. For many behavioral research teams, adapting an existing proprietary or open-source model is the most practical and scientifically reasonable option. Although training a model from scratch offers the highest degree of control over model behavior and data pipelines, it generally requires substantial data, infrastructure, and specialized expertise. In contrast, hosting and fine-tuning an open-source model allows data to remain on institutional servers and provides greater control over model versioning and updates, which may support reproducibility in research settings. This approach, however, requires institutional infrastructure and technical personnel capable of deploying, maintaining, and securing the system over time. Finally, proprietary models have

XSL•FO
RenderX

the lowest technical barrier and minimal infrastructure requirements. They can typically be integrated into existing mHealth platforms relatively quickly and without significant upfront investment in computing resources, which makes them well-suited for pilot studies or early-stage development. However, this convenience may come with reduced transparency regarding model architecture and training data, and less direct control over how updates are managed. Therefore, selecting an appropriate LLM is a methodological decision that balances scientific and logistical considerations within the realities of a given intervention.

Figure 4. Considerations for deciding what type of large language model (LLM) is most suited for a behavioral intervention. AI: artificial intelligence; API: application programming interface; RAG: retrieval-augmented generation.

Design Intervention Architecture and Safety Guardrails

After selecting the model, attention shifts to architectural design. This includes developing prompting strategies that define the LLM's role, tone, and boundaries, as well as implementing guardrails to mitigate risks such as inappropriate medical advice or failure to detect crisis language. Furthermore, decisions related to short-term context windows, long-term memory mechanisms (eg, user summaries), and RAG need to be made. These architectural choices directly influence personalization, safety, and reproducibility.

Regarding safety guardrails, researchers should consider safety risks related to inappropriate or out-of-scope responses and the potential for algorithmic bias arising from training data used in both proprietary and open-source models. Because LLMs are trained on large-scale datasets that may reflect historical and societal biases, model outputs may differentially represent or respond to users based on factors such as language, culture, gender, or health status. In behavioral health contexts, such biases may influence user engagement, perceived empathy, and the relevance of behavioral recommendations, potentially contributing to inequities in intervention delivery and outcomes. Therefore, researchers should consider strategies to identify and mitigate bias, including diverse evaluation samples, human review processes, and ongoing monitoring of model performance across user subgroups.

Pilot Testing and Iterative Refinement

The final phase involves pilot testing, evaluation, and iterative refinement of the intervention. Depending on the stage of development, researchers may consider feasibility studies, pilot randomized trials, or hybrid effectiveness-implementation

XSL•FO
RenderX

designs to assess clinical outcomes and implementation factors, such as adoption, usability, and sustainability. Aligning early system evaluation with these study designs may support the translation of LLM-based interventions into rigorous behavioral and clinical research. A human-in-the-loop review may be important in early implementation to assess response quality, empathic tone, clinical alignment, and safety adherence. Additionally, user-centered design, such as usability testing and iterative feedback from users, may help ensure that these interventions are acceptable, understandable, and responsive to the needs of the target population.

While evaluation metrics for LLM-based behavioral interventions are still evolving, a combination of automated technical assessment with human-centered evaluation is increasingly used in practice [30,31]. For the RENEW intervention, automated evaluation included a structured assessment of response quality to examine relevance, hallucination, and completeness of retrieved data. In parallel, human evaluation included clinician review of responses for fidelity to behavioral strategies (eg, alignment with motivational interviewing principles), as well as assessment of empathic tone, clarity, and clinical appropriateness.

Conclusions

LLMs offer new opportunities to enhance personalization and adaptability in digital behavioral interventions. However, integrating LLMs into behavioral interventions requires deliberate architectural, methodological, and ethical decision-making. This viewpoint provides a structured synthesis of LLM foundations tailored to behavioral science, translates technical concepts into intervention-relevant design considerations, and grounds these principles in an applied case example. By combining conceptual explanation with practical implementation experience, we aim to offer behavioral researchers a clear and actionable framework for early-stage LLM integration. Along with these strengths, several limitations should be acknowledged. First, the RENEW-AI and RENEWAL projects are in the early stages of implementation, with formal evaluations of effectiveness, safety, and long-term engagement ongoing and therefore not included in this paper. Second, this framework focuses specifically on LLM-based systems and may not generalize to other AI approaches, such as reinforcement learning or unsupervised modeling. Third, although we describe architectural safeguards and grounding mechanisms, ongoing monitoring for model drift, hallucinations, and potential biases across demographic groups is not elaborated on in this paper.

Acknowledgments

The authors would like to thank Dr Amy Bucher, Chief Behavioral Officer at Lirio, for generously reviewing our manuscript and providing valuable feedback on its technical accuracy. ChatGPT (GPT-4o; OpenAI) was used to assist with improving the clarity and flow of the written text.

Data Availability

The manuscript discusses the author's experiences in integrating artificial intelligence (AI) into a behavioral intervention. No datasets were used in the preparation of this work. There are no associated datasets available for this manuscript.

Funding

NS is funded by the Rheumatology Research Foundation Scientist Development Award (Identifier No. 1346603). No other external financial support or grants were received from any public, commercial, or not-for-profit entities for the research, authorship, or publication of this article.

Authors' Contributions

NS conceptualized the paper and drafted the original manuscript. DP and MM assisted with the visualizations. AC contributed to the technical accuracy of the content, and SM and LB reviewed and provided feedback on the overall manuscript. All authors have read and approved the final version of the manuscript.

Conflicts of Interest

LB, the second author of this manuscript, serves as editor-in-chief of *JMIR mHealth* and *uHealth*. All other authors declare no other conflicts of interest.

Abstract

Background: Liver transplant candidates and recipients require continuous care throughout the transplant trajectory, including pretransplant prehabilitation and long-term posttransplant management. Conventional care models are constrained by time, distance, and limited health care resources and may therefore be insufficient to meet patients' needs across the continuum of care. Digital health technologies offer new approaches to remote care delivery and self-management support in liver transplantation.

Objective: This scoping review aimed to map the technological modalities, intervention components, outcome measures, and implementation issues associated with digital health technologies used across the care continuum for adult liver transplant candidates and recipients and to identify gaps for future digital continuity-of-care research.

Methods: Nine English- and Chinese-language databases—PubMed, Embase, CINAHL, Web of Science, the Cochrane CENTRAL, CNKI, Wanfang Data, VIP Database, and SinoMed—were searched from inception through July 10, 2026. Original quantitative, qualitative, and mixed methods studies involving adult liver transplant candidates or recipients and the use of digital health technologies for care beyond conventional in-person settings were eligible. The review followed the Arksey and O'Malley framework, was refined using the Joanna Briggs Institute methodology for scoping reviews, and was reported in accordance with the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) guidelines.

Results: The search identified 7746 records, and 28 studies were included. Telehealth platforms or remote management systems were used in 24 studies, and remote education was included in 22 studies. From the 28 studies, 5 focused on pretransplant/candidacy, 9 focused on early posttransplant recovery, 4 focused on long-term survivorship, 8 were cross-stage/mixed, and 2 had unspecified posttransplant timing. No study focused only on the perioperative/inpatient-to-home transition stage. A total of 9 randomized intervention studies were identified. Among these studies, positive findings were more common for medication or treatment adherence, self-management, health behaviors, psychological outcomes, and selected health service outcomes. Results were less consistent for quality of life, physiological outcomes, and functional outcomes. From the 28 studies, 15 reported implementation-related outcomes. Reported barriers included limited device access, privacy concerns, limited uptake, and difficulties with sustained engagement.

Conclusions: Current evidence is concentrated in early posttransplant recovery. Evidence across transplant stages and outcome domains is uneven. Studies focused on the perioperative/inpatient-to-home transition stage are lacking. Future studies should use multicenter designs and standardized outcome measures; include longer follow-up; and evaluate implementation, equitable access, and costs.

Introduction

Background

Liver transplantation (LT) is a definitive treatment for a range of end-stage liver diseases [1,2]. Advances in surgical techniques, perioperative management, and immunosuppressive therapy have substantially improved posttransplant survival [3]. A 50-year dataset from the European Liver Transplant Registry, covering 169 centers in 32 countries, showed overall survival rates of 83% at 1 year and 61% at 10 years after LT [4]. Despite its lifesaving potential, LT entails lifelong immunosuppressive therapy and persistent risks of acute rejection and multisystem complications [5,6]. Many recipients also face substantial financial burdens, barriers to resuming social roles, and other psychosocial and practical challenges [7]. Long-term health management across the posttransplant trajectory is therefore essential. Continuity-of-care interventions may strengthen self-management, support rehabilitation and social reintegration, and improve quality of life (QoL) among liver transplant recipients [8].

Continuity-of-care extends professional health care services from the hospital to patients' homes and communities, enabling patients to receive coordinated and ongoing support after discharge and helping to address their out-of-hospital care needs [9,10]. Evidence suggests that high-quality continuity-of-care interventions can improve self-management and, ultimately, health outcomes and QoL [11]. In LT, the care continuum spans the pretransplant waiting period, the early posttransplant transition, out-of-hospital rehabilitation, and lifelong follow-up [12]. Liver transplant candidates may experience advanced disease, complications, and psychological distress, requiring continued monitoring and support [13,14]. After transplantation, recipients remain at risk of rejection and other short-term and long-term complications and require continued follow-up and self-management support [15]. Including both candidates and recipients allows digital health applications to be examined across the full transplant trajectory. Current continuity-of-care models for liver transplant candidates and recipients continue to rely primarily on outpatient follow-up, supplemented by telephone follow-up and home visits [6]. These approaches are constrained by high outpatient workloads, geographic and temporal barriers, incomplete follow-up information, and substantial time and financial costs [16].

Digital health technologies, including telehealth, mobile apps, wearable devices, and remote monitoring systems, provide new ways to deliver care outside conventional clinical settings [17-19]. In transplantation, these technologies can support remote monitoring, follow-up, education, and communication between patients and health care professionals [20]. Evidence from solid organ transplantation suggests that digital health may support medication adherence, self-management, and selected clinical outcomes [21]. A recent scoping review by Gao et al [22] summarized the modalities, intervention components, and outcomes of telehealth used in home-based care for adult liver transplant recipients, providing an initial evidence base for the use of digital technologies in this field.

Despite growing evidence of the potential value of mobile health (mHealth) in the continuity of care for LT, existing research has focused predominantly on posttransplant recipients and has largely consisted of single-center studies with small samples. The literature is further characterized by limited use of theoretical frameworks, fragmented technological approaches, substantial heterogeneity in intervention components, and insufficient coverage of the full transplant trajectory.

Objectives

This scoping review aimed to map the current use of digital health technologies in continuity of care across the liver transplant trajectory. Specifically, we sought to (1) identify the principal technological modalities, intervention components, and outcome measures reported for pretransplant candidates and posttransplant recipients; (2) examine the advantages, implementation limitations, and appropriate care contexts of different digital health approaches; and (3) identify gaps in theoretical grounding, intervention design, outcome evaluation, and clinical translation to inform the development of specialty-specific digital continuity-of-care models for LT.

Methods

Study Design

This scoping review systematically mapped and synthesized evidence on the use of digital health technologies to support continuity of care across the liver transplant trajectory. The review was conducted according to the framework developed by Arksey and O'Malley [23], informed by updated methodological guidance from the Joanna Briggs Institute (JBI) [24], and reported in accordance with the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) guideline (Checklist 1) [25]. A review protocol was not prospectively registered.

Search Strategy

An initial PubMed search was used to identify relevant terms and refine the search strategy. Reference lists of relevant studies were also hand searched. A total of 9 electronic databases were searched from inception through July 10, 2026: PubMed, Embase, CINAHL, Web of Science, Cochrane CENTRAL, CNKI, Wanfang Data, VIP Database, and SinoMed. Search concepts were developed using the PCC (population, concept, and context) framework. MeSH and free-text terms were combined using Boolean operators, truncation, and wildcard symbols. The complete database-specific search strategies are provided in Multimedia Appendix 1.

Inclusion and Exclusion Criteria

The inclusion criteria were developed according to the PCC framework recommended by the JBI as follows:

- Population: studies involving liver transplant candidates or recipients aged 18 years or older were included.
- Concept: original empirical studies evaluating the application of digital health technologies in continuity of care for LT were included. Relevant technologies included mobile apps, telehealth or web-based platforms,

XSL•FO
RenderX

internet-based communication technologies, remote monitoring or wearable devices, intelligent robots, and other digital technologies used to support continuity of care. These technologies were used for education, monitoring, consultation, self-management, rehabilitation, or psychosocial support.

- Context: studies conducted across the liver transplant care continuum in clinical, home, community, or virtual settings were eligible. Care could be delivered remotely or through hybrid online and face-to-face models and could occur before or after transplantation. Eligible contexts included pretransplant care, hospital-to-home transition, postoperative recovery, and long-term follow-up.

Original empirical studies using quantitative, qualitative, or mixed methods were included. Eligible study designs included randomized controlled trials (RCTs), nonrandomized intervention studies, observational studies, feasibility studies, pilot studies, technology development and user evaluation studies, and qualitative studies.

We excluded studies that (1) were reviews, study protocols, case reports, conference abstracts, editorials, commentaries, or letters; (2) involved only liver transplant recipients younger than 18 years or did not allow separate extraction of data for adult participants; (3) involved multiple organ transplant populations and did not allow separate extraction of liver transplant–specific data; (4) used digital technologies solely for research data collection rather than for the provision of patient care, health management, or continuity of care; (5) used digital technologies only for medical imaging, disease diagnosis, surgical navigation, organ allocation, risk prediction, or other technological applications unrelated to continuity of care in LT; or (6) were duplicate publications.

Study Selection

After duplicate records were removed using EndNote 2025 (Clarivate), 2 reviewers (SWQ and LYY) independently screened titles and abstracts and subsequently assessed the full texts against the eligibility criteria. A third reviewer (LJH) verified the search strategy and the final inclusion and exclusion decisions. Disagreements were resolved through discussion among the 3 reviewers.

Data Analysis and Synthesis

Two reviewers (SWQ and LRY) independently extracted and cross-checked study-level data using a standardized Microsoft Excel worksheet developed by the review team. Extracted data included study characteristics, participants, transplant timing, intervention and comparator characteristics, digital technologies, intervention content, outcomes, study findings, and implementation-related information. Two additional reviewers (LJH and CZJ) checked the extracted data for completeness and consistency. Disagreements were resolved by discussion, with SJ acting as an adjudicator when required.

The analytical categories for technology modalities, intervention components, outcome domains, and transplant trajectory stages were not prespecified. Consistent with JBI guidance, they were developed iteratively after review of all included studies and relevant literature [24,26]. Recurring characteristics were grouped into conceptually similar categories through team discussion. Technology modalities were classified by digital delivery medium, intervention components by clinical or supportive function, and outcomes by the constructs measured. Multiple coding was allowed because studies could include more than one technology, component, or outcome.

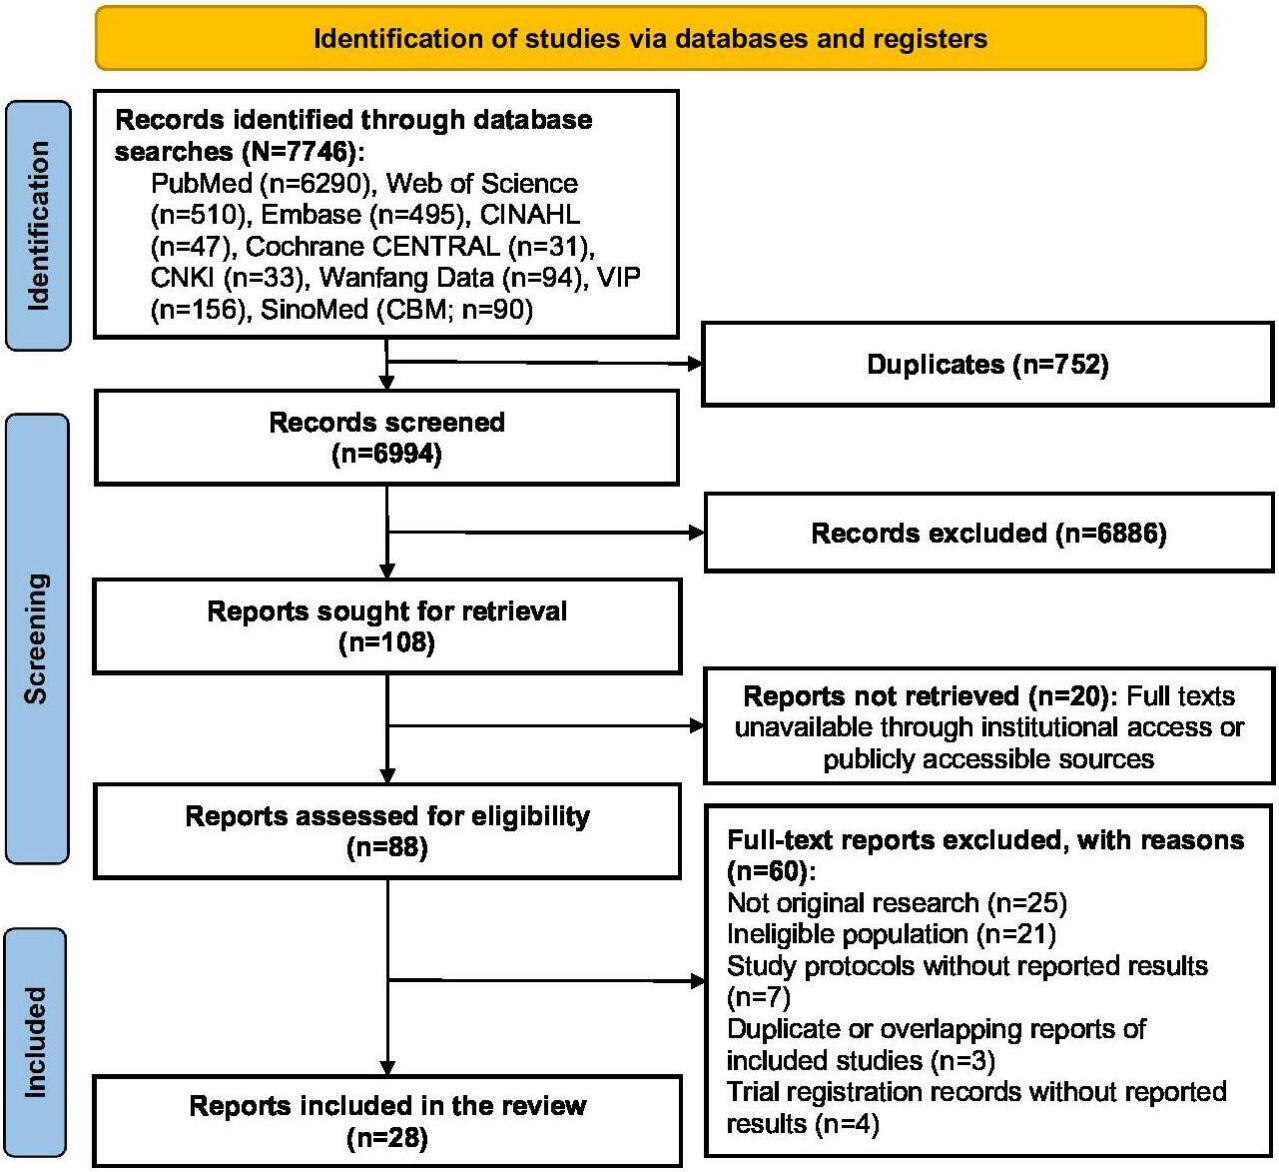
For stage-specific mapping, an additional coding framework was developed to locate each intervention along the liver transplant trajectory. Stage assignment was based primarily on participants' transplant status at the initiation of the intervention and the intended context in which the intervention was delivered, rather than on the final follow-up time point. The pretransplant/candidacy stage included transplant evaluation, wait-list management, decision support, and prehabilitation before LT. The perioperative/inpatient-to-home transition stage encompassed interventions actively delivered during the index transplant hospitalization, postoperative inpatient recovery, discharge planning, and transition to home. Technology onboarding or training performed immediately before discharge was not, by itself, considered a perioperative intervention when the substantive digital care began after discharge. Early posttransplant recovery was operationally defined as interventions initiated after discharge and targeting care within the first posttransplant year. Long-term posttransplant survivorship was defined as interventions initiated at or beyond 1 year after LT or interventions clearly targeting stable long-term recipients whose reported posttransplant timing was consistent with a survivorship context. The 1-year threshold was used as an analytical anchor rather than a biological cutoff and was informed by posttransplant survivorship literature [27,28]. The perioperative/inpatient-to-home transition stage was defined by clinical events rather than a fixed postoperative interval [29,30]. Studies in which the intervention or study population spanned more than one stage and stage-specific findings could not be separated were classified as cross-stage/mixed. If a study involved posttransplant recipients but did not report sufficient information to determine intervention timing, the stage was coded as not specified rather than inferred.

No formal critical appraisal or risk-of-bias assessment was performed. Evidence from different study designs was synthesized descriptively and interpreted according to the study design. The findings were not used to establish evidence certainty or rank intervention effectiveness.

Ethical Considerations

Ethical approval was not required because this scoping review used data from published studies and did not involve the collection of primary data from human participants.

Results



Study Selection

The database searches identified 7746 records. All records were imported into EndNote 2025, and 752 (9.71%) duplicates were removed, leaving 6994 records for title and abstract screening. Two reviewers (SWQ and LYY) independently screened these records against the eligibility criteria, and 6886 (98.46%) records were excluded. Of the 108 reports sought for retrieval, 20

XSL•FO
RenderX

full-text reports could not be obtained through the institutional or publicly accessible sources available at the time of screening, leaving 88 reports for full-text eligibility assessment. Of these, 60 were excluded because they were not original research (n=25), involved an ineligible population (n=21), were study protocols without reported results (n=7), were duplicate or overlapping reports of included studies (n=3), or were trial registration records without reported results (n=4). A total of 28 studies were included in the review. Figure 1 presents the PRISMA-ScR flow diagram.

Figure 1. PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) flow diagram.

Study Characteristics

The extracted data were synthesized to characterize the included studies by author, publication year, country, study design, sample size, participant age, comparator, intervention technology, and reported outcomes. Because of substantial heterogeneity in study designs and outcome reporting, a meta-analysis was not appropriate; findings were therefore synthesized narratively and summarized in tables.

The characteristics of the 28 included studies are summarized in Table 1. The 28 included studies were published between 2012 and 2026, with 16 (57.1%) published in 2021 or later. The studies were conducted in seven countries. The United States and China contributed the largest number of studies (n=11 each, 39.3%), followed by Australia (n=2, 7.1%). Austria, Belgium, Brazil, and Turkey each contributed 1 (3.6%) study.

Table . General characteristics of the included studies (N=28).

Study/year/country	Study design	Transplant trajectory stage	Population	Duration	Sample size	Age
Knihs et al [31], 2024, Brazil	Technological product development and validation study	Posttransplant timing unspecified	Patients who underwent LT[a], nurses, and IT professionals	Not applicable	28 participants (17 patients, 7 nurses, and 4 IT professionals)	Patients: 16 - 76 years; professionals: 23 - 47 years
Hickman et al [32], 2019, Australia	Qualitative study	Long-term survivorship	Adult LT recipients ≥12 months posttransplant	Not applicable	28	Mean 53 (SD 13; range 24 - 68) years
Goswami et al [33], 2024, United States	Pilot study	Cross-stage/mixed	LT candidates and recipients with ALD[b]/AUD[c]	12 weeks	42 (23 pretransplant/evaluation; 19 posttransplant)	Median 49 (IQR 39 - 63) years
Andrä et al [34], 2022, Austria	Single-center cohort study	Cross-stage/mixed	Liver transplant recipients enrolled in an outpatient aftercare program	2 months	124 (42 app users; 82 nonusers)	Entire cohort: 63.2 (range 19 - 76) years; app users: 55.4 years
Delman et al [35], 2021, United States	Retrospective cohort study	Cross-stage/mixed	Adult OLT[d] recipients	6-month follow-up	344 (274 pre–COVID-19; 70 COVID-19 era)	Pre–COVID-19: mean 53.2 (SD 17.1) years; COVID-19 era: mean 56.2 (SD 10.9) years
Lee et al [36], 2019, United States	Randomized controlled trial	Early posttransplant	Adult liver transplant recipients aged 18 years or older	90-day intervention; follow-up to 180 days	106 randomized; 100 completed and analyzed (50 intervention; 50 control)	Intervention: median 58.5 (IQR 51 - 65) years; control: median 60 (IQR 56 - 65) years
Tian et al [37], 2021, China	Cohort study	Early posttransplant	Adult OLT recipients	2-week intervention; 12-month follow-up	110 enrolled; 102 analyzed (52 telemedicine; 50 usual care)	Overall: mean 46.65 (SD 9.66) years; telemedicine: mean 45.35 (SD 10.44) years; usual care: mean 48.00 (SD 8.68) years
Koc et al [38], 2022, Belgium	Prospective cohort study	Long-term survivorship	Stable adult liver transplant recipients at least 12 months posttransplantation	Median follow-up approximately 2 years	115 (87 remote monitoring; 28 standard follow-up)	Median: autonomous remote monitoring 59.1 years; nonautonomous remote monitoring 67.2; standard follow-up 66.0
Volk et al [39], 2014, United States	Pilot pre-post study	Pretransplant/candidacy	Adult liver transplant candidates	Mean completion time 15 (range 7 - 28) minutes	56 enrolled; 53 completed	Median 56 (range 20 - 67) years
Bailey et al [40], 2017, United States	Randomized controlled trial	Pretransplant/candidacy	Adult patients awaiting LT and caregivers	8-week intervention; follow-up to 12 weeks	115 (56 SMI[e]; 59 LDE[f])	Self-management intervention: mean 56.4 (SD 9.9) years; education: mean 55.6 (SD 10.0) years
Konjeti et al [41], 2019, United States	Retrospective cohort study	Pretransplant/candidacy	Adult veterans referred for OLT evaluation	Not applicable	190 (91 telehealth evaluation; 99 direct referral)	Telehealth: 60.1 years; direct referral: 60.0 years
Hickman et al [42], 2021, Australia	Randomized feasibility study	Long-term survivorship	LT recipients ≥6 months posttransplant	12 weeks	35 (23 intervention; 12 delayed-intervention control)	Intervention: 50±15 years; control: 51±15 years

[a]LT: liver transplantation.

[b]ALD: alcohol-related liver disease.

[c]AUD: alcohol use disorder.

[d]OLT: orthotopic liver transplantation.

[e]SMI: self-management intervention.

[f]LDE: liver disease education.

[g]MASLD: metabolic dysfunction-associated steatotic liver disease.

[h]DCD: donation after cardiac death.

A wide range of study designs was represented, including 7 (25.0%) RCTs, 2 (7.1%) randomized feasibility/pilot feasibility trials, 6 (21.4%) cohort studies, 4 (14.3%) quasi-experimental or single-group pre-post studies, 3 (10.7%) pilot studies, 2 (7.1%) single-arm feasibility studies, 2 (7.1%) technology development and preliminary application or validation studies, 1 (3.6%) cross-sectional model development and internal validation study, and 1 (3.6%) qualitative study.

With respect to the comparative structure, 17 (60.7%) studies included a distinct comparator group, such as a randomized concurrent control group, a nonrandomized concurrent comparator group, or a historical comparator group. An additional 5 (17.9%) studies used a single-group pre-post design. The remaining 6 (21.4%) studies included neither an external comparator group nor a formal pre-post comparison and primarily focused on technology development and validation, qualitative exploration, cross-sectional model development, or single-arm feasibility and implementation assessment.

According to the transplant trajectory classification, 5 studies focused on the pretransplant/candidacy stage [39-41,45,46], 9 on early posttransplant recovery [36,37,44,53-58], 4 on long-term survivorship [32,38,42,48], 8 were classified as cross-stage/mixed [33-35,43,47,49,51,52], and 2 involved posttransplant recipients for whom intervention timing was not specified [31,50]. No study focused exclusively on the perioperative/inpatient-to-home transition stage.

Modalities and Application Contexts of Digital Health Technologies for Liver Transplant Candidates and Recipients

Among the included studies, 5 principal digital health technology modalities were identified: mHealth apps (n=8), telehealth platforms or remote management systems (n=24), intelligent robots (n=3), portable wearable or mobile devices (n=4), and internet-based communication technologies (n=20). These categories were not mutually exclusive because individual interventions could use more than one modality. Telehealth platforms or remote management systems were the most frequently reported modalities. The identified technologies were used mainly for communication, monitoring, education, follow-up, rehabilitation, and self-management support (Table 2). One qualitative study [32] did not directly implement a digital health intervention and was excluded from the modality

XSL•FO
RenderX

counts; it was retained as complementary evidence on user needs and implementation context.

Table . Digital health technology modalities and core functions.

Technology modality	Number of studies, n	Forms	Core functions
Mobile health apps	8 [31,34,36,37,45,51,54,56]	Smartphone-based or tablet-based applications, including dedicated apps and WeChat-based apps	Education, medication management, diet and exercise guidance, health monitoring; rehabilitation, and self-management support
Telehealth platforms or remote management systems	24 [33-39,41-45,47-58]	Web-based or platform-based systems integrating video visits, communication, monitoring, assessment, and feedback	Communication, remote monitoring, alerts, clinical decision support, education, follow-up, and multidisciplinary support
Intelligent robots	3 [37,56,58]	Telemedicine or remote monitoring robots	Physiological data collection, video communication, individualized guidance, and abnormality feedback
Portable wearable or mobile devices	4 [36,42,44,45]	Smartwatches, activity trackers, Bluetooth-enabled monitoring devices, and home-based exercise devices	Physiological and activity monitoring, data transmission, reminders, goal setting, and remote feedback and rehabilitation
Internet-based communication technologies	20 [33,35-37,40-42,45,46,48-58]	Videoconferencing, web portals, WeChat, text messaging, and telephone calls	Consultation, education, test-result feedback, medication support, rehabilitation and lifestyle guidance, and psychosocial support

Core Intervention Components of Digital Health Technologies for Liver Transplant Candidates and Recipients

Five major intervention components were identified: remote education (n=22), remote data monitoring or health assessment (n=16), teleconsultation (n=14), psychosocial support (n=10), and remote rehabilitation or exercise guidance (n=8). These categories were not mutually exclusive, and their distribution varied across the transplant trajectory (Table 3). Early posttransplant recovery contained the broadest combination of components: all 9 studies included remote education, and 8 each included monitoring or health assessment and teleconsultation [36,37,44,53-58]. Pretransplant/candidacy interventions focused on education and decision support, psychosocial support, prehabilitation, and remote transplant assessment [39-41,45,46]. Long-term intervention studies emphasized remote monitoring, lifestyle management, and rehabilitation [38,42,48], whereas cross-stage/mixed studies used combinations of education, monitoring, teleconsultation, and psychosocial support [33-35,43,47,49,51,52]. No study focused exclusively on the perioperative/inpatient-to-home transition stage.

XSL•FO
RenderX

Table . Intervention components across the liver transplant trajectory.

Main intervention components	Number of studies, n	Main functions/content	Transplant trajectory distribution
Remote education	22 [31,33-37,39,40,42-46,48,49,52-58]	Transplant/disease education, medication use, diet and nutrition, complication prevention, self-monitoring, lifestyle management, decision support, relapse prevention, and peer/family education	• Early posttransplant: n=9 [36,37,44,53-58] • Cross-stage/mixed: n=6 [33-35,43,49,52] • Pretransplant/candidacy: n=4 [39,40,45,46] • Long-term survivorship: n=2 [42,48] • Posttransplant timing unspecified: n=1 [31]
Remote data monitoring or health assessment	16 [34,36-38,42,44,45,47,49-51,53,54,56-58]	Vital signs, glucose and weight, physical activity, laboratory/imaging results, immunosuppressant levels, liver function, frailty, and longitudinal health records	• Early posttransplant: n=8 [36,37,44,53,54,56-58] • Cross-stage/mixed: n=4 [34,47,49,51] • Long-term survivorship: n=2 [38,42] • Pretransplant/candidacy: n=1 [45] • Posttransplant timing unspecified: n=1 [50]
Teleconsultation	14 [35-38,41,49-51,53-58]	Remote assessment and follow-up, triage, test-result feedback, medication adjustment, and individualized clinical guidance	• Early posttransplant: n=8 [36,37,53-58] • Cross-stage/mixed: n=3 [35,49,51] • Pretransplant/candidacy: n=1 [41] • Long-term survivorship: n=1 [38] • Posttransplant timing unspecified: n=1 [50]
Psychosocial support	10 [33,40,46,48,49,52-54,57,58]	Illness uncertainty, emotional support, relapse prevention, coping and behavior change, and peer/family support	• Early posttransplant: n=4 [53,54,57,58] • Cross-stage/mixed: n=3 [33,49,52] • Pretransplant/candidacy: n=2 [40,46] • Long-term survivorship: n=1 [48]
Remote rehabilitation/exercise guidance	8 [37,42,45,48,49,54,56,57]	Exercise and prehabilitation, lifestyle/weight management, rehabilitation follow-up, individualized activity goals, and family-supported rehabilitation	• Early posttransplant: n=4 [37,54,56,57] • Long-term survivorship: n=2 [42,48] • Pretransplant/candidacy: n=1 [45] • Cross-stage/mixed: n=1 [49]

Outcome Measures and Effects of Digital Health Technologies

Across the 28 included studies, reported outcomes were mapped into 6 nonmutually exclusive domains: physiological or functional indicators, psychosocial outcomes, clinical and health service utilization outcomes, self-management-related outcomes, health-related QoL, and implementation-related outcomes or patient experience (Table 4). Self-management-related outcomes were most frequently assessed (17/28, 60.7%), followed by implementation-related outcomes or patient experience (15/28, 53.6%) and clinical or health service utilization outcomes (10/28, 35.7%). Physiological or functional indicators and health-related QoL were each reported in 7 (25.0%) studies, whereas psychosocial outcomes were reported in 5 (17.9%) studies. Because individual studies often assessed more than one outcome domain, studies could contribute to multiple categories.

XSL•FO
RenderX

Table . Outcome domains and their distribution across the liver transplant trajectory.

Outcome domain	Number of studies, n	Main measures/outcomes	Transplant trajectory distribution	Design representation
Physiological/functional indicators	7 [38,42,44,45,47,48,54]	Tacrolimus concentration, serum creatinine, vital-sign thresholds, body weight/BMI, fasting and postprandial glucose, Liver Frailty Index, 6-minute walk test, physical activity, and metabolic indicators	• Long-term survivorship: 3 • Early posttransplant: 2; Pretransplant/candidacy: 1 • Cross-stage/mixed: 1	• Randomized: 2 • Nonrandomized: 5
Psychosocial outcomes	5 [40,46,48,53,54]	Illness uncertainty, depression, anxiety, perceived stress, alcohol craving, abstinence self-efficacy, hope, confidence in behavior change, and emotional self-efficacy	• Pretransplant/candidacy: 2 • Early posttransplant: 2 • Long-term survivorship: 1	• Randomized: 4 • Nonrandomized: 1
Clinical and health service utilization outcomes	10 [33,35-38,41,44,46,50,54]	Readmission, length of stay, hospitalization/follow-up costs, outpatient utilization, complications, adverse events, rejection, graft/patient survival, alcohol relapse, and transplant evaluation/triage	• Early posttransplant: 4 • Pretransplant/candidacy: 2 • Cross-stage/mixed: 2 • Long-term survivorship: 1 • Posttransplant timing unspecified: 1	• Randomized: 3 • Nonrandomized: 7
Self-management-related outcomes	17 [34,36,39,40,42,43,45,46,48-50,52-57]	Disease/medication knowledge, organ-quality decision knowledge, medication and follow-up adherence, treatment adherence, self-efficacy, self-care, self-management behavior, and behavior-change confidence	• Early posttransplant: 6 • Pretransplant/candidacy: 4 • Cross-stage/mixed: 4 • Long-term survivorship: 2 • Posttransplant timing unspecified: 1	• Randomized: 9 • Nonrandomized: 8
Health-related quality of life	7 [36,40,42,49,52,53,55]	FACT-G[a], SF-12v2[b], SF-36[c], liver transplant-specific quality-of-life instruments, multidimensional physical, psychological, and social domains	• Early posttransplant: 3 • Cross-stage/mixed: 2; Pretransplant/candidacy: 1 • Long-term survivorship: 1	• Randomized: 5 • Nonrandomized: 2
Implementation-related outcomes and patient experience	15 [31,33,34,36,38,39,42,44-46,48,50,51,56,58]	Participation, attendance, completion, system mastery and use, consultations/messages, satisfaction, acceptability, usability, accessibility, and privacy and digital-access concerns	• Early posttransplant: 4 • Pretransplant/candidacy: 3 • Long-term survivorship: 3 • Cross-stage/mixed: 3 • Posttransplant timing unspecified: 2	• Randomized: 3 • Nonrandomized: 12

[a]FACT-G: Functional Assessment of Cancer Therapy-General.

[b]SF-12v2: 12-Item Short Form Health Survey, Version 2.

[c]SF-36: 36-Item Short Form Health Survey.

The distribution of outcomes varied across the transplant trajectory. In the pretransplant/candidacy stage, the evidence focused primarily on decision-related knowledge, self-management, psychosocial adjustment, alcohol-related behavior, frailty, and physical fitness. Early posttransplant studies covered the broadest range of outcomes, particularly medication adherence, self-care and self-management, readmission and other health service outcomes, physiological monitoring, psychological adjustment, and QoL. Long-term survivorship studies more often assessed lifestyle behavior, cardiometabolic or functional outcomes, self-management, and implementation-related experience. Cross-stage/mixed studies contributed mainly to self-management, clinical/service utilization, QoL, and technology-supported follow-up outcomes. No included study focused exclusively on the

XSL•FO
RenderX

perioperative/inpatient-to-home transition stage; this phase was represented only within broader cross-stage care models.

The strength and type of evidence also differed across outcome domains. Randomized studies accounted for 9 of the 17 studies assessing self-management-related outcomes and 5 of the 7 studies assessing health-related QoL. Psychosocial outcomes were also predominantly represented by randomized designs (4/5). In contrast, clinical and health service utilization outcomes (3/10, randomized), physiological or functional outcomes (2/7, randomized), and implementation-related outcomes or patient experience (3/15, randomized) were more frequently reported in nonrandomized, feasibility, pilot, cohort, or development-oriented studies. Accordingly, Table 4 is intended as an evidence map rather than an effectiveness summary. Detailed quantitative findings from randomized intervention studies are presented separately in the *Findings From Randomized Intervention Studies* section and Table 5, whereas quantitative findings from nonrandomized studies are summarized in the *Findings From Nonrandomized Studies* section and Table 6.

XSL•FO
RenderX

Table . Key findings from randomized intervention studies (n=9).

Study	Study design and transplant trajectory stage	Intervention and comparator	Main outcome(s)	Key quantitative and statistical findings
Lee et al [36], 2019	• Randomized controlled trial • Early posttransplant	Telemedicine-based home monitoring program vs standard care	Hospital readmission and HRQoL[a]	90-day readmission was lower with telemonitoring (28% vs 58%; *P*=.004). Physical functioning at 90 days also favored intervention (75 vs 60; *P*=.02), whereas most other SF-36[b] domains did not differ significantly
Bailey et al [40], 2017	• Randomized controlled trial • Pretransplant/candidacy	Telephone uncertainty self-management intervention vs liver-disease education	Illness uncertainty, depression, anxiety, uncertainty management, self-efficacy, and HRQoL	No significant between-group differences were found in illness uncertainty, depression, anxiety, self-efficacy, or FACT-G[c] QoL[d] at either follow-up (all *P*>.05)
Hickman et al [42], 2021	• Randomized feasibility study • Long-term survivorship	Telehealth-delivered Mediterranean diet + exercise program vs delayed-intervention control	Dietary adherence, anthropometric/metabolic outcomes, functional status, and HRQoL	MEDAS[e] change favored intervention (+2.4 vs −0.1; *P*=.004), as did MCS-12[f] (+2.8 vs −2.0; *P*=.03). Most anthropometric, biochemical, and functional outcomes did not differ significantly
Dolanbay et al [43], 2025	• Randomized controlled trial • Cross-stage/mixed	Web-based education vs control	Immunosuppressive medication-related symptoms, symptom distress, and medication adherence	Symptom occurrence (90.96 vs 112.49; *P*=.009) and symptom distress (19.98 vs 53.51; *P*=.009) were lower, and medication adherence was higher (49.33 vs 46.18; *P*=.001) in the intervention group
DeMartini et al [46], 2018	• Randomized pilot feasibility trial • Pretransplant/candidacy	Tailored text-messaging relapse-prevention intervention + standard care vs standard care	Alcohol use/relapse, stress, abstinence self-efficacy, craving, and feasibility	At 8 weeks, positive urine EtG[g] tests occurred in 0/8 intervention participants vs 2/6 controls; no formal between-group test was reported. Self-reported drinking did not differ (*P*=.19). Stress showed a condition × time interaction (*P*<.05), without significant between-group differences at weeks 4 or 8
Lu et al [49], 2023	• Randomized controlled study • Cross-stage/mixed	Internet-enabled hospital-community-family continuity-of-care model vs conventional continuity care	Self-care, self-management, and HRQoL	At 3 months, self-care, self-management, and multiple LT[h]-specific QoL domains favored intervention (all reported *P*<.05); medication-management scores were 22.87 vs 17.29
Zhai et al [53], 2021	• Randomized controlled trial • Early posttransplant	Mobile health platform–based continuity of care vs routine care	Psychological outcomes; hope, adherence, self-care, self-management, HRQoL, and satisfaction	Medication adherence (12.14 vs 8.69; *P*<.001) and self-management (44.86 vs 34.45; *P*<.001) were higher, while anxiety and depression were lower. Total QoL also favored intervention, although not all QoL domains differed significantly

XSL•FO

Study	Study design and transplant trajectory stage	Intervention and comparator	Main outcome(s)	Key quantitative and statistical findings
Pan et al [54], 2023	• Randomized controlled study • Early posttransplant	WeChat educational app + supervised family intervention vs routine care	Glycemic control, medication adherence, self-management, anxiety/depression, and complications	Glycemic control, medication adherence, self-management, and psychological outcomes favored intervention (all *P*<.001). Postoperative complications were lower (2.22% vs 17.14%; *P*=.02)
Wang et al [57], 2023	• Randomized controlled trial • Early posttransplant	Remote rehabilitation management vs routine postoperative follow-up	Treatment adherence and self-care capacity	Treatment adherence (85.03 vs 64.58; *P*<.001) and self-care capacity (95.38 vs 72.23; *P*<.001) were higher with remote rehabilitation management

Table . Key findings from nonrandomized quantitative studies (n=18).

Study	Study design and transplant trajectory stage	Digital application/intervention	Key quantitative findings
Knihs et al [31], 2024	• Technology product development and validation • Posttransplant timing unspecified	Educational mobile game for home care	Patient SUS[a] mean=80; professional usability ratings were >75%. No clinical-effect comparison was performed
Goswami et al [33], 2024	• Pilot study • Cross-stage/mixed	Tailored virtual alcohol use disorder treatment program	76% (32/42) participants completed the program. Relapse occurred in 22% of completers vs 80% of noncompleters (*P*=.002); this comparison was observational
Andrä et al [34], 2022	• Single-center cohort study • Cross-stage/mixed	Mobile app for outpatient LT[b] aftercare	91.9% (124/135) agreed to participate, 57.3% (71/124) had a compatible device, and 33.8% (42/124) used the app. Privacy concerns were reported by 59.5% of users
Delman et al [35], 2021	• Retrospective cohort study • Cross-stage/mixed	Telehealth-centered transplant service during COVID-19	Telehealth accounted for up to 85% of clinic visits. Hospital stay was shorter in the COVID-era cohort (8.5 vs 13.1 d; *P*=.02); patient and graft survival did not differ significantly
Tian et al [37], 2021	• Cohort study • Early posttransplant	Telemedicine follow-up management	Telemedicine was associated with shorter initial hospitalization (16.31 vs 19.12 days; *P*=.03), lower initial cost (*P*=.049), and lower 30-day readmission (*P*=.02); 12-month survival did not differ significantly
Koc et al [38], 2022	• Prospective cohort study • Long-term survivorship	Telemedicine remote monitoring program	Remote monitoring users had fewer outpatient visits (2 vs 5; *P*<.001) and more TAC[c] determinations (8 vs 6; *P*=.001), with no significant difference in graft rejection (2.6% vs 3.6%; *P*=.34)
Volk et al [39], 2014	• Pilot pre-post study • Pretransplant/candidacy	Web-based organ-quality decision aid	Knowledge, risk perception, and willingness to consider less-than-perfect donor organs improved after the intervention (all *P*<.001); decision confidence did not change significantly
Konjeti et al [41], 2019	• Retrospective cohort study • Pretransplant/candidacy	SCAN-ECHO[d] telehealth triage for LT evaluation	Rejection after full transplant workup was lower with telehealth triage (23.1% vs 55.6%; *P*<.0001), suggesting fewer potentially futile evaluations
Ertel et al [44], 2016	• Nonrandomized observational pilot • Early posttransplant	Video education plus telehealth home monitoring	95% viewed all educational videos and mean satisfaction was 29/30. 30-day and 90-day readmission rates were 20% and 30%, respectively; no comparative statistical test was performed
Duarte-Rojo et al [45], 2023	• Single-arm pilot and feasibility trial • Pretransplant/candidacy	Wearable-supported and app-supported home prehabilitation with remote coaching	21/31 participants entered the intervention and training adherence was 57%. Among completers, LFI[e] improved (*P*=.03) and 6MWT[f] increased from 318 to 358 m (*P*=.005)

XSL•FO
RenderX

Study	Study design and transplant trajectory stage	Digital application/intervention	Key quantitative findings
Wang et al [47], 2023	• Cross-sectional model development/internal validation • Cross-stage/mixed	TeLeFI[g]	TeLeFI models showed cross-validated *C*-statistics of 0.78 and 0.76; the model incorporating virtual chair stands improved frailty classification (NRI[h]=0.70; *P*=.002)
Catalli et al [48], 2026	• Single-arm quasi-experimental pre-post study • Long-term survivorship	Telehealth shared medical appointments	Several psychosocial and self-efficacy measures improved among post-LT participants (*P*=.001-.03), whereas BMI reduction was not significant (32.0 to 30.1 kg/m²; *P*=.06)
Wang et al [50], 2012	• Single-group pre-post implementation study • Posttransplant timing unspecified	Internet information platform for follow-up	Follow-up laboratory-result time decreased from 240 to 5 minutes, scheduled follow-up adherence increased from 82.3% to 95.6%, and adverse events decreased from 11.8% to 4.4%
Li et al [51], 2024	• Technology system development/preliminary application • Cross-stage/mixed	Whole-lifecycle digital health management system (SWOR[i])	The system was implemented in 1730 organ transplant recipients, including 488 LT recipients. No comparative LT-specific patient-effect estimate was reported
Liu et al [52], 2019	• Quasi-experimental controlled study • Cross-stage/mixed	WeChat-based peer education	Medication-adherence measures improved at selected follow-ups, but total adherence was not significantly different at 12 months (*P*=.07). Between-group QoL[j] differences were not significant
Sun et al [55], 2019	• Single-group pre-post study • Early posttransplant	WeChat-based multidisciplinary continuity care	Self-care (*P*=.002), transplant knowledge (*P*<.001), and medication-adherence distribution (*P*<.001) improved at 3 months compared with discharge
Tian et al [56], 2019	• Prospective nonrandomized controlled cohort • Early posttransplant	Telemedicine robot follow-up	Total adherence was higher with robot-based follow-up (84.0 vs 61.4; *P*<.001), with shorter follow-up time and higher satisfaction (both *P*<.001)
Xue et al [58], 2019	• Single-arm feasibility study • Early posttransplant	Remote follow-up management system	81.1% (30/37) eligible recipients participated, system mastery was 100%, and 86.7% (26/30) completed 2 weeks; satisfaction was generally >4/5

Findings From Randomized Intervention Studies

Among the included studies, 7 were conventional RCTs and 2 additional studies used randomized feasibility or pilot feasibility designs. This review separately examined these 9 randomized intervention studies to provide a more specific account of the reported intervention effects and statistical findings (Table 5). According to the transplant trajectory classification used in this

XSL•FO
RenderX

review, 4 studies focused on early posttransplant recovery [36,53,54,57], 2 on the pretransplant/candidacy stage [40,46], 2 spanned multiple stages of posttransplant care [43,49], and 1 focused predominantly on long-term posttransplant survivorship [42]. No randomized study focused exclusively on the perioperative/inpatient-to-home transition stage.

Across randomized studies, favorable findings were more consistently reported for proximal outcomes, including medication or treatment adherence, self-management or self-care, dietary behavior, psychological outcomes, and selected health service outcomes. For example, telemedicine-based home monitoring reduced 90-day readmission (28% vs 58%; *P*=.004) [36], and a WeChat-based intervention reported fewer postoperative complications (2.22% vs 17.14%; *P*=.02), together with improvements in glycemic control, adherence, self-management, and psychological outcomes [54]. Findings for broader outcomes were less consistent. The long-term diet and exercise feasibility trial improved Mediterranean diet adherence and mental HRQoL but not most anthropometric, biochemical, or functional outcomes [42], whereas the 2 pretransplant randomized studies reported limited or inconsistent between-group effects [40,46].

Several interventions with favorable findings used repeated digital contact together with education, monitoring, professional feedback, rehabilitation guidance, or family support. However, the studies differed in population, transplant stage, intervention intensity, comparator, follow-up duration, and outcome measurement, and 2 were designed primarily to assess feasibility. The findings were therefore synthesized descriptively and were not used to infer the superiority of specific intervention modalities or components.

Findings From Nonrandomized Studies

Of the 19 nonrandomized studies, 18 reported extractable quantitative findings and are summarized in Table 6; the remaining study was a qualitative study of long-term liver transplant recipients [32] and therefore did not contribute quantitative effect estimates. The nonrandomized evidence encompassed cohort comparisons, quasi-experimental and single-group pre-post studies, pilot and feasibility studies, and technology-development or model-development studies. Because these designs differed substantially in their susceptibility to confounding, selection effects, and secular trends, the numerical findings are presented descriptively and are not interpreted as causal estimates of intervention effectiveness.

Pretransplant studies addressed decision support, transplant triage, and prehabilitation. A web-based decision aid improved several knowledge and risk-perception measures [39], telehealth triage reduced the proportion of patients completing a full evaluation before being judged ineligible [41], and home-based prehabilitation improved Liver Frailty Index and 6-minute walk distance among completers [45]. Early posttransplant studies focused mainly on monitoring and follow-up. Telemedicine follow-up was associated with shorter initial hospitalizations, lower costs, and lower 30-day readmission rates without significant survival differences [37], while other studies reported improvements in adherence, self-care, follow-up efficiency, or short-term feasibility [50,55,56,58].

Among long-term and cross-stage populations, remote monitoring reduced outpatient visits while maintaining comparable graft-rejection outcomes [38], whereas lifestyle and peer-support interventions produced mixed behavioral, psychosocial, and QoL findings [33,48,52]. Several studies evaluated technology usability, implementation, or model performance rather than therapeutic effectiveness [31,47,51]. Overall, favorable findings frequently arose from single-arm comparisons, self-selected users, historical controls, or small pilot cohorts and should therefore be interpreted cautiously.

Implementation-Related Outcomes of Digital Health Technologies

Structured implementation-related outcomes or patient-experience measures were reported in 15 of the 28 included studies [31,33,34,36,38,39,42,44-46,48,50,51,56,58]. These outcomes primarily assessed participation and uptake, intervention completion, system mastery and frequency of use, satisfaction, acceptability, usability, accessibility, and user concerns related to digital technology. From the 15 studies, 3 used randomized designs [36,42,46], whereas the remaining 12 used nonrandomized cohort, pilot, single-arm feasibility, pre-post, or technology-development designs. Accordingly, these measures were interpreted as indicators of implementation feasibility and user experience rather than as evidence of clinical effectiveness.

Uptake and engagement varied across studies. In 1 outpatient app study, 91.9% of eligible recipients agreed to participate, but only 57.3% had a compatible device and 33.8% ultimately used the application; 59.5% of users reported privacy concerns [34]. Other studies reported generally favorable short-term completion, usability, or satisfaction [31,33,44,45,58]. The qualitative study [32] provided complementary evidence on recipients' preferences and perceived barriers. Implementation evaluations were distributed across early posttransplant recovery (n=4), pretransplant/candidacy (n=3), long-term survivorship (n=3), cross-stage/mixed care (n=3), and unspecified posttransplant timing (n=2); none focused exclusively on the perioperative/inpatient-to-home transition stage. Overall, willingness to participate, technological access, actual uptake, and sustained engagement emerged as related but distinct implementation dimensions.

Discussion

Principal Findings

This scoping review mapped digital health technologies across the liver transplant trajectory and identified substantial variation in technological modalities, intervention components, study designs, and outcomes. Telehealth platforms or remote management systems were the most frequently reported technological modalities, and remote education was the most common intervention component. Evidence was unevenly distributed across the transplant trajectory. Early posttransplant recovery was the most frequently studied stage, whereas no included study focused exclusively on the perioperative/inpatient-to-home transition stage. Compared with the previous scoping review of telehealth in home-based care

XSL•FO
RenderX

for adult liver transplant recipients [22], the present review included both transplant candidates and recipients and examined intervention components, outcomes, study designs, and implementation evidence across different stages of the transplant trajectory.

Randomized studies more often reported favorable findings for outcomes closely related to the intervention, including medication or treatment adherence, self-management and self-care, dietary behavior, psychological outcomes, and selected health service outcomes [36,42,43,49,53,54,57]. Findings were less consistent for broader outcomes such as overall QoL, physiological or functional measures, and longer-term clinical outcomes [40,42,46]. This pattern may reflect differences in how directly these outcomes can be influenced by short-term digital interventions. Behavioral and self-management outcomes may respond more quickly to repeated education, reminders, monitoring, or feedback, whereas broader clinical and QoL outcomes are influenced by multiple clinical and psychosocial factors and may require longer follow-up.

Several randomized interventions with favorable findings combined repeated digital contact with education, monitoring, professional feedback, rehabilitation guidance, or family support [36,42,49,53,54,57]. These interventions generally extended beyond one-way information delivery and maintained communication between patients and health care professionals. However, this pattern should not be interpreted as evidence that multicomponent interventions are superior. The included randomized studies differed substantially in population, transplant stage, intervention intensity, comparator, follow-up duration, and outcome measurement, and this review did not compare the effects of individual intervention components. The observed pattern therefore identifies a potential direction for intervention design rather than a specific effective combination of components.

Stage-specific mapping showed that digital health was used to address different care needs across the transplant trajectory. Pretransplant interventions addressed decision support, psychological and behavioral support, transplant assessment, and prehabilitation [39-41,45,46], but the evidence remained limited and heterogeneous. Early posttransplant recovery had the broadest range of intervention components and the largest concentration of studies, with particular emphasis on education, monitoring, teleconsultation, medication management, rehabilitation, and follow-up [36,37,44,53-58]. In contrast, long-term survivorship studies focused more on remote monitoring, lifestyle and metabolic management, rehabilitation, and psychosocial support [32,38,42,48]. Cross-stage interventions addressed broader continuity-of-care needs through combinations of education, monitoring, consultation, peer support, and longitudinal management [33-35,43,47,49,51,52].

The absence of studies focused exclusively on the perioperative/inpatient-to-home transition represents an important evidence gap. Some cross-stage interventions included elements relevant to discharge and follow-up, but no intervention was designed and evaluated specifically for this transition period. This gap should not be interpreted as indicating a lower need for digital support; rather, it reflects the current distribution of research across the transplant trajectory.

Implementation findings further showed that initial willingness to participate should not be equated with successful implementation. Across studies, acceptability, technological access, actual uptake, and sustained engagement varied and represented distinct implementation dimensions [32,34]. High satisfaction or short-term completion therefore does not necessarily indicate that an intervention can be sustained or integrated into routine transplant care. Overall, the current evidence suggests that digital health may be most useful when incorporated into structured follow-up pathways that support communication, monitoring, education, self-management, and professional feedback. However, much of the evidence for physiological, health service, and implementation outcomes came from nonrandomized, pilot, feasibility, cohort, or technology-development studies. These findings should therefore be interpreted as evidence of potential clinical utility and implementation feasibility rather than definitive comparative effectiveness.

Strengths and Limitations

This review has 5 key strengths. First, the search covered 9 English-language and Chinese-language databases, capturing evidence from both international and Chinese settings, and included both liver transplant candidates and recipients across a range of clinical contexts including donor organ decision support [39], alcohol-related behavioral risk management [33,46], and long-term recipients' care preferences [32]. Second, qualitative evidence was included to complement quantitative findings on patient needs and implementation context. Third, evidence was organized by a transplant trajectory stage framework, clearly identifying evidence gaps such as the lack of perioperative transition studies. Fourth, randomized and nonrandomized evidence were synthesized separately to avoid conflating heterogeneous study designs, and implementation-related outcomes (uptake, usability, acceptability, and so on) were incorporated to support real-world clinical translation. Finally, the review followed established scoping review guidance (Arksey and O'Malley framework, JBI guidance, and PRISMA-ScR) to ensure transparency and reproducibility.

Several limitations should be considered when interpreting the findings. First, the scoping review protocol was not prospectively registered. Second, no formal critical appraisal or risk-of-bias assessment of included studies was performed, so findings should not be interpreted as establishing the certainty of evidence or comparative effectiveness of specific interventions. Third, 20 potentially relevant reports could not be retrieved in full text, which may have introduced selection bias and limited the comprehensiveness of the evidence base. Fourth, substantial heterogeneity in study designs, intervention characteristics, follow-up periods, and outcome measures precluded quantitative synthesis. Many included studies were small, single-center pilot/feasibility designs with limited longitudinal evidence [33,39,42,44-46,58], and their findings should be considered exploratory. These limitations indicate that the field remains at an early stage of development, requiring

XSL•FO
RenderX

further evidence to establish the effectiveness of digital health interventions in liver transplant care.

Recommendations for Future Research and Development

Future research should strengthen the methodological rigor and comparability of digital health studies in LT. The current evidence includes relatively few randomized trials, while many studies were small, single-center, pilot, feasibility, cohort, or pre-post studies. Studies evaluating effectiveness should use multicenter comparative designs with justified sample sizes and longer follow-up. Greater consistency in outcome selection and measurement is also needed. Researchers should use validated measures where possible, prespecify primary and secondary outcomes, and report intervention content, delivery mode, intensity, duration, adherence, and attrition in sufficient detail. Reporting guidance such as CONSORT-EHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and Online Telehealth) may improve transparency and facilitate future evidence synthesis [59].

Research priorities should also reflect the transplant trajectory. Pretransplant studies should further evaluate digital approaches for decision support, behavioral and psychological support, and prehabilitation. Early posttransplant research should examine whether improvements in adherence and self-management are sustained and translate into clinical or health service outcomes. Long-term studies should place greater emphasis on lifestyle management, functional recovery, cardiometabolic risk, psychosocial adjustment, and sustained engagement with follow-up care. The perioperative/inpatient-to-home transition requires particular attention because no included study focused exclusively on this stage. Future interventions could address discharge preparation, early symptom monitoring, medication management, and communication between patients and the transplant team.

Intervention development should also clarify which components contribute to meaningful and sustained outcomes. Several randomized interventions with favorable findings combined repeated digital contact with education, monitoring, professional feedback, rehabilitation guidance, or family support. However, the current evidence does not establish which individual components or combinations are responsible for these findings. Future studies should describe intervention components, delivery processes, professional contact, personalization, caregiver involvement, and intervention fidelity more consistently. Comparative or optimization designs may help examine the contribution of individual components and distinguish the effects of technology from the clinical support delivered through it.

Implementation should be treated as a core research outcome. Future studies should examine not only satisfaction or usability but also access, uptake, engagement, workflow integration, maintenance, and scalability. The effects of digital care on the workload of transplant nurses and other health care professionals should also be assessed, including how patient-generated data are reviewed and how responsibilities are distributed within multidisciplinary teams. User-centered design should remain central [60], and privacy and data security should be considered throughout intervention development and implementation [61].

Equity and economic sustainability require parallel evaluation. Digital interventions may improve access to specialist care but may also disadvantage patients with limited device access, internet connectivity, digital skills, health literacy, or confidence in using technology. Older adults may face additional usability and accessibility barriers, although age alone should not be treated as a proxy for inability to use digital care [62,63]. Future studies should assess digital access and literacy, include patients and caregivers from diverse socioeconomic and geographic backgrounds, and consider training, caregiver support, alternative access methods, and hybrid care models. Economic evaluations should include development, equipment, maintenance, staffing, training, data management, and patient-side costs and assess whether reductions in travel, outpatient visits, or unplanned service use offset implementation costs. Effectiveness, implementation, equity, and economic outcomes should be considered together when assessing the long-term role of digital health in routine liver transplant care.

Conclusions

This scoping review mapped digital health technologies across the liver transplant trajectory. Most studies focused on early posttransplant recovery. Randomized studies more often reported positive findings for adherence, self-management, health behaviors, and selected psychosocial or health service outcomes, while findings for QoL, physiological outcomes, functional outcomes, and long-term clinical outcomes were less consistent. No study focused exclusively on the perioperative/inpatient-to-home transition stage. Much of the current evidence came from nonrandomized, pilot, feasibility, or small single-center studies. Future studies should use stage-specific and multicenter designs, improve the consistency of intervention and outcome reporting, and assess long-term implementation, access, and costs.

Generative AI Use

No generative AI tools were used for manuscript preparation, writing, editing, or data-related analyses in this study.

Funding

This work was supported by the Scientific Research Project of the Education Department of Jilin Province (JJKH20250227KJ) and the Jilin Provincial Department of Finance (J1SRCZX2025-074). The funders had no role in the design or conduct of the review; literature searching; study selection; data extraction, analysis, or interpretation; preparation of the manuscript; or the decision to submit the manuscript for publication.

Abstract

Background: Diabetes self-management education and support requires scalable digital solutions, making mobile health (mHealth) interventions increasingly vital. Despite their proven clinical efficacy, the real-world translation and scalability of these interventions are severely hindered by fragmented and opaque reporting. To address this methodological gap, the World Health Organization developed the mHealth evidence reporting and assessment (mERA) checklist to standardize reporting transparency.

Objective: This study aimed to systematically evaluate the reporting completeness of published randomized controlled trials (RCTs) on mHealth interventions for adult diabetes using the mERA checklist; identify critical reporting gaps; analyze how these deficiencies undermine feasibility, scalability, and sustainability; and propose targeted strategies for future optimization.

Methods: A PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses)–compliant systematic review was conducted. Five major databases (PubMed, Embase, Web of Science, MEDLINE, and the Cochrane Library) were systematically searched for relevant RCTs published from inception to July 2026. Data extraction and reporting completeness assessments were conducted using the 16-item mERA core checklist. Nonparametric and categorical analyses were used to evaluate factors associated with reporting completeness.

Results: A total of 144 RCTs conducted across 49 countries were included in the final analysis. The mean overall mERA reporting score was 6.74 out of 16 (SD 2.71). While basic characteristics such as intervention delivery (n=128, 88.9%) and technology platform (n=117, 81.3%) were well reported, critical system-level domains were largely omitted. Specifically, interoperability (n=12, 8.3%), data security (n=28, 19.4%), compliance with guidelines (n=41, 28.5%), and intervention fidelity (n=53, 36.8%) were severely underreported. Additionally, reporting completeness was significantly higher in studies published between 2016 and 2026 (*P*=.01) and in multicomponent interventions compared to single-component ones (*P*=.04).

Conclusions: Empirical research on mHealth interventions for adult diabetes exhibits systemic structural flaws in reporting, particularly concerning system integration, data security, and regulatory compliance. These omissions significantly undermine the transparency, reproducibility, and real-world scalability of digital diabetes care solutions. Future trials must rigorously adopt standardized reporting frameworks such as the mERA checklist to bridge the gap between clinical efficacy and large-scale public health policy translation.

KEYWORDS

mobile health; mHealth; systematic review; diabetes; mobile app; reporting guidelines

Introduction

Diabetes is a chronic metabolic disease characterized by elevated blood glucose levels resulting from insufficient insulin production or ineffective insulin use [1]. Its global burden continues to rise rapidly. According to the Noncommunicable Disease Risk Factor Collaboration, 828 million adults were living with diabetes in 2022, an increase of 630 million since 1990 [2]. Nearly 59% of these patients—approximately 450 million adults—remain untreated, with the largest treatment gaps concentrated in low- and middle-income countries (LMICs) [2]. Concurrently, disparities in treatment coverage are widening between high-income Western countries and regions with low treatment coverage, including Pacific island nations, South Asia, and sub-Saharan Africa, reinforcing the need for delivery models that can reach populations with limited access to conventional services [2]. The economic burden is similarly substantial, with global costs projected to increase from US $1.3 trillion in 2015

XSL•FO
RenderX

to US $2.2 trillion by 2030, representing up to 2.2% of the global gross domestic product [3].

Traditional health care facilities are increasingly inadequate to accommodate the growing demand for chronic disease care. Consequently, traditional diabetes self-management education and support services require integration with highly scalable digital health systems [4,5]. Mobile health (mHealth) interventions—including smartphone apps, videoconferencing, and SMS text messaging—can provide remote care, health education, and self-management support [4]. By 2023, global smartphone penetration reached 6.92 billion users, representing approximately 86% of the world population [6]. This widespread adoption positions mobile technology as a viable infrastructure to overcome geographical and resource barriers, facilitating a continuous, technologically supported self-management feedback loop for patients [6].

Evidence from randomized controlled trials (RCTs) and meta-analyses supports the clinical potential of mHealth for adults with type 2 diabetes mellitus [7-9]. A meta-analysis of 41 studies found that app-based interventions significantly improved glycemic control compared with standard care, with a mean hemoglobin A_{1c} reduction of 0.49% (95% CI –0.65% to –0.32%) [7]. Real-world evidence has also shown clinically relevant benefits. In 2023, Heald et al [9] evaluated the Healum collaborative care planning app in the UK National Health Service primary care and reported, over 6 months, a 7.4% mean percentage reduction in hemoglobin A_{1c}, a 0.7% reduction in BMI, and a mean EQ-5D-5L score increase of 0.0464.

Clinical effectiveness, however, does not by itself ensure that an intervention can be reproduced, implemented, or scaled. Translation into routine and reimbursable care is hindered when intervention reporting is fragmented or insufficiently transparent [10,11]. Vague descriptions of delivery processes can limit evidence synthesis and practical application [10-12], whereas failure to report the frequency and duration of app use makes dose-response relationships difficult to assess [6]. Furthermore, critical parameters such as implementation feasibility and technological adaptability across diverse health care settings remain underreported [7]. As a result, comparisons across studies become less reliable, and decision-makers lack key evidence for judging real-world feasibility, scalability, and long-term sustainability [6,13].

To improve reporting transparency, the World Health Organization mHealth Technical Evidence Review Group developed the 16-item mHealth evidence reporting and assessment (mERA) core checklist, which covers intervention content, implementation context, and technical features [14]. Rather than measuring clinical efficacy, the mERA checklist assesses whether reports contain the information needed to understand and replicate an intervention. Previous applications of the mERA checklist reveal substantial gaps: data security and privacy protection have been reported in 0% of studies, cost assessments have been reported in only 13%, and compliance with national clinical guidelines such as HIPAA (Health Insurance Portability and Accountability Act) or diabetes self-management education and support standards have been reported in only 20% [15]. A 2022 systematic review further found that none of the assessed mobile diabetes interventions in LMICs had applied mERA guidelines [16], reflecting a widespread tendency to prioritize clinical outcomes over process evaluation. These limitations ground the rationale for this study. Given that adult diabetes management demands rigorous data interaction, privacy protection, and cost control, systematically auditing current RCT literature via the mERA checklist is methodologically imperative to address the bottlenecks hindering large-scale digital health policy translation.

Therefore, this study used the mERA checklist as a systematic evaluation framework to analyze the reporting quality of published RCTs evaluating adult diabetes mHealth interventions. By analyzing compliance rates across mERA items, this study identified systemic reporting blind spots in current digital health literature. Furthermore, it explored how these deficiencies undermine the feasibility, scalability, and sustainability of digital diabetes care solutions. Finally, this study proposes targeted strategies to optimize future digital health interventions.

Methods

Study Design

This systematic review was conducted and reported in accordance with PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 checklist [17]. The completed PRISMA 2020 checklist is provided in Checklist 1. This review was not registered.

Inclusion and Exclusion Criteria

The eligibility criteria for this review were structured as follows.

Study Design

Only peer-reviewed RCTs evaluating intervention efficacy were included. Conversely, feasibility studies, pilot trials, conference abstracts, and unpublished studies were excluded.

Participants

Eligible participants were adults (aged ≥18 years) with a confirmed diagnosis of type 1 or type 2 diabetes mellitus. Studies evaluating patients with gestational diabetes mellitus were excluded.

Interventions

All mHealth interventions designed for health promotion or disease management were eligible for inclusion. Acceptable delivery modalities encompassed SMS text messaging, telephone calls, emails, wearable devices, mobile apps, web portals, and hybrid interventions.

Search Strategy

This study systematically searched PubMed, Embase, Web of Science, MEDLINE, and the Cochrane Library to identify relevant studies available from the inception of each database to July 2026. Only articles published in English were included in the analysis. Keywords related to mHealth, diabetes, effectiveness, and RCTs were used (detailed in Multimedia Appendix 1). Within each database, terms were combined using the “OR” operator, followed by the integration of results across databases using the “AND” operator. The comprehensive search

XSL•FO
RenderX

strategies and specific keywords are thoroughly described in Multimedia Appendix 1, ensuring transparency and reproducibility of the retrieval process.

Study Selection

Duplicate entries were removed using the EndNote software (version 21; Clarivate Analytics), followed by a manual cross-check to ensure data integrity. The corresponding authors of 17 research reports were contacted to request the complete manuscripts. Of these 17 authors, 15 (88.2%) responded and provided the required data, and the remaining 2 (11.8%) studies were excluded because the corresponding authors did not reply, rendering the necessary data unavailable. Subsequently, 2 independent reviewers (XY and JS) screened all titles, abstracts, and full texts according to the predefined inclusion criteria. Discrepancies were resolved through consensus-seeking discussions with a third reviewer (MH). Reasons for excluding full-text articles were meticulously documented. The detailed search strategies can be found in Multimedia Appendix 1.

Data Extraction

Three researchers (XY, JP, and JS) completed data extraction. Prior to the formal process, the research team underwent standardized training, during which XY introduced the mERA core checklist and clarified its 16 items. A pilot assessment was then conducted to evaluate interrater reliability, after which the Fleiss κ coefficient was calculated, and all discrepancies were discussed iteratively to reach a consensus. During the formal extraction phase, 2 researchers (JS and JP) independently extracted data from each study using a standardized form, with any unresolved disagreements adjudicated by a third researcher (XY). The extracted variables included the first author, publication year, country, mHealth intervention type, participant digital literacy, compliance with mERA core items, and funding sources.

Data Synthesis and Analysis

Descriptive statistics were used to summarize study characteristics and mERA reporting completeness. Continuous variables (eg, total mERA scores) are presented as medians and IQRs due to nonnormal distribution, whereas categorical variables are presented as frequencies and percentages. The normality of continuous data was evaluated using the Shapiro-Wilk test.

To explore factors associated with reporting completeness, nonparametric tests were used. Specifically, the Mann-Whitney *U* test was used to compare total mERA scores between 2 independent groups. The year 2016 was selected a priori as the temporal cutoff because the mERA reporting guideline was published in that year [14]; studies were therefore grouped as 2009 to 2015 and 2016 to 2026. The Kruskal-Wallis *H* test was used for comparisons across more than 2 groups. For categorical variables (ie, item-by-item adherence rates), differences between groups were analyzed using the Fisher exact test or Pearson chi-square test as appropriate based on expected cell counts. All statistical analyses were performed using R (version 4.5.0; R Foundation for Statistical Computing). A 2-tailed *P* value below .05 was considered statistically significant.

Classification of mHealth Intervention Types

To categorize mHealth intervention types, we applied a component-based classification approach. Each intervention was classified according to the primary technological modality used to deliver the intervention. When an intervention incorporated additional digital components beyond the primary modality, it was classified as a multicomponent intervention rather than being assigned to a single technology category.

The intervention categories were defined as follows: (1) mobile app–based interventions, referring to interventions primarily delivered through smartphone or tablet apps; (2) SMS text messaging–based interventions, referring to interventions mainly delivered through SMS text messages; (3) website-based interventions, referring to interventions delivered through web-based platforms; (4) wearable device–based interventions, referring to interventions involving wearable sensors or devices for monitoring or feedback; and (5) combined interventions, referring to interventions that integrated 2 or more technological modalities (eg, mobile app plus SMS text messaging or mobile app plus wearable devices).

Therefore, categories such as “mobile app,” “mobile app and wearable devices,” and “mobile app and SMS” represent mutually distinguishable intervention strategies rather than overlapping categories.

Evaluation of Evidence Reporting

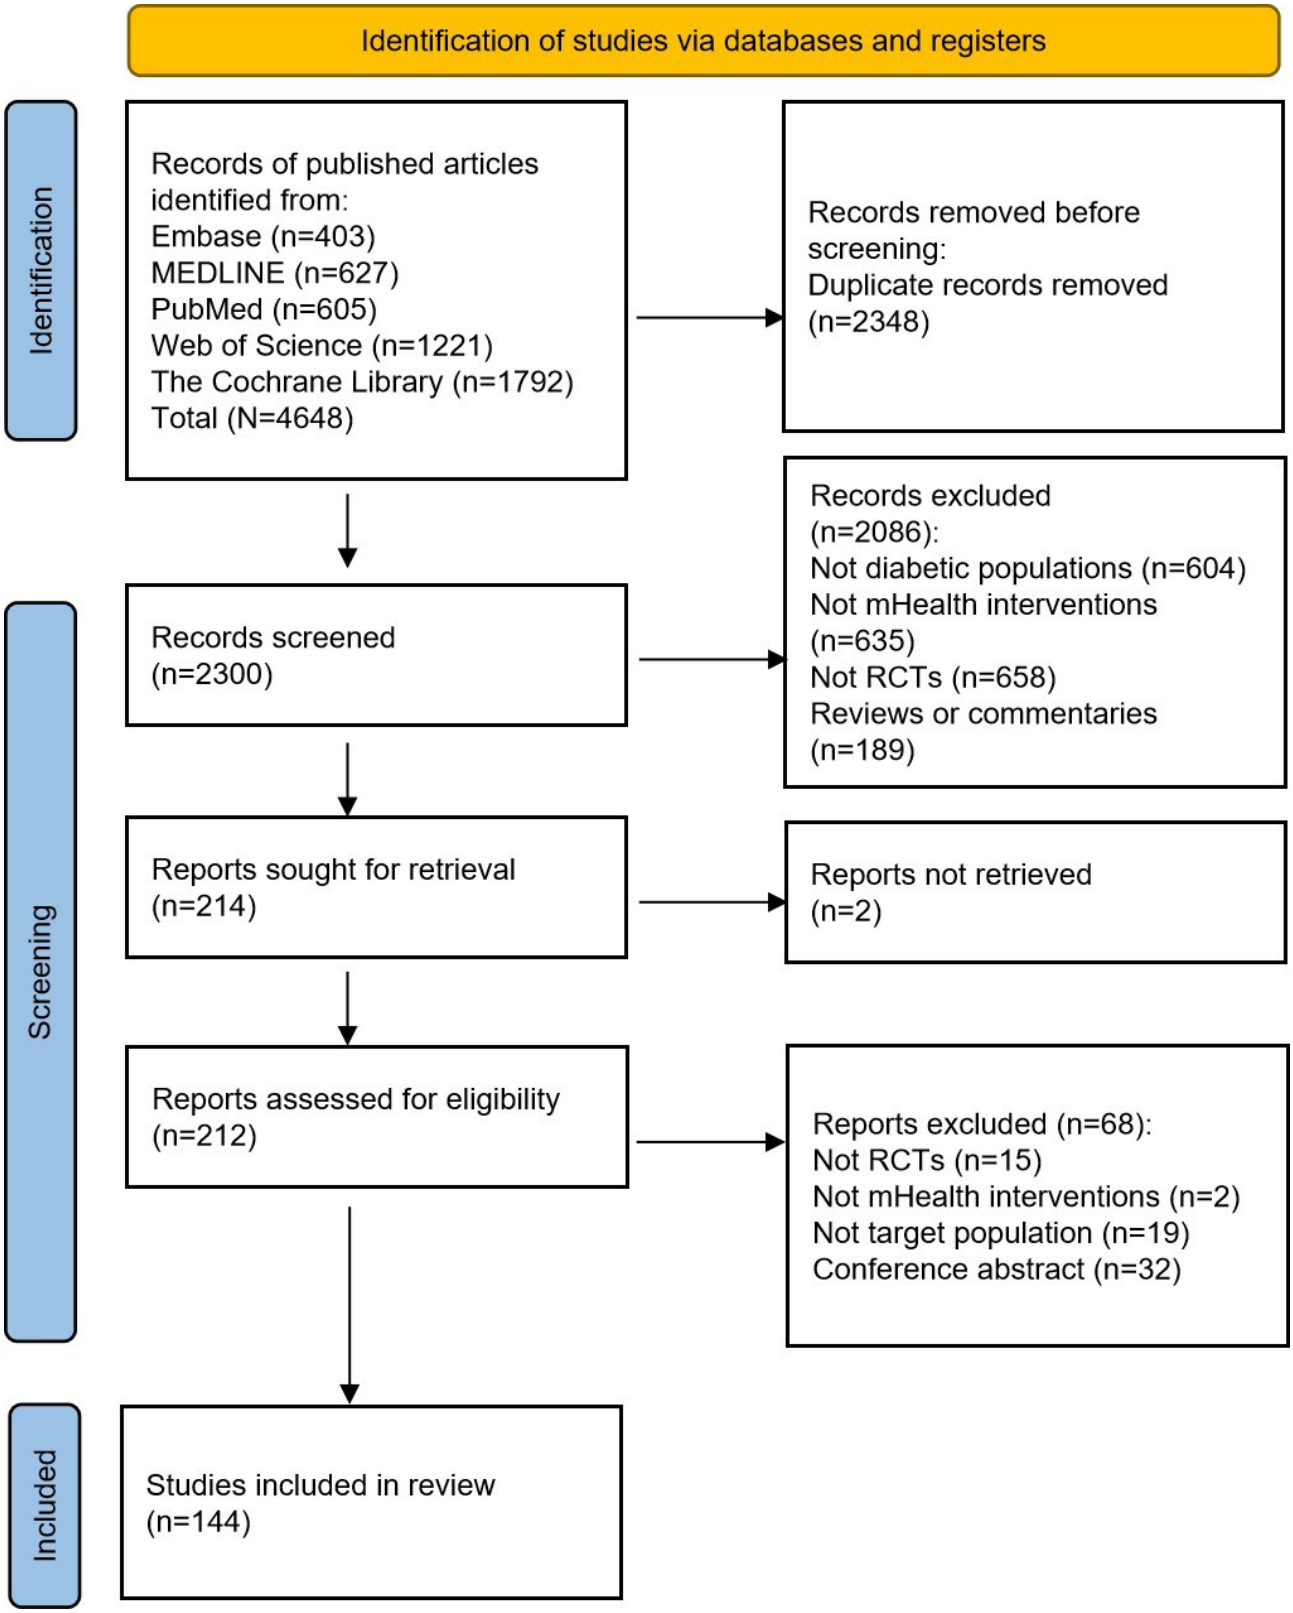
To assess the quality of evidence reporting in each study, we adopted the mERA core checklist in accordance with the guidelines proposed by Iribarren et al [18]. The mERA core checklist consists of 16 items, which represent the minimum set of information that should be reported to ensure the replicability of an intervention. These items cover the intervention content, technical characteristics, and implementation context, as well as participants’ engagement and experience with the intervention. An item was classified as “reported” if it was adequately described in the included papers and their supplementary files. Conversely, if an item was absent from the included papers, it was classified as “unreported.” In this process, the evidence related to mHealth interventions in each study was evaluated based on the criteria specified in the mERA core checklist. During the evaluation, reviewers assigned a score of either 1 or 0 for each criterion to each study, where a score of 1 indicated that a specific mERA assessment criterion was met and a score of 0 indicated that it was not met. The assignment table for each evaluation indicator of each study is provided in the Multimedia Appendix 2.

Interrater reliability measures the degree of agreement among evaluators. Given that our assessment process involved multiple evaluators, testing their interrater reliability was not only crucial but also essential. To this end, we conducted a preassessment in which 3 studies were randomly selected following the recommendations put forward by Agarwal et al [14]. During the scoring process, evaluators assigned a value of either 1 or 0 to each study, where 1 indicated that a specific assessment criterion of the mERA checklist was met and 0 indicated that it was not met. To evaluate the interrater reliability, we used the Fleiss κ coefficient [19]. It should be noted that in the

XSL•FO
RenderX

context of grading health care research, a κ value as low as 0.41 is considered acceptable [20]. The results of the preassessment showed that for the 3 randomly selected studies, the interrater reliability values were 0.65, 0.83, and 0.82, which are far higher than the recommended acceptable threshold.

Results



Overview

Figure 1 shows the rigorously updated PRISMA 2020–compliant flow diagram outlining the study selection process. The initial systematic literature search across 5 databases yielded a total of 4648 records (Embase: n=403; MEDLINE: n=627; PubMed: n=605; Web of Science: n=1221; Cochrane Library: n=1792). Following the removal of 2348 duplicate records before screening, 2300 records remained for title and abstract evaluation. This initial screening phase resulted in the exclusion of 2086 records. The specific categorical reasons for exclusion at this stage were no diabetic populations (n=604), no mHealth interventions (n=635), no RCTs (n=658), and reviews or commentaries (n=189).

Full-text retrieval was sought for the remaining 214 reports, of which 2 could not be retrieved, resulting in 212 reports assessed for detailed full-text eligibility. Upon careful examination, 68 reports were excluded for the following reasons: not the target population (n=19, 27.9%), not RCTs (n=15, 22.1%), not mHealth interventions (n=2, 2.9%), and conference abstracts (n=32, 47.1%). The final sample consisted of 144 studies included in the review [9,21-163].

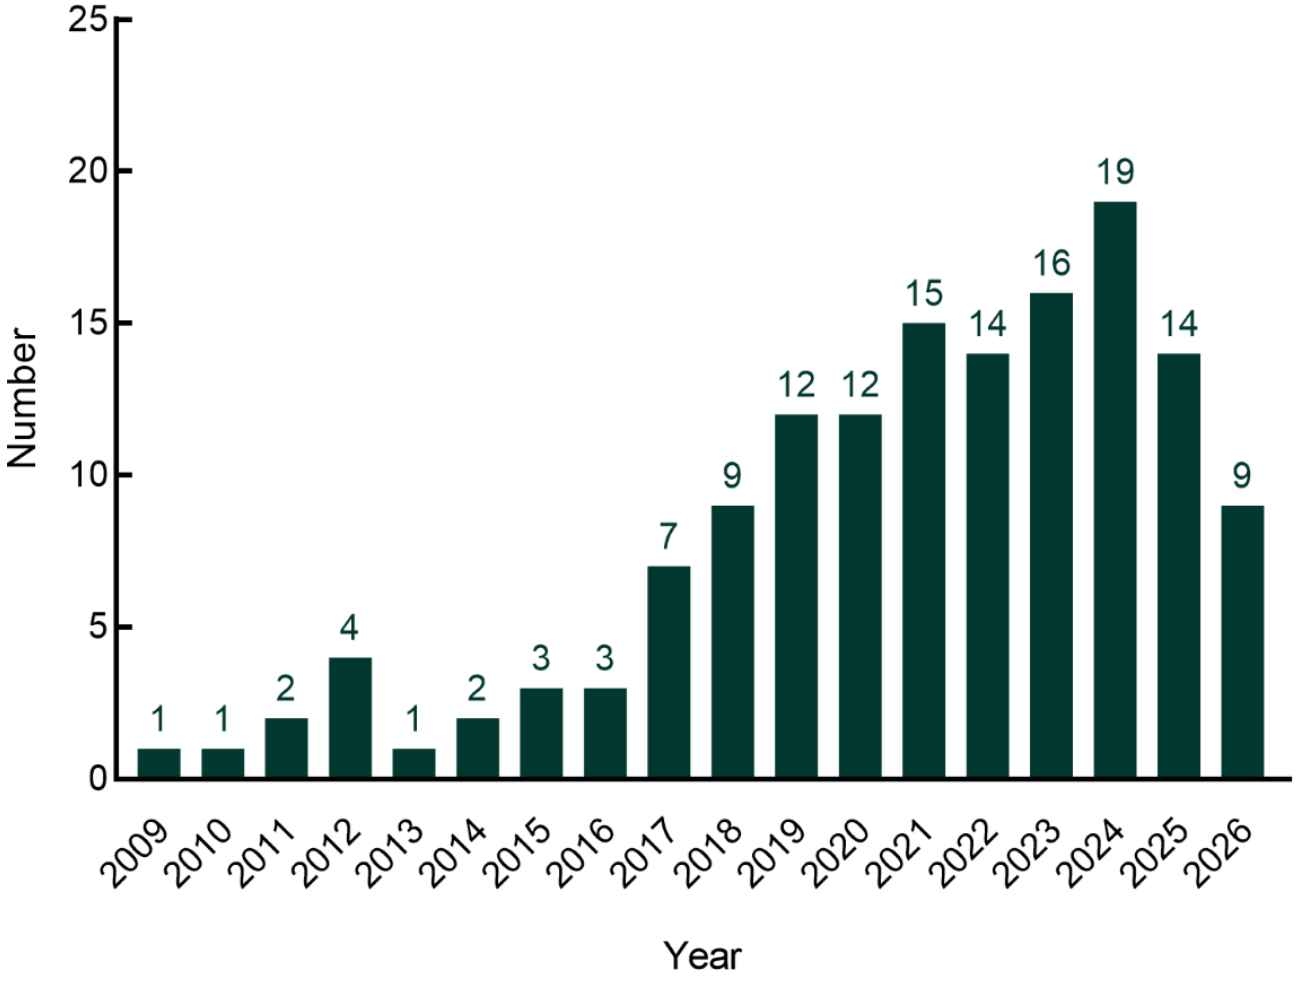
Study Characteristics

Table S1 in Multimedia Appendix 2 delineates the comprehensive characteristics of the 144 included trials. The included studies were conducted across 49 countries. The leading single-country contributors were China (n=24, 16.7%), the United States (n=22, 15.3%), South Korea (n=9, 6.3%), India (n=6, 4.2%), and the United Kingdom (n=6, 4.2%); Spain and Iran also contributed 4.2% (n=6) of the studies each. Most studies (n=76, 52.8%) included digital literacy or device ownership as an eligibility criterion.

The number of mHealth intervention RCTs increased progressively from 2009 to 2026 (Figure 2), with studies



XSL•FO
RenderX

published from 2016 to 2026 accounting for 90.3% (130/144) of the included evidence. Studies published from 2020 to 2024 represented 52.8% (76/144) of all included trials.

Table 1 shows the distribution of mHealth intervention types. Single digital modalities were classified as single-component interventions, whereas combinations of technologies were classified as multicomponent interventions. Mobile app–based interventions were most frequent (74/144, 51.4%), followed by websites (20/144, 13.9%) and SMS text messaging (20/144, 13.9%). Multicomponent interventions constituted 13.9% (20/144), including mobile apps plus wearable devices (15/20, 75%), mobile apps plus SMS text messaging (4/20, 20%), and websites plus SMS text messaging (1/20, 5%).

Intervention modalities also evolved over time. Early studies (2009-2015; 14/144, 9.7%) mainly used single-channel approaches. After 2016 (130/144, 90.3% of the studies), mobile app–based interventions remained dominant, and all multicomponent interventions were from this period.

Figure 2. Number of randomized controlled trials on mobile health interventions for adult diabetes.

Table . Distribution of mobile health intervention types for adult patients with diabetes (N=144).

Intervention category	Studies, n (%)
Single-component interventions	
Mobile app	74 (51.4)
Website	20 (13.9)
SMS text messaging	20 (13.9)
Voice call	4 (2.8)
Video	5 (3.5)
Email	1 (0.7)
Multicomponent interventions	
Mobile app and wearable devices	15 (10.4)
Mobile app and SMS text messaging	4 (2.8)
Website and SMS text messaging	1 (0.7)

Quantitative Assessment of mERA Reporting Completeness

An overall reporting completeness score was calculated for each study based on the 16-item WHO mERA checklist (0 to 16 points). Across the 144 included RCTs, the mean overall mERA score was 6.74 (SD 2.71), with a median score of 6 (IQR 5-8; range 1-15). No study fulfilled all 16 criteria.

Factors Associated With mERA Reporting Completeness

Nonparametric and categorical analyses were conducted to evaluate factors associated with overall scores and item-specific reporting completeness.

Reporting completeness increased over time. Studies published after the mERA guidelines (2016-2026; 130/144, 90.3%) had higher overall reporting scores than pre-2016 publications (2009-2015; 14/144, 9.7%; median: 7 (IQR 5–8.75) vs 5 (IQR 4–5.75); mean: 6.90 (SD 2.74) vs 5.21 (SD 1.89); Mann-Whitney *U* test=528.5; *P*=.01).

After excluding 8 multicountry studies, high-income countries (HICs; 78/136, 57.4%) and LMICs (58/136, 42.6%) showed no significant difference in total reporting scores (median: 6 (IQR 5–8) vs 7 (IQR 4.25–9); mean: 6.50 (SD 2.26) vs 6.78 (SD 3.22); Mann-Whitney *U* test=2219.5; *P*=.85). Item-level analyses showed unadjusted *P*<.05 differences for items 1, 2, 6, and 12. Detailed item-level results are presented in Table 2.

XSL•FO
RenderX

Table . Item-by-item analysis of mHealth evidence reporting and assessment (mERA) reporting completeness across different intervention modalities and socioeconomic settings (N=144).

mERA core items	Overall reporting rate, n (%)	Single component (n=124), n (%)	Multicomponent (n=20), n (%)	*P* value[a]	HICs[b] (n=78), n (%)	LMICs[c] (n=58), n (%)	*P* value[d]
Item 1	21 (14.6)	19 (15.3)	2 (10)	.74	6 (7.7)	15 (25.9)	.004

Item 3	12 (8.3)	10 (8.1)	2 (10)	.67	5 (6.4)	5 (8.6)	.74
Item 4	128 (88.9)	110 (88.7)	18 (90)	>.99	69 (88.5)	51 (87.9)	.92
Item 5	78 (54.2)	65 (52.4)	13 (65)	.30	39 (50)	31 (53.4)	.69
Item 6	23 (16.0)	19 (15.3)	4 (20)	.53	6 (7.7)	14 (24.1)	.007
Item 7	40 (27.8)	35 (28.2)	5 (25)	.77	23 (29.5)	14 (24.1)	.49
Item 8	80 (55.6)	67 (54.0)	13 (65)	.36	41 (52.6)	36 (62.1)	.27
Item 9	21 (14.6)	17 (13.7)	4 (20)	.50	11 (14.1)	8 (13.8)	.96
Item 10	70 (48.6)	58 (46.8)	12 (60)	.27	39 (50)	26 (44.8)	.55
Item 11	90 (62.5)	75 (60.5)	15 (75)	.21	48 (61.5)	35 (60.3)	.89
Item 12	78 (54.2)	69 (55.6)	9 (45)	.38	36 (46.2)	38 (65.5)	.03
Item 13	90 (62.5)	73 (58.9)	17 (85)	.03	50 (64.1)	34 (58.6)	.52
Item 14	28 (19.4)	24 (19.4)	4 (20)	>.99	18 (23.1)	6 (10.3)	.05
Item 15	41 (28.5)	32 (25.8)	9 (45)	.08	17 (21.8)	21 (36.2)	.06
Item 16	53 (36.8)	43 (34.7)	10 (50)	.19	30 (38.5)	18 (31.0)	.37

[a]*P* value derived from chi-square or Fisher exact test for the comparison between single-component and multicomponent interventions.

[b]HIC: high-income country.

[c]LMIC: low- or middle-income country.

[d]*P* value derived from the chi-square or Fisher exact test for the comparison between HICs and LMICs (excluding 8 multinational studies).

Multicomponent interventions had higher overall reporting scores than single-component interventions (mean: 7.75, SD 2.94 vs 6.57, SD 2.65; median: 7.5, IQR 5.75-9.25 vs 6, IQR 5-8; Mann-Whitney *U* test=900.5; *P*=.04). Item 13 showed an unadjusted *P*<.05 difference, which did not remain significant after Benjamini–Hochberg false discovery rate (BH-FDR) correction.

To reduce confounding from multinational frameworks, we restricted the geographical comparison to 5 leading publishing nations (China, the United States, South Korea, India, and the United Kingdom; 66/144, 45.8% of the studies). Median reporting scores were 7.5 for China, 6.0 for the United States, 7.0 for South Korea, 5.0 for India, and 5.5 for the United Kingdom. The Kruskal-Wallis *H* test did not show a significant overall difference (*H*=8.21; *P*=.08).

Findings on the Essential mHealth Criteria

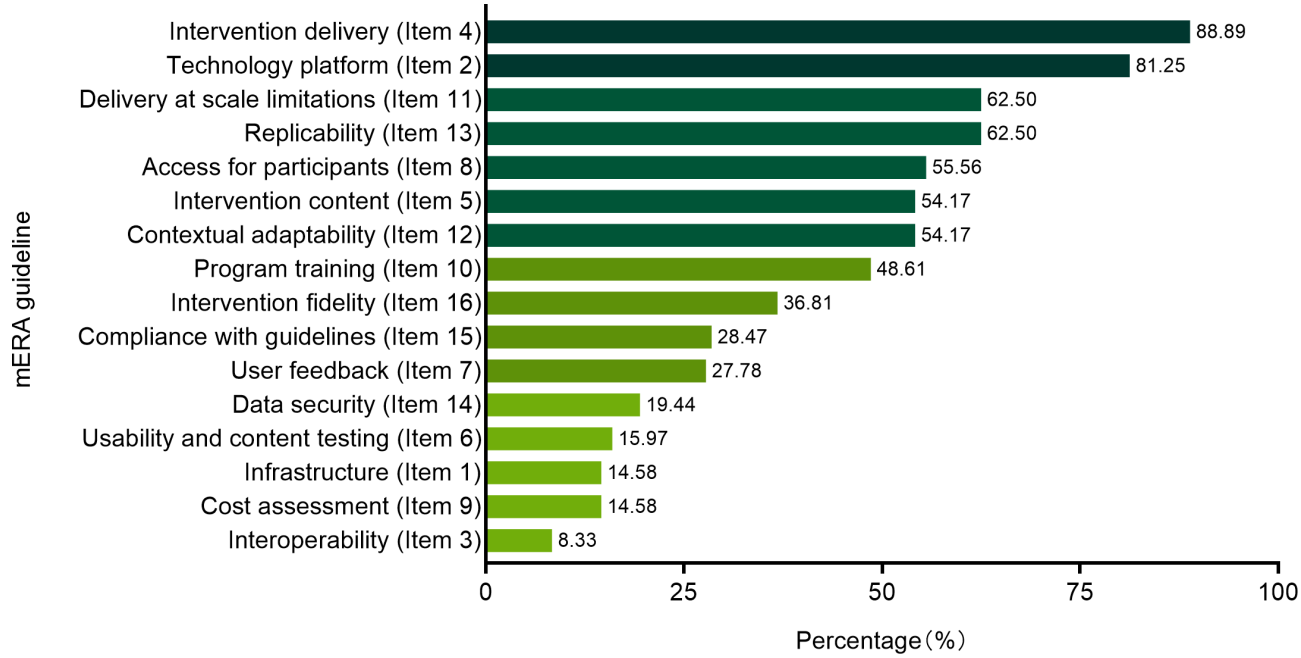

Figure 3 shows the evaluation results of the 16 basic mHealth criteria. Technology platform (item 2) was reported in 81.3% (117/144) of the studies, whereas intervention delivery (item 4) was reported in 88.9% (128/144).

Interoperability (item 3) was reported in only 8.3% (12/144) of the studies. Data security (item 14) was reported in 19.4% (28/144), and compliance with guidelines (item 15) was reported in 28.5% (41/144).

Cost assessment (item 9) was present in 14.6% (21/144) of the trials. Program training (item 10), scalability limitations (item 11), contextual adaptability (item 12), and intervention fidelity (item 16) were reported in 48.6% (70/144), 62.5% (90/144), 54.2% (78/144), and 36.8% (53/144) of the studies, respectively.

Figure 3. Reporting completeness of mobile health interventions for the 16 items of the mHealth evidence reporting and assessment (mERA) checklist.

Discussion

Principal Findings

This systematic review shows that reporting of adult diabetes mHealth RCTs remains uneven. Basic intervention delivery and technology platform information is generally described, whereas system-level and implementation domains—including interoperability, data security, regulatory compliance, and intervention fidelity—are much less consistently reported. These gaps limit readers' ability to interpret, reproduce, and translate interventions into routine practice. The updated analyses further suggest that reporting improved in more recent studies and tends to be more complete for multicomponent interventions, although substantial omissions remain. Together, these findings reinforce the central purpose of mERA: reports should provide sufficient information on intervention content, context, and technical characteristics to support interpretation and replication [14].

Comparison With Prior Work and the Real-World Consequences of Omission

Our findings extend prior evidence that evidence of clinical effectiveness in diabetes mHealth interventions does not necessarily indicate that their technical and implementation characteristics have been reported comprehensively. Previous systematic reviews have shown that mHealth interventions can improve glycemic and patient-centered outcomes while also demonstrating substantial heterogeneity in intervention delivery and implementation reporting [16]. In LMICs, for example, a systematic review of 30 studies found that implementation outcomes such as acceptability, appropriateness, and cost were reported inconsistently and that the mERA checklist had not been routinely applied [16]. Against this background, the present review shows that the reporting problem persists at the level of intervention specification itself: although core delivery characteristics are usually described, technical features needed to understand how an intervention functions and how it could be reproduced remain much less visible. The mERA framework was specifically developed to address this gap by establishing a minimum reporting set for the content, context, and technical features of mHealth interventions [14].

The low reporting of privacy, security, and regulatory information is particularly important because mHealth interventions routinely generate, transmit, or store sensitive health information. In our review, these features were frequently not described. This does not indicate that the interventions were insecure or noncompliant; rather, it indicates that these characteristics could not be established from the published reports. Previous reviews of mHealth apps have similarly identified privacy and security as important weaknesses requiring explicit attention during app design and evaluation [164]. Moreover, digital health data quality is multidimensional and closely linked to downstream clinical, research, clinician, and organizational outcomes [165]. Therefore, reporting security architecture, data governance, storage arrangements, authentication, and relevant regulatory requirements should be regarded as part of intervention characterization rather than as optional technical detail. Such information is essential for readers to judge whether an intervention can be safely transferred from a research setting into routine care.

Interoperability emerged as the most consistently overlooked core technical domain in the updated dataset. This finding is consequential because the value of many mHealth interventions depends on whether patient-generated data can move reliably among the mobile intervention, clinical information systems, and other digital health infrastructure. Standard-based approaches such as the SMART (Standard Based, Machine Readable, Adaptive, Requirement Based, and Testable) guidelines based on the Fast Healthcare Interoperability Resources demonstrate the feasibility of developing interoperable applications across heterogeneous health information systems but also highlight the practical challenges involved in moving from prototype-level interoperability to

XSL•FO
RenderX

production deployment [166]. Thus, the absence of interoperability reporting should not be interpreted simply as evidence that interoperability was absent. Instead, it represents an important reporting gap that prevents assessment of data exchange mechanisms, interface standards, integration with electronic health records, and the extent to which manual data transfer was required. Similarly, intervention fidelity was often insufficiently reported, limiting the ability to determine whether observed effects were attributable to the intended intervention or to deviations in delivery, engagement, or implementation intensity. These omissions are particularly important when evaluating complex, multicomponent interventions.

The updated analyses also modify the interpretation of temporal change and intervention complexity. Studies published from 2016 onward had significantly higher reporting scores than those published from 2009 to 2015, suggesting an improvement in reporting completeness after the introduction and dissemination of the mERA checklist and related digital health reporting standards [14,138]. However, the overall median score of 6 out of 16 (IQR 5-8) indicates that this improvement did not translate into comprehensive reporting across all domains. Multicomponent interventions also tended to be more completely reported than single-component interventions. This association should be interpreted cautiously: it does not establish that technological complexity itself causes better reporting. Multicomponent interventions may instead include more detailed methodological descriptions because they involve more components, delivery pathways, or implementation procedures. Importantly, the present data do not support the earlier claim of an inverse relationship between technological complexity and reporting transparency. More broadly, the distinction between methodological quality and reporting completeness remains essential. Reporting guidelines such as CONSORT-EHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and Online Telehealth) complement rather than replace design-specific risk-of-bias assessment by encouraging authors to describe intervention characteristics, context, and implementation sufficiently for readers to evaluate applicability and reproducibility [138].

Limitations

Several limitations should be considered when interpreting these findings. First, reporting completeness was assessed from the information available in published articles and supplementary materials; a low reporting score, therefore, indicates lack of documented information rather than confirmed absence of the underlying technical feature. Second, the analysis was designed as a meta-research assessment of reporting quality rather than a clinical effectiveness meta-analysis, so the relationship between reporting completeness and treatment effect could not be examined. Third, although the dataset was expanded to 144 trials and included studies published up to 2026, the evidence base remains heterogeneous with respect to technologies, intervention components, countries, and publication periods. Fourth, the HIC vs LMIC comparison excluded 8 multinational studies, and the country-level Kruskal-Wallis analysis was limited to 5 selected high-contributing countries; these analyses, therefore, should be interpreted as exploratory rather than definitive explanations of geographic differences. Finally, the present study focused on RCTs published in English, which may limit generalizability to pragmatic evaluations, observational studies, implementation studies, and non–English-language evidence, particularly from settings with fewer research and publication resources.

Conclusions

This updated review of 144 adult diabetes mHealth RCTs published from 2009 to 2026 demonstrates a persistent gap between reporting of intervention delivery and reporting of the technical and implementation characteristics needed for replication and translation. Overall mERA reporting remained modest (median 6/16, IQR 5-8). Although technology platform and intervention delivery were reported in 81.3% (117/144) and 88.9% (128/144) of the studies, respectively, interoperability (12/144, 8.3%), data security (28/144, 19.4%), regulatory compliance (41/144, 28.5%), and intervention fidelity (53/144, 36.8%) remained incompletely reported. Reporting completeness was significantly higher in studies published from 2016 to 2026 and in multicomponent compared with single-component interventions, but these associations do not eliminate substantial deficiencies in system-level reporting.

These findings suggest that improving digital health evidence requires reporting standards to be implemented alongside conventional trial reporting requirements. The mERA checklist provides a structured minimum set of items for describing mHealth interventions, whereas the CONSORT-EHEALTH checklist provides complementary guidance for reporting randomized evaluations of eHealth and mHealth interventions [14,138]. Future diabetes mHealth trials should explicitly report interoperability mechanisms, data security and governance, regulatory considerations, intervention fidelity, and implementation procedures. Such reporting would improve reproducibility, facilitate evidence synthesis, and allow health care organizations to assess whether interventions can be transferred safely and sustainably into routine practice. The priority should therefore shift from documenting only whether an intervention works to documenting sufficiently how, where, and under what technical and implementation conditions it works.

Acknowledgments

The authors declare the use of generative AI (GenAI) in the research and writing process. According to the Generative AI Delegation Taxonomy (2025), the following tasks were delegated to GenAI tools under full human supervision: proofreading and editing and translation. The GenAI tool used was Google Gemini 3.1 Pro. Responsibility for the final manuscript lies entirely with the authors. GenAI tools are not listed as authors and do not bear responsibility for the final outcomes.

Funding

The authors declared no financial support was received for this work.

Authors' Contributions

XY, X Huang, and MH contributed to the systematic review's conception and research question. XY contributed to the database searches. XY, X Huang, and MH participated in the selection of included studies. XY, JS, and JP extracted data from the selected studies. XY, X Hu, and MH were involved in statistical analysis and manuscript drafting. All authors gave final approval for the version to be published and agree to be accountable for all aspects of the work, ensuring that questions related to the accuracy or integrity of any part of the work are appropriately investigated and resolved.

Conflicts of Interest

None declared.

Abstract

Background: Digital health technologies (DHTs) offer opportunities to support poststroke self-management and rehabilitation, but their implementation may be hindered by mismatches between technological design, stakeholder needs, and care contexts. Synthesizing stakeholder perspectives can clarify implementation priorities and gaps in the evidence.

Objective: This study aimed to synthesize stakeholders' perceptions, experiences, and recommendations regarding DHT implementation in poststroke self-management and rehabilitation and to map the findings to the NASSS (Nonadoption, Abandonment, Scale-Up, Spread, and Sustainability) framework.

Methods: Six databases (PubMed, MEDLINE, Embase, Scopus, CINAHL, and Web of Science) were searched from inception through October 2025. Eligible studies were English-language, peer-reviewed primary studies using qualitative, quantitative, or mixed methods designs to report stakeholder perspectives on DHTs in poststroke care. Two reviewers independently screened studies, extracted data, and assessed methodological quality using the Mixed Methods Appraisal Tool (MMAT). A convergent integrated synthesis was conducted: quantitative findings were transformed into textual descriptors, combined with qualitative findings, coded inductively, and subsequently mapped deductively to NASSS domains and subdomains. Disagreements were resolved through consensus or by third-reviewer adjudication.

Results: Of 15,262 records identified, 42 studies published between 2019 and 2025 were included: 24 qualitative, 8 quantitative, and 10 mixed methods studies. Patients, health care professionals, caregivers, and members of the public were represented in 32, 19, 8, and 3 studies, respectively, with some studies including multiple groups. Evidence concentrated on the condition, technology, value proposition, and adopter-system domains. Stakeholders valued personalized functions, intuitive interfaces, timely feedback, and digital support that complemented human care. Barriers included stroke-related motor, cognitive, communication, and sensory impairments; unequal digital access and literacy; caregiver demands; staff workload and training needs; and poor integration with clinical routines. Data privacy and unclear payment arrangements also raised concerns. Evidence on organizational readiness and wider-system determinants was limited, and no eligible study directly examined interaction and adaptation over time. Methodological concerns included nonresponse bias and insufficient interpretation of integrated findings in mixed methods studies.

Conclusions: Stakeholder perspectives indicate that DHT implementation in poststroke care should combine accessible, personalized design with support for patients, caregivers, and health care professionals, alongside integration into clinical workflows and clear data governance and financing arrangements. The NASSS mapping identified priorities beyond usability, but current evidence does not establish sustained adoption, scale-up, or spread. Longitudinal studies in routine care are needed to evaluate adaptation and sustainability.

Introduction

Background

Stroke remains a major public health challenge worldwide and a leading contributor to mortality and disability [1]. According to the 2021 Global Burden of Disease (GBD) study, there were 93.8 million prevalent cases of stroke, 11.9 million new stroke events, and 7.3 million deaths from stroke [2]. Without strengthened prevention, treatment, and long-term care strategies, the global stroke burden is projected to continue increasing substantially by 2050 [3]. Nearly half of patients who are poststroke experience long-term disabilities that compromise independence and quality of life, resulting in ongoing needs for rehabilitation, self-management support, and long-term care [4].

The rapid development and adoption of digital health technologies (DHTs) have created unprecedented opportunities for supporting chronic disease management and home-based rehabilitation [5]. DHTs refer to technology-enabled tools that support health information delivery, monitoring, and care management, such as patient portals, mobile apps, wearable devices, and telemedicine platforms [6]. By making care more accessible and flexible and potentially reducing costs, DHTs could extend stroke support beyond traditional clinical settings and facilitate clinical decision-making, personalized care, and service delivery for populations with diverse needs, including those in low-resource settings [7].

DHTs are increasingly used to support poststroke monitoring, self-management, rehabilitation, and remote consultations [8]. Growing evidence suggests that digital health interventions can improve several clinically relevant outcomes among patients who are poststroke. For example, digital health–enabled stroke management has been associated with improved blood pressure control and reduced stroke recurrence [9]. In addition, meta-analytic evidence indicates potential benefits for poststroke cognitive functioning [10]. Home-based mobile health interventions have also shown potential to support risk-factor control and continuity of poststroke care [11]. By offering alternative and personalized interventions, DHTs can help overcome barriers to care and mitigate workforce shortages. DHTs may offer opportunities for scale-up, although successful dissemination and maintenance of intervention fidelity depend on the implementation context and sustained organizational support [12].

DHTs can deliver their potential benefits only when they are successfully implemented in clinical practice [7,13]. Real-world implementation requires not only evidence of clinical effectiveness but also a clear understanding of how DHTs are perceived, adopted, and integrated by relevant stakeholders [7]. Stakeholder perspectives from patients, caregivers, health care professionals (HCPs), organizations, funders, and policymakers are therefore essential for identifying the practical needs, contextual barriers, and system-level conditions that shape the implementation of DHTs in stroke care [14]. The NASSS (Nonadoption, Abandonment, Scale-Up, Spread, and Sustainability) framework was developed to support the evaluation and implementation of technology-supported health care programs [15]. Its seven domains cover the condition, technology, value proposition, adopters, organization, wider system, and interaction and adaptation over time, providing a structured lens for analyzing the implementation complexity of DHTs in stroke care [15,16].

Objectives

An increasing number of primary studies have examined the use of DHTs to support self-management and rehabilitation in patients who are poststroke [17-20]. However, few systematic reviews have synthesized this evidence through a structured implementation framework such as the NASSS framework. Applying the NASSS framework can help identify implementation determinants across diverse clinical and care settings and support more comparable, theory-informed implementation research [13]. The aims of this mixed methods systematic review were (1) to explore the perceptions, experiences, and recommendations of key stakeholders regarding the implementation of DHT in poststroke self-management and rehabilitation and (2) to map these findings onto the NASSS framework. This review provides implementation-oriented evidence to guide the future integration and scaling of DHT interventions in stroke care.

Methods

Search Strategy

We followed the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines [21]. The review protocol was registered in PROSPERO (International Prospective Register of Systematic Reviews; CRD420251112158). We searched 6 databases (PubMed, MEDLINE, Embase, Scopus, CINAHL, and Web of Science) from inception through October 2025. Reviews were excluded, but their reference lists and those of eligible studies were checked for additional records. Controlled vocabulary and free-text terms were tailored to each database. The full search strategies for all databases are available in Multimedia Appendix 1.

Eligibility Criteria

DHTs were defined as technology-based interventions that use data collection, automated analysis, feedback, or remote communication to support rehabilitation or disease management [8]. Studies were eligible if they (1) investigated a DHT, including therapy or education app, digital rehabilitation services, automated reminders, self-administered online services, or objective monitoring tools; (2) involved patients with stroke or stakeholders relevant to their care, including patients, family caregivers, family members, and HCPs; (3) reported qualitative or quantitative evidence on stakeholder perspectives, experiences, recommendations, or implementation challenges; and (4) were published in English. The intended end users had to include patients with stroke. We excluded technologies used only to deliver therapist-led exercises without data storage, feedback, or interactive functionality and communication-only services (eg, email, chat, or videoconferencing) without an autonomous or scalable digital component.

XSL•FO
RenderX

Study Selection

After deduplication in EndNote X9 (version 9.3.3; Clarivate Analytics), 2 reviewers independently screened the titles and abstracts of retrieved articles from the search strategy that potentially adhered to the study eligibility criteria. Full texts were then reviewed by the 2 reviewers for inclusion in the review. Disagreements were resolved through discussion and, when consensus could not be reached, through adjudication by a third reviewer.

Quality Appraisal

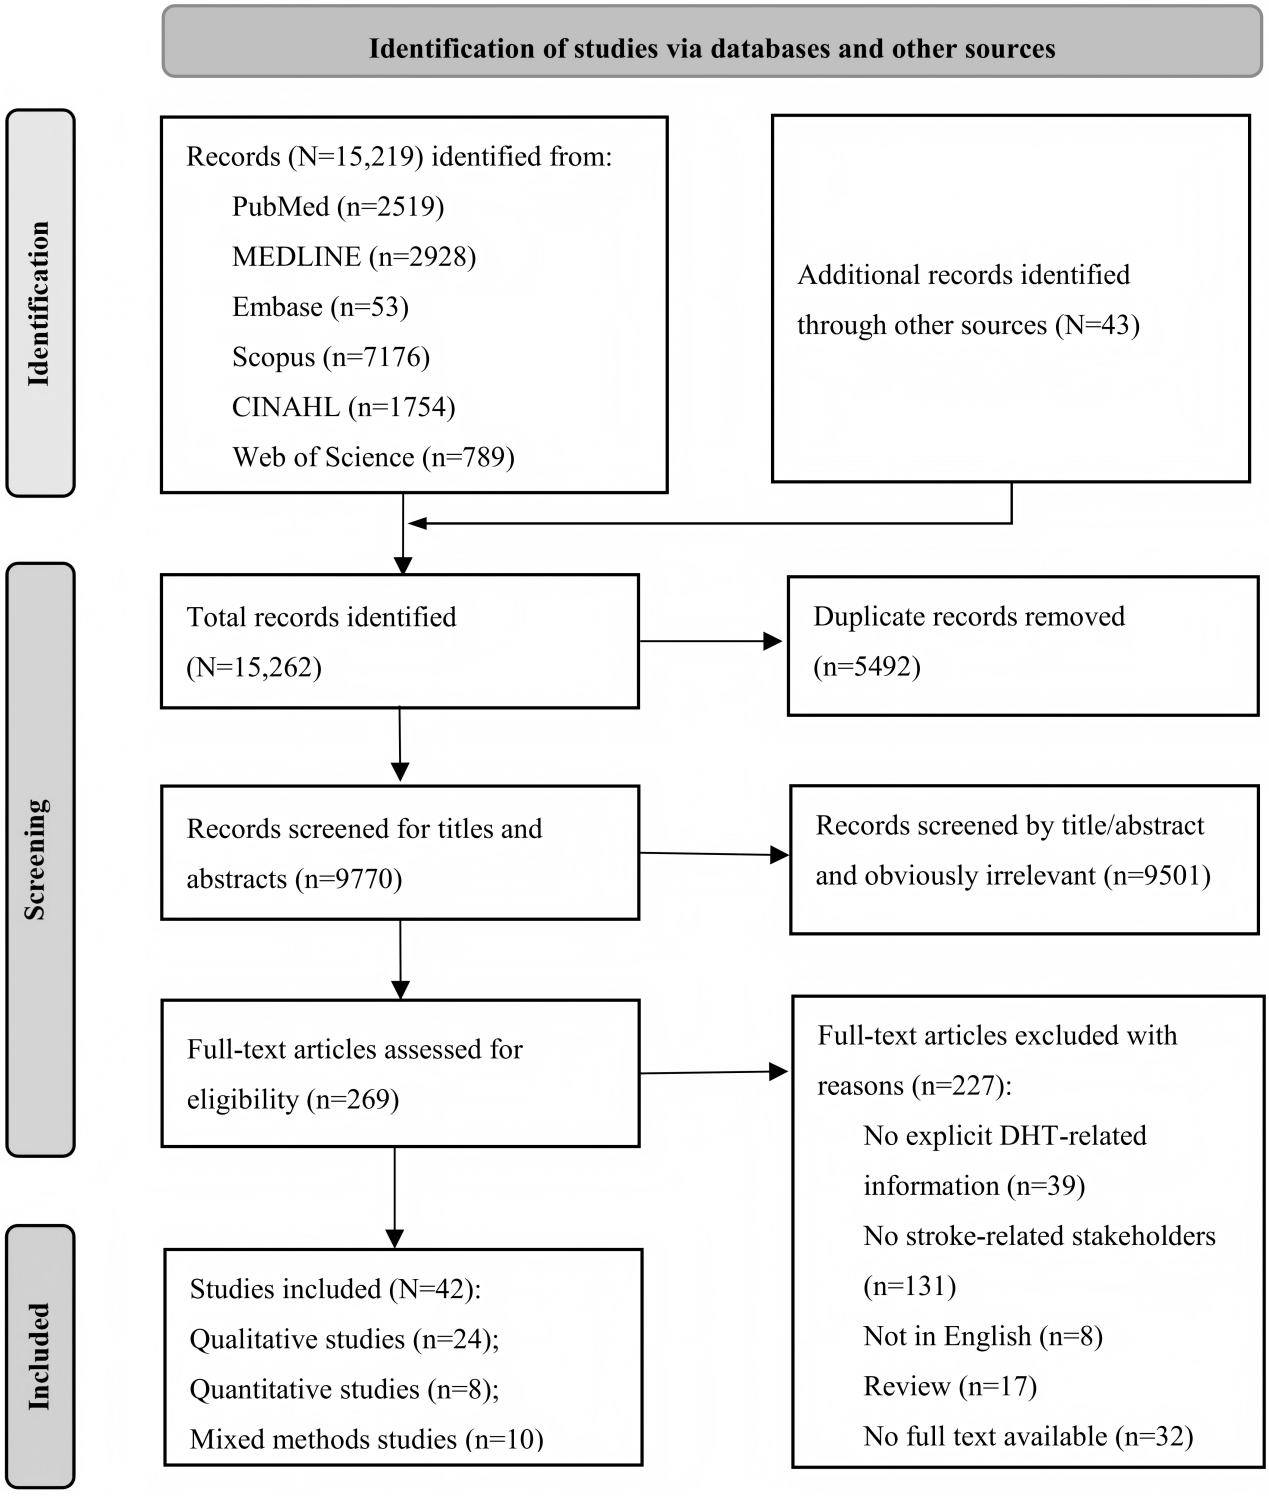
Two reviewers independently appraised the included studies using the 2018 Mixed Methods Appraisal Tool (MMAT) [22]. No study was excluded on the basis of the MMAT appraisal, and no overall numerical quality score or statistical weighting was applied. Criterion-level methodological concerns were considered when interpreting the breadth and strength of the NASSS-mapped findings.

Data Extraction

A shared Microsoft Excel extraction form, aligned with Joanna Briggs Institute guidance, was piloted on a subset of studies and refined before full extraction [23]. Two reviewers independently extracted publication details, country, design, data collection and analysis methods, participant characteristics, setting, DHT types, implementation context, and stakeholder findings. Discrepancies and unclear reporting were discussed by 3 authors, and the agreed decisions were recorded in the final extraction file.

Data Synthesis and Integration

We used a convergent integrated synthesis to analyze qualitative, quantitative, and mixed methods findings together [24]. Quantitative results were transformed into textual descriptors that retained the direction, magnitude, population, and context of the original result; qualitative findings and mixed methods results were extracted as author interpretations supported, where available, by participant quotations. The analysis proceeded in 3 stages. First, 2 reviewers independently applied open codes to the integrated findings without using the NASSS framework as an a priori coding structure. Second, related codes were compared and refined inductively into clinically meaningful categories through team discussion. Third, these categories were mapped deductively to the 7 NASSS domains and their subdomains using MAXQDA 2020 (VERBI Software) [25]. The NASSS framework was selected because it provides a common structure for comparing interacting implementation determinants across heterogeneous technologies, stakeholders, and care contexts [16,26,27]. As NASSS was originally developed primarily for evaluating individual implementation cases, we used it as an organizing framework. A category could be mapped to more than 1 domain when it represented distinct mechanisms. Findings that did not fit an existing subdomain were retained and used to develop 2 adapted technology subdomains. Disagreements were resolved through consensus or adjudication by a third reviewer.



Results

Literature Search Results

The searches identified 15,262 records. After 5492 duplicates were removed, 9770 records underwent title and abstract screening, and 269 articles were assessed in full text. Of these, 227 were excluded and 42 studies were included (Figure 1): 24 qualitative studies [17,18,20,28-48], 8 quantitative studies [19,49-55], and 10 mixed methods studies [56-65]. Devittori et al [55,66] published related studies in 2024 and 2025. Because the latter extended the former, only the 2024 study was included in the synthesis [55]. One included study used NASSS in its primary analysis [31]. Four stakeholder groups were represented: patients with stroke, caregivers, HCPs (including physicians, nurses, occupational therapists, and physiotherapists), and members of the public.

XSL•FO
RenderX

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart of the systematic review. DHT: digital health technologies.

Study Characteristics

Detailed characteristics of the 42 included studies are presented in Multimedia Appendix 2. The included studies were published between 2019 and 2025, with the number of publications increasing from 2022 onward. Studies were conducted in 21 countries: Australia (n=7), the United States (n=5), the United Kingdom (n=4), and China (n=3) were the most represented, while the remaining 23 studies were distributed across 17 countries. Settings included hospitals (n=14), rehabilitation centers (n=8), communities (n=4), homes (n=2), combined hospital-community settings (n=2), and multiple settings (eg, homes, hospitals, and communities; n=4). Two studies were conducted online, and 1 analyzed published user reviews of commercial stroke apps. The remaining 5 studies reported only geographical coverage without specifying the study setting. Six studies reported no funding, 18 received national research funding, 8 received institutional or association grants, 5 reported other funding, and 5 did not report funding.

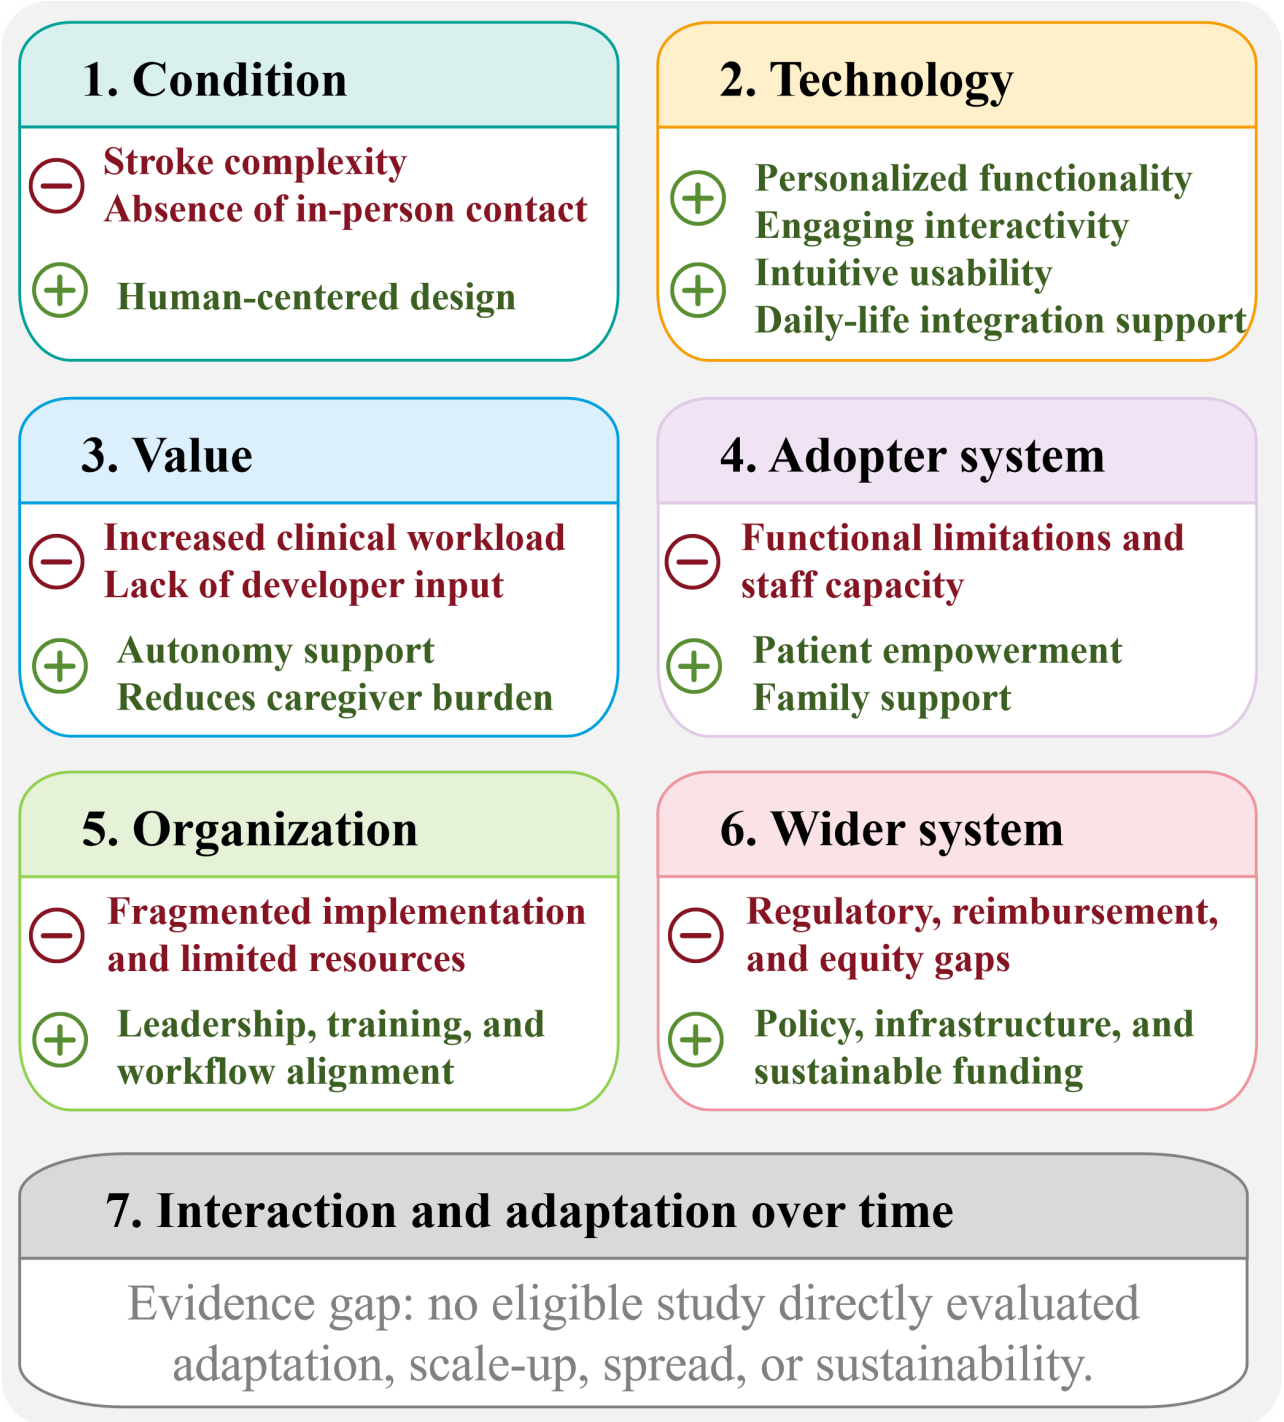
XSL•FO
RenderX

Participant Characteristics

Of the 42 studies, 32 included patients, 19 included HCPs, 8 included caregivers, and 3 included members of the public. Because individual studies could include more than one stakeholder group, these stakeholder-study counts exceed 42. Sixteen of the 32 patient-related studies included only patients with stroke. By study design, the 24 qualitative studies included 441 participants, the 8 quantitative studies included 830 participants, and the 10 mixed methods studies included 1550 participants. Overall, studies reported 1197 men and 1319 women participants. Gender was not reported for 305 participants. Sample sizes ranged from 4 to 48 for qualitative studies, 13 to 486 for quantitative studies, and 19 to 1194 for mixed methods studies. Technologies included mobile apps, wearable devices, telemedicine platforms, virtual reality systems, rehabilitation robots, and AI-enabled tools used for remote monitoring, personalized rehabilitation, and disease management.

Methodological Quality of Included Studies

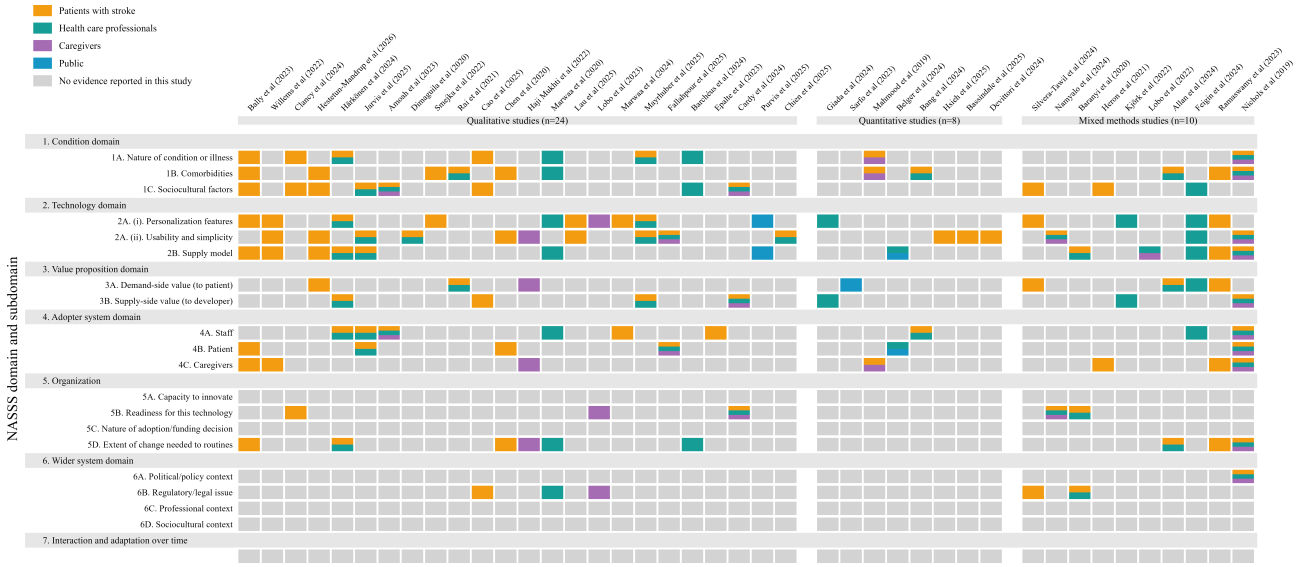
Quality appraisal results are detailed in Multimedia Appendix 3. Among the 24 qualitative studies, most showed coherence between their aims, data collection, analysis, and interpretation, although 2 did not clearly report data-collection procedures [29,44]. Among the 8 quantitative studies, measures and analyses were generally appropriate; 5 had a low risk of nonresponse bias [49-52,55], whereas 3 had a higher or unclear risk because response rates or differences between respondents and nonrespondents were insufficiently reported [19,53,54]. Only 4 of the 10 mixed methods studies adequately interpreted the outputs of qualitative-quantitative integration [56,58,60,63].



Themes

Overview

Inductive content analysis generated clinically meaningful categories, which were subsequently mapped to the NASSS domains and subdomains across the 42 studies. Evidence was concentrated in the condition, technology, value proposition, and adopter-system domains. No relevant evidence was identified for organizational capacity to innovate, the nature of organizational adoption or funding decisions, the professional context, the sociocultural context at the wider system level, or interaction and adaptation over time. Two adapted subdomains were added within the material features to distinguish personalization and accessibility from usability and simplicity. Figure 2 summarizes facilitators, barriers, and evidence gaps across the 7 domains. Figure 3 shows the study-level distribution of stakeholder evidence.



XSL•FO
RenderX

Figure 2. Synthesis of implementation determinants across the 7 NASSS (Nonadoption, Abandonment, Scale-Up, Spread, and Sustainability) domains. Green plus signs denote facilitators and red minus signs denote barriers reported by stakeholders. Domain 7 is shown in gray because no eligible study directly examined adaptation, scale-up, spread, or sustainability. The facilitators and barriers shown summarize key findings rather than providing an exhaustive list; detailed findings are presented in the Results section.

XSL•FO
RenderX

Figure 3. Matrix summarizing stakeholder perspectives reported across NASSS (Nonadoption, Abandonment, Scale-Up, Spread, and Sustainability) domains and subdomains. Columns represent 42 studies grouped by design, and rows represent NASSS domains and subdomains. Stacked colors indicate multiple stakeholder groups within the same study and subdomain [17-20,28-65].

Condition Domain

The first NASSS domain focuses on the illness-related context in which an intervention or technology is implemented. Across the included studies, stakeholders emphasized the context-dependent nature of DHTs, highlighting how the characteristics of stroke, together with the scope and setting of implementation, shaped technological requirements and constraints. Consideration of the stroke or clinical context was reported in 22 studies.

Nature of Condition or Illness

Across the included studies, perspectives on DHTs were predominantly patient-centered, reflecting the complex and heterogeneous nature of stroke [48]. Stroke-related impairments, including motor, cognitive, communication, emotional, visual, attentional, and fatigue-related difficulties, were frequently reported to constrain patients' capacity to engage with digital technologies and self-management activities [30,35]. Stakeholders viewed DHTs as supportive tools to facilitate poststroke self-management and rehabilitation rather than as standalone solutions [18]. The long-term and evolving recovery trajectory of stroke was identified as a challenge for the implementation of DHTs. While digital support was increasingly regarded as necessary to sustain rehabilitation and ongoing care beyond the acute phase [38,44], multiple studies emphasized that patients remained central to their recovery journey, with technology serving a complementary role [20]. Maintaining person-centered care, preserving human connection, and tailoring the balance between digital and face-to-face support to individual needs were consistently identified as key facilitators of effective implementation in poststroke contexts [42,51].

Comorbidities

Stroke commonly co-occurs with other chronic conditions [36]. Common comorbidities include cognitive, memory, language, and attention deficits, as well as psychomotor, fine motor, and sensory impairments [18,38]. Motivation to use DHTs was influenced by the perceived severity and relevance of the target problem, such as sleep disturbance [33]. Management of hypertension, diabetes, HIV/AIDS, and coronary heart disease was also considered important [34]. As noted by a participant, "Stroke is often a consequence of other chronic diseases such as hypertension, diabetes, HIV/AIDS, and coronary heart disease. Many with these underlying risk factors remain at risk if not well managed" [57]. Barriers therefore extended beyond clinical impairment to limited digital literacy, inadequate home infrastructure, and low motivation [29,34]. Many studies excluded people with moderate-to-severe cognitive impairment or aphasia, which limits the representativeness and generalizability of the evidence [19,20,52].

Sociocultural Factors

Stroke recovery demands longitudinal, human-centered technologies rather than one-off interventions [40]. Patients, caregivers, and clinicians consistently regarded in-person contact as important for safety, respect, and therapeutic relationships [18,20,35]. One patient noted: "It has to be personal by talking to each other in person and not via video call" [18]. Digital rehabilitation could not replace human interaction and care [29]. Acceptance was facilitated when DHTs complemented face-to-face care, incorporated culturally appropriate features, and involved family members [29,31]. Moreover, some HCPs have expressed concerns that DHTs could be mistaken for a substitute for clinical input, raising fears of professional displacement [44]. Acceptance of technology is further influenced by age, cultural norms such as familial caregiving expectations, and disability-related stigma [56]. Older adults required interfaces adapted to physical, cognitive, and social needs [35]. In younger adults, the reported underuse concerned stroke-specific digital tools rather than general digital literacy; limited age-targeted design and the perception that existing tools were intended for older populations may reduce relevance and engagement [17].

RenderX

Technology Domain

The technology domain refers to the materials, data, knowledge, and supply-related characteristics of DHTs. Most included studies (30/42, 71.4%) primarily focused on proposed functions, technical features, and user interface design. Based on the findings, 2 key aspects related to material characteristics were identified. In contrast, issues concerning knowledge development and intellectual property were addressed far less frequently.

Personalization Features

Material features of DHTs were reported as facilitators. Personalization was a central material feature of DHTs. It addressed heterogeneity in patients' impairments, goals, and recovery trajectories [18,28], particularly through adaptable interface design and prioritization of core functions [64]. Features such as adjustable text size, zoom functions, and simplified layouts were perceived as enhancing accessibility for users with sensory or motor impairments [40,42]. Establishing an individualized information library enables autonomous retrieval of relevant information, covering topics like stroke causes, medication, prognosis, and follow-up care [18,49]. In addition, providing opportunities to explore advanced information through external resources and reliable project-specific websites is considered beneficial [47]. Patient-entered health data enabled tailored alerts and reminders [30,33,40,56]. Continuous customized support can maintain motivation, self-management, and empowerment [41]. Personalization also enhances user-friendliness and promotes long-term adherence to ambulatory monitoring [47,60,64]. The interactive features such as chatbots, scoring, rewards, animations, and motivational toolkits were also considered important to successful DHT design [38,39].

Usability and Simplicity

Across studies, simplicity and intuitive navigation were central to adoption. Patients preferred systems that required little cognitive effort and remained stable, free from advertisements and disruptive updates [18,28]. As an HCP noted, "Keep it as simple as possible; these are all terms that people, especially with cognitive impairments, find difficult to understand" [28]. Stable interfaces with clear navigation, free from advertisements and disruptive updates, were regarded as essential for usability and cognitive accessibility [38]. "I think it needs to be easy to use. Some people I find are surprisingly lazy, and if it's not easy to use the first time, they just won't go back and try again," a health expert noted [47]. Systems integrating medication reminders, activity-based goal setting, structured daily routines, and self-monitoring functions (eg, symptoms, sleep, and physical activity) within user-friendly diaries or checklists were perceived as highly relevant and supportive of daily use [30,31]. Incorporating stroke education and rehabilitation guidance boosted relevance and immersion [29]. These features increased the likelihood that a technology could be incorporated into everyday life rather than used only during a short study period [31].

Supply Model

Across studies, relevant and timely feedback was identified as a central facilitator of engagement with DHT [31,32]. DHTs commonly generated personalized behavioral reports [28], providing feedback on progress, adherence, and outcomes [19,54]. Patients particularly valued positive and corrective feedback to sustain motivation and to make slow recovery trajectories visible [42]. One patient noted, "I need more feedback. If I have doubts, I can use it as a reference" [37]. DHTs generated behavioral health reports based on individualized health data and on users' performance [55]. Patients received feedback after submitting their daily performance scores [43]. As a patient explained, "Tracking your recovery so that you can actually see or know you're recovering. It's such a slow process. You want something that gives you feedback each day on how you're going" [17]. Clinicians also relied on real-time or near-real-time feedback to monitor patient activity and inform follow-up, valuing automated updates that required minimal manual oversight. For example, staff using the VERA (Virtual Engagement Rehabilitation Assistant) system valued automatic updates: "as long as it gives me feedback, like how many times this patient exercised over the weekend" [31]. Feedback delivered through visual [39], auditory [55], interactive [54], and rapid real-time formats [19] was associated with improved user experience, with rapid feedback and embedded encouragement further supporting motivation and emotional resilience [19,36,54].

Value Proposition Domain

The value proposition domain concerns whether the technology is worth developing or introducing for patients, clinicians, and suppliers. Across stakeholder groups, DHTs were broadly perceived as adding value beyond usual care, particularly in enhancing efficiency, accuracy, and accessibility [49].

Demand-Side Value (to the Patient)

Patients reported that DHTs could improve education, monitoring, and access to follow-up support. Quantitative research has indicated that more than 80% of users are satisfied with the technical performance and perceived health benefits of DHTs [50,56]. Patients valued reminders for home exercises, timely health information, access to therapists, and the ability to monitor progress [63,64]. Nevertheless, trust in clinicians and health care organizations generally exceeded trust in digital systems, and infrequent phone use, limited flexibility, and low perceived treatment relevance reduced demand [56]. Caregivers anticipated reduced workload [37], whereas HCPs were concerned that poorly designed monitoring and messaging systems could generate anxiety and additional clinical work [34].

Supply-Side Value (to the Developer)

Developer-related perspectives were reported in 7 studies, but they mainly came from HCPs involved in co-design rather than from commercial technology developers. Systematically eliciting the "voice of stroke patients," prioritizing requirements, and providing reliable educational resources were considered essential [31,40]. From the demand-side perspective, patients similarly emphasized that developers ensure easy access to

XSL•FO
RenderX

reliable educational resources [35]. Automation was valued for providing consistent monitoring and prompts, but it did not remove the need for clinical oversight, validation, or accountability [29]. The absence of direct industry perspectives limited conclusions about intellectual property, commercial incentives, interoperability, and scalability.

Adopter System Domain

Clinicians, patients, and family caregivers were identified as key stakeholder groups whose roles are expected to evolve with the adoption of DHTs. The adopter domain focuses on these groups' capacity, motivation, and willingness to adopt and sustain the use of DHTs.

Staff

Within the adopter system, HCPs linked patient-generated data with clinical decision-making. Medical staff emphasized the importance of timely, transparent access to patient data and digital resources as a prerequisite for engagement [31]. DHTs enable clinicians to monitor patients' health status longitudinally, manage structured clinical records, and use decision-support tools to guide clinical care [30]. These capabilities supported phased goal setting, remote monitoring, and continuity of care during transitions to community-based rehabilitation teams [17]. However, barriers to adoption were also prominent. Many clinicians reported high workload, limited training and digital literacy, and insufficient organizational support [38]. Clinicians were also reluctant to recommend technologies that lacked public funding, institutional approval, or clear evidence of benefit [41].

Patient

Intuitive, adaptable, and intrinsically motivating DHTs facilitated patients' transition from passive care recipients to active self-managers and increased awareness of their health status and recovery progress [32]. Patients valued the autonomy to determine when and how to engage with DHTs, which influenced both adoption and sustained use [43]. DHTs also supported home-based recovery by promoting independence in daily activities and rehabilitation, thereby fostering a sense of control that was often less evident in clinic-centered care [38]. This emerging digital awareness reflected patients' increasing recognition of their poststroke capabilities and energy limitations in everyday life. However, physical, cognitive, and emotional consequences of stroke, together with fatigue and low confidence in using DHTs, constrained sustained engagement for some patients [20,45].

Caregivers

Family caregivers were important implementation partners who provided technical assistance, emotional encouragement, and structure for daily routines. Family and peer support could reduce isolation and reinforce engagement [28]. However, caregivers also faced limited digital literacy, distrust of technology, competing demands, and family tension [18]. Sustainable implementation therefore requires explicit assessment of caregiver capacity, training and support for those who choose to participate, and safeguards against transferring clinical or technical responsibilities to families without adequate resources [28,37].

Organization

This domain addresses organizational capacity, readiness, adoption decisions, and the changes required to integrate DHTs into routine stroke care. Evidence was reported in 10 qualitative and 4 mixed methods studies but was limited to readiness for this technology and the extent of change needed to routines; no relevant data were identified for capacity to innovate or for the nature of organizational adoption or funding decisions.

Capacity to Innovate

No eligible study directly examined an organization's systemic capacity to innovate, such as its ability to absorb repeated technological change, maintain innovation infrastructure, or learn across implementation cycles.

Readiness for This Technology

Organizational readiness was constrained by fragmented implementation processes, poor resource allocation, and limited integration with clinical information systems [37,38]. An analysis of user reviews found that 39 of 46 stroke apps had been developed by nonmedical or noneducational entities, often with limited clinical validation or alignment with health-system standards [40]. A patient noted, "With the stroke, once you actually leave hospital, that's it. That's all. I've had absolutely no follow-up, none whatsoever...They, they just toss you out the door, and that's it; you're on your own" [20]. Facilitators included leadership support, protected implementation time, clinical validation, staff training, and clearly assigned responsibility for monitoring and follow-up.

Nature of the Adoption or Funding Decision

No eligible study directly evaluated how organizations made formal adoption, procurement, or internal funding decisions. References to reimbursement and public funding were coded under the wider-system domain because they concerned policy-level arrangements rather than a documented organizational decision-making process.

Extent of Change Needed to Routines

Because stroke care is multidisciplinary and crosses organizational boundaries, DHT implementation may require substantial changes to routines [18]. Studies identified a need for standardized digital care pathways, validated repositories, and mechanisms for sharing information across settings [30]. Dedicated implementation coordinators could support interoperability, training, and communication between technology teams and clinical services [36]. Caregivers should be recognized as optional partners with defined roles and support, not as substitutes for professional care [38]. One HCP said, "I believe that non-governmental organizations and hospitals can work together to help stroke patients, primarily to involve those responsible" [37]. Technologies that did not align with person-centered, integrated care risked superficial use or abandonment [44]. Organizational readiness depends on favorable conditions, such as leadership support, clear roles, and protected time for adaptation [65].

XSL•FO
RenderX

Wider System Domain

The wider system domain encompasses political, economic, and regulatory contexts that shape the implementation of DHTs and influence their scalability and long-term sustainability. Only 6 included studies reported determinants operating at the broader health care, social, or policy system level.

Political/policy Context

Despite the proliferation of DHTs, evidence to guide policy remained limited [35,65]. While technology-supported models may succeed temporarily through local improvisations or pilot projects, they ultimately falter without supportive regulatory frameworks and sustainable financing [38]. Long-term viability demands aligned policy, standardized protocols, and systemic investment, not just technical innovation [40].

Regulatory/legal Issues

While participants acknowledged that data sharing enables personalized feedback, it was also perceived as requiring trade-offs in personal privacy. As a clinical manager noted, “when you want to understand somebody, data must be collected in several areas, and based on these data you can provide feedback. So, you give up some privacy to be coached" [28]. The use of cameras or images within apps raised additional privacy concerns for some users [56]. Another requirement involves obtaining patient consent for sharing sensitive data [38]. The issue is the authenticity of the app, as users felt they were being scammed into paying for features within the app [35]. Moreover, users who contacted customer care services for assistance did not receive a reply, which increased their fears [40]. Unclear reimbursement and payment arrangements created uncertainty for providers and could exclude people unable or unwilling to pay. Trust therefore depended on transparent data practices, credible governance, responsive support, and equitable financing [56].

Professional Context

No eligible study directly examined how professional regulation, accreditation, liability standards, or interprofessional jurisdiction shaped implementation.

Sociocultural Context at the Wider-System Level

No eligible study directly examined population-level sociocultural norms or public discourse as wider-system determinants. Patient-level and family-level cultural findings were retained in the sociocultural factors domain.

Interaction and Adaptation Over Time

No study directly evaluated the seventh NASSS domain. The evidence focused on anticipated use, co-design, cross-sectional experience, or short-term feasibility; it did not track how DHTs were adapted, abandoned, embedded, scaled, spread, or sustained in routine care. This absence limits conclusions about long-term sustainability.

Discussion

Principal Findings

In this review, we synthesized findings from 42 studies to examine stakeholder perspectives on DHTs in poststroke care. The findings were organized within the NASSS framework. The DHT-specific subdomains identified may inform the future development and optimization of DHTs [26]. The earliest included study was published in 2019, and the number of publications increased from 2022 onward, reflecting the rapid development of stroke-related DHTs in recent years [4]. Our findings indicate that the 4 stakeholder groups recognize the importance of the proposed functions, features, and user interface design elements of DHTs, such as personalization, feedback mechanisms, and alert functions. These are seen as essential for the effective use of DHTs in stroke care. A key concern raised by stakeholders related to data security, its ownership, and payment for DHTs. Despite the evident benefits that DHTs could offer patients with stroke in terms of their health, patients emphasized that safety and reliability must be guaranteed as a prerequisite for use. In particular, the supply side adopts a supportive role, focusing on aligning technological solutions with user needs. Our review also revealed that there is limited discussion of clinical and technical accountability among regulators and policymakers. Evidence concerning the adoption of regulatory standards was limited [67]. This suggests that further research should focus on regulatory aspects, particularly in the context of clinical implementation [14].

Personalization, Usability, and Feedback

The perceived usefulness and ease of use of technology are the most significant determinants of its adoption, providing users with a sense of agency in managing their stroke condition [40]. Although designing tailored DHTs is more time-consuming than adopting a one-size-fits-all approach, this approach enables consideration of the unique characteristics, needs, and preferences of different stroke populations, which may enhance user experience, engagement, and adherence [18,32]. Therefore, tailoring both functionality and interface design to specific stroke subgroups is essential [35]. Patients emphasized the need for design elements that favor simplicity and are easy to use and intuitive. For older adults in particular, providing technical support tailored to their needs can enhance their digital skills and address usability barriers [68]. The number of tailored versions required depends on the nature of the condition, associated comorbidities, and sociocultural factors related to stroke. Moreover, by integrating wearable DHTs into clinical care, personalized, data-driven intervention effects can lead to results that are superior to those achieved with the use of generalized clinical data [20]. DHTs can be used to provide personalized health recommendations based on specific patient data, which has the potential to motivate patients, modify their behavior, and tailor their medication and treatment plans [20,69]. Therefore, features of DHTs should facilitate a personalized approach to meet patients’ needs. The findings highlight the critical role of timely and relevant feedback within DHTs in supporting stroke survivors’ engagement and facilitating the monitoring of disease progression. Both patients and clinicians value personalized, frequent feedback mechanisms, as these

XSL•FO
RenderX

help to sustain motivation and enhance recovery tracking [29,59]. Patient portals have the potential to enhance patient engagement in managing their health by allowing access, for example, to discharge summaries, medications, laboratory results, and secure patient-provider communication. Providing visual, auditory, automated, and real-time feedback enhances the user experience, promotes emotional resilience, and supports long-term recovery [70].

Digital Literacy and Human Support

To reduce the "digital divide," ongoing education and programs are essential to enhance digital literacy among both patients and HCPs, ensuring they can effectively use DHTs [19]. DHTs can be delivered either as a purely self-help tool or with human guidance, and incorporating human guidance has been shown to enhance treatment adherence and improve outcomes. In addition, software developers should involve end users in the design and testing phases to ensure that DHT systems align with users' contextual needs and seamlessly integrate into existing routines. Empowering patients with access to their health data not only fosters a sense of control over their own health management but also enhances patient satisfaction [38]. This active involvement can strengthen the patient-provider relationship by promoting shared decision-making and encouraging greater engagement in the management of their condition. The success of such use is often dependent on coordination across home, clinic, and rehabilitation center networks. The role of technology is to facilitate this, rather than to create fragmentation. Caregivers can be better supported through structured training programs, such as toolkits, workshops, or digital courses that build their competence in using DHTs and understanding stroke-related needs [37,46]. Additionally, integrating peer support groups can reduce isolation and foster resilience. Ensuring caregivers have ongoing access to professional guidance and emotional support empowers them to provide consistent, person-centered care [71].

Financing, Regulation, and Data Privacy

Consistent with previous systematic reviews, this study identified a scarcity of health economic evaluations of DHTs in stroke care [72]. There remains a recognized need for ongoing regulation to govern the clinical use of DHTs and the contexts in which they are implemented, underscoring the importance of further research into regulatory frameworks, particularly regarding clinical integration [14]. National-level research funding accounted for the largest proportion of support for the included studies, highlighting its critical role in driving high-quality research on DHTs in stroke care. To ensure equitable access, policy-level decisions are required on reimbursement, welfare support, and public investment, with the aim of positioning digital health as a public good rather than a consumer product. Safety and confidentiality are important ethical issues in DHTs. Studies suggest that users often hesitate to share their personal information with unfamiliar suppliers due to fear of data misuse. Consequently, this affects how users interact with the technology [61]. The amount of personal and health data collected varies depending on the purpose of the intervention; therefore, it is essential to inform users about what data are collected, how they are used, and where they are stored [12].

Implications for Practice

To our knowledge, this is the first systematic review–level synthesis of stroke-related DHT evidence organized using the NASSS framework. This review summarizes the key priorities for optimizing DHTs. The general positive attitude toward DHTs among stakeholders creates a foundation of trust [4]. To maximize impact, future practice should prioritize delivering specific, personalized information and interventions tailored to the diverse characteristics and preferences of patients with stroke. The involvement of family members in the implementation and management of DHTs is important to enhance social and mental support. To ensure the effectiveness and quality of management programs, it is essential for health care providers and other program stakeholders to strengthen training and education, clearly define responsibilities, establish communication platforms, and create supervision and feedback processes [67]. Moreover, given the identified resource limitations, future research should better define the cost-effectiveness and equitable distribution of stroke-related DHTs to ensure long-term sustainability.

Recommendations and Future Directions

Future implementation of DHTs in poststroke care should be treated as a system-level program jointly owned by patients, caregivers, HCPs, developers, organizations, and policymakers. From the outset, implementation plans should define clinical ownership, patient and caregiver support, staff training, workflow integration, escalation pathways, technical maintenance, interoperability, data governance, and sustainable financing. Particular attention should be given to equitable access and to accommodating stroke-related motor, cognitive, communication, and sensory limitations [38]. The absence of evidence regarding interaction and adaptation over time in the NASSS framework also highlights a critical research priority. Longitudinal mixed methods studies embedded in routine care should combine repeated stakeholder assessments with usage, clinical, organizational, and economic data to examine adaptation, scale-up, and sustainability across settings and service transitions. Consistent reporting of implementation processes and contextual changes would help distinguish initial acceptability from sustained adoption and identify which support mechanisms remain effective over time.

Limitations

Several limitations should be acknowledged. First, restricting the review to English-language, peer-reviewed publications and excluding gray literature, conference proceedings, and trial registries may have introduced language and publication bias. Second, although the search combined controlled vocabulary and free-text terms, the diversity and rapidly evolving terminology of DHTs may have led to the omission of relevant terms or studies. Third, interrater agreement coefficients were not prospectively calculated or retained for study screening, quality appraisal, or NASSS mapping. Fourth, the evidence primarily represented patients, caregivers, and HCPs, with limited input from software developers, industry representatives,

XSL•FO
RenderX

and policymakers. This restricted consideration of commercialization, regulation, and scalability. Finally, substantial heterogeneity in DHT functions, apps, settings, and target populations may have contributed to variability across findings and limited their generalizability.

Conclusions

Successful implementation of DHTs in poststroke care requires more than technical functionality. Technologies should accommodate stroke-related impairments, digital access and literacy, caregiver capacity, and the routines of multidisciplinary services. Organizations should define clinical ownership, training, interoperability, data governance, and sustainable financing before deployment. NASSS can be used prospectively to identify implementation complexity and evidence gaps, but the present literature provides insufficient longitudinal evidence to infer sustained use, scale-up, or spread. Future studies should therefore evaluate adaptation and outcomes over time while reporting how patient, caregiver, professional, organizational, and policy priorities are addressed.

Acknowledgments

The authors would like to express their sincere gratitude to Dr Yuanxi Jia from the National University of Singapore for her invaluable guidance and expertise on the methodology of this systematic review. The authors confirm that no generative AI tools were used at any stage in the preparation of this manuscript. The authors take full responsibility for the accuracy, originality, and integrity of the manuscript.

Funding

This work was supported by the National Key Research and Development Program of China (grants 2023YFC3605200 and 2023YFC3605201), the Beijing "Young Seedling Program: for High-Level Innovative and Entrepreneurial Leading Talents (grant 2-1-008-0260), and the Clinical Medical Research Promotion Program of China Medical Foundation (grant 2025CMFA04).

Data Availability

All data analyzed during this study are included in this published article and in its Multimedia Appendix information files.

Authors' Contributions

Jing Zhao and HC conceived and designed the study. Jing Zhao performed the literature search, conducted data extraction, and drafted the manuscript. Jie Zhao, XL, YC, and XW conducted the study selection, quality assessment, and data curation. Jie Zhao and YD provided critical revisions and edited the manuscript for intellectual content. HC supervised the project and finalized the manuscript. All authors have read and approved the final manuscript.

Abstract

Background: Consumer wearables are increasingly being integrated into health research for data collection. Although they are attractive to use, the accuracy of their photoplethysmography (PPG)-based measurements can be influenced by user characteristics such as sex, age, BMI, and skin tone. However, our knowledge regarding the validity of these measurements in certain populations, such as those with darker skin tones, seems limited. This is concerning as uncorrected differences in measurement accuracy can lead to health disparities when consumer wearable measurements are used more frequently. A potential cause for the gap in our knowledge regarding consumer wearable validity is the underrepresentation of certain population groups in studies validating PPG-based consumer wearables.

Objective: This scoping review aimed to map the representation of different sex, age, BMI, and skin tone groups in studies assessing the validity of PPG-based pulse rate, heart rate variability, blood pressure, peripheral blood oxygen saturation (SpO_2), and respiratory rate measurements of consumer wearables.

Methods: A literature search was conducted in Scopus, PubMed, and IEEE Xplore in July 2025. Papers were eligible if they assessed the validity of consumer wearable PPG-based measurements, expressed as the agreement with a reference method. From the included papers, the study population distribution of sex, age, BMI, and Fitzpatrick scale was extracted. To evaluate the representation, percentages of people in specific age, BMI, and skin tone groups were estimated based on reported means and SDs. The median percentage of participants in each population group, as well as the total percentage, is reported.

Results: After the removal of duplicates, 734 papers were screened for eligibility. Following title and abstract screening, 238 papers remained, of which 186 passed full-text screening and were included in the review. Most of the studies (n=160) focused on pulse rate. Sex, age, BMI, and Fitzpatrick scale were reported by 179 (96.0%), 178 (96.0%), 101 (54.0%), and 35 (19.0%) out of 186 studies, respectively. While the median representation was 0% (IQR 0%-8%) for both older adults (>65 y) and individuals with obesity (BMI>30 kg/m^2; IQR 0%-13%), aggregate participation across all studies was higher (1290/6367, 20.0% and 473/3428, 14.0%, respectively). Individuals with underweight (BMI<18.5 kg/m^2) remained rare (median 3%, IQR 0%-7%), and the aggregate was 7.0% (225/3428). The median percentage of people with darker skin tones (Fitzpatrick type V and VI) participating in a study was 0%.

Conclusions: Based on our results, it can be concluded that older adults and people with underweight, obesity, or darker skin tones are generally underrepresented in studies assessing the validity of consumer wearable PPG-based measurements. Future validation studies should focus more on the representativeness of the study population. This can be achieved by setting a benchmark for representativeness and including study population representatives during the study design process.

Introduction

In 2012, the first commercial wrist-worn pulse rate sensor was released via a Kickstarter campaign [1]. It was developed for athletes to keep track of their pulse rate during training without having to wear a chest strap. Now, a little more than a decade later, the sensing functionalities of consumer wearables have expanded significantly. In addition to pulse rate, these wearables measure, among others, heart rate variability (HRV), peripheral blood oxygen saturation (SpO_2), respiratory rate, blood pressure, skin temperature, and skin conductance. Using these measurements, composite measures such as stress and sleep quality scores are also derived. The added sensing functionalities have broadened the use of consumer wearables from a tool to enhance exercise performance in athletes to health and well-being monitoring for consumers. It is forecasted that the number of smartwatch users will reach 740.53 million in 2029 [2].

Not only have consumers embraced wearables, but the use of consumer wearables in health research is also increasing. A scoping review published in 2022, mapping the use of wearables in health research, identified 179 studies, of which 163 used a consumer wearable [3]. An increase in the number of studies using wearables published per year was observed, rising from 1 in 2013 to 21 in 2017 and doubling to 56 in 2020. In these studies, consumer wearables were implemented for various purposes, ranging from examining correlations between wearable-derived outcomes and other physiological outcomes to developing risk prediction models, disease screening, and monitoring.

The integration of consumer wearables into health research is attractive, as they enable continuous and remote measurements of diverse outcomes while being more comfortable for participants and often more affordable than medical-grade or research-grade sensors. It should be noted, however, that many consumer wearable measurements, including pulse rate, HRV, SpO_2, blood pressure, and respiratory rate, are based on photoplethysmography (PPG). PPG is an optical measurement technique in which light is used to detect changes in blood volume in the skin microvascular bed [4]. The signal produced by this technique is sensitive to external factors, such as environmental light and movement, as well as user characteristics that influence the optical properties of the skin, such as sex, age, BMI, and skin tone [5-7]. For example, melanin in the skin, a determinant of skin tone, absorbs and scatters light, which influences the PPG signal quality [5]. The validity of PPG-based measurements thus varies between measurement conditions and users.

In the last few years, concerns have been raised about our limited knowledge regarding the validity of PPG-based consumer wearable measurements in certain population groups, such as people with darker skin tones or older individuals [8-10]. As manufacturers often do not report the validity of their consumer wearable measurements, researcher-initiated validation studies are being conducted to compare consumer wearable measurements with a reference method. Thus far, these validation studies have reported the accuracy of consumer wearable measurements under different conditions, such as during rest, physical activity, or sleep, in both controlled laboratory settings and free-living conditions [11,12]. However, the influence of characteristics such as sex, age, BMI, and skin tone on measurement validity remains largely unclear, and studies investigating this influence appear to be scarce [13-15]. If potential differences in measurement validity remain unidentified, these differences could contribute to variations in the accuracy of consumer wearable–based risk prediction, disease screening, and monitoring tools across populations. In turn, this may lead to an increase in health disparities—defined as preventable differences in the opportunity to achieve optimal health—as the integration of consumer wearables into health research and, eventually, health care progresses [8-10].

It is hypothesized that the underrepresentation of certain population groups in studies assessing the validity of PPG-based consumer wearable measurements contributes to the gaps in our knowledge about the validity of these measurements in different populations. To improve our understanding of these topics, the potential gaps in the representation of different population groups need to be identified and addressed. The aim of this scoping review is to systematically map the representation of different sex, age, BMI, and skin tone population groups in studies assessing the validity of PPG-based consumer wearable measurements, including pulse rate, HRV, blood pressure, blood oxygen saturation, and respiratory rate. Additionally, we will evaluate the representation of these different population groups to determine which groups require increased representation in future validation studies to enable the investigation of differences in measurement validity between population groups.

Methods

Study Design

This study was performed between May 2024 and August 2025 using the methodological framework for scoping reviews proposed by Arksey and O'Malley [16]. The registration and protocol for this review are available on the Open Science Framework (OSF) [17]. This review is reported according to the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) extension for scoping reviews (PRISMA-ScR; Checklist 1) guidelines [18].

Eligibility Criteria

Papers eligible for inclusion in this scoping review were those assessing the criterion validity, the agreement of a new measurement method with a criterion measure, of one or more commercial wearable sensors for measuring pulse rate, HRV, blood pressure, respiratory rate, and/or oxygen saturation in humans. The following exclusion criteria were applied:

- The wearable sensor that was validated is a chest strap, as chest straps are considered a criterion measure [19].
- The wearable sensor that was validated is not and was not at any point commercially available to consumers, as this scoping review focuses on consumer wearables only.
- The wearable sensor that was validated is not meant to be worn continuously during daily activities, as we consider

XSL•FO
RenderX

this an important characteristic of a true consumer wearable device.
- The wearable measurement that was validated was measured using a method other than PPG, as this scoping review focuses on PPG-based measurements only.
- N=1 or case studies are excluded as this review has a focus on the distribution of characteristics within study populations.
- Animal studies are excluded, as this scoping review focuses on human participants.
- Reviews, editorials, opinion pieces, and protocols are excluded, as these are not primary research papers.
- No full text could be obtained, or insufficient information was provided in the full text. At least the sample size, the reference method used, and the name and brand of the wearable used should be mentioned to be able to verify if other exclusion criteria apply.
- Publication languages other than English are not considered, as English is the language in which all involved reviewers are proficient.

Search Strategy

A literature search was conducted on June 11, 2024, in the databases Scopus, PubMed, and IEEE Xplore. To update the results before publication, the same search was repeated on July 16, 2025. The main concepts included in the search strategy were “PPG-based measurements,” “validity,” and “consumer wearable.” The keywords for these concepts were selected through pilot searches. The search strategy for all 3 databases can be found in Multimedia Appendix 1. Additionally, the reference lists of reviews returned by the database search were reviewed to identify additional papers.

Screening and Selection

The database search results were uploaded to EndNote 20 (Clarivate) for duplicate removal, after which the remaining papers were uploaded to Rayyan for screening. Prior to initiating the official screening process, the screening guide was tested by 2 reviewers (RMS and FOD) during a pilot screening round with 10 papers. There were no conflicts between the 2 reviewers, and no adjustments were made to the screening guide. The reviewers, RMS and FOD, then proceeded to independently screen the papers for eligibility based on title and abstract, after which a full-text screening took place. Conflicts were resolved through discussion between the 2 reviewers.

Data Charting

Extracted data included information on the type of publication, wearable, study context, recruitment and eligibility, and study population. A complete overview of the data items extracted is presented in Table 1. Most studies do not report how they assessed sex; therefore, it is often unclear whether they report sex or gender. For consistency within this review, we will refer to this characteristic as sex. For skin tone, it was decided to extract the Fitzpatrick scale as this is how most studies report skin tone [13], and as it is the measure recommended by several guidelines, including the US Food and Drug Administration (FDA) guideline on pulse oximeter evaluation, the guidelines for the evaluation of consumer wearable pulse rate validity published by the INTERLIVE network, and the ANSI/CTA (American National Standards Institute/Consumer Technology Association) standard [19-21].

The data charting form was created by RMS in Microsoft Excel. This form was used independently by 2 data extractors in a data charting pilot (RMS and FOD) with 10% of the included papers. For the main data items of interest, for example, study population characteristics, the percentage agreement between the 2 extractors was 95.5%. However, the agreement on the level of physical activity was low (40%). Therefore, additional guidelines for extracting the level of physical activity were added to the data extraction form, after which RMS proceeded with charting the data of the remaining papers independently.

Table . Extracted data items from 186 studies assessing the validity of consumer wearable photoplethysmography-based measurements.

Category	Extracted information
Publication information	Title, year of publication, first author, and DOI
Wearable	Brand, model, version of operating system, and intended wear location
Context	Study location, reference device, and level of physical activity
Recruitment and eligibility	Recruitment location, recruitment channels, and eligibility criteria
Study population	Sample size, distribution of sex, age, height, weight, BMI, and Fitzpatrick scale, and disease status

Synthesis of Results

With the extracted data, the number of studies per PPG-based measurement, the number of wearable brands and models, studies per year, and per study location were determined. Additionally, the recruitment locations and eligibility criteria were summarized.

Evaluating Representation

To provide an overview of the representation of population groups, 2 different approaches were applied. First, for the characteristic sex, the percentage of women in a study was extracted or calculated based on the number of women and the sample size. Based on this percentage, studies were categorized as equal distribution (at least 40% men or women), men-dominant or women-dominant (more than 60% men or women, respectively), men only, or women only. As none of the studies reported the participation of intersex individuals, this review can therefore only report the distribution of men and women.

XSL•FO
RenderX

Second, for age, weight, height, BMI, and Fitzpatrick scale, the weighted mean (SD) was calculated to capture the distribution of these characteristics in the included studies. Additionally, for age, BMI, and Fitzpatrick scale, the percentage of participants in commonly used groups of these characteristics was estimated to better visualize the representation of these different groups (Textbox 1) [22-24]. The percentages were estimated based on probability, using the mean and SD reported by the included studies [25]. First, the *z*-scores for the boundaries of each group were calculated using the provided mean and SD. Second, to estimate the probability of a value equal to or less than the boundary *z*-scores occurring, known as the cumulative distribution function, the *pnorm* function was used in RStudio (version 2023.6.1.524) with R (version 4.4.1). The percentage of participants in a group was then estimated by subtracting the cumulative distribution function of the lower boundaries from the cumulative distribution function of the upper boundaries. A threshold was applied to ensure that percentages lower than the contribution of 1 participant were rounded to 0. For age, the distribution was often truncated at 18 years of age, as studies only included adults. In these cases, the *ptruncnorm* function with a lower bound of 18 was used instead of the *pnorm* function.

Textbox 1. Age, BMI, and skin tone categories used in a scoping review of 186 studies assessing the validity of consumer PPG-based measurements.

Age categories (years)

- Children: <13
- Adolescents: 13 - 17
- Adults: 18 - 65
- Older adults: ≥65

BMI categories (kg/m^2)

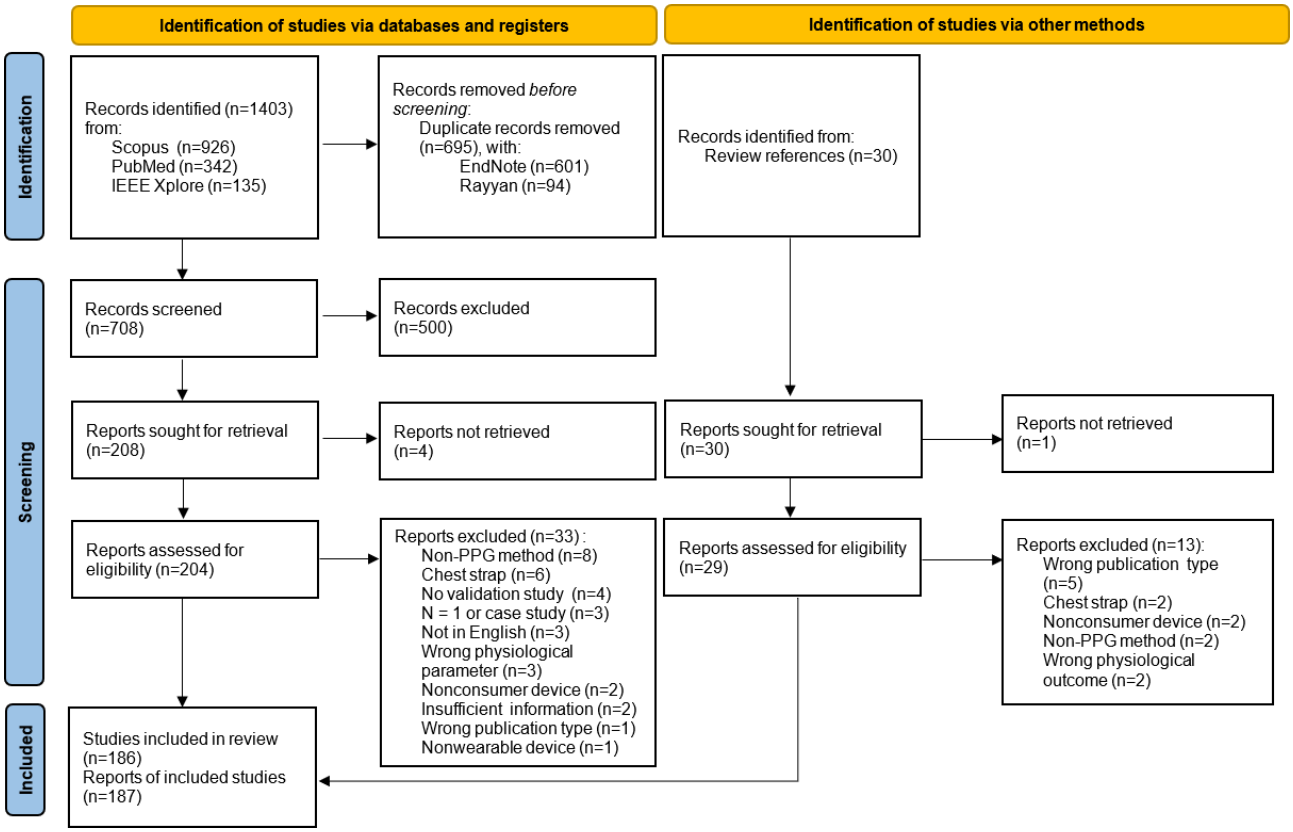
- Underweight: <18.5
- Normal weight: 18.5 - 25
- Overweight: 25 - 30
- Obesity: ≥30

Skin tone categories

- Fitzpatrick type I: always burns, never tans
- Fitzpatrick type II: usually burns, tans less than average
- Fitzpatrick type III: sometimes burns mildly, tans about average
- Fitzpatrick type IV: rarely burns, tans more than average
- Fitzpatrick type V: rarely burns, brown tone
- Fitzpatrick type VI: rarely burns, dark brown or black tone

To visualize the distribution of the representation across studies, the median (IQR) of the percentage of participants within each category was reported. To quantify the representation in all studies combined, the total number of participants within each category was calculated based on the estimated percentages. All plots and quantitative analyses were performed in RStudio (version 2023.6.1.524) with R (version 4.4.1).

To evaluate whether a population group was sufficiently represented, the median and total percentage of participants in this population group were compared to a predetermined benchmark [26]. For the purpose of this review, the selected benchmark is equal representation of all population groups. For example, for BMI with 4 groups, the percentage of participants in each BMI group should approach 25%. This benchmark was selected as equal representation of all population groups is desirable when statistically comparing group results.



Results

Study Selection

A total of 1403 papers were identified and extracted from PubMed, Scopus, and IEEE Xplore (Figure 1), of which 695 were identified as duplicates and removed, leaving 708 papers for title and abstract screening. Based on title and abstract screening, 500 papers were excluded, and an additional 5 papers were excluded because the full text could not be retrieved. Screening the reference lists of relevant reviews identified 29 additional papers for full-text screening. In the end, 233 papers were included in full-text screening. Based on full-text screening, 187 papers remained for inclusion, providing results from 186 individual studies.

General Study Characteristics

Of the 186 included studies (n=8786 participants), 160 (n=6461 participants) examined pulse rate, 25 (n=2053) oxygen saturation, 19 (n=887) HRV, 7 (n=326) blood pressure [27-33], and 5 (n=329) respiration rate [34-38]. The median (IQR) sample size was 30 (19-49) participants [19,39]. The publication year ranged from 2015 to 2025 (Figure 2), and studies were performed in 32 countries (Table 2). Across all studies, 33 wearable brands and 129 different models were used. Most of the examined wearables were wrist-worn (119 models), and some were worn on the upper arm (3 models), the finger (2 models) [40-44], or in the ear (5 models) [42,45-47]. Most studies (106 studies) validated 1 wearable device; the remaining 80 studies validated 2 to 7 wearable devices. Additional information about the study characteristics of studies for each examined PPG-based measurement can be found in Multimedia Appendix 2. The extracted data for each paper can be found in Multimedia Appendix 3.

Participant Eligibility and Recruitment

Eligibility Criteria

Of the 186 studies, 150 studies provided eligibility criteria for their study populations, and 69 (37.0%; n=3640 participants) studies stated that adults were eligible for participation. Moreover, there were 31 of 186 studies (7.0%; n=1001 participants) that only included younger adults, 10 (5.0%; n=684 participants) studies that only included children and/or adolescents, 4 (2.0%; n=97 participants) that only included older adults [38,92,163,185], and 1 (n=60 participants) that included children, adolescents, and adults [178]. Eight studies used BMI-based exclusion criteria, either excluding people who were underweight (3 studies) [78,116,188], people with overweight (1 study) [176], people with obesity (2 studies) [77,177], people with clinical obesity (BMI≥40 kg/m^2, 1 study) [108], or both people who were underweight and overweight (1 study) [131].

Health Status

According to the description of the populations, out of 186 studies, most of them (n=137, 74.0%) included healthy populations. There were 47 (25.0%) studies that used the Physical Activity Readiness Questionnaire to screen participants for inclusion. Exclusion criteria for cardiovascular diseases

XSL•FO
RenderX

(n=81, 44.0%), musculoskeletal injuries, diseases, or disabilities (n=46, 25.0%), and pregnancy (n=11, 6.0%) were common. Of 186 studies, 49 (26.0%; n=4921 participants) were performed on patient populations with various conditions. These conditions included cardiovascular diseases (21 studies), respiratory diseases (8 studies) [38,49,53,82,101,166,169,202], surgeries (4 studies) [33,36,98,108], disabilities (3 studies) [167,197,208], breast cancer (1 study) [92], COVID-19 (1 study) [123], chronic musculoskeletal pain (1 study) [211], and cystic fibrosis (1 study) [116].

Recruitment Location

Of the 186 studies, 91 (49.0%) studies provided information on the recruitment location; 46 (25.0%) studies recruited participants from a hospital, and 26 (14.0%) studies recruited participants from a university or research group exclusively. Other recruitment settings included local communities and associations (n=9, 5.0%) [55,80,92,132,136,140,142,185,187], patient organizations (n=3, 2.0%) [167,197,208], professional environments such as the military (n=3, 2.0%) [121,174,176], and a physical activity challenge (n=1, 1.0%) [188]. One study included participants from a previous trial [148].

Reporting of Study Population Characteristics

In the 186 studies reviewed, the most reported study population characteristics were age and sex (n=178, 96.0%, and n=179, 96.0%, respectively), followed by BMI (n=101, 54.0%), weight (n=102, 55.0%), height (n=98, 53.0%), and finally the Fitzpatrick scale (n=35, 19.0%; Table 3). Over time, the percentage of studies reporting weight and height remained stable at ~50% (Figure 3). The percentage of studies reporting BMI fluctuated over time, with a minimum of 0% (0/2) in 2015 and a maximum of 77.0% (10/13) in 2025. An upward trend in the reporting of the Fitzpatrick scale was observed from 2019 to 2025 (1/24, 4.0% to 5/13, 38.0%).

Figure 3. The percentage of consumer wearable photoplethysmography-based measurement validation studies per year reporting BMI (A), Fitzpatrick scale (B), weight (C), and height (D).

Age, BMI, weight, and height were mostly reported as mean or median combined with an SD, SE, or IQR (age: 158/178, 89.0%; BMI: 98/101, 97.0%; weight: 98/102, 96.0%; height: 94/98, 96.0%). A lower percentage of studies additionally reported the range (age: 44/178, 25.0%; BMI: 25/101, 25.0%; weight: 25/102, 25.0%; height: 23/98, 23.0%). Reporting of the Fitzpatrick scale was highly variable, with studies either reporting a combination of mean, median, SD, or IQR (12/35, 34.0%), the percentage of participants in each level or in a combination of at least 2 levels (6/35, 17.0%, for both), the range (5/35, 14.0%), or a combination of these options (6/35, 17.0%).

Representation of Study Population Characteristics

Representation of Men and Women

In 179 studies (n=8203 participants), the percentage of women in a study was 43±19%. Most of the studies (102 studies, n=4570 participants) included an approximately equal percentage of men and women. There were 46 men-dominant studies (n=2637 participants), 17 women-dominant studies (n=688 participants), 11 men-only (n=277 participants) [59,121,135,146,157,164,167,174,199], and 3 women-only (n=31 participants) studies [35,136,213].

Representation of Age Groups

The weighted mean (SD) of age across 149 studies (n=6367) reporting these statistics was 44 (11.9) years. The lowest reported age was 1.2 months [127], and the highest reported age was 94 years [126,202]. In the 112 studies (n=5088), which did not exclude older adults and reported the mean (SD), the median (IQR) percentage of older adults in a study was 0% (0%-8%). The total estimated number of older adults participating across the 149 studies that reported the mean (SD) was 1290 of 6367 participants (20.0%). The results of each examined PPG-based measurement separately are presented in Table 4 and Multimedia Appendix 4. Of these 1290 estimated older adults, 1247 (97.0%) participated in studies with a focus on patient populations. From 2021 to 2024, the total percentage of older adults participating each year increased from 23% to 38% (Multimedia Appendix 5).

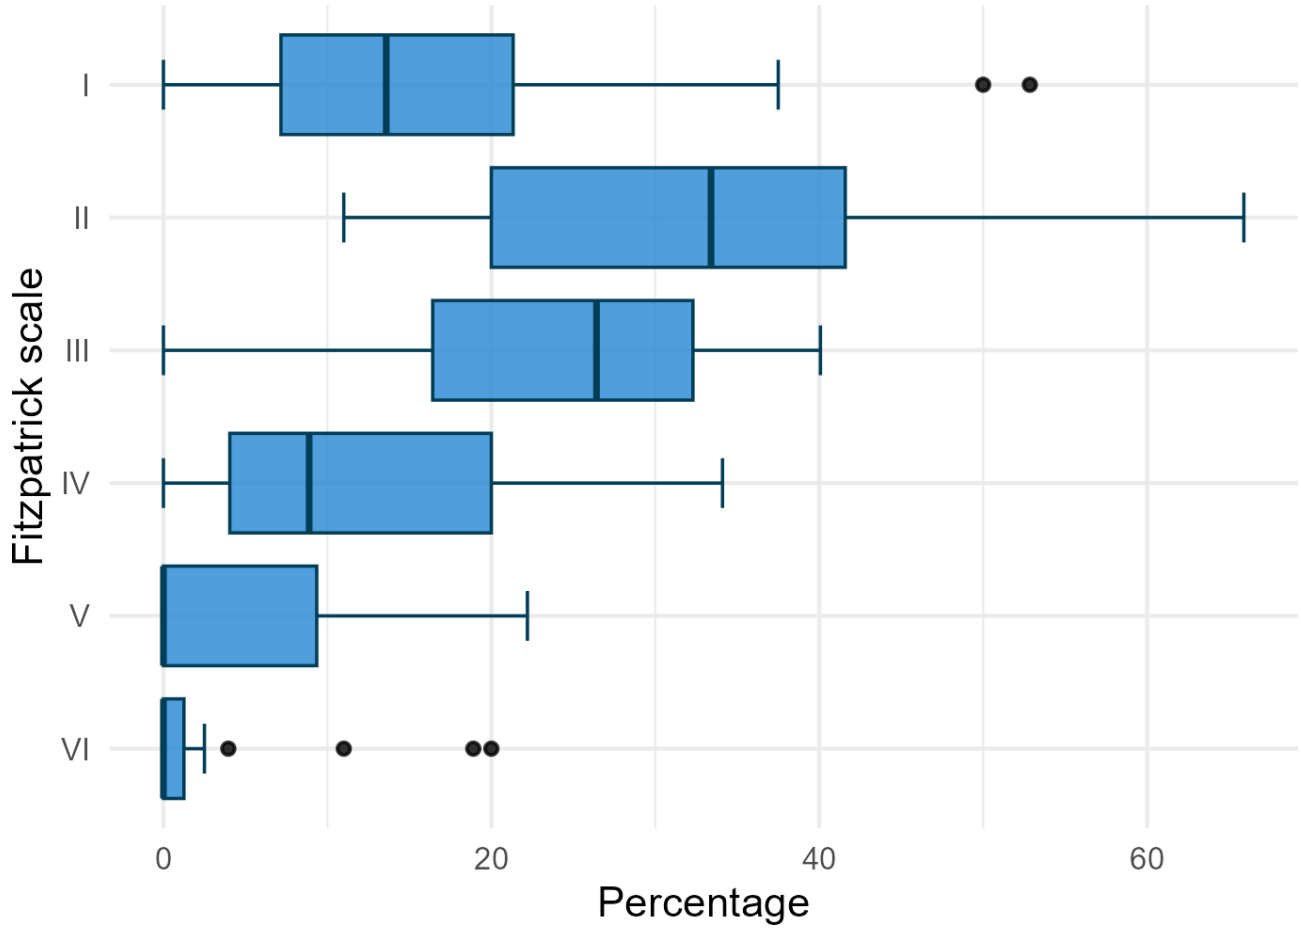
Representation of BMI Categories

Based on 89 studies (n=3428), the weighted mean (SD) of BMI was 24.8 (4.2) kg/m^2, with BMIs ranging from 16.3 [118] to 52.0 kg/m^2 [34]. In these studies, the median (IQR) percentage of people with underweight, normal weight, overweight, and obesity in a study was 3% (0%-7%), 51% (38%-70%), 31% (18%-37%), and 0% (0%-13%), respectively (Figure 4). Of the 3428 participants, it was estimated that 225 (7.0%) were underweight, 1602 (47.0%) had normal weight, 1048 (31.0%) were overweight, and 473 (14.0%) had obesity. Of the 473 estimated participants with obesity, 364 (77.0%) participated in studies that focused on patient populations. The representation of people with obesity increased over time from 4% in 2016 to 22% in 2022, after which it decreased to 15% in both 2023 and 2024 (Multimedia Appendix 5).

XSL•FO
RenderX

Figure 4. Boxplot of the distribution of the estimated percentage of participants in 4 BMI (kg/m^2) categories in 89 studies (n=3428 participants) validating consumer wearable photoplethysmography-based measurements.



Representation of Fitzpatrick Scale Categories

In the 19 studies (n=876) that reported the mean (SD) or percentage of participants in each Fitzpatrick scale category, the majority of participants fell in type II (median 33%, IQR 20%-42%), while the minority were in types V and VI (median 0%, IQR 0%-9% and median 0%, IQR 0%-1%, respectively; Figure 5). Over the years, the representation of the different categories fluctuated, with no clear trend toward increasing or decreasing representation of any category (Multimedia Appendix 5).

Discussion

Principal Findings

This scoping review aimed to provide an overview of the representation of different sex, age, BMI, and skin tone groups in studies assessing the validity of PPG-based consumer wearable measurements. Based on the inclusion of 186 studies, our results indicate that the representation of the different population groups is not equal. In particular, older adults, people who were underweight, people living with obesity, and people with darker skin tones (Fitzpatrick type V or VI) are underrepresented compared to other groups. When interpreting our findings, it is important to consider the following points of discussion: (1) the reporting of user characteristics by the included studies; (2) the benchmark used for evaluating representation; and (3) the relevance of evaluating both study-level and total representation.

First, the results of this study revealed that a large percentage of studies assessing the validity of consumer wearables' PPG-based measurements did not report BMI and skin tone. Not only does this limit our ability to fully evaluate the representation of these characteristics in this review, but it also indicates a critical gap in the available evidence. The nonreporting of these characteristics provides a barrier to investigating the influence of these characteristics on measurement validity. To increase the reporting of study population characteristics like BMI and skin tone, reporting guidelines for consumer wearable validation studies, such as those provided by the INTERLIVE network and the ANSI/CTA, could help. These reporting guidelines recommend the reporting of study populations' sex, age, weight, height, BMI, and skin tone distribution for studies validating pulse rate measurements and could be extended toward other PPG-based validation studies [19,20]. To truly achieve improved reporting, guidelines like those from the INTERLIVE network should additionally be endorsed by journals that publish validation studies [214,215].

Second, the benchmark used to evaluate representation impacts what is considered sufficient representation and underrepresentation. For example, using equal representation as a benchmark, we consider people with underweight, with a median representation of 3%, to be underrepresented. However, using the prevalence of underweight in the general population, namely 1.6%, as a benchmark, the representation of people who are underweight would be considered sufficient [216,217]. The most suitable benchmark depends on the study's aim. When the aim is to investigate the influence of sex, age, BMI, and skin tone on wearable measurement validity, equal representation of these groups is a suitable benchmark. However, if a validation study aims to reflect performance in a specific target population or the general population, then equal representation of all groups would not be a suitable benchmark. For this purpose, the prevalence of sex, age, BMI, and skin tone groups in the target or general population should be used as a benchmark. The

XSL•FO
RenderX

Clinical Trial Diversity Rating framework, developed by the Institute for Clinical and Economic Review, can then be used to evaluate if this benchmark is sufficiently met [26]. Selecting a suitable benchmark is an important step toward achieving study population representativeness.

Third, in this review, we evaluated representation at the level of individual studies as well as total representation. There are population groups that had low representation at both levels, such as children and adolescents, people who are underweight, and people with darker skin tones (Fitzpatrick types V and VI). However, for older adults and people with obesity, although the representation at the study level was very low, the overall representation was higher. This discrepancy can occur if there is a particular subset of studies in which a group is highly represented, while in other studies, the representation is low. For example, in this scoping review, there was a subset of studies with large sample sizes conducted in patient populations in which older adults were highly represented, while in the remaining studies with smaller sample sizes, almost no older adults participated. In these validation studies, the older adults represented are thus mostly older adults living with disease, who might not be an accurate representation of healthy older adults. This pattern was only observed because we evaluated representation both at the level of individual studies and at the overall level, indicating the relevance of evaluating both levels. In addition to evaluating representation at these 2 levels, it would have been valuable to examine the representation of demographic characteristics intersectionally. Based on the information provided by the included studies, this was not feasible. In reality, the 4 characteristics investigated in this review coexist in one individual, and their cumulative effect is what influences signal quality. An older individual with obesity and dark skin, for example, could present an "intersectional stress test" that current algorithms frequently fail. This necessitates stratified sampling and reporting in future validation studies.

Increasing the Representation of Underrepresented Population Groups

There are 2 explanations for the underrepresentation observed in this review. The first cause is the active exclusion of some population groups through exclusion criteria. For example, many of the validation studies investigating pulse rate measurement validity included in this review had a vigorous exercise component, which can be harmful to some population groups, including older adults. Likely due to this ethical consideration, 31 studies excluded older adults. The second cause is barriers to participation related to other elements of the study. These elements included the research question, the composition of the research team, the recruitment methods, the complexity of research processes, and the required investment of time and resources from the participants [218]. For example, none of the studies had skin tone-based eligibility criteria, yet the representation of people with darker skin tones was very low, which suggests that some other study elements could have prevented their participation.

Irrespective of the cause, the underrepresentation of older adults, people who are underweight, people with obesity, and people with darker skin tones currently provides a barrier for us to gain a better understanding of the differences in measurement validity between population groups. If there are relevant differences in consumer wearable measurement validity between these groups, as suspected, we need to take them into account when analyzing consumer wearable measurement data and interpreting the results. If not, differences in the accuracy of consumer wearable-based risk prediction, disease screening, and monitoring tools between populations may be created, exacerbating already existing health disparities as the implementation of these tools progresses. Additionally, a reduced accuracy of these tools in older adults and people with obesity poses a public health risk, as these tools can be used to screen for conditions that are more prevalent in these population groups (eg, atrial fibrillation and sleep apnea) [219]. Increasing the representation of the "missing" population groups in consumer wearable validation studies is therefore vital. To increase the representation of these groups, a suitable benchmark for representation should be selected during the study design process, and the representativeness of the study population should be evaluated based on that benchmark throughout the entire study. Ideally, this evaluation should not only be conducted by the research team but also by funding agencies, journals, peer reviewers, and other stakeholders in the research process. Additionally, researchers should involve their study populations in the study design process to reduce barriers to participation.

Strengths and Limitations

This scoping review is the first to provide a systematic overview of the representation of sex, age, BMI, and skin tone groups in consumer wearable validation studies. Through an extensive search in 3 electronic bibliographic databases and the reference lists of 58 reviews, we were able to include 186 relevant papers. To ensure the transparency of our methods, the entire review process was guided by a protocol that is openly available on OSF. Nevertheless, this review has some limitations that need to be considered.

The representation of age, BMI, and skin tone groups was estimated based on the reported mean (SD), assuming a normal distribution. Though this approach allowed us to visualize the representation of these population groups, there is likely some overestimation or underestimation in these percentages. We hypothesize, based on our results, that the distribution of age, BMI, and skin tone is more likely to be skewed to the right in the included validation studies. An overestimation of the percentage of older adults, people with obesity, and people with darker skin tones in this review is therefore more likely. This suggests that the true representation of these population groups could be even lower than the percentages presented in this review. This is important to take into account when interpreting our findings, as is the fact that there is likely still variation in the representation within the categories applied in this review. Especially within the category of adults, which includes both young adults (18 - 40 y) and middle-aged adults (41 - 64 y), the high representation of young adults might mask the underrepresentation of middle-aged adults. Similarly, as no breakdown of the representation of the demographic groups per brand or model is reported in this review, it is important to note

XSL•FO
RenderX

that there may be differences in the adequacy of representation between different devices, which are not reported in this review.

Another limitation of this review is the use of the Fitzpatrick scale to assess the representation of skin tone. The Fitzpatrick scale was included in this review because alternative measures are currently limited, and this scale is recommended by current reporting guidelines. However, it does not accurately depict the true representation of different skin tones with different melanin content, which truly impacts the PPG signal by absorbing and scattering the light [5]. Therefore, we recommend that future validation studies consider the use of melanometry, a method using reflected light that has been suggested as an objective quantitative measurement of skin melanin [220]. Future studies should also consider using arterial blood gas as a reference standard for measuring SpO_2 instead of finger pulse oximeters. It is a critical limitation that many included studies used finger pulse oximeters, as these devices also exhibit pigment-related bias. Comparing wearables against them, rather than arterial blood gas, may obscure the true extent of skin tone inaccuracies. Additionally, it should be noted that BMI, like the Fitzpatrick scale, is a crude proxy for what it aims to measure, namely, adiposity. Although BMI is convenient for reporting and provides a general overview of the representation of different body sizes, future validation studies focusing on the mechanistic determinants of the validity of PPG-based measurements should consider measuring body composition.

Additionally, it is important to consider that this review only included studies that were published in English. This could have resulted in an underrepresentation of studies conducted in Asia, Africa, and South America, thereby reducing the representation of darker skin tones observed in this review. During the screening of the search results, only 3 studies were excluded based on the language criterion. This suggests that our search strategy, in general, was not very effective in retrieving non-English validation studies. If a similar review is performed in the future, we therefore recommend investigating methods to improve the retrieval of non-English studies, such as including local scientific literature databases.

Conclusions

With this scoping review, we aimed to identify underrepresented population groups by mapping the representation of sex, age, BMI, and skin tone groups in 186 consumer wearable PPG-based measurement validation studies. Based on the results, we conclude that older adults, people with underweight or obesity, and people with darker skin tones are generally strongly underrepresented in consumer wearable validation studies. Researchers making use of PPG-based consumer wearable measurements in their studies should, therefore, be aware of the limited knowledge of the measurement validity in these population groups and take this uncertainty into account when interpreting their findings. To avoid the creation of further health disparities, there should be more focus on the representativeness of consumer wearable validation study populations. More transparent reporting of study population characteristics and the use of benchmarks for representation will allow researchers and other stakeholders in the research process to evaluate the representativeness of a study population. To achieve study populations that properly represent the target population, representatives from the target population should be included in the study design process.

Acknowledgments

In the process of this review, ChatGPT (free version) was used in the creation of the R script to provide suggestions for the code. These suggestions were then verified by testing the code and reading other sources. Additionally, Grammarly was used to improve the spelling and grammar of the written text.

Funding

This work was supported by the RECENTRE HTSF program, financed by the 4TU.Federation (grant 4TU-UIT-468).

Data Availability

After the publication of this manuscript, a CSV file with the extracted data and R scripts will be uploaded to the related project in OSF [17]. A CC-BY-4.0 license will apply.

Abstract

Background: Mindfulness interventions are considered an effective strategy for preventing mental health problems among health care workers (HCWs). While prior reviews have often included facilitator-guided or multicomponent interventions, it is unclear whether self-guided digital mindfulness interventions can also be effective without professional or in-person support.

Objective: This systematic review aimed to investigate the effects of self-guided digital mindfulness interventions on the mental health and well-being of HCWs.

Methods: This work was conducted as part of the DeLiGHT project. We searched electronic databases, including PubMed (MEDLINE), Embase, Cochrane CENTRAL, PsycINFO, PsycARTICLES, and the Japan Medical Abstract Society database, from inception in 2010 to July 25, 2023. To ensure timeliness, we performed an updated search on December 27, 2025. Database searching yielded 37,851 abstracts and 145 studies that examined the effectiveness of digital health interventions for workers in the initial 2023 screen. In the present study, we limited the included studies to those that met the following criteria: randomized

XSL•FO
RenderX

controlled trials (RCTs) using self-guided digital mindfulness interventions (eg, smartphone apps or web-based programs) delivered without face-to-face or professional support compared to waiting list controls or usual care among HCWs. The updated search in 2025 yielded 6328 additional records, of which 11 studies were examined. Study quality was assessed using the Cochrane Risk of Bias tool, with meta-analyses conducted using a random-effects model.

Results: A total of 9 RCTs with 3088 participants were included in the final analysis. The study populations were diverse, covering North America, Europe, Oceania, and Asia. Interventions were delivered via various digital platforms, including commercial mindfulness apps (n=3), social networking service tools (n=3), and web-based programs (n=3), with an average duration of 6.17 weeks (range: 1.5 - 18 wk). Five studies assessed outcomes only postintervention, and 4 included short-term follow-up (4 - 12 wk); no long-term effects were evaluated. The meta-analysis showed a significant beneficial effect on depression (standardized mean difference [SMD]=−0.44, 95% CI −0.88 to −0.00; *P*=.049), anxiety (SMD=−0.29, 95% CI −0.51 to −0.06; *P*=.011), perceived stress (SMD=−0.42, 95% CI −0.77 to −0.06; *P*=.02), and well-being (SMD=0.20, 95% CI 0.09 to 0.30; *P*<.001) immediately postintervention. The adherence rates reported across studies were highly variable, ranging from 19% to 56%. According to the Cochrane Risk of Bias tool, most studies were rated as having some concerns or a high risk of bias. The certainty of evidence included in the analysis ranged from “Low” to “Very Low.”

Conclusions: Overall, low to very low certainty evidence suggests that self-guided digital mindfulness interventions may have short-term beneficial effects on depression, anxiety, perceived stress, and well-being among HCWs. Future high-quality studies are needed to examine the long-term effects and cross-cultural generalizability of these interventions.

KEYWORDS

digital intervention; occupational stress; psychological intervention; self-guided intervention; telehealth

Introduction

Health care workers (HCWs) are at high risk of experiencing mental health problems worldwide [1,2]. A systematic review has reported that the prevalence of mental health symptoms is high among HCWs: depression (13%), anxiety (16%), and traumatic stress (22%) [3]. Another systematic review reported that half of HCWs experience burnout [4], characterized primarily by emotional exhaustion and compassion fatigue, which negatively impacts patient care [5]. These mental health challenges affect not only the well-being of HCWs but also the quality of care provided to patients [6], potentially leading to long-term negative consequences on community health care systems. Therefore, effective and accessible interventions that focus on individual-level approaches, which are likely easier to implement, are urgently needed to improve the mental health of HCWs.

Mindfulness interventions are an effective nonpharmacological approach for improving mental health [7]. Mindfulness refers to paying attention to present-moment experiences in a nonjudgmental and accepting manner [8]. In particular, there is a growing interest in self-guided digital mindfulness interventions, which do not require face-to-face delivery or professional support, as scalable and accessible approaches. Systematic reviews have shown the effectiveness of face-to-face mindfulness interventions in improving the mental health of HCWs, including individuals with depression, anxiety [9,10], and emotional exhaustion [11], as well as in promoting their well-being [12]. Mindfulness is the most commonly used psychological group intervention for reducing distress symptoms in HCWs [13]. Mindfulness is an acceptable intervention for HCWs because it has a reasonable rationale and can be done quickly [14]. However, HCWs often face barriers when engaging in mental health interventions, such as limited availability (eg, shift work), high job demands, concerns about stigma, and negative social judgments, as well as issues related to disclosure and confidentiality, which are more common among HCWs than other workers [15]. In this context, self-guided digital interventions, which are not provided by professionals or delivered in person, may have advantages in engaging HCWs in the interventions.

Digital mindfulness interventions can overcome the barriers of logistics and time availability by providing flexible access and standardized content at a low cost [16]. Self-guided digital mindfulness tools have already been widely used, and over 560 mindfulness apps are available on the market [17]. However, the effectiveness of self-guided digital mindfulness interventions on the mental health of HCWs is still unclear. A previous systematic review reported on the effectiveness of web-based mindfulness-based interventions for HCWs. However, it focused primarily on the COVID-19 pandemic, with half of the included studies conducted in a single country, leading to a risk of overestimation and limited generalizability [18].

It did not restrict itself to self-guided interventions and included nonmindfulness components such as cognitive behavioral therapy, music therapy, and positive psychology interventions. Additionally, another review included studies involving students, searched only a single database, and did not conduct any quantitative analyses of the effects of web-based tools and mobile apps [19]. Considering advancements in technology and synthesizing the findings of randomized controlled trials (RCTs) conducted over the past 10 years with participants limited to HCWs, and not restricted to the pandemic period, may provide a more comprehensive and accurate understanding of the effectiveness of digital mindfulness interventions on the mental health of HCWs. If self-guided digital mindfulness interventions are found to be effective, such interventions may be promoted

XSL•FO
RenderX

even in emergency situations like pandemics and in low-resource settings.

This systematic review and meta-analysis thus aimed to address this gap by examining the effectiveness of self-guided digital mindfulness interventions without face-to-face, professional, or personal support components on mental health and well-being among HCWs from 2010 to 2025.

Methods

Study Design

This work was part of an overarching large-scale systematic review project developing Minds-compliant guidelines for general preventive interventions using digital health technologies for mental health (the DeLiGHT project; [20]), funded by the Japan Agency for Medical Research and Development.

The review protocol has been registered in the UMIN registry (registration number: UMIN000051631). The method was reported according to PRISMA (the Preferred Reporting Items for Systematic Review and Meta-Analysis) 2020 guidelines (Checklist 1) [21]. Among the included literature in the DeLiGHT project, this review reported on the effectiveness of fully automated digital mindfulness interventions for HCWs.

Data Sources, Search Strategy, and Study Selection Process

In the DeLiGHT project, we initially searched for publications from 2010 to July 25, 2023, across databases such as PubMed (MEDLINE), Embase, Cochrane CENTRAL, PsycINFO, PsycARTICLES, and the Japan Medical Abstracts Society database. The search was limited to studies published from 2010 onward, reflecting the widespread adoption of smartphones and web-based platforms. The search terms are detailed in Multimedia Appendix 1. Search terms were comprehensively selected, referring to previous reports on digital health technology [22] and outcomes [23]. The search strategy was constructed using combinations of population- and intervention-related terms. In addition, study design-related words were applied to restrict the search to randomized controlled trials. Although outcome-related terms were included to improve feasibility given the broad scope of the literature, we acknowledge that the inclusion of outcome terms may increase the risk of missing relevant studies, in line with the recommendations of the Cochrane Handbook [24,25]. We included all studies that followed the inclusion criteria of participants, interventions, comparisons, and outcomes (PICO): (P) any type of employee or worker; (I) any type of nonpharmacological intervention aiming at primary prevention using digital health technologies (eg, exercises, diet, lifestyle, and psychological interventions such as cognitive behavioral therapy); (C) any type of control condition; and (O) mental health conditions, positive mental health, and work-related outcomes. In the subgroup considerations, HCWs were defined using terms explicitly referring to medical and health professionals (eg, physicians, nurses, pharmacists, psychologists, therapists, and health care providers). In addition, studies using an RCT design and published after 2010 were included. The language was limited to English or Japanese. Exclusion criteria were as follows: (1) studies targeting participants who have any specific disorder, (2) studies including participants who are not employees or workers, (3) studies applying any interventions aimed at secondary or tertiary prevention, and (4) studies aiming to evaluate the treatment effects of interventions on specific disorders or symptoms. One investigator (M Iida) removed duplicate entries, and the remaining articles were shared with all co-authors. During the first screening phase, based on the eligibility criteria, each article's title and abstract were independently assessed by pairs of investigators, with one investigator being a staff member from an external contracting agency. Following this, 2 investigators independently reviewed the full texts of studies that passed the first screening. Any disagreements were resolved through discussion and consensus among all authors. Reasons for study exclusion were documented during the full-text review phase. Microsoft Excel was used to manage all identified studies.

The DeLiGHT project's database search initially retrieved 37,851 abstracts (from 2010 to July 25, 2023). During the initial screening, after removing 15,485 duplicates and 3275 older studies published before 2010, 19,091 records remained for further review, of which 18,806 were excluded. Subsequently, 285 records were forwarded for full-text screening. Following the full-text review, 140 studies were excluded. Finally, 145 RCTs were identified as digital interventions aimed at improving workers' mental health.

An updated search was conducted on December 27, 2025, in PubMed (MEDLINE), Cochrane CENTRAL, PsycINFO, PsycARTICLES, and the Japan Medical Abstracts Society database, using the same search terms (Multimedia Appendix 1). Notably, Embase could not be used for the updated search due to access restrictions. However, even in the original search, which included Embase, all studies ultimately included in this review were indexed in PubMed. Moreover, previous research has suggested that the additional benefit of supplementing PubMed with Embase may be limited in some fields [26]. Taken together, these considerations suggest that the absence of Embase is unlikely to have materially affected the comprehensiveness of the update. The search was limited to studies published from 2023 onward, to update the search of the DeLiGHT project. In the 2025 update, eligible RCTs were directly identified in accordance with the selection criteria of this study, which are described in the next section.

Selection Criteria for the Review of Digital Mindfulness Interventions

In this study, we limited the included studies according to the criteria for this review: (P) HCWs, including workers in clinical hospitals or emergency units; (I) digital mindfulness interventions; and (O) mental health symptoms (ie, depression, anxiety, perceived stress, traumatic stress reaction, and sleep quality), emotional exhaustion, compassion fatigue, and positive mental health and well-being. Digital mindfulness interventions in this review were defined as technology-assisted mindfulness interventions aimed at fostering greater attention to and awareness of present-moment experiences [7,27], delivered via digital platforms without face-to-face components or professional or personal support, as described in previous

XSL•FO
RenderX

reviews of digital mindfulness interventions [28,29]. Following this definition, we excluded interventions primarily focused on other approaches (eg, cognitive behavioral therapy-based skills) or interventions that could not be evaluated for the extent to which they emphasized mindfulness. Complex or multimodal interventions were carefully discussed in terms of eligibility by NS, AI, and KI. For multimodal interventions, eligibility was determined based on whether mindfulness was described as the primary intervention component in the intervention rationale and content descriptions, with decisions made through independent review and consensus among the reviewers. The yoga component was included in this review if it was delivered via a digital tool without professional support, as yoga has been recognized as a primary discipline and practice with the potential to cultivate mindfulness [30].

Data Collection Process and Data Items

Among the 145 records identified in the initial screening (DeLiGHT project, from 2010 to July 25, 2023), 3 investigators (NS, AI, and KI) assessed the studies' eligibility in pairs. In the update, 2 investigators (NS and KI) conducted both the initial and full-text reviews in accordance with the current studies' eligibility criteria (ie, mindfulness for HCWs). They consolidated the data, which included information such as publication year, authors' names, study location, participants' characteristics (eg, HCWs), number of participants, intervention details, control group information, outcome variables, and adherence or dose. Follow-up assessments were defined as outcome measurements conducted after the immediate postintervention assessment, and were used to evaluate the short-term sustainability of intervention effects on the same mental health outcomes.

Risk of Bias Assessment

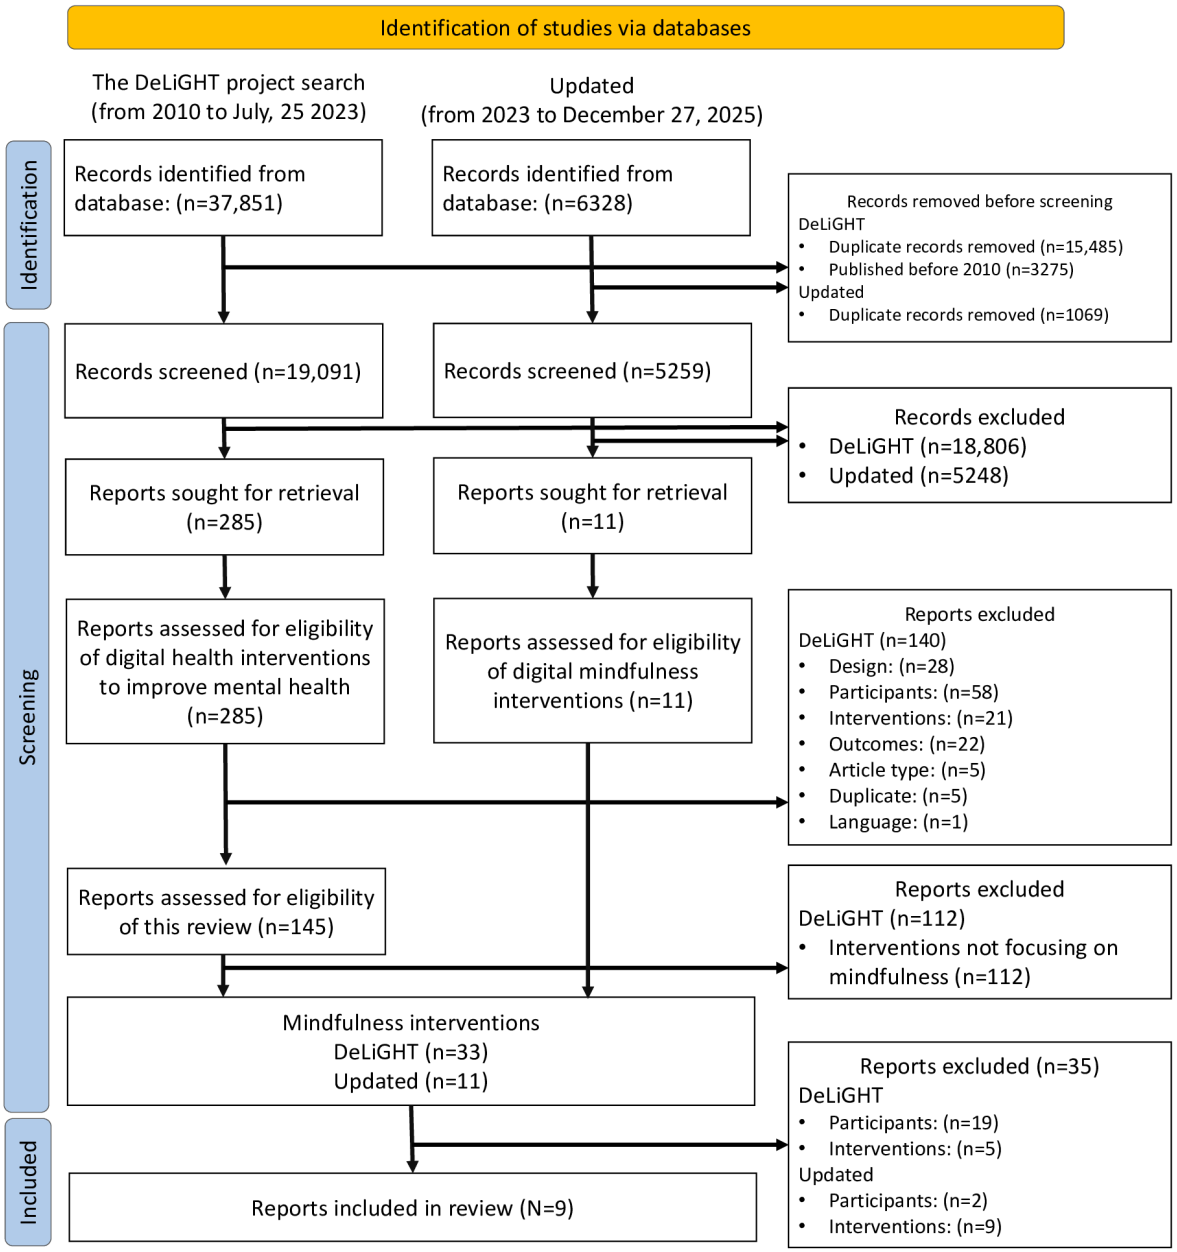
Six investigators assessed the risk of bias independently in 3 pairs (NS, AI, M Iida, KW, YKob, and KI) using the recently revised Cochrane risk-of-bias tool for randomized trials (RoB 2.0) [31]. This tool comprises 5 bias domains: bias arising from the randomization process (domain 1), bias due to deviations from intended interventions (domain 2), bias due to missing outcome data (domain 3), bias in measuring the outcome (domain 4), and bias in the selection of the reported result (domain 5). For each domain, a series of signaling questions with answers (yes, probably yes, no information, probably no, and no) determine the risk of bias (low risk, some concerns, and high risk). Any discrepancies in the quality assessment were addressed through discussion and consensus among the authors.

Synthesis of Results and Meta-Analysis

In the analysis, we synthesized all of the included interventions and outcomes. A meta-analysis was performed if at least 3 eligible studies had the same outcome. The effect size was calculated based on the difference in the change of baseline scores between the intervention and control. The standardized mean difference (SMD) was used to assess the effect of interventions. Meta-analyses were performed for the mean effect on each outcome of mental health symptoms (eg, depression, anxiety, and perceived stress), emotional exhaustion and compassion fatigue, and each outcome of positive mental health and well-being. Meta-analysis was performed at each time point (immediately postintervention and follow-up) for each outcome. A random-effects model was used to consider differences in the treatment effect from study to study. When the SD of change from baseline was not shown, it was calculated based on the assumption that the correlation between scores at baseline and those at follow-up was 0.5 [32]. Heterogeneity between studies was measured through the I^2 statistic (low, moderate, and high heterogeneity corresponding to I^2 values of 25%, 50%, and 75%, respectively) [33]. Funnel plots and Egger tests were used to assess potential publication bias for the meta-analyses [34,35]. Consistent with the Cochrane Handbook [36], tests for funnel plot asymmetry were interpreted with caution because fewer than 10 studies were included, and statistical power is known to be low under such conditions. For outcomes with I^2 more than 75%, we performed sensitivity analyses by excluding outliers identified through visual inspection of funnel plots.

We used the Grading of Recommendations Assessment, Development, and Evaluation (GRADE) approach to assess the certainty of the evidence [37].

Statistical significance was set at a 2-sided $P<.05$. Analysis was conducted using IBM SPSS Statistics Version 28.0. (Japanese version). Meta-analysis was performed in R version 4.5.1 (R Foundation for Statistical Computing) with the *metafor* package [38].



Results

Database Searching

Among the 145 studies identified in the DeLiGHT project, we excluded 112 articles because their interventions did not focus on mindfulness. Among 33 mindfulness intervention studies for workers, we excluded 24 studies for reasons such as participants (ie, not targeting HCWs; n=19) and interventions (ie, digital mindfulness without personal or in-person support; n=5). An updated database search retrieved 6328 abstracts (from 2023 to December 27, 2025), and 5259 abstracts were screened after removing duplicate records. Subsequently, 11 studies were assessed for eligibility for digital mindfulness interventions, but all studies were excluded. Finally, 9 studies [39-47] were included in the systematic review. The study selection process is illustrated in Figure 1. A list of 35 studies excluded at full-text screening, along with reasons for exclusion, is provided in Multimedia Appendix 2.

Figure 1. Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) 2020 flow diagram of the systematic review search results. DeLiGHT: Developing minds-compliant guidelines for general preventive intervention using digital health technologies for mental health.

Study Characteristics

The characteristics of 9 RCTs are presented in Table 1. The total number of included participants was 3088 (ranging from 41 to 2182 in 1 study) [39-47]. Countries where studies were conducted varied, including Western countries (the United States or Canada [42,45]), England [46], Australia [47], Iran [39,44], and other Asian countries (South Korea [40], Singapore [41], and Thailand [43]). Of the 9 included studies, 3 studies [40,42,46] delivered the intervention before the COVID-19 pandemic.

Characteristics of Interventions

The average intervention period was 6.17 weeks, ranging from 1.5 weeks [41] to 18 weeks [46]. Regarding the platforms used:

- Commercial apps: three RCTs [41,46,47] used interventions involving a commercial mindfulness app ("Headspace").
- Social networking service (SNS) tools: three RCTs [39,43,44] used interventions involving SNS messaging platforms.
- Other platforms: others used original apps [40,45] and a web-based program [42].

Regarding follow-up assessments, 5 studies [39,40,44-46] measured outcomes only immediately postintervention, and 4 [41-43,47] measured outcomes twice: immediately postintervention and at follow-up (ranging from 4 to 12 wk after the postintervention period). No studies evaluated long-term effectiveness beyond this timeframe.

Outcome Measures and Data Synthesis

The included studies assessed a broad range of psychological outcomes. Perceived stress was the most frequently measured outcome (n=6) [40,42,43,45-47], followed by depression and anxiety (n=5) [40,41,43,45,46]. Other measures included emotional exhaustion and compassion fatigue (n=4) [39,45-47], as well as positive mental health constructs such as well-being (n=4) [40,41,46,47].

Certain outcomes, including sleep quality (n=2) [41,44], self-efficacy (n=1) [40], symptoms of PTSD (n=1) [41], and fear of COVID-19 (n=1) [41], were excluded from the meta-analysis due to an insufficient number of studies for robust synthesis.

Adherence to the prescribed dose was reported in 6 out of 9 studies. Program completion rates were documented in 3 studies [41,42,45]. Among these, 56.4% (22/39) of participants completed more than 80% of the required practice duration in one study [41], and 55.3% (89/161) completed 6 or 7 modules in another [42]. In contrast, 1 study reported that 19% (13/69) of participants completed more than 75% of the daily sessions [45]. The average frequency of weekly usage was reported in 5 studies [42,43,45-47]. Specifically, 28% (19/69) of participants completed at least 1 session per week [45], 41% (29/71) used the program 1 to 3 times per week [47], and the average weekly usage was 2.1 (SD 1.5) days [42]. In the Taylor et al [46] study, 66.6% (452/679) of participants practiced 3 or more days per week. Furthermore, in the Luangapichart et al [43] study, 22.2% (10/45) of participants used the program 4 or more days per week, with 3 or more sessions per day.

Risk of Bias

Table 2 presents the risk of bias assessed using RoB 2.0. All studies were evaluated as having a high risk of bias. In many studies, domains 1, 2, and 5 were rated as low or as having some concerns; however, domains 3 and 4 were frequently rated as high. Consequently, the overall bias across all studies was determined to be high.

Meta-Analysis

The results of the meta-analysis are shown in Figure 2. Digital mindfulness interventions demonstrated significant beneficial effects in improving the postintervention scores of individuals with depression (k=5, SMD=-0.44, 95% CI −0.88 to −0.003; *P*=.049), anxiety (k=5; SMD=−0.29, 95% CI −0.51 to −0.06; *P*=.011), perceived stress (k=6; SMD=−0.42, 95% CI −0.77 to −0.06; *P*=.021), and well-being (k=4; SMD=0.20, 95% CI 0.09 to 0.30; *P*<.001). No significant effectiveness was observed in addressing emotional exhaustion or compassion fatigue. Additionally, no long-term efficacy was identified for perceived stress during the follow-up periods, which ranged from 4 to 12 weeks after the postintervention period. The heterogeneity varied from low to high (I^2=0% in well-being, 50% - 60% in anxiety and emotional exhaustion or compassion fatigue, and over 80% in depression and perceived stress).

Sensitivity analyses excluding Luangapichart et al [43], which reported a notably larger intervention effect, significantly reduced heterogeneity for depression (k=4; SMD=−0.18, 95%CI −0.28 to −0.07; *P*=.001; I^2=0%) and postintervention perceived stress (k=5; SMD=−0.25, 95% CI −0.40 to −0.10; *P*<.001; I^2=28.1%).

Figure 2. Summary of meta-analysis [39-43,45-47]. (A) Mental health symptoms and disorders: (1) depression and (2) anxiety [40, 41, 43, 45, 46], (3) perceived stress (post) [40, 42, 43, 45, 46, 47], (4) perceived stress (6-mo follow-up) [42, 43, 47]. (B) Emotional exhaustion and compassion fatigue [39, 45, 46, 47]. (C) Positive mental health and well-being [40, 41, 46, 47].

Publication Bias

Multimedia Appendix 3 presents funnel plots of the included studies. We qualitatively and quantitatively assessed publication bias by visually inspecting funnel plot asymmetry. The visual inspection suggested symmetry. Egger tests were not significant for all outcomes. Although no clear evidence of funnel plot asymmetry was observed, these findings should be interpreted cautiously due to the limited number of included studies.

Certainty of Evidence

The GRADE evidence profile is presented in Multimedia Appendix 4. The certainty of evidence for the outcomes included in the analysis ranged from “Low” to “Very Low.”

Discussion

Principal Findings

Overview

This systematic review and meta-analysis evaluated fully automated digital mindfulness interventions for HCWs, ultimately including 9 RCTs with 3088 participants. Adherence

XSL•FO
RenderX

and dose varied widely across the included studies. Results showed that these interventions had moderate, beneficial effects on depression (SMD=−0.44, 95% CI −0.88 to −0.003), anxiety (SMD=−0.29, 95% CI −0.51 to −0.06), and perceived stress (SMD=−0.42, 95% CI −0.77 to −0.06) immediately postintervention, as well as a slight improvement in well-being (SMD=0.20). However, the interventions did not significantly impact emotional exhaustion or compassion fatigue, and there was no evidence of sustained effects on perceived stress during the follow-up period, which ranged from 4 to 12 weeks after the postintervention period. Heterogeneity across studies was low in well-being but moderate to high in other outcomes.

Effects on Depression, Anxiety, and Perceived Stress

Digital mindfulness intervention was effective in improving depression, anxiety, and perceived stress among HCWs. This result was consistent with a previous report that workplace mindfulness interventions improved mental health [9]. While previous meta-analyses of workplace mindfulness interventions, which predominantly included face-to-face or facilitator-guided programs, reported large pooled effects on composite mental health outcomes (eg, SMDs >0.6) [9], the present review demonstrated moderate effects (eg, SMD=−0.44, 95% CI −0.88 to −0.003 for depression) despite focusing exclusively on self-guided digital interventions. This pattern is consistent with the lower intensity of digital interventions. An earlier systematic review reported the effectiveness of web-based mindfulness interventions, including those with professional assistance for HCWs during COVID-19 [18]. However, it included an app with various components (ie, cognitive behavioral approach) other than mindfulness [48] and half of the included studies were from one specific country, leading to a risk of overestimation of effectiveness. In this study, we excluded interventions that did not focus solely on mindfulness or those with professional or personal support. The present findings could provide more precise insights into the effects of digital mindfulness interventions as a primary prevention strategy for the mental health of HCWs.

Effects on Well-Being and Potential Mechanisms

The results demonstrated the effectiveness in improving the well-being of HCWs. This finding was consistent with previous reviews [9,12]. Our review measured well-being using the World Health Organization-Five Well-Being Index (WHO-5) and the Warwick Edinburgh Mental Well-being Scale (WEMWBS). Mindfulness enhances skills to accept negative emotions and to cope with distress [49,50], leading to emotional stability and calmness. Additionally, mindfulness promotes greater attention to and awareness of present moment experiences [27] and may encourage individuals to be active and vigorous in pursuing something that they want to focus on. Positive affects, including relaxed, calm, active, vigorous, and energetic states, were measured by both WHO-5 and WEMWBS. Mindfulness also nurtures self-acceptance and self-compassion; it may reduce self-criticism and improve self-esteem. This contributes to enhancing items on the WEMWBS, such as “feeling good about myself” and “feeling confident.” Digital mindfulness interventions can increase positive aspects of mental health while also reducing negative emotions.

Effects on Emotional Exhaustion and Compassion Fatigue

No significant effectiveness was shown in addressing emotional exhaustion or compassion fatigue. One previous systematic review of mindfulness for nurses reported its effectiveness in improving personal accomplishment (a subscale of burnout), but no effectiveness was observed for emotional exhaustion or depersonalization [51]. Another meta-analysis of interventions for nurses also reported nonsignificant effectiveness across all subscales of burnout [52]. However, these meta-analyses included only 2 studies to estimate the efficacy. More studies are needed to draw firm conclusions. A previous review of RCTs of both individual-based and organization-based interventions for reducing burnout among physicians reported beneficial integrated effectiveness on all burnout subscales [53]. There remains uncertainty about the effectiveness of digital mindfulness interventions on emotional exhaustion. Nevertheless, it may be necessary to consider using such interventions in conjunction with structural or organizational strategies (eg, working hour limitation)

Cultural and Occupational Contexts

Cultural and occupational contexts may also influence the effectiveness of digital mindfulness interventions. The included RCTs were conducted across diverse regions, including Europe and Asia, where cultural norms regarding emotional expression, self-care, and help-seeking may shape engagement with mindfulness practices. In addition, occupational differences among HCWs, such as those between nurses and physicians, may affect baseline stressors, workload, and responsiveness to self-guided interventions. These contextual factors should be considered when interpreting the findings and their generalizability.

Heterogeneity Across Interventions

A substantial heterogeneity observed in this study may also be attributed to the variability in intervention characteristics, including duration, number of modules, and delivery modes. For instance, intervention durations ranged from 1.5 weeks [41] to 18 weeks [46], and content delivery varied between smartphone apps (eg, commercial apps [41,46,47], original apps [40,45], SNS tools [39,43,44]), and web-based platforms [42]. Although the limited number of studies precluded a subgroup analysis to statistically quantify the impact of these variations, our sensitivity analysis indicated that excluding specific outliers significantly reduced statistical heterogeneity. This suggests that while structural differences exist, they may not be the sole driver of the observed inconsistency. Nevertheless, this variability highlights a challenge in synthesizing evidence. To facilitate more precise comparisons and identify optimal intervention components, future research should strive for greater standardization in intervention protocols and reporting.

Limitations

While our meta-analysis indicated a beneficial trend of the intervention on mental health outcomes, the certainty of evidence assessed by the GRADE approach remained “Low” or “Very Low.” These results suggest that the true effect may be substantially different from the estimate of the effect. The

XSL•FO
RenderX

primary factor reducing the certainty was the "very serious risk of bias" identified in all included studies. Methodological limitations, such as a lack of blinding or allocation concealment and reliance on self-reported outcomes, were present in many studies and may have led to an overestimation of the effects. Furthermore, inconsistency across studies for depression and perceived stress outcomes, as well as imprecision of the estimates for emotional exhaustion, further contributed to the lower certainty grades. Therefore, the current findings should be interpreted with caution. To establish more certain evidence, future research requires well-designed, high-quality RCTs that minimize the risk of bias. In addition to these points, this review has several limitations. First, only nine studies met the inclusion criteria, which restricts the generalizability of the findings. The inclusion of outcome-related terms in the search strategy may have increased the risk of missing some relevant studies, as noted in the Cochrane Handbook [25], and should be considered a limitation of this review. Additionally, a high risk of bias was observed in the quality assessment using the RoB2 tool, primarily due to self-reported outcome measures. Due to the nature of digital mindfulness interventions as psychosocial interventions, blinding of participants was not feasible in most studies, which may have introduced performance bias alongside reporting and detection bias. This introduces potential bias and may impact the reliability of the results. Furthermore, the included studies exhibit considerable heterogeneity in intervention content, making it challenging to draw consistent conclusions across studies. In addition, the quality of the included digital mindfulness applications may have varied, as not all interventions were clearly reported to be developed or supervised by qualified mindfulness experts. This variability in app quality should be considered when interpreting the findings. The review also includes several RCTs with small sample sizes, limiting the statistical power of these studies. The results from Egger tests and a visual inspection of the funnel plots provide little indication of publication bias. Yet, because only a small number of studies were included, conclusions regarding publication bias should be drawn with caution. The language restriction to studies published in English or Japanese may have resulted in the exclusion of relevant research published in other languages, thereby narrowing the scope of this review. The long-term effects of the interventions still need to be clarified, as few studies evaluated outcomes over an extended period. Adherence rates were reported in some studies but could not be formally linked to outcomes due to limited and inconsistent reporting. Future individual participant data meta-analyses could examine adherence–outcome relationships in self-guided digital mindfulness interventions. Although classified as self-guided, some interventions allowed minimal asynchronous contact, which may have influenced adherence and effect size. Finally, this study's findings, derived from RCTs, present a limitation because the inherent research design often involves human-mediated interventions, such as reminders and economic rewards, which likely enhance adherence. Therefore, in real-world settings where such self-guided digital mindfulness interventions are used without human facilitation, the opportunity to achieve similar levels of adherence—and thereby comparable effects—may be significantly reduced, potentially resulting in smaller observed effects in real-world data contexts. Although beyond the primary scope of this review, ethical and implementation considerations such as user privacy, data security, and responsible data management are important issues for the real-world deployment of digital mindfulness interventions. These factors should be carefully addressed in future research and implementation efforts.

Conclusions

Given the high risk of bias across all included studies, the findings should be interpreted with caution. Nevertheless, health care organizations may consider integrating digital mindfulness interventions as an accessible, short-term mental health support tool for reducing depression, anxiety, and perceived stress among HCWs. However, additional strategies may be needed to address persistent emotional exhaustion and compassion fatigue.

Abstract

Background: Patients with chronic diseases often struggle to maintain sufficient physical activity (PA) and reduce sedentary behavior in daily life. Just-in-time adaptive interventions (JITAIs), delivered through mobile health technologies such as mobile apps, wearable devices, sensors, and ecological momentary assessment, offer timely and personalized support based on individuals' changing needs. However, the evidence base for their use in promoting PA and reducing sedentary behavior among patients with chronic diseases remains fragmented.

Objective: This review aimed to describe study characteristics and design features of JITAIs, summarize reported evaluation findings related to PA and sedentary behavior, and identify barriers and facilitators related to engagement and use of JITAIs.

Methods: A comprehensive literature search was conducted in PubMed, Embase, Web of Science, CINAHL, and Scopus from database inception to June 2025. Two researchers independently screened the records, selected eligible studies, and performed data charting to ensure rigor and consistency.

Results: A total of 14 studies were included in this review. Of these, 6 primarily targeted PA, 1 focused solely on sedentary behavior, and 5 addressed both PA and sedentary behavior. Of the remaining, 6 studies provided preliminary evidence supporting the positive effects of JITAIs in promoting PA among individuals with chronic diseases, while 3 studies suggested positive effects on reducing sedentary behavior. Barriers and facilitators influencing the use of JITAIs in this population were identified. Barriers included technological usability and literacy, burden and intrusiveness of the intervention, perceived value and acceptability, external and contextual barriers, and privacy and data security concerns. Facilitators included enhanced motivation and behavioral engagement, increased awareness and self-monitoring, usability and integration into daily life, timely and personalized support, and support from health care professionals and the care environment.

Conclusions: This scoping review identified preliminary evidence suggesting that JITAIs may help reduce sedentary behavior and promote PA among patients with chronic diseases. However, more large-scale, high-quality randomized controlled trial studies are needed to strengthen evidence and generalizability.

physical activity; sedentary behavior; just-in-time adaptive intervention; digital health; chronic disease

Introduction

According to the World Health Statistics 2023 report published by the World Health Organization, noncommunicable diseases account for approximately 41 million deaths annually, representing 74% of all deaths worldwide [1]. Chronic diseases, such as cardiovascular diseases, chronic respiratory diseases, and diabetes, are long-term conditions that generally require

XSL•FO
RenderX

ongoing medical care and sustained self-management [2]. These conditions can often be prevented or managed through behavioral changes, particularly by increasing physical activity (PA) and reducing sedentary behavior. PA refers to any bodily movement produced by skeletal muscles that results in energy expenditure, whereas sedentary behavior refers to any waking behavior characterized by low energy expenditure while sitting, reclining, or lying [3,4]. Regular PA is associated with improved cardiovascular health, glycemic control, and mental well-being [5,6]. However, many patients with chronic diseases have difficulty achieving sufficient levels of PA and limiting sedentary time in daily life. Prolonged sedentary behavior has been associated with impaired metabolic function, obesity, anxiety, depression, and increased risks of hypertension, diabetes, cardiovascular disease, and other adverse health outcomes [7-9]. Therefore, reducing sedentary behavior and promoting PA are important components of chronic disease management.

Traditional lifestyle interventions designed to reduce sedentary behavior and promote PA may be effective in controlled settings, but they often rely on standardized, fixed plans that deliver the same type and intensity of support to all patients at predetermined time points [10]. This approach may overlook individual variability and dynamic changes in patients' needs, potentially resulting in insufficient, excessive, or poorly matched support [10]. Digital health, which refers to the use of digital technologies to support health care delivery, monitoring, and self-management, offers opportunities to provide more timely and personalized behavioral support [11]. Within digital health, mobile health (mHealth) interventions use mobile phones, wearable activity trackers, sensors, and other wireless technologies to monitor health behaviors and deliver intervention content in everyday settings [12]. In interventions targeting PA and sedentary behavior, mHealth tools can track steps, activity intensity, sedentary time, and location, as well as deliver feedback, reminders, motivational messages, and activity suggestions [13].

In recent years, just-in-time adaptive interventions (JITAIs) have emerged as a promising mHealth approach to supporting behavior change [14]. A JITAI is designed to provide the right type and amount of support at the right time by adapting intervention delivery to a person's current needs, context, or state of vulnerability and opportunity [14,15]. In practice, JITAIs commonly use data from wearable sensors, mobile apps, ecological momentary assessment (EMA), or contextual information, such as time of day, location, and recent activity patterns, to determine when and how support should be delivered [15,16]. Key JITAIs design components typically include decision points, tailoring variables, intervention options, decision rules, and proximal or distal outcomes [16]. Previous studies have applied JITAIs across a range of health behavior areas, including smoking cessation, alcohol reduction, dietary improvement, and mental health support, suggesting that they may provide more personalized and timely support in daily life than traditional interventions [17,18]. In the field of PA promotion and sedentary behavior reduction, JITAIs have increasingly been applied among individuals with diabetes, cardiovascular disease, and other long-term conditions [19-21].

A key potential advantage of JITAIs is their ability to use data from mobile phones, sensors, and self-reports to deliver context-sensitive support that accounts for daily fluctuations in symptoms, motivation, routines, and opportunities for PA [19-21].

Despite these potential advantages, the evidence base for the use of JITAIs to promote PA and reduce sedentary behavior among patients with chronic diseases remains fragmented. Existing studies also showed their implementation may be affected by potential disadvantages, as JITAIs often depend on patients' access to and ability to use mobile or wearable technologies, which can create barriers related to technical problems, device compatibility, and user burden [15,16]. Frequent or poorly timed prompts may also lead to notification fatigue or disengagement [15,16]. How these advantages and disadvantages influence PA and sedentary behavior outcomes among patients with chronic diseases has not been consistently synthesized across existing studies. Moreover, current studies also differ in their design and evaluation outcomes, making it difficult to evaluate the effectiveness of JITAIs in promoting PA and reducing sedentary behavior in this population. Therefore, we conducted this scoping review focusing on studies in which JITAIs designed to reduce sedentary behavior and/or promote PA among patients with chronic diseases. The review aimed to describe the study characteristics and design features of JITAIs, summarize reported evaluation findings related to PA and sedentary behavior, and identify barriers and facilitators related to engagement and use of JITAIs. By mapping this evidence, the review may inform the development of future JITAIs that are more acceptable and suitable for supporting PA promotion and sedentary behavior reduction in chronic disease self-management.

Methods

Study Design

This scoping review was systematically conducted following the methodological framework proposed by the Joanna Briggs Institute (JBI) [22]. The review was reported in accordance with the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) checklist (Checklist 1) [23]. Ethical approval was not required for this scoping review, as no new data were collected.

Research Questions

The research questions of this scoping review were identified as follows:

- What are the key study characteristics and design features of JITAIs designed to reduce sedentary behavior and promote PA in patients with chronic disease?
- What evidence exists regarding the evaluation of these JITAIs in terms of PA and sedentary behavior?
- What barriers and facilitators have been reported in relation to the engagement and use of JITAIs among patients with chronic disease?

Eligibility Criteria

The eligibility criteria were established based on the population-concept-context (PCC) framework proposed by the JBI [22]. The inclusion criteria were as follows: (1) population: studies involving adults (aged 18 years and older) diagnosed with one or more chronic diseases; (2) concept: studies that used JITAIs aimed at reducing sedentary behavior and/or promoting PA, where JITAIs were defined as interventions that use sensor technologies (eg, accelerometers, GPS, and light sensors) embedded in mobile devices to collect real-time behavioral and contextual data and deliver tailored support at moments when behavior change is most likely to occur [17]; (3) context: studies conducted in a variety of settings, including health care, community, and home settings, where JITAIs were used to support behavior change in individuals with chronic conditions; and (4) types of evidence sources: both quantitative and qualitative studies were included. Mixed methods studies were also eligible. Only peer-reviewed articles published in English were considered. Studies were excluded if they focused solely on healthy populations, used nonadaptive or nondigital interventions, or did not provide sufficient detail on the intervention characteristics or outcomes of interest.

Search Strategy

In collaboration with two independent university medical librarians in China, a systematic search was conducted across 5 electronic databases, including PubMed, Embase, Web of Science, CINAHL, and Scopus, covering literature from database inception to June 2025. An initial exploratory search was performed in PubMed to identify relevant keywords and MeSH terms based on titles and abstracts of pertinent studies. Boolean operators were used to capture studies related to the 4 core concepts: “just-in-time adaptive interventions,” “physical activity,” “sedentary behavior,” and “chronic disease.” To define the scope of chronic conditions, 10 diseases were selected based on the list published by the Office of the Assistant Secretary for Health of the United States [24]: hypertension, type 2 diabetes (T2D), chronic obstructive pulmonary disease, stroke, heart failure, coronary artery disease, chronic kidney disease, hyperlipidemia, asthma, and arthritis. Conditions that were psychiatric (eg, schizophrenia), acute, or not conducive to self-management (eg, dementia) were excluded as this review focused on chronic physical conditions in which PA and sedentary behavior can be targeted through patient-led or patient-engaged self-management [25]. These conditions may require different intervention approaches or rely more heavily on management led by clinicians or caregivers, and were therefore beyond the scope of this review. Additionally, a snowballing technique was used to manually screen the reference lists of included studies to identify further relevant literature. The PubMed search strategy is presented in Table 1, while the complete search terms, strategies, and results for other databases are provided in Multimedia Appendix 1.

Data Management

Data Selection

The search results were imported into EndNote software (version X9.1; Clarivate). After removing duplicate records, two researchers (JG and FC) independently screened the titles and abstracts of all retrieved studies to assess initial eligibility based on the predefined inclusion criteria. Studies that met the inclusion criteria during title and abstract screening were retrieved in full text and further assessed for eligibility. Any discrepancies between the two primary researchers were resolved through discussion or adjudicated by the third reviewer (YC).

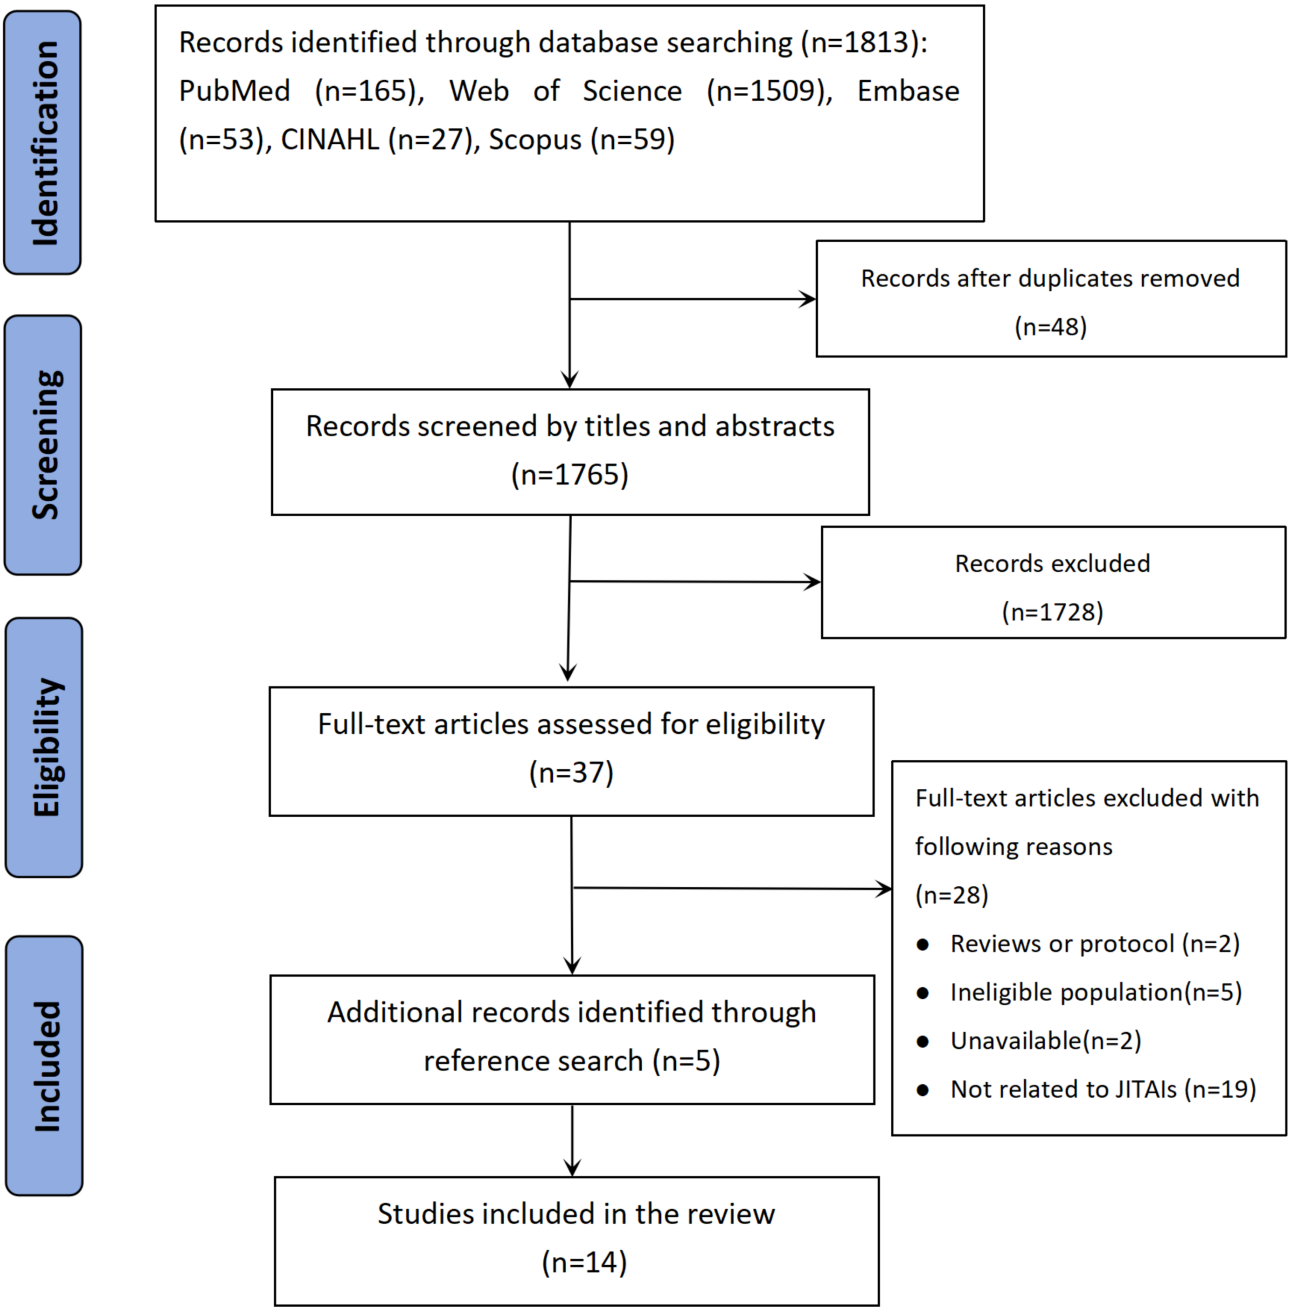
Data Extraction

Two researchers (JG and MH) independently extracted and recorded data using a predesigned standardized Excel form (Microsoft, 2022). The data extraction process was guided by the review's research questions and included the following information: (1) characteristics of included studies such as first author, year of publication, country, objectives, study design, population and setting, and sample size; (2) design characteristics of JITAIs, including theoretical framework, target behaviors, sensors/data sources, tailoring variables, decision points, intervention options, decision rules, prompt frequency/timing, adaptation mechanisms, intervention duration, engagement, and implementation-related measures; (3) evaluation of JITAIs in terms of PA and sedentary behavior; and (4) reported barriers and facilitators related to engagement and use of JITAIs. A third reviewer (YD) independently reviewed the extracted data from all included studies. Any discrepancies between the two primary researchers were resolved through discussion or adjudicated by the third reviewer (YD).

Data Synthesis and Analysis

Data synthesis and analysis were conducted using a descriptive and narrative approach, in line with the objectives and research questions of this scoping review. Given the heterogeneity of study designs and target populations, a meta-analysis was not conducted. Data on study characteristics, design features of JITAIs, and evaluation findings were descriptively synthesized and tabulated to summarize the overall profile of the included studies [26]. Where appropriate, similar JITAI design components were grouped into categories. For example, decision rules were categorized as EMA-based if-then rules, sensor-triggered or sedentary-threshold rules, scheduled rules, microrandomization rules, or coach- or staff-supported rules. Additionally, qualitative data and open-ended data were synthesized using inductive thematic analysis to identify reported barriers and facilitators related to the engagement and use of JITAIs among patients with chronic diseases [27]. Two

XSL•FO
RenderX



reviewers (JG and FC) independently coded relevant qualitative findings and extracted statements. Codes were compared, refined, and grouped into overarching themes and subthemes. Discrepancies in interpretation were resolved through discussion or adjudicated by the third reviewer (YD). Final themes and findings were reviewed by the full research team to ensure coherence, transparency, and consistency with the review questions.

Results

Search Results

A total of 1813 records were identified through searches of 5 electronic databases. After removing 48 duplicates, 1765 records remained for title and abstract screening, of which 1728 were excluded based on relevance. The full texts of the remaining 37 articles were assessed for eligibility, resulting in the exclusion of 28 studies. An additional 5 relevant studies were identified through reference list screening. Finally, 14 studies were included in this scoping review. The PRISMA flow diagram of study selection is shown in Figure 1.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram of study selection. JITAI: just-in-time adaptive intervention.

Characteristics of Included Studies

The publication years of included studies ranged from 2015 to 2025. The majority (n=9) were conducted in the United States [28-36], while the remaining 5 were carried out in Ireland [37], Australia [38], the Netherlands [19], Singapore [39], and the Czech Republic [20], respectively. All studies were described as feasibility or pilot studies, including 4 qualitative studies [19,31,37,38], 3 randomized controlled trial (RCT) studies [28,29,32], 6 single-armed feasibility or pilot studies [20,33-36,39], and 1 prospective cohort study [30]. Sample sizes ranged from 8 to 108 participants. Among those, 4 studies recruited individuals with T2D [19,20,35,38], 3 targeted individuals undergoing or completing cardiac rehabilitation [28,31,33], and 2 included individuals with stroke [30,37]. The remaining studies enrolled participants with hypertension (n=1) [29], spinal cord injury (n=1) [34], acute coronary syndrome or those who had undergone coronary revascularization (n=1) [33], individuals who were overweight or obese (n=1) [36], and older adults with a chronic condition (n=1) [39]. More details of the characteristics of included studies are presented in Table 2.

Table . Characteristics of included studies.

Author	Year of publication	Country	Objectives	Study design	Population and setting	Sample size
Hietbrink et al [19]	2025	Netherlands	To assess the acceptability of EMA[a]-driven, just-in-time adaptive lifestyle support in individuals with T2D[b]	Qualitative study	• Population: people diagnosed with T2D • Age: mean 70.5 (SD 9) years • Setting: hospital	8
Cardy et al [37]	2024	Ireland	To explore the perspectives of people with strokes, their caregivers, and health care providers on the delivery of an adaptive, personalized mHealth[c] intervention to promote PA[d] after stroke	Qualitative study	• Population: people with stroke, caregivers, health care workers • Age: 54.5, 66.5, and 34 years • Setting: hospital and community	People with stroke (n=12); caregivers (n=6); health care workers (n=10)
Golbus et al [28]	2024	USA	To support cardiac rehabilitation patients in increasing and sustaining PA using a mobile health intervention	RCT[e]	• Population: people were enrolled in cardiac rehabilitation based on a qualifying diagnosis • Age: mean 59.5 (SD 10.7) years • Setting: medical and community health care center	108
Novak et al [20]	2024	Czech Republic	To describe the development and piloting of the mHealth intervention and its final version to be evaluated in the ENERGISED trial	Pilot study	• Population: people diagnosed with prediabetes and T2D • Age: between 40 and 76 years • Setting: hospital	10
Bai et al [29]	2022	USA	To determine the effectiveness of wearable activity trackers alone or in combination with behavior change strategies for promoting PA among individuals with prehypertension or hypertension	RCT	• Population: prehypertension or hypertension patients • Age: mean 55 (SD 8.8) years • Setting: medical clinics, community	44 (control: 22; intervention: 22)

[e]RCT: randomized controlled trial.

[f]JITAI: just-in-time adaptive intervention.

[g]CVD: cardiovascular disease.

[h]CHD: coronary heart disease.

Design Characteristics of JITAIs

Among the included studies, 13 reported on the design characteristics of JITAIs, with 2 studies using the same version of the JITAIs [31,32], resulting in a total of 12 unique JITAIs. Additionally, 8 of the JITAIs were grounded in theoretical frameworks [19,20,29,32-34,38,39], with social cognitive theory being the most commonly applied [32,34]. Overall, 6 JITAIs

XSL•FO
RenderX

[28,30,32-34,37] were designed to primarily target PA behavior, 1 focused solely on sedentary behavior [36], and 5 addressed both sedentary behavior and PA [20,29,35,38,39]. Most studies used wearable devices, smartphone apps, or both to collect PA or sedentary behavior data. Wearable or sensor-based data were used in studies (n=11) [20,28,29,31-36,38,38,39] using Fitbit or smartwatch devices, activity trackers, smartphone accelerometers, or external accelerometers. Several studies (n=4) also incorporated EMA or self-report data. Additional contextual data, such as location, weather, time of day, or day of week, were used in Hietbrink et al [19], Golbus et al [28], Daryabeygi-Khotbehsara et al [38], Mair et al [39], and Novak et al [20]. Two studies [31,32] also included app-entered clinical or health data, such as symptoms, blood pressure, heart rate, medication use, or self-reported health measures.

Tailoring variables could be grouped into 5 categories: behavioral variables, contextual variables, self-reported momentary states, goal/progress variables, and clinical or safety-related variables. Behavioral variables included step count, sedentary bout duration, walking status, activity intensity, and recent PA patterns [20,28,29,31-36,38,39]. Contextual variables, including time of day, weather, location, weekday/weekend, or study phase [19,20,28,38,39]. Self-reported momentary states, such as mood, fatigue, restrictions, cravings, readiness, and energy [19,33,34]. Goal- or progress-related tailoring was used in 6 studies [20,29,33,34,38,39]; for example, Novak et al [20] tailored messages according to recent step counts, weekly step goals, and individual action plans. Clinical or safety-related tailoring, such as symptom-triggered safety responses, was mainly reported in Elnaggar et al [31] and Park et al [32].

Decision points also differed across studies. Some interventions (n=4) [20,34-36] used sensor-triggered decision points, where prompts were delivered when a behavioral threshold was detected. For example, Pellegrini et al [35] delivered prompts after 20 minutes of consecutive sedentary time; Thomas et al [36] tested prompts after 30, 60, or 120 minutes of sedentary behavior; Novak et al [20] used Fitbit-detected inactivity or walking patterns; and Hiremath et al [34] triggered feedback when moderate-intensity wheelchair-based activity was detected. Other studies (n=5) [28,31,32,38,39] used scheduled or semi-scheduled decision points. Golbus et al [28] and Daryabeygi-Khotbehsara et al [38] also used microrandomized decision points, where participants could be randomized to receive or not receive an intervention message at predefined times or contexts. EMA-based decision or assessment points were used in Hietbrink et al [19] and Sengupta et al [33].

Intervention options could be grouped into PA prompts (n=9) [19,20,28,31-34,38,38,39] sedentary break prompts (n=5) [20,35,36,38,39], goal-setting or planning support (n=7) [20,28,29,33,34,38,39], feedback and encouragement (n=8) [19,20,29,31-34,39], education or coping support (n=5) [19,20,31-33], and safety prompts, which were specifically reported in Elnaggar et al [31] and Park et al [32], where participants reporting symptoms such as chest pain or shortness of breath received safety-related guidance. Decision rules were mostly simple and rule-based, which could be classified as EMA-based if-then rules, sensor-triggered if-then rules, sedentary-threshold rules, scheduled rules, microrandomization rules, and coach- or staff-supported rules. EMA-based if-then rules were used in 2 studies. Hietbrink et al [19] matched text messages to EMA-reported activity, mood, location, restrictions, weather, or cravings, while Sengupta et al [33] used EMA and goal information to trigger reminders or reinforcement messages. Four studies [20,34-36] adopted sensor-triggered or sedentary-threshold rules, where prompts were delivered after predefined behavioral states such as inactivity, low-intensity walking, moderate-intensity wheelchair activity, or prolonged sedentary time. Scheduled rules were used in 4 studies [20,31,32,39], with messages delivered at fixed daily or weekly times. Probability-based or availability-based microrandomization was used in Golbus et al [28] and Daryabeygi-Khotbehsara et al [38], where participants were randomized to receive or not receive messages at predefined decision points, sometimes conditional on availability. Four studies [29,31-33] used coach- or staff-supported decision rules, where participant data were reviewed by coaches or study staff to support tailored feedback, motivational messages, or safety guidance.

The adaptation mechanisms could be grouped into sensor-based tailoring, contextual tailoring, self-report-based tailoring, goal/progress-based tailoring, and coach- or staff-supported tailoring in this study. Sensor-based tailoring was used in 6 studies [20,34-36,38,39], which adapted messages according to step count, sedentary time, activity intensity, or walking patterns. Contextual tailoring based on time, weather, location, or day of week was used in 5 studies [19,20,28,38,39]. Two studies [19,33] adopted self-report-based tailoring, which used EMA responses such as mood, fatigue, restrictions, cravings, or readiness for activity. Goal/progress-based tailoring (n=6) [20,29,33,34,38,39] adapted feedback according to whether participants were meeting activity or sitting goals. Four studies [29,31-33] used coach- or staff-supported tailoring, which involved study staff or health coaches reviewing participant data and providing individualized feedback. Furthermore, a total of 12 studies reported intervention duration of JITAIs, which ranged from 7 days to 6 months, and was typically 2 to 12 weeks. Further details regarding the design characteristics of the JITAIs are provided in Table 3.

Table . Design characteristics of JITAIs[a].

Study	Theoretical framework	Target behavior	Sensors/data sources	Tailoring variables	Decision points	Intervention options	Decision rules	Prompt frequency/timing	Adaptation mechanisms	Intervention duration
Hietbrink et al [19], 2025	Behavior maintenance	PA[b]	EMA[c] self-report via SMS link/mobile phone. No passive wearable sensor was used. Participants completed EMAs on activity, location, mood, condition/restrictions, weather, and cravings. Baseline web-based survey measured self-efficacy and phase of behavior change.	Activity, location, mood, physical/mental restrictions, weather, cravings; plus baseline self-efficacy and phase of behavior change used to select suitable messages.	Each EMA prompt functioned as a decision point. EMAs were delivered at 1‐2 semirandom time points per day: once in the morning and once in the afternoon/evening.	Lifestyle support messages, including PA prompts, motivational/reflective messages, skill-building tips, and coping support	EMA-based if-then rules	EMA prompts 1‐2 times/day; intervention options delivered by text message, maximum 2 intervention messages/day.	Contextual tailoring and self-report-based tailoring	2 weeks
Golbus et al [28], 2024	Not reported	PA	Smartwatch data from Apple Watch or Fitbit Versa; mobile study app; step count measured after message delivery. Contextual data included weather, time of day, day of week, and time since enrollment.	Weather, temperature/precipitation, time of day, weekday/weekend, duration in study. Some messages could include preferred name, gain/loss framing, emoji, or dashboard hyperlink.	Participants were randomized 4 times/day to receive either no message or a PA-promoting message.	PA-promoting text messages or no message, with additional exercise planning, feedback, and self-monitoring components	Probability-based microrandomization	4 activity-message decision points/day over the trial; expected activity message rate ≈1/day due to 25% probability at each point.	Contextual tailoring	6 months

Study	Theoretical framework	Target behavior	Sensors/data sources	Tailoring variables	Decision points	Intervention options	Decision rules	Prompt frequency/timing	Adaptation mechanisms	Intervention duration
Novak et al [20], 2024	Self-regulation theory	PA and sedentary behavior	Fitbit Inspire 2 activity tracker; HealthReact platform; Fitbit step count, walking cadence proxy, heart rate to confirm wear, and syncing pattern.	Fitbit-detected walking/sitting patterns, step count, heart rate/wear status, recent step counts, weekly step goal progress, individual action plans/routines, baseline step goals, Fitbit syncing reliability, phone type, internet access/mobile data availability.	Main decision points included 5 min walking with 60 - 100 steps/min between 8 AM and 8 PM; 30 min with zero steps plus heart rate detection between 4 and 8 PM. Other decision points were individual routine-based reminders and fixed weekly times.	PA prompts, sedentary break prompts, action-plan reminders, goal review, feedback/encouragement, and health education	Sensor-triggered if-then rules plus scheduled rules	Expected 3 - 6 messages/week. Caps: Stand Up max 1/day; Walk Faster max 2/day with ≥60 min interval. Goal review: Friday 8 - 10 PM; Feedback/encouragement: Sunday 6 - 8 PM; Health education: Tuesday 6 - 8 PM.	Sensor-based tailoring, contextual tailoring, and goal/progress-based tailoring	2 weeks
Bai et al [29], 2022	Motivational interviewing and self-determination theory	PA and sedentary behavior	Fitbit Charge HR 3/Fitbit device for self-monitoring; ActiGraph wGT3X-BT used to assess MVPA[d], steps, and sedentary time.	Fitbit-derived activity progress; step counts; PA goals; goal review information used by the health coach.	Not reported.	Self-monitoring, goal setting/review, adaptive feedback	Coach-led goal/feedback rules	Not reported	Goal/progress-based tailoring	12 weeks

Study	Theoretical framework	Target behavior	Sensors/data sources	Tailoring variables	Decision points	Intervention options	Decision rules	Prompt frequency/timing	Adaptation mechanisms	Intervention duration
Daryabeygi-Khotbehsara et al [38], 2022	Behavior change techniques	PA and sedentary behavior	iMOVE Android app; SORD wearable sensor for real-time sitting, standing, and walking detection; Bluetooth connection; smartphone GPS for location; OpenWeather API for weather; Android time data; cloud server/database.	Sitting/standing/walking status; location, especially home vs workplace; weather conditions; time of day; weekday/weekend; personal sitting and walking goals.	Five daily decision windows included morning, lunchtime, afternoon 1, afternoon 2, and evening, from 8 AM to 8:30 PM. Randomization occurred only when participants were available: not driving, not sleeping, not already active, and connected to the intern.	"Sit less/move more" prompts, goal setting	Availability-based microrandomization	5 decision points/day; 70% intervention probability, split into 35% Sit Less and 35% Move More; 30% no-message control.	Sensor-based tailoring, contextual tailoring, and goal/progress-based tailoring	Not reported
Lau et al [30], 2022	Not reported	PA	Accelerometer plus EMA surveys; retrospective self-report assessments; acceptability questionnaire.	Daily activity and health-related symptoms: mood, cognitive complaints, fatigue, and pain.	Not reported.	Monitoring only	Not reported	8 EMA surveys/day for 7 days.	Not reported	7 days

Study	Theoretical framework	Target behavior	Sensors/data sources	Tailoring variables	Decision points	Intervention options	Decision rules	Prompt frequency/timing	Adaptation mechanisms	Intervention duration
Thomas et al [36], 2015	Not reported	Sedentary behavior	Android smartphone; B-MOBILE app; smartphone onboard accelerometer; validated algorithm classifying behavior as sedentary behavior or nonsedentary behavior in 1-minute epochs; SenseWear Mini Armband/objective multisensor monitor for assessment in the B-MOBILE study.	Continuous sedentary minutes, sedentary behavior vs nonsedentary behavior state, walking-break condition, walking-break completion, total daily reminders after 5 and 10 minutes of continued sedentary behavior minutes, total daily PA minutes, and number of walking prompts met.	Participants reached condition-specific sedentary thresholds: 30, 60, or 120 continuous sedentary minutes. The app also triggered reminders after 5 and 10 minutes of continued sedentary behavior after a walking prompt.	Walking-break prompts, reminder prompts, feedback display	Sedentary-threshold if-then rules	Three conditions were tested: a 3-min walking break after 30 min of sedentary behavior, a 6-min walking break after 60 min of sedentary behavior, or a 12-min walking break after 120 min of sedentary behavior; additional reminders were delivered after 5 and 10 min if sedentary behavior continued.	Sensor-based and tailoring	21 days

[a]JITAI: just-in-time adaptive intervention.

[b]PA: physical activity.

[c]EMA: ecological momentary assessment.

[d]MVPA: moderate to vigorous physical activity.

[e]CVD: cardiovascular disease.

[f]ML: machine learning.

Engagement and implementation-related measures were inconsistently reported across studies. Reported measures included study retention, wearable-device use, EMA completion, app use, goal setting, message exposure and responsiveness, intervention-delivery fidelity, usability, and satisfaction. Four studies [33,34,36,39] reported quantitative engagement and delivery-fidelity data. Hietbrink et al [19] and Daryabeygi-Khotbehsara et al [38] mainly reported qualitative acceptability or development-stage feedback, while Golbus et al [28], Bai et al [29], Elnaggar et al [31], and Park et al [32] provided limited objective usage or response data. Further details are presented in Multimedia Appendix 2.

Effectiveness of JITAIs in Reducing Sedentary Behavior and Promoting PA Among Patients With Chronic Disease

Of the 14 included studies, 7 objectively measured PA. Three RCTs [28,29,32] reported preliminary evidence of a positive effect of JITAIs on promoting PA. In the study by Golbus et al [28], participants' 60-minute step counts significantly increased within the first 30 days following the intervention. In the study by Park et al [32], the intervention group had a higher mean daily step count compared to the control group (P=.02). Similarly, Bai et al [29] found that participants in the Fitbit plus health coaching group increased their daily step count (P<.01) and moderate to vigorous physical activity (MVPA) (P<.05), with an improvement in daily MVPA compared to those in the Fitbit-only group (P<.05). Four nonrandomized studies reported PA outcomes, with three demonstrating positive effects [30,34,35]. Studies by Hiremath et al [34] and Pellegrini et al [35] reported increases in PA levels compared to baseline (both P<.05). The study by Lau et al [30] also showed that a higher proportion of light and moderate to vigorous PA was recorded among participants receiving JITAIs. However, the study conducted by Sengupta et al [33] found no significant change in PA levels compared to baseline.

Three studies [29,35,36] objectively measured sedentary behavior, including 1 RCT and 2 nonrandomized studies. In the RCT conducted by Bai et al [29], participants in the Fitbit plus health coaching group preliminarily demonstrated a reduction in sitting time (P<.01). Among the 2 nonrandomized studies, both reported a reduction in sedentary time or behavior compared with baseline (P<.05) [35,36]. Further details are provided in Multimedia Appendix 3.

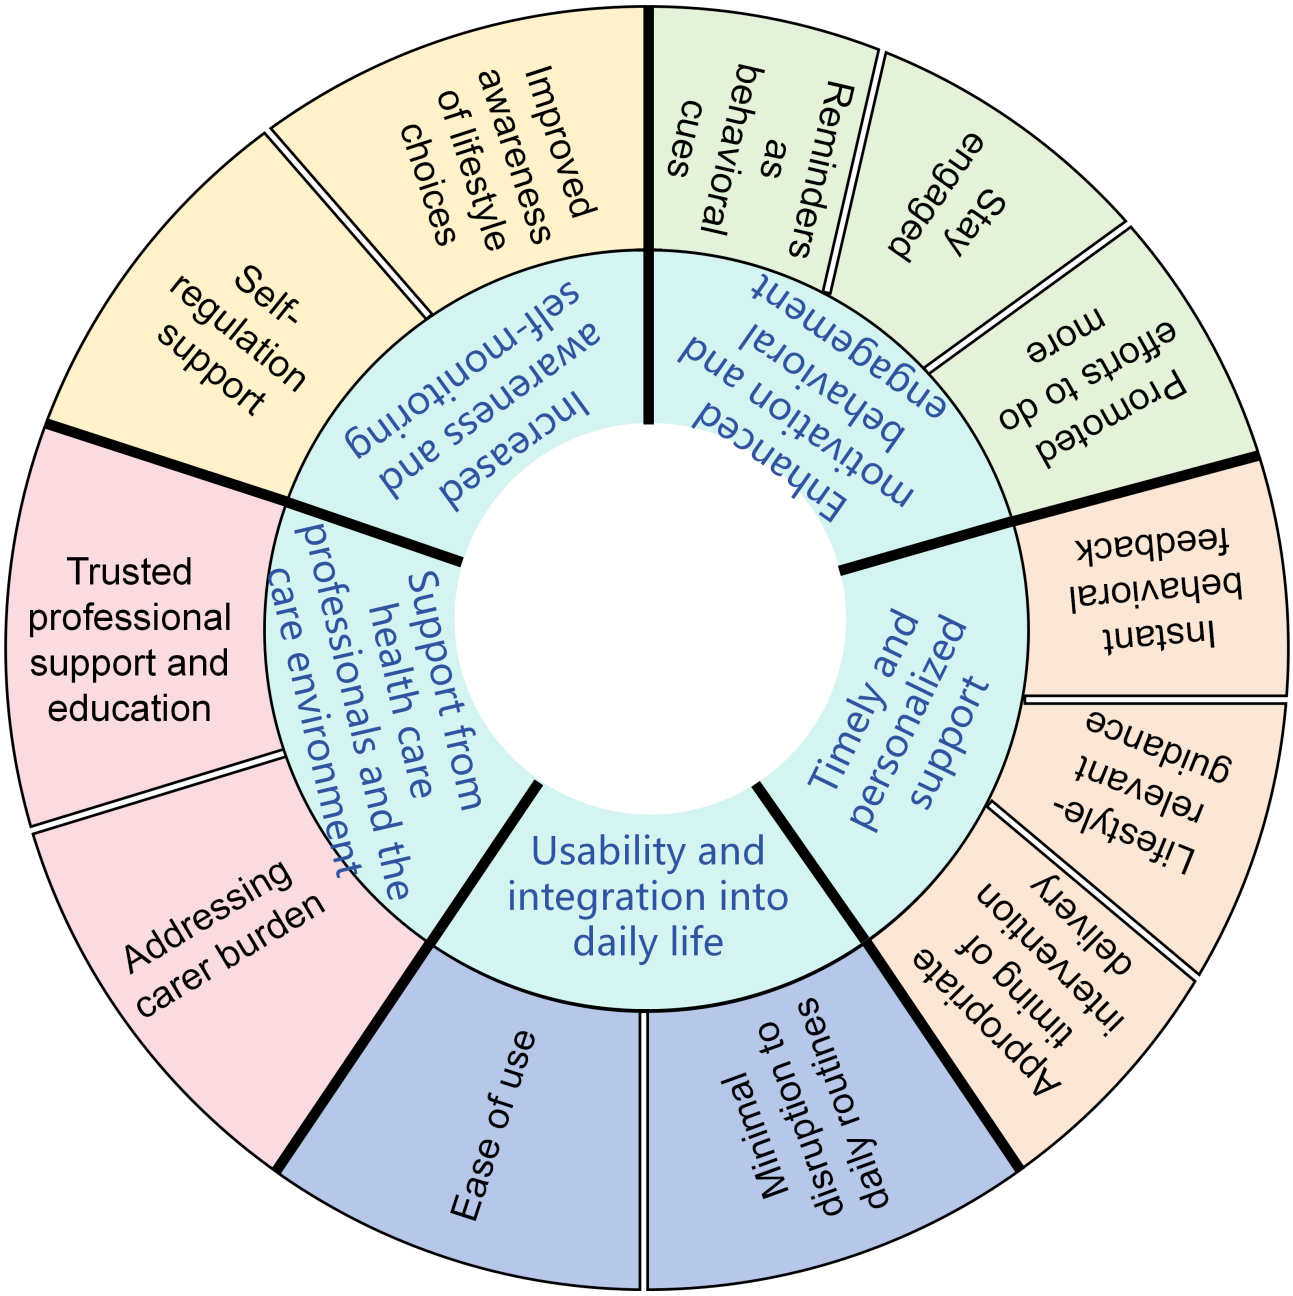
Barriers and Facilitators of JITAIs in Promoting PA and Reducing Sedentary Behavior Among Patients With Chronic Disease

Barriers Related to Engagement and Use of JITAIs

Several barriers were identified that may hinder the use of JITAIs in promoting PA and reducing sedentary behavior among patients with chronic diseases [19,20,31,34,37-39] (Figure 2). These barriers were categorized into five overarching themes: (1) technological usability and literacy, including limited familiarity with technology, device and app usability challenges such as small text or rigid settings, connection and performance issues such as devices unable to detect low-intensity or short-duration activities; (2) burden and intrusiveness of the intervention, including perceived time burden, repetitive or unengaging content, and lifestyle incongruence; (3) perceived value and acceptability, including limited perceived usefulness and psychological resistance; (4) external and contextual barriers, including the impact of epidemic restrictions and environmental or situational incompatibility; and (5) privacy and data security concerns, including reluctance to share data and perceived data protection.

Figure 2. Barriers related to engagement and use of just-in-time adaptive interventions (JITAIs).



Facilitators Related to Engagement and Use of JITAIs

The facilitators identified across the six included studies [19,31,34,37-39] were synthesized into five major themes: (1) enhanced motivation and behavioral engagement, including promoted efforts to "do more," stay engaged and reminders as behavioral cues (eg, just-in-time reminders prompted timely action and supported formation of new routines and habits); (2) increased awareness and self-monitoring, including improved awareness of lifestyle choices and self-regulation support; (3)

XSL•FO
RenderX

usability and integration into daily life, including ease of use and minimal disruption to daily routines; (4) timely and personalized support, including appropriate timing of intervention delivery (eg, participants felt supported "in the moment"), lifestyle-relevant guidance and instant behavioral feedback; and (5) support from health care professionals and the care environment, including trusted professional support and education, and addressing caregiver burden (Figure 3).

Figure 3. Facilitators related to engagement and use of just-in-time adaptive interventions (JITAIs).

Discussion

Principal Findings

To the best of our knowledge, this is the first scoping review to systematically map and synthesize the existing literature on JITAIs specifically aimed at reducing sedentary behavior and promoting PA in individuals with chronic disease. A total of 14 studies were finally included in this review, and we systematically summarized the key characteristics of delivery methods and components used in JITAIs designed to reduce sedentary behavior and promote PA, and explored the existing evidence regarding the evaluation of these interventions in improving PA levels and reducing sedentary time. Additionally, this review also identified reported barriers and facilitators associated with the use of JITAIs among individuals living with chronic diseases. The findings contribute to a clearer understanding of how JITAIs are currently operationalized and provide a foundation for guiding future research and intervention development in chronic disease management.

Among the included studies, most of them provided participants with instructions on how to operate these technologies. As the integration of wearable activity trackers becomes more common, user training and support are essential to maximize engagement and minimize technological barriers [20,28]. The widespread

XSL•FO
RenderX

use of built-in accelerometers and GPS sensors indicates that sensor-based context detection is a central feature of current JITAIs [30,35]. By identifying timely opportunities for intervention, these technologies may support more personalized and responsive behavioral prompts. Additionally, the intervention options and decision rules identified in this review suggest that most JITAIs used relatively simple designs. The frequent use of PA prompts, goal-setting or planning support, and feedback/encouragement indicates that most interventions focused on motivating participants to initiate or maintain PA, whereas fewer studies specifically targeted sedentary breaks. Safety prompts were reported only in Elnaggar et al [31] and Park et al [32], suggesting that symptom- or risk-related tailoring remains limited despite its relevance for patients with chronic disease. Decision rules were also mostly predefined and rule-based, which, although practical and transparent, indicates that many current JITAIs are adaptive mainly to predefined behavioral or contextual triggers rather than continuously learning from individual responses over time. Future research could therefore explore more dynamic and data-driven adaptation strategies that can continuously learn from users' evolving behaviors and intervention responses.

In this review, most included studies reported preliminary evidence of a positive effect of JITAIs in promoting PA among patients with chronic disease. JITAIs provide personalized, real-time support based on individual context, such as location, time of day, or recent activity levels, which may enhance the relevance and timeliness of prompts and promote behavioral engagement [15,16]. The use of wearable sensors and mobile apps may also support continuous monitoring and feedback, potentially enhancing motivation and self-awareness [15,16]. In addition, many interventions incorporated behavior change techniques such as goal-setting, reminders, and feedback, which have been shown to support PA improvement [40]. However, the findings from one study [33] found no significant change in PA levels compared to baseline. One possible explanation for the lack of significant change in PA levels in the study could be the exclusive inclusion of female participants. Factors such as caregiving responsibilities, differing motivational drivers, and social or cultural expectations may influence women's engagement with PA interventions [41]. Three studies [29,35,36] reported preliminary evidence of a positive effect of JITAIs in reducing sitting time and promoting breaks in sedentary behavior. The effects may be related to the real-time and context-sensitive design of JITAIs, which allows prompts or support to be delivered when individuals are likely to be sedentary, such as after prolonged inactivity or during sitting-related contexts, including watching television or working at a desk [29,35,36]. The timely cues may help interrupt habitual sedentary patterns and encourage individuals to take breaks, stand, or engage in light activity. However, the overall evidence base for JITAIs in promoting PA and reducing sedentary behavior remains limited by small sample sizes, few RCTs, and short intervention durations. In this review, only one study [28] had an intervention duration of 6 months, whereas the remaining studies involved relatively shorter intervention periods. The limited durations may not be sufficient to determine whether JITAIs can produce sustained behavioral changes or maintain long-term user engagement. Future research could therefore use RCT designs adequately, include longer intervention and follow-up periods, and recruit more diverse chronic disease populations across different clinical and community settings to further establish the effectiveness of JITAIs.

The identification of multiple barriers to JITAI use among patients with chronic diseases highlights important challenges that need to be addressed to optimize their utility. Most studies reported that technological usability and literacy emerged as a significant obstacle. Issues such as small text sizes, rigid app settings, and unreliable detection of low-intensity or brief activities can compromise user experience and reduce engagement, aligning with previous findings, which emphasize the digital divide, particularly among older or less technologically experienced populations commonly affected by chronic conditions [42,43]. Future interventions can adopt inclusive design principles that accommodate users with varying levels of digital literacy. This involves simplifying user interfaces, enabling customizable text sizes and display settings, and ensuring device compatibility with a wide range of PA levels, particularly low-intensity movements common among individuals with chronic diseases. Incorporating user-centered design through participatory development processes may enhance both usability and acceptability by aligning intervention features with patient needs and preferences [31,37]. Additionally, the burden and intrusiveness of the intervention represent another critical barrier. Patients reported perceptions of excessive time demands, repetitive or not engaging content, and misalignment with their daily routines, which may undermine adherence [20,34,38,39]. The results underscore the necessity for interventions that are not only effective but also seamlessly integrate into users' lifestyles, minimizing disruption and maximizing relevance. Moreover, perceived value and acceptability also influence intervention uptake. Limited perceived usefulness and psychological resistance, potentially stemming from skepticism toward new technologies or concerns about personal capability, suggest that patient education and motivational strategies are crucial components for successful implementation [19]. Privacy and data security concerns were reported in several studies, reflecting widespread apprehension regarding data sharing and protection, similar to the findings from Muhunzi et al [44]. Future interventions should ensure transparent data policies and robust security measures while granting users control over their personal information to build trust, enhance sustained engagement, and support the further development of JITAIs.

Limitations

This scoping review has several limitations that should be acknowledged. First, although a comprehensive search strategy was used, some relevant studies may have been missed due to publication bias or limitations in database indexing. In addition, only peer-reviewed articles published in English were included, which may have excluded relevant studies published in other languages or gray literature. Second, the heterogeneity of the included studies in terms of population characteristics, intervention designs, and duration limited our ability to quantitatively synthesize findings or make direct comparisons across studies. Third, many included studies had small sample sizes and short follow-up periods, which may limit the

XSL•FO
RenderX

generalizability of the findings and make it difficult to determine whether the reported effects can be sustained over time. Additionally, most studies were conducted in high-income countries, which may limit the applicability of findings to low- and middle-income settings. Therefore, the conclusions should be interpreted with caution. Future systematic reviews with meta-analyses and risk-of-bias assessments are warranted to more rigorously evaluate the effectiveness of JITAIs in promoting PA and reducing sedentary behavior.

Conclusions

This scoping review identified preliminary evidence suggesting that JITAIs may help reduce sedentary behavior and promote PA among patients with chronic diseases. However, the evidence supporting this conclusion remains limited by the small number of RCTs, small sample sizes, short intervention and follow-up periods, and heterogeneity across studies. Therefore, these findings should be interpreted as preliminary. Future research could use RCT designs with sufficient sample sizes, longer follow-up periods, and more diverse chronic disease populations to further establish the effectiveness and generalizability of JITAIs.

Abstract

Background: Orthotic treatment for adolescents diagnosed with idiopathic scoliosis is long-term and often associated with challenges related to treatment adherence. Traditional patient monitoring strategies include clinical visits combined with patient discussions, clinical examination reports, and the use of standard questionnaires. Sensor-assisted monitoring is explored to improve treatment outcomes, with technology influencing different aspects of the health care system.

Objective: The scoping review aimed to map evidence based on 3 research questions (RQs), namely user experience and perception, monitoring tools, and technology-assisted approaches, including smart orthoses with sensors, during orthotic treatment for an adolescent patient (aged 10 to 17.11 y) diagnosed with idiopathic scoliosis.

Methods: A systematic search was conducted in MEDLINE, Embase, PsycINFO, Cochrane Library, CINAHL, Web of Science, and Scopus as 2 complementary search components. The primary search targeted studies on smart orthoses, also called braces, and scoliosis, while the secondary search focused on user experiences with orthotic treatment to capture all 3 RQs. PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-analyses extension for Scoping Reviews) guidelines and checklist supported searching, analyzing, and reporting the results systematically. Predefined inclusion and exclusion criteria were followed for screening. All articles published up to May 2024 were included. Moreover, 2 independent reviewers screened 2088 articles in 2 stages of screening. Data coding was conducted using the 3 RQs by data extraction and its synthesis.

Results: A total of 88 articles met the inclusion criteria. Evidence from user experience studies highlighted discomfort, psychosocial burden, and demand for real-time feedback. Monitoring relied primarily on patient-reported outcome measures (PROMs) such as questionnaires and logbooks. Culturally adapting to patients' diverse global needs helps capture richer and more candid user perspectives. Sensor-based systems used temperature, force, or pressure, electromyography, and motion sensors to track orthosis wear time, pressure distribution, activity, and posture. Two overarching monitoring themes emerged: subjective (patient-reported or user experience) and objective (technology-assisted or sensor-based) monitoring. Integrated approaches synthesize both.

Conclusions: Subjective clinical tools and objective technologies help monitor orthosis wear of adolescent patients with idiopathic scoliosis. Co-design of a user-centered scoliosis management system for adolescents that integrates PROMs with measured sensor data could provide a multidimensional view of orthosis adherence along with psychosocial and clinical effectiveness. Future research will focus on user-centered care, with real-time integrated monitoring, to provide clinically meaningful feedback that motivates adolescents to achieve their treatment goals.

Introduction

Background

Scoliosis refers to the deformity of the spine, thorax, and trunk. The root cause of scoliosis can differ. About 80% of cases are classified broadly by etiology as idiopathic scoliosis [1,2]. The International Scientific Society on Scoliosis Orthopedic and Rehabilitation Treatment reports that idiopathic scoliosis is diagnosed in seemingly healthy children and tends to progress rapidly at puberty [3].

Nonsurgical treatment options for scoliosis management include observation, physiotherapeutic-specific exercises, special inpatient rehabilitation, and bracing [3]. Bracing combined with exercise is an effective conservative treatment approach for patients with adolescent idiopathic scoliosis [4]. Since the last decade, scoliosis orthoses or braces have been considered the gold standard for decreasing the progression rate of curves, based on the multicenter study "Bracing in Adolescent Idiopathic Scoliosis Trial" from the United States and Canada, which demonstrated that the success of orthotic treatment increases with higher wearing hours [5]. However, treating adolescents with prolonged unpredictable treatment outcomes is challenging [6,7]. The most affected are female individuals with a higher diagnosis rate than male individuals [1], and the rate of deformity is highest at the beginning of puberty, during adolescence [2].

The hours of orthosis wear stand as an integral component of the treatment [8]. These orthoses can be rigid or soft, varying in construction, correction principles, and clinical outcomes. Ali et al [9], in the systematic review, compare 20 different orthoses and highlight their differences. Greater curve correction is obtained with rigid orthoses, while soft orthoses can deliver correction, enhanced comfort, and engage the patient's muscles [9].

The Cobb angle is the clinical measure that quantifies the degree of spinal deformity. At the same time, the Risser stage assesses skeletal maturity on a 0‐5 scale, using either a US or a European scale where 5 means complete maturity. In addition to these clinical approaches, patient-reported questionnaires support with valuable information on the patients' emotional and psychological burden [10]. Different patient monitoring tools support clinicians in long-term scoliosis management in adolescents by assessing the effectiveness of orthoses and enabling patient-focused treatment adjustments [11,12]. Digital health care–based monitoring using sensors can support the treatment journey [2]. As technology advances, there is a need to update and integrate sensors with digitalized monitoring solutions to improve bracing outcomes. Mobile-based health monitoring systems are emerging to track adolescent treatment compliance and well-being [13]. Scoliosis care and treatment protocols have been inconsistent globally, with regional variants. Different health care providers involved in scoliosis treatment identified the need for increased research collaboration and standardization of treatment protocols globally [2]. Accepting these diverse and significant contexts that address user needs within scoliosis, integrating both health-oriented and technology-driven strategies, can be useful for future co-designs.

Context and Significance

User Experience and Perception

In scoliosis orthotic management, patient adherence to treatment goals is significant but challenging [8,10]. Adherence to orthotic treatment is a process that may begin with experiencing symptoms, consulting a therapist, becoming aware of visible spinal deformity, and receiving attention from family members. It may then progress to seeking care by accepting the diagnosis, discussing options with an orthotist, agreeing to treatment and living with an orthosis, and adapting psychosocially. Each step can influence the patient's compliance. Thus, treatment with orthosis is a process that depends on the combined effort of patients, family, physicians, and orthotists to reach treatment goals [14,15]. The treatment aims to enhance the patient's quality of life by addressing current and long-term needs. The target of scoliosis management includes preventing curve progression and thereby reducing physical disability, improving body aesthetics, delivering daily functioning, overall well-being, including mental health, and improving self-esteem [16]. To achieve these broader treatment goals, it is essential to incorporate evaluation and monitoring methods that capture patients' experiences and perceptions of treatment challenges and their preferences [17].

Monitoring Tools

Different questionnaires are designed for monitoring patients. Questionnaires are frequently used to objectively assess patients' subjective experiences, such as physical function and psychological well-being [18-20]. Capturing meaningful patient-reported information enables health personnel to understand treatment adherence better and recommend more effective interventions. Clinicians need to discuss essential aspects of orthosis adherence, such as the actual hours the orthosis is worn compared with the prescribed duration, and the effectiveness of prescribed exercises [21]. This information can support prognosis and guide treatment decisions. Record cards or patient logbooks can give additional information to track patient observations between visits [22]. These methods represent traditional and nontechnological approaches to monitoring. While pain is not typically a primary clinical issue in orthosis-treated adolescent patients with idiopathic scoliosis, some questionnaires include pain subscales because these tools were originally developed for broader scoliosis populations. Pain-related items were therefore reported when present in included studies but interpreted cautiously.

Technology-Assisted Approaches

Sensor-assisted technologies are evolving toward personalized and intelligent orthotic management systems that enable real-time monitoring and communication among patients,

XSL•FO
RenderX

caregivers, and health care professionals. Various wearable sensors have been developed to objectively monitor orthosis use, including temperature, pressure, force, and motion sensors (eg, studies by Fregna et al [8], Rahman et al [23], Zou et al [24], Cordani et al [25], Tymińska et al [26], and Donzelli et al [27]). For instance, in the study by Donzelli et al [27], sensor data provides information on actual orthosis wear hours, aiding clinicians in planning personalized treatment goals. Smart textile sensor systems for scoliosis monitoring are attracting research interest [28]. These technologies can quantify orthosis wear time and adherence, providing clinicians with objective information to support individualized treatment decisions. Data collected from these devices can be displayed through mobile applications or web-based platforms, allowing continuous monitoring of treatment progress [17]. More recently, wearable sensors integrated with AI have expanded opportunities for personalized monitoring and decision support (eg, studies by Cordani et al [25], Dehzangi et al [29], Zhu et al [30], and Li et al [31]). However, further evidence is needed to determine how these technologies can best support clinical decision-making and improve outcomes in adolescents.

Among existing reviews of adolescent idiopathic scoliosis management, the study by Raudenbush et al [32] provides an overview of studies evaluating, diagnosing, and treating adolescent patients with idiopathic scoliosis. Previous scoping reviews have explored evidence of successful treatment outcomes predominantly using the Cobb angle and quality-of-life questionnaires [33], and another study consolidated user needs, particularly regarding body image schema in adolescent patients with idiopathic scoliosis [34]. The scoping review includes studies from 2020 that capture the themes relevant to integrated sensor-based wearables, particularly electromyography systems, AI, and relevant platforms, and reports the persistent gap in laboratory design and long-term clinical validation [35]. There appears to be a lack of scoping review that integrates patient-reported outcome measures (PROMs) with technology-assisted monitoring approaches for adolescent idiopathic scoliosis.

It is important to distinguish between subjective and objective approaches to monitoring orthotic treatment in adolescents with scoliosis. Subjective approaches capture the patient's lived experience and perceptions, including comfort, usability, adherence challenges, psychosocial burden, and satisfaction with treatment, typically assessed through PROMs, questionnaires, or interviews. In contrast, objective approaches rely on technology-assisted monitoring tools, such as embedded sensors, temperature or pressure measurements, wear-time trackers, or other digital systems that quantify orthosis use or biomechanical parameters without relying on self-report. A third category includes integrated approaches, which combine patient-reported measures with objective sensor-based data to provide a more comprehensive understanding of both adherence and user experience. This distinction provides a clearer conceptual framework for synthesizing the existing literature and interpreting how different monitoring strategies contribute to treatment optimization.

Aim and Research Questions

The primary aim of this study was to determine the existing evidence on monitoring approaches spanning user experiences, clinical patient-monitoring tools, and technology-assisted systems for optimizing adherence and outcomes in the treatment and management of adolescent idiopathic scoliosis.

The integration of health and technology requires a detailed review to identify gaps and emerging technologies with the potential to improve patient care, especially for adolescents. This scoping review aims to estimate current evidence on user experience and perception of adolescents on diverse monitoring tools, including the technological and clinically assisted approaches, as part of conservative orthotic management for adolescents with idiopathic scoliosis. The research questions (RQs) are listed in Textbox 1.

Textbox 1. Three research questions (RQs).

RQ-A

- User experience and perception: What is known about user experience, perception, and needs related to orthosis-related monitoring in adolescents with idiopathic scoliosis?

RQ-B

- Monitoring tools: What patient-reported or digital monitoring tools have been used to assess adherence, comfort, or treatment progress in bracing among adolescents with idiopathic scoliosis?

RQ-C

- Technology-assisted approaches: What technology-assisted or sensor-based monitoring systems have been used in the management of bracing for adolescents with idiopathic scoliosis and which parameters do they capture?

Methods

Rationale for Scoping Review

A systematic review addresses defined, narrow questions with a strict assessment of evidence, while scoping reviews are ideal for examining emerging areas, clarifying definitions, and identifying research gaps [36,37]. A scoping review is particularly well-suited to this topic, given the complexity of the RQs and the interdisciplinary nature, allowing exploration of the breadth and depth of available evidence and supporting the identification of key concepts and gaps. Given the diverse study designs on this topic, including both health and technological perspectives, a scoping review enables a more inclusive and exploratory synthesis of available knowledge.

XSL•FO
RenderX

Framework

Arksey and O'Malley [37] provide the methodological framework of the review process that included systematic identification, selection of articles based on inclusion and exclusion, and charting of evidence across predefined RQs [38]. Data extraction into tables, its analysis, and presentation were defined by the Joanna Briggs Institute that uses qualitative content analysis and data visualization approaches [39]. The PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) and the checklists were used to report these processes as suggested by [40]. In the review, the PRISMA-ScR guidelines and the PRISMA-ScR checklist were followed. CONSORT-EHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and Online Telehealth) was reviewed for completeness because some included studies involve tech-assisted interventions, but PRISMA-ScR remains the main reporting framework [41].

Protocol and Registration

The protocol was prepared before conducting the search. RQs helped to guide the database search and the data collection in accordance with the scoping review framework. It is registered in INPLASY (ID INPLASY2025100032).

Information Sources and Search

The research team developed the scoping review protocol, drawing on existing literature to initiate discussions with university librarians, after a joint dialogue with specialized librarians and researchers. Search trials of the Medline database were prepared and tested first. A 2-step search strategy was finalized to comprehensively address all RQs. Based on this defined search strategy, librarians conducted the search in the 7 databases, namely MEDLINE, Embase, PsycINFO, Cochrane Library, CINAHL, Web of Science, and Scopus [42,43]. The results from both searches in each database were consolidated to generate the final single EndNote 21 (Clarivate) file that was compiled by the librarians. All articles published up to May 2024 were considered. Both the search strategies for each database are provided in Multimedia Appendix 1.

Eligibility Criteria

The primary criterion is that every article must include at least 1 patient participant, aged 10 to 17 years and 11 months (17.11 y) and diagnosed with idiopathic scoliosis [3]. If studies contain diagnoses other than adolescent idiopathic scoliosis and results are presented together, the article shall be excluded. Textbox 2 illustrates inclusion and exclusion criteria based on the Population, Intervention, Comparison, Outcome, and Study design (PICOS) framework, along with other generic criteria.

XSL•FO
RenderX

Textbox 2. Inclusion and exclusion criteria.

Inclusion Criteria

- Population
  - (1) Diagnosis: Patients diagnosed with adolescent idiopathic scoliosis
  - (2) Age: Between 10 years and 17.11 years.
- Intervention: Idiopathic scoliosis treatments with orthosis, with or without physical activities (including training, physical activity, and exercises).
- Comparators: All comparators are eligible (including no comparator, placebo, or other orthotic treatments).
- Outcomes: Not applicable (scoping review design).
- Study: All articles meeting search criteria considered.
- Publication type: Peer-reviewed articles and conference papers; opinions and medical hypotheses.
- Availability: Full-text accessible through institutional affiliations (eg, OsloMet, Aalborg University).
- Language: English only.

Exclusion Criteria

- Population
  - (1) Diagnosis:
  - Congenital scoliosis, neuromuscular scoliosis, or other nonadolescent idiopathic scoliosis types.
  - Articles with incomplete participant information or without patient participants.
  - Studies with healthy subjects.
  - (2) Age: Below 10 years or above 17.11 years and unclear age information from full text.
- Intervention: Nonorthotic treatments, including surgical interventions.
- Study: Simulation studies without patient involvement (eg, model-based or radiograph-only analysis). Studies focused solely on orthosis or prototype development without clinical or patient testing, without patient-reported outcomes or user perspectives.
- Publication type: Book reviews, editorials, conference abstracts (eg, oral presentations, short abstracts without details), short papers without peer review, commentaries, errata, letters to the editor.
- Availability: Articles not accessible in a readable format; ongoing or incomplete trials without published results.
- Language: Articles not available in English and with English abstracts but foreign-language titles or published in non-English journals.

Selection of Sources of Evidence

Overview

The Rayyan software tool was used to organize and manage the screening process. Each article was compared against its duplicates to retain only 1 version, following priority order based on the following database sources: MEDLINE, Embase, PsycINFO, Cochrane Library, CINAHL, Web of Science, and Scopus. Rayyan's reference comparison features helped highlight differences between duplicate entries. Duplicates were manually removed to ensure accuracy, despite the ability of Rayyan's feature to remove duplicates as groups with a certain percentage of duplication.

Articles published in health sciences typically present patient information clearly, particularly in the Methods section. However, this level of detail was often lacking in technology-focused or prototype-based studies, even when participants were involved. When further clarification was required, articles were annotated using the labeling feature of Rayyan. Such articles with partial or ambiguous information were retained and moved to full-text screening. Through digital meetings, the 2 independent researchers (AM and PG) resolved ambiguity according to the predefined inclusion and exclusion criteria. Most disagreements were resolved through discussions, and when necessary, a third researcher (MP) provided input. For example, disagreements regarding age limits in the eligibility criteria were resolved using the International Scientific Society on Scoliosis Orthopaedic and Rehabilitation Treatment (SOSORT) 2012 guidelines, which specify that adolescent idiopathic scoliosis is for ages 10 to 17 years (specifically 17 y and 11 mo), ages 3 to 9 years as juveniles, and ages 18 years and older as adults [3]. Furthermore, in cases where participant demographics varied from article to article, independent reviewers resolved them by verifying the full text during online meetings. Full texts were retrieved through university affiliations, specifically OsloMet and Aalborg University, and 22 articles were acquired with support from OsloMet University for full-text screening.

Language was considered as a criterion; articles that had English abstracts but were written in foreign languages fell outside the scope of this review. All articles excluded during the abstract and title screening phase used predefined exclusion labels in the Rayyan software. For example, the label "foreign language"

XSL•FO
RenderX

was used to exclude articles. If the title appeared in square brackets (eg, [German] in the Rayyan software tool) or if the journal title was in a non-English language, they were excluded at title and abstract screening. The user-defined label in the Rayyan software helped trace the stage.

Participant demographics were another eligibility criterion. Articles that failed to meet the inclusion criteria, specifically age or disease diagnosis, were the most common and challenging eligibility criteria. If the article included at least 1 participant younger than 10 years or older than 17.11 years, it was excluded despite valuable insights. Articles with unclear age ranges but reporting mean and SD, or referencing Risser stages, were considered on a case-by-case basis. Studies that included both juvenile and adolescent participants were excluded as results cannot be separated (eg, study by Lou et al [44]).

Data Charting

During the charting process, independent reviewers encountered challenges organizing multidisciplinary articles, which were resolved by iteratively refining a table structure based on charted data samples. The final table was refined through multiple meetings. The extracted data items were organized as columns.

Data Items

During data extraction, included studies were categorized according to the primary monitoring approach used: (1) subjective monitoring, focusing on patient-reported outcomes and user experience; (2) objective monitoring, using technology-assisted or sensor-based tools to quantify orthosis use or treatment parameters; or (3) integrated monitoring, combining both subjective and objective measures. This categorization was applied consistently across study characteristics and informed the narrative synthesis.

The data extraction table included columns for study characteristics, including participant demographics related to scoliosis and age, followed by columns for clinical and technological RQs. Due to variability in how age was reported across studies, this information was standardized as “mean age (SD)” supplemented with reported age ranges (lower-upper limits) in Multimedia Appendix 2. These age data are finalized for each selected article by verifying inclusion criteria, demographic tables, or results sections, and are presented as age range (minimum year-maximum year). For example, when the Risser stage is represented as the upper limit, it is presented as range (minimum year-maximum Risser 2/3). Risser stages 2 to 4 correspond to mean ages ranging from 13.1 (SD 1.1) to 14.8 (SD 1.0) years in adolescent patients with idiopathic scoliosis, which is less than 18 years [45]. Other study data extracted as part of this review included publication year, country data, author information, journal data, participant data, including the male-to-female ratio, and study methodology [39]. In alignment with the RQs, additional data were extracted on orthosis types, clinical monitoring instruments (eg, questionnaires), technology-based sensor monitoring parameters, data analysis methods, participant feedback and their perspectives, study strengths, results, and proposed future directions. The result of this phase is a detailed data extraction table, which is provided in Multimedia Appendix 2.

Data Synthesis Approach

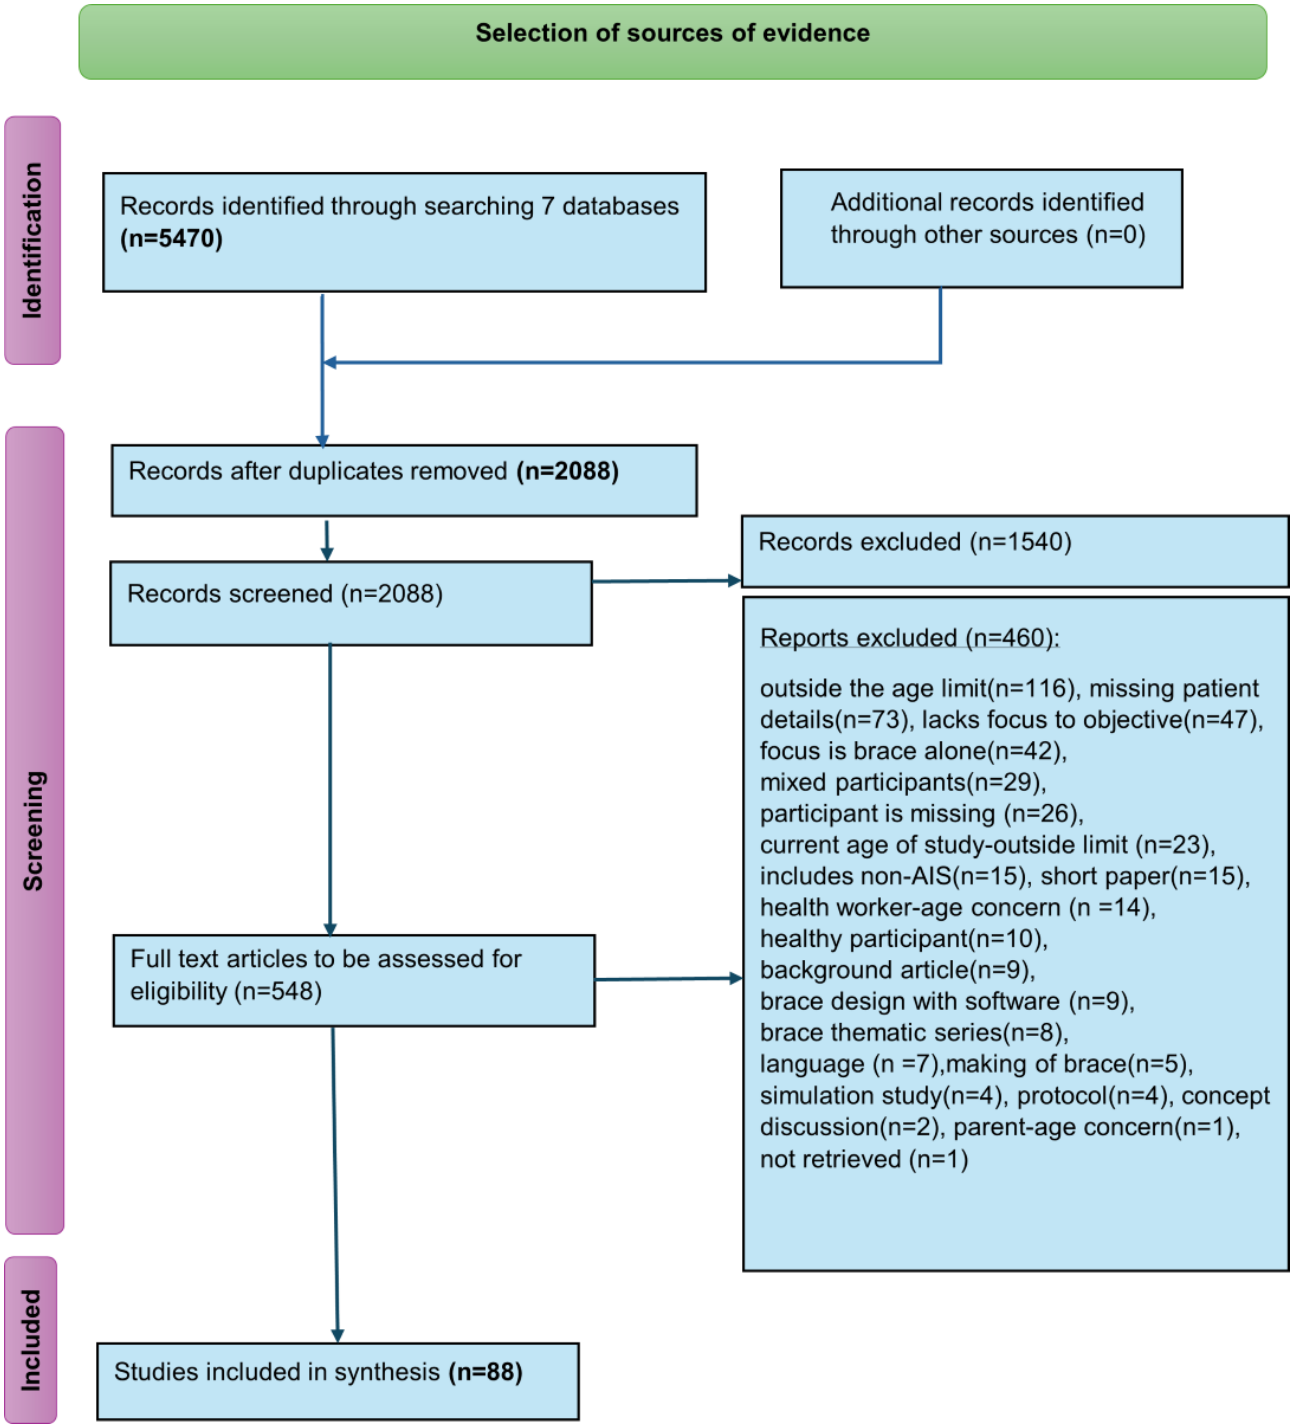
The refined table aligns with the 3 RQs, helping condense the 2 main themes that emerged from data synthesis. AI was not used in data synthesis. The detailed data extraction table records key findings from each article. The time-based evolution of selected data items based on the 3 RQs is presented as illustrative figures that are created using these data in Microsoft Excel using Insert Tab/PivotChart and PivotTable features.

Ethical Considerations

The research was conducted independently. The funder (University) played no role in the formulation of the study design, data analysis and interpretation, or writing of this paper.

Results

Overview



A total of 5470 records were identified from 7 databases: MEDLINE (n=1016), Embase (n=1472), PsycINFO (n=30), Cochrane Library (n=178), CINAHL (n=518), Web of Science (n=798), and Scopus (n=1458). Due to overlap between the 2 search strategies, approximately 61.8% (3382/5470) of the duplicate articles were removed. A total of 2088 articles were identified for further screening based on their titles and abstracts, followed by full-text screening. Exclusion of articles was applied based on the predefined eligibility criteria in Textbox 2, specifically targeting participants diagnosed with idiopathic scoliosis and aged 10-17.11 years.

During full-text screening, articles (n=460) were excluded using user-defined exclusion criteria (as illustrated in Figure 1), which helped identify the stage at which each article was removed in the Rayyan software. For example, 7 articles were excluded at the full-text stage that were not captured at the first phase and were labeled as “language (n=7)” as in Figure 1. Article exclusions were predominantly based on participant demographics and alignment with the review objectives. Some exclusion categories were conceptually related. To avoid duplicate counting, each article was assigned 1 primary reason that was the most appropriate and explanatory reason. Exclusion reasons include age outside the inclusion criteria (n=116), follow-up study design with older participants (n=23), missing patient or participant information (n=73 and n=26), protocol-only publications without participants (n=4), and short papers with missing data (n=15). Studies with ineligible participants were excluded, for instance, studies involving surgical interventions (considered mixed participants; n=29), nonidiopathic scoliosis diagnoses (n=15), healthy participants (n=10), and parents (n=1). Delphi studies involving clinicians only were also excluded (n=14). The remaining exclusions were due to a lack of alignment with the scoping review objectives, including orthosis-focused, design-, simulation-, manufacturing-, thematic-, background-, or concept-based studies. Moreover, 1 article was excluded because it was not available in a readable format. A total of 88 studies (Table 1) were included for data extraction using Microsoft Excel. Each row in the data extraction table corresponds to an article, thereby yielding 88 rows. Table 1 summarizes the study characteristics of each included article based on the research objectives. This process is presented in

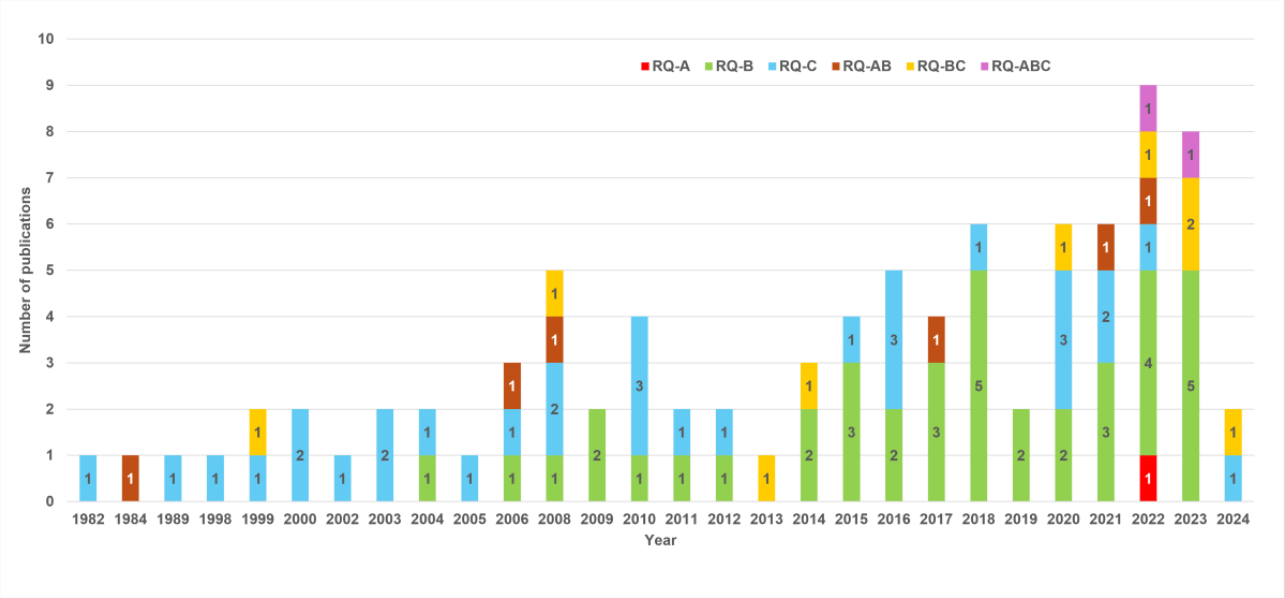
Study Characteristics

Mapping to RQs

All 88 studies for data extraction were classified into 3 predefined RQs (RQs-A, B, or C; A presenting user experience and perception, B presenting monitoring tools, and C presenting technology-assisted approaches. Articles were labeled by relevancy (A, B, C, AB, BC, AC, and ABC) in the extraction table. The Venn diagram (Figure 2) illustrates the thematic overlap among the included studies. The largest group of studies (n=39, B1-B39 as listed in Column 2 of Table 1) addressed only B, focusing primarily on subjective monitoring methods such as questionnaires and self-reports, and the next largest group of 31 studies (C1-C31 as listed in Column 2 of Table 1) addressed C alone, most of which involved small-scale or pilot implementations of technologies, such as sensors and smart orthosis. Only 2 articles [126,127] addressed all 3 RQs, 6 addressed RQs A and B [113-118], and 9 addressed RQs B and C [5,19,119-122,124,125]. These distributions indicate a persistent integration gap between clinical (subjective) and technology-based (objective) monitoring in adolescent idiopathic scoliosis care. Furthermore, the results highlight that no published study meets the eligibility criteria of adolescents diagnosed with idiopathic scoliosis and aged 10-17.11 years, which integrates user experience and perception with technology-assisted approaches (RQs A and C, n=0).

Two main themes that evolved from the findings are (1) subjective (patient-reported or user experience) monitoring using questionnaires with patient-reported outcomes, interviews, and logbooks capturing the patient experience; and (2) objective (technology-assisted or sensor-based) monitoring using sensor-based systems measuring parameters such as temperature, pressure, force, and motion, and a real-time, clinically integrated support system. Integrated approaches combine both. Each included study is coded into these categories S, O, or I, as illustrated in Table 1.

Figure 2. Visual illustration of study characteristics based on 3 RQs. A: User experience and perception (RQ-A), B: Monitoring Tools (RQ-B), and C: Technology-Assisted Approaches (RQ-C).



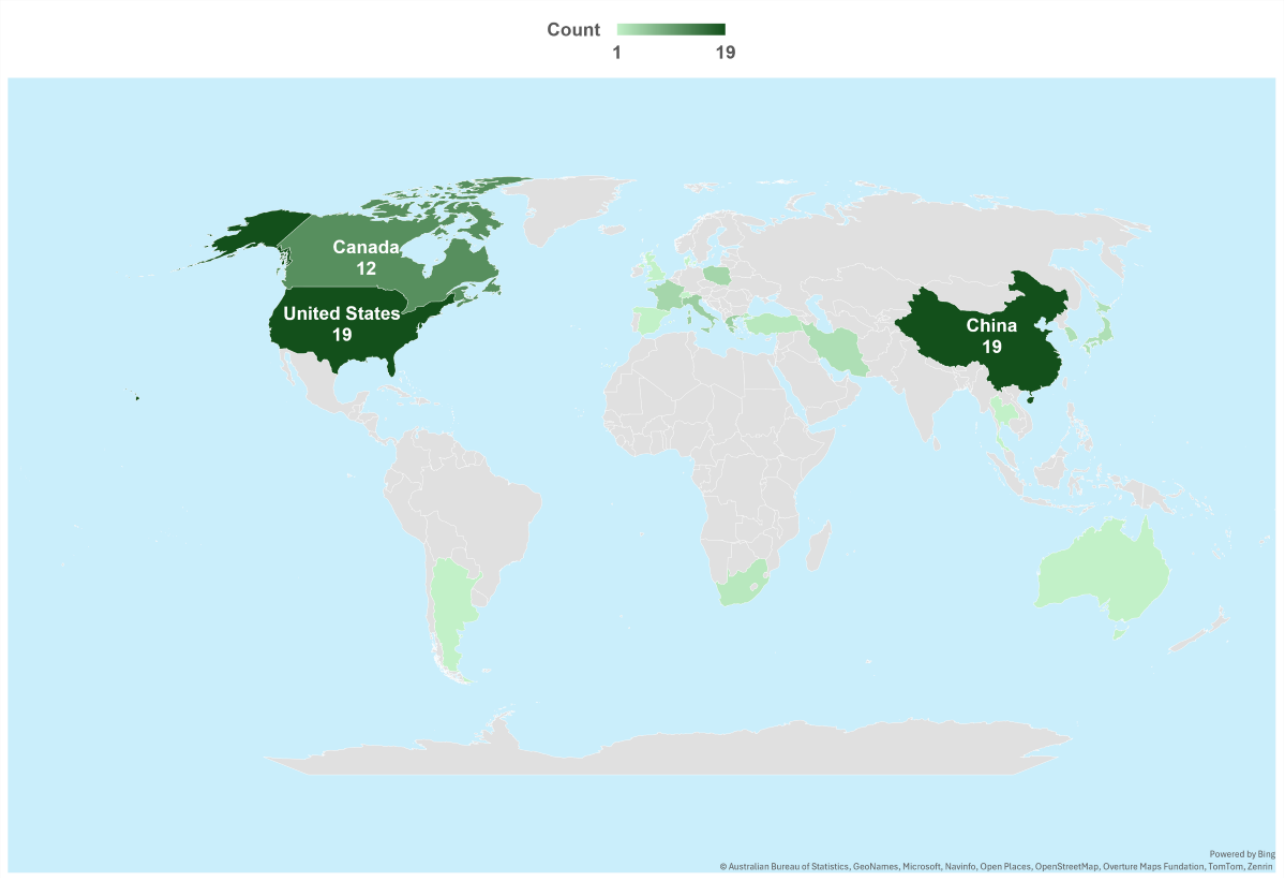
Publication Trends

The number of publications in the focus area has increased over time, as illustrated in Figure 3. Technology-based monitoring has been in use for over 4 decades and accounts for 47.73% (42/88), where 42 studies are categorized into 3 subgroups (C1-C31, BC1-BC9, and ABC1-ABC2), as listed in Column 2 of Table 1. The evolution of articles over time indicates that research on technology-based monitoring has a long history, underscoring the need for updates as technology continues to advance.

Research incorporating patient-reported outcomes emerged approximately a decade later. Once these tools were adopted, an increasing number of studies began to focus on capturing previously unheard patient needs as part of the treatment burden. Articles that combined subjective monitoring tools with sensor-based approaches demonstrate a trend since 1999 toward integrating subjective (RQ A or B) and objective (RQ C) measures. Since 2022, research on user-centered integrated monitoring has gained momentum. These trends are illustrated as publications over time, with research areas and their combinations (Figure 3).

XSL•FO
RenderX

Figure 3. Number of publications over time based on the three research questions A, B, and C.



Global Contributors

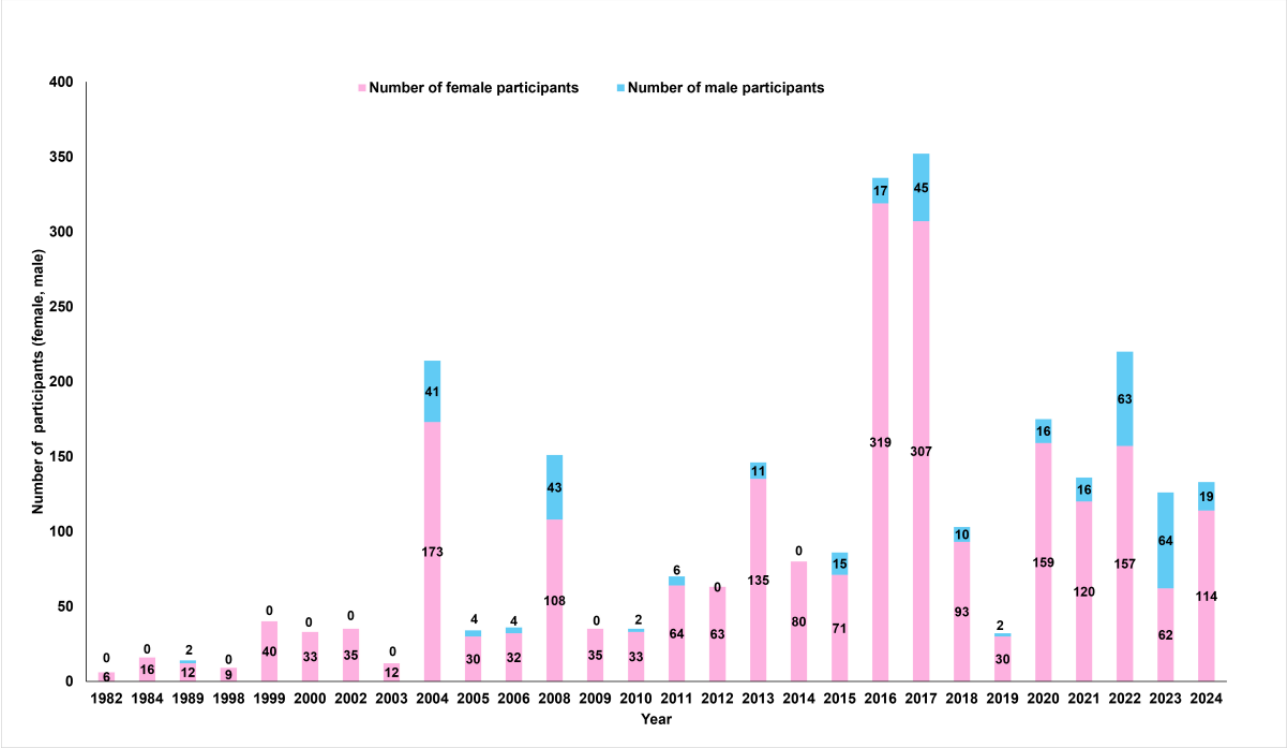
Research output was concentrated in a few countries: the United States [5,19,23,29,68,70,78,82,89,94,96,102,105,108,109,111,116,117,127] and China [30,46,47,58,62,75,76,77,84,88,92,93,100,115,120-124,125,126] (n=19 each) contributed the most, followed by Canada [57,63,86,87,91,95,98,99,103,107,110,119] (n=12); other contributors included Italy [61,71,72,81,97] and Greece [49,60,67,85,114] (n=5 each), France [90,104,112,118] and Poland [51,69,74,79] (n=4 each), Iran [48,50,65], Japan [113,122,123], and South Korea [54,55,56] (n=3 each), South Africa [59,64], and Turkey [53,80] (n=2 each), and Argentina [66], Australia [83], Denmark [73], Spain [52], Switzerland [101], Thailand [22], and the United Kingdom [106] (n=1 each; Figure 4 and Table 1).

The observed trends indicate that research in multidisciplinary health and technology domains with a user-centered focus is concentrated in a few leading countries, such as China, the United States, and Canada, with small contributions from other regions. Subjective and objective monitoring with the patient as a participant requires approval in accordance with the relevant country's ethical guidelines. Geographic distribution shows the ethical constraints and regulatory challenges in conducting studies that integrate health and technology among participants diagnosed with diseases, such as idiopathic scoliosis.

XSL•FO
RenderX

Figure 4. Visual representation of global contributors among the 88 included publications.

Orthosis Types



Across the 88 studies, a range of rigid and soft orthoses was reported, including Boston [60,89,103,107,116,119], Milwaukee [65,88], Chêneau [30,71,74,104], and Rigo System Chêneau [59,64], along with various Thoracolumbosacral orthoses, such as rigid [70,72], underarm [120], and other types include the Sforzesco brace [71], Providence [73,102], Charleston, Wilmington [23,96], SpineCor [115], dynamic derotation brace [85], CAEN brace [90] and asymmetric Scoliosis Brace by SLC clinic [49] as well as fiberglass [97], custom-fabricated [76], 3D-printed [125], garment [100], and semirigid [119]. Unfortunately, some articles [114,118] report on the use of braces or orthosis without specifying the type. Some articles report the use of orthosis without reporting the exact type or other specifications (eg, studies by Lin et al [121,125]), while some full-text reports the patient's use of orthosis. For example, the study by Sapountzi-Krepia et al [114] mentions that the orthosis was worn for more than 12 hours, while Bertuccelli et al [81] report on orthotic treatment. Details from all included articles are reported in Table 1. The orthosis used in that study will influence participants' perspectives and patient-reported outcomes. Given the broad scoping focus on analyzing generic challenges in scoliosis orthotic management, we consolidated the observations based on the evolved themes.

Sex

Sex distributions broadly reflect the higher female prevalence [1,2], with negligible male representation until 2004 and increases thereafter (Figure 5). Although male individuals remain underrepresented overall, their contribution to research has improved since 2004. Studies that explore sex-specific needs and perspectives have yet to be reported in detail. The use of patient-reported tools in research has stimulated researchers since 2004 to capture the distinctive needs of male individuals, which differ from those of female individuals, especially during adolescence. In 1 study that used a comparison of bracing versus observation reported no significant overall health-related quality of life (HRQoL) reduction with bracing; however, they reported about family-activity difference favoring male individuals [78]. More focus is needed to know sex-based monitoring preferences in the future, especially for adolescents treated with orthoses.

XSL•FO
RenderX

Figure 5. Sex distribution trend of all included articles.

Subjective Monitoring (RQ A and RQ B)

Subjective monitoring in the management of adolescent patients with idiopathic scoliosis primarily evolved from research on patients' lived experience and perceptions, as reflected in RQ A and traditional clinical monitoring approaches relevant to RQ B. These strategies use different tools to capture patients' needs. For example, clinicians rely on self-reports, relevant questionnaires to address needs (eg, stress or quality of life), and interviews to capture user perceptions. Over time, they have become central to understanding psychosocial and cultural factors influencing orthosis compliance.

Questionnaires as a Subjective Monitoring Tool

Questionnaires and patient logbooks capture user compliance and user-reported data that support subjective scoliosis management for adolescent patients with idiopathic scoliosis [76]. Studies verify that exercise with bracing is associated with improvements in quality of life and functional outcomes, using PROMs or logbooks [58,62,63]. Comparative studies recorded efficacy differences between rigid versus flexible orthoses and captured discomfort and acceptance via a visual analog scale questionnaire, along with open-ended items [128]. The use of "open-ended" items in questionnaires, along with other sensor monitoring in a mixed design, was found beneficial for evaluating patient needs [124]. A combination of subjective data from interviews with sensor-based objective data reports about mal-appearance, inconvenience, and psychological distress [126]. Future studies should integrate PROMs with objective sensor-derived data to provide a more comprehensive understanding of user experiences and treatment adherence.

Among the included studies, subjective monitoring reports the use of Scoliosis Research Society-22 Patient Questionnaire, Brace Questionnaire, Bad Sobernheim Stress Questionnaire (Brace/Deformity), Italian Spine Youth Quality of Life, EQ-5D-5L, and 36-Item Short-Form Health Survey [51,52,55,67,71,75,76,124]. A multicenter study found that adolescents with more severe scoliosis underestimated their deformity and body image. Perception tools Walter Reed Visual Assessment Scale, Spinal Appearance Questionnaire, and Trunk Appearance Perception Scale were also used as a clinical tool to capture user perception [118]. The medium of communication to express influences subjective monitoring. The language of the questionnaire tool, including verbal and pictorial illustrations, is used to capture the user's perspective on the disease condition, and cultural adaptation of questionnaires based on the research focus can influence the expression of that perspective. Other main instruments included Pediatric Quality of Life Inventory [82], Posterior Trunk Symmetry Index [80], Brief Pain Inventory [83], and psychological scales (State-Trait Anxiety Inventory, Beck Depression Inventory-II) [84] to capture often unexpressed psychological aspects of adolescent patients with idiopathic scoliosis burden.

Cross-Cultural Adaptations of Monitoring Tool

Cross-cultural adaptation of the standardized questionnaires is the strategy used to improve user acceptability and relevance among culturally diverse populations. Among the articles included in the review, 6 studies adapted the Bad Sobernheim Stress Questionnaire from the base language to another target language (Japanese, Spanish, Persian, Greek, Polish, and Chinese) [47-49,51,52,113], 2 adapted the Brace Questionnaire (Turkish and Korean) [53,56], and 1 each adapted to Korean Quality of Life Profile for Spine Deformities [54], Korean Italian Spine Youth Quality of Life [55]. Across these studies, the Scoliosis Research Society Patient Questionnaire-22 (and its revised version) was commonly used as a reference instrument for comparative analysis. The adaptation processes follow an

XSL•FO
RenderX

established methodological process, incorporating forward-backward translation, expert review, pilot testing, and evaluation that includes test-retest reliability, internal consistency, and validity with reference tailored to the study objectives (eg, study by Jafarian et al [48]). Collectively, these articles address RQ B by demonstrating the utility of culturally adapted questionnaires for monitoring, and RQ A by capturing patient perceptions within routine care.

User Perceptions

Given the scoping focus on analyzing long-term challenges in scoliosis orthotic management, we consolidate generic user experience and perceptions. In a qualitative study, patient interviews revealed that they were afraid of what the doctors might say during the next feedback session [114]. Orthosis compliance and outcomes vary based on the orthosis used by the participant. For instance, the Milwaukee brace, a type of orthosis, was reported to cause emotional strain and barriers, including issues with clothing fit, restricted movement, and social limitations [117]. Across the included studies, physical and emotional challenges related to orthosis wear were consistently noted: discomfort, restricted movement, heat or climate-related issues, clothing difficulties, and social limitations. The only article from RQ A that used patient-reported data from in-depth semistructured interviews with Chinese adolescents who described activity- and heat-related discomfort and a desire for more personalized, co-designed orthoses. Active patient participation in the intervention is a recommendation [46]. Chinese randomized trial reports the use of a specially designed thin undergarment that improved comfort and compliance [76]. Although the study was conducted in China, similar climatic and seasonal conditions may also influence orthosis use in patients from other geographical regions. Family dynamics (eg, parental reminders) also influenced adherence and contributed positively to scoliosis management among adolescents. These patterns address RQ A user experience and perceived barriers or facilitators, and RQ B, especially the use of clinical tools such as logbooks to monitor adherence.

Psychological or Emotional Well-Being

Bracing in adolescent patients with idiopathic scoliosis has a significant impact on HRQoL, reporting psychological, motor, social, and school-related challenges [66]. Studies use tools, for example, Body Appreciation Scale (BAS) and trunk appearance perception scale to examine body aesthetics and user perception that considers self-image, trunk perception, and psychological outcomes [68,118]. Reduced body-related attentional biases are reported with the use of psychotherapy [81]. Long-term orthotic treatment is demanding. Still, progress in trunk correction and self-visualization offers a sense of positivity. Studies have demonstrated an optimistic view of bracing when studied using the trunk appearance perception scale as orthoses can influence trunk correction, leading to greater satisfaction with orthotic treatment [61]. Likewise, using another visualization score, the BAS gave a similar perspective from the orthosis-treated and control group [68]. This underscores the need for interdisciplinary psychological and social support for adolescent patients with idiopathic scoliosis.

Family Context

The patient's family also played a significant role in handling challenges and managing scoliosis, as reported in the articles included. In Argentina, a study using a brace questionnaire recommended separate patient and parent surveys to reduce response bias [66]. Polish studies using Bad Sobernheim Stress Questionnaire-brace or deformity found comparable stress in adolescents and parents, with parents overestimating deformity-related stress; spinal appearance questionnaire comparisons emphasized the roles of both mothers and fathers [69,74]. Accepting cultural diversity, the roles of both parents, mother and father, and family bonding are recognized as influential parameters for adolescents' emotional coping.

Societal or Socioeconomic Context

Subjective tools identified peer perceptions at school as sources of stress or anxiety [113]. In a Spanish cohort using Bad Sobernheim Stress Questionnaire-brace, no embarrassment was reported among adolescents wearing Rigo System Chêneau orthosis with close family and friends at school [52]. Financial burdens were noted (orthosis and consultation costs) [51]. Rural versus urban comparisons showed similar moderate orthosis-related stress and low deformity stress, with greater appearance concern among rural participants with larger lateral shift [79].

To sum up the findings, addressing RQs A and B by mapping psychosocial parameters relevant to subjective monitoring (eg, sex, well-being, family, and school or society) influences patient perspectives on stress, body image, and daily life.

Objective Monitoring (RQ-C)

Sensor Types and Parameters

Early systems (1980s) were developed in controlled settings with static assessments. Over time, objective monitoring expanded to include electromyography (EMG), pressure or force, temperature, and motion sensors that captured orthosis use, activity, and physiological responses.

EMG

EMG is used to evaluate neuromuscular responses to bracing. There are limited (n=3) studies using EMG. The oldest included study, from 1982 in Canada, reported that it was unable to detect any observable trend among the 6 female individuals [110]. Even though the results were not promising, objective monitoring to understand the effect of orthosis began to evolve. Moreover, 2 other studies that used EMG demonstrated how orthosis improved spinal stability by stimulating muscle engagement [95] and the feasibility of wearable EMG sensor-based posture tracking for daily activities [111].

Motion

Movement tracking represents activity in daily life; 1 study reported no significant difference in walking activity between adolescent patients with idiopathic scoliosis and controls using a smartphone-based approach [112]. Multimodal systems combining accelerometers, gyroscopes, and force are gaining research interest recently [29].

XSL•FO
RenderX

Pressure or Force

Studies monitored strap or pad forces and interface pressures to support fit, personalization, and compliance, ranging from calibrated measurements to embedded or load-monitoring systems and mapping approaches linking tension, pressure, and correction [103,106,107,129]. One system reported a decline in tightness without monitoring and improved compliance with monitoring or refitting [29]. Works characterized different research interests that include corrective force patterns [87,89], explored respiratory mechanics under bracing [93], examined posture-specific force changes [85], and used exercise-related pressure patterns to inform personalized exercise selection [97]. Adjustable orthoses logged pressure and temperature over extended periods [121].

Temperature

Temperature sensors quantified wear time with high accuracy and were used to explore adherence patterns. Prospective cohorts recorded orthosis wear at set intervals over months and reported associations between higher compliance and improved outcomes, with features for time-based feedback, as reported in [23,96,105]. Other studies that use temperature-based reporting monitoring report high accuracy in estimating daily wear, increased daily wear with compliance counseling, and associations between reduced adherence and curve progression in night-time bracing [102,108,109]. Studies compared orthosis types, estimated compliance in dynamic systems, and examined temporal patterns (for eg, higher weekday or night-time wear; relationships with stress and satisfaction) [5,19,101,122,123,125]. Together, these sensor families demonstrate the feasibility of objective monitoring of muscle activity, strap or pad forces and interface pressure, wear time, and movement or activity during orthotic treatment.

Wear Time and Adherence

In temperature-based studies, wear time was derived from periodic logging and compared with diaries and/or clinical outcomes; high accuracy versus diaries was reported, and adherence counseling and visit-time feedback were associated with increased wear [23,96,108,109]. Findings describe differences by time period (eg, weekday or night-time patterns), declines in orthosis tightness over time without monitoring, and improved adherence with feedback-enabled systems [29,122]. In night-time bracing, lower adherence was associated with curve progression [102]. Large cohort data supported a dose-response relationship between longer wear and reduced progression to surgical thresholds [5]. These studies address RQ C by quantifying orthosis wear time and adherence patterns, and by relating adherence to treatment outcomes.

Integration of Subjective and Objective Monitoring

Integrated clinical monitoring, along with relevant data visualization, is gaining importance due to its design strength. Integrated monitoring of adolescents with idiopathic scoliosis orthotic treatment combines subjective patient-reported outcomes with objective sensors to track both perceived burden and real-time adherence. Integrated monitoring combines 9 articles with RQs B and C, which include compliance monitoring and interviews, as well as a randomized controlled trial using automated pressure-adjustable orthoses and variant temperature or heat sensors, linking wear quality with HRQoL outcomes [5,19,119-125]. Moreover, 2 studies that demonstrate the integration of 3 RQs with an all-around monitoring approach that merges user perspectives with clinical and technological approaches, namely qualitative interviews and psychosocial questionnaires, to capture lived experience [126,127]. Integration of subjective and objective monitoring is progressing.

Real-Time Monitoring

This scoping review tries to collect evidence from all selected databases up to the search date, which allowed the inclusion of engineering articles from the 1980s and 1990s. These early studies reflect efforts to measure orthosis adherence objectively; however, they relied on nonportable devices, limiting monitoring to controlled laboratory environments. Research growth is an indicator of how technology and health research are advancing over time, with a growing focus on user-focused solutions that include portable and compact solutions. At the same time, objective sensors and adherence logs provide real-time data. Integration of patient needs, cultural context, and comfort, along with biomechanical and compliance metrics, can provide assurance in scoliosis management and serve as a convergence that enables accurate adherence measurement, personalized feedback, and improved clinical decision-making for patient-centered care.

One configuration involved force sensors with a mobile mini-program for daily uploads, enabling remote clinician monitoring and scheduled follow-ups, and was evaluated in 28 adolescents, with satisfaction assessed at 6 months [30]. The design load-monitoring system for objective monitoring developed by Lou et al [98] tracks both the quantity and quality of orthosis wear. The combination of objective data supported with PROMs both supports adherence and patient-reported experience [124]. These findings demonstrate the feasibility of real-time or connected monitoring with clinic-linked follow-up, complementing subjective tools to provide a more complete view of orthosis use.

These innovations target continuous data collection and personalized solutions that help health personnel and empower adolescent users to play an active role in their treatment, reducing the effort required of health personnel [26,30,31]. Advancements could lead to patient-friendly, effective scoliosis management and improve long-term outcomes with more focus on distinct aspects of monitoring adolescent patients with idiopathic scoliosis.

Discussion

Summary of Key Findings by RQs and Themes

The review identified 2 central themes, namely subjective monitoring and objective monitoring, with limited integration. RQs A and B capture subjective monitoring that relies on patient-reported outcomes and qualitative user-experience data, consistently documenting discomfort, restricted movement, heat or climate concerns, clothing challenges, peer-related anxiety, and the influence of family dynamics. Cross-cultural adaptations were common and used standard translation procedures. The

XSL•FO
RenderX

exercise program in combination with orthotic treatment improves quality of life as well as body function. The RQ C, objective monitoring demonstrated feasibility using temperature (wear-time quantification), pressure or force (fit, personalization, and corrective load), EMG-based neuromuscular response, and motion (activity or posture). Temperature-based monitoring showed high accuracy for wear-time estimation and was associated with increased adherence when coupled with counseling or feedback; dose-response patterns linked greater wear with reduced progression. The strict age restrictions, along with the exclusion of studies involving mixed-age idiopathic scoliosis cohorts, probably narrowed the evidence base and reduced the inclusion of potentially relevant sensor-based research. Connected systems enabling remote follow-up were feasible in small samples.

Clearly distinguishing between subjective and objective monitoring approaches is clinically meaningful. While objective tools offer precise and continuous measurements of orthosis wear and biomechanical parameters, they do not capture how adolescents experience orthotic treatment in daily life. Conversely, patient-reported measures provide critical insight into comfort, usability, and psychosocial impact but may be influenced by recall bias or social desirability. Integrated approaches that combine both perspectives appear particularly promising, as they acknowledge that treatment adherence and effectiveness are shaped by both measurable behaviors and lived experience. This framework helps contextualize current evidence and highlights directions for future digital health development in scoliosis care.

Interpretation and Clinical Implications

Different PROMs and qualitative tools capture adherence to comfort, climate, clothing, and psychosocial context, which are not accessible from imaging alone, while sensor-based systems provide objective quantitative data on wear time and the quality of orthosis wear. A combination of diverse modalities supports individualized adjustments (eg, orthosis fit or tightness and targeted exercises) by providing tailored psychosocial support. Family involvement and feedback mechanisms were associated with better adherence.

Mixed methods designs that link temperature-based adherence with HRQoL instruments illustrate how clinicians can monitor both use and impact to guide timely interventions. Although Thermobrace was excluded (due to participants with a diagnosis of hyperkyphosis along with remaining idiopathic scoliosis), temperature-based approaches, in general, were used and reported accurate wear-time estimation [27]. A recent Chinese pilot study reports the use of an integrated sensor, namely force and temperature, that provides a comprehensive understanding of the compliance by demonstrating data from 12 patients by comparing subjective and objective monitoring for 1 month and found that patients' self-reported data exceeded the sensor's actual average wear time [24]. User acceptance of objective monitoring provides reassurance and perceived helpfulness as a long-term supportive tool [17]. A recent study reports that subjective patient-reported data, along with automated alerts to clinicians at predefined thresholds, can increase usability and engagement, supporting users in meeting prescribed orthosis-wear recommendations during the study period [130].

Implications for Research and Future Directions

Evidence collected over time across multidisciplinary technological and clinical research suggests a gap for integrated user-centered approaches. Studies need to include standardized monitoring protocols, detailed reporting of clinically relevant participant demographics, and harmonized outcomes, which would improve comparability and inclusiveness of research across disciplines. In the future, subjective monitoring questionnaires are to be culturally adapted and validated, especially focusing on orthotic treatment (eg, study by Caronni et al [131]). Research could also expand sex-specific analyses, evaluate acceptability across cultures, and test multimodal systems (eg, temperature, pressure, or motion) in larger, longitudinal cohorts that support patient rehabilitation.

An integrated workflow can combine subjective PROMs with objective technology-based monitoring, supported by structured clinical interventions and timely feedback, to enhance adherence throughout treatment and patient rehabilitation [130]. For example, real-time review could empower adolescent users and their families by enabling earlier identification of nonadherence and supporting personalized treatment adjustments. The system needs to ensure user and patient security and trustworthiness, and provide patient-specific guidance [132], in line with the nation's protocols.

The continued gap in integrating subjective patient experiences with technology-assisted monitoring might be due to structural barriers, such as the stages of technology readiness of emerging innovations for integration into clinical workflows, existing ethical complexities in clinical trial approval processes, and user acceptance and trust in new technologies. The integration of subjective and objective monitoring advances slowly. Technological evidence must be rigorously validated before it can be used in a clinical trial. Thus, innovative technologies are typically evaluated through phased testing to improve technology readiness. Objective sensor data (eg, body-pressure distribution on a scoliosis orthosis) are tested on a mannequin or a laboratory-based test environment with clinically relevant pressure patterns, serving as the preparatory analysis for the future clinical trial [133]. These stages of testing and preparation ensure feasibility, safety, and effectiveness.

Standardized protocols should be established for data handling and clinically aligned technology-based monitoring to support personalized, data-driven care for adolescents with idiopathic scoliosis. Detailed testing has been conducted and reported to prepare for future clinical testing of a real-time contact pressure monitoring solution and highlights that future monitoring solutions for adolescent idiopathic scoliosis during bracing need to consider patient comfort [134].

Future research directions across the 3 RQs highlight critical gaps and opportunities. For RQ A, there is a need to strengthen the focus on lived experiences and user perceptions, which remain the least represented in the current literature. Currently, no existing review integrates (RQ A) user perspectives, wishes, and needs with technology-based monitoring (RQ C) in the

XSL•FO
RenderX

context of adolescent idiopathic scoliosis. For RQ B, monitoring tools should evolve to include questionnaires that address technological perspectives, usability challenges in daily life, concerns related to personal and health data security, and new needs. For RQ C, technology updates should be integrated into the health care system that uses real-time monitoring and time-bound clinically significant feedback. In the future, co-design of systems with stakeholders can help to develop a user-friendly solution that can be widely accepted and suitable for rigorous use.

Challenges

Methodological diversity among the included articles complicated appraisal using established tools Critical Appraisal Skills Program, Joanna Briggs Institute, and Mixed Methods Appraisal Tool, which were not compatible with engineering-focused studies that often lack a clinical structure, underscoring the need for frameworks that bridge engineering and clinical research. Variability was observed in the reporting of CHERRIES (Checklist for Reporting Results of Internet E-Surveys) checklist items related to methodological details across included studies, with more comprehensive reporting in health science–focused research (eg, cultural adaptation of questionnaires) and comparatively limited descriptions in technology-focused studies, where standardized questionnaires were often used as data collection tools secondary to technological evaluation [135]. Informal appraisal without formal methodological appraisal proceeded alongside iterative data coding, which is acceptable in scoping reviews.

Inconsistent reporting of participant details (age, diagnosis, and orthosis type) was more common in engineering papers; lack of focus on RQs and emphasis on technology alone led to exclusions. Along with orthosis monitoring, soft orthosis, including garment orthosis and vests, were included in the scope. However, due to the strict requirements for patient-based studies, many studies were excluded because they often lacked patient participation criteria. Only patient-tested solutions were retained, which led to the exclusion of several early-stage prototypes under RQ C.

Strengths

Having a specific and focused target group, adolescents diagnosed with idiopathic scoliosis, led to the exclusion of technologically noteworthy studies. On the other hand, this focus strengthened the scoping review's ability to identify gaps and highlight future needs toward interdisciplinary research. The inclusion of diverse article types spanning medical and engineering fields enriched the analysis. The 2 independent reviewers, one with a medical background and the other with a technological background, helped with this process. Screening benefited from Rayyan-supported comparisons; however, final inclusion and exclusion decisions were made manually, using human-judgment-guided selection.

Limitations

This review is limited by sample size constraints, lack of longitudinal data, poor reporting in engineering studies, and insufficient risk of bias evaluation, which may affect the robustness of the evidence base. The review included articles from the listed databases that are digitally available and English-language publications, leading to the exclusion of relevant studies that were published in other language publications, nondigital form, or sourced from unindexed repositories.

Our strict age inclusion criteria (10 - 17.11 y) excluded multiple technology-focused papers with mixed-age samples, likely reducing the number of eligible sensor-based studies. Clinically significant parameter Cobb angle was considered during protocol development. However, a broader approach was adopted to accommodate variability in reporting, especially in nonhealth publications.

Conclusions

This scoping review of 88 included studies reveals the clear growth in adolescent patients with idiopathic scoliosis conservative monitoring from separate subjective and objective approaches toward integrated, patient-centered models. Questionnaire-based tools remain essential for capturing psychosocial burden, body image, and cultural context, but they cannot measure real-time adherence or biomechanical quality. Technological solutions that use sensors provide objective information, progressing from static laboratory setups to portable, connected systems that enable remote oversight and timely feedback. Subjective tools and objective sensors provide complementary views of adolescent orthosis wear. Combining patient-reported outcomes with sensor data offers the greatest potential, as it provides a multidimensional view of adherence, comfort, and clinical effectiveness. However, reporting inconsistencies and limited scalability persist, especially in technology-focused research. In the future, research should better integrate health and technology disciplines, integrate culturally adapted objective and subjective metrics, and co-design a user-centered solution that motivates adolescents to ensure usability. Moving beyond pilot studies to mixed method clinical trials and real-time platforms will enable personalized care, improve adherence, and optimize outcomes. The convergence of subjective and objective monitoring marks the shift toward holistic management of adolescent patients with idiopathic scoliosis, aligning clinical precision with patient motivation.

Acknowledgments

We are grateful to OsloMet librarians Elisabeth Karlsen and Ingjerd Legreid Ødemark for their assistance in developing, documenting, and implementing the tailored search criteria for this scoping review. We are also grateful for support from Klaus Jøran Tollan and Vegard Syrstad, OsloMet librarians for cleaning and exporting DOI, and for the collection of full texts, respectively. The generative AI -powered tools: Microsoft Copilot was used to condense and restructure text for clarity, and Grammarly was used for language correction.

Abstract

Background: Advances in sensor technologies and increased adoption of wearables and smartphones by individuals have led to an abundance of patient-generated health data (PGHD). This data, when used effectively, could help to further augment the process of shared decision-making (SDM) to enable patient-centered care. However, the possible integration and usage of PGHD introduces complexities and challenges, which warrant considering both health care professional (HCP) and patient perspectives.

Objective: Summarize the relevant works from the past 10 years that reflect the perspectives of both HCPs and patients as key stakeholders on potential barriers and enablers to the integration of PGHD for SDM. We analyzed both perspectives to surface key challenges and opportunities with integrating PGHD throughout patient journeys, as well as clinical workflows.

Methods: Electronic searches were done using 3 databases: PubMed, ACM Digital Library, and IEEE Xplore for papers published between March 2013 and March 2023. Enablers and barriers mentioned by the stakeholders in included papers were extracted and analyzed using thematic analysis. An existing six-stage workflow model for integrating PGHD was used as a reference for deductive coding. Subsequently, considering barriers and enablers faced by both the HCPs and patients uncovered various tensions and alignments of perspectives, which could be addressed in future work and can inform concepts, designs, and development in PGHD for SDM.

Results: A total of 53 publications were included in the scoping review. Six main overarching themes for barriers and enablers were identified: (1) patient-provider relationship, (2) patient characteristics, (3) organizational factors, (4) medical ethics and law, (5) data-driven workflow, and (6) design and technology. The 6-stage workflow was further expanded based on the new findings to include 4 additional stages, which include contextual considerations outside of traditional clinical environments. In addition to partially corroborating previously established barriers in the 6-stage workflow model, several new barriers and enablers were identified throughout all stages. This model helps to further align the needs of HCPs and patients beyond the clinical setting and could benefit system designers who plan to integrate PGHD for SDM.

Conclusions: This scoping review demonstrates that there are several factors to consider for effectively integrating PGHD into health-related SDM. Notably, such factors extend outside the boundaries of traditional clinical settings. Although there is agreement between HCPs and patients on certain factors, there are also tensions to be addressed. Our augmented 10-stage workflow model offers system designers an overview of the challenges and enablers to consider while designing for PGHD integration in clinical workflows and patient journeys to improve SDM.

Introduction

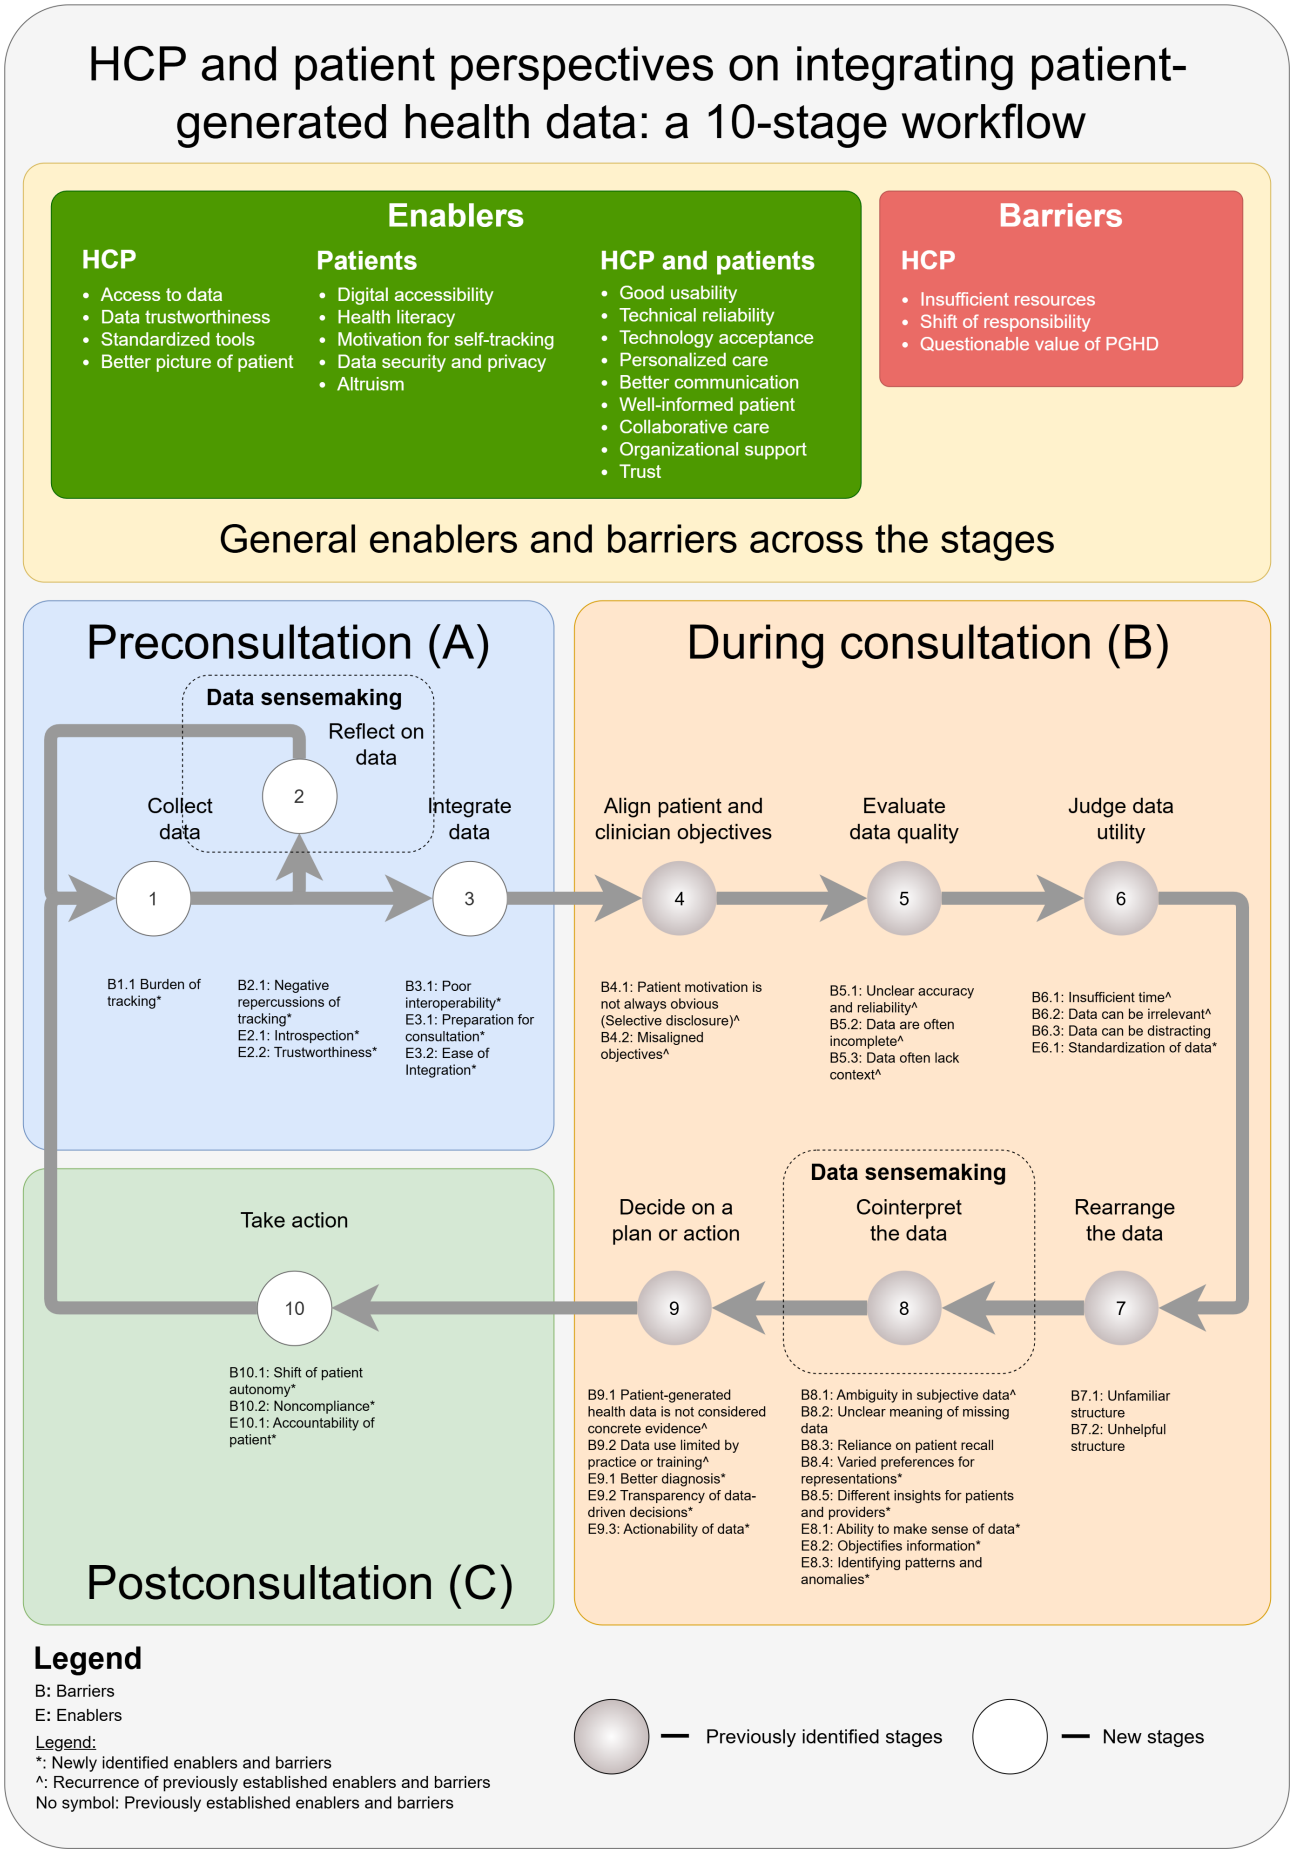
Overview

The challenges of aging populations and noncommunicable diseases across society have led to increased demands and stress on health care systems. Digital health technologies are seen as an enabler to solving such challenges. A review of telemedicine for chronic diseases revealed that wearable devices can help improve the management of chronic conditions by allowing for continuous monitoring of vital signs and reducing patient loads from hospitals [1], thereby improving the delivery of health care services. However, digital health technologies and consumer health care technologies are still facing hurdles in entering the integrated clinical market due to several factors such as infrastructure, technical training, and legal and ethics-related barriers [2]. Digital health technologies pave the path toward more personalized health care, and a key enabler to this end is the use of patient-generated health data (PGHD).

The rise of the Quantified Self movement led by people who track many kinds of data about themselves [3,4], followed by the mass market adoption of self-tracking technologies, coupled with advancements in mobile sensing technologies, has led to an increase in patients bringing their health data to clinical consultations via patient-initiated or clinician-initiated tracking [5,6]. PGHD refers to data created, recorded, or gathered by patients (or by family members or other caregivers) to help address one's health concerns [7]. Notably, PGHD excludes data from electronic health records (EHRs), records entered by health care professionals (HCPs), and patient-reported outcomes. The integration of PGHD has been known to bring about benefits such as (1) *better contextualization of symptoms* [8], (2) *better clinical decision-making* [9], and (3) *personalized and participatory care* [10,11].

Although PGHD has the potential to play a key role in the digitalization of health care, several challenges [12] lie in the path toward the adoption of PGHD as a foundation for enabling novel and additional insights and applications in clinical practice. Unlike traditional clinical data, which is typically produced through the actions of HCPs in tightly controlled clinical conditions, PGHD are usually gathered throughout situated daily living under strongly varying and individual circumstances. This poses challenges for the interpretation and reliability of PGHD with varying quality [13], but also opens opportunities in the form of "objective data windows" into daily living that would otherwise not be available. Akin to medical and health information being available through internet search [14], PGHD integration in patient journeys and clinical workflows is likely to impact medical examination and shared decision-making (SDM)—the collaborative process between an HCP and a patient to make health-related decisions [15,16] serving as a cornerstone of person-centered care.

We posit that the integration of PGHD in the health care context has resulted in a complex sociotechnical system where PGHD could traverse throughout the health data lifecycle [17] and be interacted with by multiple actors—humans and machines—resulting in the emerging field of human-data interaction [18]. Given the vital role PGHD plays in improving SDM [19] and empowering patients in proactively managing their health, it is essential to understand the needs and perspectives of patients and HCPs on how it can be integrated into care pathways.



Over the past years, prior works have investigated PGHD from diverse perspectives—how individuals track data [20], how HCPs (can better) integrate data in clinical workflows [12], and how patients and HCPs collaborate with data [21]. However, there is a gap in holistically evaluating the needs and values of the key stakeholders—patients and HCPs—along patient journeys and HCPs' clinical workflows. Using an ecological lens to surface system-level interactions and reduce misunderstandings between stakeholders [6,21], our scoping review aims to map how patients and HCPs perceive the integration of PGHD within SDM processes across patient journeys and clinical workflows.

The main contributions of this scoping review paper are as follows: (1) a 10-stage workflow for aligning HCP and patient perspectives on the common barriers and enablers while integrating PGHD across patient journeys and clinical workflows, (2) mitigation strategies to overcome barriers across the patient journeys and clinical workflows, and (3) aligning areas of tension between HCP and patients across the data-enabled clinical workflows and patient data journeys and corresponding alignment strategies.

We use the findings of this scoping review to formulate a model—cf. 10-stage workflow model in Figure 1—which designers and health care technologists can use to analyze or pave data-enabled patient journeys and clinical workflows. By creating better data-enabled patient journeys, relationships between patients and HCPs can be improved, whereby patients could easily share information with HCPs and deliberate their preferences while participating in SDM [16].

Background

Overview

We drew on prior work on PGHD and patient-HCP collaboration with PGHD. This sets the context on how technology has influenced the relationship between patients and HCPs, resulting in both alignments and tensions on integrating PGHD across patient data journeys and clinical workflows.

PGHD

The Quantified Self movement, powered by the rise of technological advancements and increased accessibility to wearables, has led to increased patients bringing opportunistically captured PGHD to consultations [5,22]. *Quantifiers*—those who are part of the Quantified Self—are motivated to understand more about themselves through numbers and modify their lives accordingly [23]. They engage in such practices by using tracking technologies to self-collect personal data, including physiological, behavioral, or environmental information [24,25]. On the other hand, patients might engage in clinician-initiated tracking, which is purposefully capturing PGHD while receiving treatment or instructed by HCPs for long-term chronic care.

PGHD has also been enabled by remote monitoring technologies, which allow HCPs to issue technologies such as wearables and smartphone apps to patients who can take part in long-term treatment (eg, for postoperative care). The availability of PGHD during in-person consultations could facilitate more objectively grounded discussions between HCPs and patients. It could help to give HCPs a clearer picture of a patient's condition, improving the SDM process [7,19]. HCPs also believe that the integration of PGHD could improve symptom monitoring and assessment between visits, help personalize interventions and monitoring plans, aid with assessing clinical outcomes, promote patient self-management and behavior change support and prevention, as well as improve care delivery and quality assurance [22].

Motivated by the vision that PGHD are believed to help HCP "fill in the gaps" [26] and to unlock their potential, national frameworks have also been developed which guide their integration and governance. For example, the European Health Data Space [27], Digital Health Applications [28], and the UK's Personalized Health and Care 2020 framework [29] are frameworks or legislation that support the use, governance, interoperability, and integration of PGHD, fostering the uptake of digital health technologies by patients and HCPs alike. However, there are several technical, social, and organizational challenges to integrating PGHD in clinical practice [7,12].

From an HCP's perspective, PGHD can be challenging to use unless optimally prepared due to time constraints during consultations [12,30,31], the presence of irrelevant information or data, unfamiliarity with the structure of the collected data [32], and poor integration of PGHD into EHR systems [9], clinical workflows, and procedures. Furthermore, overheads due to administrative tasks related to data processing have been shown to create unnecessary workload and even burnout among health care providers [33].

From a patient perspective, there have been usability issues with the technologies, a shift in patient autonomy [31], increased occurrences of over-engagement with data which could in turn lead to a broad range of issues, including anxiety or depression and increased burden of tracking [9]. Moreover, patient expectations of HCPs to review their PGHD in its entirety during a time-limited consultation [34], emotional attachment and subjective view of their PGHD, and selective disclosure of PGHD could prevent doctors from having an unbiased view of patients' data [21].

Figueiredo and Chen [35] systematically explored the various dimensions of PGHD (eg, type, intended use, and duration) and highlighted the critical need to consider sociotechnical factors for its successful integration. This aligns with the broader shifts in health care, including the rise of information infrastructures in health care [36] and increased *data work* required of both patients and HCPs. The HCI community has also embarked on efforts to have a deeper understanding of this phenomenon [37,38]. PGHD integration should seek to balance the needs and interests of both patients and HCPs, as PGHD "negotiation" [21] between them may increase tensions and "asymmetries" [6] between them. Such tensions underscore the importance of designing systems that appropriately mediate the interaction between patients and HCPs, thereby enabling effective patient-centered care and SDM.

Designing for PGHD Integration and Patient-HCP Collaboration

Past works show that the generation of PGHD is not performed at a single point in time. Two seminal works evaluate this from a systematic perspective, though not specifically from the patient's viewpoint. Li et al [20] derived a stage-based model of personal informatics systems with five stages, namely (1) data preparation before tracking, (2) collection of information about oneself, (3) integration of information for sensemaking, (4) reflection on their personal information, and (5) taking action based on the information reflected upon. Primarily targeted toward the "quantifiers," it emphasizes the need for personal informatics systems to be designed in a "holistic manner across the stages." Epstein et al [39] subsequently adopted a *lived informatics* [40] perspective to characterize the integration of self-tracking into a quantifier's daily life. While these models primarily focus on personal use by "quantifiers," their stages and concepts can also be applied to patients who generate and share their data during clinical consultations. To systematically address the barriers HCPs face when integrating PGHD, West et al [12] developed a 6-stage workflow for integrating PGHD in clinical settings. The six stages are, namely, (1) aligning patient and HCP objectives, (2) evaluating data quality, (3) judging data quality, (4) rearranging the data, (5) interpreting the data, and (6) deciding on a plan or action. Overall, there needs to be alignment between HCPs and patients to pave the path toward patient-centered care.

Andersen et al [41] describe how patients and HCPs might have varying concerns in a clinical setting and emphasize that it is a challenge to align their concerns. They explain that for HCPs, concerns are about "professional issues to do with diagnosing and curing disease in accordance with accepted medical

XSL•FO
RenderX

standards." Whereas for a patient, concerns typically are about "personal experience and quality of life issues." They introduce a set of concepts for analyzing concerns that arise during the design of e-Health systems, those being (1) meaningful and making sense to both HCPs and patients, (2) actionable, wherein either HCPs or patients can act on it, and (3) feasible, wherein it is easy and convenient to do so within the organizational and social context [41]. Adopting the concepts by Andersen et al [41] for designing e-Health systems, we posit that the PGHD collected by patients must be (1) meaningful through structured scaffolding of how and what data is collected and presented; (2) actionable, where both HCPs and patients could craft and adopt appropriate (and possibly personalized) treatment plans; and (3) feasible where in-depth user-centered design methods could be used to understand how different hospital systems work, HCPs' practices, and the variances in sociocultural practices around patients' collection and sharing of PGHD among different geographic locations. To effectively integrate PGHD into patient data journeys, it is essential to adopt a systemic lens to this challenge and to address the needs of the adopters [42].

Research Gap and Motivation

Over the years, several publications have investigated the integration of PGHD into clinical practice from the patients' or the HCPs' perspectives [7,21,31,43-48]. To date, a summary of the enablers and barriers to using PGHD from both perspectives has not been published yet. In a study on patient-provider collaboration in the context of irritable bowel syndrome and weight management, Chung et al [21] emphasize that collaboration occurs in every stage of self-tracking and suggest that due to the social nature of patient-provider collaboration with data, it is necessary to investigate how HCPs and patients' roles shift across the stages. We aim to address this gap and align patient and HCP "concerns" [41] for better integration of PGHD in patient data journeys and clinical workflows.

Methods

Study Design

This scoping review is reported following the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) [47]. The scoping review approach was chosen over a systematic review process [49] to determine coverage of literature on the topic of PGHD integration in clinical pathways from the perspectives of both HCPs and patients, with an aim of aligning their needs. Prior reviews [12,25,50,51] around PGHD have focused primarily on a single stakeholder—HCPs. A formal review protocol was not registered or made publicly available.

We used the methodology formulated by Peters et al [52] to investigate the following research question: What barriers and enablers exist among key stakeholders—HCPs and patients—to integrate PGHD to inform SDM?

Search Strategy

Overview

After reviewing prior works in this area and having a consultation among the coauthors, we narrowed down to ACM Digital Library, PubMed, and IEEE databases, which cover research in both technical and medical fields. The search was conducted in PubMed, ACM Digital Library, and IEEE Xplore, chosen to capture literature spanning clinical, technical, and human-computer interaction domains. The search was conducted in March 2023 for papers published between March 2013 and March 2023. We chose 2013 as the starting year as it was a crucial point in the evolution of the field of digital health technologies driven by the democratization of smartphones and wearables [53]. Furthermore, in 2013, acknowledging this phenomenon, the FDA released its first clear framework on how digital health apps and wearables integrations would be regulated for personal and clinical use [54].

Several keywords were initially selected after considering highly visible related works in the area. Thereafter, the first and second authors discussed common themes to narrow down to the keywords in a scheme that can be summarized as follows:

1. patient-generated data *OR* patient-generated health data *OR* [...]
   AND
2. patient-reported outcomes *OR* self-tracking *OR* digital health
   AND
3. shared decision-making *OR* [...]
   AND
4. enablers *OR* barriers OR perspectives OR [...]

As the terminologies patient-generated data and PGHD have been used in prior work, both keywords were included in the search query. Other related keywords indicated as "[...] " and Boolean operators were included in the entire search query, which can be found in Multimedia Appendix 1.

Inclusion and Exclusion Criteria

The aim of applying inclusion criteria (ICs) and exclusion criteria (ECs) is to extract only publications relevant to the objective of this scoping review. We used the following set of ICs: (1) papers published in English in conference proceedings or a peer-reviewed journal, (2) papers related to noninvasive wearables that generated PGHD (eg, smartwatch, blood pressure monitor, etc) and patient self-reported data via journaling, etc, (3) studies which involved either HCPs or patients or both, (4) studies that explicitly mention SDM in person or remotely, mediated via technology, or have elements of SDM, and (5) the type of self-tracking could either be patient- or participant-initiated or clinician-initiated.

We used the following set of ECs: (1) review papers and study protocols, (2) papers referring solely to the personal health record of the patient, (3) papers with implants or wearables that require invasive surgery, and (4) gray literature and policy documents.

Further details about the IC and EC can be found in Multimedia Appendix 2.

XSL•FO
RenderX

Screening Process

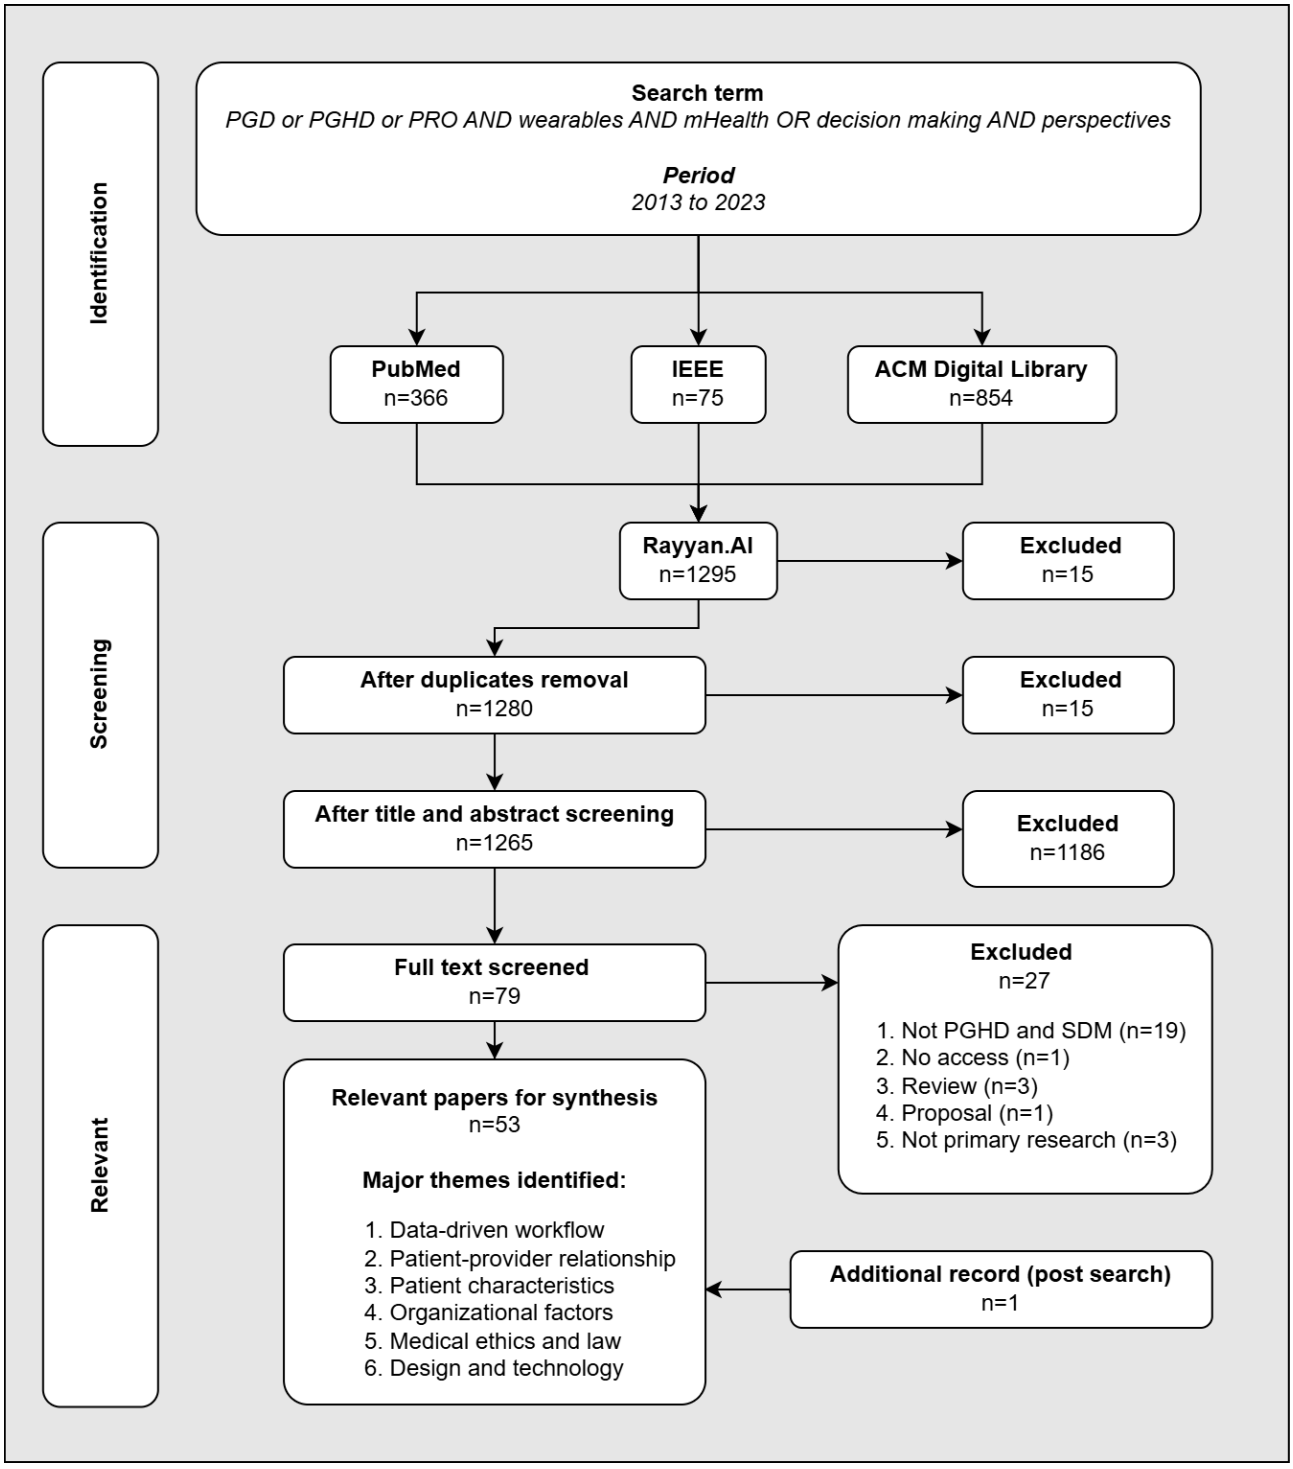
To streamline the paper selection and review process, the results were exported to an AI-assisted collaborative review tool, Rayyan, which aids in duplicate detection and scoring suggestions. The AI system learns the patterns in the decision criteria and gives scoring suggestions after the author makes at least 50 inclusion or exclusion decisions. The first and second authors independently performed abstract screening and review of papers, and conflicts were resolved through discussions between the first and the second author after considering the research protocol and research question. The first author subsequently extracted the data from the final selection of papers. The detailed procedure is reported in the Results section.

Collating and Summarizing the Data

The extracted data were analyzed using a hybrid deductive-inductive thematic analysis guided by the 6-phase framework by Braun and Clarke [32] and the integrated approach to hybrid coding outline by Fereday and Muir-Cochrane [55] by a single researcher (see positionality statement in next subsection). The 6-stage workflow model initially proposed by West et al [12] was used as an a priori deductive framework. Initial data handling and preliminary inductive coding were performed by the first author using Excel (Microsoft Corp). To facilitate systematic analysis, the data and initial codes were then imported into MAXQDA (version 22). The first author conducted another round of familiarization to immerse in the data to refine the codes after consultation with the second author. Concurrently, open inductive coding was applied to capture barriers and enablers that fell outside the predefined framework. To ensure conceptual alignment, after reviewing the first 10 papers, the first author discussed code discrepancies with the second and last author. After coding for all the papers, the first, second, and last authors discussed the final codes and discussed the emerging themes. Clinician was used as shorthand for a wider understanding of HCP in this step. The detailed subthemes and corresponding categorization can be found in the codebook in Multimedia Appendix 3. We did not perform a formal critical appraisal of the papers, as the aim of this scoping review was to map the breadth of barriers and enablers reported across diverse study designs rather than to estimate any effect sizes.

Positionality

The lead researcher is a PhD candidate with a background in human-computer interaction and digital accessibility and has industry experience in digital transformation and building systems for Digital Health Interventions. He comes from a highly digitized nation in Southeast Asia with a robust health care system leading in digital health. His PhD research agenda focuses on PGHD integration in cardiac prevention pathways, and as such, he has vested interests in understanding the sociotechnical factors influencing its integration. To manage potential biases in single-coder analysis, he kept notes of his coding process and discussed emerging codes and themes with the second and last author. The authors have a background in the field of human-computer interaction, digital health, health informatics, cardiology, and digital health interventions for physical activity behavior change and human-computer interaction.



Results

Identified Papers

Our search in the ACM, PubMed, and IEEE digital libraries resulted in 1295 records. The distribution of the results was as follows: ACM 854, PubMed 366, and IEEE 75. After the automatic removal of duplicates by Rayyan and manual removal by the first author, 1280 papers remained. Next, the first and second authors read all titles and abstracts to filter by IC and EC, and 1186 papers were removed, resulting in 79 papers. After full-text screening, 27 papers were removed. Finally, 52 papers were selected for the full-text review by the first two authors. The first author subsequently performed the data extraction using a predefined Excel sheet that captured study characteristics and stakeholder-reported barriers and enablers. One paper was manually added as it was mentioned as an influential related work in four papers [34,44,47,56] published in subsequent years, resulting in 53 papers [6,7,9,12,13,21,30,31,34,43-48,56-93] (see Multimedia Appendix 4). A validation check-in was performed with the last author after reviewing 25 papers. The flow diagram for the review is provided in Figure 2.

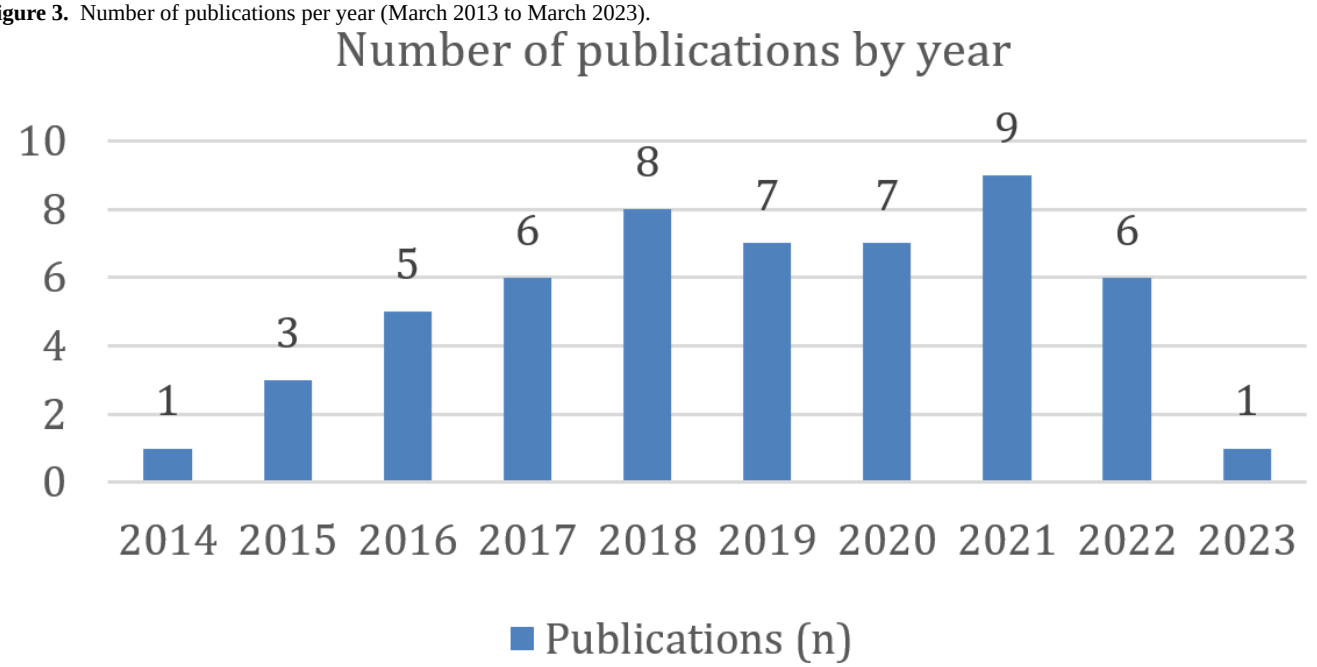
Characteristics of Included Papers

The works predominantly originated from English-speaking countries (Table 1). About 50% (n=33) of them were from the United States and more than 10% (n=7) from the United Kingdom. The final number is higher than in 53 studies, as some studies were conducted in more than one country.



XSL•FO
RenderX

Table . Number of included studies by country of study setting.

Country/region	Values, n (%)
United States	33 (53.2)
United Kingdom	7 (11.3)
South Korea	3 (4.8)
Netherlands	3 (4.8)
Italy	2 (3.2)
India	2 (3.2)
Germany	2 (3.2)
Canada	2 (3.2)
Japan	1 (1.6)
France	1 (1.6)
Denmark	1 (1.6)
China	1 (1.6)
Brazil	1 (1.6)
Belgium	1 (1.6)
Australia	1 (1.6)
European Union	1 (1.6)
Total	62 (100)

The number of papers published annually (Figure 3) has steadily climbed and peaked in 2021. The drop in 2022 could be due to the COVID-19 pandemic, which resulted in a decline in in-person consultations. Furthermore, as the search was conducted in the first quarter of 2023, this resulted in a low count. Most of the papers were about noncommunicable diseases and chronic conditions. Only one paper included perspectives of patients with communicable diseases [91].

Figure 3. Number of publications per year (March 2013 to March 2023).

Factors Affecting the Integration of PGHD for SDM

In this section, we present the findings related to our guiding research question. The analysis identified several enablers and barriers related to the following six themes: (1) patient-provider collaboration with data, which refers to the interaction between HCPs and patients and several factors that affect this interaction, such as trust, expectations over data use, etc; (2) patient characteristics were mainly attributed to factors influencing patient behaviors and tracking habits or the effects of tracking; (3) organizational factors were related to processes within health care systems that could be improved or existing barriers preventing PGHD from integrating effectively into clinical

XSL•FO
RenderX

workflows; (4) medical ethics and law refer to ethical and legal considerations such as patient autonomy, the use of PGHD for insurance purposes, and the questionable value of PGHD for clinical decisions; (5) data-driven workflow-related factors are broadly associated with characteristics, processes, and tools related to data, such as integration, standardization, relevance, trustworthiness, etc; and finally, (6) design and technology refer to the technical implementation of tools that generate or use PGHD and the consideration of human factors in such tools.

The heatmap (Figure 4) shows the breakdown of themes by barriers and enablers and stakeholders based on the number of occurrences throughout the 53 papers selected for this review. Multiple coded segments within the same study were counted as a single occurrence. We also present a detailed heatmap showing the breakdown of codes by barriers and enablers raised by HCPs and patients in Figure 5. In Multimedia Appendix 5, we present an Excel sheet with detailed mapping of clinician or patient enablers or barriers across the 53 papers.

	Well-informed patient	4	2	0	0

The most significant enabler for PGHD integration is how it could promote patient-provider collaboration with data, especially concerning improving communication, allowing for patient-centered care, and providing HCPs with a better picture of the patients. Aspirations followed this in terms of having mechanisms that enable effective sensemaking of health data and having data-driven clinical workflows.

Among barriers, data-driven workflow (eg, lack of standards, poor integration, and lack of access to data) has emerged as the most significant, followed by organizational factors (eg, unavailability of tools and lack of time) and patient characteristics (eg, selective disclosure of data and increased burden of tracking). In the subsequent sections, we will delve deeper into the specific factors.

XSL•FO
RenderX

Patient-Provider Collaboration With Data

Patient-provider collaboration with data is mainly seen as an enabler for the integration of PGHD. The key enablers include the ability to offer personalized care, facilitate communication between patients and HCPs, and improve diagnosis. For example, "both healthcare providers and patients use data to approach the unknown, whether they use it to identify the possible causes of infertility, to identify the fertile window, to decide on potential treatments, or to choose follow-up treatments" [56]. PGHD is also seen as an aid in building trust by objectifying subjective information: the physiotherapists found that the information provided by FitViz helped them in conducting "patient-driven" consultations [66].

While patients are often enthusiastic about sharing the data with HCPs, "patients also wanted to use their data to get recognition for their efforts and to show their doctor they take their health plan seriously" [21]. HCPs are concerned about a shift of responsibility as they might be more accountable for the data shared by the patients: "clinicians were concerned that by having continuous access to patient data, they would become responsible for monitoring that data for concerning changes that may be indicative of a mental health crisis, such as a manic episode or a suicide attempt" [65] and feel an obligation to interpret and explain the data: "simply" receiving PGHD around daily symptoms created a feeling of an 'obligation to act' for the clinicians" [71]. Moreover, with the capability of remote monitoring, patients "want to have the ability for their physician to conduct remote monitoring to verify the treatment plan is working and to pick up early warning signs of relapse or deterioration" [48].

Patient Characteristics and Perceptions

HCPs, in general, are worried about the (unintended) consequences of patients tracking and bringing their PGHD to consultations. They feel that an increased emotional attachment of patients to their PGHD could lead to depression and anxiety. For example, therapists highlight that "depression could be a potential side effect of tracking" [84] and patients could also "overreact to [negative] data" [43]. Both HCPs and patients have concerns about the effort required for tracking and feel that tracking could increase patients' burden; in a study by Ancker et al [91], a diabetes patient who had given up self-monitoring of blood glucose said, "it's too cumbersome for me."

In addition, patient motivations for sharing data with HCPs are not always clear due to *selective disclosure*, as the "patient makes the decision about what kind of data the clinician can see. [As a result] clinicians [were] uncomfortable" [65] with such data unless they had the entire dataset. HCPs are concerned about the "increased transparency via PGHD and how it could lead to noncompliance [by patients]" [31].

Although most feedback was negative, HCPs feel that having access to data could allow patients to better engage with their data through *introspection* and *motivate* them to self-treat their conditions. Patients feel more self-aware of their condition, and self-tracked data helps them see their habits [21]. Furthermore, patients also believed that sharing their data could benefit future research for treating patients with similar conditions: "they hoped their Fitbit data would benefit future veterans" [78].

Data-Driven Workflow

The data-driven workflow theme comprised several enablers and barriers. Within the theme, there are several factors considered as enablers, among which the generation of data, data actionability, and having access to standardized tools integrated well into the clinical workflow.

From the HCP's perspective, data sensemaking is a key enabler for unlocking the value of PGHD. For example, HCPs feel that "when patients struggled to identify triggers, visualizations of quantitative analyses could help patients and providers understand underlying nutrient-symptom relationships" [31]. Data sensemaking enabled patients to effectively use PGHD, facilitating better reflection of their health conditions and empowerment of self-care. For example, in a study of diet monitoring, "HCPs and participants were able to [make sense of their data to] identify eating patterns or potential triggers and used Foodprint as a structuring artifact to discuss actionable next steps" [34]. However, in a study with diabetes patients and providers, "commercially available visualizations that are built using clinical guidelines were useful for providers but not for patients" [83]. HCPs want standardized tools to interact with data and better understand the patient's condition. For instance, HCPs stress the importance of a "uniform clinician interface that integrates [PGHD] from various individual tools, supporting the findings in previous studies" [85] and take appropriate action, leading to better data actionability. Contextual information—how and when the data was collected—is also mentioned as a key to data actionability. Access to the data's context could allow for the discovery of "possible confounds including emotional and physical health, hydration, and exercise" [82]. Integration could enable HCPs to *access* and review data before consultations. In one of the studies, "geriatricians preferred to review the data before the consultation, and then implement a new part of their care plan based on the data" [70].

There are also several barriers identified. The introduction of new tools and technology meant that HCPs must have the necessary *literacy for* interacting with data. Some "[HCPs] doubt their ability to advise on tracking; many providers doubt patient ability to review tracking data" [30]. HCPs also highlight the need for better *data integration* with existing EHR and electronic medical records systems. For example, Zhu et al [81] found that as "commercial sleep tracking technology did not support data exporting or sharing, many clinicians continued to use paper sleep diary."

HCPs were also concerned about PGHD's *quantity*, *quality*, and *reliability*, which could, in turn, affect its *trustworthiness*. When "different patients use different apps, it [became] difficult for health care providers to interpret the data and assess the reliability of each app" [58]. Regarding the amount of data, some HCPs' feedback about receiving or reviewing data relevant to the consultation, given that unnecessary data could result in ineffective decision-making. From the patient's perspective, there is also a lack of awareness about what to track. As a result, "many wanted to track more data than may be feasible" and

XSL•FO
RenderX

wanted to have "smart defaults for how to track because they did not know what would reasonably balance burden and usefulness" [46].

Organizational Factors

Organizational factors mainly encompass factors about a health care organization such as a hospital. The primary barrier is HCPs' lack of time—"the cardiologists in our sample already encounter problems with data overload in their daily practice" [80] and the need for more time and effort to review patient data. HCPs share that "patient-provided data sources will add layers of data assessment to practice, and questioned whether this information may adversely affect efficient workflow" [87].

HCPs need more support, tools, and incentives from upper management to integrate PGHD into clinical care practices. HCPs feel that although activity monitoring tools could help to streamline means of collecting data, "current activity monitoring tools are insufficient to address program specific prehabilitation assessment needs; to exacerbate this challenge, stakeholder tailored tools do not currently exist" [67]. Regarding clinical workflow, HCPs feel that the ready availability of PGHD before consultations could be beneficial in allowing them to review patients' conduct to *prepare for consultations* beforehand, leading to better consultations.

> *Nearly all providers agreed that the best time to receive the patient-generated health report was immediately before a scheduled clinic visit.* [92]

This, in turn, leads to better consultations: "pre-visit notes helped health experts focus on participant goals and questions when reviewing food photos" [34].

Medical Ethics and Legal Aspects

Medical ethics and legal aspects refer to the responsibility of HCPs, ethics, reimbursement, and legal aspects of data. HCPs are worried about regulations such as HIPAA (Health Insurance Portability and Accountability Act) obstructing the introduction of PGHD into their care practices. Furthermore, autonomy is a factor for concern among HCPs and patients. For example, some "older adults perceived that monitoring PGHD increased the transparency of their (lack of) engagement in healthy behaviors" and "perceived [it] as a threat to autonomy" [31]. Finally, the unproven value of PGHD in health care—"lack of evidence for use" [9] of PGHD raises ethical concerns about how such data can be used for clinical decision-making, thereby limiting its adoption. An HCP felt frustrated rearranging the PGHD data and structuring it as evidence within their clinical framework [87]. Within the broader theme of ethics and legalities, one HCP mentions how PGHD could benefit insurance concerning a patient's recovery: "I think it's also good to show insurance kinda, hey, we are making changes, you know, getting them better in this aspect" [84].

Design and Technology

Both HCPs and patients highlight that well-implemented technologies with good usability can be a driver for adoption and sustained use. For example, among patients, learnability and ease of use—subqualities of usability—are favorable for patients in two studies: "GeniAuti made their recording process easier in everyday life" [60] and "ease-of-use of DiaFocus and found it easy to use and easy to learn to use" [57].

For HCPs, the usability of their tools is a key factor for adopting PGHD and missing features such as "inability to sort the data" [89] and added additional time. HCPs are also concerned about the reliability of the applications and the technologies that the patients adopted, especially when patients might use a myriad of them based on their preferences. On the other hand, "when hospitals offer the same app that has been clinically validated to all patients, health care providers can become, over time, knowledgeable about [it]" [58].

Overall, both stakeholders believe that technologies should be designed to be accessible so that population groups such as older adults can adopt these technologies.

> *Clinicians also alluded to old age as a potential challenge as the older generation is not as fluent with mHealth, wearable technology, and other devices that collect PGHD.* [31]

In a particular study, a participant's medical condition—rheumatoid arthritis—caused issues with their participation due to the tool's [lack of] accessibility [63].

PGHD Across a Patient Data Journey and HCP's Clinical Workflow: 10-Stage Workflow

Our analysis includes a wide range of barriers and enablers which can be arranged across a patient's journey and HCP's clinical workflow to provide logical flow. In doing so, we extend and augment the work by West et al [12]—a 6-stage workflow model aligning patient and HCP objectives—and the work by Li et al [20]—the stage-based model of personal informatics systems—to demonstrate how PGHD is integrated beyond clinical settings (Figure 1). Our updated workflow identifies four new stages encapsulated within the pre- and postconsultation phases in addition to the existing stages identified by West et al [12]—stage (1) align patient and HCP objectives, stage (2) evaluate data quality, stage (3) judge data quality, stage (4) rearrange the data, stage (5) cointerpret the data, and stage (6) decide on a plan or action. It also emphasizes the dyadic relationship between the HCPs and patients and the numerous factors influencing the integration of PGHD along the patient journey and HCP's clinical workflow. It starts from the data collection (stage 1) stage till a clinical action is taken (stage 10) and repeats (especially for patients with chronic or multiple conditions). The following subsections describe the newly added steps in further detail.

Collect Data (Stage 1)

Data collection is a crucial stage where patients initiate the tracking of PGHD. In some cases, they might be embarking on this activity on their own or through social influence; on the other hand, it could have been due to instructions from their HCP, for example, when treating medical conditions over the long term. However, it is also worth noting that the monitoring process requires additional effort—although there are methods for passive collection, for example, through wearable or stationary sensing devices, these do require considerable effort to set up and maintain. As such, both active (eg, through

XSL•FO
RenderX

occasional questionnaires or more frequent ecological momentary assessment) as well as passive sensing introduce an additional burden to patients—on top of managing their medical condition.

> *[Patients] mentioned that daily measurements were too burdensome or medicalizing, especially when they perceived their symptoms or blood pressure to be stable.* [69]

Reflect on Data (Stage 2)

In the reflection stage, patients can interact with the data they collected through the various sensemaking mechanisms available. This could be presented as data summaries, PDF reports, or graphs of different formats. However, at this stage, there are both facilitators and barriers. By accessing such data, patients could reflect on their physiological data such as stress levels, weight, etc, and information such as physical activity trends.

> *[P]atients looked to their data for self-awareness of their current lifestyle and described its value in terms of helping them see their habits.* [21]

This could allow them to be well-informed about themselves before consultations. However, if "veterans do not understand or trust the data, it could be difficult for them to be motivated to use it" [78]. There were also incidents in specific medical conditions—for example, in mental health—where having access to such data could reinforce negative views of their condition and agitate symptoms [72] or demotivate patients. Additionally, the constant recurrence of a condition—hence having increased tracking burden—also prevented some patients from self-monitoring: "many unengaged patients reported being easily discouraged by their [arterial fibrillation] AF recurrence, which they said caused them to self-monitor less" [77].

Integrate Data (Stage 3)

The integrate data stage entails the import of data into a clinical setting. Here, the patient attempts to "upload" their data into clinical systems, or the HCP could manually associate them with their EHR systems (a common need to store the foundations for decision-making). However, at this stage, HCPs faced trouble importing such data due to incompatibilities or insufficient interfaces to their systems. In a study, although "patients used mobile apps for their sleep diary, clinicians who received this data had to manually input each data point" [81] due to limitations in data sharing functionalities. There were issues about poor interoperability of self-tracking technologies—primarily due to the nonstandardization of devices or technologies—which prevented seamless integration into EHR systems. Notably, current-generation digital technologies for supporting sensemaking from PGHD cannot easily scale novel data types, handle incomplete or incongruent data, or integrate multimodal PGHD streams.

Take Action (10)

Finally, in the *taking action* stage, after a consultation with an HCP, the presence of data could allow patients to be more accountable for self-treating their conditions based on decisions made during the consultations. However, in some cases, there was a concern about the HCP's ability to monitor patients' conditions remotely or with more granular details; this could invade patients' privacy and threaten their *autonomy* [31]. In addition to this, although HCPs could give recommendations to patients on what tools to use to control their condition, they might not necessarily comply with it:

> *Providers sometimes recommended tracking tools to patients for clinical diagnosis and management. However, patients do not always follow those recommendations.* [13]

Tensions Between HCPs and Patients

Having mapped the barriers and enablers across the 10 stages, we now turn to the cross-cutting tensions that emerged between HCP and patient perspectives throughout the workflow. Excerpts from relevant papers are presented below each point:

Regarding tension 1, patients need clarification or are unaware of the *relevance of data* and need more *health literacy*. This results in (*time-limited*) HCPs facing an overload of (unnecessary) data.

> *[There is] a need to negotiate with patients when determining which data elements to collect, set patients' expectations for communication about PGHD, and let patients know that they would not be contacted if everything was normal.* [89]
>
> *Older adults and clinicians perceived that the lack of clinical knowledge by patients leads to a collection of irrelevant PGHD and decreases the usefulness of the information.* [31]

Regarding tension 2**,** patients, at times, have a subjective and emotional connection with their data and were hoping for detailed explanations of the data they brought for consultations. HCPs, however, intend to view the data objectively while making clinical decisions. This can result in mismatched expectations over collected data by patients and sometimes misunderstandings over how HCPs made clinical decisions using the data, which results in ineffective consultations.

> *Patients also expected providers to engage with the data and provide a personalized treatment plan.* [21]
>
> *The conflicting views often led to disagreement between the caregivers' and experts' interpretations of the children's challenging behaviors.* [60]

Regarding tension 3, patients feel that increased monitoring and visibility of PGHD could lead to disruption of their autonomy and loss of privacy; however, HCPs feel that having (access to) more (readily available) data could allow for better health support.

> *Participants were concerned about talking to clinicians they needed to become more familiar with and about the privacy of their PGD.* [68]

Regarding tension 4, HCPs desire a *complete picture of the patients (to facilitate decision-making*) but at the same time feel challenged by *increased workload* due to the increased data and insufficient time to handle them.

XSL•FO
RenderX

> *Provide the Context, Longer View, and Whole Picture.* [90]
>
> *If patients share the collected data with their doctor, the interpretation of the data and appropriate response becomes the doctor's response.* [80]

Regarding tension 5, patients have issues trusting the HCP's ability to interpret and review data. Furthermore, HCPs themselves had self-doubts about their capabilities.

> *These barriers include a lack of time to review detailed records, questions about providers' expertise, and skepticism about additional benefits of reviewing data.* [30]
>
> *The visualizations also caused some unease for [participants], who mentioned feeling "embarrassed" or "anxious" about giving the impression that they lacked necessary knowledge to explain the visualizations.* [82]

Regarding tension 6, patients and HCPs have varied preferences on which type of problem to focus on and how they wanted the data to be represented.

> *Patients and providers differ on the type of problem to focus on.* [83]
>
> *Data gives different insights to patients and providers.* [83]
>
> *Patients and providers use different representations of data to identify problems.* [83]

Regarding tension 7, ethical and legal challenges of data privacy, patient autonomy, and HCP accountability.

> *...the use of mHealth contributed to them being in control of their own health and to bring their own perspectives to the fore in consultations with health care professionals.* [69]
>
> *Older adults felt that monitoring PGHD increased the transparency of their (lack of) engagement in healthy behaviors.* [31]

Discussion

Summary of Results and Implications

Across the 53 reviewed papers, we identified 6 overarching themes influencing the integration of PGHD into patient journeys and clinical workflows to enable SDM: patient-provider collaboration, patient characteristics and perceptions, organizational factors, medical ethics and law, data-driven workflow factors, and design and technology. Furthermore, we surface 7 cross-cutting tensions faced by HCPs and patients. These findings are relevant for system designers and health care practitioners seeking to digitalize clinical pathways through the integration of PGHD.

Despite the potential of PGHD, there are still significant challenges. There is a lack of transparent processes, standardized tools, and communication about how data should be presented during consultations; individuals bringing their PGHD to consultations would currently most likely add additional workload for HCPs by providing irrelevant and nonstandard data and expecting interpretation. Furthermore, varying patient motivations and their selective data disclosure add layers of complexity to the relationship between HCPs and patients while integrating PGHD into clinical workflows.

Unpacking such challenges while making health and care increasingly patient-centric and assuring that patients feel heard and empowered is an essential goal in many national and international health care strategies (eg, other studies [94-97]). SDM is a key enabler of patient-centered care and helps with fostering adherence and self-determination as well as proactive approaches to health and care. In our 10-stage workflow model, we posit that stage 8 "cointerpretation of data"—or collaborative sensemaking between HCPs and patients—is the primary enabler for successful SDM when integrating PGHD. Prior work indicates that collaborative sensemaking of PGHD can improve patient-provider communication by facilitating deeper discussions regarding personal values and granting HCPs a more nuanced understanding of treatment progress [19,98]. As such, we argue that system designers should prioritize the development of interfaces that scaffold this collaborative sensemaking process to enable SDM.

Toward Enabling Integration of PGHD in Patient Journey and Clinical Workflows

Information infrastructures in health care are embedded within social arrangements and technologies and are spatiotemporal in nature [36]. HCI has a central role to play in investigating them and creating health care technologies that are fit for purpose [17].

In a clinical context, HCPs may already be facing increased risk of burnout due to poor technology integration [33], and given the potential benefits and burden PGHD brings, there is a need to prioritize how data-related tools can be better integrated. On a higher level, there needs to be organizational support in creating policies and processes to support the use of PGHD and creating data-driven workflows that seamlessly integrate such data into clinical practices. However, we identified challenges in a clinical setting involving how patients collect data and collaborate with HCPs in a clinical context.

Work on aligning and interactively navigating priorities between HCP and patient [12,21] appears clearly implicated. Tensions could arise from patient preferences or the subjectivity of data due to the emotional connectivity of the data conflicting with HCPs adopting a very objective view of data with their medical background—typically due to medical ethics. By juxtaposing the needs and priorities of both stakeholders, we discussed the alignments and tensions between them. We also identified design opportunities for system designers to consider addressing and balancing the stakeholders' priorities adequately by proactively building on enablers and avoiding or decisively tackling barriers.

Overall, the scoping review outcomes emphasize a need to adopt a systemic lens on the issue of integrating PGHD into clinical practice by considering its flow across the patient data journey and clinical workflows. Our research team, consisting of the first, second, and last authors, conducted a thorough review of the existing 6-stage workflow model [12] and the emerging codes to establish the new stages and the enablers and barriers

XSL•FO
RenderX

at each stage, and the potential tensions. This process resulted in the augmented 10-stage workflow model (Figure 1). This model (see simplified model in Multimedia Appendix 6) includes pre- and postconsultation phases, as well as corroborated formerly identified barriers and enablers and newly identified ones.

Addressing Barriers

To facilitate the practical application of our findings, we organize the barriers across the stages along with potential mitigation strategies in Table 2.

Table . Barriers and mitigation strategies.

Stages	Barriers	Mitigation strategies
Preconsultation		
Collect data (stage 1)	Burden of tracking	• Use passive tracking as much as possible and recommend only tracking that is necessary for consultations.
Reflect on data (stage 2)	Negative repercussions of tracking	• Educate patients on possible negative impacts of data and offer adequate resources to obtain support on data sensemaking.
Integrate data (stage 3)	Poor data integration	• Standardize interfaces and data export formats among commercial devices and applications for better integration into EHR[a] systems.
Post consultation		
Take action (stage 10)	Shift of patient autonomy and noncompliance	• Ensure that patient preferences on how their data is viewed and accessed are respected and communicated with them transparently. • Educate patients on the benefits of adherence.
All stages		
N/A[b]	Overburdened HCPs[c]	Across all stages: • Implement data sensemaking support in-line with clinical workflows. • Consider shifting to partially automated sensemaking steps that already occur before consultation
N/A	Lack of time for HCPs	• Introducing tools to improve the operational efficiency of clinical workflows
N/A	Questionable value of PGHD[d]	• Conduct empirical research on PGHDs and how they improve patient-centered care.

[a]EHR: electronic health record.

[b]N/A: not applicable.

[c]HCP: health care professional.

[d]PGHD: patient-generated health data.

Addressing Tensions

Apart from addressing key barriers, it is essential to address divergent perspectives resulting in tensions between the stakeholders. Given the dyadic relationship between patients and HCPs during SDM, it is essential to understand potential misalignments between both stakeholders, which results in tensions. In Table 3, we delineate these specific tensions alongside targeted alignment strategies designed to harmonize stakeholder expectations and foster collaborative care.

XSL•FO
RenderX

Table . Tensions and alignment strategies.

Number	Tension	Alignment strategies
1	Patients' lack of awareness about what data to bring vs time-starved HCPs[a]	Improve health (data) literacy of patients, align expectations, or establish standards over what data are needed for the consultation and for SDM[b], thereby engendering mutual trust.
2	Patients' subjectivity vs HCPs' objectivity	HCPs should set expectations regarding how PGHD[c] would be used for SDM and provide an explanation of how they influenced the SDM process.
3	HCPs' need for access to patient data vs patients' desire for privacy and autonomy	Patients and HCPs should set boundaries over how and when HCPs track PGHD to maintain patient autonomy. Appropriate privacy mechanisms could be designed for dynamic configuration of consent.
4	HCPs want to have a complete picture of patients vs limited consultation time	Equipping HCPs with the necessary tools such as clinical decision support and AI-assisted systems could help augment HCPs with PGHD interaction.
5	Patients' perception of lack of HCP data literacy affected trust	Improve HCPs' data literacy capabilities and assure patients about their abilities to make data-driven decisions.
6	Differing perspectives and approaches that patients and HCPs have when interacting with PGHD for diagnosis	Tools should promote mutual understanding between both patients and HCPs and support problem identification, preferably in an automated manner [83].
7	Ethical and legal need for addressing the dilemma of data privacy and patient autonomy vs HCP accountability	Foster cross-sectoral collaboration between patients, HCPs, and legislators to co-design the most appropriate governance frameworks for a given chronic disease context. This could include steps such as implementing dynamic consent and adapting policies such as HIPAA[d] in the United States and EHDS[e] to ensure that they do not diminish the quality of care [99]. Furthermore, alignment with medical ethics standards should incorporate national and contextual nuances, allowing for safeguards such as involvement of ethical committees for ethical oversight.

[a]HCP: health care professional.

[b]SDM: shared decision-making.

[c]PGHD: patient-generated health data.

[d]HIPAA: Health Insurance Portability and Accountability Act.

[e]EHDS: European Health Data Space.

Some of these alignment strategies could be considered as implications for design at an organizational or policy level based on the health care system. At an organizational level, system designers can adopt generative co-design activities with HCPs and patients, such as the approach by Höppchen et al [100] to design clinical pathways which systematically align the integration of PGHD.

Limitations

Our scoping review's findings were based on the papers derived from 3 databases, and other unpublished or nonpeer-reviewed works could be available in other repositories. They reflect studies primarily conducted in English-speaking, high-income countries, partly a result of limiting our search to English papers. As such, our review may underrepresent perspectives from low- and medium-income countries where infrastructural capabilities, sociocultural factors, and health care systems may vary significantly. We also acknowledge that no critical appraisal was conducted for individual studies as they are optional for scoping reviews and additionally due to the heterogeneity of the study designs included in our review. Furthermore, as mentioned in the positionality statement above, there could be researchers' subjectivity in the interpretation of the findings. As HCPs and patients unequally contributed to the findings, the perspectives should be explicitly assessed in empirical work and in a balanced manner. However, these preliminary findings give readers and designers a sense of factors to consider when integrating PGHD into digital health technologies and wider health care systems.

XSL•FO
RenderX

Conclusions

PGHD has immense potential to enhance patient-centered care and lead toward P4 (predictive, preventive, personalized, and participatory) medicine. However, its widespread integration in clinical settings still needs to be improved. Our research question aimed to paint a holistic and ecological understanding of the PGHD integration barriers and enablers perceived or experienced by patients and HCPs to better facilitate PGHD integration. By reviewing works from the past 10 years and incorporating both patient and HCP perspectives, we identified several enablers and barriers across 6 key themes. We build on the previous 6-stage model by West et al [12], adding 4 new stages beyond the clinical setting, including "collect data," "reflect on data," "integrate data," and "take action," and added the perspectives of both patients and HCPs to identify new barriers and enablers across the various stages of interaction with PGHD. Our 10-stage workflow model of aligning patient and HCP objectives in integrating PGHD implies several challenges to be tackled in a complex health data ecosystem [18] and health data lifecycle [17]. Furthermore, the model forms the foundation for deriving design implications around tensions and alignments between HCPs and patients along data-enabled patient journeys and clinical workflows. By addressing challenges introduced by PGHD, SDM could be more efficient for both parties, leading to better patient-centered care and life-accompanying personalized data-enabled health. Future work should investigate how our workflow model performs in real-world settings and expand evidence from underrepresented regions to improve the global applicability of PGHD integration among different health care systems.

Acknowledgments

We would like to thank all our colleagues who helped with proofreading this paper. The authors declare the use of generative AI (GenAI) in the research and writing process. According to the GAIDeT (2025; Generative Artificial Intelligence Delegation Taxonomy), the following tasks were delegated to GenAI tools under full human supervision: (1) proofreading and editing and (2) reformatting. The GenAI tool used was ChatGPT (version 4.5; OpenAI). Responsibility for the final paper lies entirely with the authors. GenAI tools are not listed as authors and do not bear responsibility for the outcomes. Declaration submitted by the collective.

Abstract

Background: Cancer affects multiple physical, psychological, and social aspects of an individual's life. Cancer survivors frequently report unmet needs long after diagnosis and require ongoing support. AI is increasingly embedded in patient-facing digital health technologies (DHTs) in oncology, yet its impact on different domains of patients' and survivors' health-related quality of life (HRQOL) remains unclear.

Objective: This systematic review aims to (1) examine how AI has been integrated into patient-facing DHTs designed to support cancer survivors, (2) narratively synthesize the potential effects of these technologies on HRQOL and provide preliminary quantitative estimates through an exploratory meta-analysis, and (3) explore broader changes in additional patient-reported outcomes (PROs; secondary aim).

Methods: PubMed, PsycINFO, Embase, Scopus, CINAHL, and the Cochrane Library were searched for articles published between January 2020 and August 2025. Reference lists of included articles were hand-searched for additional eligible studies. Eligible studies enrolled cancer survivors of any age and disease stage, evaluated a patient-facing DHT with AI components, and assessed HRQOL. Nonoriginal research and non-English reports were excluded. Risk of bias was assessed in all controlled studies using RoB 2 (revised Cochrane risk of bias 2) or ROBINS-I V2 (Risk of Bias in Non-Randomized Studies—of Interventions, Version 2), according to study design. Data on HRQOL and other PROs were synthesized narratively, and exploratory random-effects meta-analyses were conducted for HRQOL domains.

Results: Eight reports from 7 studies from China and the United States (N=2867 participants) met the inclusion criteria, and 3 (n=292 participants) contributed to the exploratory meta-analysis. All studies included adults with various cancers at different stages and times since diagnosis. Most studies showed low risk of bias or some concerns (RoB 2), but one was evaluated as having a serious risk of bias (ROBINS-I V2). AI applications ranged from symptom monitoring to targeted education. The narrative synthesis suggested positive effects on selected HRQOL domains, particularly general health, with more pronounced effects in studies conducted in China. Exploratory meta-analyses demonstrated provisional moderate positive effects on global health (Hedges g=0.77, 95% CI 0.15 - 1.40) and social functioning (Hedges g=0.75, 95% CI 0.08 - 1.42), but no effects on physical functioning, role functioning, or emotional well-being. Other PROs indicated generally high user satisfaction and adherence, improved mental health outcomes, and reductions in physical symptoms. Only minor and mild adverse events were reported.

Conclusions: Current evidence, although limited, suggests that AI-enabled patient-facing DHTs may benefit survivors' HRQOL and other PROs, particularly in early survivorship. However, our findings are based on small and heterogeneous studies and should therefore be interpreted with caution. Robust trials with adequate sample sizes, longer follow-up, and appropriate control conditions, including DHTs without AI components, are needed to determine the specific contribution of AI.

Introduction

Cancer affects not only physical health but also the emotional, social, and psychological well-being of patients and their close networks across the cancer trajectory [1]. Cancer survivors often face symptoms, lifestyle adjustments, and report information needs that persist long after cancer treatment [2]. Although cancer survivors value continued personal follow-up care [2,3], it is rarely achievable in routine practice due to limited health care resources, competing priorities, geographic barriers, and the growing number of individuals living with and beyond cancer [4]. These challenges highlight the need for scalable solutions that can complement traditional survivorship care.

Patient-facing digital health technologies (DHTs), such as mobile apps and digital therapeutics, may help bridge these gaps by delivering accessible, personalized, and timely support to patients in diverse settings [5]. Unlike DHTs designed for health care professionals, patient-facing DHTs are directly operated by patients themselves, enabling self-monitoring, symptom reporting, psychoeducation, and behavioral interventions in daily life [5]. Incorporating AI components into DHTs might further enhance their potential impact [6,7]. For instance, machine learning (ML) and natural language processing (NLP) can facilitate the processing and interpretation of large volumes of heterogeneous data, including symptom reports, sensor data, and medical records [8]. These technologies can thereby enable patient-facing DHTs to provide tailored feedback, adapt digital interventions to individual needs, or identify moments when users are most receptive to receiving an intervention [8,9]. However, these potential benefits should be weighed against important concerns. Embedding AI into patient-facing DHTs may introduce additional risks to data privacy and exacerbate existing gaps in digital access [10], and consequently in access to health care. Furthermore, understanding how patients perceive and use these tools is necessary, as their experience will strongly influence engagement and uptake [11].

Although interest in patient-facing DHTs is increasing, few trials examine their effects from the patients' perspective [12]. Patient-reported outcomes (PROs) are critical indicators of how individuals perceive their health, functioning, and quality of life, as well as the impact of interventions on their daily lives [13]. PROs capture dimensions of health that cannot be observed or measured by clinicians alone and are particularly relevant in chronic and oncological conditions where maintaining quality of life is a primary treatment goal [14]. Health-related quality of life (HRQOL) represents a key multidimensional construct spanning physical, psychological, and social domains [15,16]. Various instruments exist to assess HRQOL, ranging from generic measures to cancer-specific scales, each assessing different facets of survivors' lived experiences [15,17]. However, it remains unclear whether AI-enabled DHTs adequately address the complex physical, emotional, and social needs of cancer survivors [18]. To address this gap, this systematic review aims to (1) examine how AI has been integrated into patient-facing DHTs designed to support cancer survivors, (2) narratively synthesize the potential effects of these technologies on HRQOL and provide preliminary quantitative estimates through an exploratory meta-analysis, and (3) explore broader changes in additional PROs (secondary aim).

Methods

This systematic review followed the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 guidelines (Checklist 1) [19]. The protocol, including a detailed description of the search strategy, is registered in the PROSPERO systematic review registry (CRD420251021466).

Database Search

The search strategy consisted of 4 concept blocks (cancer, AI, DHT, and HRQOL) and combined free-text and thesaurus terms using AND/OR Boolean operators. Initial terms were identified by the first author (AI) through scoping searches and key articles in the field. The strategy was refined iteratively in consultation with a co-author (HCL) to capture relevant synonyms, acronyms, and spelling variants, and it was reviewed by an experienced librarian. Search strings were adapted for each database, and we focused on articles containing any of the terms in the title, abstract, and, where possible, the keywords. No further filters or language restrictions were applied at the search stage.

We conducted an initial search on May 20, 2025, in PubMed, PsycINFO, Embase, Scopus, CINAHL, and the Cochrane Library, covering records published from January 1, 2020, to the search date. The start date (January 1, 2020) was chosen to account for the rapid development of AI and to ensure the inclusion of the most recent evidence [20,21]. A second search was conducted in the same databases on August 26, 2025, adding 3 terms that had not been included previously. Therefore, we obtained a large number of duplicates. The reference lists of all included publications were screened to identify additional potentially relevant studies.

Eligibility Criteria

Reports were eligible if they (1) enrolled cancer survivors at any disease stage, including those undergoing active treatment or palliative care (in accordance with the definition of the National Cancer Institute) [22], (2) evaluated patient-facing DHTs that explicitly included AI components (AI-enabled DHTs), and (3) reported an assessment of HRQOL. For the purposes of this review, AI-enabled DHTs refer to patient-facing DHTs that incorporate an AI component, whether embedded within the platform or operating as an external module.

Nonoriginal reports, including other reviews, editorials, commentaries, conference abstracts, and study protocols, were excluded. Only studies that included a control group (eg, usual care and non–AI-enabled DHTs) were eligible for inclusion in the meta-analysis.

Although we initially considered including non-English articles relying on software-generated translations, these were ultimately excluded because we could not validate them with a native speaker and therefore could not avoid potential misinterpretation. However, these studies are cited in the results for completeness.

XSL•FO
RenderX

Study Selection

All identified references were screened using Covidence (Veritas Health Innovation Ltd) [23], and duplicates were automatically excluded. Two authors (AI and PC or KETT) independently screened all titles and abstracts against previously agreed-on inclusion and exclusion criteria. The same 2 authors screened the full texts of all articles previously included by at least one author to make a final decision on inclusion. Any disagreements were resolved through discussion or by consulting a third author. The study selection process is summarized in a PRISMA 2020 flow diagram.

Data Extraction

Data extraction was supported using SciSpace [24] and Perplexity [25]. All machine-extracted information was verified against the original manuscripts to ensure that no relevant information was misinterpreted or missed (AI) and validated by a second author (PC or KETT). Data were extracted from the published articles and any supplementary materials, and no individual participant data were requested. Where information was unclear or insufficiently detailed, we contacted the authors for clarification. However, no responses were received.

Collected data included (1) study information: title, authors, year, journal, country, and study design; (2) sample characteristics: sample size, sociodemographic information, and cancer-related characteristics for both intervention and control groups; (3) DHT details: type, purpose, AI components, input data sources, and output type; (4) HRQOL outcomes: baseline and postintervention measurements, instruments used, domains assessed, and main findings; and (5) additional PROs: instruments used and key results. When multiple articles reported on the same study, all relevant publications were considered to provide a comprehensive description of the methods and outcomes.

Risk of Bias

For randomized controlled trials (RCTs), the risk of bias was assessed using the revised Cochrane Risk of Bias 2 (RoB 2) tool [26], and for non-RCTs, the ROBINS-I V2 (Risk of Bias in Non-Randomized Studies—of Interventions, Version 2) [27]. Single-arm studies were not formally assessed for risk of bias and were reported narratively without inclusion in any quantitative synthesis.

Two authors (AI and LKJ) independently evaluated each study across all domains, with possible ratings of low risk, some concerns, or high risk (RoB 2), or low, moderate, serious, and critical concerns (ROBINS-I V2). The evaluations were then compared, and any discrepancies were resolved through discussion. When multiple articles reported on the same study, all relevant publications were considered to provide a comprehensive assessment.

Data Synthesis

For the purposes of this systematic review, studies were grouped as controlled (including randomized and nonrandomized trials) or single-arm studies. Controlled studies were eligible for quantitative synthesis (meta-analysis), whereas single-arm studies were only summarized narratively.

Narrative Synthesis

HRQOL outcomes were summarized using a narrative synthesis approach (AI) [28]. Given the small number of studies included, thematic clustering was not feasible. Instead, we presented results on a study-by-study basis, describing the reported direction and highlighting any patterns across interventions where possible. Similarly, we used a descriptive narrative approach to describe PROs beyond HRQOL.

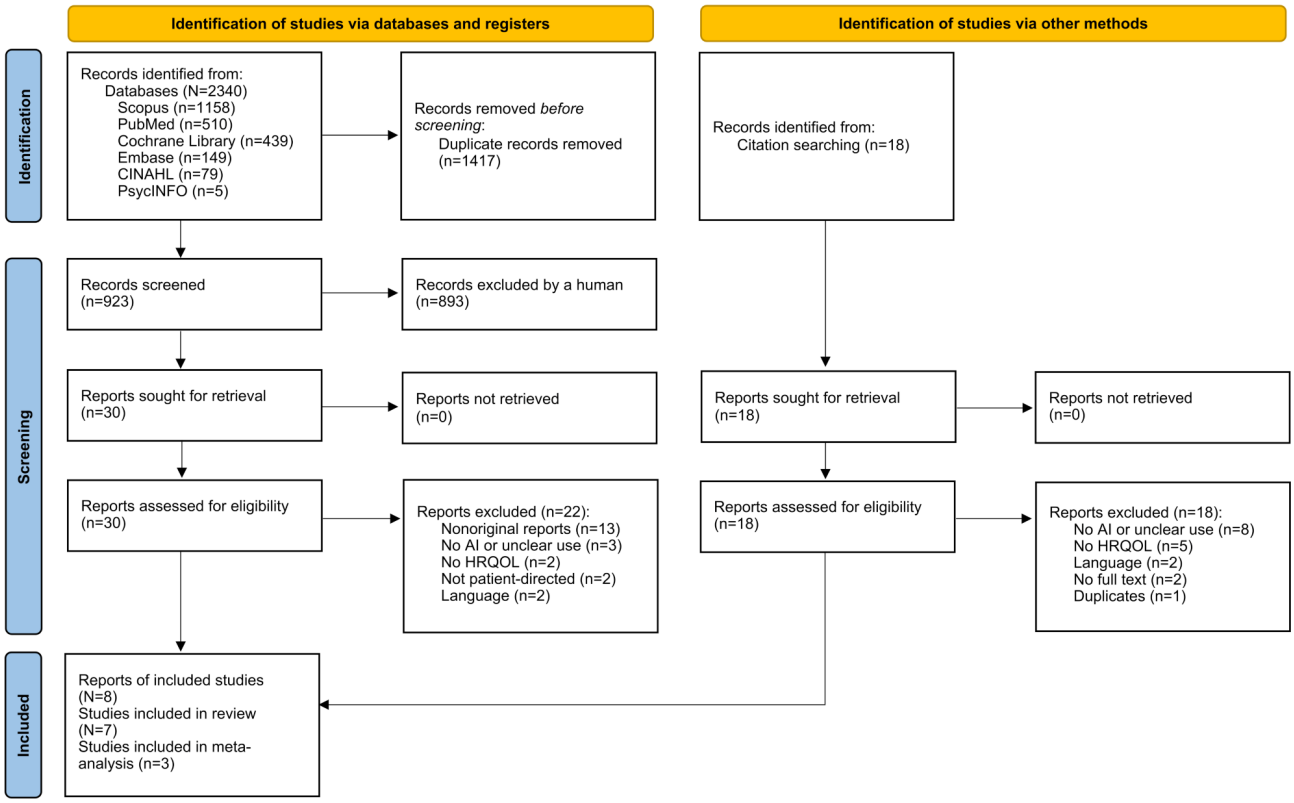
Meta-Analysis

Because HRQOL instruments varied across studies, we extracted all domains reported at all time points and compared the underlying items to align conceptually similar domains across different instruments (Multimedia Appendix 1). We pooled outcomes only for domains that were conceptually comparable across instruments. For all instruments, higher scores indicated higher HRQOL. When studies reported multiple follow-up time points, we included the assessment closest to the end of the intervention to minimize heterogeneity in exposure duration.

For controlled studies, we conducted exploratory meta-analyses using random-effects models due to the clinical and methodological heterogeneity across digital health interventions and populations with cancer. For continuous HRQOL outcomes, provisional effect sizes were calculated as standardized mean differences (Hedges *g*) with 95% CIs. When authors reported SEs, we converted them to SDs to ensure comparability across studies. When the reported variability measure was not specified as SD or SE, it was assumed to represent SD, as SD is more commonly reported in HRQOL research. When studies reported both intention-to-treat and per-protocol analyses, we used data from the intention-to-treat analyses.

Statistical heterogeneity was assessed using the I^2 statistic. Sensitivity analysis was performed using a leave-one-out approach. Results of individual studies and pooled effect estimates were visually displayed using forest plots. Study characteristics and extracted outcome data were summarized using tables. All analyses were performed using the *meta* command suite in Stata (version 9.5; StataCorp LLC) [29].

Results



Study Selection

A comprehensive search of 6 scientific databases identified 2340 records (Figure 1). After removing duplicates (n=1417), 923 records were screened. Of these, 30 full-text articles were assessed for eligibility, and 8 publications from 7 studies (N=2867 participants) met the inclusion criteria and were included in the review.

Two potentially relevant records published in Chinese were excluded because reliable translation and validation were not feasible. One was a pilot study from an already included study [30], and the other reported data from a distinct study not otherwise included in this review [31]. Citation searching did not identify any additional eligible studies.

XSL•FO
RenderX

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 flow diagram. HRQOL: health-related quality of life. Source: [19].

Study Characteristics

The 7 included studies comprised 2 single-arm studies [32,33], 3 RCTs [34-37], 1 partial-crossover RCT [38], and 1 non-RCT [39] (Table 1).

The studies covered multiple cancer types and survivorship stages (Table 1). RCTs by Schmitz et al [38] in the United States and by Hu et al [34] and Jiang et al [35] in China focused exclusively on breast cancer survivors, while a US single-arm study by Horesh et al [33] included both breast and ovarian cancer survivors. Together, these studies targeted survivorship stages from active treatment through early survivorship to metastatic disease. The RCT by Li et al [37] examined early-stage postoperative lung cancer survivors in China, and the RCT by Kamdar et al [36] focused on patients with metastatic solid tumors receiving palliative care in the United States. The remaining studies included survivors of any cancer type in different contexts. The non-RCT by Zhang et al [39] focused on patients receiving chemotherapy in China, and the single-arm study by Buchan et al [32] included individuals at any stage of disease in the United States. Quality of life was assessed in all included studies as a primary or secondary outcome, and most studies used validated HRQOL instruments.

Table . Study characteristics[a].

Study	Study characteristics	Assessment details	Sample[b]	Cancer details	HRQOL[c] measure
Buchan et al [32], 2024	United States; single-arm cohort study	Within-group comparison; monthly assessments (T0, 49.1 mo; median follow-up 8.8 mo)	2423	Mixed cancers; any stage	Not specified
Horesh et al [33], 2022	United States; single-arm pre-post study	Within-group comparison; 2 assessments (T0, 24 d)	37	Breast and ovarian cancers; on active treatment, experiencing hot flashes	WHOQOL-BREF[d]
Hu et al [34], 2025; Jiang et al [35], 2024[j]	China; RCT[e]	General information online; 3 assessments (T0, 1 mo, 3 mo)	115 (intervention=60 and control=55)	Breast cancer; early survivorship	FACT-B[f]
Kamdar et al [36], 2024	United States; RCT	Usual care; 3 assessments (T0, 4 wk, 8 wk)	79 (intervention=39 and control=40)	Mixed (solid) cancers; metastatic, receiving palliative care	FACT-G[g]
Li et al [37], 2025	China; RCT	Usual care; 2 assessments (T0, 5 mo)	36 (intervention=20 and control=16)	Lung cancer (NSCLC)[h]; early survivorship, postoperative	EORTC QLQ-C30[i]
Schmitz et al [38], 2023[j]	United States; RCT, partial crossover	Delayed intervention; 3 assessments (T0, 3 mo, 6 mo[k])	33 (intervention=17 and control=16)	Breast cancer; metastatic	SF-36[l]
Zhang et al [39], 2025[j]	China, non-RCT	Non-RCT; usual care; 2 assessments (T0, 6 mo)	144 (intervention=72 and control=72)	Mixed cancers; receiving chemotherapy	EORTC QLQ-C30

[a]In total, 8 publications from 7 studies were included in this review.

[b]Sample sizes reported in this table reflect the number of participants included in the HRQOL analyses (including intervention and control groups). They may differ from the sample sizes reported elsewhere in the publications.

[c]HRQOL: health-related quality of life.

[d]WHOQOL-BREF: World Health Organization Quality of Life Scale–Brief version.

[e]RCT: randomized controlled trial.

[f]FACT-B: Functional Assessment of Cancer Therapy–Breast.

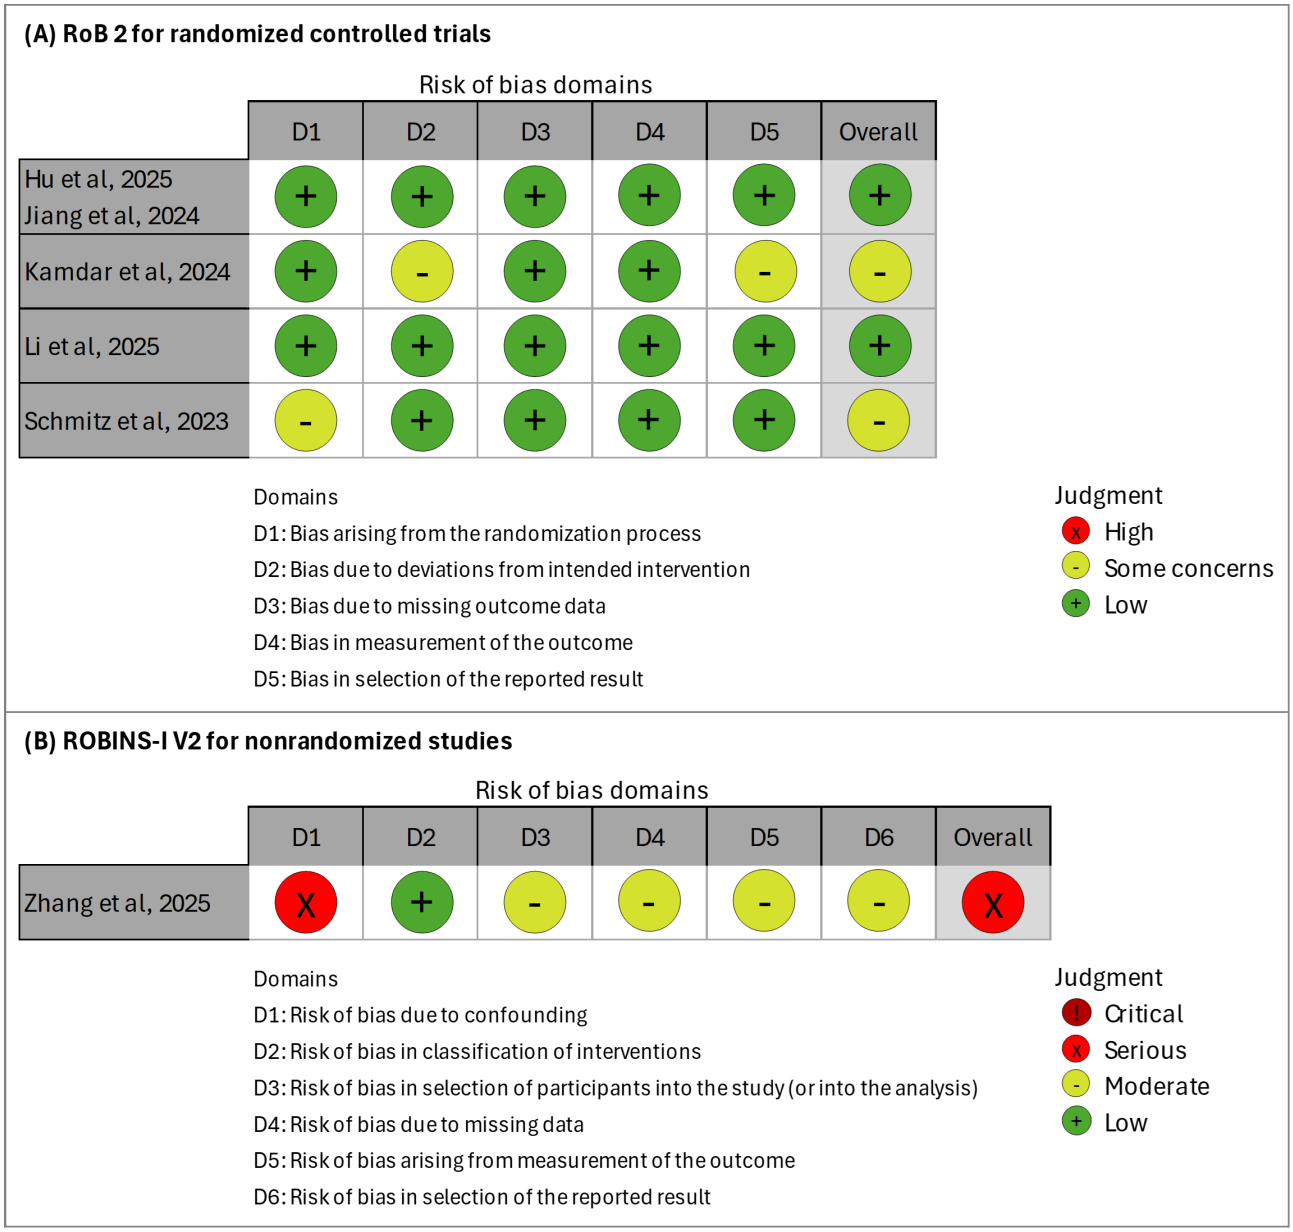
[g]FACT-G: Functional Assessment of Cancer Therapy–General.

[h]NSCLC: non–small cell lung cancer.

[i]EORTC QLQ-C30: European Organisation for Research and Treatment of Cancer Quality of Life Questionnaire–Core 30.

[j]Included in the meta-analysis.

[k]Immediate group: intervention 0 - 6 months; delayed group: 3 - 6 months; control assessed 0 - 3 months prior to intervention.



[l]SF-36: 36-item Short-Form Health Survey.

Risk of Bias

Of the 4 RCTs, 2 were rated as low risk of bias, and 2 studies were assessed as having some concerns. However, all concerns were observed in different domains and did not indicate a consistent source of bias across the evidence base. The non-RCT by Zhang et al [39] was found to be at serious risk of bias, primarily due to inadequate control of confounding factors in a time-separated convenience sample. There were additional concerns regarding the unclear management of exclusions and missing data. Furthermore, inconsistencies in the reporting of results suggest caution when interpreting the findings. No studies were evaluated as high (RoB 2) or critical (ROBINS-I V2) risk of bias. Therefore, none were excluded. Further details on the risk of bias evaluation are available in Figure 2.

XSL•FO
RenderX

Figure 2. Risk of bias assessment: (A) RoB 2 (Revised Cochrane risk of bias 2) for randomized controlled trials, (B) ROBINS-I V2 (Risk of Bias in Non-Randomized Studies—of Interventions, Version 2) for nonrandomized studies [34-39].

Aim 1: AI-Enabled DHTs for Patient Support in Cancer

Purpose

Most of the DHTs included in this review aimed to provide home-based support for monitoring and managing physical symptoms associated with cancer treatment, such as pain, nausea, fatigue, and sleep disturbances [33-36,38,39]. Three studies addressed psychosocial needs by offering supportive care [33-35,38]. Two studies specifically targeted cardio-oncology rehabilitation [37] or nutritional support for cancer survivors [32] (Table 2).

XSL•FO
RenderX

Table . Description of digital health technologies.

Study	Name	Purpose
Buchan et al [32], 2024	Ina	AI-driven virtual text message–based nutrition assistant providing evidence-based, personalized nutritional counseling, recipes, and symptom management support to improve dietary habits, symptom control, and HRQOL[a] for diverse cancer types.
Horesh et al [33], 2022	Bubble	AI-VR[b] intervention, delivered via mobile apps (Bubble and Luna) and VR goggles, with elements of cognitive behavioral therapy and mindfulness-based stress reduction, to reduce hot flash frequency and severity, alleviate psychological distress, improve sleep quality, and enhance HRQOL in women with breast and ovarian cancers. The intervention takes place in the "Frosty" virtual environment and is led by an avatar named Luna.
Hu et al [34], 2025; Jiang et al [35], 2024	AI-TA	AI-driven intelligent interactive mobile app designed to reduce physical, psychological, and social premature frailty, thereby improving HRQOL among young breast cancer survivors through personalized content delivery, symptom tracking, and 2-way web-based follow-up with health care professionals.
Kamdar et al [36], 2024	ePAL	Digital therapeutic mobile app designed to manage cancer-related pain in patients with advanced cancer through active pain monitoring, an AI algorithm that triages patient symptoms and identifies specific barriers to pain control, patient education modules, and real-time clinician outreach to address identified barriers to pain management.
Li et al [37], 2025	Recovery Plus Health (Recovery Plus USA Inc)	Cardio-oncology rehabilitation program delivered via the Recovery Plus mobile app using AI-driven exercise prescriptions with real-time heart rate monitoring to improve cardiopulmonary fitness, reduce cancer-related symptoms (fatigue, anxiety, and daytime dysfunction), and enhance HRQOL in early-stage lung cancer survivors.
Schmitz et al [38], 2023	Nurse AMIE	Conversational AI–based supportive care intervention delivered via Amazon Echo Show with Alexa to address symptoms (pain, fatigue, sleep disturbance, and distress), provide nutritional guidance, and improve HRQOL in patients with metastatic breast cancer.
Zhang et al [39], 2025	Not specified	Deep learning platform for symptom management designed to provide continuous, personalized symptom management for patients with cancer undergoing chemotherapy, aiming to reduce anxiety and depression and improve HRQOL by delivering real-time nursing support, symptom monitoring, and medical guidance outside hospital visits.

[a]HRQOL: health-related quality of life.

[b]VR: virtual reality.

Delivery Modality

Of the 4 interventions delivered via mobile applications, 2 were application-only [34-36], and 2 were delivered in combination with wearable devices such as virtual reality (VR) goggles [33] or heart rate bands [37]. The remaining interventions were delivered through web platforms or portals accessible on both computers and smartphones [39], via text messaging [32], or through a voice-based virtual assistant [38].

XSL•FO
RenderX

Six interventions included a human component alongside the DHTs. Three interventions encouraged participants who reported high symptoms to contact the health care team [32,37,38], and 2 automatically notified the health care team when any alarming symptoms were observed [36,38]. In 2 interventions, health care professionals supervised AI-driven recommendations and adjusted them when necessary [32,37]. Two DHTs also encouraged questions and peer group discussions [34,35,39].

AI Components

Across the interventions, AI was mainly used to personalize and optimize supportive care delivery. NLP was used for text analysis of patient input and for generating personalized responses, enabling the development of conversational interfaces [32,35,37]. ML and predictive analytics were used to predict patient needs, triage symptoms, and adapt interventions in real time [32,35,36,39]. Knowledge graphs and expert systems provided structured decision support, ensuring evidence-based recommendations [32,35,36]. Recommender systems combined keyword analysis and filtering to personalize the delivered content [33-35]. Other DHTs included AI-driven exercise prescription systems that adjusted training parameters based on wearable data [37], as well as speech recognition for voice-interactive virtual assistants [38].

Input Sources and Output Types

The included studies can be classified into 3 groups. First, several interventions in breast cancer used patient-reported symptoms, survey data, and basic clinical history to provide personalized education, symptom-management guidance, and supportive follow-up [33-35,38]. Second, studies focused on more intensive symptom management in people with advanced cancer or those receiving palliative care used repeated symptom reporting, clinical records, and real-time monitoring to trigger tailored coaching, clinician outreach, or escalation [36]. Third, studies centered on nutrition or broader supportive care used baseline medical and nutrition history, treatment details, and user input to deliver individualized advice, recipes, nursing guidance, and interactive messaging [32,37,39].

Aim 2: Effect on HRQOL

Multimedia Appendix 2 presents the magnitude and direction of changes for all presented outcomes.

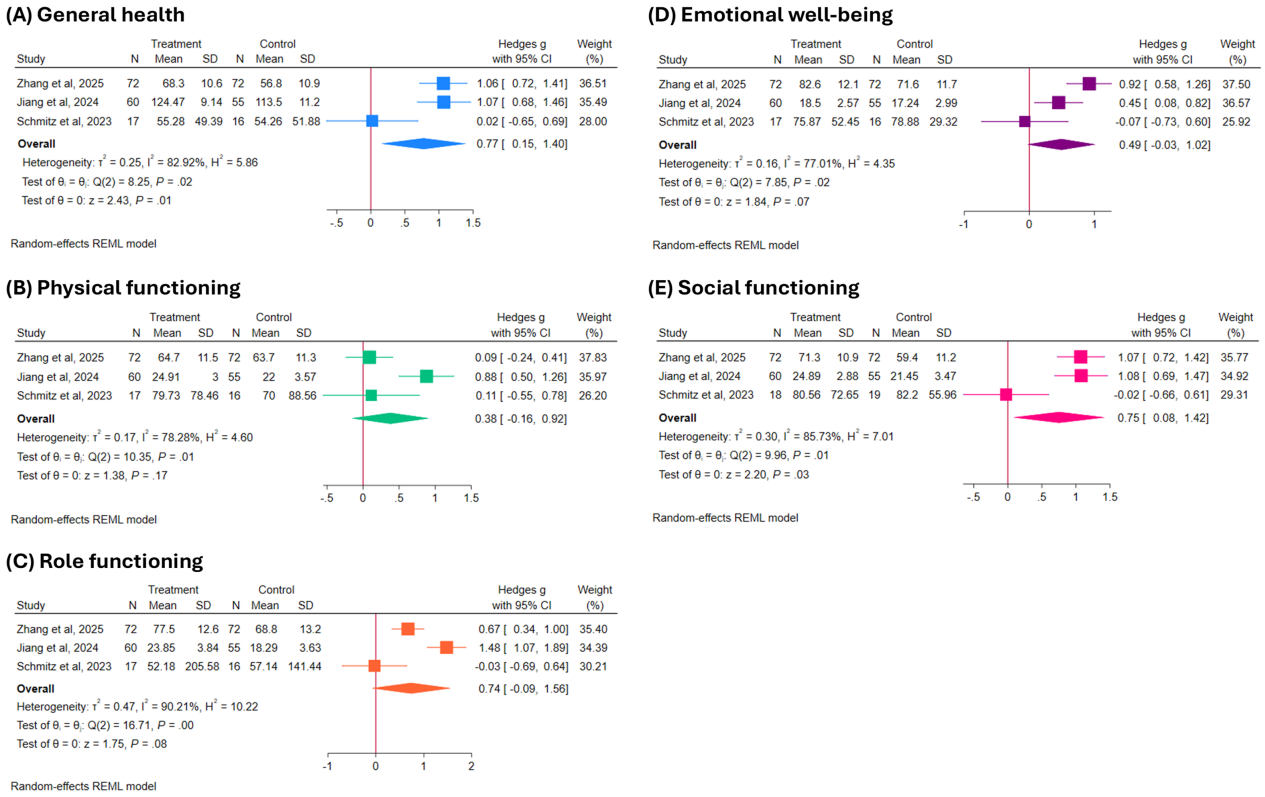
Narrative Synthesis of HRQOL Findings

Across 5 controlled studies, the 3 studies conducted in China reported improvements in at least one HRQOL domain, while the 2 US studies found no significant changes. Li et al [37] found that the intervention group showed improved global health status compared with usual care at 5 months postintervention, although no between-group differences were observed across subdomains. Zhang et al [39] reported significant improvements across nearly all HRQOL domains in the intervention group, including overall health status, role functioning, cognitive functioning, emotional functioning, and social functioning. Physical functioning (sometimes referred to by the authors as “somatic function”) was the only domain that did not differ significantly between groups at 6 months postintervention [39]. Jiang et al [35] reported that although some HRQOL domains did not change significantly at 1-month postdiagnosis, all domains, including overall HRQOL, physical, social or family, emotional, and functional well-being, as well as breast cancer-specific concerns, showed significant between-group improvements by 3 months. Hu et al [34], reporting on the same study population, similarly found that total HRQOL improved significantly more in the intervention group than in the control group over this period. In the RCTs conducted by Kamdar et al [36] and Schmitz et al [38] in the United States, no significant effects of the intervention on HRQOL were observed.

The 2 single-arm studies conducted in the United States showed similar results. Buchan et al [32] reported that 81% of users experienced some improvement in their HRQOL after using the Ina virtual dietitian. Horesh et al [33] observed within-group improvements in physical and psychological domains 24 days after the intervention, with no changes in social or environmental domains.

Quantitative Synthesis of HRQOL Findings

From the 7 identified studies, 3 (n=292) contributed to the exploratory meta-analysis examining the effect of AI-enabled DHTs on HRQOL [35,38,39]. Studies were excluded from the meta-analysis for the following reasons: single-arm studies (n=2) [32,33], lack of quantitative HRQOL data (n=1) [36], reporting HRQOL change scores without corresponding pre- and postintervention values (n=1) [37], and multiple publications from the same study (n=1) [34]. For studies with incomplete HRQOL data, we contacted the authors but received no response. In cases of duplicate publications, the report providing the most comprehensive HRQOL data was used [35]. The 3 studies included in the meta-analysis were judged to have low [34,35], some concerns [38], and serious risk of bias [39], primarily due to potential confounding.



Five HRQOL domains were analyzed: general health, physical functioning, role functioning, emotional well-being, and social functioning. In the exploratory meta-analyses, statistically significant pooled effects were found for general health (Hedges g=0.77, 95% CI 0.15 to 1.40; P=.01; I^2=82.9%) and social functioning (Hedges g=0.75, 95% CI 0.08 to 1.42; P=.03; I^2=85.7%), both indicating moderate effect sizes. However, the high heterogeneity across these analyses warrants cautious interpretation. No statistically significant effects were found for physical functioning, role functioning, or emotional well-being (see Figure 3 for estimates).

Leave-one-out sensitivity analyses indicated that the pooled effect was sensitive to individual studies for 4 of the 5 HRQOL domains. Specifically, excluding the US study by Schmitz et al [38] increased effect sizes for general health, role functioning, emotional well-being, and social functioning, while physical functioning remained stable across all exclusion scenarios (full results are provided in Multimedia Appendix 3). Excluding the studies by Zhang et al [39] or Jiang et al [35] did not change the statistical significance of the pooled effects for any domain.

Due to the small number of included studies, other subgroup analyses, as well as formal tests for publication bias (Egger regression) and visual inspection of funnel plots, were not feasible [26].

XSL•FO
RenderX

Figure 3. Forest plots of pooled mean differences in various health-related quality of life domains: (A) general health, (B) physical functioning, (C) role functioning, (D) emotional well-being, and (E) social functioning [35,38,39]. REML: restricted maximum likelihood.

Aim 3: Changes in Other PROs

In addition to HRQOL, the included studies reported other PROs, including user satisfaction and adherence, mental health, physical symptoms, additional PROs, and adverse effects.

User Satisfaction and Adherence

Five studies reported outcomes related to satisfaction or acceptability [32,33,36,38,39]. Across these studies, users consistently rated the DHTs positively, with high scores for ease of use, clarity, and overall experience. Satisfaction levels generally exceeded 70%, and usability assessments indicated strong acceptability of the DHTs. Most users found the content helpful and the DHTs easy to navigate. However, in Zhang et al [39], a small proportion reported difficulties with navigation, internet access, or understanding specific content.

Adherence and engagement with the DHTs varied across studies. Overall, most users engaged with the DHTs at least occasionally, though the frequency and consistency of engagement differed by intervention type and activity. High adherence rates were reported in 2 interventions targeting early survivorship in China, with 88% to 97% of participants completing prescribed sessions or following recommended activities [34,37]. Engagement with DHTs targeting patients with advanced cancer in the United States declined gradually over time, with weekly use dropping from initially high rates to lower levels by later weeks [36,38]. Furthermore, specific features within single DHTs were used at varying rates. For example, most participants used nutritional tips, whereas fewer used the suggested recipes in the virtual dietitian intervention by Buchan et al [32].

Mental Health

Across the included studies, 4 of 6 interventions that reported mental health outcomes showed improvements. The US single-arm hot flash intervention study reported significant reductions in perceived stress, general psychological distress, and illness perceptions from pre- to postintervention [33]. Another study targeting women with breast cancer in China showed greater decreases in psychological frailty, psychological distress, symptom frequency, and global distress in the intervention group compared with controls on follow-up [34,35]. However, the US study by Schmitz et al [38] showed no significant between-group differences in distress among metastatic breast cancer survivors. Additional evidence indicated mixed effects for anxiety. Two controlled studies from China found decreases in anxiety. While Zhang et al [39] reported greater improvement in the control group than in the intervention group, Li et al [37] found the opposite. In addition, the RCT in US patients with metastatic cancer by Kamdar et al [36] found that anxiety worsened in the intervention group compared with the control group. Depression was assessed only in the study by Zhang et al [39] involving patients with mixed cancer undergoing chemotherapy in China, which found greater improvements in the intervention group than in the control group.

Physical Symptoms

Across the included studies, several DHTs showed improvements in physical symptoms. The virtual dietitian intervention by Buchan et al [32] reported high perceived usefulness for symptom management, with approximately one-third of users showing reductions in both symptom count

XSL•FO
RenderX

and total symptom severity over time. Significant reductions in hot flash interference and frequency, along with improvements in overall sleep quality, sleep onset latency, and subjective sleep quality were observed in a US hot flash intervention [33]. Similarly, a controlled study to manage premature frailty in young breast cancer survivors from China showed greater reductions in fatigue and physical symptoms, and an increase in physical activity in the intervention group, although group-by-time effects were not significant [34]. The RCT by Kamdar et al [36] found significant reductions in pain severity over 8 weeks, with a higher proportion of participants achieving substantial pain improvement compared with the control group. Additional benefits were reported in fatigue and daytime dysfunction, following the digital cardio-oncology rehabilitation program by Li et al [37]. One controlled study of US metastatic breast cancer survivors found no significant between-group differences in pain, sleep, and fatigue [38].

Other PROs

Other PROs were examined in the studies by Hu et al [34] and Jiang et al [35], which evaluated social support and self-efficacy following a digital humanistic program to manage premature frailty in young breast cancer survivors. Social support increased over time in both the intervention and control groups, with greater improvement observed in the intervention group [34,35]. In addition, Jiang et al [35] reported an increase in self-efficacy among participants receiving the intervention.

Adverse Effects

Across the included studies, adverse events were occasionally reported and generally mild. A small proportion of participants experienced cybersickness in the AI-VR intervention by Horesh et al [33] for the management of hot flashes. In the premature frailty trial conducted in China, adverse changes were uncommon, with only a few participants showing increases in symptom levels or declines in HRQOL [34]. A US intervention for pain management in patients with advanced cancer showed a small but statistically significant increase in anxiety symptoms in the intervention group, although values remained within the mild range and below clinically significant thresholds [36]. No adverse effects were identified in 2 studies [37,38], and the remaining manuscripts did not report adverse events [32,35,39].

Discussion

Principal Findings

This systematic review synthesized evidence on available patient-facing AI-enabled DHTs and their effect on HRQOL and broader PROs in cancer populations. Eight publications from 7 studies conducted in China and the United States evaluated a range of mobile- and web-based interventions, most of which aimed to support at-home symptom management. AI was used to personalize recommendations (eg, exercise, nutrition, and symptom triage), adapt delivery formats (eg, VR and voice interfaces), and tailor educational content. Overall, the effects on HRQOL were mixed. Results from the narrative synthesis showed that among the 5 controlled studies, all 3 RCTs conducted in China found significant improvements across multiple HRQOL domains, including global health status, role, cognitive, emotional, social, and functional well-being, while neither of the 2 US RCTs found significant between-group effects. The 2 single-arm US studies suggested within-group improvements, although the absence of control groups limits the interpretability of those findings. An exploratory meta-analysis of 5 HRQOL domains showed modest improvements only in general health and social functioning, but no effect on physical functioning, role functioning, and emotional well-being. However, these results should be interpreted with caution given the small number of contributing studies, limited sample sizes, heterogeneity, and the presence of risk-of-bias concerns in individual studies. Other PROs, including mental health, physical symptoms, self-efficacy, and social support, also showed mixed but generally encouraging results. Mental health outcomes were variable, with some DHTs reducing distress or anxiety and others showing no effect or small, but not clinically significant, increases in anxiety. Despite considerable heterogeneity in both interventions and populations, most DHTs were associated with improvements in key physical symptoms, including pain, fatigue, and sleep. User adoption and satisfaction were generally high, and only mild adverse effects were reported occasionally.

Several patterns might help explain the variation in effects across studies and guide the design of future AI-enabled DHTs for cancer survivorship care. Improvements in HRQOL and other PROs were more frequent in the trials conducted in China, particularly for general health, whereas effects were less consistent across specific HRQOL domains. Two trials conducted in the United States showed no benefits in HRQOL, while 2 observational studies from the United States lacked control groups. Methodological factors, including small samples, heterogeneous measures, and short follow-up periods, likely contributed to these differences. In digital oncology research, changes in HRQOL might require sustained use of DHTs over time, as physical and psychological symptoms develop gradually [40,41]. Trials with short follow-up periods may, therefore, have lacked sufficient time to detect change, even when adherence was high. Another explanation might be differences in perceptions of AI-enabled DHTs and in-person consultations across cultures [42]. These may influence how patients interpret symptom feedback, interact with automated recommendations, and integrate digital tools into their routines. Furthermore, cross-national research suggests that social desirability bias varies across cultures, with relatively higher levels observed in China [43]. This may have led to more favorable evaluations of AI-enabled DHTs, especially in clinician-administered surveys. However, these cultural explanations remain speculative and cannot be distinguished from other country-level differences.

Our findings should be interpreted in the context of heterogeneous definitions of cancer survivorship across studies, which translate into substantial differences in symptom burden and care needs. While some interventions targeted patients with metastatic or advanced disease receiving ongoing or palliative treatment, others focused on disease-free survivors after curative therapy. Consistent with this heterogeneity, trials reporting no improvements in HRQOL tended to include patients with metastatic disease. Previous studies have shown that, among

XSL•FO
RenderX

patients with high symptom burden in palliative care settings, supportive DHTs alone are often insufficient to improve overall HRQOL, although they may alleviate specific physical symptoms [44]. Our results have partially confirmed these findings. While AI-enabled tools may offer more personalized and proactive support than traditional DHTs, their benefits may be limited in advanced disease settings. This suggests that AI-enabled interventions should be integrated with comprehensive supportive care to improve HRQOL in advanced cancer.

Studies showing positive effects on HRQOL and PROs often included human involvement. This aligns with broader evidence that digital tools can initiate but rarely sustain long-term engagement among populations with complex needs without human involvement [45]. Hybrid models that combine AI-enabled monitoring and personalization with clinician or nurse follow-up leverage the strengths of both technology and human support. Thus, they can better translate digital engagement into behavior change and symptom improvement. Interventions that supported question-asking and peer discussion also reported positive effects on PROs. Features that enable communication with clinicians or connect patients with peers may increase self-efficacy, normalize experiences, and reduce isolation—mechanisms that are widely recognized in cancer survivorship research [46]. However, AI components themselves may introduce bias. For example, NLP or large language model–based systems that classify patient input or triage symptoms can introduce systematic measurement shifts, which could affect clinical decision support [47,48]. These findings highlight the value of designing comprehensive DHTs as platforms for holistic support.

User satisfaction and engagement were high across studies, indicating strong acceptability of DHTs containing AI components in cancer survivorship care. Notably, the effects observed on HRQOL and other PROs are similar to those reported for previous digital health interventions without AI [41,46]. However, because none of the studies included equivalent DHTs without AI components, we cannot determine whether these effects are attributable to the AI functionality, other DHT features, or nonspecific effects. Therefore, integrating AI might not significantly alter patients' experiences, either by enhancing outcomes or introducing new barriers. Instead, the effectiveness of DHTs on PROs seems to depend primarily on design quality and relevance of support rather than on whether the underlying system relies on AI. Future research should focus on larger, multisite, longitudinal trials, more diverse populations with cancer, the use of traditional DHTs without AI components for control purposes, and the identification of different engagement trajectories among users. In practice, AI-enabled DHTs may support HRQOL when paired with adequate human follow-up, peer-support features, and careful patient selection based on disease stage, symptom burden, and digital readiness.

Limitations

Our findings should be interpreted in light of several limitations. First, clinical heterogeneity limits the validity of pooled estimates. The included studies covered diverse types of cancer and stages of survivorship, making a single pooled estimate for cancer survivors problematic. Furthermore, the 3 different HRQOL instruments used across studies introduce measurement heterogeneity. Readers should, therefore, interpret findings from the exploratory meta-analyses with caution.

Second, the small number of eligible studies and participants limits the statistical power of the meta-analyses. While the narrative synthesis provides additional insights, the results from the meta-analyses should be considered exploratory.

Third, methodological limitations across studies reduce comparability and generalizability and may inflate observed effects. These limitations include small sample sizes, lack of control groups or randomization, short follow-up periods, and reporting limitations. None of the studies included equivalent DHTs without AI components, so it is not possible to determine whether the observed benefits are due to AI functionality, other DHT features, or nonspecific effects.

Fourth, geographic confounding limits generalizability. The limited geographical diversity (primarily studies from China vs US) prevents the isolation of intervention effects from country-level factors such as health care systems, cultural context, or implementation characteristics.

Fifth, how AI was defined and operationalized varied across studies, ranging from rule-based decision support to ML algorithms. This complicates direct comparisons across interventions and limits the interpretability of pooled findings. Furthermore, although the search strategy was intentionally broad and included multiple AI-related terms, studies that did not adequately describe the technical components of their DHTs may have been missed. Future reviews would benefit from applying a prespecified AI classification framework.

Finally, research on AI-enabled DHT is advancing rapidly. The numerous protocols identified during the screening process suggest that more publications are forthcoming. A living systematic review approach may, therefore, be valuable for maintaining an up-to-date evidence base.

Conclusions

This review provides a timely synthesis of evidence on AI-enabled DHTs for cancer care and establishes a conceptual and methodological foundation for future work. Although effects on HRQOL were mixed, some interventions showed benefits across HRQOL domains and other PROs. Importantly, as none of the studies used control groups with equivalent DHTs without AI components, the observed benefits cannot be attributed specifically to the AI components. Our findings are preliminary, and it is too early to conclude whether patient-facing AI-enabled DHTs improve cancer survivorship care. Future research should employ active control conditions to isolate the contribution of AI features specifically.

Abstract

Background: Suicide is a leading cause of preventable mortality worldwide, with more than 700,000 deaths annually. Although suicidal ideation fluctuates rapidly, conventional risk assessments rely on retrospective self-report collected infrequently, and the detection of short-term suicide risk remains limited. Passive digital sensing using smartphones and wearable devices enables continuous monitoring of behavioral and physiological signals associated with suicide-related outcomes. However, current evidence remains fragmented, without a clear framework for translation into clinically interpretable risk indicators.

Objective: This scoping review synthesized and mapped passive digital markers associated with suicide-related outcomes via the layered hierarchical sensemaking framework (LHSF), which structures information from raw sensor data to high-level behavioral markers. We aimed to illustrate a clinically interpretable mapping of digital markers for suicide-specific digital phenotyping.

Methods: Following Arksey and O'Malley and the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) guidelines, this scoping review was conducted using the population-concept-context framework (population: not restricted; concept: passively collected digital data from smartphones or wearable devices; and context: suicide-related outcomes). PubMed, CINAHL, PsycINFO, and IEEE Xplore were searched for studies published between 2015 and 2025. Studies were included if they (1) collected passive digital data from smartphones or wearable devices, and (2) measured suicide-related outcomes. Narrative mapping was conducted using LHSF to distinguish between low-level features (ie, measurable properties extracted from sensors) and high-level behavioral markers (ie, clinically meaningful constructs interpreted from low-level features).

Results: Of 626 studies identified, 14 (2.2%) met inclusion criteria. Six (42.9%) used predictive modeling, and 8 (57.1%) conducted correlational analyses. Among predictive studies (area under the curve [AUC]=0.56-0.89), a lower heart rate variability predicted an elevated suicide risk in 1 study (AUC=0.89). Of correlational studies, 7 (87.5%) of 8 reported at least one significant association between passive sensor data and suicide-related outcomes. Mapped to the LHSF, low-level features spanned 7 domains, linked to high-level markers, such as autonomic dysregulation, sleep disturbance, social withdrawal, smartphone use patterns, and suicide-related expression. Physiological indicators of autonomic regulation were associated with suicide-related outcomes in all 4 studies examining them and achieved the highest predictive performance (AUC=0.89). Smartphone use metrics were significantly associated in both studies, whereas linguistic (2/3 studies, 66.7%) and location-based features (2/2 studies, 100%) were associated with at least one outcome, with nonsignificant findings for some indicators or studies. Sleep parameters and movement intensity showed few significant associations.

XSL•FO
RenderX

Conclusions: Physiological indicators were associated with suicide-related outcomes across all relevant studies and showed the highest predictive performance (AUC=0.89), followed by smartphone-derived behavioral features. Linguistic and location-based features showed mixed associations, whereas sleep- and activity-related indicators showed few significant associations. Future research should prioritize multimodal data integration, algorithmic refinement, and external validation to strengthen clinical utility in digital suicide phenotyping based on the LHSF.

suicide; passive sensing; digital phenotyping; smartphones; wearable devices; scoping review; suicide-related outcomes

Introduction

Suicide is a leading cause of preventable mortality worldwide, with more than 700,000 individuals dying by suicide annually, accounting for approximately 1% of all deaths globally [1,2]. Recognizing its substantial public health burden, the United Nations has included a Sustainable Development Goals (SDG)–specific target (SDG 3.4.2) to reduce the national suicide mortality rate by one-third by 2030. Interviews and self-reported questionnaires are frequently used to evaluate suicide risk, such as suicidal ideation, plans, and past behaviors via standardized instruments [3,4]. However, these measures are typically administered at a single clinical encounter or at intervals and rely on individuals' recall of experiences over extended periods (eg, the past week or month) [5]. In practice, suicidal thoughts and related risk processes are highly dynamic, with meaningful fluctuations occurring over short timescales. Coppersmith et al [6] found that episodes of elevated suicidal ideation often lasted only 1 to 3 hours on average. An ecological momentary assessment (EMA) study in psychiatric inpatients with depression reported that momentary hopelessness and perceived burdensomeness significantly predicted suicidal ideation at the next assessment [7]. EMA studies indicate that only high-frequency, in situ assessments can capture short-term risk processes [8,9]. Consequently, conventional suicide risk assessments based on retrospective recall and infrequent administration often fail to detect brief but clinically critical risk elevations [8,9].

Researchers have increasingly used digital data as a complementary source of behavioral and psychological information to advance early identification and intervention. Recent advances in information and communication technologies have enabled passive digital sensing via smartphones and wearable devices, which has become a promising tool for continuous monitoring of mental health–related physiological and behavioral changes [10]. These devices capture real-world data on physiological reactions, physical functions, and daily activities, and enable assessments beyond clinical settings with ecological validity. This has fueled digital phenotyping research aiming to infer mental health states from patterns in digital traces [11]. Despite increasing digital sensing research on suicide risk, studies report heterogeneous digital indicators, including physiological (eg, heart rate variability [HRV]), behavioral (eg, physical movement), and smartphone-derived contextual features (eg, text language use).

However, this recent evidence remains inconsistent, and the sensors or digital features most robustly associated with suicidal thoughts and behaviors remain unclear for several reasons. First, the robustness of sensor signals is often insufficient; many passive sensing features, including physiological measures, lack stability across devices or populations and provide limited incremental value beyond traditional self-report measures [12]. Second, individual heterogeneity makes universal indicators difficult to define, as suicide risk is an idiosyncratic process rather than a monolithic state [13]. Although specific markers, such as active midnight smartphone use (11 PM to 1 AM), may predict next-day ideation, other indicators, such as decreased social frequency, remain ambiguous. These indicators may signal crisis for some but represent benign routine for others [14]. Such variability, often referred to as phenotypic equifinality, indicates that similar digital behaviors reflect different risk levels based on an individual's baseline, complicating standardized interpretation. Third, traditional gold-standard interviews often miss the proximal, transient triggers (eg, acute midnight loneliness or sudden sleep deprivation) that are visible only through "screenomics" data [15], creating a disconnect between real-time digital markers and traditional interviews. Consequently, clear guidance on the sensors or digital features that should be prioritized for reliable monitoring is lacking, limiting the translational potential of digital sensing in suicide or other clinical risk assessment.

Addressing these limitations requires a structured framework that can systematically translate passive sensor data into clinically meaningful suicide-related states. Mohr et al [16] proposed the layered hierarchical sensemaking framework (LHSF), which conceptualizes the transformation from low-level sensor data to high-level behavioral markers. This scoping review aimed to apply the LHSF to (1) systematically map how digital sensor data were transformed into low-level features, high-level behavioral markers, and suicide-related outcomes; and (2) propose a clinically interpretable structure for suicide-specific digital phenotyping to develop actionable digital markers.

Methods

Overview

This scoping review was conducted based on Arksey and O'Malley's methodological framework and the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) guidelines (Checklist 1) [17,18]. The review was guided by the population-concept-context framework (population: not restricted; concept: passively collected digital data from smartphones or wearable devices; and context: suicide-related

XSL•FO
RenderX

outcomes). The study was conducted through collaboration among 3 research teams, with external validation performed by separate research teams. Fourteen studies were analyzed based on the LHSF using a structured data charting and synthesis approach [16], and Google Sheets was used as a data management tool. The protocol was registered in the Open Science Framework [19].

Search Strategy

Textbox 1 summarizes the query terms used in the search strategy. The search strategy was developed iteratively using the population-concept-context framework to ensure alignment with the review objectives. Four databases (PubMed, CINAHL, PsycINFO, and IEEE Xplore) were searched for studies published between January 1, 2015, and December 31, 2025. The search combined suicide-related terms with those related to digital sensing, as summarized in Textbox 1 (see full search strings in Multimedia Appendix 1). The final search was conducted in December 2025. Gray literature was excluded from the scope of this review. This boundary was established because the primary objective was to map granular digital signals onto the structured LHSF framework, which requires fully detailed and finalized descriptions of raw sensor processing, feature extraction, and statistical verification—details that are often omitted or partially reported in non–peer-reviewed literature. The reference list screening was conducted to identify additional relevant studies. A librarian at the affiliated medical library was consulted to review and refine the search strategy to enhance comprehensiveness and accuracy.

Textbox 1. Summary of the search terms.

Suicide-related terms include the following:

- Suicide
- Suicidal ideation
- Suicide attempt
- Suicide risk
- Suicidal behavior

Digital sensing terms include the following:

- Smartphone
- Wearable devices
- Passive sensing
- Digital marker
- Digital phenotype

Eligibility Criteria

We included studies that reported correlational or predictive analyses that explored digital markers with suicide-related outcomes. Studies that relied solely on active data collection methods or did not assess suicide-related outcomes were excluded. No language restrictions were applied. Textbox 2 summarizes the detailed inclusion and exclusion criteria. The publication period was restricted to studies from January 2015 onward, corresponding to the introduction of digital phenotyping in clinical research and wearable devices [20].

Textbox 2. Inclusion and exclusion criteria.

Inclusion criteria

- Full-text, peer-reviewed studies (including articles published online ahead of print)
- Studies that used passively collected digital data from smartphones or wearable devices
- Studies that measured suicide-related outcomes, including suicidal ideation, plans, attempts, behaviors, or suicide risk
- Studies that analyzed associations between passive digital data and suicide-related outcomes or developed predictive models to examine suicide-related outcomes

Exclusion criteria

- Studies that used only active data collection methods (eg, online surveys, self-report questionnaires, or ecological momentary assessment apps)
- Studies that did not assess suicide-related outcomes and only focused on general mental health indicators (eg, depression, stress, or nonsuicidal self-injury)
- Feasibility studies that did not examine associations or predictive relationships between passive digital data and suicide-related outcomes
- Reviews, protocols, commentaries, conference abstracts, or non–peer-reviewed studies

RenderX

Study Selection

Two authors (SK and JK) independently screened the titles and abstracts of potentially eligible studies, followed by full-text review. If disagreements arose, they were resolved through discussion between 2 reviewers, and those not resolved were adjudicated by the principal investigator (HK).

Data Charting

Two authors (SK and JK) initially extracted the data, which were reviewed by the principal investigator (HK). Subsequently, 2 separate teams (WTC and YZ; and TTL and ZYAT) provided external validation and contributed to refining the analysis. Discrepancies were resolved through team discussion. Google Sheets was used to organize a structured data matrix for data charting. The data charting form was developed by the research team and refined through discussion prior to full data extraction. Study characteristics, device and sensor types, and low-level features and high-level behavioral markers were charted. Narrative mapping was conducted according to the LHSF [16]. This scoping review followed Joanna Briggs Institute recommendations for scoping reviews [21]. Consistent with these guidelines, methodological quality assessment was not performed.

Data Synthesis Using the LHSF

The LHSF was applied to organize data from raw sensor inputs to inferred behavioral patterns related to suicidality [16]. On the basis of the 4 hierarchical layers, the extracted features were grouped:

1. Sensor: hardware- or software-based sources within smartphones, wearables, or apps that passively collected environmental or behavioral data (eg, accelerometer, photoplethysmography, and phone usage logs);
2. Low-level features: quantitative indicators derived directly from raw sensor data (eg, step count and HRV);
3. High-level behavioral markers: psychosocial or behavioral patterns inferred from combinations of low-level features (eg, sleep disturbance and social withdrawal); and
4. Suicide-related outcomes: clinical indicators, such as suicidal ideation, suicide attempts, or suicide risk.

To synthesize findings across the 4 levels, we organized and categorized extracted features according to the LHSF structure. While the original framework was retained, specific digital features and behavioral markers were refined and expanded based on the included studies to reflect recent advances in digital phenotyping research. This approach enabled us to map contemporary empirical evidence onto the existing framework.

To ensure consistent operationalization across layers, explicit decision rules were applied during data charting. A feature was classified as a low-level indicator (layer 2) if it represented a directly quantifiable, sensor-derived measurement requiring no inferential interpretation. A construct was classified as a high-level behavioral marker (layer 3) if it represented a psychosocial or clinical construct that required aggregating or theoretically interpreting one or more low-level features. When the original study explicitly used a term corresponding to a layer 3 construct, it was retained as source defined. When no such label was present, 2 authors (SK and JK) independently derived a conceptually equivalent label based on the analytical context of the original study, indicated by superscript “a” in Table 1. Discrepancies in layer assignment or label derivation were resolved through discussion. A detailed overview of the operationalization criteria applied to each study is provided in Multimedia Appendix 2.

Table . Passive data sources and extracted features mapped to the layered hierarchical sensemaking framework (LHSF).

Study	Device	LHSF layer 1: sensor	LHSF layer 2: low-level features	LHSF layer 3: high-level behavioral markers	LHSF layer 4: suicide-related outcome (measures)
[22]	Smartphone	SMS text	Linguistic inquiry and word count–based word proportions (eg, first-person pronouns, emotion-related words) and communication activity (eg, message counts and sent-to-received message ratios)	Psychological and behavioral patterns[a] (self-focus, sentiment, and social engagement)	Suicide attempts: high risk; suicidal ideation: moderate risk; depressed and positive episodes: low/minimal risk (retrospective episode-based interview)
[23]	Smartphone	Screen time app	Smartphone screen time per app category	Smartphone use patterns[a]	Suicide risk: past suicide attempts, suicidal ideation frequency, suicide threat, and perceived likelihood of death by suicide (Suicidal Behaviors Questionnaire-revised)
[24]	Wearable (wristband)	Photoplethysmography sensor	High-frequency HRV[b] power	Reduced parasympathetic activity	Suicide severity: suicidal ideation and behavior (Columbia-Suicide Severity Rating Scale)
[25]	Smartphone, wearable (wristband)	Electrodermal activity sensor	Number of autonomic events	Autonomic arousal	Suicidal ideation (EMA[c])
[26]	Smartphone, wearable (wristband)	Not stated but sensors embedded in wristband	Sleep minutes and step counts	Sleep patterns and activity patterns	Suicidal ideation (Patient Health Questionnaire-item 9)
[27]	Smartphone	SMS text	Incidence of sleep-related text messages, the number of nightly texts sent, and the number of unique nightly hour bins	Sleep disturbance	Suicidal ideation; suicide attempts (clinical interview)
[28]	Smartphone, wearable (wristband)	Not stated but sensors embedded in wristband	Root-mean-square of successive differences, resting heart rate, total steps, and sleep duration	Distress, physical activity, and sleep disturbance	Next-day suicidal ideation (EMA using Columbia-Suicide Severity Rating Scale-based items)
[29]	Wearable (compression shirt)	Electrocardiogram and pressure sensors	HRV indices and respiratory rate	Autonomic imbalance	Current suicidal ideation; history of suicide attempts (Schedule for Affective Disorders and Schizophrenia-Lifetime version–based clinical interview)
[30]	Smartphone	Global positioning system, actigraphy (sensor was not stated); health data aggregation app; and phone usage logs (app usage logs)	Distance walked, time spent at home, steps taken, and app usage (binary)	Behavioral changes in daily activity profiles	1-week suicide-risk events (electronic health records)
[31]	Smartphone, wearable (wristband)	Three-axis accelerometer	Time in bed, sleep onset latency, sleep duration, wake after sleep onset, and sleep efficiency	Sleep disturbance	Next-day suicidal ideation (EMA)

XSL•FO
RenderX

Study	Device	LHSF layer 1: sensor	LHSF layer 2: low-level features	LHSF layer 3: high-level behavioral markers	LHSF layer 4: suicide-related outcome (measures)
[32]	Smartphone	GPS	Time at home, entropy (location variability), and distance traveled	Social connectedness, behavioral withdrawal, and anhedonia	Next-week suicidal events: attempts, psychiatric hospitalization, suicide-related emergency department visits (Self-injurious Thoughts and Behaviors Interview, weekly experience sampling method, Columbia-Suicide Severity Rating Scale); same-week/next-week suicidal ideation (weekly experience sampling method)
[33]	Wearable (wristband)	Photoplethysmography sensor, accelerometer, and gyroscope	Heart rate and HRV, movement index, wear-free time, step count, walking/running time, other exercise time, resting time, and total sleep time	Stress states (autonomic dysregulation), daily behavioral patterns[a]	Elevated suicide risk: suicidal ideation and behavior (Hamilton Depression Rating Scale-item 3)
[34]	Smartphone	Screen capture app	Dictionary-based word counts	Expression related to suicide risk[a]	Passive/active suicidal ideation, suicidal planning (EMA)
[35]	Smartphone	Screen capture app	Smartphone screen time (screenshot image counts, any use, and proportion of use)	Temporal patterns of smartphone use[a]	Suicide risk: suicidal ideation, suicidal planning, and suicidal desire (EMA)

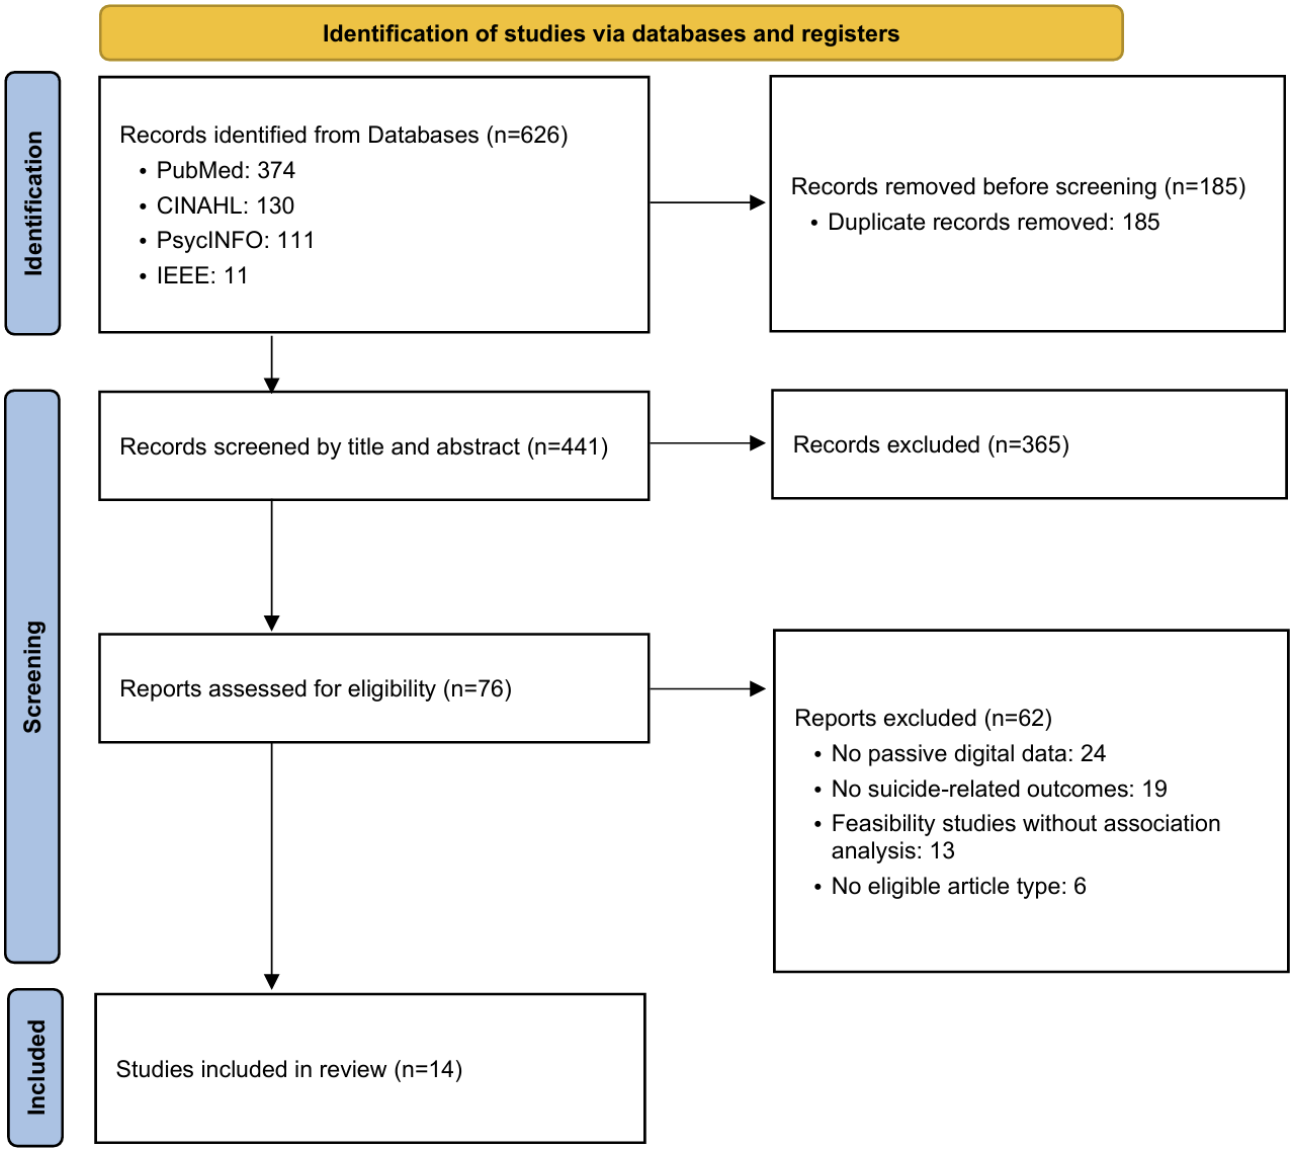
[a]These categories represent high-level behavioral markers (LHSF layer 3) derived by the authors and were not explicitly defined as such in the original studies.

[b]HRV: heart rate variability.

[c]EMA: ecological momentary assessment.

Synthesis of Evidence Strength Across Feature Domains

To summarize the strength of evidence across feature domains, each study was classified according to the statistical results reported in the original article. A study was counted as showing a significant association for a given feature domain if at least one indicator in that domain was significantly associated with, or predictive of, at least one suicide-related outcome, such as suicidal ideation, planning, attempts, risk, or events. This classification was retained even when other indicators or outcomes within the same study were nonsignificant. Domain-level evidence was then described by the number of studies reporting significant associations, rather than by a single subjective judgment. Predictive performance was interpreted against a conventional discrimination threshold of an area under the curve (AUC) of 0.80 or above.



Results

Selection of Sources of Evidence

We conducted the final search in December 2025 and identified 626 studies across the 4 databases (PubMed: n=374; CINAHL: n=130; PsycINFO: n=111; and IEEE Xplore: n=11). After removing 185 duplicate records, 441 (70.4%) articles were screened based on their titles and abstracts. Of these, 365 (82.8%) records were excluded, and 76 (17.2%) full-text articles were assessed. Subsequently, 62 (81.6%) articles were excluded (Figure 1). Ultimately, 14 (18.4%) studies were included [22-35]. Reference list screening identified no additional eligible articles.

XSL•FO

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram.

Characteristics of the Included Studies

Table 2 presents the characteristics of the included studies. Publication years of the 14 included studies ranged from 2020 to 2025, with most of the studies published in 2025 (n=5, 35.7%). Most studies were conducted in the United States (n=11, 78.6%). All included studies used observational designs, in which 12 (85.7%) were longitudinal studies, and 2 (14.3%) were cross-sectional. Furthermore, 11 (78.6%) studies were in prospective design, and 3 (21.4%) were retrospective ones. Regarding characteristics of participants, 3 (21.4%) studies included adolescents, and 11 (78.6%) studies included only adults. Most studies targeted high-risk populations (n=12, 85.7%), such as individuals who visited emergency departments for suicide-related reasons, psychiatric inpatients or outpatients, and those with a history of suicidal ideation or behavior. Duration of passive data collection varied across studies, ranging from 24 hours to 6 months.

Ammerman et al[b] (2025) [34]	United States	• Observational • Longitudinal • Quantitative • Prospective	79	• High-risk adults who reported past-month active suicidal ideation or behaviors • Age: mean 35.15 (SD 11.07; range: 20 - 63) y	• Female ratio: 68.3% • Community setting	28 d
Jacobucci et al[b] (2025) [35]	United States	• Observational • Longitudinal • Quantitative • Prospective	79	• High-risk adults who reported past-month suicidal ideation or behaviors • Age: mean 35.15 (SD 11.07; range: 20 - 63) y	• Female ratio: 68.3% • Community setting	28 d

[a]Passive data were collected and analyzed cross-sectionally over a 2-week period within a larger longitudinal project.

[b]Studies 34 and 35 utilized the same dataset; however, they analyzed different independent variables (passive sensing-based text patterns vs. smartphone screen time).

Regarding demographic composition, most study samples were predominantly White or Caucasian, with White participants comprising 57% to 90% of samples across studies reporting race or ethnicity. Female participants comprised the majority

XSL•FO
RenderX

across all studies, with female ratios ranging from 56% to 84.8%. Although most studies recruited high-risk adult clinical populations, 3 (21.4%) studies included adolescents. Among studies reporting clinical diagnoses, depressive and anxiety disorders were the most represented conditions. Socioeconomic status was inconsistently reported; where reported, samples tended to include participants with different levels of college education or current employment. Detailed demographic and clinical sample characteristics are presented in Multimedia Appendix 3.

Passive Data Sources and Extracted Features Mapped to the LHSF

Overview

We mapped the passive data sources and features extracted from the 14 studies according to the 4-layer structure of the LHSF (Table 1) [16]. Results were presented from data sources to suicide-related outcomes. High-level behavioral markers (layer 3) were labeled using the terminology reported in the original studies. When not explicitly defined, conceptually similar descriptors derived by the authors were indicated with the superscript "a" (Table 1).

LHSF Layer 1: Sensors

Passive sensing devices were categorized as smartphones and wearable devices. All wearable devices were wristband based, except for 1 study that used a compression shirt equipped with sensors to measure the respiratory rate [29]. Smartphones were used either alone or in combination with wearable devices in studies that assessed suicide-related outcomes via EMA [25,28,31,34,35] or experience sampling method [32].

Wearable devices primarily collected physiological signals, including photoplethysmography [24,33], electrodermal activity [25], accelerometer and gyroscope data [33], electrocardiogram signals [29], and pressure sensor data [29], which were used to derive indicators, such as HRV and autonomic nervous system responses. In contrast, smartphones captured behavioral data, including location information via a global positioning system [30,32], accelerometer-based sleep metrics [31], screen time [23], screen capture data [34,35], phone usage logs [30], and SMS text data [22,27].

LHSF Layer 2: Low-Level Features

Low-level features were extracted from sensor data and categorized into physiological, behavioral, and digital indicators. Physiological indicators included heart rate and HRV indices, respiratory rate, and electrodermal activity [24,25,28,29,33]. Behavioral and physical activity indicators comprised step counts, distance traveled, exercise and rest duration, total sleep time, and mobility entropy [26,28,30-33]. Digital behavioral indicators included smartphone screen time and phone usage logs [23,30,35], dictionary-based word counts [34], number of nighttime text messages sent [27], and ratios of sent-to-received text messages [22]. Studies that analyzed text message content included dictionary-based linguistic features, such as emotion-related or sleep-related word usage [22,27].

LHSF Layer 3: High-Level Behavioral Markers

High-level behavioral markers were derived through an integration of low-level features. Studies (n=4, 28.6%) that leveraged physiological low-level features mapped these indicators to markers that reflected reduced parasympathetic activity or autonomic dysregulation, corresponding to altered autonomic nervous system regulation [24,25,29,33].

Studies (n=6, 42.9%) based on behavioral low-level features identified high-level markers that captured changes in overall daily activity profiles. These markers included sleep patterns or sleep disturbance, changes in activity patterns and activity levels, social connectedness, behavioral withdrawal, and anhedonia, which reflected behavioral and psychosocial characteristics [26,28,30-33].

Studies (n=4, 28.6%) that used smartphone-based digital behavioral features and reported high-level markers included smartphone use patterns or temporal changes in use, changes in daily activity profiles, and sleep disturbance [23,27,30,35]. In addition, 3 (21.4%) studies derived high-level markers from text-based analyses, which included expressions related to suicide risk, self-focus, sentiment, and social engagement, representing psychological and behavioral patterns [22,27,34].

LHSF Layer 4: Suicide-Related Outcomes

Suicide-related outcomes were assessed using clinical measures and real-time monitoring. Outcomes included suicidal ideation and planning, suicide attempts, severity, risk, and events.

Many studies reported suicide-related outcomes measured via EMA or experience sampling methods [25,28,31,32,34,35], including those that administered standardized clinical questionnaires via EMA [28]. In addition, several studies assessed suicide-related outcomes via structured clinical interviews or standardized questionnaire items [23,24,26,28,29,32,33]. The Columbia-Suicide Severity Rating Scale was the most frequently used clinical instrument [24,28,32]. One study identified suicide-related events from electronic health records [30].

Associations and Predictive Relationships Between Passive Digital Markers and Suicide-Related Outcomes

Overview

Table 3 presents the statistical analyses and main findings of the relationships between passively collected digital features and suicide-related outcomes across the 14 studies.

XSL•FO
RenderX

Table . Association and prediction between passive digital markers and suicide-related outcomes.

Study	Outcome type	Main statistical analysis methods	Predictive metric	Predictive performance	Main findings	Further suggestion
[22]	Association	Mixed effects models (generalized linear and linear mixed effects models)	Not applicable	Not applicable	• Steeper increases in anger (χ^2_3=7.83; *P*=.049) and steeper decreases in positive emotion (χ^2_3=41.67, *P*<.001) over time were associated with suicide attempt episodes (high risk) compared with other episodes (moderate risk, minimal or no risk). • Increases in self-focus did not uniquely distinguish suicide attempt episodes from all other episode types (*P*=.37 when compared to positive mood episodes).	• Prospective, frequently assessed designs • Objective classification of suicide-related events • Larger samples for adequate power • Development of machine learning models for real-time prediction of suicide risk • Advanced Natural Language Processing beyond dictionary-based methods
[23]	Association	Zero-inflated negative binomial regression and hierarchical regression analysis	Not applicable	Not applicable	• Higher use of entertainment apps in girls and reading apps in boys was associated with increased suicide risk (girls: β=.23 - .25; *P*<.001; boys: β=.28 - .29; *P*<.001). • Video game use was associated with higher suicide risk among boys experiencing cybervictimization (β=.27; *P*=.01).	• Replication in clinical high-risk samples • Longitudinal studies incorporating passive sensing from earlier waves • Repeated baseline and longitudinal assessment of suicide risk • Examination of contextual factors associated with media use

XSL•FO

[35]	Association	Bayesian zero-inflated negative binomial multilevel model	Not applicable	Not applicable	Within-person increases in smartphone screen time were associated with higher near-term (<3 h) suicidal ideation (passive: *b*=0.04, 95% CI 0.02 - 0.06; active: *b*=0.04, 95% CI 0.02 - 0.07) and suicidal planning (*b*=0.15, 95% CI 0.02 - 0.26).	• Examination of screen content and contextual factors • Refinement of temporal modeling • Validation in larger and more diverse samples

[a]HRV: heart rate variability.

[b]AUC: area under the curve.

[c]Ref 32 reported both associational (effect estimates) and predictive (AUC) findings from a single modeling approach and was classified as a predictive study for the analytic-approach count.

Statistical Analyses and Predictive Modeling

Across the 14 studies, 6 (42.9%) used predictive modeling approaches [25,26,28,30,32,33], and 8 (57.1%) conducted association or correlational analyses [22-24,27,29,31,34,35]. One predictive study [32] also reported association findings from the same modeling framework and was therefore included in the predictive group. Among studies that used predictive models, reported model performance varied, and AUC values ranged from 0.56 to 0.89.

Physiological Indicators

All 4 (28.6%) studies examining physiological digital features related to autonomic regulation reported at least one significant association with suicide-related outcomes [24,25,29,33]. Increased high-frequency HRV at night was significantly associated with decreased suicide severity [24]. Autonomic arousal events derived from electrodermal activity improved the model performance for predicting the severity of suicidal ideation; however, adding these features worsened model fit when the outcome was the presence of suicidal ideation [25]. Lower HRV-related features were identified as key predictors of an elevated suicide risk with excellent discrimination (AUC=0.89 for the multistep model) [33]. In contrast, physiological activity and sleep data had limited predictive value for suicide risk [33]. Individuals with a history of suicide attempts also exhibited increased respiratory rates and higher low-frequency to high-frequency HRV ratios compared with those without such history [29].

Mobility and Geolocation Indicators

Two (14.3%) studies examining mobility and geolocation-derived behavioral markers reported at least one significant association with suicide-related outcomes [30,32]. Behavioral changes derived from smartphone data predicted suicide risk events over 1 week with acceptable classification performance (AUC=0.78) [30]. In one predictive study that also examined within-person associations [32], greater increases in homestay were significantly associated with next-week suicidal events (adjusted odds ratio=1.99, *P*=.01); however, predictive accuracy based on the homestay model was modest (AUC=0.64). Other geolocation features, such as entropy and distance traveled, were not significant predictors of suicidal incidents. Additionally, no geographical information was associated with next-week suicidal ideation [32].

Smartphone Use Patterns

Two (14.3%) studies examining smartphone use patterns reported significant associations with suicide-related outcomes [23,35]. Higher entertainment and reading app use in girls and boys, respectively, were associated with increased suicide risk; additionally, video game use was associated with elevated risk among boys who had experienced cybervictimization [23]. Within-person increases in smartphone screen time were associated with higher levels of near-term (within 3 h prior to EMA assessment) suicidal ideation and planning [35].

Sleep Indicators

One case series study examined participant-specific associations between actigraphy-derived sleep features and next-day suicidal ideation using individual-level (within-person) regressions [31]. Assessed sleep metrics included time in bed, sleep onset, sleep duration, sleep efficiency, and wake after sleep onset. Among the 5 sleep metrics assessed, only wake after sleep onset was significantly associated with higher next-day suicidal ideation, and this association was observed in only 1 of the 7 participants. Sleep features examined in predictive contexts likewise showed no incremental predictive value [26,28].

Linguistic and Communication Markers

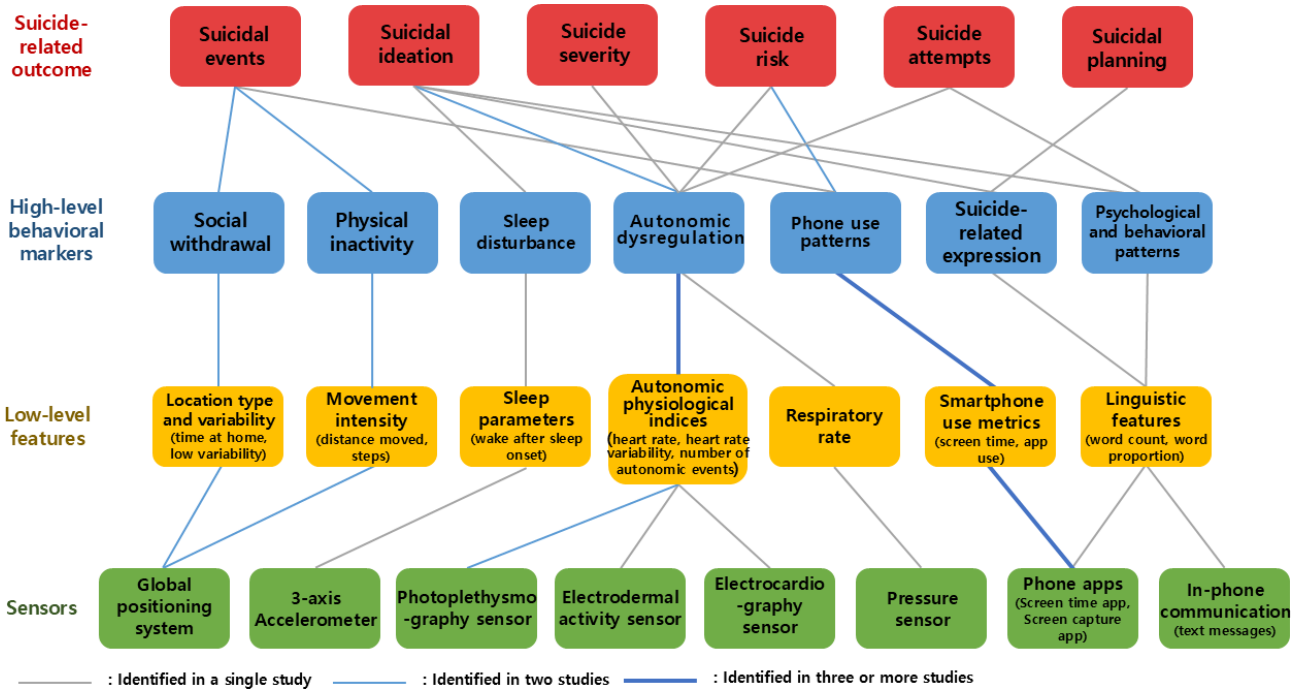
Three studies examined linguistic and communication-based markers derived from smartphone text data [22,27,34]. Of these, 2 reported at least one significant association [22,34], and 1 reported no significant association [27]. In a study by Ammerman et al [34], smartphone text patterns related to suicide risk were significantly associated with both passive and active suicidal ideation, as well as suicidal planning. In a retrospective episode-based analysis [22], trajectories of emotion-related language differed across suicide risk levels: before suicide attempts, anger increased and positive emotion decreased over

XSL•FO
RenderX

2 weeks, although self-focus did not consistently differentiate episode types. In contrast, sleep-related linguistic features and nocturnal texting patterns were not significantly associated with suicidal ideation or suicide attempts [27].

Nonsignificant or Limited Predictive Performance

Two (14.3%) studies reported nonsignificant or limited predictive performance for sleep- and activity-related passive features [26,28]. In predictive contexts, passively collected sleep and physical activity features had limited or no incremental predictive value for suicidal ideation when compared with, or added to, clinician-rated or self-reported measures [26,28]. In one study, passive sensor data alone demonstrated poor predictive performance for next-day suicidal ideation (AUC=0.56) and did not improve prediction when combined with EMA features [28].



Future Research Directions Identified Across Studies

Across the included studies, several directions for future research were identified (Table 3). First, many studies emphasized the need for replication in larger and more diverse samples, along with the use of longitudinal designs, and more frequent assessments to improve the robustness and generalizability of findings [22-24,27,28,31,33,35]. Second, a consistent focus was placed on improving data quality and methodological approaches, including refinement of passive sensing features, optimization of temporal resolution, and the application of more advanced analytic techniques such as machine learning and natural language processing [22,25-28,33-35]. Third, these findings collectively highlight the critical need to bridge the gap between passively collected digital data and clinically interpretable indicators of suicide risk [30,32]. Although diverse data streams and analytic approaches are increasingly used, there remains a lack of structured approaches to translate low-level digital features into meaningful behavioral or clinical constructs. This underscores the importance of developing frameworks that can systematically organize and represent the relationships between raw data and clinically relevant suicide-related outcomes. Further details are provided in Table 3.

LHSF-Based Conceptual Synthesis of Passive Digital Markers and Suicide-Related Outcomes

Figure 2 presents the LHSF-based conceptual mapping synthesizing the reported associations between passive digital markers and suicide-related outcomes. Low-level features extracted from passive sensors consisted of 7 domains, including location type and variability, movement intensity, sleep parameters, autonomic physiological indices, respiratory rate, smartphone use metrics, and linguistic features.

Figure 2. Layered hierarchical sensemaking framework–based conceptual mapping of reported associations between passive digital data and suicide-related outcomes.

Across the 4 layers of the LHSF, physiological sensor-derived features were linked to autonomic dysregulation markers in all 4 relevant studies and showed associations with very diverse outcomes, including suicidal ideation, suicide severity, risk, and attempts. Behavioral and mobility-related features derived from the global positioning system and accelerometers mapped to high-level markers that captured social withdrawal, physical inactivity, and sleep disturbance. These markers showed associations with suicidal ideation and suicide-related events. Smartphone use metrics mapped to smartphone use patterns and were linked to suicide-related events and risk indicators, including suicidal ideation and planning. Linguistic features extracted from text messages mapped to high-level markers that reflected expression related to suicide risk and psychological and behavioral patterns. These markers were associated with suicidal ideation, planning, and suicide attempts. Overall, mapping revealed that passive digital markers were represented across multiple hierarchical levels of the LHSF and linked to diverse suicide-related outcomes.

Discussion

Main Findings

This scoping review proposed a suicide-specific adaptation of the LHSF to integrate fragmented evidence from digital sensing studies into clinically meaningful behavioral markers in suicide research. The adapted LHSF organized diverse digital features into higher-order constructs, such as autonomic dysregulation, sleep disturbance, and psychosocial dysfunction, and provided a conceptual bridge between technical sensor outputs and clinically interpretable suicide-related states.

Physiological Indicators

Autonomic indicators, particularly HRV-related features, were significantly associated with suicide-related outcomes in all 4 relevant studies and achieved the highest predictive performance among the included studies (AUC=0.89) [33]. Beyond prediction, HRV and autonomic measures were repeatedly associated across the broadest range of suicide-related outcomes in correlational studies, including suicide severity, current suicidal ideation, and attempt history [24,29]. However, they should be interpreted alongside other behavioral and contextual markers [24,36]. This pattern is consistent with prior evidence linking autonomic dysregulation to suicide risk [36,37]. Suicidality was associated with dysregulation of the autonomic nervous system, reflected in reduced parasympathetic activity and altered HRV [36]. Electrodermal activity improved model performance for predicting the severity of suicidal ideation; however, it worsened model fit when the outcome was the presence of suicidal ideation [25].

Passive physiological monitoring, including HRV assessment using wearable devices, might complement conventional suicide risk assessments, particularly for individuals who did not accurately disclose their suicidal ideation or behavior. Passively collected physiological data could be processed into HRV indices that reflect autonomic nervous system regulation and dysregulation [38,39]. These physiological changes could be clinically meaningful, as substantial alterations in HRV might be interpreted as indicators of psychological distress. However, as predictive performance varied across studies and outcomes, such measures should be appropriately considered as objective correlates associated with suicide-related risk rather than stand-alone clinical markers.

Mobility and Geolocation Indicators

Mobility- and geolocation-derived indicators suggest that changes in spatial behavior may reflect proximal signals of suicide-related risk, particularly when considered as within-person deviations rather than absolute behavioral levels. Increases in homestay and reductions in mobility were associated with subsequent suicidal events, indicating that disruptions in daily movement patterns might capture short-term risk dynamics [30,32]. These behavioral shifts might represent early manifestations of psychosocial withdrawal and loss of daily structure, both well-established precursors of suicidal crises, rather than reflect isolated symptoms. Therefore, abrupt deviations from an individual's routine can be interpreted as signals of functional deterioration difficult to capture using conventional self-reporting methods.

However, the predictive value of geolocation features differed across indicators; measures such as entropy and distance traveled were not significantly associated with suicide outcomes [32]. These findings could suggest that mobility-based markers might be sensitive to contextual and individual variability and thus should be interpreted in relation to personalized baseline patterns. From a clinical perspective, this supports an approach that prioritizes within-person changes over static thresholds, reflecting a broader shift toward dynamic and temporally sensitive models for suicide risk assessment [28].

Smartphone Use Patterns

Although smartphone use patterns captured dynamic behavioral changes associated with short-term suicide-related outcomes, their interpretation remained highly context dependent. When individuals spend more time on their smartphones, they are more likely to experience near-term suicidal ideation and planning, suggesting that heightened device engagement might reflect acute psychological states preceding suicide risk [35]. Research indicated significant associations between specific app usage patterns and suicide risk, with certain types of media use being linked to elevated risk under specific conditions [23]. In addition, behavioral changes derived from passively collected smartphone usage data demonstrated the ability to predict suicide-related events over short time frames, including suicide attempts and psychiatric emergency visits [30].

As a result, smartphone-derived behavioral data could serve as real-time proxies for the underlying cognitive and emotional processes. However, digital behaviors were inherently ambiguous and thus might reflect multiple psychological functions, including coping, avoidance, and social interaction. Hence, smartphone-based indicators should be interpreted with caution and combined with other data sources such as EMA or clinical assessments, to improve their reliability and clinical interpretability.

Sleep Indicators

Few sleep-related indicators were significantly associated with suicidal outcomes [31]. Only one actigraphy-derived metric, wake after sleep onset, was significantly associated with next-day suicidal ideation, and only in 1 of 7 participants at the individual level; other sleep parameters were not significantly associated [31]. A likely explanation is methodological rather than substantive. As actigraphy infers sleep from movement, it detects sleep with high sensitivity but poorly identifies wakefulness, so periods of quiet wakefulness are often misclassified as sleep, and metrics such as wake after sleep onset are often underestimated [40]. Self-reported sleep, in contrast, may capture the subjective distress more proximally linked to suicidal states, which could explain why passively sensed sleep metrics may show fewer significant associations. These findings suggest that the associations observed here may reflect current measurement constraints rather than the absence of a meaningful link. Methodological refinements, such as validating movement-based estimates against polysomnography and averaging across multiple nights to obtain more stable

XSL•FO
RenderX

parameter estimates [41], together with larger samples and more consistent measurement strategies, may strengthen future findings and clarify the role of sleep-related digital markers.

Linguistic and Communication Markers

Linguistic and communication-based indicators derived from smartphone data provided additional insights into suicide-related cognitive and emotional states, although findings varied across specific features. Text-based patterns that reflected suicide-related content were significantly associated with both passive and active suicidal ideation and planning [34]. Furthermore, longitudinal analyses demonstrated that temporal changes in emotion-related language, such as increases in anger and decreases in positive emotions, could differentiate suicide attempts from lower-risk states [22]. These findings suggest that language use may capture shifts in affective and cognitive processes preceding suicidal behavior.

However, not all linguistic features were significantly associated with suicide-related outcomes. Self-focus and sleep-related language patterns did not reliably distinguish between suicide risk states in some analyses [22,27]. Overall, linguistic markers may provide valuable indicators of internal psychological states. However, their clinical utility depends on integrating multiple features and considering variability across individuals and contexts.

Clinical Implications

These findings highlight the potential of passive digital markers for clinically meaningful suicide risk monitoring. In practice, the continuous monitoring of physiological, behavioral, and digital signals helps expand our assessment beyond static, retrospective viewpoints toward more dynamic and temporally sensitive models of suicide risk [12]. Approaches that prioritize within-person deviations from individual baseline patterns may enable earlier detection of subtle changes preceding suicidal crises, particularly among those who may not disclose suicidal ideation or behavior [14,34].

However, the predictive performance reported across the included studies requires careful interpretation. Among the predictive studies, AUC ranged from 0.56 to 0.89. In clinical screening contexts, AUC values of 0.80 or above are generally considered the minimum threshold for adequate discrimination [42]. By this standard, only one study achieved excellent performance (AUC=0.89) [33], whereas one study approached but did not reach this threshold (AUC=0.78) [30]. The remaining studies reported AUCs below this threshold (range 0.56-0.74) [26,28,32], and one predictive study reported only relative model performance improvements rather than an AUC [25]. These findings indicate that passive digital sensing for suicide risk prediction is still at an early stage and does not yet meet the performance levels required for clinical screening tools. Nevertheless, these AUC values should be interpreted in light of the inherent difficulty of predicting rare events such as suicidal behaviors and the reliance on passive data alone without integration with clinical assessments.

From a clinical perspective, these findings suggest that passive digital monitoring systems may function as continuous and low-burden safety nets and identify emerging risks in everyday contexts. In addition, integrating these digital markers into intervention frameworks, such as Just-In-Time Adaptive Interventions, may facilitate timely and context-sensitive responses, supporting early intervention before suicidal crises intensify [43]. These approaches may be particularly useful in community and outpatient settings, where continuous monitoring using only conventional assessment methods is unfeasible. Specifically, our findings suggest that physiological markers, such as HRV, which showed the strongest predictive performance and the broadest range of associations in our review, combined with behavioral and linguistic indicators, may provide a more context-sensitive approach to suicide risk assessment.

Study Limitations and Future Research

This review has several limitations. First, the relatively small number of included studies (n=14) limits the generalizability of our findings and the ability to establish a robust consensus on digital markers. Second, the lack of standardized data collection and extraction of suicide-related digital features across studies may have contributed to inconsistencies in the findings and limited comparability between studies. This issue is further compounded by simplified device classifications that do not account for variability across device brands, models, or operating systems (eg, iOS vs Android). Third, as a scoping review, this study did not formally assess the methodological quality of the included studies or perform a quantitative synthesis, such as a meta-analysis. Fourth, the exclusion of gray literature may have introduced publication bias. Although peer-reviewed publications were targeted to ensure complete technical descriptions for LHSF mapping, relevant negative or null results may exist outside these databases, potentially narrowing our synthesized evidence base. Fifth, most studies (78.6%) were conducted in the United States, and included samples were predominantly White or Caucasian samples and mostly female participants. This demographic and geographic homogeneity limits the generalizability of the present findings to culturally and demographically diverse populations. These limitations reflect the emerging nature of research in passive digital sensing for suicide-related outcomes and highlight the need for more rigorous and standardized methodological approaches. However, this review provides a structured framework for selecting digital markers for suicide prevention and offers a foundation for future research in digital suicide phenotyping.

Several directions for future research have emerged based on this review. First, future studies should adopt prospective longitudinal or real-time designs to examine multimodal integration, combining passive sensor data with EMA and electronic health record data to enhance clinical context and interpretability. Second, large-scale validation studies using advanced analytic approaches, such as machine learning and natural language processing, are needed, along with rigorous external validation, to improve the discrimination between general psychological distress and suicidal crises. Third, future research should move beyond correlational and predictive modeling and focus on intervention-focused research, such as clinical trials to develop and test actionable digital phenotypes within intervention frameworks, such as Just-In-Time Adaptive

XSL•FO
RenderX

Interventions frameworks. These approaches may enable real-time clinical alerts or timely responses when specific digital markers are detected. Fourth, future reviews in the field of digital suicide phenotyping should consider incorporating gray literature to mitigate potential publication bias and establish a more comprehensive evidence base. Fifth, future research should prioritize the inclusion of demographically and geographically diverse samples to strengthen the generalizability and clinical translatability of passive digital markers across cultural contexts.

Conclusions

This scoping review provides a suicide-specific adaptation of the LHSF to organize fragmented evidence on passive digital sensing into clinically interpretable behavioral markers. Physiological indicators related to autonomic regulation were associated with suicide-related outcomes across all relevant studies and showed the strongest predictive performance (AUC=0.89). Furthermore, smartphone-derived behavioral markers demonstrated additional potential for capturing proximal changes in suicidal states, whereas linguistic markers showed more variable findings. In contrast, sleep- and activity-related indicators showed few significant associations. This review clarifies how passive digital features can be translated into higher-order behavioral constructs and advances the conceptual foundation for digital suicide phenotyping. These findings highlight the potential of integrating multimodal digital data to enable continuous, real-time monitoring of suicide risk in natural settings. Future research should focus on improving the reliability, interpretability, and external validity of digital markers to develop clinically actionable systems for early detection and timely intervention in high-risk populations.

Abstract

Background: The increasing prevalence of chronic illness presents a significant global health challenge due to growing end-of-life suffering. Palliative care is now an essential health service under Universal Health Coverage. Its integration into primary health care and use of mobile health (mHealth) have been recommended to improve access.

Objective: This study aimed to synthesize evidence on how mHealth interventions in home-based palliative care work, for whom, and in what context.

Methods: This realist review identified global evidence relevant to mHealth interventions for home-based palliative care through searches of 9 electronic databases (ie, MEDLINE, Embase, PsycINFO, Global Health, CINAHL, Web of Science, Cochrane Database of Systematic Reviews, Scopus, and Global Index Medicus), and forward citation tracking of included articles conducted in March 2026. The review followed the 5 key stages of a realist review: scoping the literature to assess what is important about the context of mHealth intervention in home-based palliative care and what mechanisms might be important in how such interventions result in their intended outcomes; articulating the underlying program theory and refining the review scope through consultation with international palliative care experts; conducting iterative searches for and appraisal of relevant evidence; extracting data; and narratively synthesizing the data, prioritized by relevance and rigor to generate conclusions and recommendations. The Framework of Complexity in Palliative Care Context, adapted from Bronfenbrenner's Ecological Systems Theory, was applied to examine the contextual influences and interactions among factors within the multilayered system. Context-mechanism-outcome configurations were developed and iteratively tested to refine the program theory for mHealth in home-based palliative care.

Results: A total of 4134 records were identified, of which 422 (10.21%) articles were retained for full-text screening, and 126 (3.05%) studies were included in the final synthesis. The contextual factors and mechanisms that positively influence the intended outcomes include (1) alleviating concerns and mitigating perceived threats about mHealth's suitability in palliative care through proper orientation for patients and carers, along with clear guidelines for health care professionals; (2) minimizing infrastructural and technological barriers through user-friendly designs and investment in sustainable models of mHealth for home-based palliative care; (3) engaging diverse stakeholders to ensure mHealth aligns with priority health care needs, user preferences, and the operations of implementing organizations and the wider health care system; (4) streamlining health management information systems through interoperable mHealth systems implemented at different levels of care; (5) enabling access to and regular communication with relevant health care teams; and (6) facilitating access to adequate information to empower users in palliative care services.

Conclusions: mHealth interventions can enhance home-based palliative care but must align with local contexts. It is recommended that mHealth interventions ensure safety and comfort, technology competence, tailored communication, empowerment of end users, family involvement, health care worker motivation, and system integration.

KEYWORDS

community palliative care; home-based palliative care; digital health intervention; mobile health; mHealth intervention; telehealth

Introduction

The World Health Organization (WHO) advocates for digitally enabled care pathways to improve health care delivery through accurate data capture, enhanced communication, and care coordination [1]. Digital health interventions (DHIs) encompass a wide range of information and communications technologies that support health and health-related activities [2]. Mobile health (mHealth) is a subset of DHIs that uses mobile devices, such as mobile phones, patient monitoring devices, personal digital assistants, and other wireless devices, in medical and public health practice [3,4]. In palliative care, this has been achieved through the use of patient-reported outcome measures and electronic health recordings [5,6]. During the COVID-19 pandemic, mHealth facilitated the remote monitoring and management of patients' symptoms, ensuring continuity of palliative care delivery [7,8].

mHealth technologies have demonstrated a positive impact on patient education, information sharing, communication, and clinical decision-making, as well as saving costs [9]. However, significant heterogeneity has been reported in the results of prior systematic reviews of mHealth effectiveness [3,10]. Challenges in the implementation of mHealth interventions include poor access to mobile devices and networks, usability and interoperability issues, and user concerns about data security and privacy [11,12]. Moreover, mHealth interventions are complex due to their multiple interacting components, the interplay of contextual factors, and the range of systems within which they are implemented [13]. To date, there is a paucity of research developing theoretical models of how these complex interventions improve health, psychosocial, and organizational outcomes or how contextual factors may influence their effectiveness [4]. Such evidence is needed to inform the development and evaluation of mHealth interventions for home-based palliative care and to ensure they can be successfully integrated into existing services.

Palliative care is an essential health service under Universal Health Coverage. However, of 56.8 million people who require the service every year, only an estimated 12% of them have access to it. Currently, most provision is in high-income countries, while 80% of the need is in low- and middle-income countries (LMICs) [14,15]. Palliative care aims to "improve the quality of life for patients and their families facing problems associated with life-threatening illness [16,17], through the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems, physical, psychosocial and spiritual" [18-21].

Among the main strategies identified to enhance access to and improve coverage of palliative care are its integration into primary health care and the use of mHealth technology. Integrating health services within primary care is recognized as the most inclusive, equitable, and cost-effective strategy to achieving comprehensive health care coverage [22]. This approach enhances equitable access to services, especially for patients in remote or underserved areas, by enabling them to receive care in the comfort of their own homes. Furthermore, it ensures continuity of care, providing consistent and coordinated support throughout the illness trajectory, which contributes to better patient outcomes.

Leveraging technological interventions, such as mHealth into primary health care, enables timely and effective support for those in need, particularly patients in underserved regions [13,23,24]. The aim of this review was to determine how mHealth interventions improve both access to and the quality of home-based palliative care and to identify the contextual factors and mechanisms of action underlying their intended outcomes.

Methods

Design

In this realist review, we undertook a theory-informed synthesis of evidence on how, why, and under what circumstances mHealth works in home-based models of palliative care. The rationale for the design was that realist reviews provide an explanatory focus to reveal the mechanisms by which complex interventions work in relation to various contexts, allowing the development of a model that demonstrates how and why interventions work [25,26]. Realist methodology generates program theories using context-mechanism-outcome configurations (CMOCs), which are the main output of the review. Contexts (C) describe the circumstances in which the intervention is implemented, mechanisms (M) describe how the intervention works within specific contexts, and the interaction between these will lead to a particular outcome (O) [27,28].

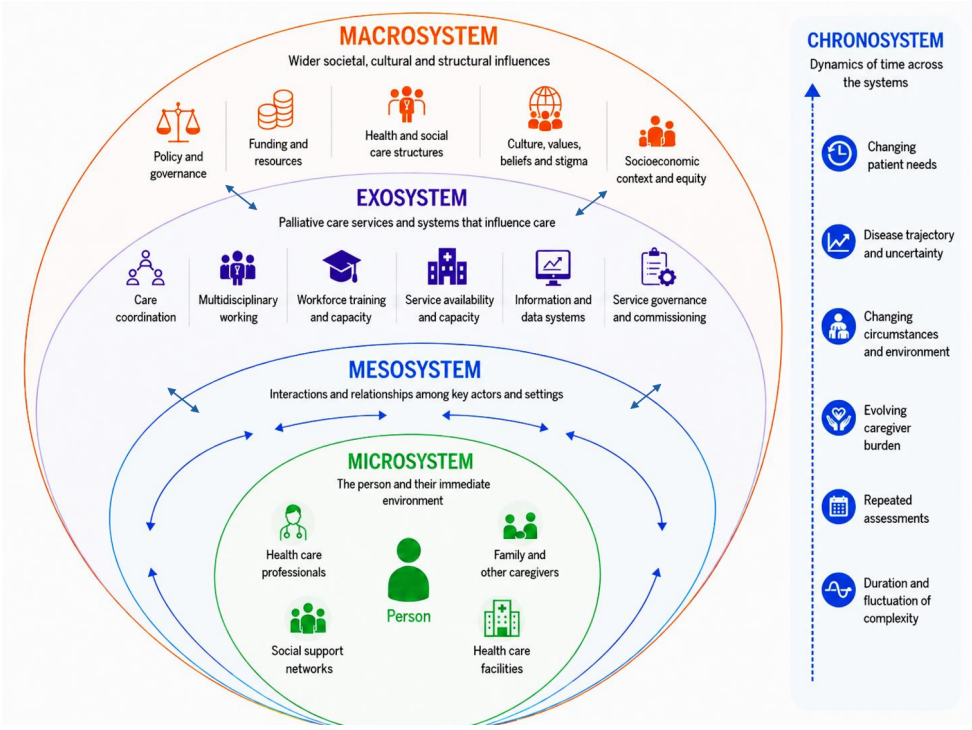
This review adhered to the 5 main stages of a realist review, comprising scoping the literature, articulating underlying program theory and refining the scope of the review with stakeholders, searching for and appraising relevant evidence, extracting data, and synthesizing data to draw conclusions and recommendations [29]. The Realist and Meta-Narrative Evidence Synthesis: Evolving Standards were used to guide reporting [27,28]. The protocol for this review was registered on PROSPERO (registration CRD42022369443).

Procedure

Scoping the Literature to Develop Preliminary Hypotheses

First, a scoping search was undertaken to explore the context of palliative care needs at home, what is important about supporting such needs, how end users might engage with mHealth interventions, and the mechanisms underpinning home-based care. Nine electronic databases were systematically searched: MEDLINE, Embase, PsycINFO, and Global Health via Ovid Technologies, CINAHL via EBSCO Information Services, Web of Science via the Clarivate Web of Science platform, the Cochrane Database of Systematic Reviews via

XSL•FO
RenderX



Cochrane Library, Scopus via the Elsevier Scopus, and Global Index Medicus via the WHO platform. The search applied a broad structure: [mHealth] AND [palliative care] AND [home-based care], combining subject headings and free-text searches of titles and abstracts. Search results were uploaded to an online data management software, Covidence [30]. The first author (NTG) screened all records for relevance to the topic of mHealth intervention in home-based palliative care, while the second and third reviewers (OA and NG) independently screened 50% of the identified articles, and any disagreement was resolved by team discussion. After title, abstract, and full-text screening, the authors familiarized themselves with the included studies and identified common themes. Preliminary *"if...then"* statements were developed to articulate how, why, and under what circumstances mHealth interventions influence home-based palliative care. These statements informed the initial context-mechanism-outcome hypotheses [29].

Articulating Underlying Program Theory and Refining the Scope of the Review With Stakeholders

The preliminary hypotheses generated from the scoping search were discussed with 14 global palliative care researchers and health care professionals through individual face-to-face and online meetings [31]. These discussions emphasized the importance of understanding the complex systems in which mHealth interventions are implemented, including their impact on technology engagement and subsequent outcomes.

To explore these contextual factors, we applied the Framework of Complexity in Palliative Care Contexts [32] adopted from Bronfenbrenner's Ecological Systems Theory [25,26]. This framework highlights interconnected environmental levels and provides a systemic perspective to analyze variations in context, multisectoral actors, and environments across different levels of the health care system (Figure 1). Insights from stakeholder consultations guided the refinement of the review scope and informed the subsequent iterative search strategy.

Figure 1. A framework of complexity in the palliative care context. Key: These levels are at the microsystem (person, needs, and characteristics), the chronosystem (dynamic influences of time), the mesosystem (interactions with family and health care professionals), the exosystem (palliative care services or systems), and the macrosystem (societal influences) (adapted from Pask et al [32], which is published under Creative Commons Attribution-NonCommercial 4.0 International License [33]).

Identify and Appraise Relevant Evidence

Following stakeholder consultation, an iterative evidence database search was conducted to identify studies relevant to the refined scope. The aim of this supplementary searching was to reach a point of theoretical saturation, where no new relevant evidence was generated for the particular theory building or testing within the synthesis [29].

The iterative search applied refined search terms informed by the scoping search and reassessment of the retained studies. In addition to the broader terms, specific functions of mHealth interventions commonly used in home settings, such as telehealth, telemedicine, and videoconferencing, were included. Searches were conducted in the same 9 electronic databases, with no restriction by year in March 2024 (full search strategy reproduced in Multimedia Appendix 1). The search results were uploaded and managed in Covidence. Only papers published in English were considered due to the practical constraints of engaging reviewers fluent in other languages.

In March 2026, the search was updated with forward citation searching of the final included studies using Google Scholar to identify more recent publications. Screening was conducted following predefined selection criteria; the first author (NTG) screened all titles and abstracts, while OA and NG independently

XSL•FO
RenderX

reviewed 50% of records. Discrepancies were resolved through team discussions.

Eligibility Criteria

The predefined selection criteria are described in Table 1.

Table . Summary of the eligibility criteria for all studies included in the review.

Eligibility domain	Inclusion criteria	Exclusion criteria
Participants or population	Patients, both adult and pediatric of all ages, with life-threatening conditions[a] or life-limiting illnesses[b], which are chronic conditions, which significantly impair quality of life and daily functioning, necessitating ongoing management to alleviate symptoms and provision of supportive care (eg, advanced dementia, progressive neurological diseases, and end organ failures [17]), or their informal caregivers (ie, *unpaid providers of physical, social, practical, and emotional support who may be blood or non–blood relatives* [34]), or formal (paid) health care professionals, community health workers, or health extension workers.	Patients solely treated within acute care or receiving only disease-modifying or curative treatment; and caregivers and health care providers with no palliative care roles
Intervention	mHealth[c] is a subset of DHIs[d] that uses mobile devices, such as mobile phones, patient monitoring devices, personal digital assistants, and other wireless devices in medical and public health practice [1,2,35]. Studies were included if they featured the practice of palliative care supported by text message, voice or video call, or application-based or web-based technology (eg, through purposely designed apps or social media platforms) using mobile phones or tablets.	Interventions that do not use mHealth or with a limited mHealth application as part of a multifaceted intervention
Context	Home-based palliative care as a service delivered to seriously ill patients in the setting that a patient calls “home” (ie, a private residence) [36,37]. Studies were included irrespective of country or region to ensure representation of diverse sociocultural contexts.	Facility-based services (eg, primary health care facilities, hospitals), nursing homes, long-term care homes, and hospices (eg, outpatient, day care, and in patient)
Outcome(s)	All outcomes associated with mHealth-supported home-based palliative care; relating to patients, informal caregivers, or health systems.	No restriction

[a]Life-threatening conditions refer to conditions associated with a high risk of mortality.

[b]Life-limiting illnesses refer to chronic or progressive conditions that substantially impair quality of life and daily functioning, requiring ongoing symptom management and supportive care.

[c]mHealth: mobile health.

[d]DHI: digital health intervention.

Quality Assessment Based on Relevance and Rigor

Appraisal Process and Prioritization

The relevance of studies in this review was assessed by considering whether they contained sufficient detail and/or theoretical discussion to inform how and in what context mHealth interventions support home-based palliative care, that is, their contribution to generating program theory [29,38]. In accordance with previous research, the relevance of contributions was defined as high (well aligned to the review questions, with rich descriptions contributing to theory), medium (with some relevance to the review question and some insights to CMOCs), or low (meeting broad inclusion criteria and providing at least one insight) [29].

The Mixed Methods Appraisal Tool (MMAT) [39] was used to assess the methodological quality and rigor of the included studies, as it is useful to assess the quality of qualitative, quantitative, and mixed methods studies. The MMAT comprises 5 quality criteria, with 3 responses for each item (ie, positive [=1] and negative or unavailable information [both=0]). The 5 items are added with a score of 5 indicating high quality. The Joanna Briggs Institute quality assessment tool was used to assess the methodological rigor of the included systematic reviews, with scores allocated on a scale from 0 to 11. Using this tool, a score of 8 or more indicates high quality, a score of 6 to 8 indicates moderate quality, and a score less than 6 suggests low quality. Three authors (NTG, NG, and OA) independently assessed the methodological quality of the studies and met to discuss their appraisal. Differences were resolved through discussion with the entire research team [40].

As a realist review approach may use only relevant data from part of an article, no studies were excluded based on

XSL•FO
RenderX

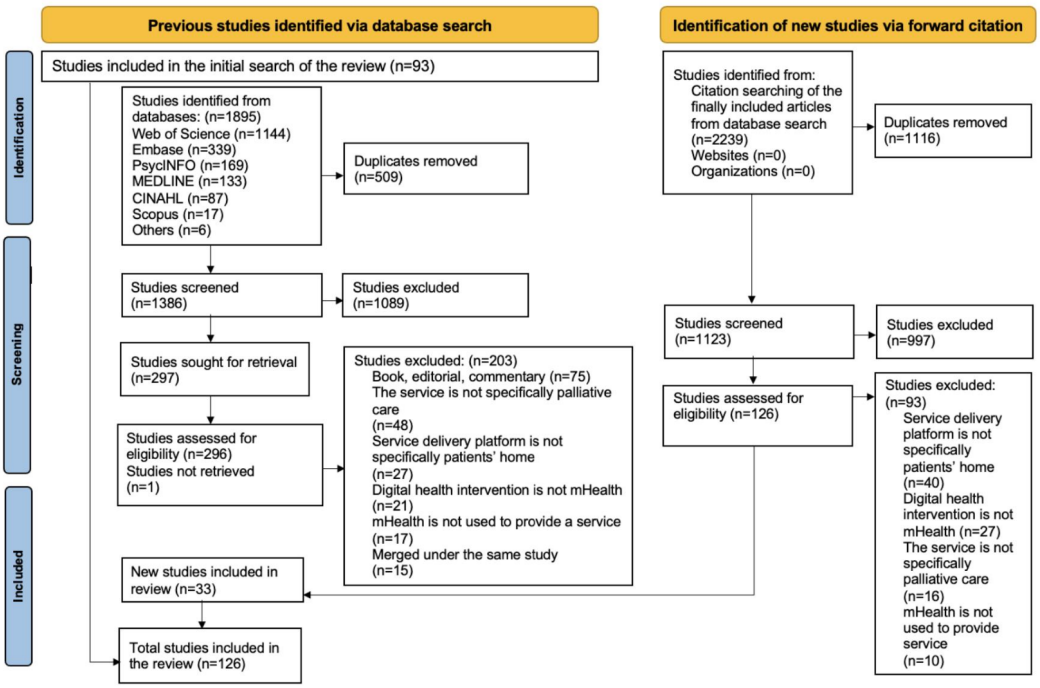
methodological quality. However, studies with high relevance and rigor were given priority during theory development [27-29,31].

Data Extraction

Bespoke data extraction forms were developed to organize information obtained from the included studies. A careful review of the introduction, methods, results, and discussion sections assisted in identifying relevant information. Descriptive characteristics, such as author, year, study aims, design, population, and country, were recorded. Details were also extracted on the intervention components, contextual factors, implied or actual mechanisms attributed to the outcome of interest, and the intervention outcomes. Data extraction was undertaken by 2 of the authors (NTG and NG) working independently. Areas of discrepancy were resolved through discussion to reach consensus.

Data Synthesis

Evidence sources were synthesized narratively, prioritizing included studies by relevance and rigor [41] and shown as a set of CMOCs. Taking an iterative approach, the first author read and reread different sources of data and coded the evidence to identify prominent recurrent concepts concerning contexts, mechanisms, and outcomes [29]. Coding was done deductively to the concepts in the Framework of Complexity in Palliative Care Context and using the priority "if...then" statements, which informed the preliminary context-mechanism-outcome hypotheses. In this process, we drew logical conclusions from the observed patterns, particularly the contextual factors influencing mHealth interventions [32] and inductively (proposing insights from recurring observations), mainly regarding mechanisms, and retroductive coding (exploring new patterns using theory to propose causal pathways) [42]. This process allowed the development of mHealth program theory in palliative care and conceptualization of the causal pathways using contexts, mechanisms, and outcomes [43,44].



Results

Search Yield and Characteristics

Overview

In total, 4134 studies were identified via database searching (n=1895, 45.8%) and forward citation searching of the final included studies in March 2026 (n=2239, 54.2%). The selection process and included articles are illustrated in the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram (Figure 2). Following the removal of duplicates and initial screening, 422 (10.21%) articles were retained for full-text screening, and 126 (3.05%) studies were included in the final synthesis, and of these, 20 (0.48%) articles from the initial scoping search contributed to the initial preliminary hypothesis generation. Details of the studies included in the final synthesis are presented in Table 2.

Figure 2. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram of articles included in the review. mHealth: mobile health.

Table . Studies included in the review.

Author, year, country	Aim	Study design	Intervention
Abahussin et al, 2023, United Kingdom [45]	To design and develop an mHealth[a]-based pain recording system to support effective pain management in cancer.	User-centered design and usability testing	A mobile app and a web-based app for adult patients with cancer in home settings to record pain details. The data were accessed by health care professionals and researchers.
Allsop et al, 2019, 21 countries in Africa (see Multimedia Appendix 1) [35]	To assess the current use of mHealth in palliative care service delivery in the African region, identify barriers to mHealth use, and determine provider priorities for research development.	Mixed methods descriptive design	Mobile phone.
Al-Mondhiry et al, 2022, United States [46]	To use community-partnered participatory research to co-design and pretest a mobile app that focuses on palliative care priorities of clinicians and patients with advanced cancer.	Co-design workshops	Mobile app, that is, wellness journal to track patient-reported symptoms, goals, and medication use; information on self-management of symptoms; community resources; and patient and caregiver testimonial videos.
Ansari et al, 2022, United States [47]	To identify technology-based communication strategies to improve health outcomes in individuals with advanced cancer.	Integrative review	Mixed technologies, for example, health information technology or electronic health reporting, data sharing systems, and telehealth programs.
Aoki et al, 2006, Japan [48]	To evaluate the implementation of telepalliative care in a rural community for patients with terminal cancer who prefer home-based palliative care.	Mixed methods study	Telepalliative care using a Polycom view station with ISDN[b] line for communication, including telephone calls among health care providers and patients, and recording of vital signs.
Archer et al, 2021 [49]	To explore the impact of digital health interventions on the psychological outcomes of patients and families receiving pediatric palliative care.	Systematic review	Telehealth consultations via video link and telephone, telehealth intervention via Zoom videoconferencing or FaceTime, and the use of a bespoke website (My-Quality.net) to collect data on patient-reported outcomes.
Baldwin et al, 2012, United States [50]	To determine what organizational factors might account for differences in the use of telehospice.	Survey	Telehospice (ie, video conferencing) used by hospice agency staff and patients.
Balasubramanian et al, 2022, India [51]	To assess the level of satisfaction of patients receiving e-palliative homecare services and to evaluate the feasibility of e-palliative care in providing palliative care to patients with advanced cancer at their homes.	Prospective observational study	Implementation of e-palliative care through a technological interface, where a homecare team led by a palliative care–trained nurse visits patients with a camera-integrated laptop and e-palliative care software app installed, allowing remote communication with a palliative care physician in the hospital.
Bandini 2025, United States [52]	To examine current perspectives from interdisciplinary providers on the use of telehealth and in-person care for outpatient palliative care among underserved patients.	Qualitative study	Telehealth use among staff serving underserved population.

XSL•FO
RenderX

Author, year, country	Aim	Study design	Intervention
Basile et al, 2024 [53]	To map the literature on the use of technology by older adults with terminal illness receiving palliative care at home and to identify the technology systems in use, the impact of technology on communication between palliative care professionals and patients, and explore the strengths or weaknesses perceived by patients regarding the use of technology.	Scoping review	Tablets, smartphones, computers, videoconferencing devices, a pen with an embedded camera, and devices for remote symptom monitoring such as smartphones and wristbands.
Bauer et al, 2026, Denmark [54]	To develop program theory for a family-focused model of telepalliative care for adult patients and their families.	Qualitative study—workshops with key stakeholders, participant observations, and ethnographic interviews	Telepalliative consultation perceptions among patients with palliative care needs, family caregivers, SPCT[c] members, allied health care personnel, community care nurses, IT personnel, and health care managers from both community and tertiary care settings.
Bensink et al, 2004, Australia [55]	To design and test an internet-based videophone for pediatric palliative care services, focusing on assessing the feasibility and benefits of using the technology for telemedicine in home settings.	Feasibility study with qualitative exploration	Videophone: use of low-bandwidth, internet-based videophone for supporting pediatric palliative care in the home, with clinical consultations conducted twice each week.
Bensink et al, 2009, Australia [56]	To investigate the acceptability of providing videotelephone-based support to families receiving pediatric oncology-related palliative care and to explore the integration of videotelephone support from the time of diagnosis through outpatient care and support.	Randomized controlled trial	Access to a videotelephone service in addition to the usual 24-h on-call telephone support service, provided by specialist nurses for patient assessment, monitoring, family education, communication, and counseling.
Bethel et al, 2021, United States [57]	To evaluate technology system usability and Comprehensive Patient Assessment for Using Telehealth at Home implementation effectiveness in seriously ill older adults and their caregivers.	Qualitative study	Comprehensive Patient Assessment for Using Telehealth at Home intervention to meet remotely and assess patients in their own home.
Bhargava et al, 2021, Canada [58]	To develop and evaluate a remote symptom self-reporting app (ie, RELIEF) for community patients with palliative care needs, assessing its feasibility and acceptability for remote monitoring of patients through regular symptom self-reporting, with a focus on using technology to improve symptom management and care delivery.	Co-design and feasibility study	Patients self-reported symptoms daily using RELIEF and received over-the-phone assessments and interventions based on alerts, and some received support for expected death in the home.
Bonsignore et al, 2018, United States [59]	To describe and evaluate a telehealth palliative care program using the TapCloud app and videoconferencing in rural areas, focusing on feasibility, usability, symptom burden, and hospice transitions.	Mixed methods study	TapCloud app for remote patient monitoring, including symptom and medication management, messaging, and photo upload, as well as videoconferencing for real-time interactions.
Bradford et al, 2014, Australia [60]	To compare the costs of pediatric palliative care medical consultations conducted via the Home Telehealth Program with in-person consultations.	A cost minimization analysis	Palliative care consultations through the Home Telehealth Program at the Royal Children's Hospital in Brisbane, involving video consultations in the home.

XSL•FO
RenderX

Author, year, country	Aim	Study design	Intervention
Bradford et al, 2014, Australia [61]	To investigate the potential of telemedicine for the delivery of specialist support in the home or local community for children with life-limiting conditions requiring palliative care.	Qualitative study	Real-time audiovisual communication links between the specialist pediatric palliative care team and families caring for a child receiving palliative care at home, facilitated by personal computers, web cameras, and the internet.
Brännström et al, 2024, Sweden [62]	To describe health care professionals' experiences of video consultations in palliative care in community homecare and nursing homes in rural areas.	Qualitative study	Video consultations to access specialist palliative care service.
Burner-Fritsch et al, 2023, Germany [63]	To identify and explore challenges for the development of electronic patient-reported outcome measures as standardized assessment in specialized palliative home care, focusing on patient, health care professional, and organizational or structural levels.	Qualitative study	Patients used the electronic version of the Integrated Palliative Care Outcome Scale on their own web-enabled devices, completing it 1 to 2 times a week for at least 2 weeks.
Caetano et al, 2024, Portugal [64]	To explore whether caregivers feel prepared to provide informal palliative home care, their experiences, and the usefulness of telehealth in managing daily activities.	Qualitative study	Telehealth to support informal caregivers.
Calton et al, 2020, United States [65]	To characterize the experience of patients with serious illness and their caregivers receiving palliative care by telemedicine.	Mixed-methods telephone survey	Telemedicine acceptability and comfort among patients and caregivers.
Cameron 2021, United States [66]	To examine the comfort and emotional support that caregivers of home hospice patients derive from using electronic tablets for telehospice.	Mixed methods study	Caregivers received electronic tablets with the AVA[d] app for telehospice participation, were given a presurvey, shown how to use the tablets, completed surveys after setting up AVA in the home, and received a postsurvey 2 wk after the death of the loved one.
Carey et al, 2023, Ethiopia [67]	To co-design, develop, and evaluate a mobile phone–based remote monitoring system for use by palliative care patients in Ethiopia.	Co-design and qualitative study	Remote monitoring system where patients and families record their symptoms and access information to self-support their needs.
Christiansen et al, 2020, Sweden [68]	To describe perceptions of mHealth and its impact on HRQoL[e] among older adults with cognitive impairment.	Qualitative study applying phenomenography	mHealth intervention (SMART4MD) to improve the HRQoL of older adults with mild cognitive impairment and their informal caregivers.
Chua et al, 2022, United States [69]	To describe trends in in-person and video visit palliative care delivery challenges before and during the COVID-19 pandemic in the United States.	Quantitative nonrandomized	Early integrated telehealth palliative care (via video visit) or in-person palliative care, with at least monthly visits; initial visit in person within 4 wk of enrollment but could be conducted via video during the COVID-19 pandemic; subsequent follow-up visits every 4 wk, either via video or in person.

XSL•FO
RenderX

Author, year, country	Aim	Study design	Intervention
Collier et al, 2016, Australia [70]	To explore clinicians' perspectives and experiences of telehealth, perspectives about benefits and challenges for patients, families, and clinicians in using telehealth applications, and identified enablers and barriers for the use of telehealth in community palliative care.	Qualitative study	The intervention included self-report assessment tools, remote activity monitoring, video-based conferences, and virtual case conferences.
Collier et al, 2025, Australia and Aotearoa, New Zealand [71]	To explore the complexities of telehealth and palliative care with a focus on access and equity.	Qualitative study	Telehealth for extending reach of palliative care in underserved groups.
Cook et al, 2001, United States [72]	To analyze the successes and challenges of implementing telehospice care focusing on the role of senior executives' support, quality of care, and provider acceptance.	Observational study	Implementation of telehospice services using telemedicine technology, including training of potential telehospice users and providing care remotely via videophones over ordinary telephone lines to patients in rural and urban communities in Kansas and Michigan for at least a year.
Coyle et al 2002, United States [73]	To explore the effectiveness and benefits of using audiovisual communication as a complementary tool in caring for patients with complex palliative care needs who are isolated at home due to their medical conditions, aiming to enhance communication and support for both the patients and their caregivers.	Case report of a 3-mo trial	Trial of a commercially available audiovisual system, specifically a videophone (TeleEye 324 TM; LeadTek Research, Inc), placed in the patient's home using standard telephone wires for a 3-mo trial period.
Cruz et al 2023 [74]	To map the available knowledge regarding the use of apps for mobile devices to support adult patients in palliative care at home, specifically focusing on mHealth apps under study or development in the home care transition process for palliative care patients.	Systematic review	Participants received the mobile app intervention for monitoring symptoms, communication with health care professionals, and potentially receiving alerts and educational materials related to palliative care. The intervention was compared with controls in some studies, and outcomes were assessed in terms of changes in daily functioning, self-efficacy, and quality of life.
Davis et al, 2015, United States [75]	To describe the telecaring intervention and its outcomes, focusing on proactively identifying and addressing the needs of patients receiving hospice care at home and caregivers through a systematic phone-based care service.	A quality improvement initiative	TeleCaring consisted of daily proactive phone calls to patients and caregivers by specialists and nurses, made up to twice daily based on the patient or caregiver's preferred frequency and timing, providing up to 14 additional staff interactions each week. The calls aimed to address questions or concerns related to care and ensure supply needs were met.
Dickman Portz et al 2020, United States [11]	To explore provider perspectives regarding the utility of mHealth in palliative care.	Qualitative study	mHealth perception of use among providers from multiple disciplines working in palliative care settings.
Disalvo et al, 2021 [76]	To identify digital health technologies evaluated for supporting timely assessment and management of people with palliative care needs at home and their carers.	Meta-review	Remote patient monitoring interventions included monitoring of biometric data or symptoms, with alerts triggered to clinicians when patient scores were outside acceptable thresholds.

XSL•FO
RenderX

Author, year, country	Aim	Study design	Intervention
Dismore et al, 2025, United Kingdom [77]	To understand the experiences of patients, carers, and specialist palliative care professionals to receive or deliver video consultations in a rural setting.	Qualitative study	Video consultation perception of use to access specialist palliative care.
Dolan et al, 2021 [78]	To assess the safety and effectiveness of virtual care in end of life and palliative care.	Review	Virtual care, that is, video consultation, mobile apps, videos, websites, telephone support, email, and alert messages.
Domínguez et al, 2026, Ecuador [79]	To evaluate the technology usability and implementation feasibility of the nonintrusive devices for telemedicine system, a low-cost, smartwatch-based pain monitoring solution for palliative cancer care co-designed with health care staff from a cancer hospital in Ecuador.	Usability and feasibility study	Wearable-based pain monitoring system.
Doolittle et al, 2019, United States [80]	To explore the feasibility and effectiveness of using a TeleHospice approach in rural hospice care, focusing on enhancing patient- and family-centered, timely care.	Product design—community-engaged model	Use of low-cost, secure mobile tablets (iPads) for videoconferencing encounters in rural hospice care settings, involving an interprofessional team.
Evering et al, 2022, The Netherlands [81]	To explore the intention to use video communication by health care providers in interprofessional terminal care settings.	Cross-sectional survey	A video communication in terminal care.
Gonzalez, 2023, United States [82]	To evaluate the perception of usability of a tablet device among palliative care patients and informal caregivers.	Cross-sectional pilot study	A home health tablet device.
Gordon et al, 2022 [83]	To explore strategies for increasing access to palliative care among individuals living in remote or rural communities through the use of telehealth applications.	Rapid review	The interventions included videoconferencing, telephone-based interventions, web-based platforms, after-hours phone support service, remote patient monitoring and management, web-based videoconference platforms, and 24/7 phone consult services.
Guo et al, 2023, China [84]	To examine telehealth readiness and its related factors among Chinese palliative care specialist nurses.	Cross-sectional study	Telehealth (readiness assessed using the Chinese version of Telehealth Readiness Assessment Tools and the Innovative Self-Efficacy Scale).
Hancock et al, 2019 [85]	To describe the current use of telehealth in palliative care in the United Kingdom, evaluate telehealth initiatives against a digital service standard, and explore whether telehealth results in a reduction in emergency care access.	Systematic review	The intervention(s) was home telemonitoring using telephone or computer software to record clinical symptoms or signs from the patient's home. Patients were required to input specific data regarding symptoms and physical parameters, with some studies including telephone support.
Harding et al, 2021, India, Uganda, and Zimbabwe [9]	To design and evaluate a mobile phone app to improve communication between family caregivers, community caregivers, and palliative care teams, assess its acceptability and mechanisms of action, and propose refinements based on stakeholder feedback.	Mixed methods study	The intervention involved the use of a mobile phone app for family or community caregivers to report nonurgent patient and family outcomes on a dashboard accessible by the clinical palliative care team in 3 LMICs. The app aimed to facilitate patient assessment, improve staff awareness of patient concerns, enhance communication, and potentially improve patient outcomes.

Author, year, country	Aim	Study design	Intervention
Haroen et al, 2025 [86]	To investigate the benefits of integrating telehealth into community-based palliative care for people living with terminal illness and their caregivers.	Review	Telehealth, that is, telephone or video consultations and phone calls.
Haydon et al, 2021, Australia [87]	To explore the costs, service activity, and staff experiences resulting from the introduction of telehealth in a community palliative care service in Queensland, Australia.	Mixed methods study	In-person and telephone-based home visits and telehealth (video consultations).
Hebert et al, 2007, Canada [88]	To determine the potential for using videophones in palliative home care and to explore factors that could inform the eligibility criteria for video visits.	Retrospective chart review	Palliative home care visits that could have been carried out using videophones, telehospice care as a support for family caregivers, testing the usability of a videophone in palliative home care, and determining the potential for home telehealth in palliative care.
Hennemann-Krause et al, 2015, Brazil [89]	To examine telemedicine as a form of home and additional support for traditional outpatient care as a way to remotely monitor and manage the symptoms of patients with advanced cancer.	Prospective, longitudinal, qualitative, descriptive, and case series study	Web conferences to remotely monitor and manage the symptoms.
Hoek et al, 2017, The Netherlands [90]	To determine whether weekly teleconsultations from a hospital-based SPCT improved patient-experienced symptom burden compared to "care as usual" in home-dwelling patients with advanced cancer.	Randomized clinical trial	Weekly teleconsultations for a period of 13 wk in addition to their usual care. First, a teleconsultation device was installed at the patient's home. Patients who had not visited the SPCT before were evaluated at the outpatient clinic or during a home visit by one of the SPCT members.
Holland et al, 2014, United States [91]	To determine the resources needed to use the system and the quality of the audio and visual components to conduct virtual visits between a clinician at an academic center and community-dwelling adults living in rural locations.	Mixed-methods field study design	Virtual visits using a 3G-enabled Apple iPad, cellular phone data service, and a web-based video conference service.
Holmen et al, 2020 [92]	To identify and review the use of eHealth to communicate and support home-based pediatric palliative care.	Convergent, systematic mixed methods review	Interventions received by the study participants included videoconferences, the use of an online tool for monitoring quality of life, and the use of iPads for videoconferencing, among others.
Hutchinson et al, 2022, United States [93]	To explore the acceptability, feasibility, and emotional responsiveness of telepalliative care.	A mixed-methods formative study	Telemedicine perception of use, that is, acceptability, feasibility, and emotional responsiveness of telepalliative care.
Jess et al, 2019 [94]	To review and synthesize current evidence regarding the use of video consultations in both general and specialized palliative care to various patient groups.	Systematic integrative review	Use of video consultations in specialized palliative care settings
Jiang et al, 2023, Australia [95]	To assess the feasibility of a TH-SPC[f] model for an Australian rural setting, focusing on integrating telehealth technology to provide specialist palliative care to rural communities.	Prospective mixed methods pilot study	Video consultations with metropolitan-located specialist palliative care physicians alongside standard care.

XSL•FO
RenderX

Author, year, country	Aim	Study design	Intervention
Johnston, 2011 [96]	To explore the use of telehealth in relation to palliative care in the United Kingdom.	Review	Telehealth use for older people.
Johnston et al, 2012, United Kingdom [97]	To evaluate the current use of telehealth applications within palliative care across Scotland and assess how these applications are perceived by patients, carers, and professionals.	Qualitative evaluation design	Telehealth activity among the key stakeholders centered on the use of videoconferencing equipment for networking, consultations, and multidisciplinary meetings, and for education and training.
Johnston 2014 [98]	To scope information available from published and unpublished research on the current state of palliative home-based technology, practitioner-focused perspectives, patient-focused perspectives, quality of life, and the implications for clinical practice.	Review	Home-based technology perspectives of use among clinicians and patients and implications on practice.
Funderskov et al, 2019, Denmark [99]	To explore the advantages and disadvantages of using video consultations in SPC[g], focusing on the experiences of health care professionals and their perspectives on video consultations.	Qualitative study	Patients referred to specialized palliative care received an initial home visit by an SPC team head physician and an SPC team nurse. They were primarily in contact with the SPC team nurse by phone and had approximately one weekly video consultation using a tablet provided by the SPC team.
Kawashima et al, 2026 [100]	To evaluate the effectiveness of and implementation requirements for telehealth in palliative care patients with advanced cancer.	Review	Telehealth ie, videoconferencing, telephone, or text-based communication.
Keenan et al, 2021, United Kingdom [101]	To explore potential divergence and convergence in relation to health care professionals' and patients' acceptability of the use of telehealth within palliative care provision through the lens of Self-Determination Theory.	Qualitative study	Telehealth perceptions among health care professionals and patients.
Kidd et al, 2010 [102]	To review telehealth applications used in palliative care settings in the United Kingdom, identify who is using telehealth, for what purpose it is being used, and to explore if telehealth use is increasing within the clinical setting.	Systematic review	The interventions for health professionals, patients, carers, nurses, and GPs[h] include telehealth services such as out-of-hours telephone support, advice services, videoconferencing, and training and education for health care staff.
Kluger et al, 2024, United States [103]	To determine whether palliative care training for neurologists and remote access to a palliative care team can improve outcomes in patients with Parkinson disease and related disorders in community settings, focusing on patient quality of life, caregiver burden, and other patient-centered outcomes.	A pragmatic, stepped-wedge comparative effectiveness trial	Palliative care education for community neurologists and provision of team-based palliative care resources via telehealth, including consultations from an academic center's palliative care team.
Kwon et al, 2026, Republic of Korea [104]	To (1) develop the Hospice@Home system, a digital in-home hospice care solution; (2) explore preliminary indications of usability and feasibility among patients with terminal cancer and their caregivers; and (3) identify challenges for future implementation.	Development and usability pilot study	Digital in-home hospice care solution for patients with terminal cancer and their caregivers.

Author, year, country	Aim	Study design	Intervention
Middleton-Green et al, 2019, United Kingdom [105]	To evaluate the Gold Line telehealth initiative in providing support to individuals at home in the last year of life, focusing on patient and carer experiences and the extension of palliative care services to those not known to specialist palliative care.	Mixed methods evaluation	Intervention components: Gold Line service, training for health care teams, use of the Gold Standards Framework, access to electronic health records, recording call outcomes, and participation in interviews.
Lee et al, 2024, Ireland [106]	To understand patient experience.	Mixed quantitative and qualitative study	Video consultation—perception of use among patients.
Lind et al, 2008, Sweden [107]	To explore and describe palliative home care patients' experiences of assessing their pain using a pain diary together with digital pen and mobile Internet technology.	A case study with cross-case content analysis	A pain diary together with digital pen and mobile Internet technology. Included introduction of pain management clinical guidelines, pain treatment for patients with at least moderate pain, and follow-up of pain treatment using the IT system developed.
Lundereng et al, 2023 [108]	To systematically map published studies on HCPs'[i] experiences and perspectives on the use of telehealth in HBPC[j].	Scoping review	Video-based technology for teleconsultations among patients, families, and health care professionals, delivered by hospital-based HCPs, hospice workers, and home care professionals either independently or in collaboration with hospital-based staff.
Ma et al, 2025 [109]	To provide a comprehensive understanding of the roles of nurses and the multilevel facilitators and barriers to implementing nurse-delivered telehealth in home-based palliative care, which could inform future policy development, research, and clinical practice.	Review	Telehealth for home-based palliative care delivered by nurses.
Mathews et al, 2023 [110]	To describe the components of telehealth palliative care interventions for patients with advanced cancer before the COVID-19 pandemic, identify intervention components associated with improvements in outcomes, and evaluate the reporting of interventions.	Scoping review	Hybrid models, telephone-based interventions, videoconference-based interventions, asynchronous web-based intervention, mainly consisting of psychosocial content and delivered by nurses in the home setting. Participants included patients, family caregivers, and patient-caregiver dyads.
Maguire et al, 2025, United Kingdom [111]	To explore the usability, user experiences, and impact of the digital dyadic remote monitoring Care and Support System for Patients and Carers for patients in the last year of life, their informal carers, and health professionals involved in their care.	Mixed methods feasibility study	Digital dyadic remote monitoring Care and Support System for Patients and Carers for patients in the last year of life.
Maudlin et al, 2006, United States [112]	To determine if a telehealth model of care would benefit veteran patients with life-limiting illness by managing their physical, emotional, functional, and spiritual care needs during the last 2 y of their lives and fostering earlier enrollment into hospice through provider education on palliative care.	Pilot testing of the Advanced Illness/Palliative Care program	Technologies used included both video (telemonitors and videophones) and nonvideo (disease management and messaging) devices.

Author, year, country	Aim	Study design	Intervention
Mccall et al, 2008, United Kingdom [113]	To test the acceptability and usability of the ASyMSp[k] in monitoring and managing symptoms of patients receiving palliative care at home.	Explorative descriptive study	A mobile phone–based technology (ASyMSp) to monitor and manage symptoms reported by patients receiving palliative care at home, involving daily completion of an electronic questionnaire over a 30-d period.
Menon et al, 2015, United States [114]	To investigate the feasibility and describe patient outcomes of palliative care consultations via telemedicine in critically ill patients, assess the impact on decreasing the burden on family members, and provide care in alignment with patient wishes.	A retrospective review	Telemedicine palliative care conferences.
Miller et al, 2021 [115]	To explore the existing literature on pediatric TM-HBPC[l] for children with serious illness to identify research, determine the effectiveness, and highlight the need for more robust information on implementation, adaptation, and maintenance of TM-HBPC models.	Systematic scoping review	The intervention involved the delivery of home-based palliative care for children with serious illness via telemedicine, typically conducted by a hospital-based pediatric palliative care multidisciplinary team, with varying session durations and scheduling, and the use of different platforms for telemedicine consultations.
Morse et al, 2021, Tanzania [116]	To design and develop mPCL[m], a web and mobile app to support outpatient symptom assessment and care coordination and control, with a focus on pain.	Human-centered iterative design framework	Participants received the mPCL app for symptom assessment and care coordination, with some being provided loaned Android devices with the app preinstalled and personal smartphones installed the app. The intervention lasted for 4 mo.
Mukamal et al, 2025 [117]	To explore the experience of nononcologic older adult patients in palliative care with telemedicine	Review	Telemedicine to enhance palliative care for older adults.
Namasivayam et al, 2022 [118]	To review and map the available evidence on the use of telehealth in providing after-hours palliative care services in rural and remote Australia.	A scoping review	The intervention was the use of telehealth services provided by RNs[n], nurse specialists, GPs, specialist physicians, after-hours coordinators, and managers to enable patients to continue receiving after-hours palliative care at home in rural and remote Australia.
Narvaez et al, 2022 [119]	To map and evaluate existing research on the use of telemedicine and telehealth in palliative care patients during the COVID-19 outbreak.	Integrative review	Telehealth interventions including video conferencing, remote monitoring, and novel ways to improve care at home.
Nguyen et al, 2020, United States [120]	To compare a tech-supported model with video consultations to a standard model of home-based palliative care to determine non-inferiority in terms of interprofessional team coordination and patient outcomes.	Pragmatic, cluster-randomized non-inferiority trial	The intervention included nurse-led home visits coupled with remote physician consultation supervision via video for patients and caregivers in the tech-supported arm. Training on video visit procedures was provided to clinicians.
Oakley-Girvan et al, 2021, United States [121]	To develop a mobile app (TOGETHERCare) that enables cancer survivors' care partners to monitor the survivors' health and provide resources for the care partners.	Product design study with user involvement	Use of the TOGETHERCare mobile app by cancer care partners for a 28-day feasibility field test to remotely monitor cancer survivors' health and their own health, as well as to provide care partner resources.

Author, year, country	Aim	Study design	Intervention
Oelschlagel et al, 2021, Norway [122]	To explore municipal health care professionals' experiences with implementing an app for remote care in palliative home care for patients with cancer.	Qualitative, descriptive, exploratory design	Implementation of a technological solution named "remote home care" in palliative home care for patients with cancer, including providing a tablet device, installing digital medical devices.
Parker Oliver and Demiris, 2004, United States [123]	To assess the readiness of hospice organizations to accept technological innovation, specifically focusing on the current use of information and communication technology by hospice employees and their receptiveness to telemedicine or other advanced technology in patients' homes.	Cross-sectional survey study	Broad ICT[o] use—no specific intervention.
Oliver et al, 2012, United States [124]	To assess the state of evidence related to telehospice services and to highlight the need for strengthening the evidence base through various research methodologies.	Mixed methods study	Telephone advice lines, videophones, personal digital assistants, pen tablets, computers, comprehensive training for providers in the implementation of telehospice projects.
Olver et al, 2005, Australia [125]	To understand nurses' experience.	Qualitative study	Videophone communication among rural palliative care nurses and their more remote general nursing colleagues.
Osuji et al, 2020, United States [126]	To assess the usefulness and appropriateness of video visits in home-based palliative care from the perspective of physicians and nurses, anchored within the NASSS[p] framework.	Comparative effectiveness trial	Video visits were used primarily for follow-up visits as opposed to admission/start-of-care; intervention: video visits for follow-up care in home-based palliative care, facilitated by a nurse connecting patients with remote physicians.
Pare´ et al, 2009, Canada [127]	To evaluate the effects of a telehomecare intervention implemented in an oncology and palliative care unit in Quebec, Canada, focusing on nurses' satisfaction with the software app, perceived quality of care, and individual and group productivity.	Pre-post evaluation design	Implementation of the SyMO software with modules for care planning, developing treatment plan, nurse assignment, visit planning, route guidance, and documentation.
Parker et al, 2021, Australia [128]	To evaluate the usefulness of CarerHelp from the perspective of health professionals caring for individuals with life-limiting illnesses.	Quantitative study	A web-based online toolkit for carers.
Paul et al, 2019, Canada [129]	To gain a preliminary understanding of the experience of using mobile web-based videoconferencing for conducting in-home palliative care consults with older rural patients with life-limiting illness, assessing the clinical effectiveness, acceptability, service impact, and technical feasibility.	A descriptive, exploratory, proof-of-concept study	Palliative care consultations via mobile web-based videoconferencing with a palliative care physician consultant from their homes, with the presence of a palliative care clinical nurse specialist, and a home care nurse to manage the technology and support the patient. Participants also received training in the use of the technology.
Peñarrubia - San - Florencio et al, 2025, Spain [130]	To explore family perspectives and experiences with telehealth in PPC[q], focusing on their needs, perspectives, concerns, and hopes to refine digital care models.	Qualitative study	Telehealth to support families caring for children with palliative needs.

Author, year, country	Aim	Study design	Intervention
Phillips et al, 2008, Australia [131]	To evaluate the effectiveness of a generic after-hours telephone support service for palliative care patients and their caregivers in a rural setting in Australia, as well as to explore the application of a computer-based Palliative Care Clinical Information System to assist with the transfer of patient information.	Mixed methods study	After-Hours Telephone Support Service provided to palliative care patients and their caregivers.
Phongtankuel et al, 2018, United States [12]	To examine informal caregivers' receptivity and interest in using mHealth apps, along with identifying the app features caregivers perceived to be most useful in-home hospice care.	Qualitative study	mHealth apps with features such as video chat, medication/symptom tracking, and educational materials to improve communication and information exchange in home hospice care.
Pinto et al, 2017 [132]	To analyze the use of eHealth technologies and mobile apps in palliative care, focusing on the strengths, weaknesses, opportunities, and threats of these technologies.	Integrative literature review	eHealth technologies in palliative care used by adults, patients, nurses, physicians, family, carers, and older people.
Pinto et al, 2017, Portugal [133]	To introduce a web-based app for monitoring comfort in patients receiving palliative care.	Multiphase electronic app development process with pilot design	Monitoring comfort remotely using a web-based app, providing self-reported data on 11 comfort-related items on a Likert scale; using the app for 15 consecutive days, inputting data at least once a day; contacting the palliative care team in case of significant symptomatic distress; accessing the app through Android or Windows operating systems on smartphones, tablets, or computers; using the app to report symptoms and distress, with researchers monitoring the data.
Putranto and Rochmawati, 2020 [134]	To explore and synthesize evidence on cancer symptom management mobile apps for patients and their families, highlighting the role of nurses and the potential extension of mobile apps for managing other life-limiting illnesses.	Scoping review	Mobile apps for managing cancer symptoms at home. Nurses are assigned to observe and assess patient symptoms through the mobile app. The main function of the mobile app system is to record an assessment of patient symptoms, provide education and skills training, and offer video media adjusted to the reported symptoms.
Rana et al, 2025, United States [135]	To further explore adult patient and caregiver perspectives on telehealth, specifically the benefits of telehealth, trade-offs with in-person appointments, and the impact on patient care and family end-of-life preparations.	Qualitative study—single-arm prospective pilot study	Telehealth to support palliative care services for children and young adults with cancer.
Royackers et al, 2016, Canada [136]	To examine the experiences of informal caregivers who cared for a family member receiving palliative care as part of the eShift model of home care, focusing on their satisfaction with care delivery and ability to support their family members to die, at home.	Interpretive description methodology with semistructured interviews	eShift model of home-based palliative care using RNs, PSWs[r], and point-of-care technology with education provided to PSWs in palliative care.

Author, year, country	Aim	Study design	Intervention
Sadang et al, 2023, India [137]	To investigate barriers and facilitators to implementing Early Integrated Palliative Care via telehealth by surveying palliative care clinicians participating in a large-scale multisite palliative care trial comparing in-person and video visit-based services.	Multisite randomized trial	Early Integrated Palliative Care via secure video and/or in-person visits by advanced practice providers or board-certified physicians specializing in palliative care and/or oncology, at least monthly, beginning within 12 wk of diagnosis of advanced lung cancer.
Salem et al, 2020, Lebanon [138]	To assess caregiver and provider perceptions of the safety and efficacy of the Distance Support Program of a home-based palliative care provider.	Qualitative study	Distance Support Program including linking patients to a primary provider, face-to-face encounter, 24/7 telephone access, provider-initiated contact, and communication via telephone, messaging, or videophone.
Salimian et al 2019, Iran [139]	To develop the initial version of a mobile app for cancer palliative care for the purpose of improving the quality of life of cancer patients.	Mixed methods study	The mobile app "Ghasedak" for cancer palliative care, which includes functionalities such as user training on cancer and palliative care, clinician appointment reminders, personal health tracking, user guide, app settings, and patient notes.
Saysell and Routley, 2003, United Kingdom [140]	To address the national shortage of consultants in palliative medicine in the United Kingdom by implementing a telemedicine project to provide access to consultant advice and support for clinical nurse specialists in palliative care.	Mixed methods study	Weekly 2-h teleconference sessions between CNSs[s] and a consultant in palliative medicine to discuss patients with unresolved symptoms or significant palliative care issues.
Septian et al, 2025 [141]	To systematically synthesize the existing evidence from systematic reviews regarding: (1) the benefits of telehealth use on the quality of care and (2) the impact of telehealth on the quality of life of terminally ill patients.	Review	Telehealth to support terminally ill patients.
Schmitt et al, 2022, United States [142]	To describe the demographics of pediatric patients receiving telepalliative care, assess patient and family satisfaction with telepalliative care, and explore motives for using telepalliative services.	Retrospective EMR[t] chart review	Telepalliative visits.
Schoppee et al, 2020, United States [143]	To evaluate the acceptability of using the PAINReportIt completed on Wi-Fi-enabled tablets in the homes of patients with end-stage cancer and their caregivers for reporting pain related to end-stage cancer.	Pretest/posttest study	The PAINReportIt tool on a Wi-Fi-enabled tablet in patients' homes for reporting pain in real time to hospice nurses, with patients and caregivers completing the tool daily for a week.
Schuessler and Glarcher, 2024 [144]	To describe formal and informal caregivers' opportunities in telepalliative care and explore the associated ethical and safety challenges.	Integrative review of qualitative and quantitative studies.	The interventions included teleconsultation, supported by a step-by-step teleconsultation intervention protocol, telehealth options via telephone or videophone, web-based information, or smartphone apps for patient self-management, and the ENABLE CHF-PC[u] intervention involving face-to-face outpatient palliative care consultation and monthly telephone care coach sessions.

Author, year, country	Aim	Study design	Intervention
Slavin-Stewart et al, 2020, Canada [145]	To assess the feasibility of using FaceTime over a mobile cellular data network to provide improved access to specialist palliative care for patients in rural Nova Scotia, focusing on using low-cost technology to enhance access to palliative care services in underserviced areas.	Observational study	Participants received regular home-based visits from a palliative care nurse who used the FaceTime app to connect with the palliative care physician in Halifax. The nurse used an Apple iPad with the FaceTime app and a cellular data package during these visits.
Steindal et al, 2023 [146]	To critically appraise and synthesize evidence on patients' use of telehealth in home-based palliative care, focusing on the advantages and challenges experienced by patients.	Systematic mixed studies review with a convergent design.	Telehealth technology for home-based palliative care, including video consultations in synchronous mode for teleconsultations and remote monitoring in asynchronous mode for symptom management.
Stern et al, 2012, Canada [147]	To explore family caregivers and palliative cancer patients' patterns of use, perceptions of, and experiences with home telehealth in the context of palliative cancer care.	Mixed methods case study with a focus on qualitative methods	The intervention included specialist nurses available 24 h per day who communicated with patients and families using videophones, with optional remote monitoring of vital signs such as blood pressure, blood oxygen levels, and heart, lung, and abdominal sounds. Communication was done via telephone or videophone as required.
Sutherland et al, 2020 [148]	To evaluate the use of video consultations as an alternative to face-to-face visits in palliative care during the COVID-19 pandemic.	Systematic review	Video consultations using various technologies, cost reduction for patients, telehealth interventions (electronic patient records, telephone advice consultations, and telehealth monitoring), and home visits.
Tasneem et al, 2019, United States [149]	To assess patient perceptions on the impact of telemedicine video visits on care and to evaluate the ease of use and impact on health management of videoconference telemedicine for palliative care oncology patients in an urban setting.	Qualitative study	Telemedicine video visits conducted through web-based face-to-face videoconferences.
Tarbi et al, 2025, United States [150]	To explore if and how recommended in-person best practices for establishing human connection are adapted to the telehealth palliative care setting to enable discovery and description of practice innovations in this new care environment.	Qualitative study	Telepalliative consultations that support clinician connection-building communication practices in rural telepalliative care encounters.
Tieman et al, 2016, Australia [151]	To explore how telehealth can provide more regular engagement, continuous monitoring, and immediate access to resources for patients and families ultimately aiming to improve the efficiency and effectiveness of palliative care delivery in the community.	Prospective cohort study	Video-based conferences, virtual case conferences, self-report assessment tools, and remote activity monitoring.
Toenne et al, 2025, Germany [152]	To evaluate the acceptance and challenges of implementing teleconsultations among specialized outpatient pediatric palliative care health care professionals.	Survey	Telehealth.

XSL•FO

Tong et al, 2022, United States [153]	To evaluate the experiences of remote volunteer palliative care consultants during the initial COVID-19 surge, examining motivations, emotional toll, lessons learned, and providing insights for future efforts in extending remote palliative care services.	Qualitative study	A palliative care virtual consultation program.
van Gurp et al, 2013, The Netherlands [154]	To describe elements of both the physical workplace and the cultural-social context of the palliative care practice, which are imperative for the use of teleconsultation technologies.	Qualitative study	Synchronous, audiovisual teleconsultation via webcam and iPad for patients with palliative care needs at home.
van Gurp et al, 2016, The Netherlands [155]	To investigate how teleconsultation supports the integration of primary care, specialist palliative care, and patient perspectives and services, as well as how patients and informal caregivers experience collaboration through teleconsultation.	Qualitative study	Teleconsultation between home-based patients with palliative care needs and a hospital-based SPCT conducted synchronously and audiovisual, including tripartite consultations between the patient, primary care physician, and SPCT.
Salvador Verges et al, 2022 [156]	To describe the current use of telemedicine in palliative care and assess stakeholders' views on the initiatives implemented worldwide regarding digital service standards.	Scoping review	Telemedicine for patient and caregiver support, professional education, and routine follow-up in palliative care.
Vincent et al, 2022, Canada [157]	To explore the experiences and perceptions of community palliative care providers, patients, and caregivers who delivered or received virtual palliative care as a component of home-based palliative care during the COVID-19 pandemic.	Qualitative study using phone and video-based semistructured interviews	Virtual palliative care as a component of home-based palliative care during the COVID-19 pandemic.
Washington et al, 2009, United States [158]	To measure telehospice acceptance in a national sample of hospice professionals from various disciplines and to explore the usefulness and ease of use of telehospice technology among different disciplinary backgrounds.	Cross-sectional study	The intervention was the use of videophone technology in the workplace for telehospice services, as demonstrated to participants through a web-based streaming video.
Weaver et al, 2021, United States [159]	To determine the acceptability of telehealth inclusion of a familiar pediatric palliative care provider during the first 2 home-based hospice visits to children, families, and adult-trained home hospice nurses in rural settings.	Case series	Virtual transition to home program with the inpatient pediatric palliative care physician joining the home hospice nurse's in-person visit as a telehealth presence using a FaceTime screen on day 1 and day 14 at home.
Whitten et al 2004, United States [160]	To investigate the use of telehospice services from patients' perspective, focusing on how telehospice is used, reasons for patient declination, and patient satisfaction and preferences regarding telehospice care.	Mixed methods	Telehospice services provided via videophones transmitting real-time video and audio images through the analog phone system, including nursing, social work, and spiritual care televisits.
Williams et al, 2024, United States [161]	To compare the provision of pediatric palliative care by delivery method.	A retrospective chart review	Telehealth for pediatric palliative care.
Wood et al, 2025 [162]	To synthesize how, why, and in which circumstances can videoconferencing be used to successfully meet the emotional support needs of adults receiving palliative care?	Realist review	Video consultations, ie, video calls among adult patients and the bereaved to support emotions by palliative care organizations.

[v]PPHC: Paediatric Palliative Home Care.

Publication dates ranged from 2001 to 2026. Studies from high-income countries were conducted in the Americas (n=45, 35.71%), Europe (n=26, 20.63%), Australasia (n=12, 9.52%), and Asia (n=2, 1.58%). The LMICs represented were from Africa (n=4, 3.17%, representing 22 countries), the Middle East (n=2, 1.58%; ie, Iran and Lebanon), and Asia (n=2, 1.58%; ie, China and India) [9,35,116]. Studies featured qualitative design, including participatory co-design studies and case studies (n=48, 38.09%), mixed method studies (n=25, 19.84%), reviews (n=33, 26.19%), and quantitative studies, which included descriptive (n=14, 11.11%), randomized (n=4, 3.17%), and nonrandomized (n=2, 1.58%) trials.

The majority of the studies met most of the quality criteria (Multimedia Appendix 1). Regarding MMAT scores, the studies scored between 0 and 5 criteria, with a median score of 4.5 (IQR

XSL•FO
RenderX

3-5). For systematic reviews and meta-analyses, the median score was 9 (IQR 8-10) on the Joanna Briggs Institute quality assessment tool.

Focus of Included Studies

Overview

mHealth emerged as a key strategy for managing symptoms and improving palliative care delivery [52,62,64,70,77]. A recurring theme across studies was the use of technology to facilitate better communication [11,46,50,100,104,125] and care coordination among patients, caregivers, and health care providers [9,59,134]. Several studies concentrated on the psychological impact of digital interventions for both patients and families, highlighting their potential to alleviate distress and improve well-being [45,68,82,116,122,139,162]. End user experiences were critically assessed, with studies delving into patient and caregiver acceptance [93,98,101,106,109], satisfaction, and usability challenges [74,80,99,105,107,121]. Barriers to and facilitators of the wider adoption and integration of telehealth (ie, the use of electronic information and telecommunication technologies to support long-distance health care) into palliative care were also explored, identifying both technical and systemic influencers [41,127,130,132,135,141,150,152,161,167]. The applicability of telehealth in rural [62,117,168] or resource-constrained settings was reported with feasibility and potential to bridge gaps in health care delivery were examined [133,136,143]. Several studies further analyzed the resource utilization and cost-effectiveness of telehealth [49,145,151]. The role of mHealth in pediatric palliative care was also highlighted, as well as the rapid implementation and effectiveness of telehealth interventions during the COVID-19 pandemic [48,51,73,95,126,159].

Type of Technology Used

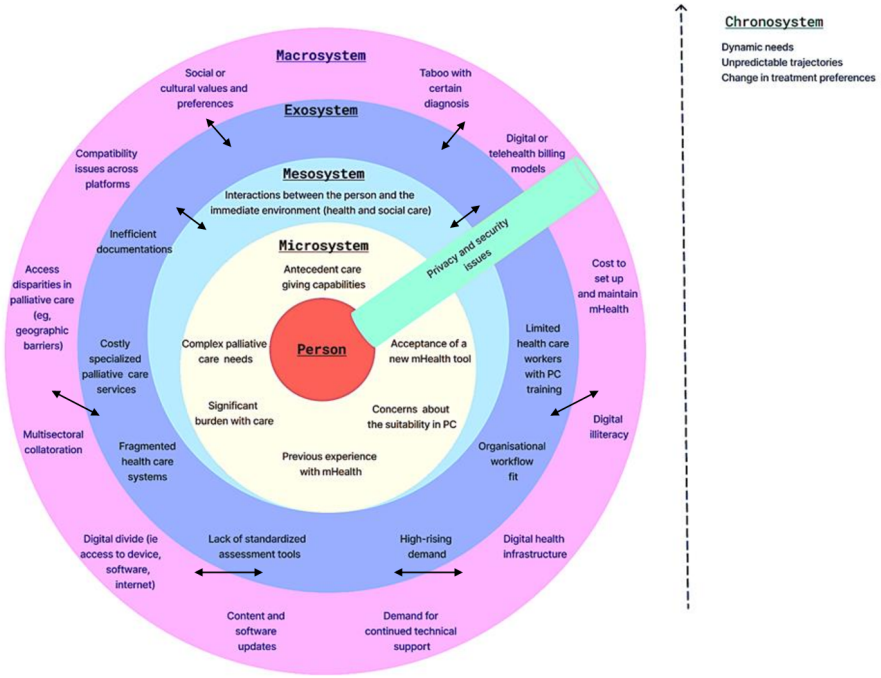
The studies assessed a broad range of electronic devices and described the features for the software used. mHealth devices used were mobile phones or mobile apps (n=23, 18.25%) [9,12,35,45,59,68,74,80,82,99,105,107,116,121,122,127,132-134,136,139,143,145,151], web-based platforms with videoconferencing features (n=15, 11.9%) [48,49,51,56,73,88,95,103,112,114,126,129,140,159,169], direct calls or SMS text messaging (n=4, 3.17%) [9,134,170], and videophones (n=9, 7.14%) [55,72,125,147,160]. The remaining studies included a mix of technologies (n=36, 28.57%) [47,56,63,83,86,87,91,92,94,102,108,110,115,118-120,123,124,137,144,146,148,149,153-155,163,165,166,171,172]. The specialized technologies in the studies were an embedded camera pen, remote symptom monitoring wristbands, and e-PC software with integrated camera laptop [51,79].

Purpose of the Interventions

mHealth was used for recording pain or other symptoms (n=9, 7.14%) [9,12,61,74,81,138,159,165,166] or remote monitoring (n=15, 11.9%) [11,47,56,63,67,78,86,89,102,111,119,124,126,129,139,147,170], support with medication [11,12], accessing information or serving as an educational resource [10,94,105,123,124,138,159,160,166], and care coordination [45,87,133,139]. Some of the mHealth apps also had built-in alert features [58,74,76]. A few studies engaged diverse stakeholder groups to help develop the interventions [70,81,84,126,127,137,139,140,153,158].

End Users of mHealth Interventions

The majority of the end users for mHealth interventions were health care professionals [35,72,76,81,84,108,122-124,127,140,164], adult patients [48,56,69,82,87,88,92,96,97,108,113,119-122,134,137,143,156,171], and informal caregivers [9,11,51,59,60,66,82,83,105,112,121-123,132,143,147,153,154,157,163,173]. Only 3 (2.38%) studies directly engaged children or adolescent patients [60,166,169], while other studies broadly explored the use of mHealth to support palliative care for the pediatric population [12,55,61,66,92,94,115,136,173].



The Contextual Factors That Influence Mechanisms and Outcomes of mHealth

Overview

The contextual factors within which mHealth interventions were described using the Framework of Complexity in Palliative Care Context [32] (Figure 3). They encompassed a range of technological, organizational, economical, and social dimensions.

XSL•FO
RenderX

Figure 3. Contextual factors mapped to the domains of the framework of complexity in the palliative care (PC) context demonstrate the relationship between concepts mapped to the interconnected environmental layers of the ecological system model. Key: microsystem (person and immediate social environment and setting), chronosystem (influences of time), mesosystem (interactions between agents in the immediate environment), exosystem (factors within health services or systems), and macrosystem (factors beyond health care) [32]. mHealth: mobile health.

In the microsystem, important concepts were persons' or mHealth end users' needs (ie, complex health care and technology-related requirements) [45,63,142]. Individuals' characteristics were also key, which included limited knowledge about and the skills to support complex palliative care needs [92,97,123,156], the burden experienced by caregivers [9,12,121,128,142], and information gaps [88,134]. Concerning the acceptance of new mHealth tools, contextual concerns reported by end users encompassed their suitability in a palliative care context [95] and the perceived burden of monitoring symptoms for patients and family carers [48]. Furthermore, health care professionals had worries regarding reimbursement with the transition to virtual models of care [49,144]. In addition, having previous experience with similar DHIs and users' technical competency appeared to influence end users' confidence in using mHealth [57,76,90,92,99]. As depicted in the mesosystem, existing interpersonal relationships significantly influenced the utility of mHealth interventions. In fragmented health care systems, communication and information exchange challenges were particularly prominent, signifying the relevance of mHealth in such contexts [9,45,63,65,66,68,72,85,89,92,95,99,100,103,106,110,112,114,122,123,127,134,137,139,140,144,147,148,151,154,156,161,164,167,171,174]. Contextual factors that were identified in the chronosystem comprised the dynamic needs and fluctuating symptoms, which influenced patients' goals of care and treatment preferences [45,47,51,63,142] and thus impacted their willingness and ability to engage with mHealth technologies. Furthermore, end users, especially older adults, needed time to feel confident and become proficient with digital health tools [51,68].

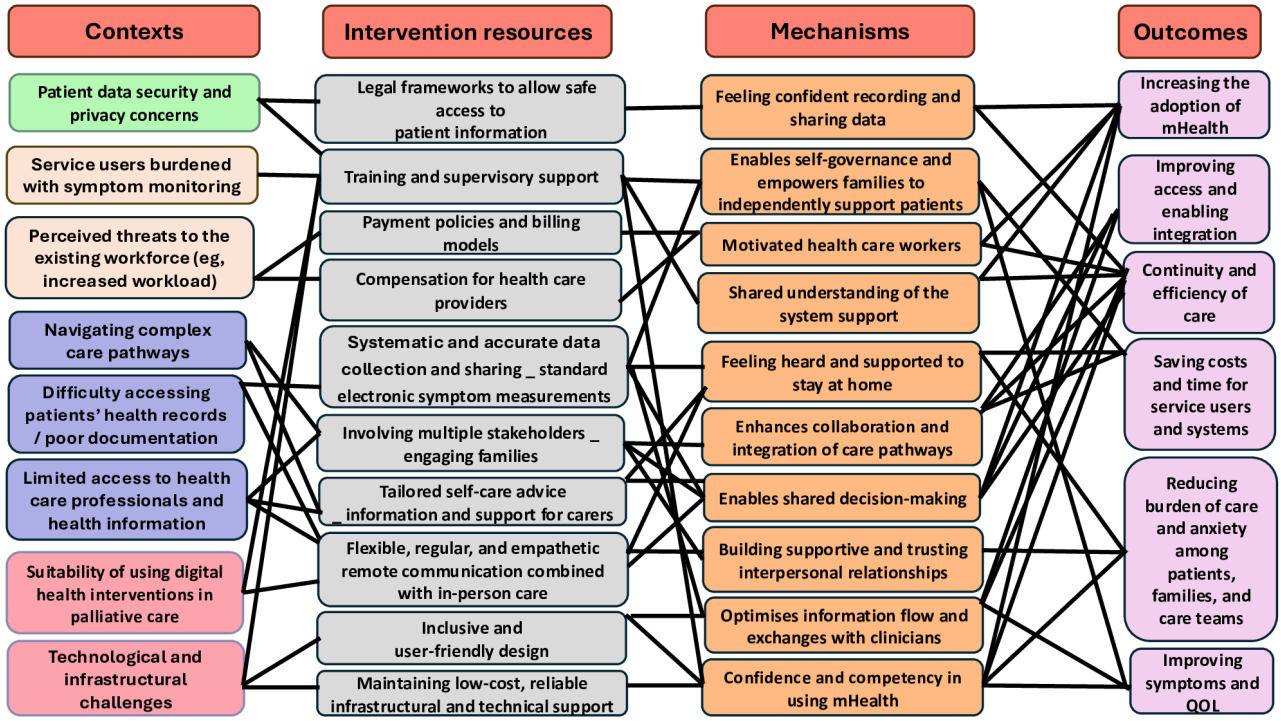
In the exosystem, there were challenges in terms of a rising demand for palliative care [9,48,85,94,95,108,110,112,115,116,118-120,127,131,136], the lack of standardized assessment tools to appropriately identify patients who require palliative care [35,94,102,105,108,113,126,133,140,143], inefficient documentation and data sharing [87,127,147], and fragmented or siloed health care interventions [60,102,147]. Finally, contextual factors in the macrosystem encompassed disparities in health care access due to geographical barriers, lack of mHealth infrastructure, and inadequate technical support for end users [35,69,71,84,91,116,118,145,174]. Aligning technology with relevant social and cultural values [54,65,67] was reported as key to the successful adoption of mHealth [12,61,88,92,103,105,107,114,121,128,134]. The studies also highlighted the need for legal and organizational frameworks and regulations to ensure data privacy and security [51,94,110,115,119,120,124,126,132,148]. Multisectoral stakeholder engagement was important in the design and implementation stages as buy-in from each stakeholder influences intervention uptake and sustained use [49,99,103,134].

The CMOCs for the refined program theory are reported below and summarized in Table 3 and shown in Figure 4.

XSL•FO
RenderX

Table . List of context-mechanism-outcome configurations (CMOCs).

CMOCs	Description of CMOCs	Evidence summary (studies which contributed to CMOCs)
CMOC 1: Mitigating concerns and perceived threats	• 1.1 There are uncertainties about the suitability of mHealth[a] interventions in palliative care contexts in which patients need regular and holistic assessment and support (C), and where monitoring of worsening symptoms could be unsettling (C). Therefore, designing such tools tailored to end users' needs and capabilities, and providing appropriate orientation on the roles of end users, the frequency and timing of use, and what to expect from the interventions (IR) creates shared understanding (M) and comfort in using them (M) to potentially improve care delivery (O). • 1.2 The concerns about patient data security and privacy (C) necessitate that standard legal and ethical frameworks are established and adhered to (ie, to protect patient information) (IR), which creates feelings of security when recording and sharing data (M), thereby increasing the uptake of mHealth (O). • 1.3 The perceived threats to health care providers in terms of additional workload with less or no pay (C) demand the recognition of mHealth-supported home-based palliative care as standard payable services (eg, through the introduction of payment policies and billing models) (IR) and appropriate compensation for the health workforce (IR). This acknowledges the efforts and time health care workers spend, motivating them (M) to use mHealth and enabling better integration of mHealth with existing health care systems (O).	• [45,47,49,63,102,107,128,149,164] • [9,12,35,45,57,60,66,69,70,105,121,132,151] • [12,56,61,69,74,97,102,103,120,134,136,147,156,157]
CMOC 2: Minimizing infrastructural and technical barriers for user-friendly and sustained mHealth use	• The diverse infrastructural and technological experiences end users have (C) require training and education (IR) and maintaining low-cost, reliable infrastructure (IR) as well as inclusive and user-friendly design alongside offering technical support (IR). This improves confidence (M) and competency in using mHealth interventions (M), thus ensuring usability and wide-scale user penetration (O), which enables the standardization of health care delivery (O).	• [redacted]
CMOC 3: Engaging multiple stakeholders for better integration	• In contexts where patients, families, and care providers are required to navigate complex health care pathways (C), the development of mHealth interventions, which involves multiple stakeholders with diverse roles (IR), creates a shared understanding of the technical and system supports required (M), enhances collaborative relationships (M), and the integration of care pathways (M), which optimize resource utilization (O), potentially saving costs and time for both service users and health care systems (O).	• [redacted]



XSL•FO
RenderX

CMOCs	Description of CMOCs	Evidence summary (studies which contributed to CMOCs)
CMOC 4: Streamlined health management information system	• In home-based palliative care contexts where accessing patients' health records and documenting or sharing data is challenging (C), electronic data recording (IR) and standardized digital symptom measurement tools (IR) enable systematic and more accurate data capturing (M) as well as remote monitoring of symptoms (IR). This gives patients and caregivers a sense of comfort (M) and confidence knowing a health care team could be remotely accessible when needed (M), avoiding the inconvenience of unnecessary visits to health care facilities (O), and enabling preemptive management of problems, thus increasing the timeliness of the required support (O).	• [illegible]
CMOC 5: Regular communication and access to care	• 5.1 In the palliative care context where frequent communication with health care providers is necessary to support complex needs, often with unpredictable trajectories and limited access to health care professionals (C), mHealth provides a flexible and empathetic communication platform (IR), strengthening relationships between service users and service providers (M). This reduces the burden of care and anxiety among patients and families/informal caregivers (O), thus enhancing quality of life (O). • 5.2 In contexts where family caregivers are routinely closely involved in care provision (C), combining both in-person and virtual care (IR) and allowing families to join the conversation on equal terms, even remotely, (IR), enables shared decision-making (M) for better management of symptoms (O).	• [illegible] • [illegible]
CMOC 6: Access adequate information to support symptom	• In the palliative care context where adequate information about complex needs and options to support patients and caregivers is required (C), mHealth provides accessible self-care advice tailored to needs and the opportunity for knowledge exchange among health care workers (IR). This empowers end users (ie, patients, families, and junior health care professionals) to independently and effectively support symptoms (M), improving the efficiency of health care delivery (O) and quality of life (O).	• [illegible]

[a]mHealth: mobile health.

Figure 4. Conceptual model of context-mechanism-outcome configurations (CMOCs) illustrating how contextual factors within a multilevel system and mobile health (mHealth) intervention resources (eg, access to information or data) activate mechanisms (eg, improved capability, confidence, or strengthened interactions), leading to outcomes such as mHealth uptake, individual clinical outcomes, and health system–level impacts. The black lines indicate commonly reported pathways between context, intervention resources, mechanisms, and outcomes. Key: The first column (ie, context) is color coded according to the levels in the framework of complexity in palliative care context. Green: cross-cutting concept across levels in the system, beige: microsystem, blue: exosystem, pink: macrosystem. QOL: quality of life.

CMOC 1: Mitigating Concerns and Perceived Threats of mHealth

mHealth implementation may be resisted by various end users due to the concerns they may have about the intervention. One of the concerns is the suitability of using DHIs in palliative care for vulnerable patients and inadequately prepared informal caregivers who are already burdened with illness and caretaking responsibilities. This is mitigated by providing appropriate orientation on what to expect from DHIs, the role of end users, and when to use such tools. This in turn creates a shared understanding and tailored use directed to goals of care. Regarding apprehensions about patient data security and privacy, mHealth interventions that are designed adhering to international and local standard legal and ethical protocols and guidelines ensure feelings of security when recording and sharing data and safeguard patient information, which will encourage uptake and sustained use. Health care workers perceived they would experience job security threats and increased workload, for example, with parallel documentation. Furthermore, conventional health care systems were anticipated to take time to adopt mHealth enhanced models, with the need to develop payment protocols or billing systems and lease with the health workforce in the implementation. The shift toward mHealth creates concerns that existing interpersonal interactions would be disrupted. Thus, both service users and providers demanded that health care visits should be a combination of in-person and mHealth. Responding to such concerns will increase the acceptance of digital health technologies for improved care delivery.

CMOC 2: Minimizing Technical and Infrastructural Barriers for Sustained mHealth Use

Despite increasing access to mobile phones and increased routine use of mHealth, universal access to mobile devices has not been achieved. Reliability issues and inadequate technical support persist as key challenges in home-based palliative care. Sustained use depends on reliable infrastructure and technology tailored to local capacities. For mHealth to effectively support health care delivery, it should accommodate users' varying capabilities. National government and institutional support, through policies that promote mHealth adoption, is essential for successful implementation. Moreover, at the design phase, it is important to ensure that the technology is user-friendly and meets the needs of patients, families, and care providers. Health care workers who are confident in their technical skills are more likely to adopt these technologies. Yet, to be inclusive, all end users should receive orientation on the technical and functional aspects of such technologies for standardized use. This will improve self-efficacy and competency, thus ensuring usability with potential for wide-scale user penetration.

CMOC 3: Engaging Multiple Stakeholders for Better Integration

In contexts where both service users and care providers are required to navigate complex health care pathways, the development of clinically meaningful mHealth interventions must be designed with relevant multisectoral stakeholders from diverse disciplines. This approach will facilitate the consideration of unique perspectives and address the utility and usability needs and preferences of patients, family caregivers,

XSL•FO
RenderX

and health care workers. It is also important to assess the experiences and expectations of various end users, their competencies, and systems constraints to achieve optimal usage for intended outcomes. Furthermore, mHealth interventions must fulfill the standard requirements of health management information systems to ensure effective implementation and integration with routine care. The integration of mHealth in home-based palliative care presents numerous opportunities to enhance care delivery. For example, when mHealth interventions are seamlessly fitting into the standard workflow, health care workers' capacity to address patients' needs will increase, which improves the care experience for patients, optimizes resource use, and potentially saves costs and time for both service users and providers.

CMOC 4: Streamlined Health Management Information System

mHealth interventions represent efficient care delivery approaches that are well accepted by patients, families, and health care providers who value collaborative care planning and enhanced care coordination to improve patient outcomes. mHealth interventions designed to allow structured collection and reporting of symptoms, such as pain, using digitalized symptom reporting tools by patients or their carers enhance appropriate and timely management. Electronic health recording allows health care providers to closely monitor patients' conditions even remotely, triaging patients based on severity of symptoms for tailored response, which results in improved quality of care and health care workers' productivity. Primary care clinicians and generalist palliative care providers could document visits and share data for remote consultations with palliative care specialists, promoting knowledge exchange among health care teams. In addition, mHealth provides the opportunity for palliative care specialists to directly connect with service users (patients and family carers) through real-time audiovisual support. mHealth facilitates home-based care, improving comfort and convenience for patients and families while reducing risks linked to facility-based treatment.

CMOC 5: Improved Access to Care

In the management of chronic life-limiting illnesses, direct access to health care providers and regular symptom support are important. mHealth interventions designed to augment home-based palliative care play a pivotal role in facilitating access by surmounting geographical constraints, particularly for underserved populations and communities residing in remote areas. In palliative care context, such tools assist patients with an advanced stage of illness who have difficulties visiting health care facilities or those facing physical barriers to conventional health care services under unique circumstances, as observed during the COVID-19 pandemic. Both health care providers and recipients benefit from reduced burdens associated with logistical challenges and financial expenses associated with traveling to distant health care facilities. Moreover, mHealth fostered close communication between patients and providers and strengthened relationships. Family carers felt more supported, and their capacity to care for their loved ones improved, which reduced the anxiety associated with providing care for patients with serious illnesses. Considering the increasing demand for palliative care and the limited number of palliative care specialists, this is highly relevant to ensuring continuity of care and access to more equitable services.

CMOC 6: Access to Adequate Information to Manage Symptoms

The implementation of mHealth interventions serves as a means of disseminating information, thereby augmenting patient engagement in their health care journey. Patients are empowered as their comprehension of illness and its management deepens through personalized self-care advice to manage common symptoms. Empowered patients are more likely to engage in proactive healthy behaviors and adhere to medical advice, which improves symptoms and quality of life. Informal caregivers also benefit from applying mHealth tools in their caregiving roles to enhance their understanding and capabilities to support their loved ones. Health care professionals also use such interventions to access educational resources to assist them in care delivery.

Discussion

Principal Findings

This study presents a novel program theory to explore how, why, and under what circumstances mHealth interventions are designed and implemented to support better access to quality home-based palliative care. A program theory (Figure 4) is proposed on the causal explanations and key implementation strategies for successfully integrating mHealth interventions to support home-based palliative care. The important underlying mechanisms highlighted for mHealth intervention to support home-based service are the comfort patients and caregivers had staying at home having access to health care teams when needed; strengthened relationships between service users and providers through regular communication; empowerment of patients, families, and health care providers to independently and effectively manage symptoms through improved knowledge and skills; shared decision-making involving families; having a shared understanding of the technical and system support required; feeling confident and safe with using such technologies; motivation of health care workers through recognition and compensation of their time and effort; and enhanced collaboration and integration with existing health care systems.

Several systematic reviews on mHealth interventions have explored perceptions of end users on the advantages and challenges of their use for home-based palliative care. Our findings are supported by these reviews [3,108], which identified similar individual, interpersonal, organizational, and health systems factors influencing engagement with and effectiveness of mHealth. In palliative care, timely access to services impacts patient comfort and quality of life. mHealth has been identified as a health system–strengthening intervention [3,175]. The impact of mHealth has also been recognized in enhancing operations in pharmaceutical supply chain management systems [176] and in improving care coordination across levels of health care [177]. In studies from sub-Saharan Africa, such benefits were observed in populations living with HIV or AIDS and cancer [178,179]. Collectively, these reviews affirm that

XSL•FO
RenderX

mHealth not only enhances individual patient care but also strengthens the broader health care system, making it more accessible, efficient, and resilient. The role of informal caregivers in adapting DHIs in resource-limited settings has also been described previously [180]. Although continuous monitoring and immediate access to information and support can reduce anxiety in patients and their informal carers, this needs to be balanced with the burden of frequent assessment and reporting of symptoms by service users [181,182]. Furthermore, the combination of face-to-face alongside virtual contacts is encouraged [183]; building rapport in an initial in-person visit to develop better therapeutic relationships with subsequent contacts through technology. This prevents the care process from becoming depersonalized and mechanical, which contradicts the principles of person-centeredness in palliative care.

Strengths and Limitations

The evidence generated in this review drew from a broad global literature to determine how mHealth interventions improve access to and quality of home-based palliative care. It also incorporated perspectives from global and local stakeholders to refine the review focus and enhance the synthesis. The application of the framework of complexity in the palliative care context strengthened the comprehensive exploration of contextual influences of mHealth for home-based palliative care demonstrating interactions of multiple factors in the system. To allow us to generate findings and to provide comprehensive recommendations for home-based palliative care, we did not restrict mHealth use by type of user, the use case, conditions or diagnosis, or type of study. The emphasis of the synthesis was on underpinning mechanisms of action that influence outcomes, which have not been explored in detail in existing literature, nor explicitly stated in the included studies. Therefore, the hypotheses suggested in this study require further testing and refinement.

Contextual variations require intervention strategies that are tailored to the needs or preferences of end users. Most of the included studies in this review were notably from high-income countries; in 7 primary and multisite studies, only 24 countries were represented from LMICs. Therefore, application of these findings from this study needs careful consideration. Despite robust search strategies, only papers published in the English language were considered.

Recommendations

We have a number of recommendations from this review. To promote the effective integration of mHealth into home-based palliative care, it is essential to advocate for policies that support its adoption and seamless integration within health care systems. This can be achieved through the collaborative co-design of mHealth solutions with multisectoral stakeholders, ensuring that such tools address contextual barriers and align with existing health care infrastructure. The development of user-friendly mHealth interventions, tailored to the specific needs of end users, should be accompanied by comprehensive orientation and technical support to enhance usability and maximize benefits. Additionally, the involvement of informal caregivers, particularly in cultures that emphasize family engagement, is crucial for shared decision-making and the creation of personalized care plans that improve patient outcomes. Investing in reliable infrastructure and support systems is vital to minimize technical failures and ensure continuous care delivery. mHealth should also be leveraged to provide self-care guidance and equip informal caregivers with the necessary skills to support patients at home, thus alleviating pressure from the health care systems. In addition, health care providers must be adequately compensated for the additional time and effort required to operationalize mHealth interventions, which would encourage their active participation in enhancing patient care. Furthermore, the impact of mHealth interventions should be rigorously evaluated to provide evidence that informs policy decisions and promotes best practices that meet the needs of end users. Ongoing research is also necessary to explore the integration processes of mHealth interventions within health care systems, applying standardized frameworks to better understand factors influencing successful implementation.

Conclusions

To enhance usability and impact of mHealth interventions, it is important to adopt strategies that focus on the important mechanisms identified in this study. These mechanisms include patient and caregiver comfort with home-based care, strengthened provider-user relationships through regular communication, empowerment through better knowledge and skills, family-inclusive decision-making, shared understanding of the technical and system supports, confidence in using technology, motivation of health care workers through recognition and reimbursement, and improved integration with existing health care systems. Further study is needed to validate and evaluate these mechanisms in tailored interventions in LMICs.

Abstract

Background: Mobile health (mHealth) uses mobile technology as a tool for prevention and health promotion. Research indicates that user engagement is crucial for effective mHealth interventions and improved health outcomes. However, many studies report low adoption rates, rapid decline after initial use, and a lack of acknowledgment of user implications in achieving outcomes. Thus, conceptualizing participation in mHealth is essential to identify key determinants for engaging users.

Objective: This scoping review aims to identify and characterize the attributes and definitions of user engagement in mHealth, examine engagement methods, and analyze barriers and facilitators influencing participation.

Methods: Following the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) guidelines, Scopus, Web of Science, and PubMed databases were searched for publications between 2000 and 2025 with a 2-stage selection process.

Results: Out of 2489 articles identified, 1416 were screened, and 52 met the inclusion criteria. Half were recently published in the last 5 years (2020 - 2025). Existing literature focused on digital interventions for specific populations and health topics. Analysis revealed four main perspectives on engagement in mHealth: (1) usage metrics, (2) subjective user experiences, (3) a hybrid approach that combines both, and (4) a goal-oriented perspective (behavior change or health outcomes).

Conclusions: To understand the complexity and multifactorial nature of participation, it is relevant to conceptualize it as a dynamic mechanism enabling users to achieve their objectives. Both quantitative use and subjective user experience should be integrated to reach the optimal intervention dose. Recognizing users' evolving needs, uniqueness, and their socioenvironmental context interdependence, it is essential to involve users in all stages (design, implementation, and iterative evaluation of mHealth). Findings will inform an e-Delphi study to establish consensus on engagement criteria.

Introduction

The World Health Organization's Global Observatory for eHealth defines mobile health (mHealth) as "medical and public health practices supported by mobile devices such as mobile phones, patient monitoring devices, personal digital assistants (PDAs), and other wireless devices" [1]. mHealth emerged as a promising approach to enhance health care, health promotion, and prevention delivery by leveraging mobile technologies such as smartphones, tablets, and wearable devices [2-5].

Community participation is a crucial element in health prevention and promotion, as highlighted by several important documents and reports. The Ottawa Charter for Health Promotion established community participation as one of the fundamental principles for health promotion [6], and the importance of community engagement in reducing health inequalities has been demonstrated [7]. Going forward, the World Health Organization's Global Strategy for Health for All by 2030 has also emphasized the importance of community participation in the design, implementation, and evaluation of public health programs [8]. These documents and reports have contributed to establishing the importance of community participation in health prevention and promotion, and encouraged governments and health organizations to partner with communities to design and implement effective health programs. Studies have also demonstrated a correlation between user engagement and the effectiveness of web-based behavior change interventions [9,10]. Evidence suggests that greater user

XSL•FO
RenderX

engagement is associated with better health outcomes in various mHealth interventions [11,12].

However, actual usage and sustained engagement with mHealth remain limited. According to data collected between 2010 and 2019 from 12,000 respondents, approximately 25% of downloaded apps were opened only once before being abandoned [13]. More recent findings based on a study of 2200 Android apps revealed that, on average, one out of every two apps is uninstalled within 30 days of initial download, with most of these occurring in the initial 24-hour period postinstallation, often due to unmet expectations or a disconnect between the app's marketing and the actual user expectation [14,15]. In addition to studying accessibility, it is therefore important to explore the actual usage of these tools [16].

Currently, there is no widely accepted definition of participation [17,18], and there is a variability [19,20] and a lack of clarity around the question of how to conceptualize engagement [21]. Sometimes described as a "suitcase word," the term engagement can be associated with "almost any action involving the population, to a greater or lesser extent." Participation can take on various forms and intensities, leading to different classifications in the literature. Comprehensive definitions of participation, its conceptual boundaries, and practical modalities are not always explicit [22]. To our knowledge, there is no consolidated consensus of the characteristics, methods, barriers, and facilitators related to user participation in this context.

Consequently, there is a need to better understand how this concept is mobilized in order to guide future evaluators and designers of digital interventions toward participatory, effective, and sustainable approaches [14].

For these reasons, given the wide and exploratory nature of the research questions and the diversity of the existing literature, a scoping review was conducted in order to identify existing literature on user participation in mHealth. The following research questions were formulated: How is user participation characterized in digital health interventions? What techniques and/or methods are implemented to involve users? What are the barriers and facilitators encountered in implementing user participation?

This paper aims to (1) identify the attributes and definitions of user engagement, (2) examine the methods used for engaging users in mHealth, and (3) identify barriers and facilitators encountered in implementing user participation.

Methods

Study Design

A scoping review was chosen as a systematic approach to map the evidence and identify key concepts and relevant theories on the subject. To guide this review, the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) checklist for scoping reviews and tip sheets documents were used [23] (see Checklist 1).

Eligibility Criteria

Articles eligible for inclusion focused on mHealth interventions targeting health promotion and prevention. All reviews and primary articles were included. The articles had to be published in English or French between January 1, 2000, and April 14, 2025.

Exclusion criteria were studies focused on clinical interventions, disease management, and tool evaluations. Studies on health worker training were also excluded. Based on existing participation research in various other subject areas, interventions that consider engagement as simple service usage (such as logging in), information reception (where users only receive information), and consultation (where users express themselves using free text and this expression has no influence on the process) were excluded [24,25].

Information Sources

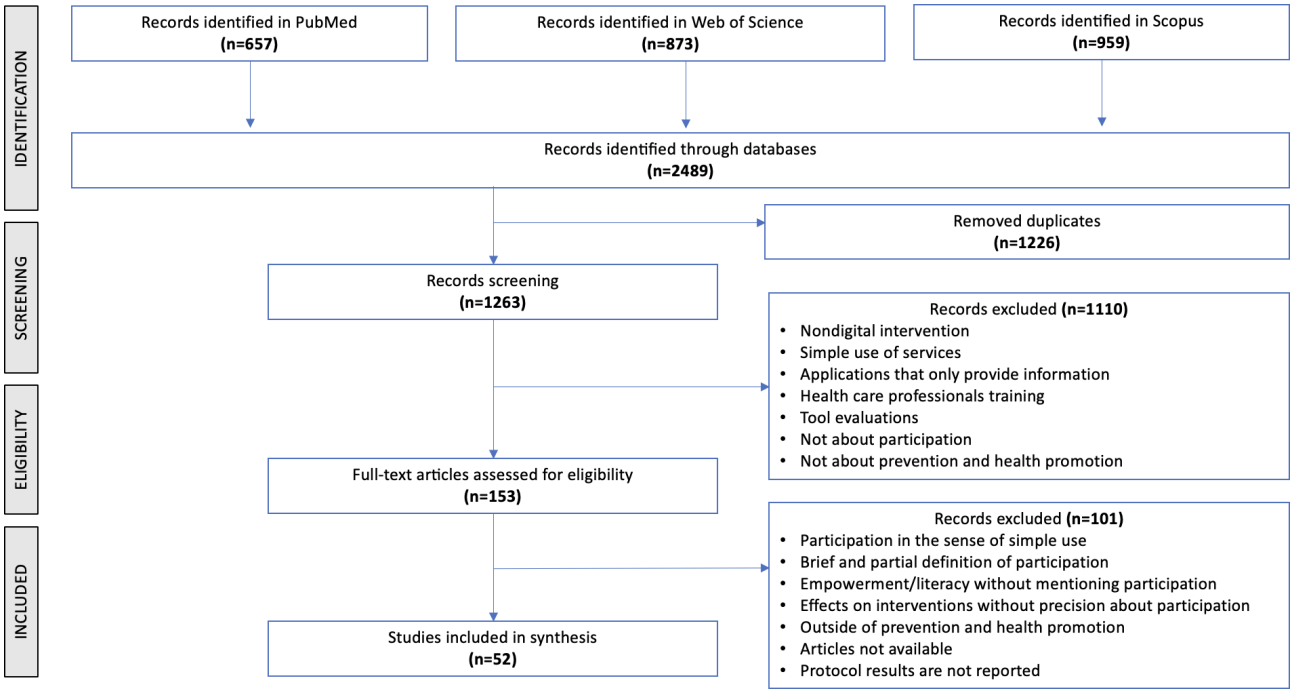
Literature searches were conducted in 3 databases: Scopus, Web of Science, and PubMed. These databases were chosen because of their focus on social behavior and medical sciences. Keywords were collected from articles of interest until saturation was reached. Then, keywords were refined considering the vocabulary of each database, adding additional keywords, using truncation to search by title, and sometimes by title and abstract. The search strategy was different for each database, adapted to the respective databases, and included the following terms divided into 3 categories relating to subject, medium, and field (see Multimedia Appendix 1).

Selection of Sources of Evidence

Search results were uploaded to Zotero to sort out duplicates. Then, the articles were transferred to Covidence, a web application for independent selection of articles by multiple researchers. A 2-stage selection process was established. First, titles and abstracts were screened by two authors (MA and OA) for inclusion or exclusion of articles. Then, discrepancies were solved through discussion until a consensus was reached. Finally, a full-text screening was carried out (MA).

Data Items and Synthesis of Results

The selected articles were analyzed using an evolving reading grid in Microsoft Excel, which includes a list of themes of interest based on the aim of the scoping review and research questions. These themes included (1) article presentation (goals, target population, etc); (2) attributes of participation (definitions, scales, etc); (3) methods used to engage users (theory, model, framework, etc); and (4) barriers, facilitators, and strategies to promote engagement.



Results

Overview

A total of 2489 articles were identified, 1226 duplicates removed, resulting in 782 unique articles. After reviewing the titles and abstracts, 153 articles were selected to read in full. Following a review of the complete articles and application of exclusion criteria, 52 articles were finally selected for analysis. Our selection process is illustrated in a flowchart (Figure 1).

XSL•FO
RenderX

Figure 1. Flowchart of the article selection process.

Description

A total of 52 articles were analyzed in this study. The chronological distribution indicates that 25 (48%) articles were published in the last 5 years (2020 - 2025), which corresponds to nearly the same number as those published over the previous 20 years (2000 - 2020), with 27 (52%) articles. Of the articles reviewed, 39 focused on digital interventions for a specific target audience, with 14 of these specifically aimed at adolescents and young adults. The 16 articles that are not about a digital intervention for a target audience are thematic articles that do not address a specific digital health intervention. In terms of health topics, 40 articles focused on a specific health issue, with prevention and/or health promotion being the most common topic in 7 articles, followed by AIDS in 5 articles, obesity in 4 articles, and tobacco in 3 articles (see Multimedia Appendix 2) [10,14,17-21,26-70].

Depending on the article, some or all of the information regarding definitions and attributes of participation, scales and methods of assessment, techniques used to involve users, and facilitators and barriers to implementing participation were obtained (see Multimedia Appendix 3) [10,14,17-21,26-70].

The results are organized into the following main subcategories to guide interpretation: (1) engagement attributes and definitions, (2) scale and gradation of participation, (3) methods and techniques used to engage users in digital health interventions, (4) difficulties and barriers to engagement, and (5) facilitators and suggestions to support sustained participation.

Engagement Attributes

First, there are different attributes depending on the discipline: according to scientists, participation is adherence and satisfaction, while for computer scientists, it corresponds to increased attention and enjoyment [21]; in behavioral literature, participation is frequency or duration, while for the gamification industry, it is subjective experience with the service including affect, interest, attention, and flow [18,26].

One recurring way of conceptualizing engagement is the duration and frequency with which the participant uses the eHealth intervention [10,21,27]. In the literature, engagement is generally considered to be ease of use, measuring interactions with the features and functions of the digital solution [17,18]. Engagement with digital health interventions can be defined by using quantity (eg, total number of times the intervention was accessed), duration (eg, total duration of use), frequency (eg, patterns of use), and depth (eg, content consumed during the intervention) [28,29].

However, when it comes to the frequency or duration of time spent using a digital service, some studies suggest that low frequency of use can be just as effective as higher frequency [26], and an increase in usage time can signal low ease of use rather than attractive content [20]. In the context of mHealth, engagement behavior is frequently assessed through passive measures of application usage [30], which fail to provide a comprehensive understanding of engagement with a digital platform [19]. Additionally, there is ongoing discourse surrounding the definition of this “more than usage” [18]. A study indicates that it is important to focus on “effective engagement” rather than simply “increased engagement” [14]. In 3 articles, the authors differentiate between engagement (meaning interactions with the tool) and effective engagement (sufficient participation in the intervention to achieve the desired effects) [14,20,31]. To achieve these desired effects, there is a need to determine an optimal duration and frequency of engagement [20]. However, the concept of optimal engagement dose is not yet clear in the field of digital health interventions [14,18]. In addition, the concept of participation is often confused with compliance, which refers to an individual following an instruction and using the intervention as intended by the developers [20,21,32].

XSL•FO
RenderX

In addition, to characterize participation, some studies focus on the user's experience, but they do not define experience in the same way [21]. For some, user experience is about interaction [17,19] or the desire of a user to use the application for longer and at frequent intervals. User experience quality is characterized by attributes of challenge, positive affect, endurance, aesthetic and sensory appeal, attention, feedback, variety/novelty, interactivity, and perceived user control [33] and includes sensual (aesthetic or novel elements that promote attention and interest), emotional (positive or negative effect elicited), and spatiotemporal (perceptions and awareness of time and the physical environment that the user experiences during use) categories [10].

Although authors assert that the subjective user experience can provide information about the degree of immersion in an application, it does not generally explain the cognitive engagement in the behavior change process. A health application can be entertaining and have good usability, but it does not necessarily lead the user to reflect on their behavior or to take action toward achieving their goals [26].

In one study, to define participation, the aforementioned elements of usage and experience are combined. Engagement in digital interventions is defined through the measures of usage extent (eg, quantity, frequency, duration, and depth) and subjective experience (eg, attention, interest, and affect) [14,34,35]. In the field of digital health behavior change interventions, engagement should therefore integrate objective measures (defined based on usage habits measured using various tools to track the number of logins, time spent online, and amount of content used during the intervention period, and also physiological measures using wearable sensors such as heart rate and electrodermal activity, as well as eye-tracking to determine psychophysiological measures) and subjective measures (defined based on self-evaluation questionnaires measuring levels of engagement with digital games and the intervention) [14,20].

Finally, the literature includes some definitions focused on the objective to be achieved: health benefit [32,36], changes for benefit [37], or behavior change [38]. One source defines participation in eHealth and health behavior change as "the process of involving users in health content in a way that motivates and drives health behavior change," while specifying that this is influenced by a number of variables [14,37-39] and is a complex process because it is evolving [39]. Engagement itself is influenced by intervention characteristics such as content, delivery mode, and contextual characteristics such as physical environment and individual characteristics; there are also potential moderators and mediators of the engagement process [21]. This multidimensional aspect is also mentioned in several articles, where engagement is described as a multidimensional process that involves, among other things, cognitive, emotional, behavioral, and social dimensions [27,30,33,36,40]. One study examined 3 fundamental dimensions: behavior, cognition, and affect. At the behavioral level, the successful usage of a given system is characterized by its routine integration into the daily lives of its users, ease of use, and intuitive interface design that requires minimal effort, and dynamic adaptability to meet the needs of users in different contexts or periods. From a cognitive perspective, mHealth must function as an effective instrument to facilitate the achievement of objectives, while concurrently offering novel perspectives through the provision of pertinent, personalized information, thereby sustaining motivation over an extended period. Finally, on an affective level, a positive experience translates into the pleasure of making progress, general satisfaction in using the application, and a feeling of attachment to the intervention, to the point of feeling its absence when it is not available [18]. Thus, for evaluation, engagement is too complex to be evaluated by a single method, and a combination of several methods should be used [21,41]. The advent of novel technologies has precipitated the application of artificial intelligence, and more specifically, machine learning techniques, in the measurement of a diverse array of engagement. These phenomena encompass goal setting, learning, problem-solving, affect, and reflection, among others [40].

Scale and Gradation of Participation

The gradation of participation in articles is present in two different ways: either within the various stages of the process or through the establishment of a gradient that characterizes a level of engagement, ranging from low to high.

The conceptual model in Yardley et al [71] distinguishes between the micro and macro levels of engagement. *Micro-engagement* refers to the user's immediate interactions with the technology's features, including the extent of intervention use (eg, number of completed activities) and the user's experience (eg, level of interest and attention during activity completion, specifically linked to attention, interest, and affect). *Macro-engagement*, on the other hand, refers to how the user engages with the overall goal of behavior change. After a period of effective micro-engagement, the user may disengage from the platform while still being immersed in the behavior change process [10,18,21,28,34]. Another similar method is proposed by Cole-Lewis and colleagues, defining *Big E* as engagement in the targeted health behavior, and *little e* as engagement in the digital intervention for behavior change [17,40,42].

Regarding scales of participation ranging from least engaged to most engaged, scales are identified in some articles, but they are not specific to digital health interventions [43-48]. First, the most common participation scale is Arnstein's 8-rung ladder of citizen participation, ranging from nonparticipation in citizen power through the stages of manipulation, information, consultation, advocacy, partnership, delegation, control, and self-management [43]. Additionally, there are classifications in terms of usage quantity: an active user may post on a forum, for example, whereas a passive user may read an informative article [44]. Alternatively, a heavy user is one who uses the intervention several times a day or 1 - 2 days per week, and a light user is one who uses the intervention twice per month or once per month, or who has not used it in the past month [45]. There is also a 4-position psychological scale on a continuum ranging from minimum to maximum engagement [46], patient participation levels at 3 levels in the health care sector [32], a 4-stage scale representing the developmental nature of patient activation [47], and other specifically designed questionnaires

XSL•FO
RenderX

for a study [47,48]. Taki et al, on the other hand, suggest a mathematical indicator of engagement that uses 5 different indices to assess user engagement based on usage [20,72].

User typologies are also found. One study classifies users based on their alcohol consumption: "trackers" monitor and track their alcohol consumption, "cut-downers" intend to reduce their alcohol consumption (similar to trackers, they used not only the monitoring features of the application but also goal-setting and feedback functions), and "noncommitters" lack the motivation to use health applications [10]. Another study categorizes users into 3 groups based on their frequency of engagement in peer interactions: "conversation starters," who initiated the highest number of threads; "frequent posters," who posted the highest number of messages on forums; and "conversation attractors," whose messages received the most responses [19].

Methods/Techniques Used to Engage Users

Many authors emphasize the need for theory-based interventions in order to engage users [34]. A theory-based intervention is a systematic approach that uses theoretical models to understand how behaviors are influenced by factors such as beliefs, attitudes, and social norms. By applying these theories to the design of digital health interventions, designers can create programs that specifically target these factors, ensuring that they are based on solid data and effectively encourage user participation [28,46,49]. These theories can be specific to health behavior change models or specific to digital interventions [28]: derivatives of behavioral and neurocognitive theories and models such as the theory of planned behavior, social cognitive theory, self-regulation theory, and social learning theory or unified theory of acceptance and use of technology, which is a theoretical model to explain the adoption and use of technology by users [49,50].

Similarly, the use of appropriate behavior change techniques (BCTs) can also increase user engagement and help them maintain healthy behaviors in the long term. This can improve the overall user experience and make digital health interventions more effective. BCTs are the smallest active components of an intervention that are capable of changing behavior [31,34,51]. The 6 most common BCTs associated with engagement were social support, goal setting, feedback, prompts/cues, self-monitoring, and rewards [31,34]. However, the author claims that they depend on their design, dose, and duration, as well as their content, to optimize their effectiveness. The most advanced and complete BCT would be useless if it did not generate interest through an attractive design, or if it was not user-friendly and intuitive to use in terms of digital functionalities [33].

Behavioral incentive strategies, including action planning, prompts, and habit formation, have been demonstrated to promote sustained use. It is imperative that techniques such as goal setting with visualization and tracking of progress [52], self-monitoring, biofeedback, and behavioral feedback are prioritized for development. Furthermore, providing a range of rewards and incentives that align with distinct core values has been demonstrated to foster sustained engagement, given the recognition that user responses to incentives vary [51]. In addition, one of the most widespread methods for engaging users is user involvement in the intervention design, a process that takes different names such as user-centered design [37,42,53,54], cocreation [55-58], codevelopment [52], or participatory design [46,59]. It is important to involve end users from the beginning of the process to ensure that the intervention is relevant and accepted by users in order to trigger effective participation afterwards [45,60,61] and increase technology literacy and access [52]. Users were also invited to implement and/or evaluate the intervention [42,62,63]. Some authors mentioned that the process is spiral and works in a loop: ideas are generated by/with the community, implemented by the community, evaluated by the community, adjusted based on community feedback, and then implemented and evaluated [41,42,54,64].

Apart from being used for co-design, personalization is a technique used on its own to engage users [60,65]. Some articles mention the need to gather individuals' needs to tailor and personalize interventions in order to engage end users [14,27,30,46,60,66], for example, in adapting content by personalizing it according to variations in psychological, social, and behavioral profiles [28,50] or based on user typologies determined during application registration (eg, through a short questionnaire and targeting the application's content according to their typology) [10]. It is imperative to ensure that the data accurately reflects the individual and their situation in order to guarantee the credibility and accuracy of information and feedback [51,58]. The overall goal is to provide instant contextual support for targeted behaviors when the individual is most likely to be receptive. Just-in-time adaptive interventions could use sensory data, for example, a smartphone or smartwatch, and momentary information directly from participants [60].

Thus, autonomy is also one of the techniques used to engage users [30]. In a structured and self-directed behavior change intervention, all participants receive the same content, but each individual is encouraged to choose their own behavioral goals and activities [47,67]. In order to provide specific recommendations based on individuals' needs, personalized feedback can be used [27,28,48].

Regarding users, some authors also suggest using online peer communities to engage users as they provide resources for sharing experiences and achieving better outcomes. These digital health communities may include discussion forums, online support groups, and social networks for patients [27,30,32,41,43,50,65,68,69]. These digital health communities are particularly important for young people and marginalized populations as they provide an opportunity to address crucial behavior change issues [69] and allow social interaction, feeling supported, and understood by the community [19,28,66] to enhance participants' engagement in the program and foster their motivation [27], mentioned as a key to engaging users [26,30,33,39]. Regarding this, despite evidence of improved intervention engagement in physical interventions, motivational support such as motivational interviewing is rarely present in health apps for smartphones. One author indicates that the reason for the limited use of motivational interviewing may be its lack of a coherent theoretical framework and proposes that self-determination theory can be used as a theoretical basis

XSL•FO
RenderX

because it shares fundamental principles with motivational interviewing [26]. Self-determination theory, used by several authors, emphasizes autonomy, competence, and social relatedness to encourage user participation [26,41,65].

While motivational interviewing provides tools for self-reflection and satisfaction, gamification can provide experiences of autonomy, competence, and relatedness by adding fun and excitement to activities [14,26,28,43,55,59], and gamification can enhance hedonic and intrinsic motivation by addressing the psychological and emotional requirements of individuals through the use of game-like components [45,58]. Intrinsic motivation refers to performing an activity solely for pleasure, excitement, and interest. Authors assert that gamification of health applications is a promising approach to counter the often-decreasing long-term motivation of health application users [45].

Finally, emotion has been identified as a key mechanism of action that can engender user experience linked to engagement. Ensuring high user satisfaction with mHealth and "avoiding negative emotions" such as frustration, disappointment, or anxiety should result in good long-term engagement and an increase in the number of positive reviews [31,51].

Difficulties in Engaging Users

Authors encountered several barriers to user engagement in digital interventions. At the country level, in several countries and populations, technological adoption has been slow due to cost, infrastructure, design models, architecture, integration, usability, and the implementation of public policies. Adoption and deployment are also dependent on the training and education of users provided by authorities [32,51].

At the intervention level, difficulty in involving all populations in participatory design is encountered due to knowledge asymmetry [63]. Lack of user involvement in the design and a lack of desired features lead to reluctance to adopt the intervention [45,65,66]. In the long term, maintaining usage is also a recurring problem [14,45,64]: there is evidence indicating that people often download an app and never use it again, with a rapid decline in usage after the first download [73,74]. Research on the specific reasons for user abandonment and low engagement in online programs has identified a lack of motivation, an absence of goal tracking, and negative feedback when goals are not met [52].

Regarding the content of interventions, there is a lack of theory-based mHealth interventions, despite the fact that some behavior change theories have been well-validated and tested in evidence-based prevention, diagnostic, and care interventions [61]. As for interfaces, some studies emphasize that interfaces are non–user-friendly [29,43,50] and that it is challenging to compete with social media and other entertainment-based applications [28,60]. As for all other online tools, data security is also a recurring concern, particularly with respect to anonymity [43,50]. Once the results of an intervention are obtained, the literature mentions the difficulty of generalizing the results to other populations due to differences in context. What works in one context for a given subgroup of the population may be less effective or even harmful elsewhere for other subgroups [37].

At the user level, technical barriers and a lack of technological skills are cited as a hindrance to participation [42,43,66]. In addition, improving health literacy directly impacts the ability to act on health information and take greater control of health as individuals, families, and communities, and is considered an essential condition for patient participation [32,36,50,51]. Engagement also varies according to sociodemographic characteristics; young women and individuals with a higher level of education are more involved [50]. Additionally, lack of support [43,66] and lack of motivation were associated with low adoption of mHealth apps [45].

Facilitators and Suggestions to Engage Users

At the user level, engagement depends on several interdependent components such as social norms, positive and negative reinforcement factors, goal-setting, self-monitoring, self-evaluation [17,49], self-efficacy [70], social support [19,49,67], motivation [34,45], trust and adherence of the participants' family, and peer modeling [37,50], especially through social media and friends or any scientific authority [45,58]. In addition, the delivery of human support has been demonstrated to positively influence engagement with digital behavior change interventions and increase adherence with mHealth interventions. Support personnel like health coaches provided individualized and personalized support, and facilitated comprehension and application of BCTs, including goal setting and receiving feedback on behaviors that had been monitored [31].

The social facilitators associated with the intervention encompass the following factors: the establishment of positive relationships and effective communication, the development of trust in the intervention's leader, the usage of the program within a social context, and the cultivation of positive connections with fellow participants. The temporal and spatial flexibility facilitators of the intervention are characterized by their accessibility and adaptability to different environments (performed within the comfort and familiarity of the participant's home, thereby eliminating the need for travel) [70].

Regarding intervention features, gamification [19,26,33,45,51,59], accessibility and ease of use [14], interactivity [67], attractiveness [55,60], confidentiality and security of personal data [14], and adapting the material for potential users from socially or educationally disadvantaged backgrounds [37] all help users to engage and are avenues to explore to increase user engagement within digital health interventions. For instance, the configuration of push notifications could be adapted to align with the preferences of the end user, or alternatively, users have the option to disable them entirely. The hypothesis was that these customizations would provide a more pleasant user experience and facilitate the daily use of the mHealth apps [50,58].

Regarding the design of the interventions, results show that involving users at all stages [26,41], addressing basic psychological needs [26] including psychosocial determinants anchored in relevant behavioral theories, such as the social

XSL•FO
RenderX

ecological model, the COM-B (capability, opportunity, motivation—behavior) model, and social cognitive theory [17], using more systematic and progressive approaches for intervention development and evaluation [48], integrated skill acquisition, positive reinforcement, integration of cultural values and group norms [49] could be explored. One study suggests letting people address their own problems in their own way, but within a structured and supportive framework [67].

A conceptual synthesis of the determinants influencing user engagement in digital health interventions, as identified in this review, is presented in Multimedia Appendix 4.

Discussion

Principal Results

This paper identified the attributes and definitions of user engagement, examined the methods used for engaging users in mHealth, and identified barriers and facilitators encountered in implementing user participation. In the literature, a variety of information was found in the articles. Some articles contained information in all the categories (definition or attributes, scale or gradation of participation, methods, and facilitators or barriers of participation), while others provided detailed information only on one category. In 18 articles, the authors mention attributes or a definition concerning participation. Engagement in digital health interventions is described as multidimensional, encompassing both objective measures (eg, usage frequency, duration, and depth) and subjective experiences (eg, attention, interest, and affect), as well as the goal of behavior change. Methods used to involve users are the most frequently cited, with 38 articles. Main methods and techniques used are theory-based intervention design, BCTs, personalization, user-centered and participatory design, peer support, autonomy, gamification, and emotion management. The obstacles encountered in involving users are discussed in 19 articles. Difficulties in user engagement in digital health interventions arise from technical, contextual, and individual barriers, while facilitators include participatory approaches, personalization, gamification, social support, and human guidance to enhance motivation, adherence, and sustained use. Some articles deal with digital interventions in general, while others are based on one specific digital intervention. The literature on this topic is recent, with half of the articles selected dating from the last 5 years.

Combining Approaches to Define Participation

The characterization of participation in digital health interventions for health promotion and prevention is complex [39] and influenced by different factors [40]. This is consistent with the complexity of digital health interventions themselves, which often involve multiple components [14,21,27,30,37-39]. Addressing this complexity requires integration of multiple approaches. The first approach is a quantitative perspective, which conceptualizes participation through measurable indicators such as duration and frequency, focusing on the extent of tool usage [10,17,21,27,28]. The second is a user experience approach, which captures subjective dimensions including attention, interest, emotions, and perceptions [19,24,28,35]. Combining these approaches enables a more comprehensive understanding of effective user engagement with mHealth tools in achieving behavior change goals of users [32,36-38]. In this context, user participation in the intervention becomes a prerequisite for the involvement of the user with their behavior change objective [17,71]. This engagement is possible when users consume an optimal intervention dose [20]. Engagement can thus be conceptualized as a continuum, ranging from minimal involvement to an excessive, potentially counterproductive level. The aim is to identify and deliver the appropriate dose of engagement for each individual, thereby enabling the achievement of their behavior change goals.

Participation Is the Goal but How Can It Be Reached?

To achieve engagement, the literature mentions various methods and techniques in three levels: (1) user-related factors, (2) intrinsic characteristics of the intervention, and (3) implementation context. It is therefore essential to have a holistic vision to ensure the effective condition of participation.

User-Related Factors

Thus, mHealth interventions should enable individuals to enter into a process that allows them to make choices aimed at maintaining or improving their health status, as stated in the Ottawa Charter [6]. This means (1) being able to improve their individual ability to act through the use of effective BCTs such as Michie's [75,76] BCTs, (2) engaging in collective discussions that correspond to the needs and demands of users, (3) providing social support such as the collective discussion that founded in this review, (4) becoming aware of the effect of their environment on their behavior and being able to act on it [27,30,32,41,43,65,68,69], and (5) finding external human resources that improve the effectiveness of applications [77].

Intrinsic Characteristic of Intervention

To better understand users' needs and involve them in the development process, one of the most commonly used methods for engaging users is cocreation, which involves users in the creation phase of the tool. This cocreation is even more valuable because one of the reasons for the long-term decline in tool usage is the absence of functionalities that users need. However, it is not sufficient to simply include users in the development process, as the mHealth functionalities must be designed to evolve with users' needs and demands. The process is a spiral and works in a loop [41,42,54,64]. Users' needs vary significantly over time, and these changes are influenced by many factors, such as life events, health experiences, and interactions with the health care system. Therefore, it is advisable to monitor users' evolving needs over time to adapt the digital intervention accordingly and meet the changing needs of users [18,78]. So, engaging users in just one step is insufficient. Perhaps, it is necessary to rethink the design methods of applications that currently attempt to suit everyone, and which, as a result, are suited to no one, even if they are intended for a targeted population group. The design should be based on a user-centered approach that incorporates cocreation methods and iterative testing. It should also offer possibilities for adaptive personalization based on behavioral profiles.

Engagement techniques are grounded in robust theoretical models, such as the COM-B framework, and can be bolstered

XSL•FO
RenderX

by gamification strategies and interactive features that provide personalized feedback. The overall digital experience should combine an intuitive and ergonomic interface for ease of use with careful design for attractiveness.

Implementation Context

Data security is also a recurring concern in terms of the functionality of the intervention [43]. Furthermore, once the results of the intervention have been obtained, there may be difficulties in generalizing the results to other populations due to differences in context: what may work in a given context for a given subgroup of the population may be less effective or even harmful elsewhere for other subgroups [37]. In addition, engagement is frequently subjective, and the factors that motivate one user to repeatedly use an application may not be applicable to another user, or may not be applicable at a specific instance [35].

These 3 different levels interact dynamically to create a complex mechanism. For example, a poor user experience can reduce motivation and lead to the intervention being abandoned prematurely [79,80], whereas a favorable sociocultural context can reinforce long-term engagement [81].

Conclusions

The current state of knowledge allowed us to have a vision of the participation of users in digital interventions. However, the concept of participation, which is described as complex, evolving, and multifactorial, is a notion on which there is as yet no consensus. This paper offers insights into user participation in mHealth, as evidenced by the results of the review. Usage of the tool, combined with the user's experience of it, serves as an indicator of participation. This participation is a prerequisite for the user to receive the optimal dose of intervention content, thereby supporting the engagement of users with their behavior change objectives. To foster such engagement, a variety of methods can be mobilized. These methods fall into 3 key categories: user-related factors, intrinsic characteristics of the intervention, and the context of implementation. Such clarifications could then inform the methodology for evaluating and developing digital interventions. In order to address this gap, the results of this review are used in an e-Delphi study with the aim of establishing a consensus definition with experts. The results of this forthcoming study will be the subject of a subsequent publication.

Acknowledgments

This manuscript was prepared without the use of generative AI tools for ideation, writing, data analysis, interpretation, or figure creation. All content was produced and reviewed by the authors in accordance with JMIR Publications' transparency and author accountability policy. DeepL Write was used solely to assist in enhancing the clarity and quality of the manuscript.

Funding

MA's doctoral thesis was supported by the University Research Schools initiative founded through the PIA3 (project reference 17-EURE-0019) as part of the Graduate Program Digital Public Health (DPH) and the MedPrev Project of the Regional Union of Private Practice Physicians of Nouvelle-Aquitaine. This work was also supported by the Ligue Contre le Cancer through a research team label. The funders had no role in the conceptualization, design, data collection, analysis, decision to publish, or preparation of the manuscript.

Data Availability

All data generated or analyzed during this study are included in this published article and its multimedia appendices.

Abstract

Background: Heart rate (HR) monitoring by wearable devices offers a physiological, personalized, and continuous method for assessing physical activity (PA) duration and intensity. However, methods to translate HR data into meaningful PA metrics are diverse and nonstandardized.

Objective: This study aims to provide an overview of how HR data are used to quantify PA behavior and estimate physiological outcomes in adult patients with cardiovascular disease (CVD).

Methods: A systematic search was performed in PubMed, Web of Science, and CENTRAL for studies published between 2014 and 2024. Eligible studies included adults with CVD or related risk factors wearing HR monitors to estimate PA. Data were synthesized narratively. The methodological quality of the included studies was evaluated using the Crowe Critical Appraisal Tool (CCAT; Michael Crowe).

Results: Twenty studies were included, spanning four HR-based PA estimation methods: (1) HR zone analysis (n=14), which assessed time spent in moderate-to-vigorous zones to evaluate guideline or training adherence; (2) physiological modeling (n=4), estimating outcomes such as energy expenditure (physical activity level) or cardiorespiratory fitness (maximal oxygen uptake); (3) change detection (n=1), using time-series and machine learning algorithms to quantify shifts in PA behavior; and (4) a derived personalized scoring system (n=1). While each approach demonstrated clinical promise of using HR data, external validation, and methodological transparency is often lacking.

Conclusions: HR-based PA estimation holds the promise of physiologically meaningful, personalized PA monitoring in CVD care. Modeling approaches and personalized scoring systems linking PA behavior to cardiovascular outcomes may provide highly needed clinical tools for PA management in patients. Research should prioritize algorithm transparency, clinical validation, and standardization.

KEYWORDS

exercise; heart rate; wearable electronic devices; fitness trackers; cardiac rehabilitation

Introduction

Engaging in sufficient physical activity (PA) is integral to the management of cardiovascular diseases (CVDs). The latest guidelines recommend ≥150 min/week of moderate-intensity PA, ≥75 min/week of vigorous-intensity PA, or an equivalent combination of both, typically expressed as the weekly accumulation of moderate-to-vigorous physical activity (MVPA), which can often be quantified using physiological indicators such as heart rate intensity zones [1]. PA is associated with reduction in cardiovascular and all-cause mortality, improvement in functional capacity and quality of life, and better control of key risk factors such as hypertension, dyslipidemia, and diabetes [1-4]. Despite the proven benefits of exercise-based cardiac rehabilitation (CR) in patients with CVD, with reductions of future cardiac events [5-7], its

XSL•FO
RenderX

long-term effectiveness is often limited by low adherence to recommended PA levels and inadequate monitoring of whether patients adhere to recommended PA levels, particularly when transitioning from supervised clinical settings (ie, phase 2 CR) to independent activities at home in phase 3 [8,9]. Nonadherence leads to a decline in cardiovascular function and undermines the potential long-term benefits of CR programs [10,11].

Continuous, accurate, and noninvasive monitoring of PA during patients' everyday activities could provide a solution to this challenge [12]. However, traditional PA monitoring methods such as self-reported questionnaires or activity logs are often subjective and prone to recall bias, and may not accurately reflect PA intensity [13,14]. Even objective methods like accelerometry primarily capture movement quantity (eg, steps and counts) and may approximate intensity (eg, via step cadence), but often do not adequately reflect physiological effort, making them less suited to fully assess PA intensity in clinical populations. In contrast, (cardiopulmonary) exercise testing or 6-minute walk tests offer objective insights but are limited to single time points and are impractical for frequent or real-world use [15,16].

Heart rate (HR) based PA estimation holds the promise of physiologically meaningful, personalized PA monitoring in CVD care. HR reflects the body's physiological response to activity intensity and is directly related to oxygen consumption and cardiac output [17]. Unlike movement-based metrics such as step count or distance walked, HR provides a direct measure of the body's metabolic demand and reaction to activity intensity, regardless of the type of exercise [18]. In line with clinical guidelines, PA intensity is often prescribed using target HR zones, especially in CR contexts [1,19]. This makes HR a more precise and individualized indicator of exertion and cardiorespiratory demand, and thus a uniquely valuable parameter for quantifying PA [19-21]. Advances in wearable technology have made near-continuous HR monitors, such as photoplethysmography-based wrist-worn devices and chest straps, accessible tools for continuous, noninvasive tracking of HR in everyday environments, provided they are properly validated.

However, translating HR data into meaningful, personalized metrics that guide patients and physicians toward adequate PA and optimal health outcomes remains a challenge. Although wearable devices can provide continuous HR measurements, there is a lack of standardized, transparent methods for interpreting this data in ways that are clinically actionable and tailored to patients' individual needs. While commercial devices such as those from Fitbit (Fitbit Inc) or Garmin (Garmin Ltd) often provide proprietary activity scores or readiness indicators, these metrics are typically based on "black box" algorithms that often rely more on accelerometer data than on HR data, and are rarely validated in clinical populations such as patients with CVD. Consequently, their clinical utility and safety in guiding PA remain uncertain.

The primary aim of this review is to explore how wearable HR monitors, including wrist-worn photoplethysmography sensors and electrocardiogram (ECG)-based chest straps across consumer-grade and research or medically validated devices, have been used to estimate and quantify PA with methodologies relevant to patients with CVD. Specifically, this review seeks to classify and describe the methodological approaches used to translate HR data into PA metrics and physiological estimates, including adherence rates and personalized scoring systems, across CR and broader CVD populations. In contrast to prior reviews that addressed wearable technologies in (tele) CR more broadly [22], this review focuses specifically on the methodological frameworks used to derive clinically meaningful PA indicators from HR data. By providing an overview of these methodologies, the review aims to offer insights into the availability and potential gaps in methods for HR-based PA monitoring in this population.

Methods

Overview

The PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 statement was followed in conducting this review (Checklist 1) [23]. This systematic review was not prospectively registered. A protocol was developed by the authors to guide the review process, but it was not published or made publicly available.

Search Strategy

A comprehensive search was conducted in PubMed, Web of Science, and the Cochrane Central Register of Controlled Trials (CENTRAL) on April 3, 2024 to identify relevant studies. The search strategy was developed based on the PICO (population, intervention, comparison, outcome) framework [24] and combined terms related to "CVD," "HR," "wearable HR monitors," and "PA" using Boolean operators. Search syntaxes were adapted for each database to account for differences in indexing and Boolean operator functionalities. Full search strings for each database are detailed in Table S1 in Multimedia Appendix 1. In addition to database searches, the reference lists of included articles were screened to identify additional relevant studies (backward citation search).

Eligibility Criteria

Studies were eligible for this review if they met the following inclusion criteria.

Population

Studies had to focus on adults aged 18 years or older with CVD. CVD was defined broadly and included individuals with coronary artery disease (CAD), myocardial infarction, acute coronary syndrome (ACS), heart failure with preserved or reduced ejection fraction (HFpEF/HFrEF), stroke, congenital heart disease, valvular diseases, and postrevascularization conditions (eg, percutaneous coronary intervention [PCI], coronary artery bypass grafting [CABG]). Studies conducted in patients with cardiovascular risk factors (eg, hypertension, diabetes, and metabolic syndrome) and in healthy populations were also considered if the authors explicitly stated that the HR-based PA estimation method described in the study was specifically intended or useful for application in cardiac populations.

XSL•FO
RenderX

HR-Based PA Estimation

Studies had to use wearable HR monitors (photoplethysmography-based wrist-worn devices or ECG-based chest straps) to estimate or quantify PA.

Study Types and Publication Criteria

Eligible studies included original research articles and study protocols. Protocols were included if they provided detailed methodological descriptions on how HR monitors or HR-based PA metrics would be used to assess PA, even if no results were reported. Including protocols allowed for the capture of methodological advancements relevant to the primary aim of the review. To ensure technological relevance, studies had to be published within the last 10 years (ie, between January 2014 and April 2024). Furthermore, only studies published in English with full-text availability were eligible.

Exclusion Criteria

Studies were excluded if HR monitors were solely used for exercise prescription or guidance, such as setting HR zones for training sessions, without quantifying or evaluating PA based on HR data. Studies were also excluded if they did not focus on a cardiac population or did not describe an HR-based PA estimation method applicable to cardiovascular health. Additionally, review articles, editorials, and conference abstracts were not eligible. Studies were also excluded if they were not published in English, were published more than 10 years ago, or lacked full-text availability.

Screening and Data Management

Duplicate records were identified and removed prior to screening, using a systematic deduplication method in EndNote, as described by Bramer et al [25] The screening process was conducted in multiple stages using Rayyan software (Rayyan Systems Inc.). Initially, 2 reviewers (PV and CB) independently screened article titles to exclude irrelevant studies. This was followed by a screening of abstracts. Articles deemed relevant based on abstract screening proceeded to full-text review, during which the reviewers assessed the complete articles to confirm their eligibility according to the predefined criteria. Studies where eligibility could not be determined from the abstract were included for full-text review. If discrepancies arose at any stage, they were resolved through discussion or, if necessary, a third reviewer (LD) was consulted to resolve them.

Data Extraction and Outcomes of Interest

A structured data extraction form was developed in Microsoft Excel and pilot-tested on 2 randomly selected studies to ensure consistent, clear, and comprehensive data collection. Two independent reviewers (PV and CB) extracted data from the included studies and any discrepancies were resolved through consensus discussions between the 2 reviewers (PV and CB); and if necessary, a third reviewer (LD) was consulted.

The primary outcome of interest in this review was the methodological approach used to translate wearable HR data into PA-related metrics or physiological estimates. Specifically, we extracted and classified how HR data were operationalized (eg, threshold-based HR zone analysis, regression-based energy expenditure models, cardiorespiratory fitness estimation, change detection algorithms, or personalized activity scores).

In addition, extracted data included study characteristics (eg, title, authors, publication year, country, funding, and design), participant demographics, HR monitor specifications, and details on the intervention or observation period (eg, training program and duration). We also extracted study-specific reported outcomes to provide contextual interpretation of each methodological approach. The reported outcome parameters varied across studies and included measurement validity indicators (eg, comparison with CPET or ECG, mean absolute [percentage] error, intraclass correlation coefficient, coefficient of determination), adherence rates, physiological outcomes (eg, maximal oxygen uptake [VO_2 max]), feasibility metrics, and safety events. Given the heterogeneity in devices, populations, and study designs, these outcomes were synthesized descriptively and were not pooled quantitatively.

Methodological Quality Assessment

The methodological quality of the included studies was evaluated using the Crowe Critical Appraisal Tool (CCAT; Michael Crowe) [26]. This tool was selected due to its flexibility and applicability across diverse study designs, making it particularly suitable for this review, which included randomized controlled trials, observational studies, feasibility studies, methodological studies, and protocol descriptions.

The CCAT assessed studies across 8 domains, including preliminaries, introduction, design, sampling, data collection, ethics, results, and discussion. Each domain is scored on a scale from 0 to 5, where 5 indicates that the criterion is fully met and 0 indicates that it is not addressed. Intermediate scores reflect partial fulfillment of the domain criteria according to the CCAT user guide [27]. Domain scores were assigned using the guidance provided in the CCAT user guide, where item descriptors support reviewer judgment when determining the final domain score [27]. The maximum total score is 40.

For protocol descriptions, only applicable domains of the CCAT were scored. Domains that were not applicable due to the absence of empirical results (eg, results and discussion) were marked as “not applicable”. The total score for protocols was recalculated as a percentage of the maximum applicable score (eg, if 6 domains were scored, the total score was calculated out of 30 instead of 40). This approach ensured that protocol descriptions were fairly assessed for their methodological relevance without being penalized for the absence of empirical findings.

Two independent reviewers (PV and CB) assessed methodological quality and resolved discrepancies through consensus discussion. CCAT scores did not influence study inclusion decisions and were used to contextualize interpretation rather than to weight or exclude findings within the narrative synthesis.

Although the CCAT is primarily designed as a methodological appraisal tool, several domains address aspects closely related to potential sources of bias (eg, study design, sampling strategy, data collection procedures, and discussion of bias and confounding). Therefore, CCAT scores provide an indirect

XSL•FO
RenderX

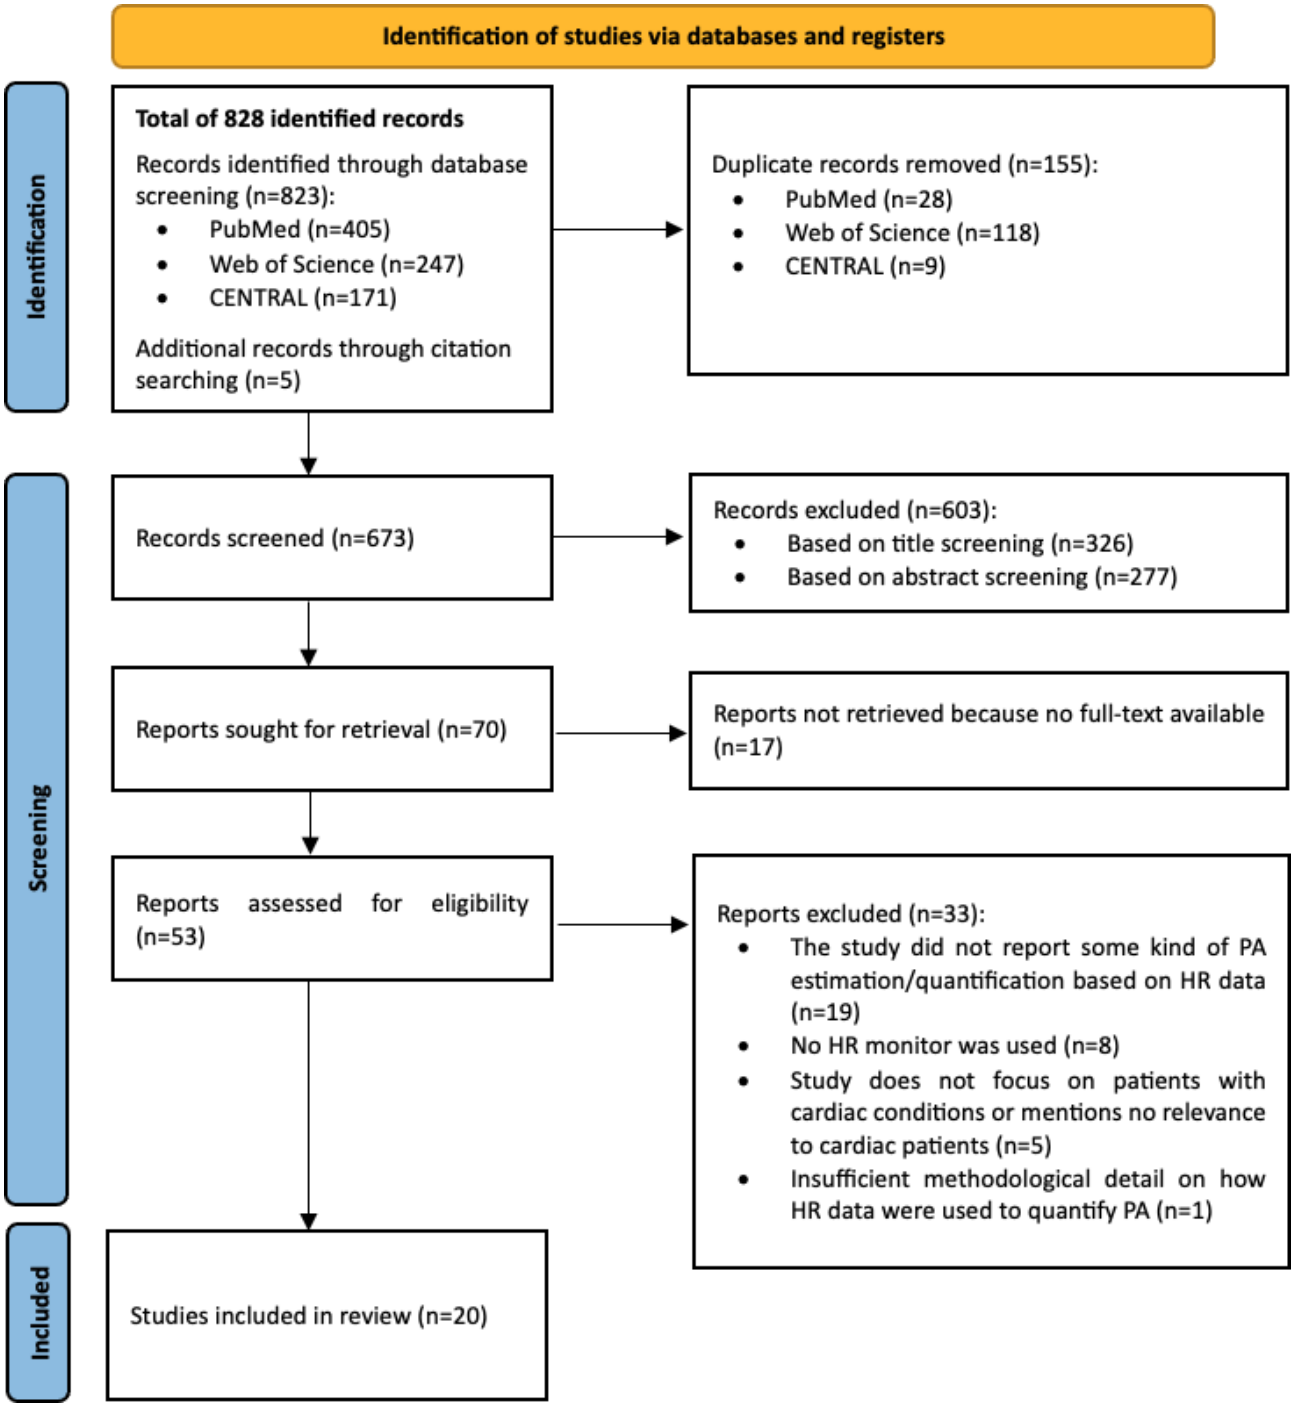
indication of methodological robustness and susceptibility to bias.

Data Synthesis

Given the heterogeneity of study designs and outcomes, a narrative synthesis was conducted. The primary aim of the synthesis was to identify and classify methodological approaches used to translate HR data into PA-related metrics.

During data extraction, the reported HR-based PA estimation methods from each study were examined and compared. Through an inductive process, recurring methodological approaches were identified and grouped into conceptual categories based on their underlying estimation strategy. This resulted in 4 distinct categories, explained in section "Heart Rate–Based Physical Activity Estimation Methods" of the Results. The categorization was discussed between the 2 reviewers (PV and CB) and finalized through consensus.

After categorization, studies within each methodological group were compared descriptively with respect to contextual characteristics such as HR monitor type, study population, and reported outcomes. Similarities and differences between studies were identified through iterative comparison across these dimensions. Methodological gaps were defined as areas where approaches lacked transparency, validation in cardiovascular populations, or consistent methodological reporting.



Results

Study Selection Process

The study selection process is summarized in a PRISMA 2020 flow diagram (Figure 1). The search for studies quantifying PA using HR monitors in patients with CVD yielded 828 results. After removal of duplicates, 673 publications were screened first on title and then on abstract. A total of 53 articles were screened on full text, 20 of which met the inclusion criteria.

XSL•FO
RenderX

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram of the selection process. HR: heart rate; PA: physical activity.

General Study Characteristics

Of the 20 included studies, 15 [28-42] were research articles and 5 [43-47] were protocol papers (Table 1, left side). The study designs included 8 [28,29,38,43-47] randomized controlled trials (RCTs), 5 [30-33,42] nonrandomized interventional studies (4 feasibility studies and 1 pre-post study), and 7 [34-37,39-41] observational studies that monitored PA patterns using HR monitors without aiming to induce behavioral change. Studies were conducted across diverse geographical locations, primarily in Europe and the United Kingdom (n=12) [29,31,32,35,36,38-40,43,45-47], followed by North America (n=5) [28,34,37,41,44], Asia (n=2) [30,33], and Australia (n=1) [42]. Sample sizes varied widely, with feasibility studies including the fewest participants (range: 5 - 31), whereas other study designs included up to 300 participants.

[d]HFpEF: heart failure with a preserved ejection fraction.

[e]Mean (SD).

[f]Not applicable; applies to protocol papers where no results were reported.

[g]CR: cardiac rehabilitation.

[h]ACS: acute coronary syndrome (ie, myocardial infarction or unstable angina).

[i]LVEF: left ventricular ejection fraction.

[j]The study was included because of its focus on developing a system specifically for patients undergoing CR, despite the feasibility here being tested in healthy individuals.

[k]Range

[l]CAD: coronary artery disease.

[m]Case-based evaluation with a limited/nonspecified number of scenarios.

[n]Median (IQR)

Population Characteristics

An overview of the study populations is shown in Table 1 (right side). In terms of health characteristics, 8 studies [29,32,33,38,39,42,45,47] focused on patients eligible for CR following ACS, CAD, or revascularization procedures (eg, PCI or CABG). Other study populations included patients with heart failure (n=2) [28,46], post-stroke patients who have experienced a stroke (n=2) [34,44], individuals with cardiovascular risk factors (n=1) [40], congenital heart disease (n=1) [36], valve disease (n=1) [35], and patients postmyocardial infarction (n=1) [43]. Two studies [37,41] investigated inpatient rehabilitation patients with mixed conditions including cardiac disorders, while 2 feasibility studies [30,31] were conducted in healthy adults, assessing HR-based PA methods intended for populations with heart diseases.

CR studies had a predominantly male representation (82% - 100% [29,33,38,39,42]), whereas populations with heart failure (55% male [28]) and populations who have experienced strokes (54% male [34]) were more balanced. Age ranged from young healthy adults (mean 26.3, SD 4.3 years [30]) to older patients with heart failure (up to mean 65.6, SD 9.3 years [28]). Patients undergoing CR typically ranged between 55.8 (SD 7.3) years [39] and 59.2 (SD 8.5) years [38]. BMI values were generally between 26 and 31 kg/m² for CR populations [29,33,38,39,42], with the highest BMI observed in patients with heart failure (33.9 - 36.4 kg/m² [28]). Beta-blocker use was the highest among patients with heart failure (98% [28]) and ranged between 17% and 91% in CR populations [29,33,38,39,42].

HR Monitors

A total of 12 out of 20 studies [29-32,34,35,37,41-44,47] used a wrist-worn HR monitor (60%), 7 [33,36,38-40,45,46] used a chest-strap (35%), and 1 [28] did not specify the type (5%) (Table 2). Polar devices were the most commonly used (6 studies) [28,29,32,43,45,46], followed by Fitbit (4 studies) [34,37,41,44] and Garmin (2 studies) [38,39]. Other brands included Samsung, Philips, Firstbeat Technologies, and custom-designed wearables.

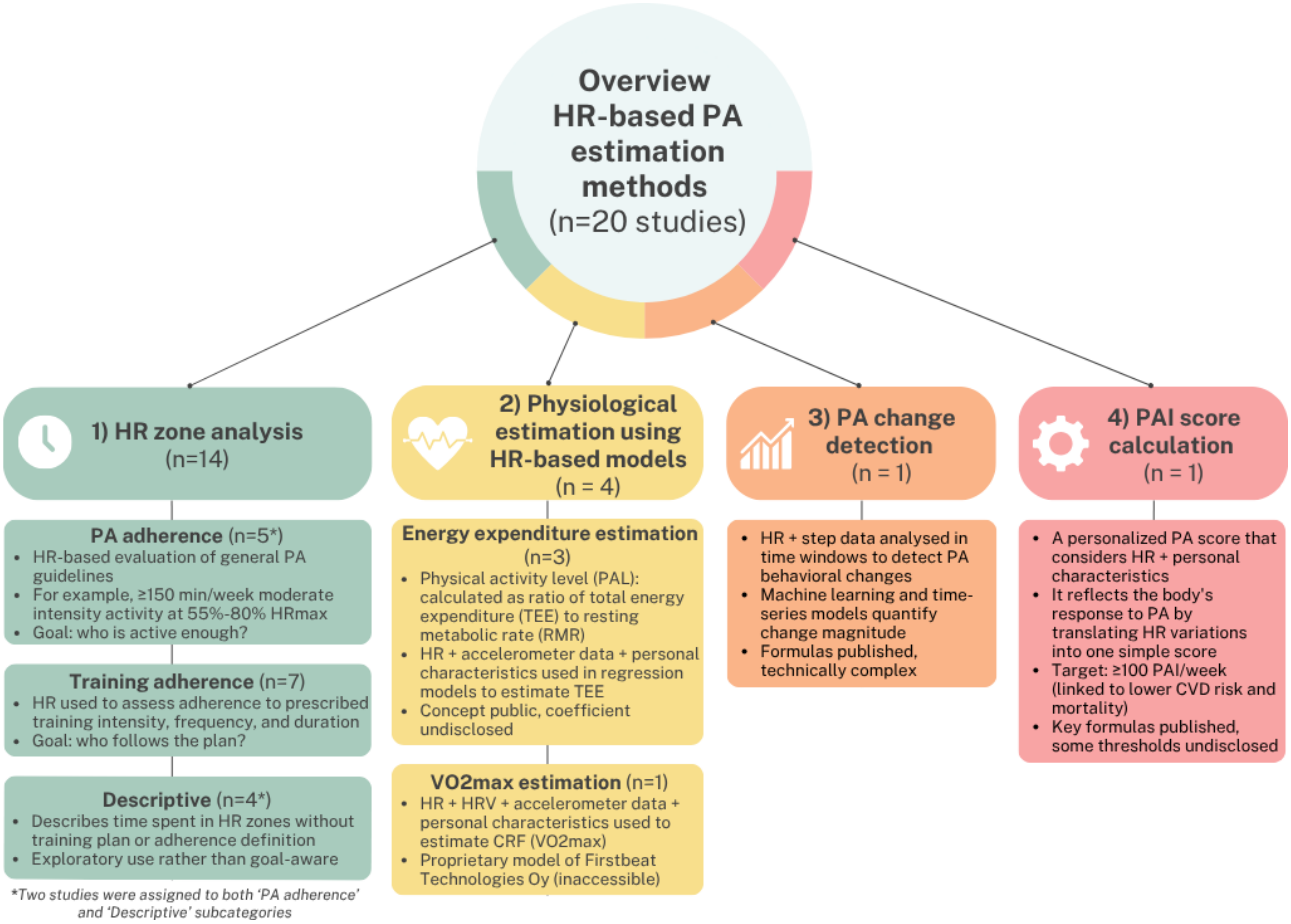
[h]TEE: total energy expenditure.

[i]RMR: resting metabolic rate.



[j]VO_2max: maximal oxygen uptake.

[k]SC: change score.

HR-Based Physical Activity Estimation Methods

Four distinct approaches to HR-based PA estimation were identified: (1) HR zone analysis, (2) physiological estimation using HR-based models, (3) PA change detection, and (4) personalized activity scoring. These methods vary in complexity, ranging from simple threshold-based evaluations to algorithmic pattern detection. Each approach is summarized in Figure 2 and further elaborated in the subsections below, while detailed study specifications are presented in Table 2 (PA estimation approach) and in Table S2 in Multimedia Appendix 1.

Figure 2. Overview of heart rate-based physical activity estimation methods identified in this review. CRF: cardiorespiratory fitness; CVD: cardiovascular disease; HR: heart rate; HRmax: maximal heart rate; HRV: heart rate variability; PA: physical activity; PAI: personal activity intelligence; PAL: physical activity level; RMR: resting metabolic rate; TEE: total energy expenditure; VO_2max: maximal oxygen uptake.

HR Zone Analysis

Across 14 of the 20 included studies [28-37,43-46], the time spent in predefined HR zones was used to evaluate PA intensity and/or adherence, either in relation to general PA recommendations, structured training goals, or purely descriptively. These approaches relied on rule-based threshold classifications rather than analytical or statistical modeling, with HR values categorized into predefined HR-based intensity zones to quantify time spent at different activity levels.

HR zones were typically defined using heart rate reserve (HRR=HRmax [maximal heart rate]–HRrest) or percentages of HRmax. HRmax was determined using age-based formulas (n=4) [31,34,37,44], sometimes corrected for beta blocker use (n=1) [37], or measured via cardiopulmonary exercise testing (CPET; n=6) [28-30,32,45,46]. HRrest was estimated using self-established definitions such as the 30th lowest HR during monitoring, the average HR between 2:00 AM and 4:00 AM, or HR observed during low-activity periods (eg, HR when <1 step/minute combined with an accelerometer count <475). Most studies relied on transparent zone definitions, and most methods were reproducible. A subdivision was made for studies that applied HR zones as (1) behavioral benchmarks (eg, to assess adherence to PA guidelines), (2) criteria for training adherence, or (3) exploratory tools to describe PA intensity.

1. PA adherence: Around 5 [28,36,37,43,44] studies assessed whether participants met general PA recommendations based on HR-derived intensity thresholds. The internationally accepted target of ≥150 minutes per week of moderate-intensity activity was typically applied, or

XSL•FO
RenderX

translated into a daily equivalent (ie, ≥21.4 minutes/day). Moderate intensity was typically defined as 40% - 70% or 40% - 80% of HRR, or 55% - 80% of HRmax. One study defined the target threshold more pragmatically, using the HR at minute 3 of a step test as the intensity cut-off. In some cases, the HR-derived method of checking PA adherence was compared with assessments based on accelerometer-based indicators (n=2 [36,43]; eg, total accelerometer counts) and/or PA questionnaires (n=3 [28,43,44]; eg, report ≥150 minutes of moderate and/or vigorous intensity activity on a PA questionnaire, like the physical activity scale for individuals with physical disabilities [PASIPD]).

2. Training adherence: A total of 7 [29-33,45,46] studies evaluated adherence to a structured training program using HR to monitor both exercise intensity and completion. These programs defined frequency, duration, and intensity in advance (eg, 3×/week, 30 - 60 min/session, 70% - 80% HRR). Qualitative adherence was assessed based on intensity, including time spent in the prescribed HR zone, average session intensity (eg, 74.8% of HRR), or retention ratios (eg, percentage of total exercise time in the zone). Quantitative adherence referred to session completion, often defined as attending ≥70% of prescribed sessions, or meeting minimum thresholds such as ≥10 minutes/day in the target zone on ≥3 days/week.
3. Descriptive: In 4 [34-37] studies, HR zones were used without a behavioral target or structured plan. These studies described the time spent in various HR zones to characterize cardiovascular load or exercise intensity without defining adherence. The aim was typically exploratory, offering insight into physiological patterns of activity.

Feedback mechanisms: Among the 14 studies using HR zone analysis, feedback strategies varied in intensity and purpose. Four [30-33] training adherence studies delivered real-time feedback via wearable devices (eg, LED color changes or vibrations) when HR deviated from target zones. In at least 6 [28,29,43-46] studies, HR data were reviewed by health professionals via dashboards or apps (eg, Polar Flow; Polar Electro), with individual (telephone-based) or group-based counseling provided with a focus on knowledge, attitudes, self-efficacy, and self-management skills, and often informed by behavior change and motivational interviewing techniques. The remaining 4 [34-37] studies used HR monitoring purely for retrospective analysis, without participant-facing feedback or behavioral guidance.

Physiological Estimation Using HR-Based Models

A total of 4 studies [38-40,47] used HR data to estimate derived physiological PA-related outcomes rather than to assess PA behavior and adherence. These outcomes included energy expenditure, expressed as physical activity level (PAL), and cardiorespiratory fitness (CRF), typically estimated as VO_2max. In both cases, HR was used as a physiological input parameter, often in combination with accelerometer data and individual characteristics to inform regression or algorithmic models.

1. Energy expenditure–PAL: A total of 3 [38,39,47] studies estimated daily energy expenditure by calculating PAL, defined as the ratio of total energy expenditure (TEE) to resting metabolic rate. TEE was estimated using multivariate regression models that included HR above rest, accelerometer-derived activity counts per minute, and participant characteristics such as age and weight. The resting metabolic rate was estimated using the Harris-Benedict equation, based on sex, weight, height, and age. While none of the studies disclosed the exact regression coefficients or intercepts used to model TEE, the overall structure of the approach was well described and reproducible in principle. PAL was used as a continuous indicator of daily activity level, and typical values range from 1.2 (bed-bound) to above 5.0 (elite athletes). In these studies, no behavioral adherence thresholds or real-time feedback mechanisms were applied to PAL scores, though retrospective comparisons were made between groups (eg, cardiac telerehabilitation vs center-based programs).
2. VO_2max estimation–firstbeat: One study by Rissanen et al [40] estimated CRF by calculating VO_2max using a wearable device during a 30-minute self-paced walk. The algorithm integrated HR, heart rate variability, and movement data, alongside participant characteristics (eg, age, sex, height, weight, and HRmax), to model aerobic capacity. The HRmax determination was not disclosed. The estimation was validated against CPET-derived VO_2max values. The model showed strong agreement, with a mean absolute error of 3.1 mL/kg/min, mean absolute percentage error of 10.4%, and intraclass correlation coefficient of 0.88. The study acknowledged reduced accuracy in subgroups such as patients with type 2 diabetes. Developed by Firstbeat Technologies Oy, the algorithm is proprietary, with only conceptual elements publicly available. It remains inaccessible and is commercially protected, limiting reproducibility and external validation.

Physical Activity Change Detection

The study by Sprint et al [41] introduced the Physical Activity Change Detection (PACD) framework, an analytical method designed to identify significant changes in PA behavior over time using HR and step count data. PACD applied time-series analysis to detect meaningful fluctuations in PA intensity, frequency, and duration.

The dataset was segmented into consecutive time windows (eg, per week). Pairs of these windows were compared using three algorithmic methods: (1) small window permutation-based change detection (sw-PCAR), which uses Kullback-Leibler divergence to measure differences in activity patterns between two time windows, with significance assessed through a permutation test. (2) distance-based dissimilarity scorer (DDS), which computes the average Euclidean distance between summary statistics (eg, steps/day, time in HR zones), with distances above 0.25 interpreted as meaningful deviations. (3) Virtual classifier (VC), a machine learning method (decision trees) trained to distinguish activity patterns between windows, using classifier accuracy as a measure of behavioral change. Key predictors of PA change were fewer bouts in the target HR zone (55% - 80% HRmax), reduced sedentary time (<5 steps/minute), and lower daily step counts.

XSL•FO
RenderX

Each algorithm produced a change score reflecting the magnitude of PA change between time windows. In this study, PACD was applied retrospectively to characterize PA changes during inpatient rehabilitation, without being used for real-time clinical decision-making. Although no open-source code was provided, the authors detailed the full methodology, including formulas and statistical techniques, enabling potential reproduction of the analysis by researchers with appropriate technical expertise.

Personal Activity Intelligence (PAI) Score Calculation

One study by Hannan et al [42] used HR data to calculate the Personal Activity Intelligence (PAI) score, a metric that transforms HR data from a wearable device into a personalized, feedback score for long-term health maintenance. The PAI algorithm integrates HR intensity and duration over a rolling 7-day period and accounts for individual characteristics such as age, sex, HRrest, and HRmax [48]. The goal is to provide a single number reflecting whether an individual maintains sufficient cardiovascular stimulus to reduce morbidity and mortality risk [49]. A weekly score of ≥100 PAI is considered optimal for health benefits based on prior retrospective longitudinal cohort studies [50,51].

In the study of Hannan et al [42], PAI was used in a 2-phase design. Participants initially wore a HR monitor in a blinded phase (without receiving feedback), followed by an unblinded phase where they had access to their PAI score and were encouraged to increase it. HRmax, needed for the PAI calculation, was estimated using an age-dependent formula ($211 - 0.64 \times age$), with correction for beta- or calcium-channel blocker use (–15 bpm), or derived via CPET when available. The authors reported that 89% of participants improved their total PAI score following access to real-time feedback. The proportion of individuals achieving ≥50 PAI per week increased from 39% to 61% across phases [42].

Key components and equations behind the PAI algorithm, originally developed by the Cardiac Exercise Research Group (CERG) at the Norwegian University of Science and Technology (NTNU), have been published in supplementary material of earlier PAI-studies [18], although these were not eligible for inclusion in this review due to their retrospective, questionnaire-based methodology and noncardiac populations (see Discussion). The model is therefore largely reproducible for researchers with sufficient technical expertise, though some implementation details (eg, thresholds to begin earning PAI) remain undisclosed.

Methodological Quality Assessment

The CCAT quality ratings ranged from 50% to 87%, with a mean of 71% (Table 3). Four studies scored above 75%, indicating high methodological quality, while 2 [26,27] studies scored below 60%, reflecting some limitations. The remaining 14 studies fell within the moderate range of 60%-75%. Most studies performed well in the domains of introduction, data collection, and discussion, with the majority scoring between 4 and 5 in these areas and no study scoring below 3. Fifteen studies [28-30,32-37,39-43,47] reached a moderate score of 3 in the design domain. Sampling and ethics were the weakest domains; 5 studies [30-32,39,45] scored below 3 for sampling, and 3 studies [30-32] scored below 3 for ethics, highlighting issues with sample representativeness and ethical reporting.

Table . Quality rating using CCAT[a]. The methodological quality of the included studies was assessed using the CCAT [26,27], which evaluates eight domains: Preliminaries, Introduction, Design, Sampling, Data collection, Ethics, Results, and Discussion. Each domain is scored from 0 to 5, with a maximum total score of 40. For protocol descriptions, only applicable domains were scored. Domains not applicable due to the absence of empirical data (eg, Results and Discussion) were marked as not Applicable (N/A). The total score for protocols was recalculated as a percentage of the maximum applicable score (eg, if 6 domains were scored, the total score was calculated out of 30).

[a]CCAT: Crowe Critical Appraisal Tool.

[b]not applicable

The methodological quality assessment was used to contextualize the interpretation of findings but did not determine study inclusion. Importantly, studies with lower scores were distributed across the different methodological categories identified in the narrative synthesis, and the methodological approaches used to derive HR-based PA metrics were largely consistent across studies irrespective of CCAT score. Overall, the quality of the included studies was moderate to high.

Discussion

Principal Findings

This review provides the first structured overview of HR-based methodologies for PA estimation in patients with CVD, highlighting their clinical utility, strengths, and the implementation gaps. We identified 4 distinct estimation approaches: HR zone analysis, physiological estimation using HR-based models, PA change detection, and personal activity intelligence score calculation. Most studies (14/20) used HR zone thresholds to evaluate PA intensity or adherence, often within CR contexts. Other methods incorporated algorithmic

XSL•FO
RenderX

modeling or machine learning to derive metrics such as energy expenditure, CRF, or behavioral change. While these approaches varied in complexity and purpose, each demonstrated the potential of HR data to provide physiologically meaningful insight into daily PA patterns.

HR Zone Analysis and Guideline-Based Adherence

HR zone analysis emerged as the most commonly applied and straightforward method of HR-based PA estimation in this review. It is straightforward because it allows for a direct translation of international PA guidelines into quantifiable metrics, specifically, the time spent in moderate-to-vigorous intensity HR zones, and it aligns with the widely adopted the frequency, intensity, time, and type framework [1,4]. As such, it provides clinicians and researchers with an accessible method to both prescribe and evaluate PA intensity in line with global recommendations.

Both the World Health Organization (WHO) and the European Society of Cardiology (ESC) advise that adults should engage in at least 150 minutes of moderate or 75 minutes of vigorous intensity aerobic activity per week, or an equivalent combination of both, with intensity defined via several physiological indicators, including %VO_2max, %HRmax, %HRR, or ratings of perceived exertion [1,4]. Among the reviewed studies, %HRmax and %HRR were used most often to define intensity zones. ESC recommends that maximal HR values should ideally be based on exercise testing rather than estimated from age-predicted formulas, especially in clinical populations and in patients on rate-limiting medications such as beta-blockers [1]. Despite this, most studies in our review relied on simple prediction equations for HRmax, which may result in less precise zone definitions. Notably, none of the included studies explicitly reported whether vigorous-intensity minutes were counted double when evaluating weekly MVPA totals. While international guidelines do allow for this (eg, 75 min of vigorous activity or an equivalent combination with moderate activity) [1,4], the absence of clear reporting may limit interpretability and cross-study comparability. Including this distinction in future reporting could help ensure more accurate and standardized assessments of adherence.

HRrest, another component needed for calculating HRR, was often defined through study-specific approaches, such as averaging nighttime HR values or identifying low-HR periods during inactivity. While literature suggests that early morning supine HR, measured immediately after waking but before getting out of bed, may offer the most reliable estimate, there is no standardized or transparent method for deriving HRrest from wearable data at the time of this writing [52]. Most commercial devices provide HRrest estimates through proprietary algorithms, leaving researchers with limited insight into how these values are calculated.

In terms of adherence assessment, some studies focused on guideline-based targets (eg, ≥150 min/week of MVPA), while others evaluated compliance with structured training programs based on the frequency, intensity, time, and type principles. Importantly, HR monitoring enabled a distinction between session attendance (frequency) and session quality (intensity and duration), offering a more nuanced understanding of adherence by distinguishing between mere participation and actual achievement of intensity and duration targets [53].

Finally, several studies integrated HR zone data into feedback mechanisms, either in real time (eg, via smartwatches with LED zone indicators) or post-session through digital dashboards and clinician-guided counseling. Effective feedback has been shown to be a key driver of behavior change in PA interventions [54]. When combined with motivational strategies such as self-monitoring and goal setting, these feedback loops may support greater behavioral change and patient engagement toward sustained PA adherence [43,44,54].

HR Versus Accelerometer-Based PA Monitoring

Several studies in this review combined HR monitoring with accelerometer-based methods to quantify PA adherence and estimate physiological parameters such as energy expenditure and VO_2max. These multimodal approaches aimed to improve accuracy and/or cross-validate findings by combining the complementary strengths of each method [55]. HR monitoring provides a direct physiological measure of exercise intensity and cardiovascular load, making it a more personalized and clinically relevant indicator of effort than mechanical metrics such as step count or accelerometer counts. Moreover, the physical demand associated with a given accelerometer value can vary substantially between individuals depending on their fitness, age, or health status [56]. For example, walking at the same pace may represent light intensity for one person and moderate intensity for another [36].

Despite these limitations, accelerometer and step count data could play a valuable role in assessing sedentary time, an increasingly recognized factor in cardiovascular health [57]. Sedentary behavior, defined as waking behavior in a sitting, reclining, or lying posture with low energy expenditure, has been associated with cardiometabolic risk, even in individuals who meet weekly MVPA guidelines [58,59]. This risk profile may reflect distinct physiological pathways, underscoring the importance of addressing sedentary behavior alongside PA adherence [60]. In the PACD study included in this review, a reduction in sedentary time (defined as time with fewer than 5 steps per minute) emerged as a key predictor of meaningful PA behavior change [41]. When paired with HR data to reflect oxygen demand and PA intensity, step-based indicators of inactivity may offer a low-burden, scalable method for tracking both sedentary time and physiological load. However, it is important to assess PA and SB as independent behavioral domains, each with distinct health effects and potentially requiring their own intervention strategies [60].

From Activity Monitoring to Physiological Outcomes

Although most studies focused on measuring adherence to PA guidelines (eg, time in zones), a smaller subset advanced toward estimating physiological outcomes from HR data, such as energy expenditure (PAL) or cardiorespiratory fitness (VO_2max). This transition from behavioral metrics to physiological modeling represents a valuable next step, especially in clinical populations where improving aerobic capacity and reducing cardiovascular risk are primary goals.

XSL•FO
RenderX

For example, three studies estimated PAL, defined as the ratio of total energy expenditure to resting metabolic rate. These models typically combined HR above rest with accelerometer data and participant characteristics [38,39,47]. PAL is widely used in nutrition science to estimate daily energy needs, but in cardiovascular care its clinical application remains limited [61]. As a descriptive metric, it lacks behavioral thresholds, is rarely linked to feedback mechanisms, and often relies on regression models with undisclosed coefficients, limiting transparency and reproducibility in research and practice. A more advanced example is the proprietary Firstbeat algorithm, which estimated VO_2max using HR, HR variability, movement data, and participant characteristics during a 30-minute walk [40]. While generalizability to cardiac populations remains uncertain and requires further validation, the Firstbeat algorithm showed acceptable agreement with CPET-derived values in athletic cohorts or adults with cardiovascular risk factors and is now embedded in commercial wearables from Garmin, following their acquisition of Firstbeat Technologies Oy in 2020 [40,62,63]. While this integration supports scalability, the proprietary nature of the algorithm limits its adaptability and full validation in diverse patient groups.

Together, these examples illustrate a growing shift from pure activity tracking toward predictive modeling of physiological capacity. By combining HR data with individual and contextual factors, such models could move beyond surface-level monitoring to support personalized CR planning and long-term health surveillance. Such approaches may help clinicians and researchers estimate meaningful outcomes, such as changes in cardiorespiratory fitness, based on daily-life activity patterns, ultimately linking daily PA behavior to cardiovascular impact.

PAI: Validation, Challenges, and Future Directions

The PAI system stands out within this review as the only approach that translates continuous HR data into a personalized, interpretable single-number feedback metric intended to motivate behavioral change over time. PAI reflects accumulated cardiovascular effort across a rolling 7-day window. In the one included PAI study in this review, short-term improvements in PAI accumulation were observed after CR participants gained access to their PAI score via a smartphone application, although evidence remains exploratory [42].

As a caveat, the commonly cited ≥100 PAI/week threshold, proposed to reduce the risk of CVD and mortality, originates from retrospective analyses of large population studies (eg, the HUNT Study in Norway) [48,51,64-68]. During the screening process of this review, eight such validation studies were identified but excluded, as none used HR monitors to calculate PAI [48,51,64-68]. Instead, PAI scores were estimated post hoc from self-reported PA questionnaires, relying on participants' recall of activity frequency, intensity, and duration [48,51,64-68]. This introduces substantial subjectivity and deviates from the intended physiological, HR-based calculation of PAI, potentially reducing both accuracy and internal validity.

Moreover, 7 of the 8 validation studies were conducted in healthy adult populations, frequently excluding participants with cardiovascular conditions. The reported mean ages were relatively young, ranging from 42.6 [64] to 55.1 [68] years. One study included participants with self-reported angina pectoris, myocardial infarction, or stroke, with a higher mean [SD] age of 67.6 [10.3] years[66]. However, activity in that group was still assessed via questionnaires, and the population was not clinically verified. To date, no validation studies have assessed the accuracy or clinical utility of PAI when calculated from real HR data in older adults or patients with CVD, populations for whom accumulating ≥100 PAI points per week may be less achievable but important. Also, the PAI algorithm rewards sustained vigorous activity more than moderate or lower-intensity efforts, limiting its applicability for clinical populations where activities such as walking or cycling are more prevalent [64]. A summary table of the characteristics of the 8 excluded PAI validation studies is available in Table S3 in Multimedia Appendix 1.

Although the algorithm is largely reproducible based on published formulas, certain implementation details remain proprietary [18]. Researchers with technical expertise can replicate the model in principle, but public tools for doing so are limited. The MIA Health app, currently the only available platform for real-time PAI calculation, expanded its availability in January 2025 from a few Nordic countries to most of Europe, North America, Australia, New Zealand, Taiwan, and Brazil, potentially increasing both clinical and consumer access [69].

Recently, a follow-up metric known as the activity quotient (AQ) was introduced by the same research group as a refinement of the PAI. Some retrospective studies have validated AQ using the same questionnaire-based methodology as PAI and report stronger associations with VO_2max and mortality [70]. However, none of these studies used HR monitors, and prospective AQ studies with wearable devices are still forthcoming [69]. In parallel to these developments, our research group is developing the Antwerp Activity Index and smart Antwerp Activity Index models [71,72] (P Vermunicht, PhD, unpublished data, 2026). These tools aim to provide HR-based, personalized activity scores by integrating daily-life HR data with individual characteristics, and are designed to predict cardiorespiratory fitness changes over time. While preliminary development has been promising, full clinical validation and prospective outcome studies are currently underway. Such emerging models may further advance the translation of HR-derived activity monitoring into actionable, personalized health guidance in cardiac populations.

Together, these developments reflect a growing interest in HR-based PA quantification and behavioral feedback. However, their clinical relevance for cardiac and older adults will depend on prospective validation in target populations, improved algorithmic transparency, and appropriate feedback tailoring for diverse activity profiles.

Future Directions and Research Limitations

The reviewed studies illustrate a diverse range of HR-based methods, from guideline-driven time-in-zone metrics to more advanced models estimating physiological outcomes and personal activity scores. This variety reflects a growing interest in using HR data not only to monitor activity but also to estimate its cardiovascular implications. Future research should prioritize validation of these methods in real-world populations with CVD,

XSL•FO
RenderX

with attention to feasibility, clinical interpretability, and predictive value. Tools that go beyond simple time-in-zone tracking and instead estimate outcomes like energy expenditure or changes in cardiorespiratory fitness may offer greater clinical value. As illustrated by systems such as PAI or the Firstbeat VO_2max model, combining HR data with individual characteristics can generate personalized feedback with the potential to guide long-term health behavior. Future work should strive for a balance between algorithmic sophistication, transparency, and accessibility.

Although not a focus of this review, a key translational consideration for HR-based PA estimation is that the validity of any derived PA metric depends on the accuracy of the underlying HR data [73,74]. Although ECG-based chest straps provide highly accurate HR measurements, they are less practical for daily monitoring. Wrist-worn photoplethysmography devices are more convenient, but their accuracy can be affected by artifacts and they should be validated against an ECG before clinical use [75,76]. Recent work from our group has therefore focused on artifact detection and cleaning procedures that operate directly on device-generated photoplethysmography HR data from commercial wearables, aiming to remove unreliable data while preserving clinically meaningful activity-related HR fluctuations [71,76-78]. Such artifact removal strategies are highly relevant when implementing the HR-based PA quantification methods described in this review, particularly in real-world cardiac populations where pathophysiological factors such as peripheral edema, poor tissue perfusion, and a higher incidence of arrhythmias may affect HR reliability [76,79].

Beyond methodological development, successful implementation of HR-based PA estimation also depends on how these metrics are embedded within broader digital care strategies. Mobile health tools that support patient education, self-management, and structured follow-up may enhance engagement and facilitate behavior change, thereby increasing the clinical relevance of HR-derived activity metrics [80,81].

This review has several limitations. It was not prospectively registered in a public database (eg, PROSPERO [International Prospective Register of Systematic Reviews]), which may limit transparency regarding protocol deviations. Although a protocol was developed to guide the review process, it was not publicly available. As a narrative synthesis, it does not provide pooled effect sizes or meta-analytic comparisons. The included studies varied widely in design, sample size, and how HR-based metrics were operationalized. While this limits direct comparability, the primary aim of this review was to map the diversity of methodological approaches rather than pool results. In addition, studies using techniques such as PACD or personalized scoring systems remain scarce, restricting broader generalization. Continued development and validation of such tools, especially in older and cardiac populations, will be essential to support their integration into clinical practice. Finally, due to the rapid evolution of wearable technologies and increasing research interest in HR-based activity estimation, new studies may have been published after the final search date. For instance, an eligible outcome paper from the OptimEx-Clin trial was published shortly after the search period [82]. While this study was not included for methodological consistency, its design was captured through the previously published protocol paper, which is part of this review. Future updates of this review could consider incorporating such newly available outcome data.

82

Conclusions

This review provides the first structured synthesis of HR-based methodologies for PA estimation in patients with CVD. Most studies relied on HR zone analysis to evaluate adherence to international PA guidelines, while others explored more advanced modeling approaches to estimate physiological outcomes such as energy expenditure or cardiorespiratory fitness.

Our findings underscore that HR monitoring offers a physiologically meaningful and scalable way to estimate PA, especially in clinical populations where traditional step-based or questionnaire-based methods may fall short. Personalized HR-based feedback systems may offer intuitive activity targets for patients. However, variability in how HR metrics are defined, validated, interpreted, and applied, currently limits comparability and implementation. Future research should focus on validating HR-based methods in real-world populations with CVD, improving methodological transparency, and tailoring feedback to individual needs. Ensuring reliable HR measurements remains a prerequisite for meaningful HR-based PA estimation in clinical practice. As wearable technologies continue to advance, HR-derived metrics hold strong potential to support more personalized and effective PA guidance in both clinical care and daily life.

Abstract

Background: Mobile information technology (IT) is increasingly being used in the health care sector, and it can play a critical role in both the care of children with congenital heart disease (CHD) and the quality of life of their families.

Objective: This study aimed to conduct a scoping review of the application of mobile health (mHealth) technologies in the care of children with CHD. We summarized the forms of mHealth interventions and effects on CHD to provide a reference for future research in this field.

Methods: We searched PubMed; Embase; Web of Science; the Cochrane Library; CINAHL; China National Knowledge Infrastructure; Wanfang Data; the Chinese Biomedical Database; VIP Chinese Science and Technology Journal Database; National Guideline Clearinghouse of the United States; the website of the Registered Nurses' Association of Ontario, Canada; the Guidelines International Network; the American Heart Association; and the American Association of Cardiovascular and Pulmonary Rehabilitation. The search period was from the establishment of the databases to June 12, 2025. The retrieved literature was screened and analyzed.

Results: A total of 519 Chinese- and English-language articles were identified, with 44 (8.5%) studies meeting the inclusion criteria. The primary forms of mHealth interventions for patients with CHD included mobile apps, wearable devices, and remote monitoring equipment. The findings indicated that mHealth technologies could improve exercise capacity, nutritional status, psychological well-being, and quality of life in children with CHD.

Conclusions: The application of mHealth in the care of children with CHD is feasible and demonstrates positive effects. Future research should emphasize peer education and patient privacy protection while further exploring remote education and health management based on theoretical frameworks and intelligent ITs to enhance quality of life for both children with CHD and their parents.

congenital heart disease; mobile health; scoping review; pediatric; telemedicine

Introduction

Congenital heart disease (CHD) is a heterogeneous group of structural abnormalities in the cardiovascular system with an incidence rate of 7–9 per 1,000, ranking as the most common birth defect. Worldwide, over 1 million infants are born with CHD each year, and China reports 150,000 to 200,000 new cases annually [1-3]. CHD comprises a complex and diverse spectrum of conditions with severe consequences, imposing substantial economic burdens and psychological distress on families and society. As a major public health concern, CHD significantly impacts children's physical and mental health, as well as their quality of life.

Traditional face-to-face intervention models are often constrained by medical costs, travel distances, and time limitations, making it difficult to provide timely and effective personalized, precise, and continuous health care services. These constraints negatively impact patient health management. In contrast, mobile health (mHealth) apps transcend temporal and spatial barriers, ensuring both the continuity and accessibility of medical resources while motivating patients to actively engage in their own health management. Guidelines indicate

XSL•FO
RenderX

that remote comonitoring of cardiac patients' cardiopulmonary rehabilitation by both families and health care professionals is feasible, safe, and effective [4]. The use of mHealth technology for home monitoring of children with CHD can help identify clinical issues, prevent unnecessary emergency visits, ensure child safety, and positively impact caregivers' psychological well-being and health care use [5,6]. Although research on the application of mHealth technology in children with CHD has been conducted both domestically and internationally, it remains in the early stages. This study aimed to summarize the applications and effects of mHealth technology in the care of children with CHD, providing a reference to promote its further development in this field.

To address this gap in the literature, this study used a scoping review methodology to examine the application of mHealth technology in children with CHD. The specific objectives were to (1) systematically identify the application of forms of mobile IT in the nursing care of children with CHD; (2) summarize the effects of mobile IT on the exercise function, nutritional status, psychological state, and quality of life of these children; and (3) identify gaps in the existing research. This study aimed to highlight the limitations of the current literature and provide directions for future research on mHealth-supported self-management for children with CHD.

Methods

Literature Search Strategy

This study used a scoping review methodological framework to systematically map the current research landscape on mHealth management for children with CHD, identifying key concepts, evidence types, and knowledge gaps. Given the limited number of studies on the specific application of mHealth technologies in this pediatric population, this review aimed to delineate the overall research landscape rather than evaluate the effectiveness of specific interventions; therefore, a scoping review was chosen over a systematic review. This report adheres to the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) checklist. We systematically searched multiple databases from their inception to June 12, 2025, including international databases (PubMed, Embase, Web of Science, the Cochrane Library, the website of the Registered Nurse and CINAHL), Chinese databases (China National Knowledge Infrastructure, Wanfang Data, the Chinese Biomedical Database, and VIP Chinese Science and Technology Journal Database), and guideline repositories (Guidelines International Network, National Guideline Clearinghouse, National Institute for Health and Care Excellence, Scottish Intercollegiate Guidelines Network, the Canadian Medical Association clinical practice guideline, World Health Organization, American Heart Association, American Association of Cardiovascular and Pulmonary Rehabilitation, and Medlive). The search strategy for this study was structured around 3 core conceptual modules: the target population (children with CHD), the intervention measures (mHealth and digital technologies), and the research context (nutrition, exercise, management, monitoring, and education). In the target population module, we combined terms for "congenital heart disease." For the intervention measure module, keywords including "mobile health," "mHealth," "telemedicine," "smartphone," "mobile application," and "WeChat" were used. The modules were combined using the Boolean operator "AND."

This search strategy was first developed for the PubMed database and subsequently adapted for other databases according to their controlled vocabularies (eg, MeSH [Medical Subject Headings] terms) and syntax rules. Although the search strings varied across different databases, the core conceptual structure remained consistent to ensure the comprehensiveness and reproducibility of the search. The search strategy can be found in Multimedia Appendix 1.

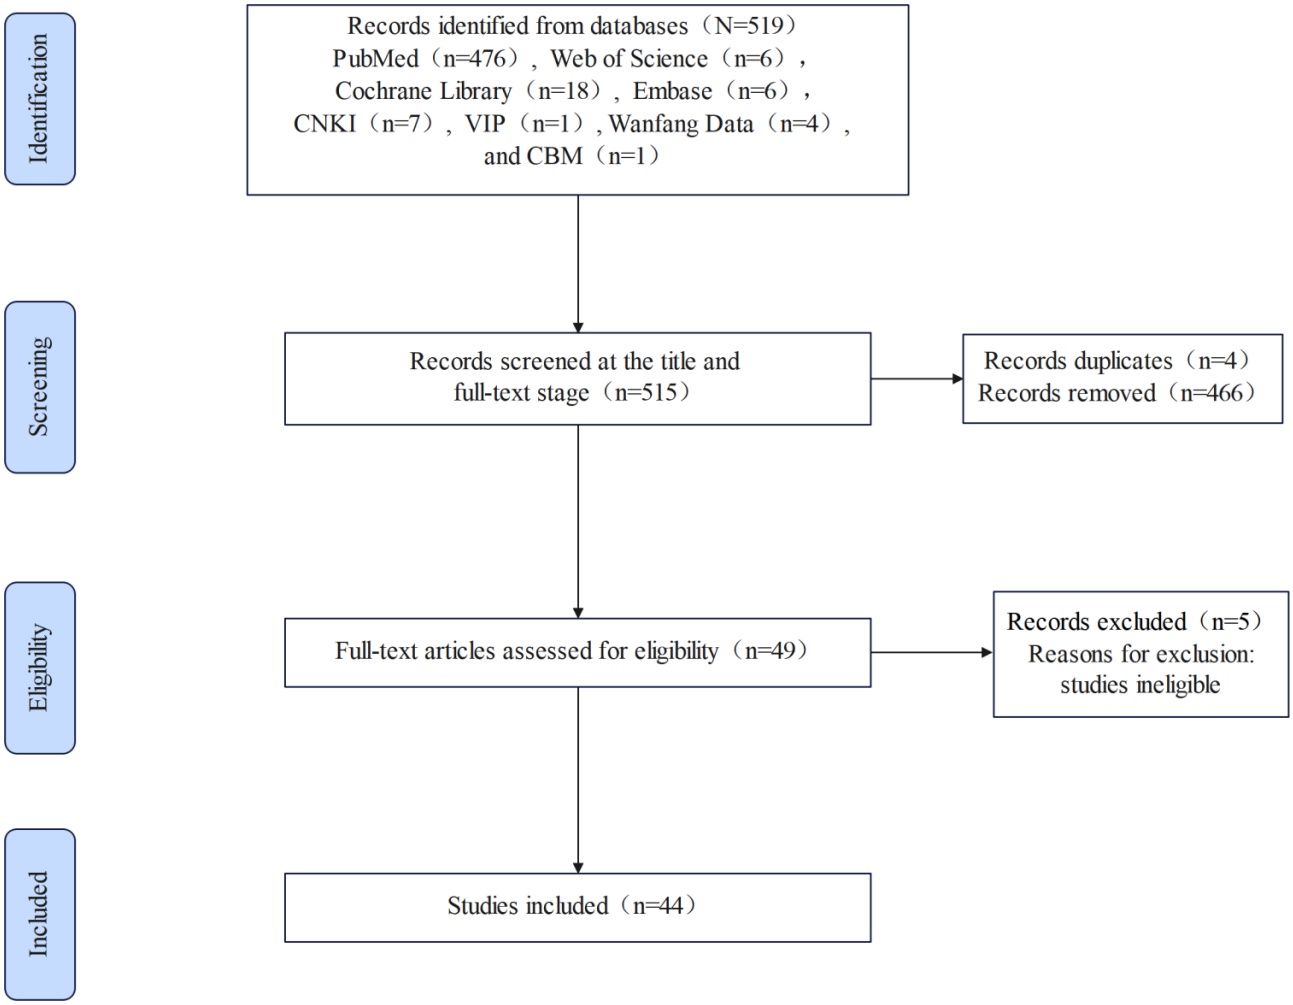
Literature Inclusion and Exclusion Criteria

Inclusion criteria were (1) studies focusing on mHealth technologies for children with CHD, (2) a study population consisting of patients with CHD aged 18 years or younger, and (3) publications in Chinese or English. Exclusion criteria were (1) duplicate publications; (2) unavailable full-text articles; and (3) case reports, conference abstracts, or similar publication types.

Study Selection and Data Extraction Process

Literature screening and data extraction were independently conducted by 2 reviewers. First, the 2 reviewers independently performed title and abstract screening and full-text screening based on the inclusion and exclusion criteria; any disagreements were resolved through discussion or by consulting a third reviewer. Subsequently, the 2 reviewers independently extracted data using a predesigned structured data extraction form (Microsoft Excel format) and cross-checked the results. The extracted information included first author, publication year, country, study type, specific form of mHealth intervention (eg, apps, remote monitoring platforms, and social media), intervention content (eg, nutritional management, exercise rehabilitation, and parental psychological support), and main study findings. During the extraction process, any discrepancies were resolved through discussion to reach a consensus.

Results



Literature Search Results

A preliminary search yielded a total of 519 relevant articles (n=476, 91.7% from PubMed; n=6, 1.2% from Web of Science; n=18, 3.5% from the Cochrane Library; n=6, 1.2% from Embase; n=7, 1.3% from China National Knowledge Infrastructure; n=1, 0.2% from VIP Chinese Science and Technology Journal Database; n=4, 0.8% from Wanfang Data; and n=1, 0.2% from the Chinese Biomedical Database). All articles were imported into a reference management software for deduplication. Of the 519 retrieved articles, after removing 4 (0.8%) duplicates, 515 (99.2%) remained for title and abstract screening. Following the review of titles and abstracts, of the 515 articles, 466 (90.5%) that were clearly irrelevant were excluded, leaving 49 (9.5%) for full-text review. During the full-text screening phase, of the 49 articles, 5 (10.2%) that did not meet the inclusion criteria were excluded, resulting in a final

XSL•FO
RenderX

inclusion of 44 (89.8%) articles, as shown in Figure 1 and Multimedia Appendix 2 [7-50].

Figure 1. Flowchart of the article screening process. CBM: Chinese Biomedical Database; CNKI: China National Knowledge Infrastructure.

Basic Characteristics of the Included Studies

Study Types and Country Distribution

Of the 44 included studies, 24 (54.5%) were intervention studies, including 9 (20.5%) randomized controlled trials and 6 (13.6%) observational studies. Geographically, 45.5% (n=20) of the studies were from China, mostly focusing on nursing interventions and health education using the WeChat platform; 20.5% (n=9) of the studies were from the United States; and 6.8% (n=3) of the studies were from Norway, emphasizing qualitative and survey research on parental acceptance of mobile apps and psychological support. The remaining studies were from India, the Netherlands, Italy, Japan, the United Kingdom, Germany, and Argentina.

Forms of Mobile IT Application

The forms of mobile IT used in the included studies comprised mobile apps for functions such as health education, symptom monitoring, and decision support; wearable devices for the collection of vital signs or physical activity data; and telemedicine platforms—including WeChat, video consultations, and telephone follow-ups—for postdischarge follow-up, home monitoring, or online guidance.

Overview of Intervention Content and Effects

The literature systematically demonstrated the broad application trend of mHealth technology in the management of children with CHD. In terms of intervention content, the studies focused on exercise intervention or cardiopulmonary rehabilitation, nutritional management, psychological support, and quality of life. Exercise interventions or cardiopulmonary rehabilitation facilitated the improvement of children's motor function through remote guidance or monitoring. Nutritional management encompassed breastfeeding guidance, removal of nasogastric tubes, and nutritional risk assessment. Psychological support primarily involved remote education and cognitive behavioral interventions to alleviate anxiety and depression in both children and their parents.

Discussion

Principal Findings

This study used a scoping review methodology to systematically examine the current status and effects of mobile IT in the nursing care of children with CHD. The findings indicate that mHealth technologies, primarily in the form of apps, wearable devices, and remote monitoring, demonstrated positive potential in improving exercise function, nutritional status, psychological

XSL•FO
RenderX

state, and quality of life in children with CHD. Additionally, these technologies significantly contributed to enhancing parental caregiving capacity and alleviating psychological burden. However, existing research still faces challenges such as high heterogeneity in interventions, lack of theoretical frameworks, privacy and security risks, and unequal accessibility of devices. These issues suggest that this field remains in the early stages of development, and future research requires further standardization and improvement.

Overview and Current Status of mHealth

mHealth uses mobile phones, apps, and monitoring devices to facilitate communication between patients and pediatric health care professionals, track health-related data, and enable access to pediatric health information. It incorporates functions such as tracking, feedback, and reminders, supporting disease screening, daily activity monitoring, medication adherence, and health education [51]. Unlike traditional telephone-based follow-up methods, mHealth has evolved toward greater specialization, systematization, and intelligence tailored to patients' disease characteristics and needs [52]. mHealth technology adherence refers to the extent to which health data transmitted by parents to health care providers align with recommended home-based symptom monitoring protocols. Parents with higher adherence to mHealth tools can more promptly identify symptoms in their children, leading to improved health outcomes [53]. Additionally, the mHealth management model offers a flexible and practical approach for remote postdischarge follow-up, diagnosis, and treatment in cardiac patients [54]. Currently, mHealth has become an indispensable medical tool; however, research on its application in CHD care remains limited. This review synthesized evidence on the use of mHealth in CHD management, aiming to provide insights for optimizing and expanding its adoption in pediatric CHD care.

Application Modalities of mHealth in Children With CHD

Mobile Apps

Currently, applications based on mobile phones, computers, and web platforms are widely used for vital sign monitoring, rehabilitation training, follow-up management, and health education in children with CHD. A study found that the implementation of an app integrating functionalities from prenatal diagnosis and neonatal screening to postoperative follow-up reduced the number of deaths among children with CHD from 598 to 353, representing a 41% decrease [7]. A survey also showed that, among 119 parents of children with CHD, 104 (87.4%) were willing to accept follow-up management based on WeChat [8]. Smartphone apps support remote monitoring of vital sign data, including oxygen saturation, blood pressure, temperature, and weight, and can assess medication adherence as well as the incidence and severity of symptoms. Relevant data can be uploaded to hospital information systems, facilitating timely awareness of the child's condition by medical staff. Furthermore, some apps incorporate integrated decision support systems to assist in formulating or adjusting treatment and nursing plans and provide health education materials in video and PDF formats along with online consultation features [9-11]. For instance, cardiac observation apps, through thoughtful design of content and functionality, effectively supplement traditional medical follow-up systems, helping parents gain more guidance and psychological support when facing their children's illness [12]. Carlson et al [13] developed a web-based automated follow-up system that automatically sends health status questionnaires to families at 30 days and 1 year after the child's discharge, aiding in the identification of high-risk patients requiring enhanced follow-up. The study also found a strong demand among families for knowledge related to heart disease and behavioral guidance. Future research could further explore the feasibility of conducting personalized remote rehabilitation, follow-up, and health education based on the severity of the child's condition and individual needs.

Wearable Devices

Current evidence indicates that wearable devices (eg, heart rate monitors, pedometers, and sensors) are primarily worn on the wrist, waist, or chest. These devices can continuously record vital sign parameters such as electrocardiography, heart rate, blood pressure, and oxygen saturation; some devices can also monitor weight changes [10,14]. However, existing studies are characterized by small sample sizes and short follow-up periods, making it difficult to assess long-term effects. Furthermore, the device models, monitored parameters, and intervention protocols vary considerably across studies, hindering cross-study comparability of results. Currently, wearables are predominantly used for monitoring, and there is a lack of integrated management models that combine them with early warning systems and remote interventions. Additionally, issues concerning the accuracy of device data, privacy and security, and children's compliance with wearing the devices require further investigation. Future research should focus on threshold setting for wearable device parameters and data storage functions. This would enable families to understand their children's health status in real time while also providing stored information to medical professionals. Such data would offer a basis for understanding children's condition at home and developing personalized intervention plans.

Remote Examination Devices

The application of remote examination devices in the diagnosis and treatment of children with CHD primarily encompasses modalities such as remote auscultation, remote consultation, remote diagnosis, and remote echocardiography. In the realm of remote auscultation, computer-aided auscultation systems, through heart sound acquisition, signal processing, and automated analysis algorithms, can effectively differentiate pathological murmurs, thereby reducing unnecessary referral burden [15]. Digital stethoscopes have also proven effective in identifying clinical issues, with no instances of missed diagnoses reported [16]. A remote diagnosis system in Japan has been successfully implemented for the prenatal diagnosis and pregnancy management of CHD in hospitals located in remote areas [17]. Regarding remote imaging diagnosis, tele-echocardiography has demonstrated accuracy, safety, and efficacy in screening children with CHD, potentially sparing families unnecessary interhospital transfer costs [18]. In terms

XSL•FO
RenderX

of teleconsultation, video-based teleconsultation saves time and medical costs for parents of children with CHD [19]. It also allows for modifications to the patient's treatment plan and facilitates communication regarding subsequent treatment strategies [20].

Despite the significant advantages demonstrated by remote examination devices, several challenges persist. Artificial intelligence–assisted auscultation requires expensive digital stethoscope equipment, and its widespread adoption and application may face economic and technological barriers. The operation of remote examination devices necessitates specialized training; the standardization of procedures and diagnostic consistency among primary health care providers require further evaluation. Furthermore, the lack of unified interoperability and data sharing standards among different devices limits the integrated application of telehealth systems. Future research should focus on reducing device costs, enhancing user-friendliness, and promoting the deployment of remote examination and diagnostic devices in primary care hospitals, thereby extending access to quality medical resources for patients in remote areas.

Potential of mHealth in Cardiac Rehabilitation

Physical Exercise

There is current evidence suggesting that mHealth technologies hold promise for enhancing the accessibility of cardiac exercise therapy and reducing implementation barriers [14]. However, findings regarding intervention effects remain inconsistent. Meyer et al [21] found that a web-based exercise intervention, while demonstrating the safety of 60 minutes of weekly physical activity, did not yield significant improvements in health-related physical fitness or quality of life among children with complex CHD. Conversely, other studies have indicated that wearable device–based cardiopulmonary rehabilitation can improve muscle endurance in children with heart disease [22]. Regarding study design, existing research on exercise interventions exhibits considerable heterogeneity. Variations in intervention duration, exercise modalities, and monitoring devices across studies render direct comparisons and synthesis of results difficult. Furthermore, most studies have small sample sizes and lack long-term follow-up data, precluding assessment of the long-term effects and safety of the interventions. The application of mHealth technologies in the field of exercise rehabilitation for children with CHD is still in an exploratory phase. Although existing evidence preliminarily confirms its safety and feasibility, its effectiveness remains unclear. Future research should conduct large-sample, multicenter randomized controlled trials that incorporate objective measures of physical capacity (eg, cardiopulmonary exercise testing) rather than relying solely on self-reports to validate the effectiveness of different exercise intervention protocols. Personalized remote exercise prescriptions could be developed tailored to children at different developmental stages—such as infants, school-aged children, and adolescents. Establishing a hospital-home remote supervision mechanism ensuring exercise safety under the joint monitoring of family members and medical staff is crucial. Additionally, exploring the integration of exercise monitoring data with early warning systems to enable real-time feedback and dynamic adjustments represents a key direction for future investigation.

Nutrition

Mobile ITs have played a positive role in nutritional risk identification and assessment, feeding guidance and nutritional improvement, and liberation from nasogastric tube feeding with associated home management for children with CHD. A telehealth home monitoring program facilitated the early identification of infants with CHD at risk of weight-for-age abnormalities, enabling timely customization of interventions by health care providers for this vulnerable population [23]. In another study, a nutritional risk assessment tool integrated into a mobile app automatically calculated and analyzed children's nutritional status upon data entry, providing decision support for clinicians to devise personalized nutritional interventions [24]. Multiple studies have demonstrated that telehealth education for parents of infants after CHD surgery—covering disease knowledge, postoperative care, home feeding, and complication management—can significantly enhance parental caregiving competence and improve the infants' postoperative nutritional status [25,26]. Notably, health education based on the WeChat platform has proven effective in improving breastfeeding efficiency and parental satisfaction for infants after CHD surgery [27]. Furthermore, remote nutritional management has been shown to promote neonatal growth and development while reducing the incidence of respiratory infections and hospital readmission rates [26]. Telehealth interventions grounded in multidisciplinary team collaboration combined with individualized patient assessment and effective communication with parents have facilitated the successful transition from nasogastric tube to oral feeding in children with CHD at home [28]. A WeChat-based discharge follow-up system also improved treatment adherence, enhanced cardiac function and nutritional status, and reduced the incidence of adverse events in these children [29].

Although existing studies generally support the positive effects of mHealth technologies on the nutritional management of children with CHD, several limitations remain. Some studies rely on parent-reported data, which may introduce recall bias, and the heterogeneity of nutritional outcome measures (eg, weight, length and height, BMI, feeding efficiency, and readmission rates) makes it difficult to conduct meta-analyses for integration. The nutritional assessment functions of mHealth tools are mostly limited to data calculation and currently lack deep integration with electronic health record systems or clinical decision support. Children with CHD are at higher nutritional risk than their healthy peers. Future research should establish a core outcome set, evaluate the differential effects of interventions across patients with varying nutritional risk stratification, focus on long-term nutritional follow-up in postoperative patients, explore deep integration of mHealth technologies with clinical nutritional guidelines, and enhance technology accessibility for low-income families.

Psychological Outcomes

Mobile ITs have also demonstrated utility in alleviating anxiety and depression and improving the psychological well-being of children with CHD, their parents, and adolescent patients. For

XSL•FO
RenderX

pediatric patients, these technologies have a positive impact on reducing anxiety and depression levels [30], with studies focusing on adolescents further confirming that mobile phone–based digital health interventions can enhance emotional well-being in this population [31]. Furthermore, Internet Plus–based health education, while enhancing disease-related knowledge among family members, can indirectly alleviate negative emotions in children and improve cardiac function while reducing complication rates [32]. At the parental level, multiple studies have shown that preoperative and postoperative health education and nursing guidance provided to parents of children with CHD via WeChat effectively ameliorates parental anxiety [33,34]. Nurse-guided mHealth interventions have also been associated with reduced anxiety and depression in parents following a prenatal diagnosis of critical CHD [35]. Additionally, telehealth services such as remote consultations and follow-up care enable timely assessment of the children's physical condition, reduce the need for hospital visits, and provide professional guidance for home care, thereby alleviating parental stress, anxiety, and depression and reducing caregiving burden [36-38].

However, existing research predominantly focuses on parental psychological states, with relatively fewer studies examining psychological outcomes in pediatric patients themselves, particularly young children. While interventions are diverse—including WeChat-based education, app-based interventions, and nurse-guided support—there is a lack of comparative studies evaluating the efficacy of different intervention modalities or assessing the long-term maintenance of psychological benefits. Furthermore, most studies use generic scales for psychological assessment, lacking condition-specific instruments validated for the pediatric CHD population. Children with CHD face unique psychosocial challenges during the transition to adulthood. Future research should prioritize the psychological health of patients during this critical transitional period, develop mHealth-based support programs for transition care, and explore integrated care models that combine psychological support for children with concurrent parental psychological interventions.

Quality of Life

There is current evidence suggesting that mHealth technology shows promising potential in improving quality of life for children with CHD and their parents, particularly demonstrating significant effects in enhancing treatment adherence, reducing complication rates, and alleviating parental caregiving burden. Studies have shown that telemedicine solutions have a positive impact on cardiovascular health [39]. Regarding the quality of life of pediatric patients, postdischarge follow-up management based on mHealth technology has demonstrated favorable intervention outcomes. Research indicates that using a WeChat-based follow-up nursing system can effectively improve out-of-hospital treatment adherence among children, reduce the incidence of adverse cardiac events, and enhance their quality of life [40]. An IT-supported transitional care model helped strengthen parental caregiving capabilities, improve nursing satisfaction, and reduce postoperative complications and readmission rates, thereby improving patient prognosis [41-43]. Remote health education targeting parents has also been associated with reduced complication rates and lower postdischarge loss to follow-up [33,44]. In terms of symptom monitoring, parents' use of mobile devices to upload daily symptom data facilitates timely identification of abnormalities by health care providers and enables prompt intervention, contributing to more positive health outcomes for children [53].

At the parental level, mHealth technologies have demonstrated multidimensional intervention value. Personalized decision support apps can enhance parents' understanding of common infant health conditions, assist them in completing health assessments and reports, and improve access to health care services [45]. Health education and psychological counseling delivered via the WeChat platform have proven effective in improving parental caregiving capacity, alleviating anxiety and grief, and reducing caregiving burden, thereby enhancing overall quality of life [46,47]. Individualized cardiac observation apps facilitate communication between parents and health care providers and improve readiness for hospital discharge [48]. Furthermore, WeChat-based guidance for preparing children for transthoracic echocardiography and for postoperative follow-up has been shown to alleviate parental anxiety and increase satisfaction with medication management [38,49]. Research focusing on mothers of children in intensive care units has similarly found that mHealth apps help reduce separation anxiety and improve the extent to which family needs are met [50].

Despite the generally positive findings, some studies have reported inconsistent effects of mHealth interventions. One telehealth home monitoring program, for instance, failed to significantly reduce psychological distress in parents of children with CHD [23]. These differences may be related to the complexity of the children's CHD and the technical usability of the mobile apps. Interventions targeting parental psychological support require further optimization. Current research exhibits considerable heterogeneity in intervention content, follow-up duration, and outcome measures, and no consensus has been reached regarding the effectiveness of interventions for parental stress. Therefore, current studies lack evidence on long-term quality of life improvements for both pediatric patients and their parents. Moreover, there is selection bias in the study designs—families willing to participate in mHealth research may inherently have higher health literacy and socioeconomic status, leading to overestimated effects [55,56]. Future research should incorporate intention-to-treat analyses and report dropout rates along with reasons for attrition. High-quality studies are still needed to identify optimal intervention strategies and the populations for which they are most appropriate.

Implementation Barriers: Health System–Level Challenges

Although the studies included in this review reported clinical effects of mHealth technologies, almost none discussed their implementation feasibility in real-world health systems. Below, we analyze barriers from 5 perspectives: cost, workflow integration, data security, equity, and recommendations for translation into practice.

XSL•FO
RenderX

Cost and Resource Allocation

Sustainable application of mHealth technologies requires ongoing hardware updates, software maintenance, and human resources. To date, no formal cost-effectiveness analysis of mHealth interventions for children with CHD has been conducted [57]. Moreover, the personnel costs associated with data monitoring are often concealed by research funding. Future studies should explicitly report direct and indirect costs as well as the incremental cost-effectiveness ratio.

Integration With Hospital Workflows

If an intervention cannot be integrated into existing workflows, its clinical efficacy loses practical relevance. Existing mHealth programs required nursing staff to periodically review data from apps but did not assess the additional workload. Furthermore, most apps were incompatible with hospital electronic medical record systems, necessitating manual data transcription and increasing the risk of errors and administrative burden [58]. Future research should prioritize platforms that seamlessly interface with electronic medical record systems and adopt automated alert algorithms to reduce manual review.

Data Security and Regulatory Compliance

mHealth technologies involve the transmission and storage of pediatric health information, and risks of privacy breaches during data collection, transmission, and storage are common. However, existing studies have inadequately described data encryption, anonymization, and user authorization mechanisms [59]. Future research should explicitly report data security measures in the “Methods” section and recommend developing open-source, locally compliant platforms.

Equity and Accessibility

The widespread use of mHealth technologies may exacerbate health inequities, with device costs and digital literacy being 2 core barriers for low-income families [60]. The initial investment in basic monitoring equipment (eg, smartphones and wearable sensors) and data plans may worsen the financial burden for some rural families, especially in the absence of insurance coverage or subsidies. Even when devices are available, insufficient digital literacy among caregivers (eg, inability to install apps or upload data) can compromise intervention effectiveness and adherence. Future research should report household income and baseline digital literacy and explore low-technology alternatives (eg, SMS text messages plus voice follow-up), device rental or subsidy programs, and community-based digital coaching as integrated support models.

Recommendations for Translation Into Practice

Future research, while reporting clinical outcomes, should focus on family acceptability, long-term intervention feasibility, nurse workload, and data security. Technologically, it is necessary to improve the accuracy of wearable devices; develop low-cost, high-precision solutions; and strengthen privacy protection and ethical compliance. Attention should be paid to digital accessibility for patients of low socioeconomic status and those in remote areas to narrow the digital divide. Research should be based on theoretical frameworks, include child-reported psychological outcomes and disease-specific measurement tools, and extend follow-up periods. Gamified interventions and qualitative research should be explored to gain an in-depth understanding of user needs.

Summary

mHealth technology holds positive potential in the nursing care of children with CHD, improving multiple health outcomes and reducing parental burden. Its mechanisms of action may be related to self-efficacy, adherence, and behavior change. Future research should conduct mechanism studies based on behavioral theory to provide a theoretical foundation for optimizing interventions.

Funding

This work was supported by two grants. The first grant is from the Guizhou Provincial Health Commission (Science and Technology Fund Project 2025, grant number zwkj2025-607). The second grant is from the Guizhou Provincial Department of Science and Technology under the Clinical Special Project (also referred to as the Guizhou Provincial Science and Technology Cooperation Achievement Project, General Program LC, where “LC” stands for “Linchuang” [meaning Clinical]), with grant number 161CHD (2026).

Abstract

Background: Structured exercise is a key component of cardiac rehabilitation (CR) for patients with heart failure (HF), but access to center-based cardiac rehabilitation (CBCR) is often limited. Mobile health (mHealth) platforms enable remote, virtual, or hybrid cardiac rehabilitation (RVH-CR) delivery.

Objective: This study aimed to evaluate the effectiveness and safety of structured, exercise-focused RVH-CR supported by mHealth compared with usual care or CBCR in patients with heart failure with reduced ejection fraction (HFrEF) or in HF populations predominantly comprising patients with HFrEF.

Methods: We searched PubMed, Web of Science, MEDLINE via Ovid, Cochrane CENTRAL, and CINAHL Complete from inception to April 27, 2026. Randomized controlled trials comparing mHealth-supported RVH-CR with usual care or CBCR were included. The primary outcome was exercise capacity, assessed by peak oxygen uptake (VO_2 peak) and 6-minute walk distance (6MWD). Secondary outcomes included health-related quality of life and safety. Data were pooled using random-effects meta-analysis stratified by comparator. Risk of bias was assessed with the Cochrane Risk of Bias Tool version 2, and evidence certainty was evaluated using GRADE (Grading of Recommendations Assessment, Development, and Evaluation).

Results: Eight randomized controlled trials with 1368 patients were included. In the CBCR comparison, mHealth-supported RVH-CR showed a statistically significant greater improvement in VO_2 peak than CBCR (mean difference [MD] 0.82, 95% CI 0.06-1.57; *P*=.03), although this finding was based on a limited number of trials. Compared with usual care, mHealth-supported RVH-CR was associated with improved 6MWD (MD 22.99, 95% CI 1.15-44.82; *P*=.04). Single-trial estimates suggested improvements in VO_2 peak (MD 2.50, 95% CI 0.88-4.12) and Minnesota Living with Heart Failure Questionnaire scores (standardized MD −0.57, 95% CI −0.98 to −0.17; *P*<.01) versus usual care. The certainty of evidence ranged from low to moderate. No intervention-related deaths or serious adverse events were reported, but sparse events and short follow-up limited conclusions regarding safety.

Conclusions: The effects of structured RVH-CR supported by mHealth differed according to comparator type, but the certainty of evidence ranged from low to moderate. Compared with usual care, mHealth-supported RVH-CR was associated with improved 6MWD. Compared with CBCR, mHealth-supported RVH-CR showed a significantly greater improvement in VO_2 peak in a limited number of trials, but superiority, equivalence, or noninferiority to CBCR cannot be concluded. Because usual care and CBCR are clinically distinct comparators, no single overall effect across comparator types should be inferred. Future studies should assess long-term outcomes and standardize structured exercise protocols across RVH-CR models.

Introduction

Background

Heart failure (HF) is a complex clinical syndrome in which structural or functional cardiac abnormalities impair ventricular filling or ejection, giving rise to characteristic symptoms and signs [1]. HF remains a significant public health challenge globally [2,3]. Guidelines emphasize comprehensive disease management for patients with HF, including evidence-based pharmacotherapy, cardiac rehabilitation (CR), and structured follow-up [4,5]. Among HF phenotypes, heart failure with reduced ejection fraction (HFrEF) is clinically distinct and has been widely studied [6]. Multiple American Heart Association clinical practice guidelines endorse CR as an effective strategy for reducing mortality and improving quality of life across the spectrum of cardiovascular disease [7-9]. Core components of CR programs include patient assessment, individualized exercise training, nutritional counseling, psychological support, and health education, delivered by multidisciplinary teams comprising physicians, nurses, exercise physiologists, behavioral health specialists, dietitians, physical therapists, and respiratory therapists [10].

Exercise-based CR has been shown to improve functional capacity and exercise tolerance, reduce overall and HF-specific hospitalization rates, and enhance health-related quality of life (HRQoL) [11]. Despite these benefits, referral and participation rates for center-based cardiac rehabilitation (CBCR) are low globally, limited by transportation, social support, and socioeconomic factors [12,13].

To address these access barriers, CR delivery has expanded beyond traditional facility-based programs to include remote, virtual, and hybrid models that may be delivered in the home, community centers, fitness facilities, or other noncenter settings [9,14,15]. Contemporary consensus documents emphasize delivery mode rather than location: virtual CR refers to synchronous, real-time audiovisual delivery; remote CR refers to asynchronous delivery with clinician monitoring, feedback, or communication; and hybrid CR combines facility-based, virtual, and/or remote components [16,17]. Digital technologies are increasingly integrated into CR delivery, offering solutions to the logistical challenges inherent to CBCR while expanding the reach of structured rehabilitation care [10,17].

In recent years, the proliferation of smartphones and mobile apps has driven growing interest in mobile health (mHealth)-supported remote, virtual, and hybrid cardiac rehabilitation (RVH-CR) delivery [18]. mHealth refers to the use of mobile and wireless technologies to support the achievement of health objectives, encompassing smartphones, tablets, mobile apps, SMS, wearable activity trackers, biosensors, and connected digital platforms that enable bidirectional communication and real-time monitoring of health data between patients and clinicians [19,20].

Objectives

In recent clinical trials, mHealth-supported RVH-CR has been evaluated for its impact on patients with HF. However, there remains a lack of systematic reviews focusing specifically on exercise-based, structured RVH-CR supported by mHealth in patients with HFrEF or HFrEF-predominant HF populations. A meta-analysis conducted by Li et al [21] in 2025 compared the effects of mHealth home-based CR interventions versus usual care and CBCR across different cardiovascular conditions but lacked a specific focus on HF. Furthermore, the majority of systematic reviews [22-25] have focused on the impact of remote technologies on HF prognosis, with limited attention to exercise-based telerehabilitation modalities (such as videoconferencing platforms, computer-based systems, smartphone applications, or web-based home monitoring systems).

Throughout this review, we use “mHealth-supported RVH-CR” as the umbrella term for eligible interventions. “Remote,” “virtual,” and “hybrid” refer to CR delivery models, whereas “mHealth” refers to the portable, wireless, or connected digital technology layer supporting exercise prescription, monitoring, data transmission, clinician feedback, or supervision. “Home-based” is used only to describe the physical setting in which some intervention sessions occurred. “Telerehabilitation” is retained only when referring to terminology used by individual trials or previous reviews; otherwise, interventions are described using the standardized categories of RVH-CR. Given the emerging but still distinct literature on heart failure with preserved ejection fraction (HFpEF), the target population of this review was restricted to HFrEF or HFrEF-predominant HF populations to maintain clinical and pathophysiological coherence.

This systematic review aimed to identify and synthesize evidence from randomized clinical trials comparing the efficacy of mHealth-supported RVH-CR versus usual care or supervised CBCR in patients with HFrEF or HFrEF-predominant HF populations.

Methods

This systematic review and meta-analysis were developed and reported according to the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines (Checklist 1) [26]. The protocol was registered in PROSPERO (CRD420251162078).

Search Strategy

We searched 5 databases (PubMed, Web of Science, MEDLINE via the Ovid interface, Cochrane CENTRAL, and CINAHL Complete) from their inception to April 27, 2026. We also manually checked the reference lists of related studies and reviews. The search strategy combined MeSH terms and keywords adjusted for each database. The electronic search strategy was developed by HZ after discussions with the other authors (Multimedia Appendix 1). Key search terms covered the following 4 concepts: “heart failure,” “cardiac rehabilitation,” “mobile applications,” and “exercise.”

Selection Criteria

Studies were eligible if they met all of the following criteria: (1) the participants were adults (aged ≥18 y) diagnosed with HFrEF, or individuals with HF predominantly characterized by HFrEF. Trials were considered HFrEF-predominant if eligibility

XSL•FO
RenderX

criteria specified reduced left ventricular ejection fraction, or if the enrolled population with HF was predominantly composed of patients with reduced left ventricular ejection fraction, as reported by the trial authors; (2) interventions were not classified as mHealth-supported RVH-CR solely because they used videoconferencing, telephone support, SMS, or general telehealth communication. To be eligible, the intervention had to combine structured exercise-based CR with a patient-facing portable, wireless, or connected digital technology that supported exercise prescription, execution, physiologic or activity monitoring, patient-generated data transmission, clinician feedback, or supervision; (3) the control group consisted of either usual care (routine outpatient follow-up and general lifestyle advice without structured exercise or mHealth technology) or CBCR (supervised, facility-based exercise training and face-to-face follow-up); (4) the study design was a randomized controlled trial (RCT); and (5) at least one prespecified outcome was reported—exercise capacity (peak oxygen uptake [VO_2 peak] or 6-minute walk distance [6MWD]) or HRQoL.

Studies were excluded if (1) SMS, telephone, or videoconferencing was used solely for one-way reminders, general health education, or administrative communication, without structured exercise management, patient-generated data capture, or rehabilitation-specific feedback; (2) the full text was unavailable or the study was incomplete; or (3) the publication was not an original report (eg, review, conference abstract, or commentary).

Study Selection

All database search results were imported into EndNote X9 (Clarivate) for automated deduplication, followed by manual verification to ensure accuracy. Two reviewers (KS and CL) independently screened titles and abstracts against the eligibility criteria, followed by a full-text review of potentially eligible records. Discrepancies at any stage were resolved through discussion, and unresolved disagreements were adjudicated by a third reviewer (HZ).

Data Extraction

Two reviewers (KS and CL) independently extracted data using a standardized form developed in Microsoft Excel. Extracted items included study characteristics, participant demographics, intervention and control group details, and outcome measures. Discrepancies were resolved by consensus, with HZ serving as an arbiter when necessary. When data were missing or unclear, the corresponding authors were contacted by email to request the required information.

Risk of Bias and Quality of Evidence

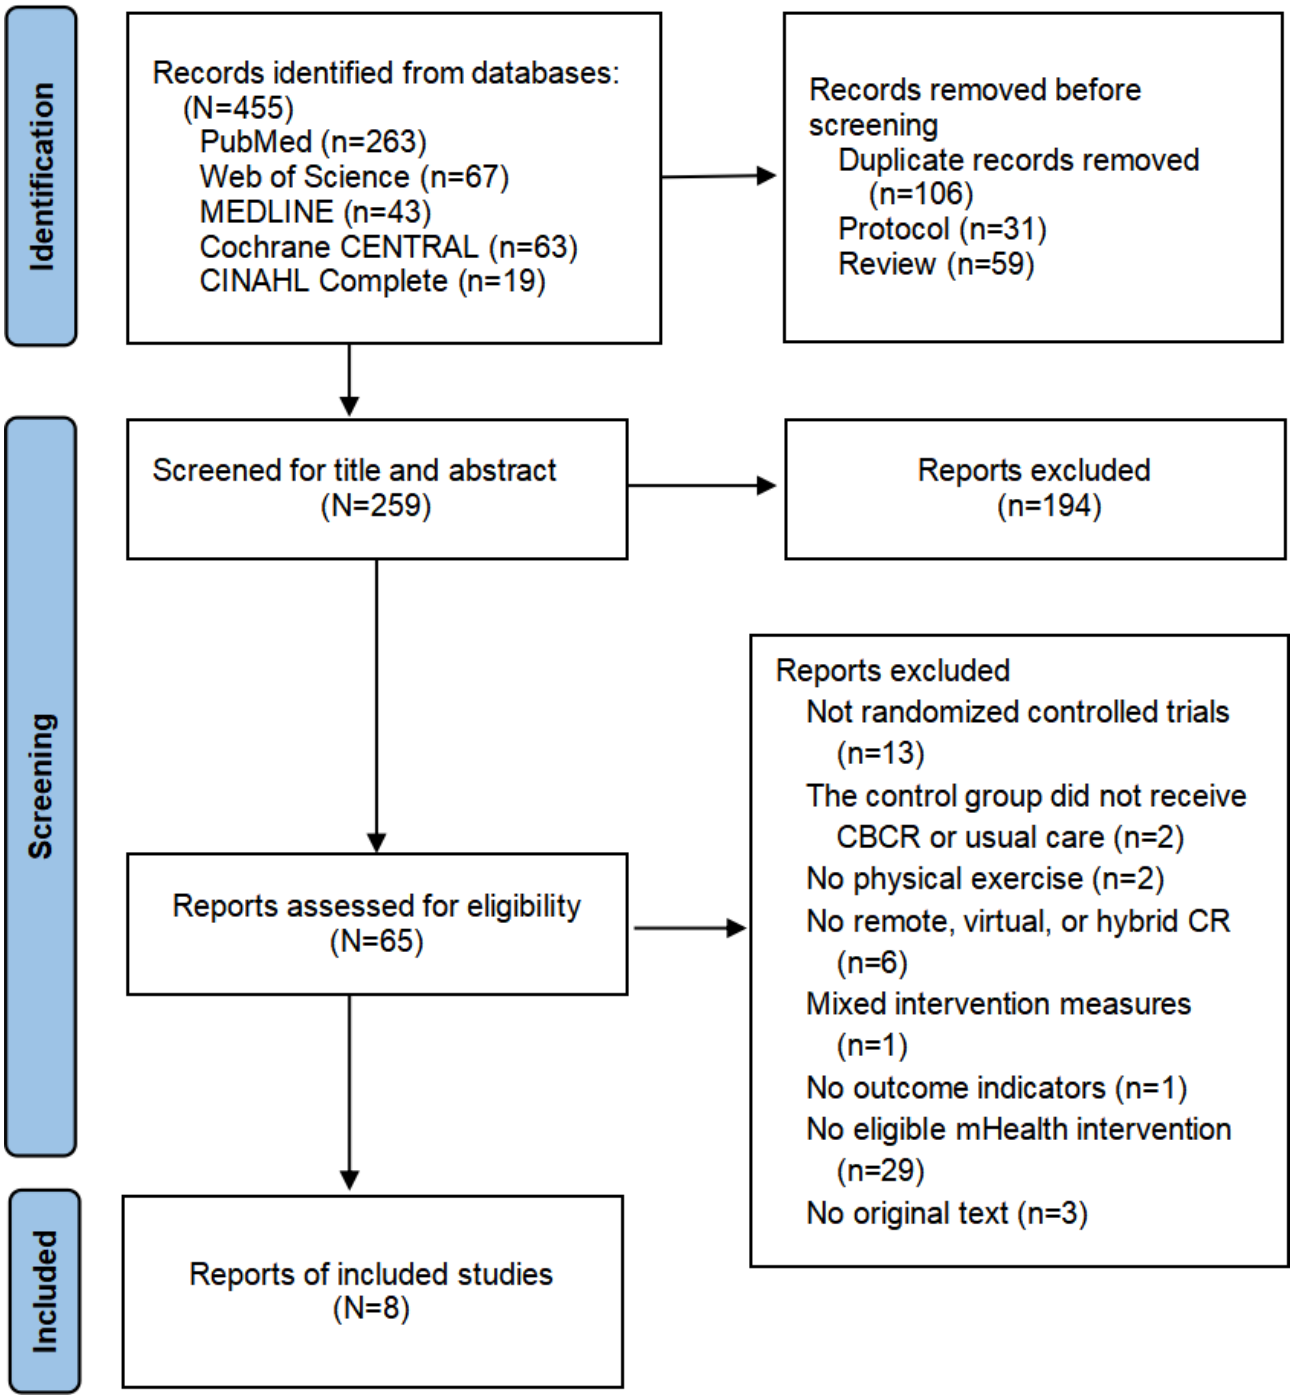
Two reviewers (KS and TL) independently assessed the risk of bias (RoB) of each included RCT using the Cochrane Risk of Bias Tool version 2 (RoB 2), which evaluates 5 domains: the randomization process, deviations from intended interventions, missing outcome data, measurement of the outcome, and selection of the reported result. Each domain was rated as low risk, some concerns, or high risk, with an overall judgment derived according to RoB 2 guidance. Disagreements were resolved through discussion, with author HQ adjudicating unresolved cases.

The certainty of evidence for each outcome was independently assessed by 2 reviewers (KS and TL) using the GRADE (Grading of Recommendations Assessment, Development, and Evaluation) framework through GRADEpro software (Evidence Prime). Evidence certainty was rated across 5 domains—RoB, inconsistency, indirectness, imprecision, and publication bias—and classified as high, moderate, low, or very low.

Statistical Analysis

The primary outcome was exercise capacity, operationalized as VO_2 peak and 6MWD. Secondary outcomes were HRQoL, assessed using the 36-Item Short Form Health Survey (SF-36) and the Minnesota Living with Heart Failure Questionnaire (MLHFQ). Where outcomes were amenable to quantitative synthesis, pooled effect estimates with 95% CIs were calculated using a random-effects model (DerSimonian-Laird method), which was prespecified to account for anticipated clinical and methodological heterogeneity across trials. Separate meta-analyses were conducted for 2 predefined comparisons: mHealth-supported RVH-CR versus usual care and mHealth-supported RVH-CR versus CBCR.

The meta-analyses were conducted using change-from-baseline values rather than postintervention values. For each outcome, pooled estimates represent between-group differences in change over the intervention period. As all outcomes were continuous, the mean difference (MD) was used when studies used identical measurement instruments, whereas the standardized mean difference (SMD) was calculated when different instruments or scale versions were used. Effect sizes were interpreted according to Cohen conventions: small (SMD 0.2), medium (SMD 0.5), and large (SMD 0.8). Statistical heterogeneity was quantified using the Cochran Q test and the I^2 statistic. Substantial heterogeneity was predefined as I^2>50%, Q test, P<.05, and clinically meaningful variability in the direction or magnitude of effects. Assessment of publication bias via funnel plot asymmetry and Egger regression test was not performed, as fewer than 10 studies were available for any single comparison—a threshold below which such tests lack adequate statistical power. All analyses were performed using Stata version 18.0 (StataCorp).



Results

Study Selection

As shown in Figure 1, 455 records were identified from 5 databases. After removing duplicates, protocols, and reviews, 259 records were screened by title and abstract. Of these, 194 were excluded, and 65 reports were assessed for eligibility.

XSL•FO
RenderX

Figure 1. Study selection. CBCR: center-based cardiac rehabilitation; CR: cardiac rehabilitation; mHealth: mobile health.

After full-text assessment, 57 reports were excluded because they were not RCTs, did not include an eligible control group, did not include a physical exercise or mHealth intervention, did not evaluate RVH-CR delivered outside traditional center-based settings, used mixed interventions, lacked relevant outcomes, or had no original text. Finally, 8 studies were included in the systematic review.

Study Characteristics

The 8 included studies [27-34] were published between 2010 and 2025. Five studies [30-34] were conducted in Europe, 2 [28,29] in Asia, and 1 [27] in Oceania. All studies were prospective, parallel-group RCTs that investigated mHealth-supported RVH-CR, with most patient exercise sessions conducted in the home setting. The included trials enrolled patients with HFrEF or HFrEF-predominant populations with HF. A condensed summary of the included studies is provided in Table 1, and detailed study characteristics are provided in Multimedia Appendix 2.

Table . Summary characteristics of the included randomized controlled trials.[a]

Study	Country	Total sample size, n (intervention:control)	Comparator	Eligibility rationale for mHealth-supported CR[b] classification
Hwang et al [27], 2017	Australia	53 (24:29)	CBCR[c] exercise plus education	Qualified as mHealth-supported[d] virtual CR because real-time video conferencing was combined with structured exercise supervision and patient-facing home monitoring of blood pressure and oxygen saturation rather than used only for remote communication.
Schmidt et al [33], 2025	Portugal	120 (75:45)	24-session supervised CBCR	Qualified because smartwatch-based exercise data upload and asynchronous clinician review supported structured home exercise prescription, monitoring, and feedback.
Piotrowicz et al [30], 2010	Poland	152 randomized; 131 included in final analysis (75:56)	Supervised center-based cycle-ergometer CR	Qualified because portable ECG[e] telemonitoring, mobile phone transmission, audiovisual prompts, and clinician contact were used to guide and supervise structured home exercise training.
Piotrowicz et al [31], 2021	Poland	850 randomized; QoL[f] analysis included 768 (377:391)	Usual care or observation with lifestyle and self-management advice	Qualified because hybrid CR incorporated connected ECG, blood pressure, weight, and device-related monitoring through a monitoring center to support structured CR delivery.
Nagatomi et al [28], 2022	Japan	30 (15:15)	Usual pharmacological and nonpharmacological care	Qualified because Fitbit-based activity monitoring, symptom/vital self-monitoring, and app/telephone feedback generated patient data used to support individualized exercise and clinical feedback.
Peng et al [29], 2018	China	98 (49:49)	Discharge education plus routine outpatient follow-up	Eligible because digital communication was integrated with structured exercise management, monitoring, and feedback rather than used only for education or reminders.
Piotrowicz et al [32], 2015	Poland	111 randomized; 107 included in final analysis (75:32)	Lifestyle and self-management advice; no supervised exercise	Eligible because portable connected monitoring was used to supervise and adjust structured Nordic walking training.

RenderX

Study	Country	Total sample size, n (intervention:control)	Comparator	Eligibility rationale for mHealth-supported CR[b] classification
Lundgren et al [34], 2023	Norway	61 (31:30)	Usual care; guideline-based exercise encouraged	Eligible because synchronous CR was used to deliver structured exercise with active clinician supervision; however, it represents the broadest boundary of the mHealth-supported category and was retained because delivery depended on patient-facing connected digital technology.

[a]Values are mean or mean (SD) unless otherwise indicated. Randomized and final analysis samples are both reported when available. Detailed study characteristics are provided in Multimedia Appendix 2.

[b]CR: cardiac rehabilitation.

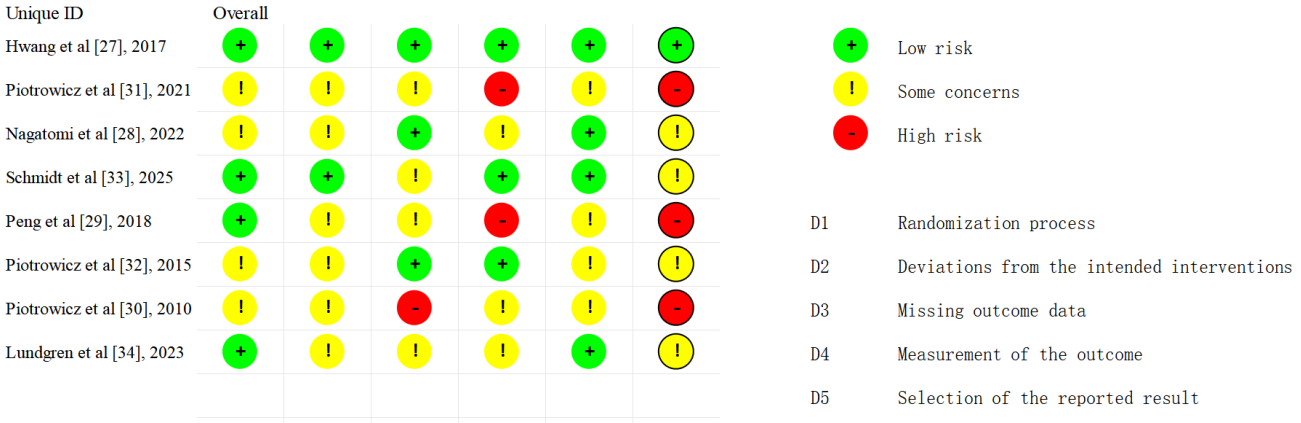
[c]CBCR: center-based cardiac rehabilitation.

[d]mHealth: mobile health.

[e]ECG: electrocardiogram.

[f]QoL: quality of life.

mHealth platforms in the included studies used broadband-connected laptops, tablet computers with videoconferencing systems, smartphones, smartwatches, and EHO (Pro Plus Company) devices [27-34]. Physiological monitoring was conducted using automated blood pressure monitors [27], electrocardiogram monitoring and transmission systems [30,31], wearable devices or smartwatches [28,33], and heart rate monitoring in a subset of participants [34]. Intervention durations ranged from 8 to 12 weeks. Exercise frequencies varied from daily to 5 times per week. The main type of exercise was aerobic exercise. Three studies also provided resistance training [28,29,31]. Two studies offered strength training [27,31]. Exercise prescriptions were generally individualized according to baseline functional capacity, symptoms, heart rate response, Borg perceived exertion score, or remotely transmitted physiological data. In most trials, physical therapists or multidisciplinary rehabilitation teams monitored progress and adjusted exercise intensity according to patient condition and training performance [27-29,33,34]. Psychological support was provided in 3 studies [30-32], nutritional counseling in 1 study [28], and lifestyle modification or self-management education was included in several studies [27,29,33,34].



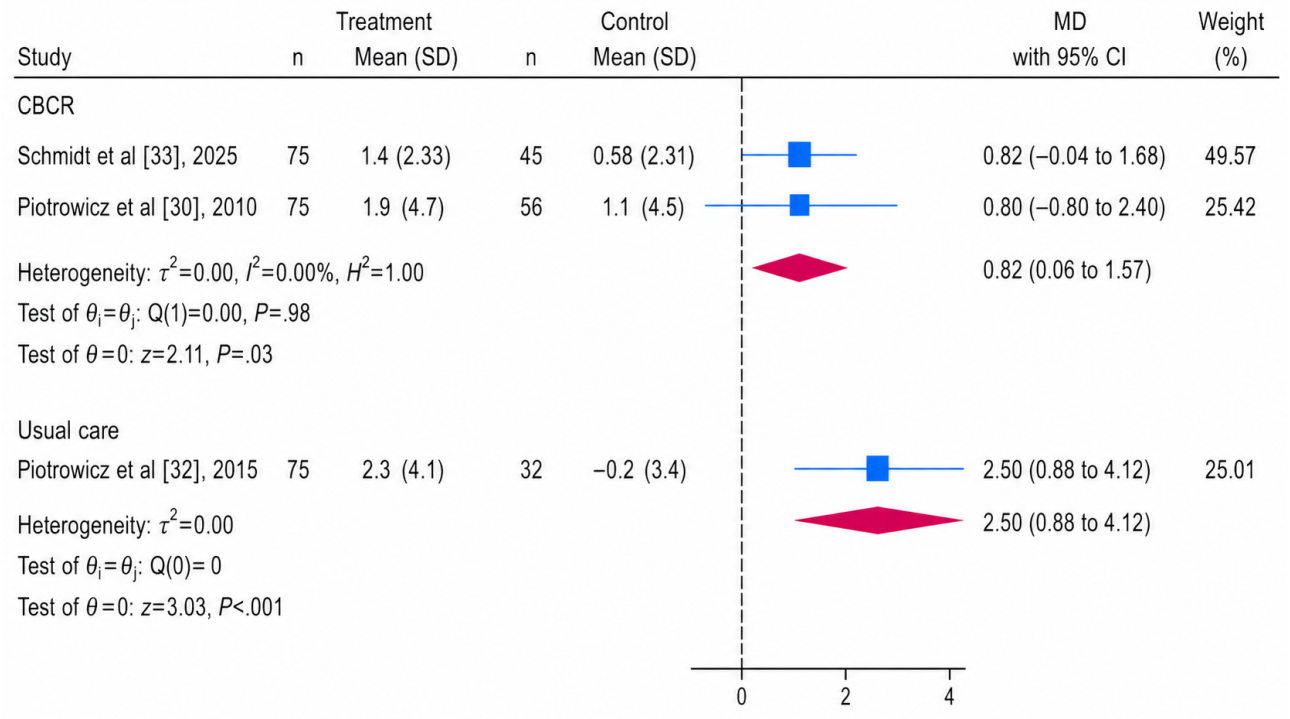
In 3 studies [27,30,33], the comparator was CBCR. In the remaining 5 studies [28,29,31,32,34], it was usual care. CBCR comprised supervised, facility-based exercise training and face-to-face educational or counseling sessions. Usual care consisted of routine outpatient follow-up, general recommendations for lifestyle modification, and self-management guidance, but excluded structured exercise training.

RoB

The included studies were assessed for RoB. One study [27] was considered to be at low risk because of concealed allocation, blinded outcome assessment, intention-to-treat analysis, trial registration, and minimal missing outcome data. Four studies [28,32-34] were rated as having some concerns, mainly due to the open-label nature of the interventions, incomplete reporting of allocation concealment or assessor blinding, baseline imbalance, or incomplete primary outcome data. Two studies [29,31] were judged to be at high risk primarily because their key outcomes were self-reported quality-of-life measures assessed in unblinded participants, whereas 1 study [30] was at high risk due to differential attrition and reliance on complete-case analysis. The most frequent sources of bias were lack of participant blinding, subjective outcome assessment, missing outcome data, and insufficient information on prespecified analysis plans. Therefore, pooled estimates for quality-of-life outcomes should be interpreted with caution, while findings based on objective exercise capacity outcomes, such as VO_2 peak and 6MWD, are likely to be less vulnerable to measurement bias but remain affected by attrition and incomplete blinding in selected trials. The RoB judgments are summarized in Figure 2. The specific details can be found in Multimedia Appendix 3.

XSL•FO
RenderX

Figure 2. Each risk of bias domain for each randomized controlled trial [27-34].



Outcome Measures

Exercise Capacity

Exercise capacity was assessed using VO_2 peak and 6MWD. Because the control groups differed clinically across studies, results were interpreted separately for comparisons with CBCR and usual care. The overall pooled estimates combining CBCR and usual care were not used as the primary basis for interpretation, because CBCR was an active exercise-based intervention, whereas usual care generally did not include structured exercise training. Therefore, we did not interpret any overall pooled effect combining usual care and CBCR, and the results below are presented separately for each comparator.

VO_2 peak was reported in 4 studies [30,32-34]. Three studies were included in the quantitative synthesis [30,32,33]. The study by Lundgren et al [34] was not included in the meta-analysis because postintervention VO_2 peak values were not reported, which precluded the calculation of change-from-baseline values and corresponding effect estimates. This study was, therefore, summarized narratively. In the CBCR subgroup, mHealth-supported RVH-CR showed a statistically significant greater improvement in VO_2 peak than CBCR (MD 0.82, 95% CI 0.06-1.57; P=.03; I^2=0%; Figure 3). One trial comparing mHealth-supported RVH-CR with usual care also showed a greater improvement in VO_2 peak in the intervention group (MD 2.50, 95% CI 0.88-4.12; Figure 3). Because this estimate was derived from a single trial, it should be interpreted as study-specific evidence rather than a pooled effect. It should not be considered evidence of established superiority over CBCR, particularly because the included trials were not designed to test superiority, equivalence, or noninferiority between delivery models.

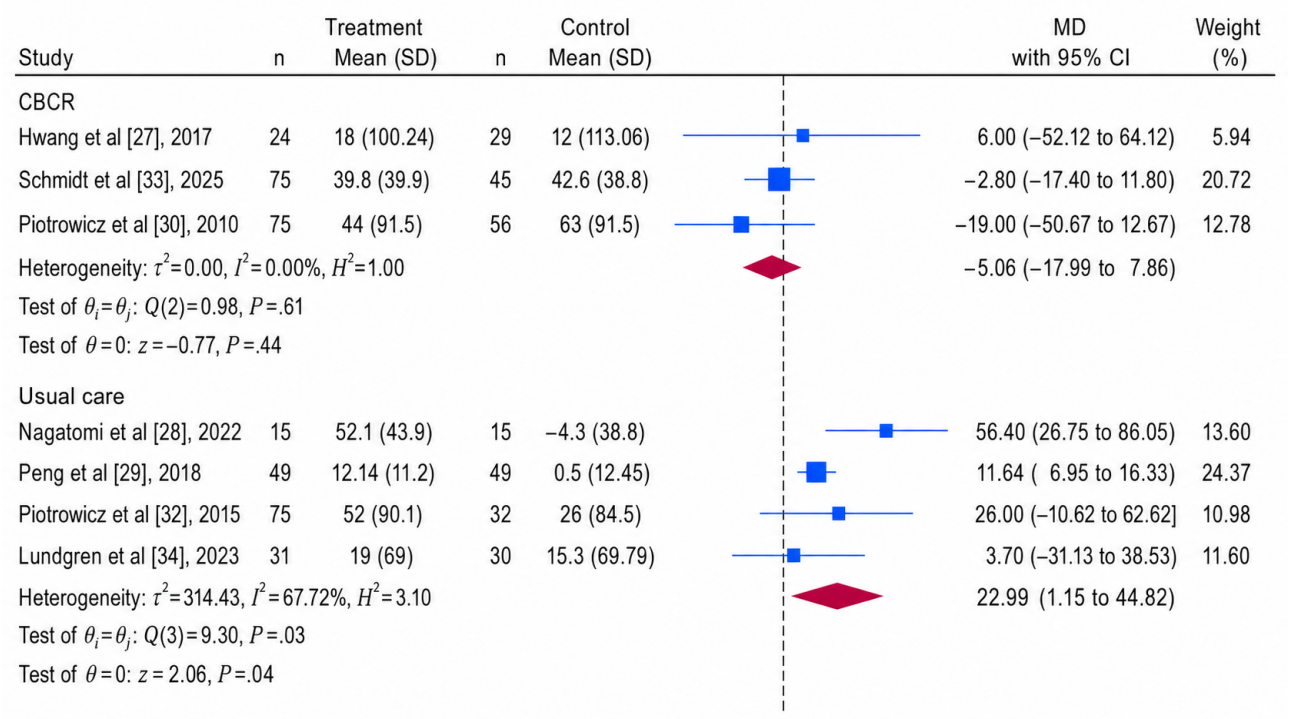


Figure 3. Forest plot showing the comparator-stratified effect of mobile health (mHealth)–supported RVH-CR on VO_2 peak [30,32,33]. CBCR: center-based cardiac rehabilitation; MD: mean difference; RVH-CR: remote, virtual, or hybrid cardiac rehabilitation; VO_2 peak: peak oxygen uptake.

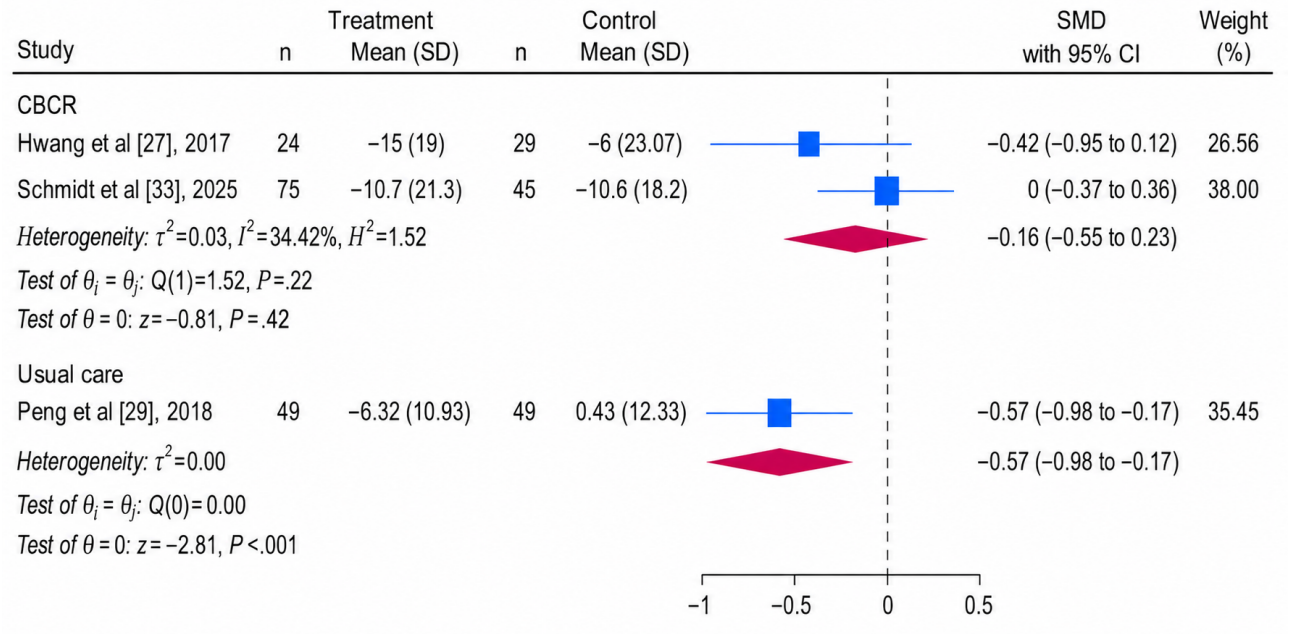
XSL•FO
RenderX

Seven studies reported 6MWD and were included in the updated meta-analysis [27-30,32-34]. The results are shown in Figure 4. In the CBCR subgroup, mHealth-supported RVH-CR was not associated with a statistically significant difference in 6MWD compared with CBCR (MD −5.06, 95% CI −17.99 to 7.86; *P*=.44), with no observed heterogeneity across trials (I^2=0%) [27,30,33]. In the usual care subgroup, mHealth-supported RVH-CR was associated with a significant improvement in 6MWD compared with usual care (MD 22.99, 95% CI 1.15-44.82; *P*=.04) [28,29,32,34]. However, heterogeneity in this subgroup was moderate to substantial (I^2=67.72%), indicating meaningful between-study variability in effect estimates.

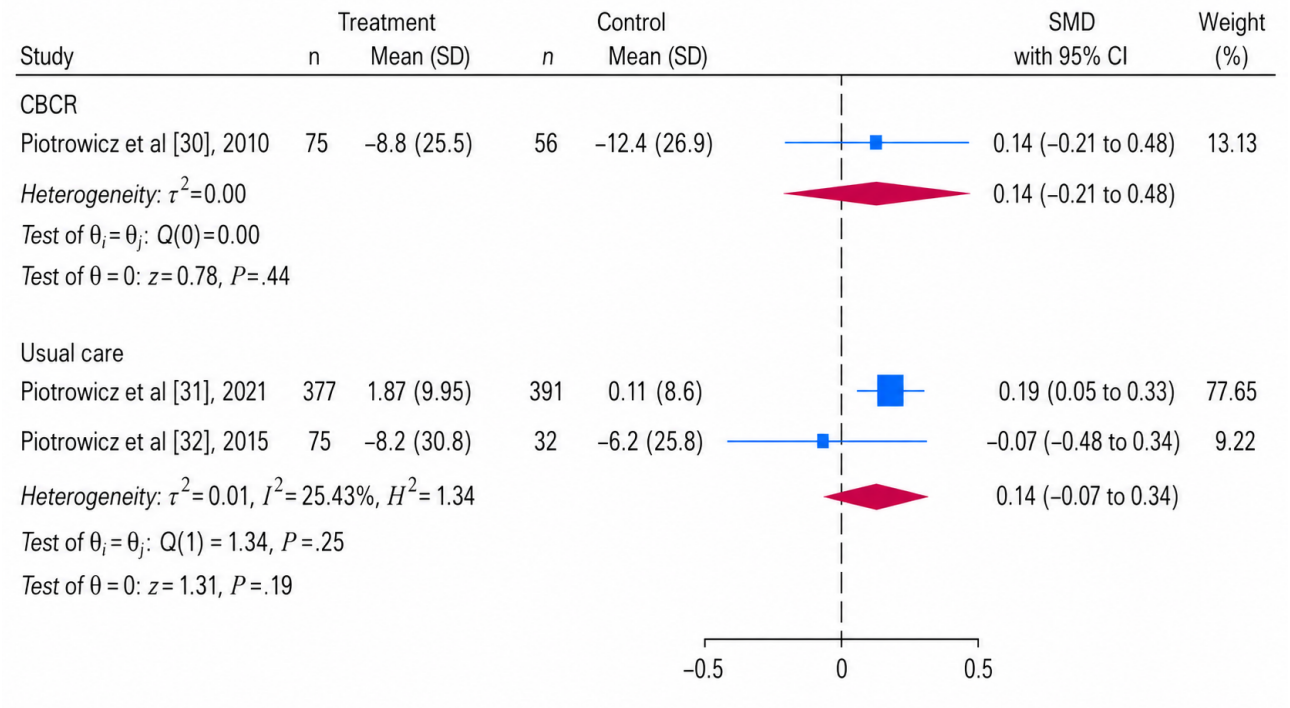
Figure 4. Forest plot showing the comparator-stratified effect of mobile health (mHealth)–supported RVH-CR on 6MWD [27-30,32-34]. 6MWD: 6-minute walk distance; CBCR: center-based cardiac rehabilitation; MD: mean difference; RVH-CR: remote, virtual, or hybrid cardiac rehabilitation.



This heterogeneity indicates variability in treatment effects across trials and may reflect differences in patient populations, baseline functional capacity, intervention intensity, exercise frequency, remote monitoring strategies, adherence support, and the content of usual care. Therefore, the pooled 6MWD estimate should be interpreted as the average effect of a structured rehabilitation package supported by mHealth across heterogeneous intervention models, rather than as the isolated effect of mHealth technology itself.

HRQoL

HRQoL was assessed using the MLHFQ and SF-36 [27,29-33]. For all HRQoL analyses, effect directions were coded so that values favoring mHealth-supported RVH-CR indicated better HRQoL. Three studies assessed HRQoL using the MLHFQ [27,29,33]. Higher MLHFQ scores indicate worse HRQoL. The results are shown in Figure 5. In the CBCR subgroup, mHealth-supported RVH-CR showed no significant difference compared with CBCR (SMD −0.16, 95% CI −0.55 to 0.23; *P*=.42). One trial comparing mHealth-supported RVH-CR with usual care showed improved MLHFQ scores in the intervention group (SMD −0.57, 95% CI −0.98 to −0.17; *P*<.01). Because this usual care comparison was based on a single study, the result should be interpreted cautiously.



XSL•FO
RenderX

Figure 5. Forest plot showing the comparator-stratified effect of mobile health (mHealth)–supported RVH-CR on the Minnesota Living With Heart Failure Questionnaire [27,29,33]. CBCR: center-based cardiac rehabilitation; RVH-CR: remote, virtual, or hybrid cardiac rehabilitation; SMD: standardized mean difference.

Three studies assessed HRQoL using the SF-36 [30-32]. Higher SF-36 scores indicate better HRQoL. The results are shown in Figure 6. In the CBCR subgroup, 1 study found no significant difference between mHealth-supported RVH-CR and CBCR (SMD 0.14, 95% CI −0.21 to 0.48; *P*=.44) [30]. In the usual care subgroup, 2 studies showed no significant difference between mHealth-supported RVH-CR and usual care (SMD 0.14, 95% CI −0.07 to 0.34; *P*=.19) [31,32]. Therefore, the separated comparator analyses did not support a clear significant effect of mHealth-supported RVH-CR on SF-36 scores. These findings should be interpreted with caution because the SF-36 studies differed in sample size, intervention structure, and rehabilitation components.

Figure 6. Forest plot showing the comparator-stratified effect of mobile health (mHealth)–supported RVH-CR on SF-36 [30-32]. CBCR: center-based cardiac rehabilitation; RVH-CR: remote, virtual, or hybrid cardiac rehabilitation; SF-36: 36-Item Short Form Health Survey; SMD: standardized mean difference.

XSL•FO
RenderX

Mortality, Hospitalization, and Adverse Events

Mortality, hospitalization, and major adverse cardiovascular events were not consistently defined or reported across the included studies, and these outcomes were not suitable for meta-analysis. Available safety data were, therefore, summarized narratively.

Across the 8 included studies, no report explicitly attributed death to the mHealth-supported RVH-CR intervention. Hwang et al [27] reported no deaths, cardiac arrest, syncope, or falls during exercise sessions. Nagatomi et al [28] reported no serious adverse events such as death or cardiac arrest; 3 readmissions occurred in each group and were not considered causally related to the intervention. Peng et al [29] reported no significant complications or adverse outcomes during the program. One study [30] reported no deaths or HF-related hospitalizations attributable to the rehabilitation program, although 1 patient in the standard rehabilitation group died following elective orthotopic heart transplantation. In the TELEREH-HF (Telerehabilitation in Heart Failure Patients) quality-of-life analysis, 2 deaths occurred in the hybrid telerehabilitation group and 2 in the usual care group during the 9-week intervention or observation period [31]. One study [32] reported no deaths or hospitalizations in either group and no cardiovascular implantable electronic device interventions during Nordic walking training. Schmidt et al [33] reported 1 death in the home-based group, which was not related to the exercise training program, and no hospitalizations, musculoskeletal injuries, or other exercise-related adverse events during the 12-week study period. Lundgren et al [34] reported no exercise session-related adverse events during real-time supervised home-based telerehabilitation; 1 death occurred in the control group before the first follow-up.

Overall, no deaths or serious adverse events were explicitly attributed to mHealth-supported RVH-CR in the included trials. However, these findings should be interpreted cautiously because follow-up periods were short, event numbers were small, and clinical end points were inconsistently defined and reported. Therefore, the available evidence is insufficient to establish definitive conclusions regarding all-cause mortality, cardiovascular mortality, hospitalization, major adverse cardiovascular events, or overall intervention safety.

Certainty of Evidence

The certainty of evidence was assessed using the GRADE framework and is summarized in Table 2. Full domain-level judgments are provided in Multimedia Appendix 4. Because usual care and CBCR were clinically distinct comparators, certainty ratings were summarized separately by comparator type. Overall, the certainty was moderate for selected exercise capacity outcomes compared with CBCR and low for most usual-care and HRQoL comparisons. The most common reasons for downgrading were RoB, a small number of studies, imprecision, heterogeneity, and the subjective assessment of HRQoL outcomes.

XSL•FO
RenderX

Table . Summary of findings and certainty of evidence by outcome and comparator.

Outcome	Comparison	Participants, n	Effect estimate	Certainty	Main reasons for downgrading
VO_2 peak[a]	RVH-CR[b] versus usual care	107	MD[c] 2.50 mL/kg/min, 95% CI 0.88 to 4.12	Low	Single-study evidence, risk of bias, and imprecision due to small sample size
VO_2 peak	RVH-CR versus CBCR[d]	251	MD 0.82 mL/kg/min, 95% CI 0.06 to 1.57	Moderate	Limited number of trials and some risk-of-bias concerns
6MWD[e]	RVH-CR versus usual care	296	MD 22.99 m, 95% CI 1.15 to 44.82	Low	Risk-of-bias, heterogeneity, and imprecision
6MWD	RVH-CR versus CBCR	304	MD −5.06 m, 95% CI −17.99 to 7.86	Moderate	Some risk-of-bias concerns and limited number of trials
MLHFQ[f]	RVH-CR versus usual care	98	SMD[g] −0.57, 95% CI −0.98 to −0.17	Low	Single-study evidence, risk of bias, subjective outcome assessment, and imprecision
MLHFQ	RVH-CR versus CBCR	173	SMD −0.16, 95% CI −0.55 to 0.23	Moderate	Subjective outcome assessment and some risk-of-bias concerns
SF-36[h]	RVH-CR versus usual care	875	SMD 0.14, 95% CI −0.07 to 0.34	Low	Subjective outcome assessment and imprecision because the CI included the null effect
SF-36	RVH-CR versus CBCR	131	SMD 0.14, 95% CI −0.21 to 0.48	Low	Single-study evidence, risk of bias, subjective outcome assessment, and imprecision
Mortality and serious adverse events	All comparisons, narrative synthesis	1368	No intervention-related deaths or serious adverse events were reported	Low	Few events, short follow-up, and incomplete or inconsistent event reporting

[a]VO_2 peak: peak oxygen uptake.

[b]RVH-CR: remote, virtual, or hybrid cardiac rehabilitation.

[c]MD: mean difference.

[d]CBCR: center-based cardiac rehabilitation.

[e]6MWD: 6-minute walk distance.

[f]MLHFQ: Minnesota Living with Heart Failure Questionnaire.

[g]SMD: standardized mean difference.

[h]SF-36: 36-Item Short Form Health Survey.

Discussion

Principal Results

This review synthesized evidence from 8 RCTs, including 1368 patients with HFrEF or HFrEF-predominant populations. In comparator-specific analyses, mHealth-supported RVH-CR showed a statistically significant improvement in VO_2 peak compared with CBCR; however, this finding was based on a small number of trials and should be considered preliminary. Compared with usual care, mHealth-supported RVH-CR improved 6MWD, whereas observed changes in VO_2 peak and MLHFQ were based on single-trial estimates and should be interpreted cautiously. No significant differences were observed for 6MWD or MLHFQ in comparisons with CBCR, and comparator-specific analyses did not indicate a clear effect on SF-36 scores. Because the included trials were not designed as noninferiority studies, these results should not be taken as evidence of equivalence or noninferiority. Although selected functional and HRQoL outcomes improved, the certainty of evidence was low to moderate due to small sample sizes, heterogeneity, and reliance on self-reported HRQoL measures. Across the trials, no deaths or serious adverse events were directly attributed to structured RVH-CR supported by mHealth; however, the limited number of events and short follow-up prevent definitive conclusions regarding safety.

The clinical significance of the statistically significant findings should be interpreted cautiously. The improvement in 6MWD

XSL•FO
RenderX

versus usual care was approximately 23 m. In patients with chronic HF, a previous study estimated the minimal clinically important difference for the 6-minute walk test to be 30.1 m [35]. Therefore, the observed effect may be clinically relevant for some patients, although interpretation should consider baseline functional status, HF phenotype, comorbidities, and follow-up duration. The VO_2 peak difference versus CBCR was statistically significant but small in absolute magnitude (MD 0.82 mL/kg/min) and was based on a limited number of trials. Therefore, this finding should be viewed as preliminary and should not be interpreted as evidence of clinically meaningful superiority over CBCR.

mHealth-supported RVH-CR may provide an access-oriented delivery option for structured CR, particularly for patients with geographic, logistical, or resource constraints [36,37]. Remote monitoring, exercise prescription, and telecommunication support may help deliver individualized exercise programs and improve selected functional outcomes, although the evidence for HRQoL remains mixed and outcome-specific [38,39]. Clinicians should recognize that improvements versus usual care reflect both structured exercise and digital support. In this context, mHealth should be viewed as the enabling technology layer supporting CR delivery, whereas RVH-CR describes the care delivery models [16,17,40].

Comparison With Prior Literature

Previous systematic reviews and meta-analyses have studied telerehabilitation or eHealth interventions in patients with HF and other cardiac conditions. Most of these studies combined different types of interventions and patient populations. Li et al [21] evaluated phase II mHealth-supported CR across a broad cardiac population, including myocardial infarction, angina, revascularization, and HF, with interventions combining exercise, education, and remote monitoring. Rampengan et al [41] synthesized 37 RCTs evaluating eHealth interventions, including automated telemonitoring, human-led communication, and structured education, focusing on outcomes such as HF-related hospitalizations, mortality, quality of life, and HF-related knowledge. Although the review demonstrated a reduction in HF-related admissions, it did not specifically assess the effects of structured, exercise-based RVH-CR on functional capacity or exercise tolerance. Similarly, Gao et al [42] and Cavalheiro et al [43] assessed home-based or telerehabilitation programs broadly across cardiovascular populations, reporting improvements in functional capacity and quality of life, but without isolating structured exercise interventions in patients with HF. In contrast, this review focused specifically on patients with HFrEF or HFrEF-predominant HF populations, evaluating structured, exercise-based RVH-CR supported by mHealth. By restricting inclusion to interventions with a clearly defined exercise prescription and a prespecified HFrEF-predominant population, this review isolates the effects of structured exercise delivered outside traditional center-based settings while allowing direct comparison with CBCR.

The present review focused on HFrEF or HFrEF-predominant populations, whereas evidence for mHealth-supported CR in HFpEF remains limited and is beginning to emerge. For example, Subramanian et al [44] recently evaluated a 6-month mHealth-based CR program in older adults with HFpEF and reported improvements in quality of life but no significant improvement in 6MWD or VO_2 peak in the overall cohort.

Strengths and Limitations

This review has several limitations that should be considered when interpreting the findings. First, the small number of included studies (n=8) and the relatively modest sample sizes in individual trials limited statistical power. These constraints also precluded subgroup analyses and meta-regression to explore sources of heterogeneity or potential effect modifiers. This limitation contributed to GRADE downgrading of evidence certainty for most outcomes. Second, several key outcome comparisons, including VO_2 peak versus usual care and MLHFQ versus usual care, relied on single-trial estimates rather than pooled effects. This substantially limits the strength of inference. The statistically significant VO_2 peak finding in the CBCR comparison was based on a small number of trials. Therefore, this result should be interpreted as preliminary and hypothesis-generating rather than as definitive evidence of superiority over CBCR. Third, HRQoL outcomes were mostly assessed using self-reported questionnaires in unblinded participants. This introduces the risk of performance and detection bias and was a principal reason for GRADE downgrading of HRQoL outcomes. Fourth, publication bias could not be formally evaluated using funnel plots or the Egger regression test because fewer than 10 studies were available for any single comparison. Fifth, although all included interventions involved structured exercise-based RVH-CR delivered through mHealth platforms, there was considerable heterogeneity in the specific technologies, monitoring strategies, feedback mechanisms, and rehabilitation protocols used across studies. Sixth, the findings apply to HFrEF or HFrEF-predominant HF populations and should not be generalized to HFpEF, for which mHealth-supported CR evidence is still emerging and requires dedicated synthesis.

Despite these limitations, this review has notable strengths that enhance its clinical and methodological value. Unlike prior systematic reviews that examined telerehabilitation broadly across heterogeneous cardiac populations or combined multiple intervention modalities, this review specifically focused on structured, exercise-based RVH-CR supported by mHealth in patients with HFrEF or HFrEF-predominant populations with HF. This allowed for a more targeted and clinically meaningful synthesis. All included interventions incorporated a clearly defined exercise prescription with patient-generated data capture or clinician-mediated feedback, isolating the effects of structured exercise from general digital health support. RoB was assessed using the Cochrane RoB 2 tool, and evidence certainty was evaluated using the GRADE framework, ensuring methodological transparency and reproducibility. Analyses were stratified by comparator type (CBCR vs usual care) to avoid interpretive confounding arising from pooling structurally distinct control conditions.

Future Research Directions

Future research should prioritize larger, adequately powered RCTs with longer follow-up to assess the durability of

XSL•FO
RenderX

mHealth-supported RVH-CR effects on exercise capacity, quality of life, cardiovascular mortality, and hospitalization in patients with HF. Standardization of mHealth platforms, exercise prescription protocols, and monitoring intensity across trials is essential to reduce heterogeneity and enable more definitive evidence synthesis. Studies should systematically report adherence rates, patient engagement, and intervention fidelity. Greater attention to underrepresented populations, including older adults, women, and individuals from low-income and middle-income settings, is needed to establish generalizability and support equitable implementation of mHealth-supported CR. Future systematic reviews should specifically evaluate mHealth-supported RVH-CR in HFpEF populations.

Conclusions

The effects of structured RVH-CR supported by mHealth varied according to the comparator type in patients with HFrEF or HFrEF-predominant HF populations. Compared with usual care, mHealth-supported RVH-CR was associated with improved 6MWD, whereas single-trial estimates suggested improvements in VO_2 peak and MLHFQ scores. Compared with CBCR, mHealth-supported RVH-CR showed a statistically significant greater improvement in VO_2 peak in a limited number of trials, whereas no statistically significant differences were detected for 6MWD, MLHFQ, or SF-36. Because usual care and CBCR are clinically distinct comparators, these findings should not be interpreted as a single overall effect across all control conditions. No intervention-related deaths or serious adverse events were reported in the included trials, but its safety still needs to be studied. Equivalence or noninferiority to CBCR cannot be inferred from the available evidence. Future studies should evaluate long-term clinical outcomes and standardize intervention protocols.

Acknowledgments

During the preparation of this manuscript, the authors used AI-assisted tools, including ChatGPT (GPT-5.6 Thinking), for language editing and minor graphical and typographical refinements of figures. The AI tools were not used for generating research data, conducting statistical analyses, interpreting results, or formulating conclusions. All AI-assisted outputs were critically reviewed and revised by the authors, who assume full responsibility for the final content of the manuscript.

Abstract

Background: Engagement is a necessary precondition for the effectiveness of mobile health (mHealth) apps for long-term physical health conditions (LTCs), particularly as health systems increasingly prioritize the deployment of scalable, self-guided digital interventions. Outside controlled research settings, where clinician involvement often drives engagement, little is known about whether, how, and why people engage with mHealth apps based on intrinsic motivation alone. Existing systematic reviews have cataloged behavioral engagement indicators but rarely assess the mechanisms underlying engagement.

Objective: This overview of systematic reviews aimed to (1) synthesize evidence on how engagement with mHealth apps for LTCs is defined, measured, and associated with health outcomes, (2) explore intrinsic and extrinsic motivational processes underlying engagement, and (3) provide practical guidance for developing scalable, user-centered digital health interventions that sustain sufficient engagement with minimal reliance on external drivers. Uniquely, we interpreted modifiable barriers and facilitators through a motivational lens that distinguishes extrinsic from intrinsic motives, mapping intrinsic motives onto autonomy, competence, and relatedness, as proposed by Self-Determination Theory (SDT).

Methods: Searches of MEDLINE, Web of Science, Epistemonikos, and gray literature (inception to June 9, 2025) identified systematic reviews reporting engagement indicators, engagement-outcome associations, or barriers and facilitators among adults with LTCs. Quantitative reviews were appraised using AMSTAR 2 (A Measurement Tool to Assess Systematic Reviews 2), and qualitative and mixed methods reviews were appraised using CASP (Critical Appraisal Skills Programme). A narrative synthesis was undertaken, and modifiable barriers and facilitators were independently mapped by 2 reviewers to extrinsic and intrinsic motivation and, for intrinsic factors, to the SDT constructs of autonomy, competence, and relatedness. Discrepancies were resolved through discussion with the wider research team.

Results: Nineteen reviews (12 quantitative, 5 mixed methods, and 2 qualitative) were included from 4684 records. Fourteen (74%) reviews did not define engagement, and the remaining 5 equated it with “usage” or “adherence,” precluding meta-analysis. Fourteen reviews reported microlevel behavioral indicators, but none captured macrolevel or effective engagement. Eight assessed engagement-outcome links; 7 reported positive associations, and 1 reported no effect. Seven reviews included nonmodifiable factors that influence engagement (eg, ethnicity), while 13 included modifiable factors. SDT mapping revealed that modifiable factors influencing autonomy (eg, personal relevance, flexibility), competence (eg, usability, technical support), and relatedness (eg, clinician endorsement, peer connection) underpin intrinsic engagement, whereas extrinsic barriers include restrictions to access (including cost).

Conclusions: Current evidence on engagement with mHealth apps remains conceptually inconsistent and methodologically fragmented, but motivational patterns are clear: engagement depends largely on intrinsic motives once external conditions are satisfied. Applying SDT provides the first mechanism-oriented explanation of how engagement operates, enabling practical recommendations for evaluating existing apps and designing future mHealth interventions that support autonomy, competence, and relatedness.

Introduction

Long-term physical health conditions (LTCs) represent a major and growing global challenge for health care systems, driven by their growing prevalence, increasing likelihood of multimorbidity, and rising costs of long-term care [1]. Digital health interventions offer scalable, flexible, and cost-effective potential to enhance LTC self-management and support patient-centered care, particularly in the context of limited health care resources and workforce constraints.

Reflecting this shift, digital health innovation has become a core policy priority. For example, the National Health Service 10 Year Health Plan for England emphasizes the role of digital technologies in empowering patients, improving access to care, and integrating physical and mental health services for people with LTCs [2]. Mobile health (mHealth) apps have garnered particular attention due to their accessibility, portability, and ability to deliver personalized interventions directly to users in real time [3-5]. With the increasing use of smartphones worldwide, mHealth apps can reach diverse populations across geographic and socioeconomic barriers [6]. mHealth apps also support multiple functions relevant to LTC self-management, including symptom monitoring, education, behavior change support, and communication with health care professionals. However, their effectiveness is partly constrained by engagement [7-9].

Engagement is necessary for effectiveness: an mHealth app that is not initiated, is insufficiently used, or is quickly abandoned cannot exert its intended effects [10]. Engagement with digital interventions is multidimensional, comprising behavioral indicators (eg, frequency and depth of use) and subjective indicators, including cognitive (perceived relevance and goal alignment) and affective (eg, interest, enjoyment, or emotional response) components [10,11]. Engagement also operates at multiple levels: the microlevel, capturing moment-to-moment interactions with the intervention (eg, logging in, completing a task), and the macrolevel (users' internalizing and integrating the intervention's goals into daily life) [11,12]. Importantly, effective engagement is not about engagement volume. Rather, it concerns the extent and type of engagement necessary to achieve desired outcomes, acknowledging that sustained use may not always be required if the user has internalized the intervention's purpose [11].

Although engagement has been described in detail using the aforementioned concepts [10-12], systematic reviews show inconsistent definitions and operationalization of engagement, impeding the synthesis of findings and making it difficult to understand if and why app use is sustained and health promoting [13,14]. As a result, there is limited consensus on how engagement should be conceptualized, how it is initiated and sustained over time, and, critically, how much engagement is "enough." This lack of clarity has contributed to widespread uncertainty about how to design mHealth apps that people will actually use, even when those apps are evidence-based and demonstrably effective under controlled conditions.

A key source of this confusion may be the limited attention paid to the motivational mechanisms underlying engagement. Engagement is often treated as being driven by features such as reminders or clinician oversight [8,11]. While such externally regulated strategies may increase short-term use, they are resource-intensive and difficult to scale, particularly in health care systems seeking to reduce clinician workload and maximize patient self-management [15]. In contrast, engagement is more likely to be sustained when individuals are internally motivated to use an app because they perceive it as personally valuable, relevant, and supportive of their goals [16]. Understanding intrinsic motives is therefore critical for realizing the scalability promise of mHealth app interventions for LTCs.

Self-Determination Theory (SDT) provides a well-established and empirically supported framework for understanding how and why people initiate and maintain behaviors [17]. SDT distinguishes between extrinsic motivation (behavior driven by external demands or rewards) and intrinsic motivation (behavior that is self-endorsed and aligned with personal values). According to SDT, intrinsic motivation is supported when three basic psychological needs—autonomy, competence, and relatedness—are satisfied. This framework is particularly relevant to mHealth apps, where achieving effective engagement often depends on users internalizing the value of app use rather than responding to extrinsic prompts alone [16,18]. Mapping app features and contextual factors onto SDT constructs offers a theoretically grounded, mechanistic understanding of how app design and features (eg, personalization, feedback, social features, and integration with care pathways) may support or undermine engagement.

Although numerous systematic reviews have reported engagement with mHealth apps for LTCs, few have synthesized findings within a coherent motivational framework [19,20]. Existing reviews frequently describe barriers and facilitators of engagement but stop short of explaining why these factors matter or how they relate to intrinsic vs extrinsic motives. This has restricted their ability to inform intervention design, evaluation, and policy, resulting in mixed findings and limited cumulative insight.

To address these gaps, this overview of systematic reviews aimed to (1) synthesize evidence on how engagement with mHealth apps for LTCs is defined, measured, and associated with health outcomes, (2) explore intrinsic and extrinsic motivational processes underlying engagement, and (3) provide practical guidance for developing scalable, user-centered digital health interventions that support effective engagement with minimal reliance on ongoing clinician input. By doing so, this overview integrates existing reviews to move beyond descriptive cataloging of "what" predicts engagement toward a theoretically grounded explanation of "how" and "why" commonly reported factors may influence it.

Methods

Ethical Considerations

This study did not involve human participants and therefore did not require ethical approval, in accordance with institutional and national guidelines.

XSL•FO
RenderX

Design

This overview of systematic reviews adhered to the PRIOR (Preferred Reporting Items for Overviews of Reviews) guidelines (Checklist 1) and was prospectively registered in the PROSPERO (International Prospective Register of Systematic Reviews; CRD42024604784) [21].

Deviations From Protocol

Three deviations were made to the registered protocol (PROSPERO CRD42024604784) prior to data extraction and synthesis to improve coherence and practical use:

1. Objective 2 in the PROSPERO registration (identify specific mHealth app-based intervention features that are associated with differing levels of engagement) was removed due to insufficient data in the included reviews.
2. A section on nonmodifiable factors influencing engagement (eg, age, sex, and ethnicity) was added to contextualize barriers and facilitators.
3. Modifiable barriers and facilitators of engagement were classified by motivational type (intrinsic or extrinsic), with intrinsically motivating indicators further mapped onto the basic psychological needs of SDT (autonomy, competence, and relatedness). This was done to propose plausible mechanisms through which app features may influence engagement.

Search Strategy

A comprehensive search was conducted in MEDLINE, Web of Science, Epistemonikos, and gray literature sources (Social Science Research Network, WorldCat, Health Management Information Consortium [Ovid]) from inception to June 9, 2025. Search terms combined keywords and MeSH related to "chronic conditions" and "mobile." No date or language limits were applied initially. The strategy was developed with domain experts and 2 senior librarians (Multimedia Appendix 1).

Eligibility Criteria

Systematic reviews were eligible if they

- included adults (≥18 y) with at least one LTC or persistent physical symptoms (eg, chronic pain or fatigue). For the purposes of this review, LTCs were defined as diagnosed physical health conditions that are persistent, require ongoing management, or have long-term consequences for health and functioning
- evaluated mHealth apps delivered via mobile phones or tablets
- reported behavioral engagement indicators, engagement-outcome associations, or barriers or facilitators to engagement

Reviews were excluded if they did not distinguish app-based interventions from other digital tools or focused solely on passive monitoring (eg, wearables). Reviews were therefore excluded when the population was defined solely by hypertension, obesity, isolated symptoms, exposures, risk factors, or health indicators, rather than by a diagnosed long-term physical condition within the scope of the review. This was based on World Health Organization (WHO) and Global Burden of Disease risk-factor frameworks reporting raised blood pressure (hypertension) and high BMI (overweight and obesity) as metabolic risk factors or health indicators rather than eligible long-term physical condition populations in their own right [22,23]. Search terms were intentionally broad to maximize sensitivity and capture related risk-factor literature; however, final inclusion was determined during screening based on how each review defined and reported the condition.

Study Selection

Search results were imported into EndNote X7 for deduplication [24]. Two reviewers independently screened titles and abstracts using Covidence, an online software tool to manage screening, extraction, and quality assessment for systematic reviews [25]. During screening, inclusion was limited to English, German, Spanish, or Turkish (the languages fluently spoken by the research team) to ensure accurate appraisal. This allowed us to note how many potentially relevant reviews were excluded for language while maintaining screening reliability. Full texts were retrieved for all records deemed potentially relevant by at least 1 reviewer. Ten percent of the full-text reviews were randomly selected for double screening to assess interrater reliability, yielding a Cohen κ of 0.62, which indicates substantial agreement between authors [26]. Discrepancies were resolved through discussion, and the remaining full-text screening was completed by the first author. Reference lists of included reviews were hand searched.

Data Extraction

Data extraction used a standardized form piloted by the research team. The first author extracted all data, with a random 10% independently checked by a second reviewer (GHB), yielding full agreement. The remaining data extraction was completed by the first author.

Quality Appraisal

Quantitative systematic reviews were appraised using the AMSTAR 2 (A Measurement Tool to Assess Systematic Reviews 2) tool and categorized as high, moderate, low, or critically low [27]. Qualitative and mixed methods reviews were appraised using the CASP (Critical Appraisal Skills Programme) qualitative checklist [28]. CASP does not provide a numeric scoring system and instead uses descriptive summaries with justifications. We considered the breadth of "yes" responses, with particular emphasis on core methodological areas, including clarity of aims, appropriateness of qualitative methodology and research design, adequacy of data collection, rigor of data analysis, clarity of findings, and the stated value of the research. We did not apply a prespecified numerical cutoff for most CASP items. Instead, reviews were judged as higher quality when "yes" responses were consistent across these core domains and when any limitations were minor or related to less applicable domains for systematic reviews, such as recruitment strategy. A random 10% were double checked, with full agreement. We considered alternative tools for quality appraisal, including the Joanna Briggs Institute (JBI) checklist for umbrella reviews. However, because our overview included qualitative and mixed methods reviews, we judged CASP to provide more explicit prompts for assessing the interpretive and methodological features of qualitative synthesis. CASP was therefore used as

XSL•FO
RenderX

a structured framework to appraise the qualitative synthesis components of the included reviews.

Data Synthesis

A narrative synthesis was undertaken. Reviews were grouped according to the engagement-related data they reported:

1. Behavioral indicators of engagement (amount, duration, depth, and frequency) [10,11]
2. Associations between engagement and health outcomes
3. Nonmodifiable barriers and facilitators of engagement (eg, age and ethnicity)
4. Modifiable barriers and facilitators of engagement (eg, digital literacy and app design)

Where definitions were absent, engagement-related terms (eg, usage, adherence, and compliance) were interpreted using the context from primary studies. For consistency in characterizing core mHealth app functionalities, we applied the WHO classification of digital health interventions [29].

Synthesis of modifiable barriers and facilitators offered insight into users' cognitive and affective responses to mHealth apps, reflecting how perceptions (eg, relevance and trust) and emotions (eg, interest and burden) influenced decisions to engage or disengage. This enabled exploration of subjective influences on engagement.

Modifiable barriers and facilitators of engagement were categorized as intrinsic or extrinsic motives. The intrinsic motives were then systematically mapped onto the 3 basic psychological needs proposed by SDT—autonomy, competence, and relatedness—using established definitions of SDT psychological needs [17].

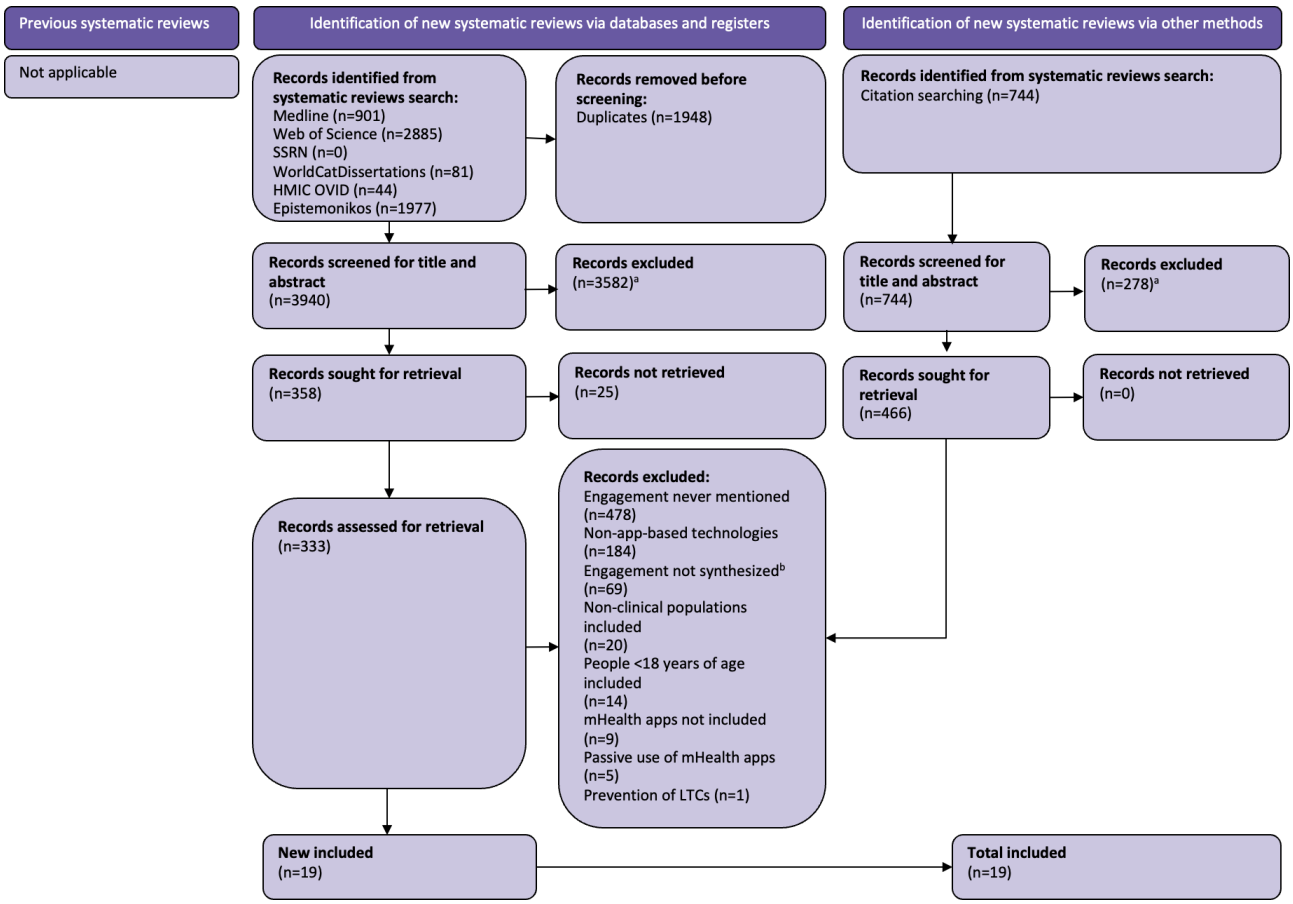
- Autonomy: experiences of volition, choice, and personal relevance
- Competence: perceptions of efficacy, capability, and mastery
- Relatedness: feelings of connection, being cared for, and a sense of belonging with others

Mapping was completed independently by 2 reviewers (JB and MMI). Decisions about which barriers and facilitators aligned with each SDT need were informed by existing theoretical and empirical literature [30,31] and refined through iterative discussions within the research team.

The frequency with which themes were mapped to each psychological need was descriptively recorded across reviews and their included primary studies to enhance the transparency of the synthesis rather than to infer effect size or relative importance.

Although the Capability, Opportunity, Motivation-Behavior (COM-B) model was initially considered as an organizing framework [32], preliminary synthesis showed that most reviews described engagement processes in terms of the quality of motivation rather than broader behavioral determinants, such as physical capability or environmental opportunity. Common descriptors included perceived personal relevance and feelings of being supported, which align more closely with SDT's distinction between intrinsic and extrinsic motivation. Given that sustaining engagement with mHealth apps typically relies on intrinsic, self-endorsed motivation rather than externally regulated behavior [17], SDT provided a more coherent and mechanistic framework for interpreting engagement processes.

Primary study overlap across the included systematic reviews was assessed using a citation matrix. Rows represented unique primary studies, and columns represented included systematic reviews. Overlap was quantified descriptively by identifying primary studies that appeared in more than 1 review and by calculating the corrected covered area (CCA) [33]. As this overview of systematic reviews synthesized data at the systematic review level, primary study overlap was used to inform transparency and interpretation only; no primary study-level outcome data were extracted, reanalyzed, or pooled.



Results

Search Results

The search identified 5888 records from databases and registers and 744 through citation searching. After removing duplicates, 4684 records including 3940 (84.1%) from databases and registers and 744 (15.9%) from other methods. Overall, 799 full-text articles were assessed for eligibility by 2 independent reviewers, of which 333 (41.7%) were identified through databases and registers and 466 (58.3%) through other methods. The primary reason for exclusion (n=478, 59.9%) was the absence of any mention or reporting of engagement-related data. Ultimately, 19 systematic reviews were included in this overview of systematic reviews [34-52]. A PRIOR (Preferred Reporting Items for Overviews of Reviews) flow diagram is presented in Figure 1.

Figure 1. PRIOR (Preferred Reporting Items for Overviews of Reviews) flow diagram of the study selection process. [a]Reviews were of long-term risk factors (obesity, hypertension, etc) and/or transitory conditions (eg, gestational diabetes mellitus) (n=197) and/or searched app stores only (n=45). [b]The primary articles included measured engagement, but this was not synthesized in the review. SSRN: Social Science Research Network.

Characteristics of Included Reviews

The 19 systematic reviews comprised 12 (63%) quantitative, 5 (26%) mixed methods, and 2 (11%) qualitative syntheses published between 2015 and 2025. Of the 17 reviews with quantitative data, 3 (18%) conducted a meta-analysis. Of the 7 reviews with qualitative data, 1 (14%) undertook a formal meta-synthesis, while the remainder used thematic or narrative approaches. LTC populations included people living with cancer (n=6, 32%), diabetes (n=4, 21%), and chronic pain (n=2, 11%). Others focused on heart failure (n=1, 5%), stroke (n=1, 5%), chronic kidney disease (n=1, 5%), osteoarthritis (n=1, 5%), Parkinson disease (n=1, 5%), traumatic brain injury (n=1, 5%), and a mixed group of LTCs (n=1, 5%).

The number of primary studies per review ranged from 3 to 30 (total n=262), with sample sizes ranging from 1 to 3606 and mean participant ages typically between 50 and 63 years. Across the 262 primary studies, the three most common study designs were randomized controlled trials (RCTs; n=111, 42.4%), qualitative studies (n=62, 24%), and observational studies (n=33, 13%). Of the 195 primary studies that reported geographic origin, 83 (43%) were conducted in North America, 68 (35%) in Europe, 24 (12%) in Asia, 12 (6%) in Oceania, 4 (2%) in South America, and 4 (2%) in Africa. Table 1 summarizes these characteristics, and Multimedia Appendix 2 provides a more detailed table.

Quality Appraisal

Qualitative and mixed methods reviews were strong overall, with 3 rated "high quality" [37,38,50], 2 rated "moderate-to-high" [44,45], and 2 rated "moderate" [36,46], though reflexivity and analytic transparency were often limited (Table 1).

Quantitative reviews were generally low quality: 6 were rated "critically low" [39,40,42,43,48,49], 5 were rated "low" [34,47,51,52], and 1 was rated "moderate" [41]. None met the criteria for high quality, mainly due to missing protocol registration, limited risk-of-bias assessment, and insufficient reporting of heterogeneity or funding (Table 1). Multimedia Appendices 3 and 4 include the quality appraisal scores for AMSTAR 2 and CASP, respectively.

Overlap of Primary Studies

Across the 19 included systematic reviews, 262 unique primary studies were identified. Primary study overlap was slight [33]. Most primary studies appeared in only one review (n=243, 92.7%), while 19 studies appeared in more than one review (19/262, 7.3%). Of these overlapping studies, 14 appeared in 2 reviews, 4 appeared in 3 reviews, and 1 appeared in 4 reviews. The total number of primary study occurrences across reviews was 287. The CCA was 0.53%, indicating slight overlap. Given the low level of overlap and because synthesis was conducted at the systematic review level, all 19 reviews were retained in the narrative synthesis.

Description of mHealth App-Based Interventions

Across the 19 reviews, 98 distinct mHealth apps were reported. The most common app functionality, using the WHO classifications of digital health interventions, was symptom self-monitoring, which was present in 17 (90%) systematic reviews. Targeted delivery of health information, often as educational content tailored to users' LTCs, was identified in 16 (84%) reviews. Alerts and reminders were reported in 12 (63%) reviews. Active user data capture, primarily for symptom tracking and remote consultations with health care providers, appeared in 8 (42%) reviews. Peer group support features were reported in 5 (26%), while user-to-system feedback mechanisms were present in 2 (11%) reviews. Only 1 (5%) review included apps where users could access their personal health records. Full characteristics are provided in Multimedia Appendix 5.

Behavioral Engagement Indicators

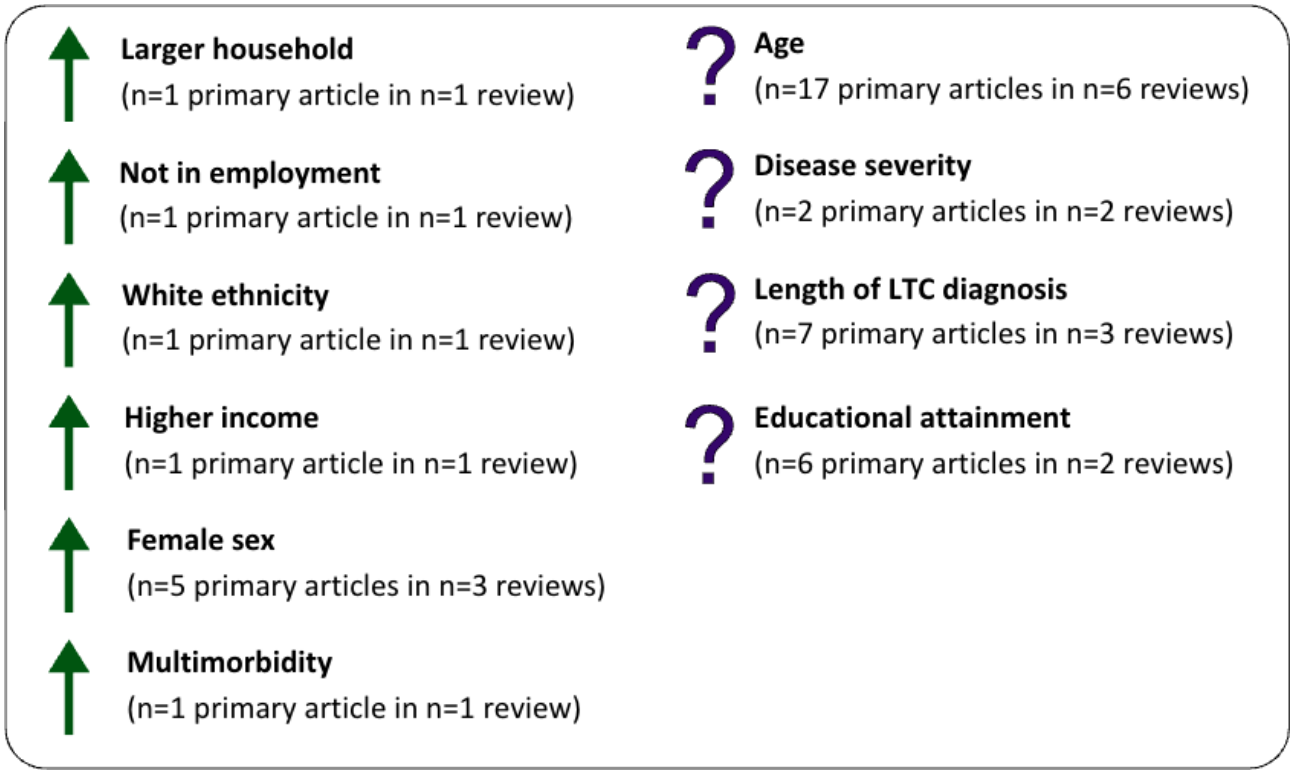
For clarity, we describe behavioral indicators as microlevel usage metrics (eg, amount, duration, depth, and frequency of use) based on previous literature [10-12].

Of the 19 included systematic reviews, only 5 (26%) explicitly operationalized engagement a priori [36-38,46,50]. Fourteen (74%) reviews reported engagement metrics, but predominantly as microlevel indicators (eg, frequency of logins, duration of use, and number of tasks completed). Terms such as "usage," "adherence," and "engagement" were often used interchangeably, with no review operationalizing macrolevel engagement (eg, integration into daily life and alignment with goals). Definitions and thresholds varied widely, precluding meta-analysis. Multimedia Appendix 6 provides a detailed summary of the engagement indicators reported in each review.

Engagement-Health Outcome Associations

Eight of the 19 (42%) reviews assessed links between engagement and health outcomes. Seven of these reviews (moderate-to-high [n=1], moderate [n=1], low [n=4], and critically low [n=1]) reported positive associations between microlevel app use and outcomes such as improved symptom knowledge, health behavior change, or reduced distress [39,41,45,47,48,51,52]. One meta-analysis (critically low quality) found no significant association [40].

Importantly, no review linked macrolevel engagement with health outcomes or if engagement was sufficient to achieve intended health outcomes (ie, effective engagement) [11]. Qualitative reviews provided insight into subjective engagement indicators, such as users' sense of motivation or identification with the intervention, but no review integrated these with quantitative outcome data. Behavioral and subjective indicators of engagement were reported descriptively in separate strands in the included reviews, with no further analysis to link them.



Nonmodifiable Barriers and Facilitators of Engagement

Seven of the 19 (37%) systematic reviews highlighted nonmodifiable user-specific barriers and facilitators of engagement [36,41,42,45,46,48,52] (Figure 2). A total of 57% (4/7) of reviews were quantitative (moderate [n=1], low [n=1], and critically low quality [n=2]), and 43% (3/7) of reviews were mixed methods (moderate-to-high [n=1] and moderate quality [n=2]).

Findings were mixed, as 2 reviews reported higher engagement among older adults (≥63 years in 1 review; age not specified in the other) [42,46], whereas another reported greater engagement among younger users [36]. Similarly, disease-related characteristics such as duration of diagnosis had mixed results, with both newly diagnosed individuals and those living with a condition for over 5 years demonstrating active engagement across different studies [36,42]. Findings related to disease severity or multimorbidity were also mixed, with one review reporting lower engagement [41] and another reporting higher engagement, potentially due to increased pain burden [40].

XSL•FO
RenderX

Figure 2. Nonmodifiable barriers and facilitators of engagement with mobile health apps reported in 37% (7/19) of systematic reviews. Upward arrows indicate higher engagement, and question marks indicate mixed findings. LTC: long-term condition.

Modifiable Barriers and Facilitators of Engagement

Thirteen of the 19 (68%) reviews reported modifiable barriers and facilitators of engagement with mHealth apps for LTCs [34,36-38,42-46,48-50,52]. Seven reviews were quantitative (moderate [n=1], low [n=2], and critically low quality [n=4]), 4 were mixed methods reviews (moderate-to-high [n=2] and moderate quality [n=2]), and 2 were qualitative reviews (high quality [n=2]).

Reviews were categorized into 9 overarching themes (Figure 3). Six themes mapped onto intrinsic motives: app design, app functionality, trust, time burden, baseline technological readiness, and baseline readiness for health behavior change; and 3 themes mapped onto extrinsic motives: awareness of the app, availability of the digital tool, and cost. The reported extrinsic motives function primarily as structural preconditions for engagement because they enable initial uptake but do not, by themselves, sustain engagement. A full thematic breakdown with illustrative quotations and frequency of reporting is provided in Multimedia Appendix 7.

For intrinsic motivation, barriers and facilitators supporting competence were the most frequently reported, appearing across 63% (12/19) of systematic reviews and 89.3% (234/262) of distinct primary studies. These included app design and functionality features that enabled users to feel capable of using the app effectively, such as ease of use, clear and accessible language, visual aids, real-time feedback, and symptom monitoring. Engagement was undermined when competence was challenged by technical problems, high data entry burden, information overload, unmet expectations, low digital literacy, or concerns that app use could exacerbate psychological distress related to the LTC.

Barriers and facilitators mapping onto autonomy were reported across 58% (11/19) of systematic reviews and 59.5% (156/262) of distinct primary studies. Autonomy-related barriers and facilitators reflected users' appraisal of relevance, control, and fit with daily life, including readiness for behavior change, perceived need for the app, ability to integrate app use into daily routines, goal-setting functionality, personalization, and privacy considerations.

Factors supporting relatedness were less frequently reported overall, with 53% (10/19) of systematic reviews and 40.5% (106/262) of primary studies, and focused on interpersonal connection and trust. Engagement facilitators included interaction with health care professionals and other users, endorsement by clinicians, secure data sharing with caregivers during emergencies, and integration with electronic medical records. Barriers to relatedness included lack of emotional connection to the app and stigmatizing or overly intrusive reminders.

The mapping of modifiable barriers and facilitators to intrinsic and extrinsic motivation informed the development of design recommendations for future evidence-based mHealth apps for people with LTCs (Table 2). Design implications were generated for all themes identified in the synthesis, irrespective of how frequently they were reported across primary studies. This approach reflects the conceptual aim of this overview of systematic reviews to understand mechanisms of engagement rather than to rank predictors by prevalence. Less frequently reported themes may still represent decisive barriers or facilitators for different user groups, LTCs, or contexts of use, and excluding them would risk overlooking design considerations essential for equitable, scalable, and effective engagement.

RenderX

Figure 3. Motivational mechanisms of engagement with mobile health apps. EMR: electronic medical record; HCP: health care professional; mHealth: mobile health.

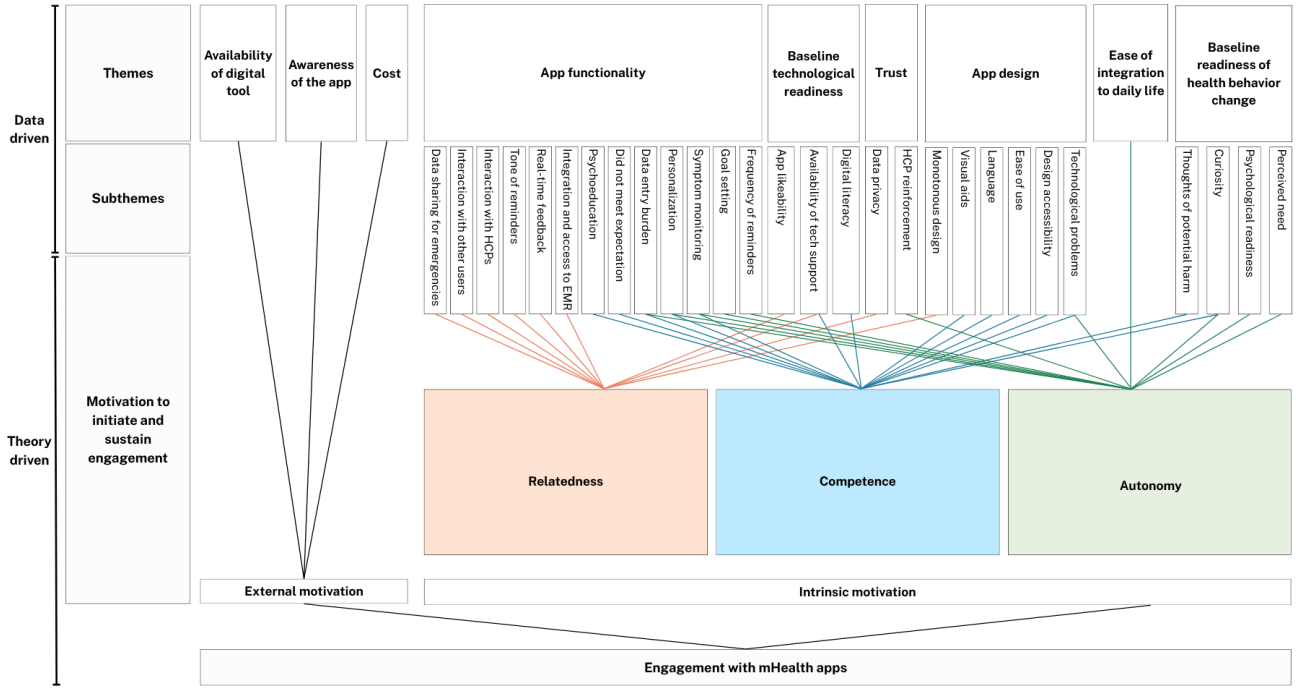

Table . Recommendations for mobile health app–based intervention development that support intrinsic and extrinsic motives.

Motivational category	Key engagement factors identified	Design implications for mHealth[a] apps
Intrinsic motivation		
Autonomy	• Limited perceived need for app use • Low psychological readiness for behavior change • Time burden and poor fit with daily routines • Perceived loss of control due to reminders or data entry demands • Privacy concerns	• Emphasize personal relevance during on-boarding • Use nonpressuring language • Reduce burden through automation • Enable flexible goal setting • Provide customizable reminders • Ensure transparency over data use • Offer tailored features that support user-led engagement
Competence	• Technical problems • Poor usability or accessibility • Information overload • Low digital literacy • Unmet expectations • Anxiety arising from symptom monitoring	• Use an accessible and intuitive design • Clear and plain-language communication • Visual information delivery • Emotionally supportive and timely feedback • Accurate expectation-setting • Ongoing technical support to accommodate varying literacy and skill levels
Relatedness	• Limited trust in app content • Absence of clinical endorsement • Lack of social or emotional connection • Stigmatizing or impersonal reminder tone	• Embed clinician endorsement • Enable optional peer interaction • Support secure data sharing with trusted others • Integrate with clinical systems • Use supportive, nonstigmatizing communication in reminders and pop-up notifications
Extrinsic motivation	• Lack of awareness of apps • Limited digital access or connectivity • Financial barriers	• Integrate app into routine care pathways • Design for low-connectivity environments (eg, offline functionality, lightweight data use) • Ensure core features are freely available and explore reimbursement, subsidy, or health system–supported funding models

[a]mHealth: mobile health.

Discussion

Principal Findings

To our knowledge, this overview of systematic reviews is the first to offer theory-informed, mechanism-oriented guidance for understanding and designing mHealth app–based interventions that support engagement among adults with LTCs. By mapping modifiable barriers and facilitators of engagement onto SDT, we move beyond descriptive lists of factors to explain why these influences matter and how they may support or undermine intrinsic motivation.

This approach aligns closely with the Medical Research Council framework for developing and evaluating complex interventions, which emphasizes the value of theory for specifying mechanisms of action, strengthening intervention design, and enhancing reproducibility. Applying SDT as an overarching motivational theory provides a coherent structure for identifying modifiable targets, linking app design and features to psychological processes that shape engagement, and treating engagement as an intentional, theorized component of an intervention rather than a by-product. The resulting recommendations (Table 2) therefore offer a workable, mechanism-based framework for integrating psychological needs into both the development and evaluation of mHealth interventions.

Across the 19 included systematic reviews, three consistent findings emerged: (1) conceptual ambiguity in engagement definitions, (2) limited and low-quality evidence on engagement-outcome associations, and (3) converging evidence on patterns in modifiable factors influencing engagement.

First, engagement was rarely defined explicitly. Reviews often used terms including “engagement,” “usage,” and “adherence” interchangeably and reported only microlevel behavioral indicators (eg, number of logins or tasks completed). No review operationalized macrolevel engagement (eg, sustained integration into daily life or alignment with goals). Consequently, the current evidence base largely reflects observed usage, limiting insight into whether engagement was clinically relevant to the person using the app.

Second, although 7 of the 8 reviews assessing engagement-outcome links reported positive associations, these findings were drawn from heterogeneous operationalizations of engagement and were often based on critically low-quality quantitative syntheses. Qualitative reviews contributed insight into subjective indicators of engagement, but no review integrated them with behavioral indicators. This methodological divide reflects broader measurement immaturity in engagement research rather than limitations of individual reviews.

Third, when modifiable barriers and facilitators to engagement were mapped to motivational processes, the vast majority were intrinsic—related to autonomy, competence, or relatedness—rather than extrinsic or structural. Most barriers and facilitators reflected whether users experienced the app as personally relevant, manageable, intuitive, trustworthy, and aligned with their own goals and capabilities. Only a small subset of factors was purely extrinsic (eg, awareness, connectivity, and cost), which is still prominent as this is the minimum needed to enable engagement. However, once extrinsic preconditions are met (eg, users can download the app), engagement largely depends on intrinsic motivational processes. Hence, mHealth apps that aim to replace or reduce clinician input must intentionally support these psychological needs.

SDT provided a clear mechanism through which to interpret these patterns, enabling us to identify specific motivational targets and derive design recommendations to guide the development of interventions that are more capable of sustaining engagement without ongoing clinician reinforcement.

Comparison With Prior Work

Our findings align with longstanding critiques that digital health research often emphasizes “how much” people engage through behavioral indicators while neglecting the quality of engagement and/or the “why” (ie, subjective [cognitive and affective] influences on engagement) [53-55]. Persistent heterogeneity in engagement terminology and measurement constrains the development of cumulative evidence and makes it difficult to establish whether disengagement reflects unmet needs of the user, symptom improvement, or success in achieving the intervention’s goal [10,56-58]. Without distinguishing between these possibilities, establishing cutoffs such as the “minimum effective dose” of engagement also remains elusive.

The positive engagement-outcome associations, such as improved symptom knowledge, health behavior change, or reduced distress, mirror earlier evidence, including Donkin et al [7] findings, but these associations remain difficult to interpret given inconsistent operationalizations and low review quality. Similarly, although persuasive design features (eg, tailoring and feedback) have been shown to improve engagement [8], none of the included reviews in this overview of systematic reviews analyzed user-level engagement or linked design features to specific mechanisms. Collectively, these findings highlight a need for standardized behavioral metrics and improved reporting of how specific app features are linked to engagement.

Implications

The implications include the evaluation of existing mHealth apps and the development of new mHealth app interventions.

Evaluation of Existing mHealth Apps

Definitions and measures of behavioral engagement indicators must be standardized. Future research should adopt a validated multidimensional operationalization of engagement that moves beyond single indicators such as logins. We recommend reporting the amount (eg, number of sessions), duration time spent (eg, minutes spent in sessions), depth (eg, number of tasks completed in the same session), and frequency (eg, number of logins) [10,11]. Complementary use of validated instruments such as the Twente Engagement With eHealth Technologies Scale (TWEETS) [59] can capture both behavioral and subjective dimensions of engagement, including interest, attention, and enjoyment. This combined approach is essential for distinguishing mere usage from outcome-relevant engagement.

XSL•FO
RenderX

Future Intervention Development

As outlined in Table 2, the motivational mechanisms identified, specifically those supporting autonomy, competence, and relatedness, translate into clear, actionable design recommendations. These recommendations connect psychological needs directly to design choices, supporting mechanism-informed intervention development.

Importantly, many autonomy- and competence-related barriers, such as digital exclusion, cost, and low digital literacy, are structural challenges requiring systemic responses. The features summarized in Table 2 include practical solutions such as offering offline or low-bandwidth app versions, SMS text message–based alternatives for users without smartphones, and device-loan schemes to expand access. To support competence among digitally excluded users, guided onboarding, clear tutorials, and accessible interface design (eg, large fonts, high-contrast modes, and multilingual options) are recommended. Moreover, partnerships with community health workers, primary care providers, and advocacy organizations (relatedness-supportive features) can improve trust and contextual relevance for the LTC populations that the mHealth apps aim to serve [60,61]. These measures directly address engagement gaps and help prevent mHealth innovations from exacerbating health inequalities [62-64]. Further work is needed to quantitatively confirm if some of these recommendations do, in fact, make a difference.

Strengths and Limitations

A key strength of this overview of systematic reviews is its theory-informed synthesis across quantitative, qualitative, and mixed methods reviews, enabling a multidimensional understanding of engagement with mHealth apps. Unlike prior syntheses focused narrowly on behavioral indicators, this review synthesized the barriers and facilitators of engagement within a motivational framework, which offers insight into subjective indicators. Applying SDT provided a coherent framework for mapping barriers and facilitators onto psychological needs and for generating design-oriented recommendations. Methodological rigor was supported through prospective PROSPERO (International Prospective Register of Systematic Reviews) registration and adherence to PRIOR guidelines.

Several limitations should be acknowledged. Review quality varied; quantitative reviews were often low quality, while qualitative and mixed methods reviews were stronger. In addition, the CASP qualitative checklist was developed for the appraisal of primary qualitative studies rather than review-level evidence syntheses. However, we considered it appropriate as a structured framework for assessing the qualitative and mixed methods components of included reviews because it provides methodological depth in domains such as reflexivity, rigor of analysis, credibility of findings, and the value of the research. This approach is also consistent with a previous overview of systematic reviews that used CASP as part of the quality appraisal of systematic reviews of qualitative studies [65]. Key populations, including older adults, people with low digital literacy, and those in rural or underserved settings, were underrepresented, limiting generalizability. Publication bias may also have excluded studies reporting no engagement-outcome associations. Applying SDT introduced some interpretive subjectivity, as most reviews were not theoretically framed; however, mappings were independently cross-checked to enhance consistency. These limitations reduce the certainty of the conclusions but highlight clear priorities for future research.

Conclusion

mHealth apps are a promising approach to supporting self-management of LTCs, but their effectiveness partly relies on users' engagement with the intervention and their ability to apply its therapeutic content in daily life. This overview of systematic reviews highlights conceptual and methodological gaps in engagement research and demonstrates the value of applying SDT to understand why engagement occurs and how it can be supported. The SDT-informed design guidance provides a foundation for developing more engaging, equitable, and user-centered mHealth app interventions. Embedding these principles in future evaluation and development can strengthen both user experience and clinical impact and contribute to more consistent, theory-driven progress in digital health.

The graphical abstract for the article is provided in Multimedia Appendix 8 .

Acknowledgments

The authors thank the senior librarians at King's College London for their assistance with the data search. No generative AI tools were used in writing the manuscript text.

Funding

This study was funded by the UK MS Society under award reference 180, and part funded by the National Institute of Health and Care Research (NIHR) Biomedical Research Centre (BRC): Maudsley.

Data Availability

All data extracted for this overview of systematic reviews are available within the article and its supplementary materials. No primary data were generated.

Abstract

Background: Despite advances in wearable mobile health (mHealth) technologies and their associated apps designed to promote physical activity, and the importance of adapting them to users, little is known about older adults' perceptions of these technologies.

Objective: This review aimed to synthesize and analyze qualitative evidence exploring the perceptions of adults aged 50 years and older regarding areas to improve, barriers to, and facilitators of wearable mHealth technologies (activity trackers and companion apps) to promote physical activity.

Methods: A qualitative systematic review and meta-ethnography was conducted. Comprehensive searches were performed across 8 databases (MEDLINE, Scopus, Web of Science, CINAHL, The Cochrane Library Plus, PsycINFO, ProQuest, and ÍnDICEs-CSIC) for articles published in English or Spanish between January 2013 and January 2024. The synthesis followed the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) and ENTREQ (Enhancing Transparency in Reporting the Synthesis of Qualitative Research) guidelines.

Results: Ten articles met the inclusion criteria and were synthesized using meta-ethnography. Three main themes emerged: (1) barriers to promoting physical activity caused by wearable mHealth technologies: personal barriers (physical aspects, perceptions about technology, and personal preferences), technological barriers (functionality, content, design, alarms, availability, and accessibility), and environmental barriers (season of the year); (2) personal facilitators (consideration that these apps improve health, perceptions about technology, and personal preferences), technological facilitators (functionality, content, and design), relational facilitators (technological and social support), environmental facilitators (seasonal variations), and health care professionals (support and monitoring by health care services); and (3) personal areas (perceptions about technology and personal preferences), technological areas (functionality, content, and design), and relational areas (technological support).

Conclusions: Although older adults acknowledge the potential of wearable mHealth technologies to promote physical activity, their effective engagement is hindered by distinct personal, technological, and environmental barriers. Bridging the digital divide requires designers to prioritize user-centered, age-friendly interfaces that are integrated with continuous support from health care

XSL•FO
RenderX

professionals. To promote genuine health equity, future research must rigorously report intersectional demographics to ensure that mHealth interventions mitigate, rather than inadvertently exacerbate, existing disparities.

Introduction

Population aging is a phenomenon of increasing magnitude worldwide. By 2025, approximately 1.2 billion people will be aged 60 years and older, reaching 2 billion by 2050 [1]. Additionally, according to the World Health Organization (WHO) forecasts, between 2000 and 2050, the percentage of people aged 60 years and older will double from 11% to 22% of the global population [2-5], surpassing the remaining population groups [6].

Population aging is associated with an increase in preventable chronic pathologies, such as rheumatism, arterial hypertension, heart disease, diabetes, chronic obstructive pulmonary disease, cerebrovascular disease, hearing loss, cataracts, depression, and dementia, as well as increasing disability, dependence, and the use of health system resources [7], which increases starting at age 55 years in men and from 60 years or more in women [7,8], accounting for 70% - 80% of health expenditures in Europe [9]. Older adults consume 50% of the time spent with primary care professionals, 70% of the time of geriatricians, and 62% of the time spent on pharmaceutical expenditure [7], which can be reduced by half if aging is accompanied by good health, reinforcing primary care and senior services [9].

Physical activity (PA), defined as any movement that involves energy consumption, has been shown to have physical and mental benefits for older adults, such as reducing cardiovascular disease, increasing quality of life, and maintaining independence [10-12]. The WHO recommends that adults older than 65 years of age should perform between 150 and 300 minutes of moderate-intensity aerobic PA or between 75 and 150 minutes of vigorous-intensity PA per week. In addition, performing 2 or more days of muscle-strengthening activities for all muscle groups and performing PA 3 or more days a week are recommended, prioritizing functional balance and moderate-intensity strength [13]. The benefits of these recommendations include decreasing the incidence of hypertension, cancer, and type 2 diabetes; improving mental health, cognitive health, and sleep; reducing cardiovascular mortality; preventing falls; and worsening bone and functional health [2,10,13,14]. Therefore, effective interventions aimed at promoting PA among older adults are necessary [14].

Information and communication technologies in health, which are being increasingly used by older people, have revolutionized how health services address the challenges of improving the quality, effectiveness, and safety of care [15,16]. Such technologies are great tools for promoting active aging. Prominent among these technologies is eHealth, defined by the WHO as "the cost-effective and safe use of information and communication technologies in support of health-related areas, including health services, health surveillance, health documentation and education, health knowledge and research" [17]. Within eHealth is mHealth, defined as medical and public health practices supported by mobile devices. In the context of PA promotion, mHealth rarely operates as a stand-alone software app; rather, it functions as a broader, integrated ecosystem that combines hardware (such as wearable activity trackers, smartbands, or smartwatches) and companion software apps [18]. The inclusion of these hybrid interventions is crucial, as their physical nature (hardware) and digital interface (software) jointly increase older adults' self-care, autonomy in decision-making, and self-efficacy in disease management. Furthermore, mHealth motivates older adults to engage in PA. At the systemic level, these technologies can improve care quality, reduce health care costs, and prevent unnecessary medical consultations. For the users, mHealth facilitates social interaction, digital inclusion, and intergenerational relationships, ultimately reducing loneliness and enhancing overall quality of life [19,20]. To this end, the characteristics of older adults, the ease and intuition of the use of devices and apps, their accuracy and veracity, and their needs, desires, and limitations should be considered [21-23]. Despite the benefits of these technologies for older people, factors such as anxiety and fear of technology, deficits in cognitive skills, health problems, lack of instructions and guidelines, and the cost of the technologies are barriers to their use [19]. Perceptions about the use of mHealth devices and apps to promote PA have been studied among parents and adolescents, which has revealed their satisfaction with these technologies and their effectiveness in promoting PA among children and adolescents [24]; however, few qualitative studies have analyzed their benefits among older adults, and few existing studies have focused on populations with specific pathologies, such as myeloid neoplasms [25] or breast cancer [26].

The success of such interventions depends on their ability to adapt to the needs of the user; thus, understanding how older adults can influence the use of mHealth devices and apps for the promotion of PA and analyzing their demands, contexts, and desires to develop more accessible, age-friendly, and acceptable technologies for this population group are essential [19].

This systematic review of qualitative evidence aimed to synthesize and analyze studies that explore the perceptions of adults aged 50 years and older regarding areas to improve, barriers, and facilitators of wearable mHealth technologies to promote PA. This information is key both for the tech developers

XSL•FO
RenderX

and for the health care professionals who recommend, train, and supervise users in their use.

Methods

Overview

A qualitative systematic review and meta-ethnography were carried out. Noblit and Hare [27] described this type of synthesis of qualitative research results, which is the most widely used qualitative synthesis approach in health care. The protocol of this review was registered in PROSPERO (CDR498374). This review was conducted following the recommendations of the Cochrane Qualitative and Implementation Methods Group Guidance [28], the ENTREQ (Enhancing Transparency in Reporting the Synthesis of Qualitative Research) statement, and the criteria of the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) Statement [29] (Checklist 1).

Eligibility Criteria

The following inclusion and exclusion criteria were used to select the articles.

The inclusion criteria were as follows: (1) published in English and Spanish from January 2013 to January 2024 to include the latest publications on the subject, (2) used any type of qualitative approach or qualitative data collection technique, and (3) analyzed the use of mHealth ecosystems, specifically wearable PA trackers and their associated mobile apps, for the promotion of PA in healthy or chronically ill adults aged 50 years and older who were community-dwelling or institutionalized, functionally autonomous, and not classified as frail. The exclusion criteria were as follows: (1) studies that included participants with cognitive impairment or any mental pathology, (2) protocol studies or studies not completed, (3) mixed designs if the qualitative data were not analyzed in a disaggregated manner, and (4) studies that included the use of the wearable mHealth technologies exclusively for dietary recommendations.

Data Sources and Search Strategy

Two researchers independently conducted the search and selection of articles and resolved discrepancies through consensus, with a third researcher consulted when necessary, following the established criteria in the following databases: MEDLINE (PubMed), Scopus, Web of Science, ÍnDICEs-CSIC, ProQuest, PsycINFO, The Cochrane Library Plus, and CINAHL. In addition, a secondary search was conducted using the reference lists of the selected articles. In cases of disagreement, a third researcher approved the study. The search strategy included a combination of keywords adapted to each database. The complete search strategy is presented in Multimedia Appendix 1.

Study Selection and Data Abstraction

Article selection was performed independently by 2 researchers, with disagreements resolved by a third reviewer. First, the titles and abstracts of the articles were examined, and those that did not meet the inclusion criteria were discarded. The full texts of the selected articles were subsequently read, and the following information was extracted from each of them using an ad hoc Excel template: authors, year of publication, paradigmatic approach, objectives of the study, characteristics of the sample and sampling techniques, data collection techniques, main results, conclusions, and evaluation of methodological quality.

Assessment of Methodological Quality

The quality of the studies was assessed with the Joanna Briggs Institute Qualitative Assessment and Review Instrument (JBI-QARI) [30], which includes 10 items with 3 response options, “yes,” “no,” and “unclear,” to evaluate the methodological quality of the qualitative studies. Studies with poor methodological quality (fewer than 5 items) were rated as “excluded” and removed from the review.

Data Analysis and Synthesis

Following Noblit and Hare’s interpretive approach [27], the findings were synthesized through reciprocal translation, evolving into a line of argument that provides an original theoretical reconceptualization of mHealth apps to promote PA.

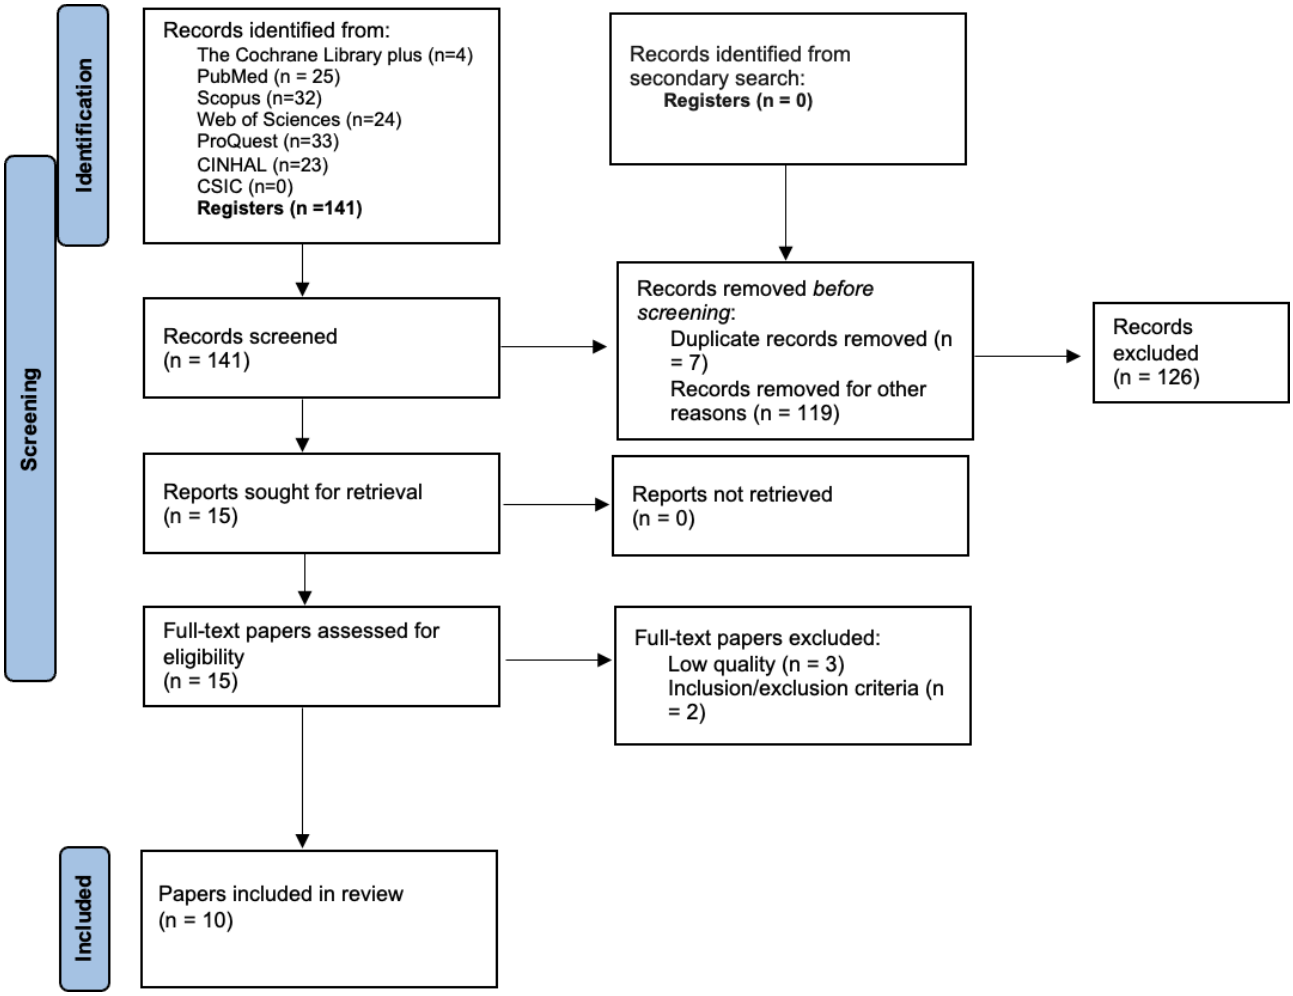
Data were systematically categorized using an abstraction form designed to distinguish between first-order constructs (participants’ quotations and metaphors), second-order constructs (interpretations based on patients’ quotations made by the original researchers), and third-order constructs (interpretations generated by our research team). By juxtaposing these layers, we moved beyond data aggregation toward a reciprocal translation of findings, synthesizing these accounts into a novel line of argument that reconceptualizes the phenomenon within the current literature (Multimedia Appendix 2).

The main themes, categories, subcategories, and codes were extracted. The codes were grouped by areas of similarity, resulting in the different themes, categories, and subcategories of facilitators, barriers, and areas for improvement for the promotion of PA among older adults. For the translation of the studies, the data were exported to a table containing the thematic tree, categories, subcategories, codes, and quotations to help us understand the relationships between the studies. No refutations or contradictions were found, as the data from all included studies were very similar. Finally, the researchers compared the translations to identify the lines of argument from which the synthesis would be developed.

Research Team and Reflexivity

The research team has previous experience in qualitative research, evidence synthesis, PA, and research involving older people. The team included registered nurses, physiotherapists, an anthropologist, and a graduate in PA. The findings were analyzed from an interprofessional perspective.

Results



Study Selection and Characteristics

Following the database search, 141 references were identified, 7 of which were eliminated because they were duplicates across several databases. After the title and abstract were read, 15 articles met the inclusion criteria; 5 were excluded because of low methodological quality, specifically the use of the Joanna

XSL•FO
RenderX

Briggs Institute tool for qualitative studies. Finally, 10 articles were included in the narrative synthesis and meta-ethnography (Figure 1).

Author and year	Paradigmatic approach	Objectives of the study	Sample characteristics and sampling technique	Data collection technique	Main results	Conclusions	Methodological quality
Moore et al (2021) [31]	Qualitative systematic review, meta-ethnography type	To synthesize qualitative studies that analyzed the experience of older people who had used a PA[a] monitoring device for several days, and to determine which factors contributed to the acceptance and use of portable devices	• Twenty articles were included with a total of 349 participants aged 51 to 94 years who had used portable devices for several days and had analyzed their experiences • Intentional convenience sampling technique	Semistructured interviews and focus groups	• Three main themes explained older adults' experience with physical activity monitoring devices • Barriers: age-associated physiology and comorbidities. They were frustrated when the devices did not have the functions they wanted, were difficult to access, did not achieve their goal or capture all their activities, and had to rely on family or friends; when they were inaccurate, cumbersome, difficult to connect, incompatible with their phone, and complex instructions • Facilitators: continuous monitoring of the device and reaching their proposed goal. Supported by their family, friends, and health care personnel. That the devices were waterproof, small, comfortable,	• The factors that positively influence the use of PA devices and apps in older adults are personal motivation, ease of use, the objective set by the users, and considering their preferences. However, to overcome perceived barriers, such as usability or physiology-related barriers, older adults must be motivated and socially supported. In addition, device-related features (charging, instructions, and so on) should be improved.	10/10

Author and year	Paradigmatic approach	Objectives of the study	Sample characteristics and sampling technique	Data collection technique	Main results	Conclusions	Methodological quality
					• Analysis of the data obtained revealed the participants' perceptions of the use of physical activity trackers, classified into the following facilitators: • Facilitators: age-associated comorbidities. Setting a small goal and increasing it. Use of reminders and routines: they wore them first thing in the morning, charged them during the night, and always left them in the same place; they also used them in situations such as TV commercials, telephone conversations, or explored new routes to achieve the set goal. They were able to anticipate potential obstacles that might prevent them from using the activity tracker (eg, running out of battery). In addition,		

XSL•FO
RenderX

					ly activity since its use reduced stress and promoted their independence; and to set goals, thus competing with family and friends • Areas for improvement: instructions for use and training on functionality		
Abouzahra and Ghasemaghaei (2020) [34]	Phenomenology	To examine the influence and effect of the use of PA monitoring devices in older adults	• 44 persons aged 65 years and older (20 men and 24 women) who had never used any PA monitoring device. • Intentional convenience sampling technique.	Two semistructured interviews with each participant.		• The use of PA monitoring devices in older adults is a complex process influenced by social (support from family and friends...), psychological (problem-solving skills), and technological (device complexity) factors. Taking these factors into account, strategies can be developed to improve the use of portable devices in this population and improve their health and quality of life.	10/10

XSL•FO
RenderX

Author and year	Paradigmatic approach	Objectives of the study	Sample characteristics and sampling technique	Data collection technique	Main results	Conclusions	Methodological quality
					• The analysis of the data revealed 3 themes, classified into the following barriers, facilitators, and areas for improvement in the use of PA monitoring devices in older adults: • Barriers: inexperience in the use of technologies and the complexity of the device. The use of alarms and the high price of the device • Facilitators: alarms, previous experience with other technologies, and support from friends and family • Areas for improvement: monitoring other health parameters		
Ehn et al (2018) [35]	Phenomenology	To explore the experiences, requirements, and preferences of older adults for the use of PA monitoring devices		Individual semistructured interviews and focus groups.			10/10

XSL•FO
RenderX

Author and year	Paradigmatic approach	Objectives of the study	Sample characteristics and sampling technique	Data collection technique	Main results	Conclusions	Methodological quality
			• Eight older adults aged 75 years and older; 6 had a mild walking disability and used wheeled walkers, and 2 participants walked without assistance. All knew how to use a smartphone, had not used an iPad, and 2 of them used computers. • Two physical activity recording wristbands were used. • Intentional convenience sampling technique.			• PA monitoring devices are an important tool to promote physical activity in older adults, but these should be easy to use and intuitive, with accurate activity log measurements, and display motivational messages.	

XSL•FO
RenderX

Author and year	Paradigmatic approach	Objectives of the study	Sample characteristics and sampling technique	Data collection technique	Main results	Conclusions	Methodological quality
					• Three themes explained the participants' experiences using the activity monitoring devices that were categorized into barriers, facilitators, and areas for improvement: • Barriers: inaccurate measurements made by the devices. Many perceived the devices as fragile and therefore could break or damage them. They were afraid of being monitored and losing privacy, and some stopped using the device when it caused some kind of problem. Another barrier was that the device instructions were not in their native language. • Facilitators: achieving the proposed goal by making them more aware of how active they were even indoors. The use of reminders		

XSL•FO
RenderX

Author and year	Paradigmatic approach	Objectives of the study	Sample characteristics and sampling technique	Data collection technique	Main results	Conclusions	Methodological quality
					and previous experience using other technologies made it easier for them to use the devices. They preferred the wristbands to be waterproof, flexible, small, comfortable, and easy to combine with clothing. • Areas for improvement: combining PA measurements with other health parameters and improvements in device battery life		
Fausset et al (2013) [36]	Phenomenology	To explore the use and attitudes of older adults toward 4 PA monitoring technologies and to learn how they integrate these devices into their daily lives	• Four married couples (6 perceived their health status as optimal and 2 as fair or poor) had a computer and internet connection and had no previous experience with any activity monitoring technology. • Intentional convenience sampling technique	Two semistructured interviews with each participant.		• Older adults perceive PA monitoring devices to be easy to use and useful as a key instrument for the promotion of healthy lifestyles. However, their high price, the inaccuracy of data measurement, and the loss of time in connecting and putting on the device are barriers to the use of these devices.	10/10

XSL•FO
RenderX

Author and year	Paradigmatic approach	Objectives of the study	Sample characteristics and sampling technique	Data collection technique	Main results	Conclusions	Methodological quality
					• The most significant findings of the study were classified into barriers, facilitators, and areas for improvement. • Barriers: the inaccuracy in measuring the parameters, the high price, and the discomfort of wearing the bracelet at night • Facilitators: the enthusiasm and willingness shown by the participants to use the device and to be able to count the steps taken correctly. • Areas for improvement: long-term use, since half of the participants stated that they would not use the device continuously		
Mercer et al (2016) [37]	Phenomenology	To examine the usability and usefulness of activity monitoring devices in chronically ill older adults		Two focus groups were conducted.			10/10

XSL•FO
RenderX

Author and year	Paradigmatic approach	Objectives of the study	Sample characteristics and sampling technique	Data collection technique	Main results	Conclusions	Methodological quality
			• 32 participants between 52 and 84 years of age with a chronic pathology. • Twelve participants did not have a cell phone, so they were provided with one. • The participants previously used a pedometer. Subsequently, they were assigned a device to use for at least 3 days. • Intentional convenience sampling technique			• For older adults with chronic diseases, wearable physical activity trackers are useful and acceptable. However, these users may need help setting up the device and learning how to interpret the data obtained.	

XSL•FO
RenderX

Author and year	Paradigmatic approach	Objectives of the study	Sample characteristics and sampling technique	Data collection technique	Main results	Conclusions	Methodological quality
					• Three themes emerged in the study that described the acceptability of the devices by the older adults, which were classified into barriers, facilitators, and areas for improvement: • Barriers: participants were uncomfortable using the device because they thought they might break it. • Facilitators: that the devices were easy to use and made them more aware of their PA level, thanks to the alerts function, turning the set daily step goal into a game or competition with other users or with themselves. Finally, participants reflected that these devices could be useful in the health sector to improve their health and that they should be avail-

					able in pharmacies and tax-free. • Areas for improvement: a simple manual of instructions, less technical terms, and clearer screens.		
Puri et al (2017) [38]	Mixed design, longitudinal quantitative study and qualitative study based on phenomenology	To evaluate the acceptability and use of activity monitoring devices in older adults considering the influencing factors identified in the literature and the technology acceptance model	• 20 adults older than 55 years of age, 12 women and 8 men. • Of the total, 18 used a computer daily, 14 owned a personal smartphone, and 17 had heard of activity monitoring devices. • Intentional convenience sampling technique	Four semistructured interviews were conducted in the qualitative part.		• Most older adults accept PA monitoring devices and perceive them as valuable to their lives. In addition, they are concerned about the features of the trackers (comfort, aesthetics, and price), whereas privacy is less of a concern for this group	10/10

XSL•FO
RenderX

Author and year	Paradigmatic approach	Objectives of the study	Sample characteristics and sampling technique	Data collection technique	Main results	Conclusions	Methodological quality
					• Three themes explained older adults' perceptions of the acceptability of activity monitoring devices organized into the following barriers, facilitators, and areas for improvement. • Barriers: participants' lack of prior experience and seniors' sense of independence caused participants not to seek support from loved ones. • Facilitators: battery life, thin and flexible wristbands, sharing data with other users, and quick access to information managed by the device to understand the level and intensity of PA performed. In addition, the increased self-awareness of the device motivated them to make lifestyle changes and to inform themselves		

XSL•FO
RenderX

Author and year	Paradigmatic approach	Objectives of the study	Sample characteristics and sampling technique	Data collection technique	Main results	Conclusions	Methodological quality
					about health-related topics. • Areas for improvement: the devices had to be easy to use, comfortable, and they were not afraid of breaking them		
Schlomann et al (2016) [39]	Phenomenology	To assess the experiences, opportunities, and barriers that older adults encounter in using PA trackers	• Six women aged 67-78 years who had no prior experience using wearable activity trackers but owned a smartphone. • Intentional convenience sampling technique	A focus group was conducted.		• Older adults are motivated to use PA monitoring devices. However, they perceive some problematic aspects that may cause some rejection in their use, such as the instructions provided, the handling, or the synchronization of these devices with the smartphone. • These aspects need to be considered for adequate use of PA monitoring in this age group.	10/10

XSL•FO
RenderX

Author and year	Paradigmatic approach	Objectives of the study	Sample characteristics and sampling technique	Data collection technique	Main results	Conclusions	Methodological quality
					• Three themes assessed the barriers, facilitators, and areas for improvement perceived by the participants in the use of the activity monitoring devices. • Barriers: problems encountered when using the devices caused them anxiety, and they had to ask for help or call the researcher. In addition, they felt that the instructions provided were very brief and not in their native language. In addition, the devices were not waterproof, were incompatible or difficult to synchronize with some smartphones, there was inaccuracy in the step count, and they did not measure other clinical parameters (blood pressure, heart rate, etc.). • Facilitators: the devices		

XSL•FO
RenderX

Author and year	Paradigmatic approach	Objectives of the study	Sample characteristics and sampling technique	Data collection technique	Main results	Conclusions	Methodological quality
					encouraged them to be more active and contributed to their personal well-being. Some participants changed their daily behavior due to the use of the device, comparing themselves with each other based on the steps they were able to take, or the information provided by their trackers. • Areas for improvement: participants did not perceive that the feedback provided by the devices forced them to be more active.		
Batsis et al (2016) [40]	Phenomenology	To evaluate the reliability and acceptability of a PA monitoring device (Fitbit) to promote behavior change in older adults with obesity residing in rural areas	• Eight older adults (4 women and 4 men) aged 65-80 years with BMI greater than 30 kg/m^2 and in need of weight loss. All participants had smartphones. • Intentional convenience sampling technique	A semistructured interview was conducted with each participant			10/10

XSL•FO
RenderX

Author and year	Paradigmatic approach	Objectives of the study	Sample characteristics and sampling technique	Data collection technique	Main results	Conclusions	Methodological quality
						• Although the use of Fitbit is accepted by older adults with obesity, they perceive that they need advice from people (health care professionals, trainers, and so on) to teach them how to interpret the results obtained on the device and increase their confidence in the use of the device, thus bringing about a change in their behavior.

					professional, trainer, and so on		

[a]PA: physical activity.

[b]mHealth: mobile health.

All the studies analyzed included adults older than 50 years, whose ages ranged broadly from 51 to 94 years. Most included mixed-gender samples, although one study exclusively analyzed the perspective of women [39]. With respect to comorbidities and functional status, several studies have moved beyond healthy populations to include individuals with chronic illnesses, older adults with obesity (BMI >30 kg/m^2), and participants with mild walking disabilities using wheeled walkers. Notably, formal categorizations of socioeconomic status (SES), culture, and ethnicity were absent from the primary studies' demographic reports. In terms of geographic scope, 5 studies were conducted in the United States [32-34,36,40], 2 in Canada [37,38], and the remaining in Sweden [35], Ireland [31], and Germany [39].

Concerning the objectives, 2 studies analyzed the barriers and facilitators perceived by older adults regarding the use of PA monitoring devices [33,39], another analyzed the experience of this population group using PA monitoring devices and their perceptions of factors influencing their long-term use [32], and the remaining analyzed the experiences, acceptability, effects, and preferences of older adults regarding the use of PA monitoring devices [34-38,40].

Most studies used the phenomenological approach [32-40], except for one study that used meta-ethnography [31]. The main data collection techniques used were focus groups [33,37], semistructured interviews [32,34,36,38,40], or a combination of both [31,35,39].

Description of the Main Findings

Seven of the analyzed studies reported the barriers, facilitators, and areas of improvement perceived by adults for the use of wearable mHealth technologies for PA promotion [31,33-35,37,38,41]; 1 synthesized the facilitators that promoted the use of wearable mHealth technologies among older adults [32], and 2 analyzed the facilitators and barriers that facilitated or hindered the use of these devices and apps [36,40].

Three major themes emerged from the narratives explaining older adults' perceptions of wearable mHealth technologies promoting PA: (1) barriers to their use of wearable mHealth technologies to promote PA: personal (physical and perceptions about technology and tastes and preferences), technological (functionality, content, design, alarms, availability, and accessibility), and environmental (seasonal variations); (2) facilitators of their use of wearable mHealth technologies to promote PA: personal (consideration that it improves health, perceptions about technology and tastes and preferences), technological (functionality, content, and design), relational (technological support and social support), environmental (seasonal variations), and health sector (support and monitoring of health services); and (3) main areas of improvement for the use of wearable mHealth technologies to promote PA: personal (perceptions about technology, tastes, and preferences), technological (functionality, content, and design), and relational (technological support). These themes are presented below with the corresponding categories, subcategories, and codes (Tables 2-4).

Barriers to the Use of Wearable mHealth Technologies for PA Promotion

Through the reciprocal translation of the primary literature, the synthesis demonstrates that mHealth ecosystem adoption among older adults is structurally hindered by an intersection of age-associated physiological decline and inadequate user-centered design. Personal barriers encompass sensory and physical deterioration, slower information processing speeds, and technology-induced anxiety, which frequently collide with an established reluctance to alter daily habits [31-35,37-40]. This vulnerability is severely compounded by technical deficits; users routinely experience frustration regarding cumbersome and fragile hardware, complex smartphone synchronization requirements, a lack of automated troubleshooting, and unreliable data visualization [31-39]. Furthermore, frequent notifications or alarms act as intrusive stressors [31,34], while high purchasing costs [33,34] and jargon-heavy instructions create severe access barriers [31,33,35,37-39]. These technical challenges are further compounded by environmental variables, as adverse seasonal weather (winter, rain, snow, and so on) restricts physical outdoor use [37,40]. These barriers are detailed in Table 2.

Facilitators for the Use of Wearable mHealth Technologies for PA Promotion

Conversely, a positive line of argument emerges when wearable technologies successfully bridge the gap between intrinsic health motivation and intuitive functionality and desire for functional independence [31-40]. At the individual level, older adults demonstrate high adherence when they perceive that tracking tools directly translate into stress reduction, pain management,

XSL•FO
RenderX

and measurable physical wellness [32-40]. From a technological standpoint, sustained engagement is facilitated by seamless, unobtrusive hardware configurations—specifically watch-like, waterproof devices featuring long battery life, flexible bands, and large, legible displays [31-35,37-40]. Software features that offer automated tracking, personalized goals, gamified self-competition, and real-time positive feedback act as powerful behavioral catalysts [31-35,37-40]. Critically, the synthesis highlights that hardware and software fail in isolation; relational and systemic scaffolding is paramount. Sustained use is driven by robust social networks (family and peers) [31,33,34,38-40] and, fundamentally, by the formal involvement of health care professionals who integrate these digital metrics into active clinical treatment plans and continuous medical monitoring [31-33,35-38,40]. Table 3 maps the comprehensive structure of these facilitators.

Areas of Improvement for the Use of Wearable mHealth Technologies for PA Promotion

To minimize early abandonment and maximize clinical utility, the synthesized data establishes explicit pathways for age-inclusive development. Participants universally demand a shift toward age-friendly engineering that prioritizes intuitive interfaces, native-language instruction manuals, enhanced data privacy, and the expansion of monitored metrics to include broader clinical parameters beyond basic pedometry [31,33-39]. Relatably, older adults highlight that closing the digital divide requires robust instructional scaffolding. Developers and health care networks must cooperate to provide accessible, nontechnical training and ongoing troubleshooting support to foster digital self-efficacy and prevent technology rejection [31,33,37]. These strategic directions for technological and clinical adaptation are synthesized in Table 4.

Results of the Analysis of the Quality of the Studies Analyzed

The methodological quality of the articles was analyzed with the JBI-QARI [30]. Table 5 shows the detailed results of the analysis of the methodological quality of the included studies after this tool was applied.

Discussion

Principal Results

The objective of this qualitative systematic review was to analyze the point of view of older adults on the aspects that can influence the use of wearable mHealth technologies for the promotion of PA and to analyze their demands, contexts, and desires to develop more accessible, age-friendly, and acceptable technologies for this population group [19].

People aged 50 years and older perceive personal barriers (physical aspects, perceptions about technologies, and tastes or preferences), technological barriers (functionality, content, design, alarms, availability, and accessibility), and environmental barriers (seasonal variations) that hinder the use of wearable mHealth technologies for the promotion of PA [31-38,40,41]. On the other hand, this population includes personal facilitators (which consider that it improves health, perceptions about technologies, and tastes or preferences), technological facilitators (functionality, content, and design), relational facilitators (technological support and social support), environmental facilitators (seasonal variations), and health professionals (support and follow-up by health professionals) that favor the use of wearable mHealth technologies [31-38,40,41]. Likewise, people more than 50 years of age perceive personal factors (perceptions about technologies and tastes or preferences), technological factors (functionality, content, and design), and relational factors (technological

XSL•FO
RenderX

support) as areas for improvement in mHealth devices and apps for the promotion of PA [31,33-38,40,41].

To illustrate the practical relevance and tangible impact of these technologies, specific mHealth interventions from synthesized studies demonstrate how targeted features can drive positive behavioral changes in vulnerable cohorts. For instance, the implementation of a commercial wearable device (Fitbit) among older adults with obesity residing in rural areas proved highly acceptable; it successfully motivated positive behavior change by providing useful real-time feedback and fostering social interaction [40]. Similarly, in a cohort of older adults living with chronic illnesses, wearable activity trackers functioned as powerful behavioral catalysts [37]. By using alert functions and setting daily step goals, these devices gamify PAs, significantly increasing users' awareness of their daily movement and transforming exercise into self-competition [37]. Furthermore, devices that allowed users to set small, progressive goals, supported by reminders and structured routines—such as wearing the device first thing in the morning—were instrumental in helping older adults develop long-term PA habits [32]. The increased self-awareness facilitated by these trackers also motivated older adults to make broader lifestyle changes and proactively seek health-related information [38]. These empirical examples underscore that when wearable mHealth technologies successfully integrate user-friendly feedback, gamification, and social support, they effectively translate theoretical facilitators into measurable health impacts for aging populations [32,37,38,40].

Comparison With Prior Work

In line with previous studies that have analyzed the use of wearable mHealth technologies among older adults [4,42], our results confirm that the following barriers hinder their use: physiological state, age, vision loss, hearing loss [31], high price [33,34], lack of interest in older adults, and inexperience and fear of using technologies and sharing data [33-35,37,38]. In addition, the results of this review coincide with those of previous studies showing the following facilitators for the use of devices and apps among older adults: previous experience with technology [32,34,38], being user-friendly [31,35], and favoring the independence and autonomy of older adults [33,35,38].

Another previous study performed on people with low back pain [43] confirmed, as in our review, that older adults must be supported by family members, friends, health professionals, and other users to be able to continuously use PA monitoring devices and apps [31,33,34,37,39,40]. In addition, older adults positively value the use of reminders and alarms [32-35,37] and receive feedback on whether they are using the device correctly [38,40]. Our results are in line with those of previous studies analyzing the use of mHealth ecosystems to promote PA in patients with myeloid neoplasms [25], revealing the need to establish specific objectives according to physiological conditions so that users can use PA monitoring devices appropriately [31,32,35].

In contrast to our findings [31,33,38,39], a study involving adolescent and young adult cancer survivors reported that PA monitoring devices were easy to use and synchronize, allowing for quick data retrieval [44]. Such ease of use is not reflected in the narratives of older adults in our review. Instead, older participants frequently expressed the belief that these technologies were not designed for them [31,35,39]. Moreover, in contrast to studies that claim that devices and apps are affordable and economically profitable [33,34], our results show that cost and access to mHealth technology are barriers for older adults [31,33-35,37,38,41]. These results highlight the need for mHealth technology to be friendlier to older adults, which has been termed age-friendly, and to be more flexible to potential users. One study reported that mHealth devices and apps should contain simple functions and simple navigation instructions to reduce the cognitive load of older adults, common and simple language, the option of zoom or large print text, and voice navigation (if they are visually impaired) [45]. These findings are consistent with the results of our studies [31-35,37-39].

For these reasons, governments, international organizations, health professionals, academic institutions, media, and the private sector must consider all these findings to eliminate the existing digital gap between older adults and the use of mHealth devices and apps. In this way, through learning and training, older adults can benefit from the use of wearable mHealth technologies by achieving better self-management of their health [46].

However, advocating for inclusive design is insufficient without addressing the economic realities of the digital health ecosystem. The technology sector generally recognizes the value of user-centered interfaces; rather, the primary barrier is economic. The high costs and lower profit margins associated with developing customized platforms often fail to support a compelling business case. To genuinely drive industry change, future research must actively develop this business case. By leveraging resources largely inaccessible to private developers—such as longitudinal electronic health records, clinical registries, and biobanks—the academic community must conduct robust Health Economics and Outcomes Research and budget impact analyses. Demonstrating a clear clinical and economic return on investment is essential for incentivizing the tech sector to prioritize and fund highly customizable, age-friendly mHealth technologies.

Limitations

This review included only articles in English and Spanish in the selected databases and excluded relevant articles on the phenomenon studied. In addition, no articles have studied the long-term use of wearable mHealth technologies among older adults, nor have the views of health professionals been considered. On the other hand, our study was based solely on the use of mHealth ecosystems that promote PA, and future studies should continue to investigate the repercussions of these devices and apps over time and from the point of view of professionals.

Another limitation of this meta-ethnography is the restricted demographic reporting in the primary literature. Although some studies detailed clinical parameters and geographic contexts, critical sociodemographic determinants such as SES, culture, and ethnicity were systematically omitted. This paucity of granular data precludes a robust intersectional analysis,

XSL•FO
RenderX

obscuring how overlapping social identities and structural inequalities influence mHealth engagement. Consequently, the current evidence may disproportionately reflect privileged cohorts and fail to capture the unique barriers faced by marginalized subpopulations. To advance health equity, future research must rigorously report diverse, intersectional demographic variables, ensuring that mHealth interventions mitigate rather than exacerbate the digital divide among aging populations.

Conclusions

This meta-ethnography demonstrates that older adults' engagement with wearable mHealth technologies for PA is not solely dictated by technological proficiency but by a complex interplay of personal, technological, and environmental factors. While usability constraints, age-related physical limitations, and privacy concerns significantly hinder adoption, older adults clearly recognize the potential of these digital health tools to enhance their well-being. Evidence from the synthesized cohorts highlights that when mHealth interventions use user-centered, age-friendly designs and integrate continuous support from health care professionals, they effectively drive sustained behavioral change and long-term adherence. However, a critical methodological gap persists in the current literature: the systemic omission of granular demographic data, specifically SES, cultural background, and ethnicity. This lack of intersectional reporting precludes a comprehensive understanding of how compounding structural inequalities shape digital health access. If mHealth is to promote true health equity, future research must transition from homogeneous sampling to rigorous, inclusive methodologies. Tech developers and clinicians must collaboratively address the multifaceted needs of diverse, marginalized older adult subpopulations. Only through this intersectional approach can we ensure that the proliferation of wearable mHealth technologies bridges, rather than inadvertently exacerbates, the existing digital divide.

Abstract

Background: The Internet of Things (IoT) represents a transformative paradigm in health care service delivery, offering unprecedented potential to enhance quality of care, operational efficiency, and patient outcomes through interconnected devices and real-time data analytics. Despite rapid adoption, implementation depends on patient acceptance as end users. While literature extensively documents technical and institutional perspectives, a comprehensive understanding of patient acceptance factors remains fragmented, with high technology abandonment rates. Systematic synthesis of patient perspectives is critically needed to inform user-centered design, effective implementation strategies, and supportive policy frameworks.

Objective: This systematic literature review aims to identify and synthesize factors influencing patient acceptance of IoT technology in health care services, barriers hindering adoption, and effective strategies for enhancing acceptance.

Methods: Following PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 guidelines, we systematically searched eight electronic databases (PubMed/MEDLINE, Scopus, IEEE Xplore, Web of Science, ScienceDirect, ACM Digital Library, ProQuest, and Google Scholar) for empirical studies published between January 2016 and December 2024. Inclusion criteria encompassed peer-reviewed empirical research examining patient perspectives on IoT technology in health care services, published in English or Indonesian. From 2537 initially identified papers, 62 studies met inclusion criteria after systematic screening and full-text evaluation. Quality assessment was conducted using the Mixed Methods Appraisal Tool.

Results: The 62 included studies represented diverse geographic contexts (Asia, Europe, North America, and the Middle East) and methodological approaches. Quality assessment revealed 45 (73%) studies of good-to-excellent quality. Perceived usefulness emerged as the strongest acceptance facilitator, identified in 55 of 62 (89%) studies, followed by perceived ease of use in 47 (76%) studies, and trust and security in 42 (68%) studies. Cost-effectiveness was identified in 32 (52%) studies as an important consideration. Primary barriers included data security concerns in 26 (42%) studies, privacy issues in 24 (39%) studies, lack of digital literacy in 22 (36%) studies, and resistance to change in 20 (32%) studies. Interoperability issues and high costs were identified in 19 (31%) studies and 18 (29%) studies, respectively. User-centered design was the most frequently recommended enhancement strategy in 20 (32%) studies, followed by user-friendly interface development in 19 (31%) studies, digital literacy programs in 18 (29%) studies, and health care professional involvement in 15 (24%) studies. Digital literacy functioned as a significant moderator, and trust served as both direct predictor and mediator.

Conclusions: Patient acceptance of IoT in health care represents a complex, multidimensional phenomenon requiring holistic approaches that integrate user-centered technology design, comprehensive digital literacy programs, trust-building mechanisms, and supportive policy frameworks. Successful implementation necessitates multilevel strategies addressing individual, organizational, and system factors simultaneously. With evidence-based, patient-centered approaches, IoT technology holds substantial potential to transform health care delivery into more proactive, personalized, and accessible services.

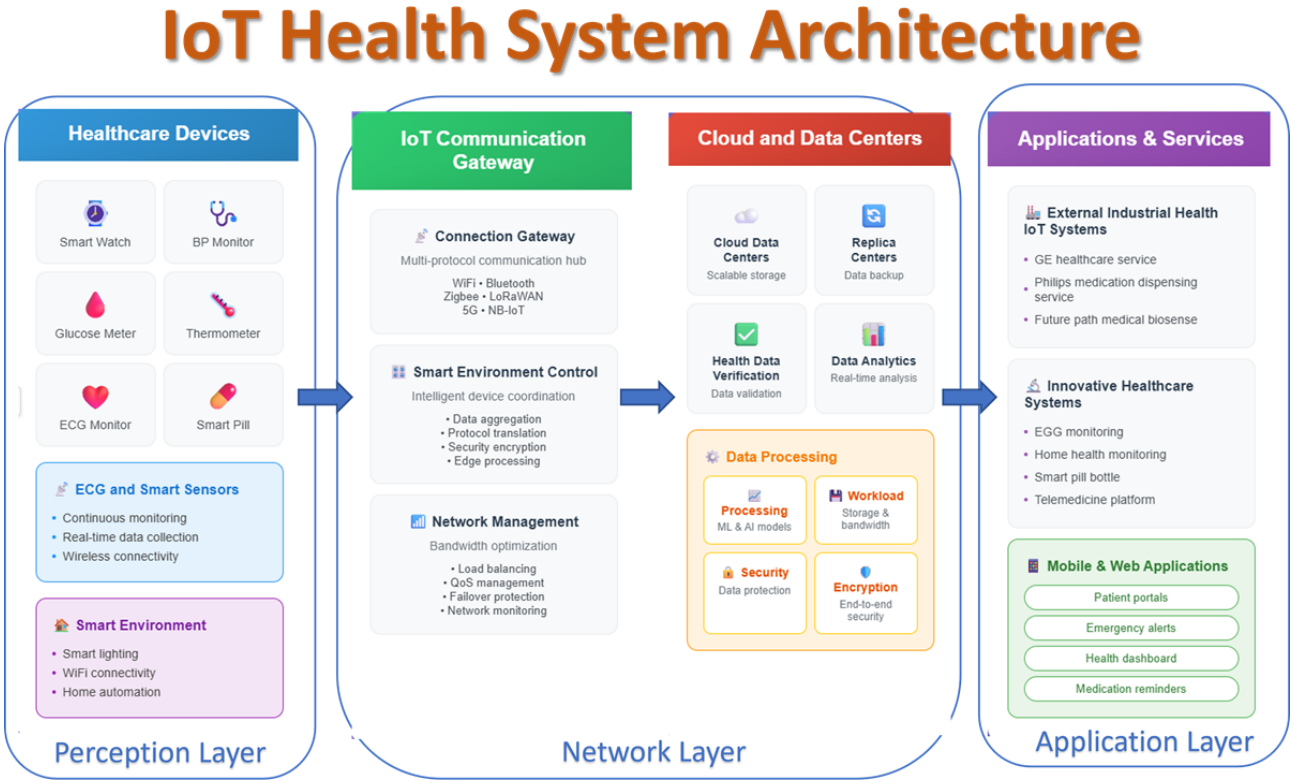
Introduction

Background

The technological developments of the coming decade demonstrate fundamental transformations that will radically change how humans live, work, and interact. According to the McKinsey Global Institute (2024) report [1], waves of technological innovation represent not merely incremental changes, but a new paradigm that will integrate AI, quantum computing, and sustainable technologies into almost every aspect of human life. This condition is driven by multidisciplinary convergence between computer science, biotechnology, nanotechnology, and AI, opening new possibilities previously considered impossible. Sustainable technology has become a central paradigm in future innovation development, with renewable energy, green computing, and environmental solutions becoming the primary focus of global research. The Intergovernmental Panel on Climate Change (IPCC) report [2] confirms that technological innovation will be key in climate change mitigation, with projections of carbon emission reductions of up to 45% through green technology implementation by 2040. Based on the context of sustainable technology as the central paradigm of future innovation, the health care sector faces urgent real challenges that require resolution through modern technology implementation. One major problem currently faced by the health care sector is the increasing older adult population experiencing multiple chronic conditions (MCCs) such as hypertension, arthritis, heart disease, cancer, diabetes, and chronic kidney disease. This multimorbidity condition impacts increased mortality, disability, decreased physical function, and reduced patient quality of life [3]. Future technology trends addressing these issues include the internet of medical things (IoMT) for continuous monitoring [4] and expansion of telemedicine and telehealth, enabling remote consultations, reducing patient waiting times, and expanding access to specialists [5]. This digital transformation specifically targets reducing the older adult population health care costs while improving their outcomes and quality of life through personal and sustainable technology solutions.



The rapid advancement of digital technology in recent decades has transformed various aspects of human life, including the health care sector. One of the most promising innovations in health care service transformation is the Internet of Things (IoT). IoT presents significant paradigm changes in health care service delivery, driven by the convergence of interconnected devices, data analytics, and communication networks. This technological synergy enables real-time patient health monitoring, remote chronic condition management, and improved efficiency in health care service operations. IoT infrastructure facilitates communication between various entities, including individuals and medical devices such as wireless sensors, thereby promoting increased access to quality and affordable health care services [6]. IoT implementation spans various health care service domains, offering innovative solutions for remote patient monitoring, medication adherence, and chronic disease management [7].

Although AI offers tremendous potential in the health care sector, the focus on IoT stems from its direct and practical applications in addressing current challenges in health care systems [8]. IoT provides basic infrastructure for collecting, transmitting, and analyzing patient data, building foundations for more sophisticated AI applications [9]. Integration of IoT devices, such as wearable sensors and remote monitoring systems, facilitates continuous data collection about physiological parameters, activity levels, and environmental conditions [10]. This real-time data flow enables proactive monitoring and early detection of health anomalies, reducing the need for frequent hospital visits and improving patient outcomes [10].

IoT refers to networks of physical devices connected through the Internet, enabling real-time data collection and exchange [11]. In academic contexts [11], IoT is described as a computing paradigm encompassing three main dimensions: communication, semantics, and interconnectivity. The communication dimension refers to devices' ability to exchange information through diverse network protocols. The semantic dimension focuses on interpretation and use of meaningful data, while interconnectivity refers to devices' ability to connect and interact in complex and dynamic ecosystems. In health care service contexts, IoT implementation (Figure 1) offers great potential for improving care quality, operational efficiency, and overall patient experience [12].

XSL•FO
RenderX

Figure 1. IoT health system architecture. BP: blood pressure; ECG: electrocardiogram; GE: General Electric; IoT: Internet of Things; QoS: quality of service.

The development of health care IoT market share shows very significant growth with latest data from Transforma Insights reporting that by the end of 2023 there were 16.1 billion active IoT devices worldwide, with growth projections reaching 399 billion devices in 2033 with a compound annual growth rate of 10%, while the total IoT market including connectivity modules and related core applications was valued at US $335 billion in 2023 and projected to increase to US $934 billion in 2033 [13]. Health care IoT adoption acceleration has been further accelerated by COVID-19 pandemic impacts, emphasizing urgent needs for remote health care solutions and digital technologies that can support health care service continuity in situations of physical and social restrictions [14].

Despite the transformative potential of IoT technology in health care services being extensively documented and discussed from technical, clinical, and institutional perspectives in various scientific literature, a comprehensive understanding of acceptance from patient perspectives as end users still shows significant limitations requiring deeper investigation [15]. This paradoxical phenomenon is reflected in high abandonment rates of digital health technologies, where various studies show that up to 50% of wearable health device users discontinue use within the first six months after initial adoption, indicating substantial gaps between the technical advancement of IoT devices and technology's ability to integrate seamlessly into users' daily lives and routines [16].

Health care IoT technology acceptance complexity is influenced by broad and multidimensional factor spectrums extending beyond mere technical considerations, including benefit perceptions related to health outcomes and quality of life improvements, ease of use related to interface complexity and learning curves, privacy concerns related to sensitive health data collection and use, social support from family and health care providers, user digital literacy levels, and demographic characteristics such as age, education, and socioeconomic status affecting technology adoption readiness [15]. Broader contextual factors such as national and regional health policies, technology infrastructure quality and availability, and cultural norms and societal values regarding privacy and personal autonomy shape ecosystem environments that can facilitate or hinder health care IoT technology adoption and diffusion in diverse populations [17].

Existing literature reviews reveal that most health care IoT research remains dominated by a focus on technical aspects such as system architecture, communication protocols, and data processing algorithms, as well as institutional perspectives emphasizing operational efficiency and cost reduction from health care provider viewpoints, while patient perspectives as end users and factors influencing their acceptance still receive inadequate attention in scientific literature [18]. This research gap becomes increasingly critical considering that successful health care IoT technology implementation depends not only on technical sophistication or system efficiency, but fundamentally depends on acceptance and adoption levels by patients as end users who will determine the sustainability and long-term impact of such technology investments [19].

This Review's Added Value

Al-Rawashdeh et al [18] conducted a systematic review of IoT adoption and the application for smart health care services, analyzing 60 studies with a focus on general adoption factors across multiple stakeholder groups, including health care providers, administrators, and patients [18]. Their review

XSL•FO
RenderX

provided valuable insights into technical architecture and institutional implementation challenges, but treated patient perspectives as one among several stakeholder categories rather than as the primary focus. Shanbehzadeh et al [20] examined health IT acceptance specifically in clinical decision support contexts, synthesizing 45 studies with emphasis on clinician adoption and workflow integration [20]. Their scope was intentionally limited to clinical decision support systems rather than broader IoT health care applications, and patient acceptance received minimal attention. Brar et al [15] explored factors affecting IoT-based health management tool adoption using technology acceptance model (TAM) extensions, focusing primarily on wearable devices with analysis of 38 studies [15]. While providing useful insights into wearable technology acceptance, their scope excluded broader IoT health care applications such as remote monitoring systems, smart hospital infrastructure, and IoMT implementations.

Our Distinctive Contributions

While several systematic reviews have examined IoT adoption in health care contexts, this review provides distinctive contributions that advance understanding of patient acceptance phenomena. We position our work relative to the most relevant prior reviews to clarify our specific contributions.

This systematic literature review (SLR) extends beyond prior work through several key dimensions: first, exclusive patient perspective focus: unlike previous reviews that included multiple stakeholder groups, we systematically examine only patient perspectives as end users, ensuring findings directly inform patient-centered design and implementation strategies. This focus addresses the critical gap between technical development and sustainable patient adoption. Second, comprehensive IoT health care scope: we encompass the full spectrum of IoT health care applications—from consumer wearables to sophisticated IoMT systems, telemedicine platforms, remote monitoring solutions, and smart hospital services—providing a holistic understanding across diverse implementation contexts rather than being limited to specific device categories or clinical applications. Third, moderator and interaction analysis: we explicitly investigate how contextual factors—particularly digital literacy, age, health conditions, and geographic contexts—moderate relationships between acceptance determinants and adoption outcomes. This analysis reveals not merely that factors influence acceptance, but how and for whom these effects operate, enabling more targeted and effective interventions.

Fourth, comprehensive barrier and strategy synthesis: we provide a systematic analysis of both barriers to acceptance (with prevalence across studies) and evidence-based enhancement strategies, creating actionable guidance for implementers, designers, and policymakers. Previous reviews emphasized either barriers or facilitators but rarely synthesized both with equal depth alongside practical strategies. Fifth, larger and more recent evidence base: with 62 studies covering the years 2016 - 2024, we capture both established patterns and emerging trends, including 55% (34/62) of studies from the 2022 to 2024 period reflecting recent technological advances, policy developments, and postpandemic shifts in health care delivery. This temporal coverage enables identification of evolving acceptance patterns and future trajectories. Sixth, explicit equity analysis: we systematically address the digital divide and equity considerations, examining how IoT health care implementation may differentially affect various demographic, socioeconomic, and geographic groups. This analysis responds to growing recognition that technology adoption can either reduce or exacerbate existing health disparities depending on implementation approaches.

Research Questions

Health care IoT technology integration has fundamentally changed diagnostic paradigms. This SLR is designed to explore the complexity of patient acceptance of IoT technology in health care services. This research question (RQ) focuses on identifying factors influencing patient acceptance of IoT technology and discovering how multidimensional interactions between these factors become supporters or barriers in adopting IoT products and solution implementation in health care services. This research also investigates acceptance enhancement strategies, usage patterns, and how these strategies can be adapted for different patient populations, technology complexity, and cultural contexts to maximize successful adoption and sustainable usage. Building on this positioning and the critical gaps identified in existing literature, our literature review addresses three primary RQs designed to examine patient acceptance phenomena in health care IoT contexts:

RQ1: What factors facilitate patient acceptance of IoT technology in health care services?

RQ2: What barriers hinder patient acceptance of IoT technology in health care services?

RQ3: What strategies have been shown to enhance patient acceptance of IoT technology?

Methods

Study Design

This SLR was designed and reported in accordance with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 statement, including the PRISMA 2020 flow diagram for study selection and explicit reporting of the search, screening, eligibility, and inclusion steps. The completed PRISMA 2020 27-item checklist is provided in Checklist 1. PRISMA 2020 was selected because it provides updated reporting guidance reflecting contemporary methods to identify, select, appraise, and synthesize studies, improving transparency and reproducibility of systematic reviews [21].

Information Sources

A comprehensive systematic search was conducted across eight electronic databases: PubMed/MEDLINE, Scopus, IEEE Xplore, Web of Science, ScienceDirect, ACM Digital Library, ProQuest, and Google Scholar, covering publications from January 2016 to December 2024. Literature searches were conducted comprehensively and systematically across major electronic databases covering a broad spectrum of scientific publications in health technology, medical informatics, and technology acceptance fields. Databases used included PubMed/MEDLINE

XSL•FO
RenderX

as the primary database for biomedical and health literature providing access to millions of papers from leading journals in health and medicine fields, Scopus as the largest multidisciplinary database covering literature from technology, engineering, and computer science fields relevant to IoT, IEEE Xplore as a specialized database for technology and engineering publications very important for IoT and embedded systems literature, Web of Science as a broad-coverage database providing citation analysis to ensure quality and impact of analyzed publications [22]. Searches were also conducted on ScienceDirect as a platform providing access to journals from various major publishers in computer science and medical informatics fields, ACM Digital Library as a primary source for computer science and human-computer interaction literature relevant to technology acceptance aspects, ProQuest as a database providing access to dissertations and theses that can provide deep insights into research topics, and Google Scholar as an additional source for identifying gray literature and publications that might not be indexed in primary databases [23].

We operationally defined "health care IoT/IoMT" as connected sensing or monitoring technologies that collect patient-related data via networked devices (eg, wearables, home sensors, and bedside systems) and transmit these data for clinical monitoring, decision support, or patient self-management; studies were considered out of scope if they examined generic telehealth without IoT components or focused solely on backend architectures without patient acceptance constructs, and we mapped extracted determinants to established acceptance frameworks (eg, TAM/unified theory of acceptance and use of technology [UTAUT] and health-behavior constructs) using a construct-to-category figure to reduce construct drift and clarify theoretical alignment. Health care IoT encompasses interconnected physical devices, sensors, and systems enabling real-time health data collection, transmission, and analysis within clinical or home settings, including wearables, remote monitoring systems, IoMT devices, and mHealth (mobile health)/eHealth applications.

Inclusion Criteria

Inclusion criteria for this research were established strictly to ensure relevance and quality of studies to be analyzed, including empirical research papers published in English or Indonesian from January 2016 to December 2024 to capture current developments in health care IoT fields during nearly the last decade when this technology began maturing and being widely adopted [18]. Studies meeting inclusion criteria must explicitly investigate IoT technology integration in health care services with primary or significant focus on patient perspectives, experiences, or attitudes as end users of such technology, as well as analyze or explore factors influencing acceptance, adoption, or continued use of health care IoT technology by patients [24]. This research also accepts various research methodology designs, including quantitative research using surveys, experiments, or statistical analysis, qualitative research using interviews, focus groups, or ethnographic observation, and mixed methods research combining quantitative and qualitative approaches to provide a more comprehensive understanding of technology acceptance phenomena [25]. Additionally, all included papers must have undergone rigorous peer-review processes to ensure methodological quality and validity of research findings to be analyzed in literature synthesis [26].

Exclusion Criteria

Exclusion criteria were established to focus analysis on studies truly relevant to research objectives and avoid bias or finding dilution from studies not aligned with the research focus. Articles primarily focusing on IoT technical aspects such as system architecture, communication protocols, data processing algorithms, or hardware development without discussing patient perspectives or acceptance will be excluded from analysis as they do not align with research objectives focusing on human factors in technology adoption [27]. Studies only discussing health care provider, hospital administrator, or medical staff perspectives without considering patient viewpoints will also be excluded as they do not provide insights into end-user acceptance, which is the primary focus of this research [28]. Opinion papers, editorials, comments, and nonsystematic reviews will be excluded as they do not provide the empirical evidence required for systematic synthesis, as will conference abstracts without full text available, as they do not provide sufficient detailed methodological information and findings for quality evaluation and data extraction [29]. Research protocols without empirical results will also be excluded as they do not provide actual findings that can be synthesized to answer formulated RQs [30].

Search Strategy Development

Search strategies were developed systematically using combinations of relevant keywords with Boolean operators to ensure optimal search sensitivity and specificity. The search strategy was developed iteratively, combining three concept groups: (1) IoT or technology terms (eg, "Internet of Things," "IoT," "wearable devices," and "smart devices"), (2) health care terms (eg, "health care," "patient," "medical," and "clinical"), and (3) acceptance terms (eg, "acceptance," "adoption," "barriers," "facilitators," and "perception"). Boolean operators (AND, OR) combined concept groups, with database-specific adaptations for syntax and field tags. The main search formula used was ("Internet of Things" OR "IoT" OR "connected health" OR "smart health" OR "telemedicine" OR "telehealth" OR "mHealth" OR "eHealth" OR "wearable devices") AND ("patient" OR "consumer" OR "customer" OR "user") OR "acceptance" OR "adoption" OR "readiness" OR "willingness" OR "perception" OR "attitude" OR "experience" OR "engagement" OR "trust" OR "retention") AND ("health" OR "health care" OR "health services" OR "medical" OR "hospital" OR "clinic" OR "home care") with syntax adaptations appropriate for each database based on specific search features and the capabilities of each platform [31]. This search strategy was also supplemented with manual searches of references from relevant papers to identify additional studies that might have been missed in electronic searches, and consultations with experts in health informatics fields to ensure completeness of relevant literature coverage [32]. Complete search strategies with database-specific syntax are available in Multimedia Appendix 1.

XSL•FO
RenderX

Study Selection and Data Extraction Process

Data screening extraction was conducted systematically by the first author using a standardized extraction form developed and tested on studies. The form captured: (1) bibliographic information, (2) study design and methodology, (3) participant characteristics, (4) IoT technology types, (5) theoretical frameworks, (6) facilitating factors with prevalence across studies, (7) barriers identified, (8) enhancement strategies, and (9) quality assessment criteria [33]. Study selection processes were managed in three sequential stages to ensure consistency and objectivity in study eligibility determination. The first stage was initial screening involving title and abstract screening of all papers identified through database searches to evaluate general relevance to research topics and basic inclusion criteria, focusing on identifying studies related to health care IoT and patient acceptance [34]. Title and abstract screening was performed primarily by the first author (ZA), with the second author (PWH) providing oversight and validation throughout the process. At the full-text screening stage, both reviewers independently assessed all 297 retrieved records using a checklist-based eligibility form with predefined, categorized exclusion reasons; reviewer decisions were directly compared. Any disagreements were discussed collaboratively until consensus was reached. Interrater reliability was calculated using Cohen κ at the full-text stage: κ=0.89 (95.6% observed agreement), indicating almost perfect interrater agreement. The second stage was full-text screening, where papers passing initial screening were evaluated in detail through full-text reading to determine final eligibility based on established inclusion and exclusion criteria, with special attention to methodological quality and finding relevance to RQs [35]. The third stage was an eligibility examination and final determination involving methodological quality assessment using appropriate evaluation instruments for each study's research design to ensure only studies with adequate methodological quality were included in the final analysis [36].

At the full-text stage, exclusions were documented using predefined, categorized reasons to support auditability of the screening workflow, including the following: (1) not patient-focused (eg, provider-only or institution-only studies), (2) not health care IoT or IoMT (eg, generic telemedicine without IoT components), (3) not empirical (eg, conceptual or commentary papers), (4) insufficient reporting to determine eligibility, and (5) duplicates or nonretrievable full texts; these reasons were recorded in the screening log alongside reviewer decisions and were summarized consistently with the PRISMA flow diagram.

To ensure accuracy, extracted quantitative data (prevalence percentages, sample sizes, and effect sizes) were systematically verified against source documents. All extracted data were organized into comprehensive tables reviewed by the research team for completeness, consistency, and accuracy. Ambiguous or unclear information was flagged and discussed among authors to reach consensus on appropriate categorization and interpretation. The standardized extraction approach ensured consistent data collection across all 62 studies, facilitating systematic comparison and synthesis of findings. The complete data extraction tables for all 62 included studies are provided in Multimedia Appendix 2 [18,19,22-32,34-82]. The software used for reference management and deduplication in this review are Zotero (version 7.0.32; Corporation for Digital Scholarship) and Mendeley Desktop (version 2.142.0; Elsevier.com). For the screening process, we managed the results with Zotero, and figure generation or statistical descriptions were created with Microsoft Visio and Microsoft Excel 365.

Quality Assessment and Risk of Bias

The methodological quality of included studies was assessed using the Mixed Methods Appraisal Tool (MMAT, 2018), which is suitable for reviews including qualitative, quantitative, and mixed-methods studies. Each study was evaluated against five criteria relevant to its methodological category, focusing on study design appropriateness, data collection rigor, analytical transparency, and coherence between RQs, methods, and conclusions. Studies with lower methodological rigor were retained to preserve the breadth of evidence but were interpreted with caution during synthesis. Quality appraisal results were used to contextualize findings rather than to exclude studies. This approach aligns with recommendations for systematic reviews in complex health and technology domains, where exclusion of lower-quality studies may obscure important contextual insights. Full MMAT ratings for each of the 62 included studies are provided in Multimedia Appendix 3 [18,19,22-32,34-82].

The systematic quality assessment of 62 studies using the MMAT revealed predominantly robust methodological quality, with 73% (n=45) achieving good-to-excellent ratings, 23% (n=14) rated as moderate quality, and only 5% (n=3) classified as low quality. Sensitivity analyses confirmed that main findings remained consistent when limited to high-quality studies, strengthening confidence in the synthesis conclusions. However, several systematic biases were identified across the evidence base, including publication bias toward positive findings, geographic concentration in Asia and Europe, and predominance of cross-sectional designs limiting causal inference. The summary of the methodological quality (MMAT assessment) is available in Multimedia Appendix 4.

Risk of bias assessment across studies was conducted considering various factors that could affect validity and generalizability of synthesis findings, including publication bias that might occur due to tendencies to publish positive results, methodological heterogeneity across studies that could affect finding comparability, variations in technology acceptance construct definitions and measurements that could affect result consistency, and selection bias in study populations that might not be representative of general patient populations [37]. Overall evidence quality evaluation was also conducted, considering finding consistency across studies, reported association strength, dose-response gradients, if any, and biological and logical plausibility of findings in technology acceptance theory contexts and health care practice [38].

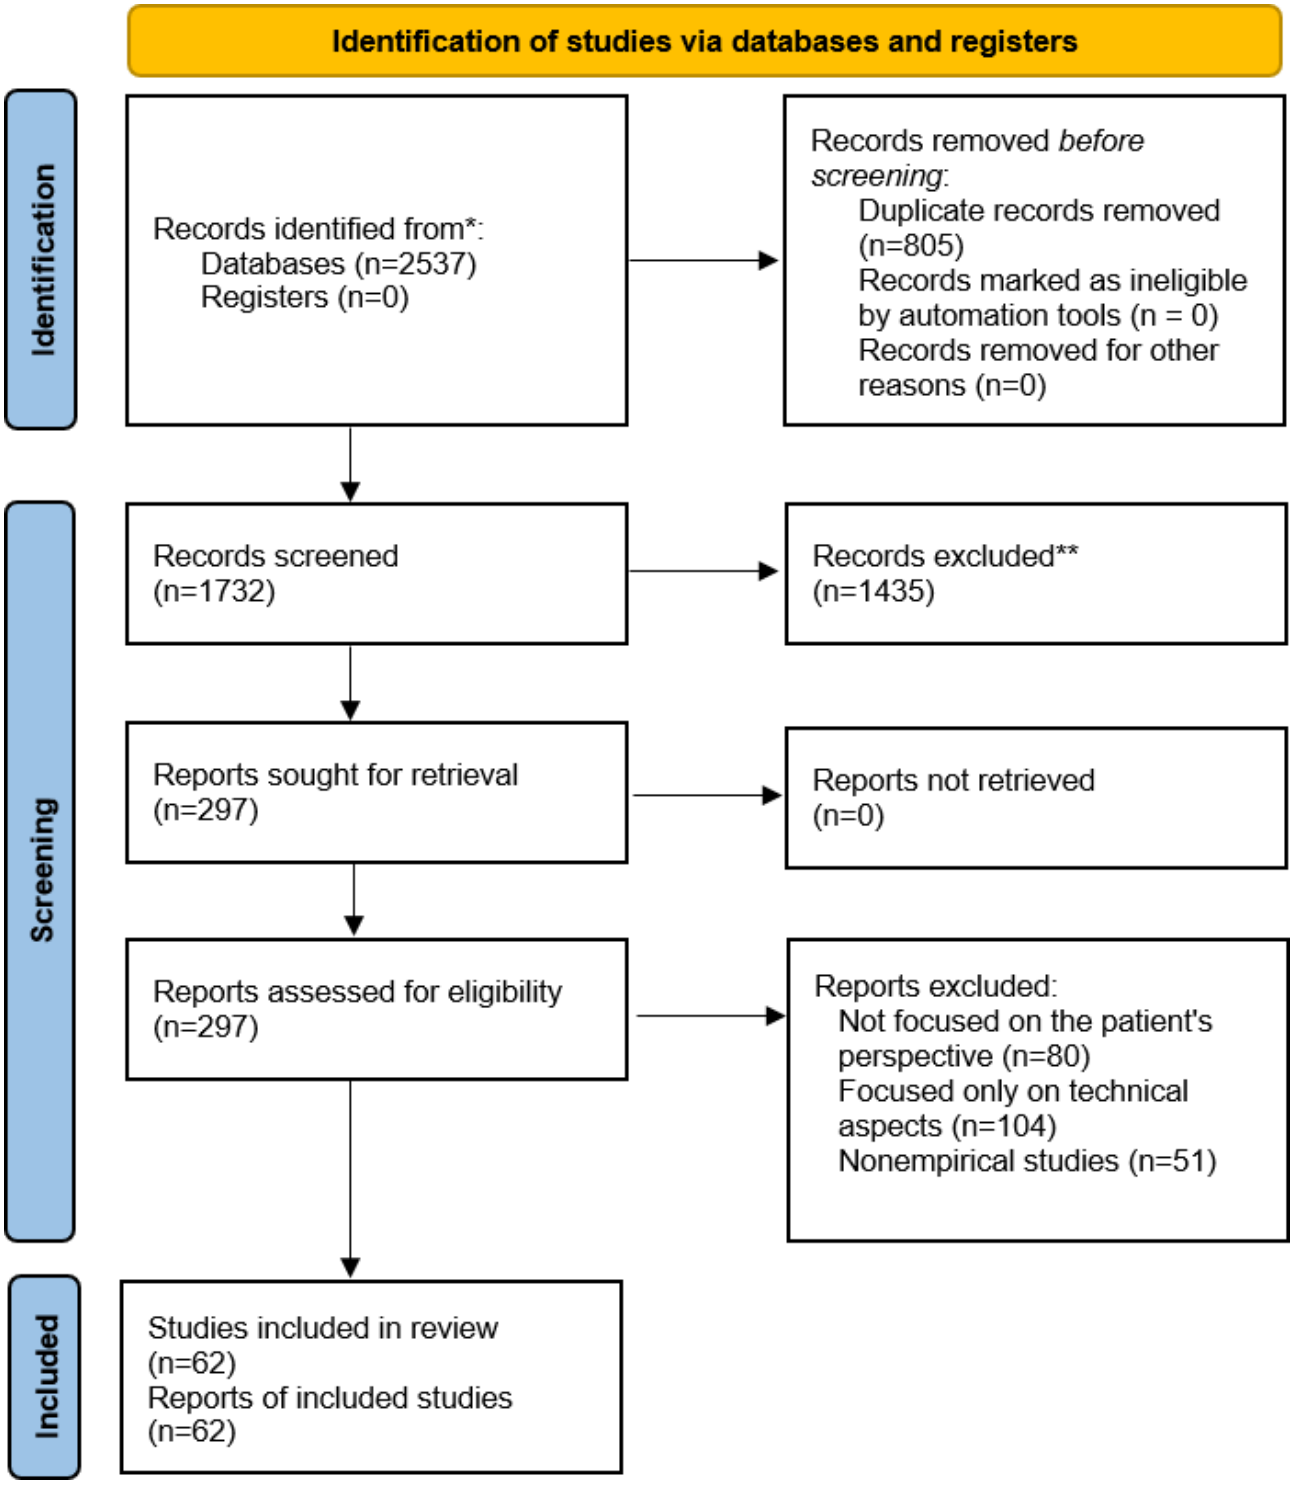
RenderX

Results

Overview



Before reporting findings by RQ, three interpretive conventions are noted. First, all frequencies and percentages in this section use the 62 included studies as the denominator (N=62) unless stated otherwise. Second, this review used a multicoding extraction protocol in which a single study could be coded under more than one thematic category; consequently, the sum of frequencies across categories exceeds 62 and cumulative percentages exceed 100%, which is expected and does not represent error. Third, reported frequencies reflect the number of studies identifying each theme (vote counting) and should be interpreted as indicators of thematic prevalence in the literature, not as mutually exclusive proportions or pooled effect estimates.

Study Selection and Characteristics

Systematic study selection processes resulted in the initial identification of 2537 papers through comprehensive searches across eight electronic databases, which then underwent rigorous screening stages according to the PRISMA 2020 protocol to ensure the relevance and quality of the studies to be analyzed [21]. After duplicate elimination using reference management software and manual verification, 1732 unique papers remained, which then underwent title and abstract screening processes based on established inclusion and exclusion criteria, resulting in 297 papers being deemed eligible for full-text evaluation [18]. Systematic full-text evaluation considering methodological quality, finding relevance, and alignment with research objectives resulted in 62 studies meeting all inclusion criteria and being included in the final synthesis of this SLR in the flow diagram process as shown in Figure 2 (PRISMA study selection flow diagram).

XSL•FO
RenderX

Figure 2. PRISMA flow diagram. PRISMA: Preferred Reporting Items for Systematic Reviews and Meta-Analyses.

Temporal publication distribution analysis shows very significant increases in research interest toward health care IoT acceptance during study periods, with exponential increases in publication numbers, especially in the last three years, where 55% of total studies were published between 2022 and 2024, reflecting progressive development of this field and increasing awareness about the importance of patient perspectives in health care technology implementation [83]. The early period 2016 - 2018 only represents 8% of total studies with a primary focus on the conceptual exploration and identification of IoT application potential in health care, while the transition period 2019 - 2021 shows 37% of studies with a focus shift toward empirical implementation and TAM validation in specific health care service contexts [39,40]. Current phase 2022 - 2024 shows research dominance with 55% of studies exploring complex system integration, regulatory frameworks, ethical aspects, and large-scale implementation, indicating evolution from fundamental research toward practical applications and more comprehensive sociotechnical considerations [27,29].

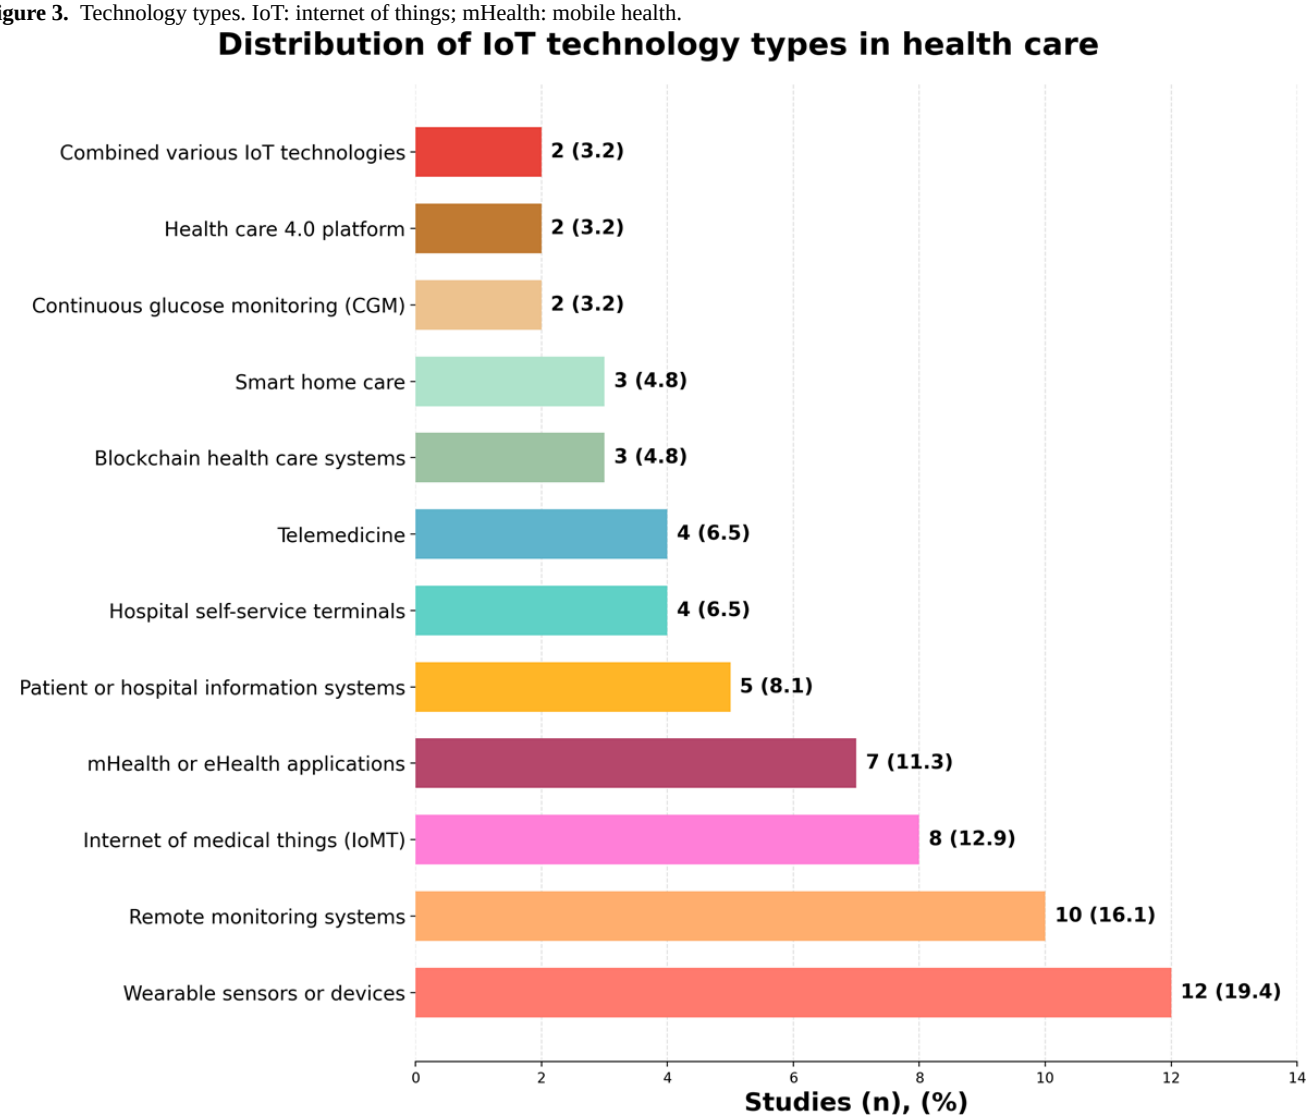
Geographic research distribution reveals fairly diverse global representation but with certain concentrations in regions with advanced research and technology infrastructure. Asia becomes

XSL•FO
RenderX

the largest contributor with 37% of research dominated by studies from China, Malaysia, India, South Korea, and Taiwan, with research focus tending to emphasize technology development aspects, cost efficiency, and practical implementation in rapidly developing health care system contexts [22,23]. Europe contributes 34% of research with even distribution across various countries, including the United Kingdom, France, Spain, and Scandinavian countries, with research characteristics giving greater attention to ethical dimensions, privacy considerations, and regulatory compliance as reflections of strict regulatory frameworks such as General Data Protection Regulation [24,39]. North America represents 8% of studies dominated by research from the United States with emphasis on usability, efficiency, and integration with established health care systems, while the Middle East contributes 13% of studies mainly from Turkey and Saudi Arabia, and the remaining 8% consists of multiregional studies or other regions [41,42].

Methodological and Technological Characteristics

Analysis of research methodologies used in 62 studies shows diversity of approaches reflecting the complexity of health care IoT acceptance phenomena and the need for diverse investigative perspectives. Quantitative studies dominate with 37% of studies using structured surveys, inferential statistical analysis, and structural model testing to identify causal and predictive relationships between various factors and technology acceptance, with common use of models such as TAM, UTAUT, and structural equation modeling to test hypotheses about acceptance determinants [25,43]. Qualitative studies represent 23% of studies using methodologies such as in-depth interviews, focus group discussions, and case studies to explore experiences, perceptions, and sociocultural contexts influencing patient acceptance of health care IoT technology, providing deep insights into nuances and complexities that might not be captured by quantitative approaches [36,44].



Mixed methods research contributes 10% by combining strengths of quantitative and qualitative approaches to provide a more comprehensive understanding and triangulation of findings from various methodological perspectives, while systematic and narrative literature reviews represent 16%, focusing on existing evidence synthesis and research gap identification in health care IoT acceptance domains [18,45]. The remaining 15% consists of model or framework development studies contributing to theoretical and conceptual aspects in understanding technology acceptance phenomena in health care contexts [29,46].

The health care IoT technology spectrum studied shows wide diversity, with complexity levels varying from simple solutions to sophisticated integrated systems. Wearable sensors and personal monitoring devices become the most studied category with 19% of studies, covering fitness trackers, smartwatches, and biometric sensors used for physical activity monitoring, vital signs, and specific health parameters with characteristics of ease of use and minimal invasiveness [47,48]. Remote health monitoring systems represent 16% of research focusing on technologies enabling continuous patient monitoring at home or nonclinical locations, including telemedicine platforms and applications integrated with monitoring devices for chronic condition management [35,49].

IoMT as more specific and complex categories were studied in 13% of studies focusing on connected medical devices integrated within formal health care service infrastructure, including hospital monitoring equipment and integrated health information systems [23,50]. mHealth and eHealth applications contribute 11% of research focusing on mobile applications and digital platforms providing health care services, education, and self-management through smartphones and tablets, often integrated with wearable devices or external sensors [30,35]. Distribution of the eight included health care IoT technology categories—wearable sensors, remote health monitoring systems, IoMT, and mHealth or eHealth applications, among others—is summarized in Figure 3.

XSL•FO
RenderX

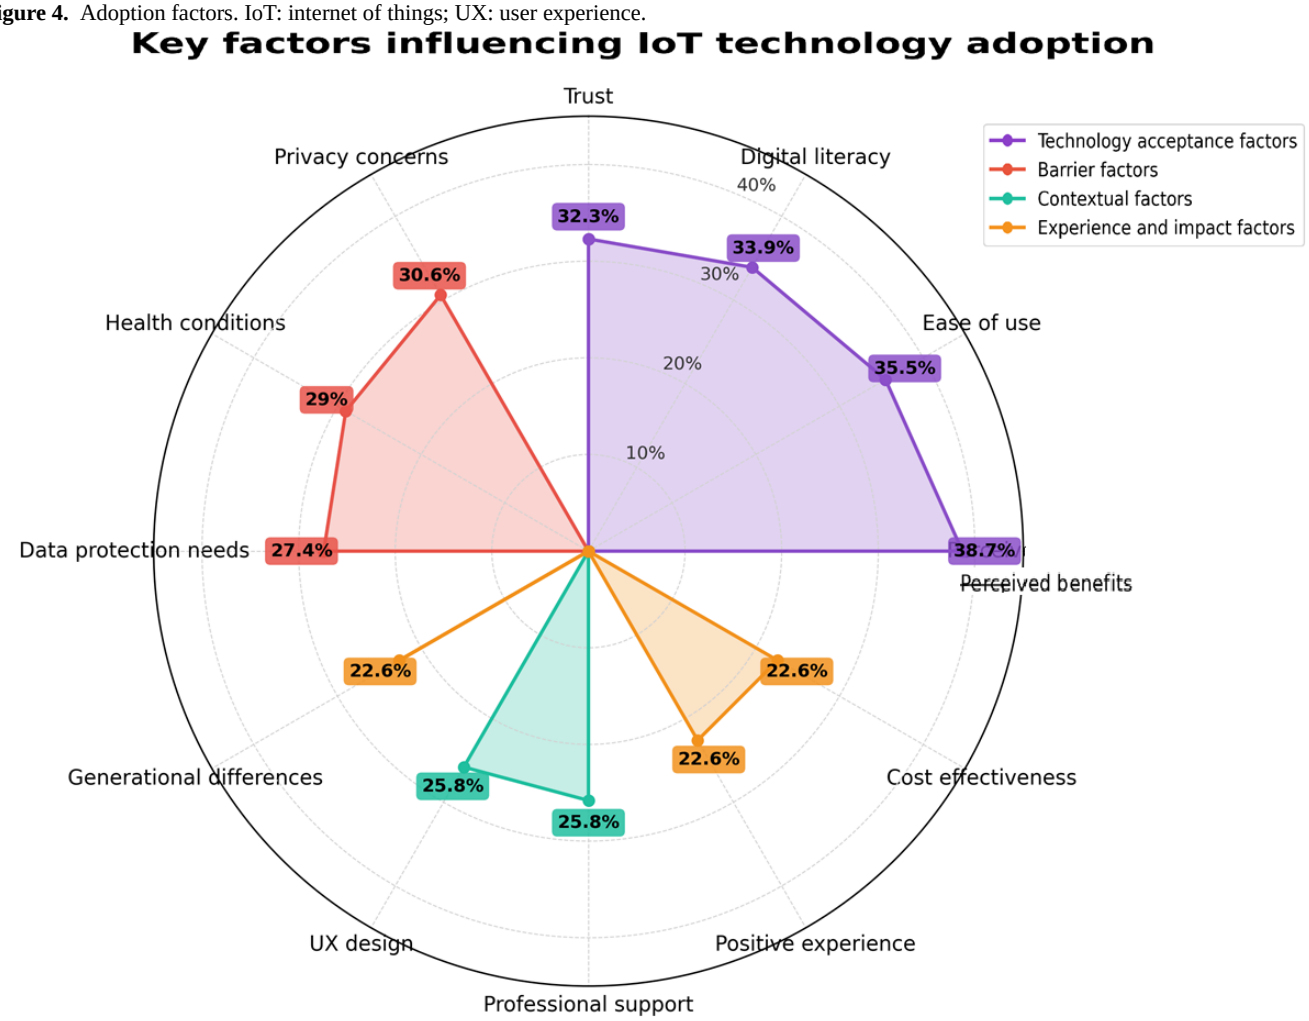
Figure 3. Technology types. IoT: internet of things; mHealth: mobile health.

Theoretical Models and Conceptual Frameworks

Analysis of theoretical models and conceptual frameworks used in the analyzed research reveals significant evolution from increasingly complex and adaptive theoretical approaches to explain multidimensional health care IoT acceptance phenomena. TAM becomes the most dominant theoretical framework used in 29% of research, with applications including testing perceived usefulness and perceived ease of use constructs as primary predictors of behavioral intention and actual use, but with various adaptations and extensions to accommodate specific health care service contexts involving sensitive data and health risks [26,52]. UTAUT and its variations are used in 19% of studies focusing on integration of more comprehensive constructs, including performance expectancy, effort expectancy, social influence, and facilitating conditions, often with the addition of health-specific constructs such as health consciousness and perceived vulnerability to improve model predictive power in health care technology contexts [43,53].

TAM and UTAUT combinations are implemented in 8% of studies attempting to integrate the strengths of both models to provide a more holistic understanding of technology adoption processes, while specialized frameworks and integrated models are developed in 13% of studies combining elements from various technology, health psychology, and sociology theories to create frameworks more suited to health care IoT adoption complexity [25,46]. An interesting theoretical development is the emergence of multitheoretical approaches integrating elements from diffusion of innovation theory, protection motivation theory, and health belief model to explain unique aspects of health care technology adoption involving risk considerations, health benefits, and social norms [43,48].

Theoretical model evolution also shows shifts from individual factor-focused approaches toward sociotechnical frameworks recognizing complex interactions between technology, individuals, organizations, and broader systems. Sociotechnical approaches adopted in several recent studies emphasize the importance of considering implementation contexts, organizational dynamics, and environmental factors affecting not only initial adoption but also continued use and technology integration into daily health care practices [18,24]. Emerging hybrid models also begin integrating temporal perspectives, recognizing that factors influencing initial adoption may differ from factors affecting continued use and long-term satisfaction with health care IoT technology [54,55].



XSL•FO
RenderX

Facilitators of Patient Acceptance Analysis (RQ1)

Analysis of the included studies revealed that perceived usefulness was the most consistently reported facilitator of patient acceptance of health care IoT technologies, identified in 55 of 62 (89%) studies. Patients were more likely to accept IoT technologies when they perceived tangible health benefits such as improved disease monitoring, early detection of complications, and enhanced self-management capabilities, particularly among individuals with chronic conditions. Perceived ease of use was reported in 47 (76%) studies, with usability playing a more prominent role among older adult patients and individuals with limited digital literacy. Trust and perceived security were identified as key facilitators in 42 (68%) studies, highlighting the importance of confidence in data protection, system reliability, and health care provider endorsement.

The findings explicitly refer to RQ1 with an analysis of facilitator factors including the prevalence of perceived usefulness which appeared in 55 of 62 (89%) studies as the strongest predictor with varied manifestations based on the context of health conditions and demographic characteristics, followed by perceived ease of use in 47 (76%) studies which showed a significant variable effect based on digital literacy with high literacy users showing a strengthening relationship between ease of use and adoption intention by 57% while low literacy users showed an increase in the importance of technical support by 64%, and trust as a multidimensional construct in 42 (68%) studies that functioned not only as a direct predictor but also as a mediator between perceived risk and usage intention with high trust strengthening the usefulness-adoption relationship by 37% through the mechanism of increasing data credibility and convenience in sharing sensitive information [43,56]. A radar-plot comparison of the relative prevalence of these facilitator categories across the 62 included studies is presented in Figure 4.

Figure 4. Adoption factors. IoT: internet of things; UX: user experience.

Analysis of theoretical models used in 62 studies shows a significant evolution from a single-construct approach to an integrated multitheoretical framework, with the TAM being the most dominant theoretical framework used in 18 (29%) studies with applications including construct testing perceived usefulness and perceived ease of use as the main predictors of behavioral intention and actual use but with various adaptations and extensions to accommodate health service-specific contexts involving sensitive data and health risks. Further, the UTAUT and its variations were used in 12 (19%) studies with a focus on a more comprehensive integration of constructs including performance expectancy, effort expectancy, social influence, and facilitating conditions, often with the addition of health-specific constructs such as health consciousness and

XSL•FO
RenderX

perceived vulnerability to increase the power of the predictive models in the context of health technologies [43,52,53]. The combination of TAM and UTAUT was implemented in 5 (8%) studies that sought to integrate the strengths of both models to provide a more holistic understanding of the technology adoption process, while specialized frameworks and integrated models were developed in 8 (13%) studies that combined elements from various theories of technology, health psychology, and sociology to create a framework that better suited the complexities of health IoT adoption [25,46].

An important theoretical development identified is the emergence of a multitheoretical approach that integrates elements of diffusion of innovation theory, protection motivation theory, and health belief model to explain the unique aspects of health technology adoption involving consideration of risks, health benefits, and social norms, whereas the evolution of theoretical models also shows a shift from an approach that focuses on individual factors to sociotechnical frameworks that recognize complex interactions between technology, individuals, organizations, and broader systems [24,43,48]. The sociotechnical approach adopted in several recent studies emphasizes the importance of considering the implementation context, organizational dynamics, and environmental factors that influence not only early adoption but also continued use and integration of technology into daily health practices, while emerging hybrid models are also beginning to integrate a temporal perspective that recognizes that the factors influencing early adoption may differ from the influencing factors' continued use and long-term satisfaction with health care IoT technologies [18,24,54,55].

Analysis of Interactions and Quantified Moderation Effects

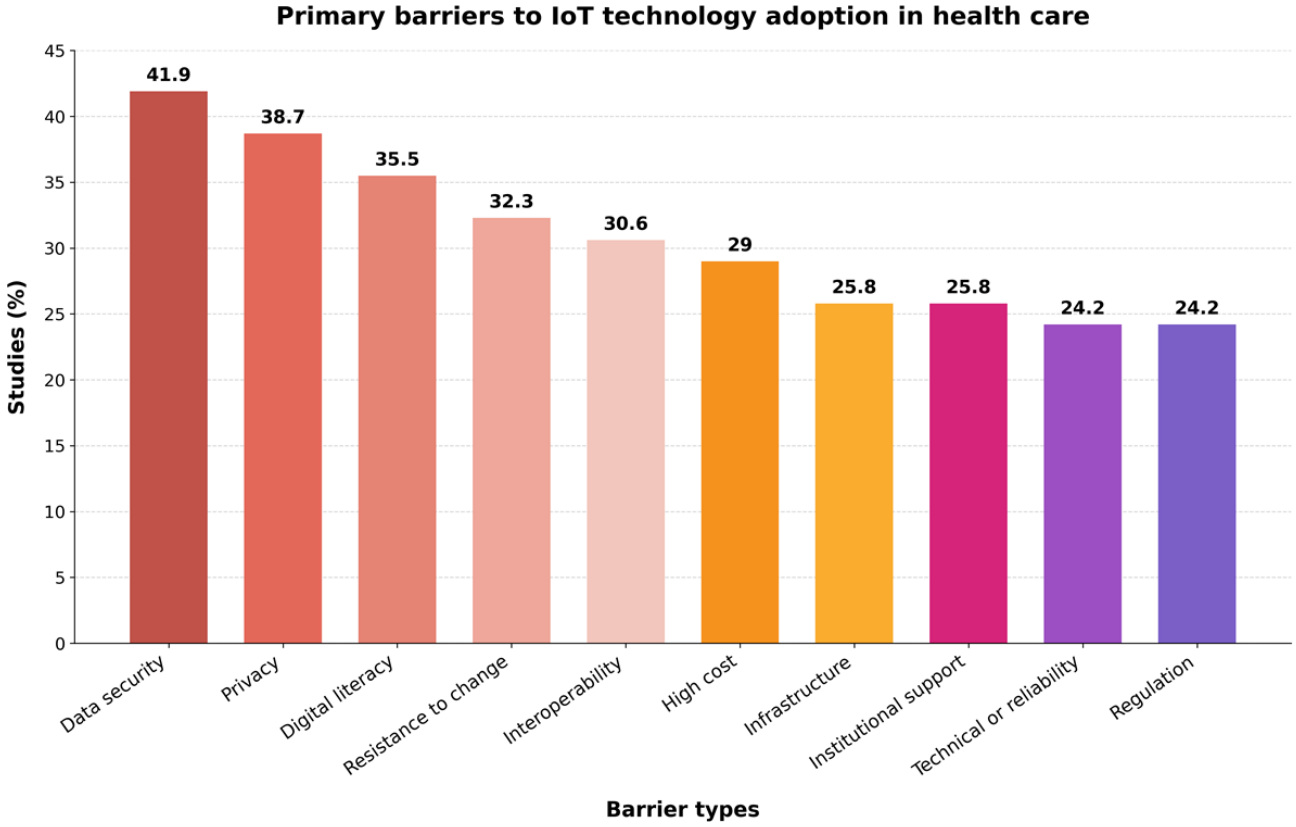
A significant finding is that acceptance determinants do not operate independently but form a complex network of interactions with substantial moderation and mediation effects. In one evidence-based study examining user-based adaptation [56], digital literacy was found to moderate acceptance relationships quantitatively: high digital literacy strengthened the perceived ease of use to adoption intention pathway by approximately 57%, while low digital literacy increased the predictive strength of technical support and training by approximately 64%. These values are specific to the sample and measurement context of that single study and are presented as illustrative estimates of moderation magnitude; they should not be interpreted as pooled or field-representative effect sizes across the 62 included studies. The consistent directional pattern across multiple studies whereby digital literacy moderates acceptance relationships carries greater evidential weight than any single quantitative estimate. Similarly, in one empirical study [43], trust was found to function as a mediator between risk perception and usage intention, with high trust associated with substantially stronger usefulness-adoption relationships; this magnitude estimate is likewise study-specific and presented as illustrative rather than definitive.

Temporal analysis reveals a significant difference between the determinants of early adoption and the factors that influence continued use, where early adoption is more influenced by ease of use, social influence, and technological novelty that provides exploratory motivation and support from the social environment, while usage continuance is more dependent on perceived usefulness that is actually experienced, integration with daily routines that determine the sustainability of use, and measured health outcomes that are meaningful to users who provide positive reinforcement for continued engagement [54,55]. These findings have significant practical implications as they show that strategies to encourage initial trials may be fundamentally different from strategies to promote long-term adoption and prevent technology abandonment in the context of health care IoT, where high abandonment rates reach 50% in the first six months, according to Attig and Franke [16] indicating a substantial gap between initial adoption and sustained use that must be bridged through different strategies.

The complex interaction between acceptance determinants was revealed through moderation and mediation analysis which showed what Ben Arfi et al [43] in an empirical study found, that social influence has a much more important role for older users (IoT immigrants) than younger users (IoT natives) with significantly different effect sizes, while Alruwaili et al [38] in a systematic review identified that older adults with chronic conditions show privacy concerns that are lower than health benefits with a trade-off ratio of 1:3.2, in contrast to older adults without chronic conditions who showed privacy and security concerns 1.8 times higher than other demographics, with family support emerging as a strong mediator of adoption explaining the 42% variance. Fehringer and Stary [56] in an evidence-based study on user-based adaptation identified a significant effect of digital literacy moderation where high digital literacy strengthened the perceived ease of use relationship to intention by 57% and increased the perceived usefulness effect by 23%, while low digital literacy strengthened the influence of support and training by 64% and made anxiety a strong predictor with 47% predictive strength. This indicates that intervention strategies must be adjusted based on the digital literacy profiles of target populations to maximize effectiveness [53,58].

Answer to RQ1: patient acceptance of health care IoT is primarily facilitated by perceived health benefits, usability, and trust in data security and system reliability.

Multilevel Barrier Analysis With a Systemic Framework (RQ2)



For RQ2 on barriers hindering patient acceptance, a comprehensive analysis of the barriers to health IoT adoption at various levels reveals the complexity of the challenges faced in the implementation of this transformative technology, where at the micro (individual) level [58], in a study on health students' perception of IoT identified psychological resistance as a significant obstacle including fear of change which emerged in 20 (32%) studies. Concerns about loss of personal connection with health care providers, anxiety about new technology, and digital literacy deficits that emerged in 22 (36%) studies manifested as knowledge and skill gaps that differed by demographic. At the meso (organizational) level [59], a multicriteria analysis of organizational barriers in Healthcare 4.0 adoption found significant challenges in integration with existing clinical workflows identified in 16 (26%) studies

XSL•FO
RenderX

including disruption to established workflows and double documentation burden, as well as resource limitations that emerged in 14 (23%) studies which included financial constraints and inadequate IT support to support long-term implementation and maintenance [51,60].

At the macro (system) level, Sharma and Joshi [61], in a study on blockchain adoption barriers, identified regulatory ambiguity and uncertainty that emerged in 15 (24%) studies as significant barriers that create hesitancy in large-scale investment, technical interoperability issues between systems identified in 19 (31%) that hinder seamless data exchange and comprehensive view of patient health data, and digital divide in the form of socioeconomic and infrastructure disparities that emerge as fundamental barriers to equitable access and adoption of health care IoT on a broad scale [22,23,31,42]. The identification of barriers at these three distinct levels—micro (individual), meso (organizational), and macro (system)—as found in the studies of Bodur et al, Gardas, and Sharma and Joshi [58,59,61], represents a significant conceptual contribution to understanding the complexity of health technology implementation, where this multilevel approach offers a more comprehensive framework than traditional conceptualizations that tend to focus on technology or user barriers in isolation, consistent with the social-ecological models advocated by Al-Rawashdeh et al and Kronlid et al [18,24]. The relative prevalence of barriers identified at the micro (individual), meso (organizational), and macro (system) levels is summarized in Figure 5.

Figure 5. Barriers to adoption. IoT: internet of things.

Data security concerns emerged as the most dominant barrier in 26 (42%) studies, reflecting the high sensitivity of patients to the protection of personal health information collected, processed, and transmitted by health care IoT devices, where these concerns are not only related to the potential for data leakage to unauthorized parties but also include concerns about the use of data for commercial purposes without explicit consent. Profiling for discriminatory purposes such as insurance or employment decisions and vulnerability to cyber-attacks can compromise privacy and security if attackers gain access to medical devices [27,55,61,62].

Privacy issues identified in 24 (39%) studies include a wide spectrum of concerns ranging from nontransparent data collection and storage practices, lack of control over data sharing with third parties, to concerns about surveillance and monitoring that can reduce autonomy and spontaneity in daily life, where research reveals that privacy concerns in the context of health IoT are related not only to what data is collected but also how often, how long data is stored, who can access it, and for what purposes data is used [29,37,39,43].

The lack of digital literacy found in 22 (36%) studies as a significant barrier refers not only to technical skill limitations but also includes limited understanding of how IoT technology works, what data is collected and how it is used, and inability to assess risks and benefits in an informed manner, where digital literacy barriers also manifest in difficulty problem-solving, inability to adjust settings for personal preferences, and challenges in interpreting data or recommendations generated by IoT systems [38,53,56,58]. Resistance to change identified in 20 (32%) studies reflects natural psychological and behavioral inertia when individuals are asked to modify established routines, learn new skills, or adapt to new ways of managing their health, where resistance to change in the context of health IoT often stems from fear of the unknown, concerns about

XSL•FO
RenderX

technology dependence, preference for human interaction in health care settings, and skepticism about whether technology can truly improve health outcomes or will create an additional burden [44,51,54,63].

Multidimensional Digital Divide Analysis With Equity Implications

An analysis of the digital divide conducted by Wu and Ho [37] in comparative studies on telemedicine adoption barriers reveals the multidimensional complexity of this phenomenon that goes far beyond physical access issues, including primary gaps in the form of urban-rural geographic disparities with a 37% adoption gap indicating significant inequity in technology access based on geographic location, and prohibitive economic barriers for low-income populations where costs are high emerged as a barrier in 18 (29%) studies, with socioeconomic status as a strong moderator of the willingness and ability to adopt health care IoT technology [34,64]. Secondary gaps manifest as digital literacy gaps with 63% variance in effective usage, indicating that even when access is available, the ability to use technology effectively varies dramatically across populations; age-related skill disparities where older populations show lower digital skills and higher technology anxiety compared to younger generations, and educational differences in system navigation abilities that create differential capacity to benefit from health care IoT technologies [38,53].

Tertiary gaps manifest as disparities in gained health benefits with 29% variation indicating that even among users who successfully adopt and use health care IoT technology, actual health outcomes and benefits achieved vary significantly, differences in continued usage patterns where abandonment rates are higher in populations with lower digital literacy and socioeconomic status, reaching 2.3× higher according to Attig and Franke [16], and variation in ability to act on data insights where lower socioeconomic groups show 42% lower capacity to translate IoT-generated data into actionable health improvements, underscoring the complexity of the challenges in achieving digital equity in health care technology implementation [34,37,64]. Wu and Ho [37] conducted an in-depth analysis of the multidimensional digital divide reveals the complexity of this phenomenon that goes beyond physical access issues (primary gaps), including skill disparities (secondary gaps) and variations in obtained health benefits (tertiary gaps), where these findings fundamentally challenge simplistic assumptions that equate the digital divide with access limitations only, and represent paradigmatic shifts toward a more nuanced understanding of digital inequity in health care consistent with the multilevel digital health equity frameworks proposed by Wakili A and Bakkali, and Alruwaili et al [29,38].

Critical implications are that interventions to address the digital divide in health care IoT implementation should be comprehensive and multifaceted, addressing all three gap levels simultaneously as recommended by Gellert et al and Cleveland and Haddara [41,63], which in addressing only primary gaps (providing devices and connectivity) without addressing secondary gaps (building digital literacy) and tertiary gaps (ensuring equitable benefit realization) will fail to achieve true digital equity and may even exacerbate existing health disparities [24,34]. However, significant inconsistencies remain in methodological approaches and digital divide conceptualization across analyzed studies, as acknowledged by Messinis et al and Ziwei et al [27,83], creating challenges in comparing findings and generalizing effective intervention strategies to address digital inequity in health care IoT contexts, indicating the need for standardized frameworks and measurement approaches in future research to enable more robust cross-study comparisons and meta-analyses.

Answer to RQ2: barriers to patient acceptance are largely driven by security, privacy, digital literacy limitations, and resistance to behavioral change.

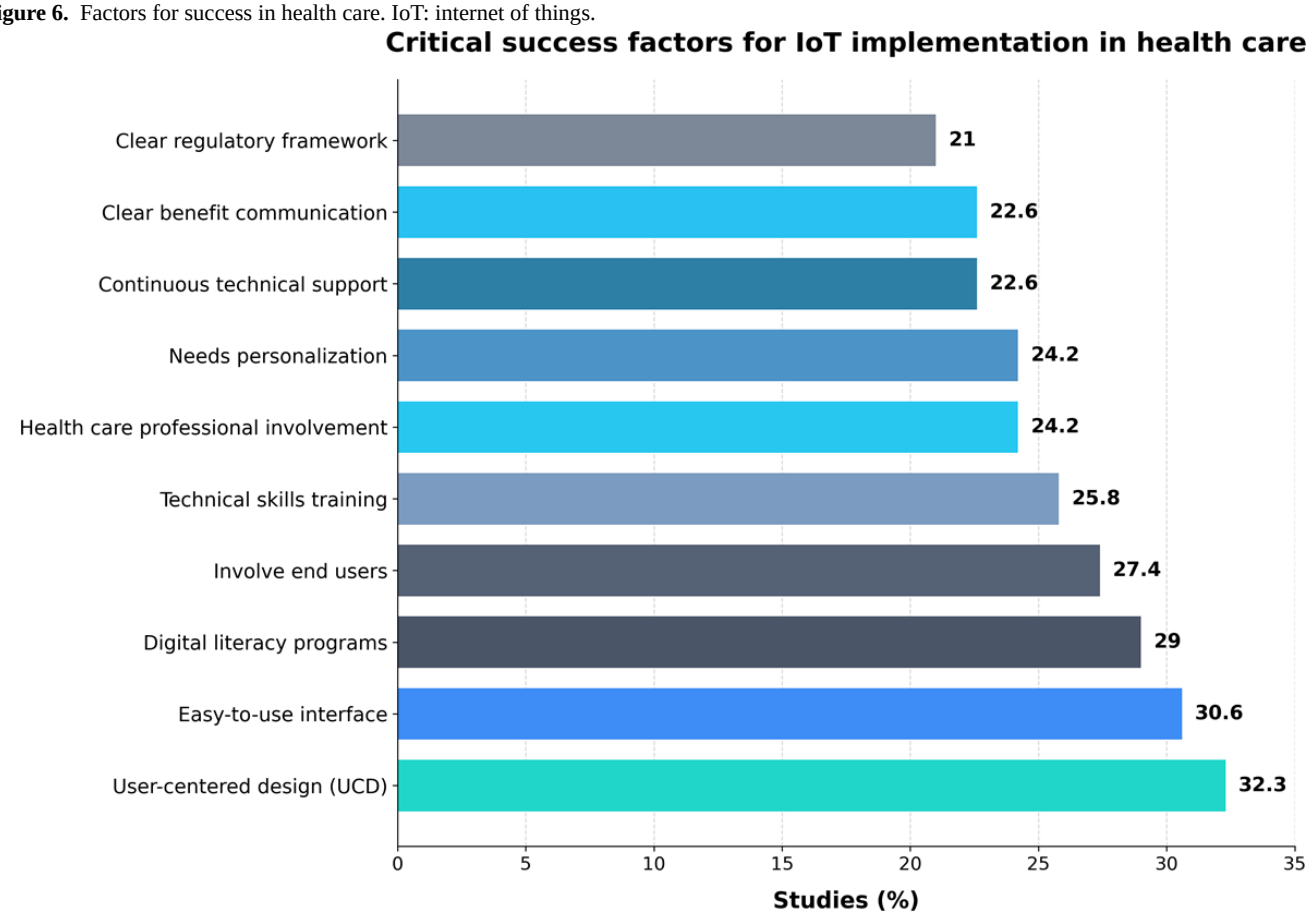
Strategies to Increase Acceptance With Evidence-Based Effectiveness

Enhancement strategies identified across the 62 included studies are presented in order of evidence strength, defined by the frequency of identification across studies and the methodological quality of the supporting evidence base. Three strategies received the most consistent and substantial support at the individual level and are synthesized below; detailed descriptions of all identified strategies across individual, organizational, and system levels are provided in Multimedia Appendix 5 [18,23,24,26,27,29,31,34-39,42-45,48,50,51,53,55,56,59,61-64,66,69,71-74,76,77,79,80,82].

User-centered design (UCD) was the most frequently identified strategy, reported across 20 (N=62, 32%) studies [26,44,50,51,56,69]. The supporting evidence base spans diverse IoT modalities—from smart hospital systems and home monitoring devices to wearable sensors and mHealth platforms—and encompasses both quantitative and qualitative study designs, with 6 of the 20 supporting studies explicitly identified as high-confidence by independent assessment. Core elements consistently described across these studies include participatory design workshops engaging patients, caregivers, and health care providers; iterative prototyping with representative users in realistic clinical scenarios; and usability testing across diverse populations with particular attention to older adult users and those with lower digital literacy. Confidence in this strategy is rated high, reflecting consistency of evidence across multiple geographic contexts and study designs, tempered by the predominantly cross-sectional nature of supporting studies, which limits causal inference about the relationship between UCD adoption and actual acceptance outcomes.

User-friendly interface development was identified in 19 (N=62, 31%) studies [26,38,53,72], with particularly strong emphasis in studies focused on older adult populations and users with lower digital literacy. Studies in this subset consistently described visual design principles that minimize cognitive burden—including clear visual hierarchy, consistent design patterns, and minimal text with iconography accessible across literacy levels—alongside responsive design features for wearable devices and customization options accommodating diverse user needs. Confidence is rated high, reflecting consistent directional evidence replicated across distinct IoT device categories, while noting that most supporting studies assess interface preferences and perceived usability rather than longitudinal adoption behavior.

XSL•FO
RenderX



Digital literacy programs were recommended across 18 (N=62, 29%) studies [38,44,48,53,56,58], representing the most geographically and methodologically diverse evidence base among the three highest-confidence strategies. Supporting studies span Asian, European, and Middle Eastern contexts and include qualitative, quantitative, and mixed-methods designs. Across these studies, effective programs were characterized by progressive skill-building with gradual complexity introduction, multimodal delivery combining hands-on workshops with peer learning and online tutorials, and targeted content addressing not only basic device operation but also data interpretation and privacy management. Confidence is rated high based on consistency across 6 studies, though the quantified moderating estimates associated with digital literacy derive from a single primary study and should not be interpreted as pooled field-level magnitudes.

Beyond individual-level strategies, the evidence base identifies organizational and system-level strategies as essential complements for sustained IoT adoption at scale. At the organizational level [66,67], in their research on smart hospital services and intelligent patient care systems identified evidence-based implementation as a systematic approach to organizational scale implementation, including trials with gradual implementation and phased evaluation that allow learning and adjustment before full-scale deployment, multistakeholder involvement through interdisciplinary design teams and patients' advisory boards that were recommended in 15 (24%) studies, and champion programs with peer influencer models and train-the-trainer approaches that were identified in 12 studies. The clinical workflow integration strategies described by Albahri et al and Westphal et al [68,69] in their study of mHealth frameworks and patient-centered information systems include redesign processes with workflow analysis and optimization that minimizes disruption to established clinical routines identified in 16 (26%) studies, active health care provider involvement in co-design with end users recommended in 15 (24%) studies, and reward systems that provide technology-related performance incentives and recognition for early adopters, collectively facilitating seamless IoT technology integration in daily clinical practice [28,70].

At the system level, Messinis et al and Lodha et al [27,62], in research on IoMT security with AI and blockchain-based systems using IoMT, emphasized the importance of digital health ecosystem development with interoperability standards such as Fast Healthcare Interoperability Resources and open standards recommended in 19 (31%) studies, supporting infrastructure in the form of health information exchanges and connectivity platforms identified in 17 studies, and cloud integration, which provides scalable storage solutions and edge computing for time-sensitive applications, which were found in 13 studies. Supportive policy and regulatory approaches identified by Sahin et al and Binci et al [70,71], in studies on remote monitoring adoption and telemedicine perceptions, include clear regulatory frameworks with streamlined approval pathways and risk-based regulatory approaches recommended in 13 (21%) studies, financial incentives through reimbursement policies and tax incentives for research and development and implementation identified in 11 (18%) studies, and insurance programs with coverage policies for IoT devices and preventive care incentives found in 9 (15%) studies, collectively creating system environments conducive to sustainable health care IoT technology adoption and diffusion [32,41,63]. An overview of enhancement strategies across individual, organizational, and system levels, together with their reported frequency of identification across the included studies, is presented in Figure 6.

XSL•FO
RenderX

Figure 6. Factors for success in health care. IoT: internet of things.

The comprehensive implementation of this strategy needs to consider the complex interactions between levels and stakeholders, where Cleveland and Haddara [63], in an exploratory study on the issue of IoT adoption for diabetes, and Al-Rawashdeh et al [18], in a systematic review of IoT adoption for smart health care, emphasize the importance of an integrated approach that aligns initiatives at different levels (individuals, organizations, and systems) to address barriers to multifaceted adoption, and ensure strategies at one level are supported and reinforced by interventions at another level [24,34].

Answer to RQ3: effective enhancement of patient acceptance requires multilevel strategies addressing technology design, user capabilities, organizational support, and systemic enablers simultaneously rather than reliance on isolated interventions. System-level strategies include clear regulatory frameworks, supporting infrastructure, and financial incentives.

Discussion

Main Findings Synthesis

This review extends existing systematic reviews on health care IoT adoption by explicitly centering patient acceptance rather than institutional readiness or technical feasibility. Unlike prior reviews that predominantly emphasize system architecture or provider perspectives, this study synthesizes empirical evidence on both facilitators and barriers from the patient viewpoint. Additionally, this review integrates contextual moderators such as digital literacy, chronic disease status, and geographic disparities, thereby offering a more comprehensive understanding of acceptance dynamics. By incorporating equity and digital divide considerations, this review addresses a critical gap in prior literature and provides actionable insights for inclusive and sustainable health care IoT implementation.

The evidence base is geographically imbalanced, with included studies concentrated in Asia (23/62, 37%) and Europe (21/62, 34%), with comparatively fewer studies from North America (5/62, 8%) and underrepresentation of many low- and middle-income settings; this distribution may limit generalizability because digital infrastructure, regulatory regimes, and baseline digital literacy vary substantially by region, and therefore the relative salience of determinants such as trust, privacy concerns, and usability constraints may differ in contexts where connectivity, affordability, and health system capacity are more limited. These bias patterns were identified through complementary sources: geographic concentration and cross-sectional dominance were determined through descriptive analysis of extracted study characteristics, while publication bias toward positive findings was inferred from observed outcome reporting patterns across included studies. These judgments are distinct from MMAT appraisal outputs, which assess intrastudy methodological quality rather than between-study reporting patterns.

This SLR reveals multidimensional complexity underlying patient acceptance phenomena toward IoT technology in health care services, where main findings show that health care IoT technology adoption cannot be explained through simple linearity approaches or single deterministic models, but requires a holistic understanding of dynamic interactions between

XSL•FO
RenderX

technological, individual, social, organizational, and systemic factors forming complex and contextual adoption ecosystems [18,24]. Comprehensive analysis of 62 studies shows that perceived usefulness consistently emerges as the strongest predictor of health care IoT acceptance in 89% of studies, but with manifestations varying greatly based on health condition contexts, demographic characteristics, and usage settings, indicating that generic TAMs need significant adaptation to capture specific nuances of health care domains [25,43].

Analysis from various studies reveals a determinant factor hierarchy affecting patient acceptance. Perceived usefulness consistently emerges as the strongest predictor of health care IoT acceptance, followed by ease of use and compatibility with patient lifestyles [30,49,72]. These findings are consistent across various geographic contexts and health conditions, suggesting the importance of a universal clear and visible benefit in driving adoption. Additionally, findings show that determinant factors work in hierarchical systems, where some become prerequisites for others. Trust, for example, not only directly affects usage intention but also acts as a mediator between perceived risk and usage intention. This hierarchy explains why interventions targeting only one adoption determinant (eg, usefulness) may fail if prerequisite determinants (eg, trust) are not met.

However, these hierarchical relationships are not static and can change based on user characteristics. For older users ("IoT immigrants"), social influence plays a much more important role compared to younger users ("IoT natives"), as shown by Ben Arfi et al [43]. Similarly, trust emerges as an important prerequisite for adoption in all age groups, but plays a stronger mediating role between risk perception and usage intention in more vulnerable populations [43]. This shows that TAMs need to consider the moderation effects of demographic and contextual variables, rather than assuming uniformity in adoption determinants across all populations.

Acceptance determinants were found to operate within complex interaction networks rather than as independent predictors, a pattern with important implications for intervention design. The moderating role of digital literacy, documented in individual primary studies [56] and directionally consistent across the corpus, suggests that uniform acceptance interventions are unlikely to be equally effective across populations with varying digital competencies; strategies targeting perceived ease of use may be most impactful for digitally literate users, while technical support and training investments may yield greater returns for lower-literacy populations. The trust mediation pattern identified in one empirical study [43] similarly implies that acceptance interventions should address risk perception and data credibility as prerequisites rather than afterthoughts, given trust's documented role as a gateway construct moderating the usefulness-adoption relationship. Notably, the quantitative magnitudes of these effects are study-specific and cannot be aggregated across the corpus; the practical significance of these moderation and mediation patterns rests on their directional consistency across studies rather than on any single effect-size estimate.

Across included studies, TAM-based models (18/62, 29%) and UTAUT-family models (12/62, 19%) are the most commonly used theoretical lenses, but the literature increasingly extends these frameworks with health care–specific constructs (eg, trust, perceived risk, privacy or security concerns, and support) to reflect ethical and context-sensitive patient decision making; theoretically, this pattern suggests that core TAM/UTAUT pathways (usefulness and effort expectancy) remain foundational, yet explanatory adequacy improves when models incorporate governance-related beliefs (trust or privacy) and capability constraints (digital literacy), thereby supporting a move from single-model explanations toward integrated sociotechnical acceptance accounts in health care IoT.

Temporal analysis reveals significant differences between initial adoption determinants and factors affecting continued use, where initial adoption is more influenced by ease of use, social influence, and technology novelty, while usage continuance depends more on actually perceived usefulness, integration with daily routines, and measured and meaningful health outcomes for users [54,55]. These findings have significant practical implications because they show that strategies for encouraging initial trials may be fundamentally different from strategies for promoting long-term adoption and preventing technology abandonment in health care IoT contexts.

Supporting and Inhibiting Factors for Patient Acceptance

This SLR research shows significant evolution in the health care IoT landscape, from an initial focus on individual devices to integrated ecosystems and platforms combining various devices, services, and data points. Zeadally and Bello [42] underscore how IoT-based connectivity has evolved to improve health care services through integration of various devices and systems, and He et al [23] show that health care IoT ecosystems now encompass various interconnected devices, from consumer wearables to advanced medical equipment, which together provide more comprehensive monitoring and services. This evolution has profound implications for patient acceptance. On the one hand, more integrated ecosystems can improve perceived usefulness and relevance, as data from various devices can be synthesized to provide more comprehensive insights. On the other hand, this creates additional complexity layers in terms of data security, interoperability, and user experience that may affect adoption.

This study also identifies health care IoT convergence trends with other advanced technologies, creating richer digital ecosystems, and changing patient acceptance landscapes. Messinis et al [27] provide comprehensive reviews of IoMT security enhancement with AI, revealing how AI is being integrated with health care IoT to improve security, privacy, and analytical functions. Integration with blockchain, as proposed by Lodha et al [62] for blockchain-based systems using IoMT networks for e-Health care monitoring and Akbulut et al [55] for personal health record access management systems based on IOTA (IOTA Foundation) distributed ledger technology, offers new approaches to address privacy and security concerns that have long been major acceptance barriers. However, these technologies also add complexity to health care IoT ecosystems that may confuse nontechnical users, potentially creating new literacy barriers.

XSL•FO
RenderX

Trends toward edge computing identified by Albahri et al [68] discussing fault-tolerant mHealth frameworks using cloud and edge computing combinations, and Ziwei et al [83] identifying shifts from pure cloud-based models to edge and fog computing architectures to reduce latency and improve privacy reflect changing balances between needs for advanced data analytics and needs for privacy, security, and real-time processing. This balance is crucial for patient acceptance, as it potentially addresses privacy concerns while maintaining advanced analytical capabilities. This technology convergence shows the emergence of "augmented health care" paradigms where digital technologies not only assist but actively expand the capacities of both patients and health care providers. In this context, questions about how users understand and interact with these complex systems become very important for patient acceptance.

This SLR reveals an interesting paradox in health care IoT adoption: while this technology is often promoted to improve human aspects of health care services (through more time for meaningful interactions and more personal care), concerns about depersonalization remain major barriers. Kauw et al [51] identify concerns about care depersonalization as potential barriers to adoption, with some patients emphasizing the importance of human interaction in health care service experiences. This paradox raises fundamental questions about how technology is positioned in health care narratives. When technology is presented primarily as a replacement for human interaction (eg, for efficiency), resistance emerges. However, when presented as an enabler of more meaningful human interactions, acceptance tends to increase. Altinay et al [57] underscore concerns that IoT technology can reduce human aspects of health care services if not implemented wisely, highlighting the importance of implementation narratives and change management strategies in determining patient responses.

Deep analysis of literature reveals fundamental tensions between the potential benefits of health care IoT technology and concerns about privacy, autonomy, and equity, having significant implications for individual adoption decisions and societal implementation policies. Privacy issues identified in 39% of research encompass not only technical aspects of data protection but also fundamental questions about health data ownership and control, rights to be forgotten in continuous monitoring eras, and surveillance potential that can damage therapeutic relationships and patient autonomy [29,39]. Research shows that traditional informed consent models may be inadequate for addressing health care IoT system complexity where data collection is continuous, purposes may evolve, and data-sharing consequences may not be fully predictable at initial consent time [27,55].

Equity considerations emerge as very important issues given health care IoT technology's potential to reduce or worsen existing health disparities depending on how technology is designed, implemented, and accessed. The digital divide identified in various research creates risks that those most benefiting from health care IoT technology—including older adult patients, those with chronic conditions, and individuals from lower socioeconomic backgrounds—may have the lowest likelihood of accessing or successfully using this technology [37,38]. Cost barriers, literacy requirements, infrastructure dependence, and design assumptions favoring younger, more educated, and more affluent users can all contribute to widening rather than narrowing health disparities if not explicitly addressed in technology development and implementation strategies [34,64].

SLR results reveal concerning gaps in health care IoT accessibility and adoption based on socioeconomic status, geographic location, and digital literacy. Studies by Dutta et al and Wu et al [34,53] identify that costs and accessibility are significant barriers to adoption in developing economies and among lower socioeconomic groups. These structural factors often interact with individual determinants, creating inequality cycles where those most needing health care IoT technology benefits are also least likely to adopt them. Low digital literacy, for example, not only hinders initial adoption but also affects ease of use perceptions and ultimately usage sustainability [53,58].

Socioeconomic dimensions of digital inequality identified by Ben Arfi et al [43] about how financial costs negatively affect usage intention, with stronger effects among lower socioeconomic groups, and Wu et al [53] are about higher perceived risks among lower socioeconomic status groups, partly due to concerns about costs and accessibility, which show that digital inequality is not just a function of technology characteristics but also reflects and potentially amplifies broader socioeconomic inequalities.

Research Limitations and Challenges

This SLR has several methodological limitations that should be considered when interpreting findings and applying results to specific contexts. Patient perspective exclusivity is both a strength and a limitation. By focusing on patient acceptance, we provide depth in understanding end-user perspectives but necessarily exclude health care provider, administrator, and policy perspectives that are also crucial for successful implementation. Comprehensive understanding of health care IoT adoption requires synthesis across all stakeholder perspectives, which our review does not attempt.

Language restrictions represent a primary limitation, as our search was limited to English and Indonesian language publications. This exclusion potentially missed relevant studies published in other languages, particularly Chinese, Spanish, Arabic, German, and Portuguese, which are prominent in health care IoT research from respective regions. This language bias may particularly affect the representation of findings from Latin America, the Middle East, and East Asia beyond English-language publications, potentially limiting cross-cultural generalizability of conclusions. Geographic representation bias is evident, with 71% (44/62) of studies from Asia (n=23, 37%) and Europe (n=21, 34%), 8% (5/62) of studies from North America, 13% (8/62) of studies from the Middle East, and minimal representation from Africa, Latin America, and Oceania (n=5, 8%). This distribution may reflect both actual research activity concentration and our English-language search limitation. Findings regarding acceptance factors and barriers may not generalize to underrepresented regions with different health care systems, cultural norms, technological infrastructure, and patient populations.

XSL•FO
RenderX

Database coverage limitations exist despite searching eight major databases. Some relevant studies may have been missed due to database indexing variations, search term limitations, or publication in journals not indexed in the searched databases. Our search strategy, while comprehensive, relied on specific keyword combinations that may not have captured all relevant papers using alternative terminology for IoT technologies or acceptance constructs. Gray literature exclusion means we did not systematically search conference proceedings, dissertations, technical reports, or unpublished studies beyond what was captured in Google Scholar. This decision, made to focus on peer-reviewed evidence, may introduce publication bias as studies with positive or significant findings are more likely to be published in peer-reviewed journals than those with null or negative results. The true extent of failed implementations or low acceptance may be underrepresented in our synthesis.

There was limited subgroup analysis due to available data and reporting heterogeneity. While we identified important moderating factors (digital literacy, age, and health conditions), many included studies did not report sufficient data for systematic subgroup analyses. Our moderator findings therefore rely on studies that explicitly examined these interactions rather than systematic subgroup meta-analyses across all studies. Cross-sectional design dominance among included studies limits our ability to assess causality or track acceptance patterns over time. Most studies examined acceptance at single time points, meaning our understanding of how factors influence initial adoption may differ from factors affecting continued use, but evidence on this distinction is limited. Longitudinal research is critically needed to understand the temporal dynamics of IoT health care acceptance.

Future research needs to address these limitations through more diverse geographic representation, standardized measurement approaches, longitudinal study designs, inclusive recruitment strategies, and systematic attention to negative cases and implementation failures as important learning sources about barriers and facilitators for sustainable health care IoT adoption. Despite these limitations, we believe our systematic approach, comprehensive database searching, rigorous quality assessment, and transparent synthesis methods provide a reliable synthesis of current evidence on patient acceptance of IoT in health care. The consistency of main findings across studies with different designs, populations, and contexts strengthens confidence in core conclusions regarding the importance of perceived usefulness, trust, digital literacy, and the need for UCD approaches.

Practical Implications of Our Approach

This SLR provides significant contributions to diverse stakeholders in health care service ecosystems with comprehensive benefits. From theoretical perspectives, this SLR contributes to the body of knowledge about technology acceptance in health care service contexts by providing a comprehensive synthesis of factors affecting patient adoption, building and expanding existing theories.

For technology developers: implementation teams should prioritize UCD and onboarding that explicitly reduces perceived effort and cognitive burden, particularly for older adults and low-literacy users, because ease-of-use and support features repeatedly emerge as acceptance-enabling conditions in the included literature.

For health care organizations: implementation strategies must be informed by a comprehensive synthesis of facilitators, barriers, and proven enhancement approaches, enabling evidence-based deployment planning.

For policymakers: equity considerations and regulatory frameworks or guidelines need to be identified through systematic analysis of barriers and contextual variations across different populations and settings that facilitate adoption while ensuring patient safety. Policymakers should strengthen governance frameworks that increase patient trust—particularly regarding privacy, security, and accountability—because security and privacy concerns are among the most frequently reported acceptance barriers in this review.

For researchers: identification of methodological gaps, under-researched populations and contexts, and priority areas for future investigation to advance both theory and practice. Future studies should move beyond cross-sectional designs by using longitudinal and implementation-focused methods and by reporting standardized acceptance constructs and context variables to enable stronger synthesis and eventual meta-analytic work.

Future Research Directions

Based on gaps identified in current literature and emerging trends in health care IoT development, several important research priorities emerge that can advance theoretical understanding and practical implementation of patient-centered health care IoT solutions. Longitudinal research represents a primary priority given the current lack of understanding about how adoption patterns, user experiences, and health outcomes evolve over extended periods with health care IoT technology. Multiyear cohort studies tracking users from initial adoption to long-term use can provide important insights into factors driving continued engagement, technology abandonment patterns, evolution in user needs and preferences, and actual health usage and health care impacts of long-term IoT use [30,35]. Comparative research across various cultural, economic, and health care system contexts emerges as a second major priority, given the current geographic bias in the literature and the need to understand how contextual factors affect adoption patterns and optimal implementation strategies. Cross-cultural studies can illuminate how factors such as collectivism vs individualism, power distance, uncertainty avoidance, and other cultural dimensions affect attitudes toward health monitoring, data sharing, technology adoption, and relationships with health care providers in health care IoT system contexts [22,48]. Economic comparative research is also needed to understand how different health care financing systems, insurance models, and economic development levels affect access and sustainability of health care IoT interventions.

Implementation science research represents the third critical priority, focusing on understanding how evidence-based health care IoT interventions can be successfully translated into real-world practice settings with diverse stakeholders, competing

XSL•FO
RenderX

priorities, resource constraints, and complex organizational dynamics. Implementation research can answer questions about optimal training models for health care providers, effective strategies for patient orientation and support, sustainable financing models for long-term technology maintenance and updates, integration approaches minimizing workflow disruption, and scaling strategies maintaining fidelity while adapting to local contexts [60,69]. Methodological innovation represents the fourth priority area, with a need to develop new research approaches that can better capture the complexity of health care IoT adoption and use. This includes the development of standardized outcome measures for evaluating health care IoT interventions, the integration of objective usage data with subjective reports for comprehensive understanding of user experiences, participatory research methods involving patients as research partners in designing and evaluating health care IoT solutions, and mixed reality research approaches that can study health care IoT use in natural settings while maintaining experimental control [44,50]. Emerging technology research represents the fifth priority, given rapid innovation in fields such as AI integration, voice interfaces, augmented reality, blockchain applications, and edge computing that can significantly change health care IoT capability landscapes and user experiences. Research in these emerging areas needs to proactively address user acceptance factors, ethical implications, implementation challenges, and potential unintended consequences before technologies are widely deployed, rather than studying acceptance after technologies are already established in markets [27,62].

Conclusions

This SLR of 62 studies published between 2016 and 2024 provides comprehensive evidence that patient acceptance of IoT technology in health care represents a complex, multidimensional phenomenon requiring holistic approaches that extend beyond technical sophistication to encompass human, organizational, and systemic considerations. With appropriate attention to patient perspectives, UCD, digital equity, and multilevel implementation strategies, IoT technology holds substantial potential to transform health care delivery toward more proactive, personalized, accessible, and effective services. However, realizing this potential requires sustained commitment to placing patients at the center of technology design, implementation, and evaluation processes, ensuring technological advancement serves human flourishing rather than merely demonstrating technical capabilities. The evidence synthesized in this review provides a foundation for such patient-centered approaches, but continued research, evaluation, and adaptation will be essential as both technologies and health care contexts continue to evolve.

Acknowledgments

We want to convey our gratitude to Universitas Indonesia for the continuous support, particularly from the Directorate of Research and Community Engagement. Generative AI tools were not used to generate scientific content, literature searching, data interpretation, or analysis. Grammarly (Superhuman Platform Inc) was used to assist with English language editing, grammar checking, and improving readability, and all text and references were reviewed and verified by the authors to ensure accuracy and originality.

Funding

This research received no specific funding from any funding agency in public, commercial, or not-for-profit sectors.

Data Availability

All data supporting the findings of this systematic literature review are available within this paper and its supplementary materials. The complete PRISMA 2020 checklist, detailed search strategies for all eight databases, screening decisions log, data extraction forms, and quality assessment ratings are provided as Multimedia Appendices. This study's characteristics table for all 62 included studies is provided as Multimedia Appendix 6 [18,19,22-32,34-82]. Raw data from individual included studies can be accessed from the original publications as cited in our reference list. Additional materials, including search strategy documentation and analysis files, are available in the OSF (Open Science Framework) repository [84]. Requests for additional data or clarification should be directed to the corresponding author.

Abstract

Background: Stress, as commonly recognized, is an integral part of modern life and can significantly affect both mental and physical health. While substantial advancements have been made in measuring physical fitness through wearable devices, the detection and assessment of mental stress remain in their early stages.

Objective: The objective of this paper is to review recent studies of wearable-based stress detection in naturalistic settings, with a specific focus on characterizing machine learning frameworks inspired by the model card approach.

Methods: This review was conducted using the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) checklist. A total of 353 articles were identified through searches in databases such as PubMed, MEDLINE, ScienceDirect, IEEE, ACM Digital Library, Web of Science, and Embase. Studies were considered eligible if they collected data from healthy adults in naturalistic settings using wearable devices and used machine learning models for stress detection.

Results: A total of 34 articles met the eligibility criteria, including 11 conference papers, 22 journal articles, and 1 preprint published between 2017 and 2024. From these studies, we analyzed key machine learning modeling decisions such as problem formulation, ground truth determination, and machine learning algorithms. Additionally, we examined the major contributions of each study, focusing on the challenges they addressed and the solutions they proposed. Based on these findings, we proposed a model card framework for reporting machine learning–based, wearable-based stress detection.

Conclusions: This scoping review highlights recent trends in machine learning models for stress detection and measurement using wearable signals. It underscores the need for improved standardization in reporting practices for datasets and key machine learning decisions, as well as the importance of addressing critical challenges associated with data collection in real-world settings. We hope this review will support and strengthen ongoing research efforts, promote knowledge sharing, and promote collaboration among researchers—ultimately advancing the field as a community.

KEYWORDS

mental health; stress detection; naturalistic setting; in the wild; field studies; wearables; physiology; machine learning models; scoping review

Introduction

Stress affects the well-being of many individuals in modern society [1,2]. From an evolutionary perspective, stress is a fight-or-flight response to perceived threat or danger, which prompts necessary survival actions to flee from dangerous situations [3]. However, sustained unmanaged stress may have long-term effects on both mental and physical health [4]. In extreme conditions, it may lead to serious adverse health outcomes such as depression, cardiovascular diseases [5-7], substance abuse, drugs and alcohol addiction, or self-harm behaviors such as suicide [8]. This underscores the importance of timely interventions or management of stress in daily life. Stress detection is fundamental to this type of support system, which permits continuous monitoring of stressful states in naturalistic settings, that is, everyday life. Given their nonintrusive and user-friendly design [9], wearables have been explored to monitor physical fitness, using metrics such as step counts or heart rates. In recent years, there have been emerging interests in using wearables to understand individuals' psychological fitness or well-being, in which stress detection and measurement are the major driving components.

Although stress detection from instruments such as wearables is not new, detecting stress in naturalistic settings poses significant new challenges. For studies conducted in controlled settings [10-12] in laboratory settings, researchers prescribe stress-inducing activities that participants engage with, such as the Trier Social Stress Test, the Stroop Color-Word Interference Test, the Montreal Imaging Stress Task, the Cold Pressor Test,

XSL•FO
RenderX

and the "Sing-a-Song" Stress Test [13]. Similarly, in studies outside of the laboratory, participants may participate in activities that are known to induce stress for some, such as hackathons, driving, or presentations [14]. In contrast, stress detection in naturalistic settings requires individuals to be involved in normal daily activities, often with significant uncertainty regarding the timing, duration, stressor, and stress responses. Moreover, there is additional complexity in dealing with motion artifacts of wearable signals resulting from ambulatory participants [13]. Both issues need to be appropriately addressed for reliable stress detection models.

The massive amounts of high-resolution data collected from wearables provide opportunities to leverage advanced analytics, machine learning (ML), and AI models for stress detection. In recent years, there has been a growing trend in stress detection research using ML as the primary modeling technique. This trend is supported by wearables data collected unobtrusively in naturalistic, real-world settings, driven in part by the availability of large-scale, open-source datasets that attempt to measure psychological constructs such as stress.

While several literature reviews have evaluated studies on wearable-based stress detection, most have focused on cataloging wearables, including their models, sensor types, and factors such as placement, cost, and usability [1,3,15-17].

Several prior reviews have examined aspects of ML-based stress modeling. For example, Namvari et al [16] focused on classification models, which discussed feature engineering approaches and summarized model performance. However, only 5 of the 23 studies included in their review were conducted exclusively in real-life or naturalistic settings. Similarly, the scoping review by Bolpagni et al [3] evaluated 56 studies, of which only 13 were conducted in real-world contexts. Their review primarily focused on preprocessing pipelines, feature extraction methods, and ML model types. Pinge et al [18] reviewed 39 studies in which stressors were predominantly derived from laboratory-induced or controlled stress-inducing stimuli, such as public speaking tasks or exposure to horror movies. Only a small subset of the reviewed studies involved those from free-living conditions. This review summarized preprocessing strategies, feature computation methods, ML techniques (including both classical and deep learning models), and commonly used performance metrics.

In summary, there are several notable gaps in the wearable-based ML-focused review for stress modeling. (1) None of these reviews focus exclusively on studies using data collected in real-world, naturalistic settings. (2) None of the reviews address methodological rigor explicitly, for example, by evaluating whether models use appropriate experimental setups to avoid data leakage [19-22]. This issue is particularly relevant but easy to overlook in wearable studies with repeated measures from the same participants, and failure to account for it can lead to overestimation of model performance. (3) None of the reviews focus on important problem formulation decisions, such as how to appropriately configure the training dataset so that input and output windows are correctly aligned so that it matches the modeling objectives, for example, whether the goal is to detect stress in the present moment (ie, nowcasting) or predict stress in the future (ie, forecasting). (4) There is no review attempting to explicitly tackle the standardization of reporting, for example, by adopting an existing ML model reporting framework such as model card [23]. This scoping review aims to address these critical gaps.

The main contributions of this paper are as follows:

1. Provided a focused review of recent studies on wearable-based stress detection exclusively in naturalistic settings using ML techniques.
2. Analyzed model performance with a focus on methodological rigor, explicitly examining potential threats to validity (eg, data leakage).
3. Analyzed key problem formulation decisions such as input and output window configuration, and distinctions between nowcasting and forecasting problems.
4. Proposed standardized report ML framework in wearable-based stress detection, inspired by the model card model reporting framework.

This review paper is organized as follows: The "Methods" section describes the process used to select papers for review, including eligibility criteria and the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) diagram. The "Results" section presents the dataset features and ML frameworks used in the selected studies. Finally, the "Discussion" section analyzes the findings, identifies limitations, and provides recommendations for future research.

Methods

Overview

We adopt a scoping review approach to systematically identify gaps in the existing literature. Although stress detection has long been studied in laboratory settings, it remains challenging to translate these findings into real-life contexts. As such, our primary goal is to map current research on stress detection, identify existing gaps, and provide an overview of ML frameworks inspired by the concept of model cards. Specifically, this review examines how ML frameworks are used to detect stress in naturalistic settings using wearable sensors. The review is guided by the methodological framework proposed by Arksey and O'Malley [24] and adheres to the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) guidelines (Checklist 1) [25].

Search Strategy

The primary search for this scoping review was conducted in April 2024 across 7 databases: PubMed, MEDLINE, ScienceDirect, IEEE Xplore, ACM Digital Library, Web of Science, and Embase. These databases were chosen for their extensive coverage of recent physiology research on stress detection. Our aim was to identify articles examining stress detection in naturalistic settings using biosignals and wearables. We restricted our search to English-language, peer-reviewed studies published between January 2017 and April 2024 that were available in full text. Initially, we tested various search strings—for instance, using "stress detection" alone yielded too many results, whereas "stress detection" AND ("naturalistic setting" OR "field study" OR "real life") yielded too few.

XSL•FO
RenderX

Ultimately, using more generic terms such as “stress detection,” “wearables,” and “physiology,” combined with AND operators, produced a sufficiently broad yet focused list of results. Research articles involving either primary or secondary data analyses (or both) were included. Primary data analysis refers to studies where data were collected by the authors, whereas secondary data analysis refers to studies using data collected by other researchers, which were either openly available or accessible upon request.

Eligibility Criteria

Studies were deemed eligible for inclusion if they used data collected in naturalistic (real-world or in-the-wild) settings. Here, naturalistic refers to situations in which stress is not experimentally induced or linked to known stress-inducing events (eg, taking a test), but instead reflects stress as it occurs in daily life. This criterion applied even if some studies use multiple datasets, including those from controlled or laboratory environments, provided that at least one dataset was collected in the wild. This decision was motivated by the fact that stress labeling mechanisms in laboratory studies differ fundamentally from those used in real-life or naturalistic contexts, where stress must be explicitly self-reported or otherwise captured from participants during their daily lives, which pose unique challenges. Given the study’s focus on acute stress, only research involving healthy populations in everyday contexts was considered. Consequently, the use of wearable devices was a prerequisite, as they facilitate continuous monitoring in daily life. Recognizing the surge in wearable technology adoption in recent years, the review encompassed studies published between 2017 and 2024. The specific eligibility criteria pertinent to this scoping review are detailed in Textbox 1.

Textbox 1. Inclusion and exclusion criteria.

Inclusion criteria

- Data were collected in naturalistic settings where participants engaged in normal, everyday activities (including work).
- Healthy participants were involved. At least one type of data was collected using wearable devices to capture physiological and/or psychological signals.
- Machine learning models or other advanced data-driven techniques were used to detect stress.
- The study needs to be published in English.

Exclusion criteria

- Data were collected only in controlled settings (eg, in laboratory environments or when participants engaged in known stress-inducing activity such as a hackathon as described in the “Introduction”).
- The participants had been diagnosed with mental health disorders or other chronic conditions.
- No wearable devices were used in the data collection process.
- No machine learning or other advanced data-driven modeling techniques were used to detect stress.
- The study was not published in English.

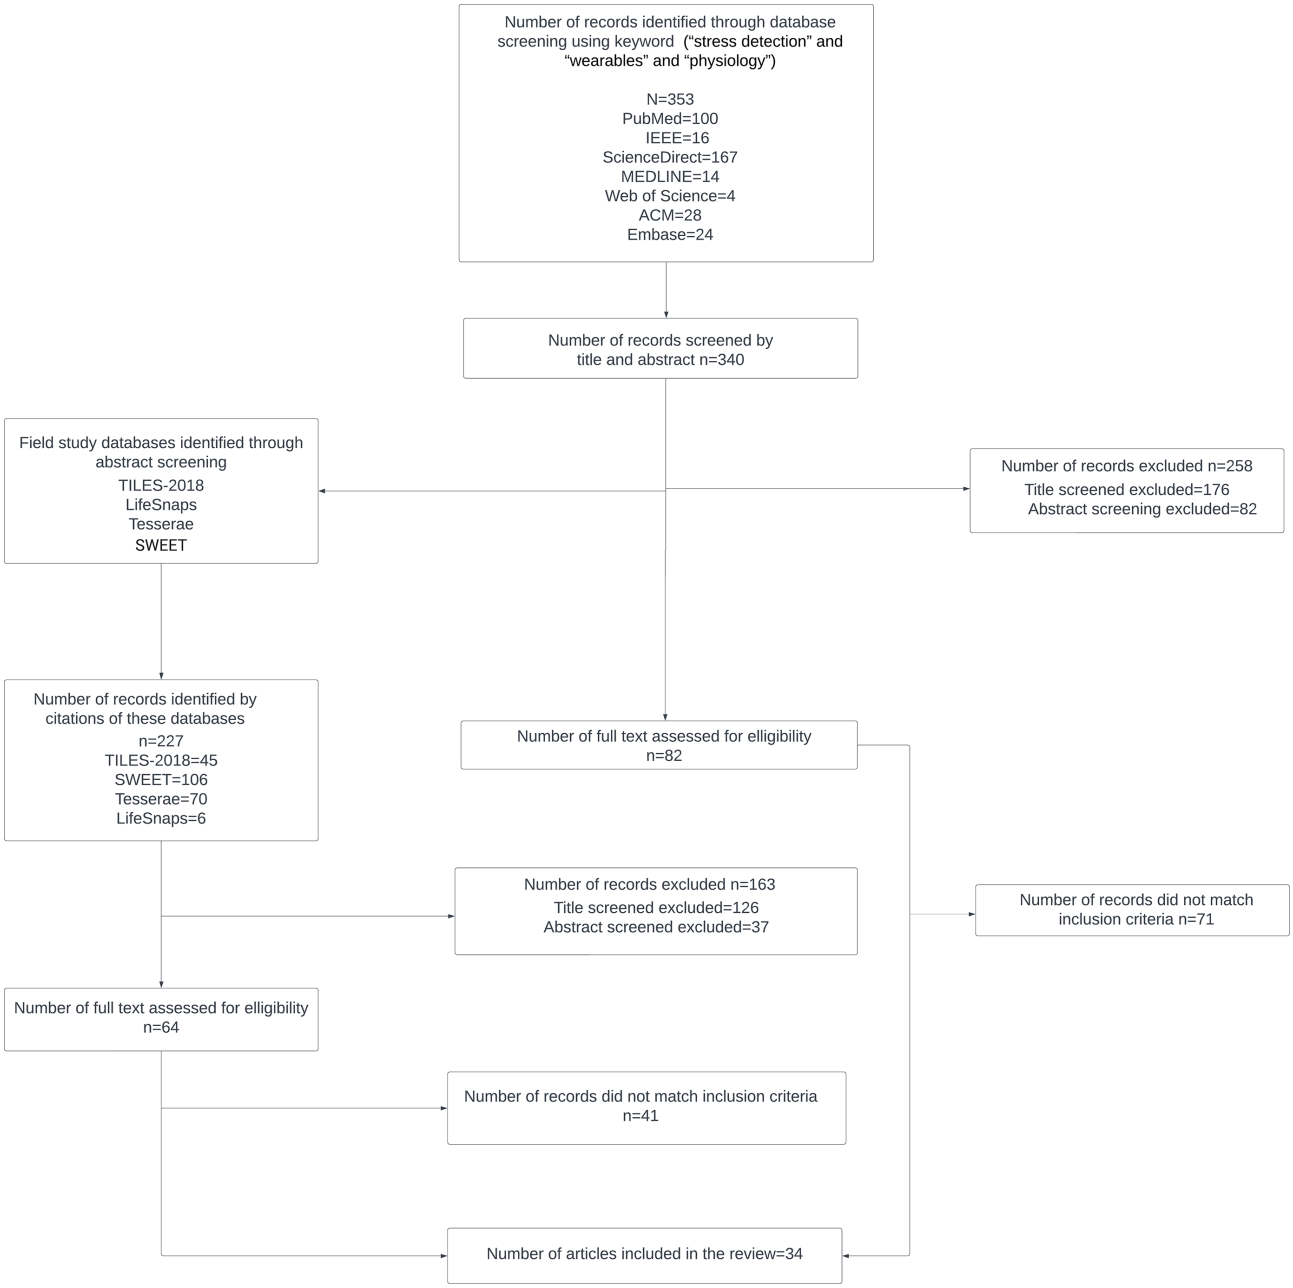
Title and Abstract Screening

We began by applying basic eligibility filters (language and publication year) within the scientific databases themselves. After eliminating duplicate entries, the first author compiled all the retrieved records into a spreadsheet and conducted the initial title and abstract screening using preagreed eligibility criteria. The third author reviewed and verified the screened records and decisions regarding the inclusion and exclusion in the spreadsheet against the same criteria. During abstract screening, we identified publicly available, on-request datasets containing naturalistic wearable data for stress detection and reviewed their citations, adding any studies that used these datasets to our review. Any ambiguities or discrepancies were resolved through discussion until consensus was reached. Since formal full parallel double-screening was not performed, Cohen κ or percentage agreement was not calculated. Finally, the remaining full-text articles were reassessed for eligibility using the specified inclusion and exclusion criteria.

Full-Text Review, Data Extraction, and Analysis

Data extraction involved classifying studies into predefined categories to facilitate evidence synthesis, with a particular focus on the design of ML frameworks inspired by model cards. Extracted data elements included availability of datasets such as indicating whether datasets were open source, available upon request, or collected within the study design, demographic information such as participants' professions, total number of participants, and geographic location, details of wearable devices and biosignals used, duration of data collection, primary research focus such as problem addressed which are either originating from domain-centric or data-centric approaches, and ML models used. Additionally, we examined the formulation of problem statements, including the selection of input and output windows for nowcasting or forecasting tasks. We also assessed validation practices, with particular attention to measures implemented to prevent data leakage, such as appropriate data partitioning and cross-validation techniques.

Results



Literature Search

As shown in the flowchart in Figure 1, a total of 353 articles were identified through database searches: 100 from PubMed, 16 from IEEE, 167 from ScienceDirect, 14 from MEDLINE, 4

XSL•FO
RenderX

from Web of Science, 28 from ACM Digital Library, and 24 from Embase. During the title and abstract screening, 258 articles were excluded for not meeting the eligibility criteria.

Figure 1. Flowchart for paper screening.

During the abstract screening phase, we identified additional datasets that were collected using wearables to model wellness-related constructs in naturalistic settings, for example, TILES-2018 [26], Lifesnaps [27], Tesserae [28], and SWEET [29]. In total, we find 227 secondary analysis papers citing those datasets, with 45 of them using TILES-2018, 106 using SWEET, 70 using Tesserae, and 6 using Lifesnaps. After further title and abstract screening, 163 studies were excluded. This left a total of 146 studies considered for full-text review, with a mixture of primary and secondary analyses. Of these, 71 studies were excluded from the primary data analysis category, and 41 studies were excluded from the secondary data analysis category based on the eligibility criteria. In the end, 34 articles were selected for inclusion in this scoping review. For a detailed description of the search and selection strategy using PubMed, please refer to Multimedia Appendix 1.

Study Characteristics

Overview

Among the 34 selected papers, 11 studies were conference proceedings (32%), 22 were journal articles (65%), and 1 was a preprint (3%). The studies were published between 2017 and 2024. Of these, 24 out of 34 (71%) studies conducted secondary data analysis using datasets collected by other researchers—either open-source or available upon request. The remaining 10 out of 34 (29%) studies performed primary data analysis based on datasets collected by the authors specifically for the reported research. Fitbit was the most commonly used

XSL•FO
RenderX

wearable device, followed by Garmin, Empatica E4, and OMsignal garments. The duration of data collection across studies ranged from a single day to several months.

Dataset Characteristics

Although the dataset is not the primary focus of this review, we provide a brief overview of the dataset characteristics since it forms the foundation for the ML models. A comprehensive overview of the datasets used in the included studies is presented in Table 1. For detailed field descriptions, please refer to Multimedia Appendix 2. The frequently-used datasets as part of the secondary data analysis are TILES-2018, SWEET, LifeSnaps, and Tesserae. The populations represented include clinical providers, office and information workers, police officers, military personnel, university students, and remote workers, while a few studies did not specify the population. The number of participants in the datasets ranged from as few as 3 to as many as 1002. The duration of data collection varied, ranging from 1 day to 10 weeks.

[b]GSR: Galvanic skin response.

Wearables Characteristic

The choice of wearables has a direct impact on the quality and diversity of data collected. A wide range of wearables has been used in these studies to unobtrusively collect data, with the most frequently used devices being the Garmin Vivosmart [22,35,38,39], Fitbit Charge 2 [21,40], OmSignal garment [41,42], Empatica E4 [20,37], Unihertz Jelly Pro smartphone [41,43], and the Imec Chillband [44]. Wearable sensors enable the capture of diverse data types across multiple modalities, including physiological data, for example, heart rate, temperature, and skin conductance [19,32,33,37,40,45-47]. Additional data types were also recorded, for example, phone usage, sleep duration, circadian rhythm, and movement

XSL•FO
RenderX

[21,35,40,48-50], audio signals [21,40,41,49], sociodemographic data [47,50], and environmental data (eg, temperature and humidity) [51]. These modalities provide options for studies to use either unimodal [20,30,36] or multimodal approaches [49,52,53].

ML Framework and Model Performances

In this section, we organize the analysis around key methodological decisions identified across the reviewed studies on wearable-based stress detection in naturalistic settings. At a high level, this task was framed as learning a mapping between the physiological signals collected from wearables and the psychological construct of stress. This was often formulated as a supervised learning framework (either a classification or regression problem), where the inputs are wearable sensing data and the outputs are stress labels.

Due to the nature of the data being collected, the reviewed studies varied across several methodological dimensions. We analyze the model frameworks along the following dimensions:

1. Ground truth stress labels: how the labels are collected and the types of labels collected.
2. Input and output windows: how to set up input-output pairs based on corresponding time windows and how the temporal relationships between input and output windows are informed by the problem being addressed—whether it involves in-the-moment stress detection (ie, nowcasting) or predicting future stress (ie, forecasting).
3. ML experiment design: how to appropriately set up ML experiments, for example, split training and testing data appropriately to avoid data leakage.
4. ML models: the primary ML algorithms used in the studies.
5. Challenges and solutions: the specific challenges that the reviewed papers aim to tackle and the main solutions proposed.
6. Analysis of model performance: analysis of model performance with respect to ML and specific solutions to address challenges, with caveats resulting from issues in reporting and methodological rigor.

Overview of Model Characteristics

Across the 34 included studies [19-22,30-59], the large majority adopted a global, population-level modeling approach, with 28 [19-22,30,32-40,42,44,46,48-50,52-59] out of 34 (82%) studies following this approach, while only 6 [31,41,43,45,47,51] out of 34 (18%) studies pursued personalization or built individualized models. With respect to model family, 21 [19,20,22,30-36,39,40,42,44,45,47,49,51,53,54,58] out of 34 (62%) studies used traditional ML, while 8 [21,37,41,43,46,48,56,57] out of 34 (24%) studies relied exclusively on deep learning. A further 4 [38,50,52,55] out of 34 (12%) studies combined traditional ML and deep learning, and 1 [59] out of 34 (3%) studies additionally incorporated a large language model (LLM), bringing the total share of studies that used deep learning in some capacity to 13 [21,37,38,41,43,46,48,50,52,55-57,59] out of 34 (38%) studies. Reporting of evaluation metrics was assessed among the 22 classification studies [19-21,30-32,35-38,42,44-49,52,55-58]. F_1-score was the most commonly reported metric, appearing in 19 [19,21,31,32,35-38,42,44-46,48,49,52,55-58] out of 22 (86%) classification studies, followed by accuracy in 12 [20,21,30-32,38,44,46,47,56-58] out of 22 (55%) studies, precision in 7 [19,32,36,38,52,57,58] out of 22 (32%) studies, and recall in 5 [32,36,38,57,58] out of 22 (23%) studies. Only 3 [42,52,55] out of 22 (14%) studies reported alternative discrimination or balance-aware metrics such as area under the receiver operating characteristic curve (AUC), balanced accuracy, or Matthews correlation coefficient (MCC), suggesting limited adoption of metrics that are robust to class imbalance. Among the 13 regression studies [22,32,34,38-41,43,50,51,53,54,59], all reported at least one quality measure such as R-squared or mean-squared error (MSE). Potential data leakage was identified in roughly half of the corpus, with 19 [30,32-35,38,39,41,42,44,45,47,49,53-56,58,59] out of 34 (56%) studies judged to have at least one source of potential leakage and the remaining 15 [19-22,31,36,37,40,43,46,48,50-52,57] out of 34 (44%) studies judged to be free of obvious leakage. Finally, in terms of temporal problem formulation, the field is dominated by nowcasting, with 27 [19-22,30-39,42-44,46,48,49,51-56,58] out of 34 (79%) studies framing their task as inferring a current or concurrent state; only 4 [40,47,50,57] out of 34 (12%) studies explicitly framed the task as forecasting a future state, and the formulation could not be unambiguously determined for 3 [41,45,59] out of 34 (9%) studies.

Details of the key components of the ML framework are presented in Tables 2 and 3, which summarize the reported best model performance; please refer to Multimedia Appendix 3 for additional details.

Ground Truth Stress Labels

The goal of ML models is to predict or estimate psychological constructs, such as stress [43]. These constructs are often referred to as ground truth labels or targets within an ML framework. Since data are collected in naturalistic settings, aligning stress labels with physiological data from wearables poses a challenge, as there are no obvious ground truth labels, unlike in controlled environments where the stressor and stress-inducing periods are known with high levels of certainty. In naturalistic settings, stress labels are typically collected from participants through self-report mechanisms, such as ecological momentary assessment (EMA) [45]. EMA involves short surveys delivered through phone-based apps, a method used by most of the studies. In this section, we outline several key decisions involved in collecting ground truth labels using EMA.

XSL•FO
RenderX

EMA Prompts Frequency and Delivery Mechanisms

EMA was most frequently administered daily [48,51,54], capturing a range of psychological constructs. In fewer instances, more frequent assessments were conducted (eg, every 30 minutes or every 2 hours throughout the day) [30-32]. In all studies, EMA prompts were triggered by predefined schedules, with most being delivered via mobile apps, often through custom-developed apps [21,48,51]. A smaller number of studies used SMS messages to deliver EMA surveys [38,39,50].

Response Window

Since the data were collected in real-world contexts, participants were not expected to respond promptly to EMA probes as they may have been busy with other tasks. To control the delay in response and ensure the accurate timing of the label, studies may put an upper bound on the delay, that is, the probe will expire after a certain period of time [32] to ensure the relevance of labels.

Types of Stress Labels and Instruments Used

The most commonly collected psychology constructs in the studies were stress, which occurred in 26 [19-21,30-39,41-48,50,51,55,57-59] out of 34 (76%) studies, anxiety in 9 [22,39,43,50,51,53,55,56,59] out of 34 (26%) studies, positive or negative affect in 9 [22,39,41,43,49-51,53,54] out of 34 (26%) studies. Various instruments were used, including the Short State-Trait Anxiety Inventory (S-STAI) [47,59], which assessed both stress and anxiety, and the Perceived Stress Scale (PSS) [21,48]. Anxiety was also measured using the State-Trait Anxiety Inventory (STAI) [42,56]. The Positive and Negative Affect Schedule (PANAS) short scale [49,53] was used to assess both positive and negative effects.

Stress Measurement Scale

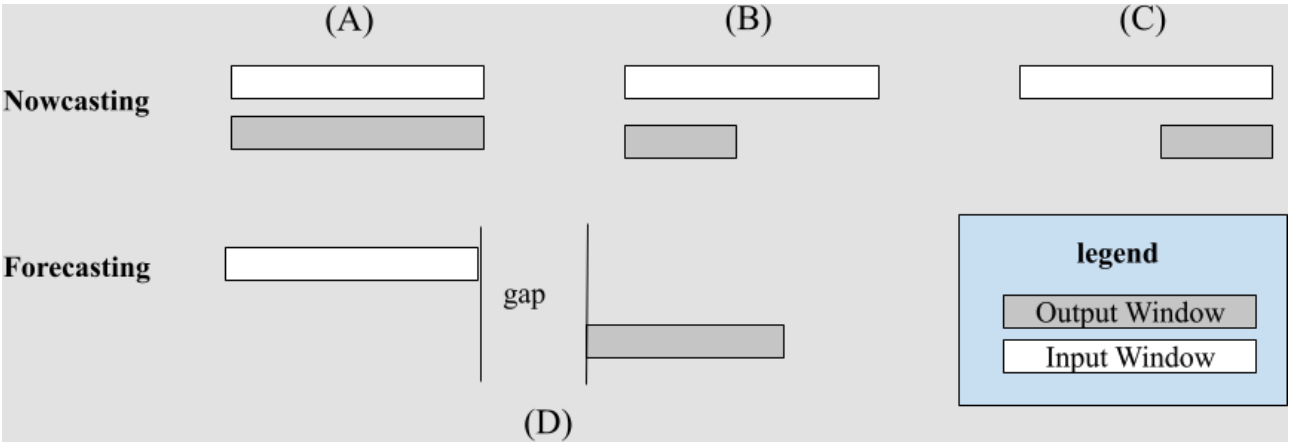
Additionally, different scales were used, such as the Likert scale [31,36,37], Numeric Rating Scale [33], and Visual Analog Scale [35], which is a gliding scale ranging from “not at all” to “extremely.” In a few studies, discrete ordered scales were used to categorize stress levels as low, medium, or high [30,58].

Preprocessing of Stress Labels

There were various preprocessing decisions researchers have made with regard to the stress labels in the reviewed studies. In most studies, the output targets in the ML model maintained the same granularity as the ground truth stress label. However, some studies applied downsampling techniques. For instance, when ground truth labels were collected every 30 minutes, they were aggregated into daily values [20,31] in modeling.

In classification studies, these outputs collected on a numeric scale were often categorized into bins or classes, such as low, medium, or high levels of stress or anxiety [19]. Most studies used binarized output targets for classification, while only a few applied multiclass classification. Due to the ordinal nature of the data, multiple categories were combined into fewer groups. For example, on a 5-point scale, ratings of 0 - 1 were classified as stress, while ratings of 2 - 4 were classified as no stress [19,32]. Another example involves merging the last 3 categories of a 5-point scale into a single “high stress” group, with the first 2 categories remaining as “low” and “medium stress” [44]. For nondiscrete values, such as on a 100-point scale, values below 50 were marked as low stress, and values above 50 were marked as high stress [35].

Two primary methods were used to define classification label thresholds: a personalized approach and a global approach. The personalized approach involved setting thresholds specific to individual participants, whereas the global approach applied the same thresholds across all participants. For personalized thresholds, various statistical methods were used, including majority voting, median calculation, and z-score analysis. The z-score method was the most commonly used [21,46,48,56], where z-scores were calculated for each individual to account for subjective variability. Data were then categorized into 2 classes; for example, negative classes included those with z-scores below zero, and vice versa. In the global approach, values were discretized using predefined scales or thresholds derived from the entire participant sample. For instance, some studies applied fixed global thresholds to classify stress and anxiety levels across all participants [42].



Input and Output Windows

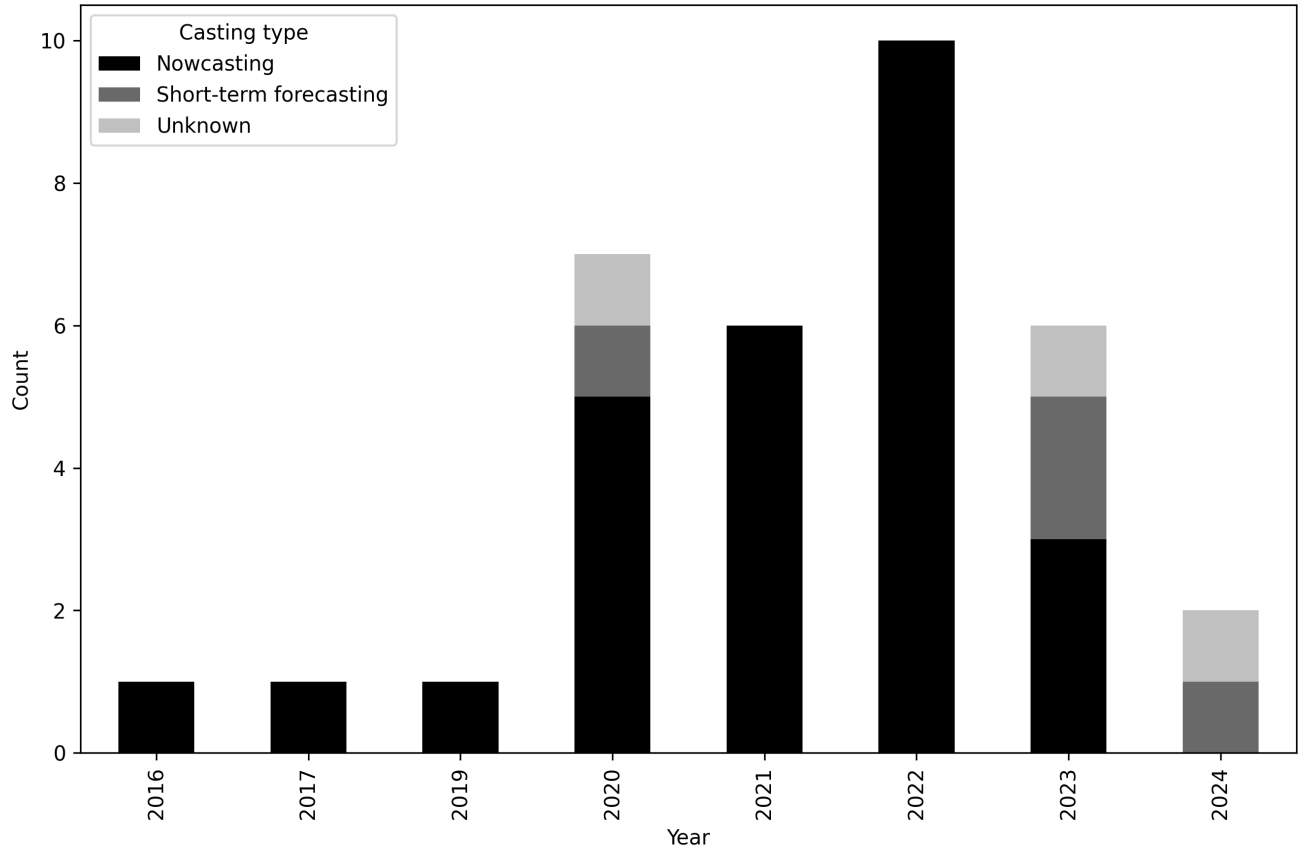
As part of the modeling framework, we extracted the input and output windows reported in the reviewed studies. The input window refers to the time frame from which input features are extracted, typically derived from physiological and behavioral signals. On the other hand, the output window defines the period during which the model predicts target outcomes corresponding to the ground truth labels, as discussed in the “Ground Truth Stress Labels” section.

We use the terms nowcasting and forecasting to describe the relationship between input and output windows. Nowcasting (Figure 2A-C) refers to models that predict outcomes, such as stress, for the present or immediate future, resulting in a very short output window with no gap between input and output windows. In contrast, forecasting (Figure 2D) predicts stress over future time periods, with short-term forecasting focusing on the immediate next period and long-term forecasting predicting stress at a time point extended further into the future.

XSL•FO
RenderX

Figure 2. The relationship between input and output windows; nowcasting versus forecasting.

Several studies have used an exact overlap between input and output windows as shown in Figure 2A, often with a window size of 24 hours [31,51]. A smaller number of studies have used shorter input-output windows, such as every 20 minutes [32], hourly [44], or every 3 hours [35]. This exact overlap is a defining characteristic of nowcasting studies, as illustrated in Figure 1.



Additionally, many studies included partial overlap, where the input window is either longer or shorter than the output window, as shown in Figure 2B and C. For example, an input window might include data from the previous day, the current day, and the next day, while the output window focuses only on the current day [51,52] or both the previous and current days [54]. In other examples, input window is shorter than the output window; for example, the input window covers 1 minute and the output window spans 15 minutes [30], or where the input window is 2 hours paired with a 1-day output window [56], or an input window that selects an optimal range between 10 and 27.5 minutes while the output window remains fixed at 20 minutes [19].

In the forecasting studies identified, the input window is chosen to be immediately adjacent and trail the output window (Figure 2D). For example, the input window may consist of data from the previous day, with the output window set for the current day [40], in which case the gap is zero. In other instances, the input window might consist of data from the last 35, 30, or 25 days, while the output window could be set for 19, 17, or 12 days [57] into the future, starting from the prediction time, in which case the gap is larger than zero.

It has been observed from the selected studies that the majority of researchers have used a nowcasting relationship between the input and output windows, as illustrated in Figure 3.

Figure 3. Number of studies formulated as nowcasting versus forecasting problem, grouped by year.

Addressing Issues of Data Leakage

The reviewed studies differed in how their training, test, and validation sets were split. Since the wearable dataset is longitudinally collected, it is typical to see multiple input-output pairs extracted from the same participants. Data leakage can occur where data points in the training set and test set may originate from the same participant. This made participant-level splitting relevant to the assessment of potential data leakage and possible inflation of reported model performance.

In our review, we observed that 13 [30,32,35,36,41,42,45,47,54-56,58,59] out of 28 applicable (46%) studies [19-21,30-32,35-38,40-48,50-52,54-59] did not explicitly address potential data leakage issues as inferred from the description of the split of training, test, or validation set, while the rest addressed data leakage issues by using strategies such as leave-one-subject-out cross-validation.

ML Models

This section provides insights into the types of ML models used. The studies included in this review primarily focused on supervised learning paradigms, addressing both classification and regression tasks. A diverse range of models was used, spanning traditional ML frameworks to end-to-end deep learning architectures. For feature extraction, most studies relied on statistical summaries [30,31,36], while a smaller subset applied Fourier transformations, particularly for analyzing heart rate variability signals [19,20,42].

Traditional ML algorithms, valued for their simplicity and interpretability, such as support vector machines (SVMs), Naive Bayes, and k-nearest neighbors (KNN), were frequently used. Additionally, various ensemble methods, including bagging and boosting techniques, were widely applied [19,44,45,47,51]. Among these, random forest (RF) was the most commonly used in studies using traditional ML algorithms [19,36,38,44,45,49,50,52,54,58,59].

Table 4 summarizes the most frequently used traditional ML models across the studies.

[a]SVM: support vector machine.

[b]KNN: k-nearest neighbors.

In addition to traditional ML, the use of deep learning models has seen a significant rise. Models explored include recurrent neural networks (RNNs) and long short-term memory (LSTM) networks, convolutional neural networks (CNNs), and LLMs. The choice of models is closely tied to the specific objectives and implications of each study, as discussed below.

Challenges and Solutions

The reviewed studies aimed to address specific challenges, each accompanied by proposed solutions. These challenges were either intrinsic to the data or inherent to the domain. Some common challenges and their corresponding solutions are outlined below

Personalization

Personalization was one of the challenges addressed in the reviewed studies, because of intrinsic between-person variability, as individuals may respond differently to the same stressors. In many of the selected studies, personalization was not considered, thus following a one-size-fits-all approach in modeling. However, a notable number of studies addressed personalization as part of the preprocessing phase. Two key personalization approaches were identified: user-based and group-based. While the user-based approach involves creating a unique model for each participant, the group-based approach groups participants based on selected attributes, such as demographics or gender.

Various clustering algorithms were used in the studies to create cohorts or groups, including k-means, spectral clustering, agglomerative clustering, mean shift, affinity propagation, and Gaussian mixture models (GMM) [51]. Some other studies also used additional techniques to enhance cluster quality, such as iterative clustering [41], which progressively refined participant groupings by repeating the clustering process multiple times. Another method listed in the reviewed studies was dimensionality reduction prior to clustering, which was achieved through principal component analysis (PCA) [43]. PCA simplified the feature space while preserving variance by projecting the data into a lower-dimensional space, whereas self-organizing maps (SOMs) [31] facilitated the organization of complex patterns within the data.

The clusters created during the preprocessing step were further trained using traditional ML techniques (eg, RF, decision trees, and linear regression) [45] as well as deep learning approaches, including metric learning with Siamese neural networks (SNNs) [43]. SNNs transform input data to ensure that similar data points are projected close together, while dissimilar points are spaced apart in the learned feature space. Additionally, feedforward neural networks (FFNs) [41] were used to fine-tune the generalized model by adjusting its weights through iterative training on group-specific data.

Clustering offers several benefits. For example, it may induce more cohesive groups as grouping users with similar characteristics helps the model detect common stress patterns within each group [45]. In another study, the user-based

XSL•FO
RenderX

collaborative filtering method is used by leveraging health information from other users. This type of model can fill gaps within groups and reduce the reliance on historical data from individual users [51].

Temporal Dependency

Data collected from wearable sensors inherently possess a time-dependent nature due to its intrinsic properties. Consequently, studies have explored methods to explicitly address these temporal dependencies to improve model accuracy, with the hope that those methods may reveal complex relationships that conventional ML models may overlook. Various models specifically designed to capture these temporal dependencies are listed below, along with a brief summary of their usage in the selected studies.

1. LSTM networks, designed to capture long-term dependencies in sequential data, were used as bidirectional LSTM (BI-LSTM) in one of the studies [21]. In that study, BI-LSTM captured both past and future values to predict current stress levels in a nowcasting setup. An hourly vector was processed in both the forward and backward directions to analyze data from start to finish and vice versa. The outputs from both directions were combined to generate the final predictions, offering a comprehensive understanding of the hourly temporal context. In another study, a lagged version of the data was explored to highlight trends over time, associating each data point with its historical values, allowing the model to learn from past trends [38].
2. Vector autoregression (VAR) [33] was used to predict current values based on past data through lag selection. Two approaches were taken: predicting sensor outcomes (eg, total sleep time and heart rate variability) using EMA variables such as stress, and predicting self-reported EMA variables based on sensor data. An impulse response function (IRF) was also applied to visualize how changes in predictor variables affect outcomes over time.
3. A hidden Markov model was used to capture how different physiological conditions evolve over time through hidden states. This study [52] aimed to detect both typical and atypical events by modeling physiological data, helping identify patterns that represent normal daily behaviors as well as deviations caused by stress and anxiety.
4. Higher-order networks [22] were used to model temporal dependencies using ensemble learning frameworks, integrating multiple ML models to predict physical, psychological, and job performance variables. These models leveraged time-dependent patterns in physiological signals by incorporating lagged data.
5. Conceptual frameworks such as dynamical systems theory [40] and chaos theory [57] have been applied to capture temporal relationships. One study used a dynamical systems model with linear regression to identify daily patterns of emotional self-regulation and stress spillover in health care professionals, effectively capturing recurring cycles. In another study that used chaos theory, phase space reconstruction was applied to transform low-dimensional data into high-dimensional data by combining stress levels from multiple days as output variables. This approach enabled the model to account for previous days' stress levels, ensuring that similar stress levels appeared closer in the reconstructed space. Additionally, integrating chaos theory with LSTM models that incorporated lagged values improved performance compared to using either chaos theory or LSTM models with lagged values independently.

Multiple Modalities

The feasibility of using all training modalities is often limited in real-world scenarios due to the restricted availability of sensors in wearables. To address this, one study focused on reducing the number of modalities during testing while incorporating more during training [46]. This was achieved using a technique called knowledge distillation, implemented as the "More to Less" framework. Knowledge distillation involves transferring knowledge from a stronger network to a weaker one by using classifier networks from different modalities. During training, the model used all available modalities, with each having its own classifier network. These classifiers exchanged knowledge through adaptive mechanisms defined in the "More to Less" framework, allowing each classifier to learn not only from its own modality but also from those performing better. As a result, testing was conducted with fewer modalities, as the network had already developed robust representations during training. This approach enhanced generalization by leveraging information from multiple modalities, even when fewer input modalities were available during testing.

Bias Mitigation

Bias in relation to demographic groupings was addressed in one reviewed study [56]. In that study, an LSTM model was used by incorporating multitask learning, which included both the protected attribute and the target variable. This approach aimed to mitigate bias related to the protected attribute. To achieve this, different loss weights were assigned. For example, if the target variable (eg, anxiety) is given a weight of 4.5 and the protected attribute (eg, gender) a weight of 0.5, the problem is treated as a multitask learning scenario. Each task has a separate loss function, ensuring that the nonprotected label, such as anxiety in this case, is prioritized.

Context Awareness

Contextual information is widely recognized as crucial in studies aimed at identifying the causes or triggers of stress, as learning context helps improve model accuracy. Various types of contextual data considered in these studies are outlined below:

1. One study compared 2 methods of context collection: ML-derived data, such as sleep and activity, versus self-reported data collected through EMA [44]. The results showed that ML-derived context significantly improved model performance over self-reported data.
2. Another study focused on key stressors among employees working from home, highlighting the role of environmental factors as contextual elements affecting stress and well-being [35]. This approach highlighted the importance of both personal and environmental context in remote work settings.

XSL•FO
RenderX

3. A separate set of studies integrated circadian cycles as a contextual factor for predicting wellness indicators—such as positive affect, negative affect, and life satisfaction—by analyzing data such as audio features, heart rate, sleep patterns, activity levels, and location [49,53].
4. Various models have been used in these studies, including ensemble methods such as gradient-boosted trees (eg, CatBoost), RF, logistic regression (LR), and linear regression.

Addressing Limited Supply of Training Data

Given the complexity of data collection in the naturalistic setting, there is a limited supply of high-quality datasets, along with challenges in capturing ground truth. To address those challenges, a study [54] explored zero-shot learning within a meta-learning framework. This framework incorporated various base learners, including RF, AdaBoost (AB), gradient boosting (GB), KNN, and LR. The approach enabled the model to learn from diverse tasks, allowing it to quickly adapt to new, unseen tasks with minimal additional training. By training on different tasks and populations, the model developed effective initialization weights, improving its ability to make accurate predictions on unseen data.

Use of LLM in Stress Detection

Recently, with advancements in AI, emerging technologies such as LLMs have been developed. These models are pretrained on vast amounts of text and can be applied to a wide range of tasks. One study in the review used LLMs along with wearable sensor data through structured prompts that incorporated user context, health knowledge, and temporal information [59]. The study focused on three approaches:

1. Zero-shot prompting: in this approach, the model received prompts without any prior examples. Models pretrained on task-specific data, such as medical or sensor data, performed better; for instance, Asclepius outperformed larger models.
2. Few-shot prompting: a small number of examples were included in the prompt to provide context for the model. This resulted in improved performance in larger models such as GPT-3.5 (OpenAI) and GPT-4 (OpenAI).
3. Fine-tuning: this method involves adjusting some or all parameters of a pretrained model using a dataset specific to the target task. HealAlpaca achieved the highest accuracy in this category.

Overall, few-shot prompting outperformed zero-shot prompting, while fine-tuning proved to be the most effective approach.

Analysis of Model Performance

In Table 3, we presented a detailed analysis of model performance and extracted key evaluation metrics, such as F_1-score, accuracy, precision, recall, and AUC for classification tasks, and MSE for regression tasks. We reported the best-performing model in each study. Where applicable, we also documented the corresponding model configurations and comparison baselines. It should be noted that data leakage considerations are only relevant for models designed to predict momentary stress labels. Six studies [22,33,34,39,49,53] fall outside this scope, including (1) statistical models (often linear or linear mixed-effects models) that fit the entire dataset to examine coefficient significance or overall goodness-of-fit; and (2) models predicting stable psychological constructs derived from one-time baseline surveys, where the unit of analysis is the individual rather than the event or time point. We identified a total of 13 studies [30,32,35,36,41,42,45,47,54-56,58,59] that had potential data leakage issues out of 28 applicable studies [19-21,30-32,35-38,40-48,50-52,54-59].

There are a few caveats in interpreting performance measures:

1. Substantial heterogeneity exists across datasets and problem formulations (eg, classification vs regression, input and output window configurations, nowcasting vs forecasting, and different discretization strategies for stress labels), making direct, apples-to-apples comparisons challenging.
2. Performance reporting is not standardized across studies. Although F_1-score is the most commonly reported metric for classification, several studies do not report it; in the case of class imbalance (which is often not reported), those metrics may not adequately reflect true model performance.
3. A notable proportion of studies (13 [30,32,35,36,41,42,45,47,54-56,58,59] out of 28 [46%] studies [19-21,30-32,35-38,40-48,50-52,54-59] among those applicable studies) has potential data leakage, most often due to inappropriate data-splitting strategies, which may inflate reported results. In fact, we note a few studies report unusually high performance (eg, with accuracy>85%), many of them with potential data leakage issues.
4. We note that a substantial proportion of studies (approximately 50%) do not report uncertainty quantification for performance metrics, such as CIs, SEs, SDs, or *P* values, making it difficult to determine whether observed performance differences are statistically meaningful or attributable to random variation.

There are several major findings:

1. Across studies, deep learning models achieved F_1-scores ranging from 0.44 to 0.72, whereas traditional ML models exhibited a wider performance range (F_1-score=0.47 - 0.90), making it difficult to draw a general conclusion about the absolute superiority of deep learning approaches. A rigorous comparison would require controlled, head-to-head experiments that hold other factors, such as data modality, problem formulation, or data split, constant. As 2 of those examples, Parousidou et al [45] show that traditional ML combined with personalization can outperform deep learning, while Pimentel et al [55] demonstrate that careful feature engineering enables traditional models to achieve superior performance relative to deep learning methods.
2. We note that performance also varied by modeling strategy: personalization-based approaches reported F_1-scores between 0.62 and 0.66; methods addressing limited data availability achieved F_1-scores around 0.70; context-aware models showed a wide range with F_1-score from 0.41 to 0.90; multimodal integration approaches reported an F_1-score of 0.72; and models accounting for temporal dependencies exhibited wide variability

XSL•FO
RenderX

(F_1-score=0.23 - 0.71). Finally, studies using LLMs reported accuracy values as high as 92%, although corresponding F_1-scores were not provided.

Ethical Considerations

Stress detection applications and associated wearable devices often involve the collection of fine-grained longitudinal data, as well as psychological profile information, either in raw form or inferred through computational models. Such data fall within the realm of sensitive private information and, if inadvertently disclosed, may pose significant risks to individuals. For example, employers could potentially misuse stress or negative affect profiles in human resource–related decision-making processes. In addition, weak data security policies may increase the likelihood of security breaches, which could enable the reidentification of individuals and lead to the leakage of personally identifiable information. Accordingly, research studies on stress detection, as well as the downstream applications built upon these systems, must adopt deliberate and robust measures to safeguard the entire data collection, storage, and processing pipeline. These measures are essential for providing a high level of assurance and protection to individuals, whether they participate as research subjects or engage with such systems as end users of downstream applications. Some emerging approaches may also be explored, such as federated learning, as suggested in one of the reviewed studies [59]. In this approach, raw data remain on the local device where they are recorded, thereby reducing the privacy risks associated with centralized cloud-based data storage and processing.

Equally important is the need for transparent and meaningful informed consent procedures. Data owners should be clearly informed about what types of data are being collected, how the data will be processed and analyzed, who will have access to the data, how long the data will be retained, and whether the data may be reused for secondary research purposes or commercial applications. Such transparency is critical for establishing trust and supporting individuals' autonomy in making informed decisions regarding participation. In addition, participants should be made aware of potential risks, including the possibility of reidentification or unintended disclosure of sensitive psychological or behavioral information. As noted, among the 14 datasets used across the reviewed studies, some based on primary data collection and others relying on secondary datasets, only 11 explicitly acknowledged obtaining proper institutional review board (IRB) approval, whereas the remaining 3 studies did not report such approval [19,20,32]. This observation highlights the continuing need for stronger ethical oversight and clearer reporting practices in stress detection research involving wearable and behavioral data.

Model Card for Wearable-Based Stress Modeling

In this section, we propose a model card framework tailored for wearable-based stress modeling, adapted from the general model card template introduced by prior work [23] in the ML community. The specific focus is on models that enable the momentary estimation of current stress or to forecast stress in the future. The original template includes sections such as model details, intended use, factors, metrics, evaluation data, training data, quantitative analysis, ethical considerations, and caveats and recommendations. Given the unique characteristics of wearable-based stress modeling, particularly the reliance on longitudinal, in-the-wild biosignal data collection and self-reported ground truth, we reorganize and customize the model card into two core components: (1) dataset and (2) modeling decisions. This structure foregrounds the data provenance and methodological choices that most strongly influence model validity, transparency, and reproducibility. A detailed model card for wearables, including its components, dimensions, and reporting requirements, is presented in Table 5 below.

XSL•FO
RenderX

Table . Proposed model card reporting template for wearable-based stress detection models.

Component and dimension	Reporting requirements
Modeling decisions	
Model metadata	• Model creators and affiliated organization • Model version, date, citation, and license • Point of contacts and link to code repository if applicable
Dataset	
Participant characteristics and context	• Participant demographics (eg, age, gender, and occupation) and their distributions • Sample size and duration and frequency of data collection • Geographic locations of participants • Naturalistic context: description of participants' typical daily life (eg, work schedules and routines) and common stressors relevant to the population under study
Wearable devices and signals	• Wearable devices used and placement • Biosignals captured (eg, heart rate, HRV[a], EDA[b], and accelerometry) and sampling frequency
Ground truth annotation	• Target variables (eg, perceived stress) and how they are captured • EMA[c] protocol details, including prompt frequency and scheduling strategy • Response window and compliance requirements • Survey instrument used • Descriptive statistics of target variables, including distributions across demographic subgroups, where applicable
Metadata	• Dataset versioning, documentation, point of contact, citations, licenses, and so on and any relevant contextual metadata (eg, time zones, device firmware, and protocol deviations)
Modeling decisions	
Data preparation	• Preprocessing steps, including handling of missing data, signal cleaning, normalization, multimodal data synchronization, and identification of subgroups
Problem formulation	• Task definition (eg, classification vs regression) • Temporal framing • Task specification • Nowcasting versus forecasting input and output window configurations
Experimental design	• Modeling setup and validation strategy • Data splitting procedures (training, validation, and test) • Assessment of potential data leakage and use mitigation strategies such as subject-level data-split
Modeling approach	• Provide detailed configuration of the model, including those do not perform well • Document hyperparameter tuning strategy and process • Report a variety of performance metrics, including uncertainty measures such as CIs, SE, or *P* value from statistical significance test • Report baseline model performance (including default model) for comparison. Decision thresholds (for classification models), if applicable
Dataset	
Ethical considerations	• Ethical approval (eg, IRB[d] and participant consent procedures) • Recruitment and sampling strategy, and discuss potential of sampling bias • Privacy protection strategy, eg, anonymization

Component and dimension	Reporting requirements
Modeling decisions	
Caveats and recommendations	• Justification of key modeling choices and the specific challenges they are intended to address • Discussion on factors influencing performance, including reporting of disaggregated performance across relevant subgroups where applicable • Discussion on sampling bias and generalization limitations, especially when transferring models across populations, contexts, or devices • Other known limitations, appropriate use cases, and guidance for interpretation

[a]HRV: heart rate variability.

[b]EDA: electrodermal activity.

[c]EMA: ecological momentary assessment.

[d]IRB: institutional review board.

Discussion

Principal Findings

Stress detection has become increasingly important due to the rising prevalence of stress in individuals' daily lives. Advances in wearable technologies have opened new opportunities for detecting stress in real-world settings. This scoping review aims to examine the existing literature on the use of ML applied to data collected from wearables in naturalistic environments for stress detection. In this section, we summarize the principal findings, the identified research gaps, and potential avenues for further investigation, while acknowledging the limitations of this review.

This review identified a lack of standardization in model reporting, which is one of the biggest barriers to advancing the field beyond existing research, and the generalizability of stress detection in naturalistic settings. This is due to substantial heterogeneity in how problem specifications are defined, with no standard format for model reporting, which limits benchmarking across current studies. The reviewed studies differed considerably in the wearables used, ground-truth labeling strategies, input-output window definitions, and ML approaches. We also identified methodological gaps, including potential data leakage, inconsistent reporting of performance metrics, limited handling of class imbalance, and relatively little explicit attention to motion artifacts. In addition, we noted that the reviewed studies addressed a range of challenges, though not uniformly, including personalization, temporal modeling, bias mitigation, modality-related concerns, challenges specific to in-the-wild settings, and the use of LLMs. These findings also motivated the proposed model card specification to improve comparability, transparency, and reproducibility across studies in the future.

Methodological Rigor

In our analysis of model frameworks, characteristics, and performance summarized in Tables 2 and 3, we observed that 13 [30,32,35,36,41,42,45,47,54-56,58,59] out of 28 (46%) applicable studies [19-21,30-32,35-38,40-48,50-52,54-59], specifically, those that developed ML models to predict momentary stress had potential data leakage issues. These issues primarily arise from ignoring the grouped structure of the data, where multiple observations or episodes are contributed by the same participant. When training, validation, and test splits are performed at the observation level rather than the participant level, data points from the same individual may appear in both the training and evaluation sets. This overlap can result in unintended information leakage from training to test data, thereby artificially inflating model performance. A commonly recommended practice to mitigate this issue is to perform data splitting at the subject level, ensuring that all observations from a given participant are assigned to a single split. Given that a substantial proportion of the reviewed studies exhibit this potential methodological flaw, the performance metrics reported in Table 3 should be interpreted with caution, as they may overestimate true generalization performance.

Another issue identified in our analysis of model performance is that a large proportion of studies do not explicitly report baseline model performance. This omission is particularly problematic in the presence of class imbalance, where commonly reported metrics such as accuracy may be misleading. For example, a naïve classifier that always predicts the majority class may achieve deceptively high accuracy, despite providing little meaningful predictive value. Moreover, performance metrics that are more robust to class imbalance, such as the AUC, are rarely reported. While some studies attempt to address this issue by using alternative measures, including balanced accuracy (BACC) or Matthews correlation coefficient (MCC), such practices remain the exception rather than the norm. In addition, we observe that a substantial proportion of studies do not report uncertainty quantification for performance metrics, such as CIs or SDs. The absence of these measures complicates performance comparison across models or approaches, as observed differences may simply reflect random variation rather than meaningful performance gains.

To address these methodological gaps, we explicitly incorporate these considerations into our proposed model card specification, with the goal of encouraging future research to adopt more rigorous experimental designs, performance measures, and reporting practices.

XSL•FO
RenderX

Standardization and Benchmarking

The complexity and richness of data collected from wearables and other devices in real-world settings create ample opportunities to explore a wide range of ML frameworks. While this flexibility allows researchers to pose a variety of research questions and explore various kinds of models, it also poses significant challenges when comparing the utility and performance of different models in tasks such as stress detection and estimation. As demonstrated in our analysis, the lack of standardization in reporting often makes it difficult to extract key specific details about ML modeling decisions, thus limiting the ability to compare model effectiveness across studies. This lack of standard and benchmarking is likely to slow progress in developing robust ML models for stress detection.

Future research could focus on the establishment of benchmark datasets and standardized tasks to enable meaningful comparisons. Additionally, the research community would benefit from adopting consistent reporting standards that ensure critical components of ML frameworks are clearly documented. For example, approaches such as model cards [23] promote transparency and reproducibility. There should also be a stronger emphasis on model quality control, including the adoption of best practices in experimental design to mitigate issues such as data leakage, which may contribute to the inflation of reported model performance. In this paper, we proposed a model card solution specifically tailored to modeling stress in the wild using wearable data, based on our analysis and understanding of the critical issues and related best practices related to modeling decisions, performance analysis, and reporting.

Longitudinal View of Stress: From Nowcasting to Forecasting

A distinguishing feature of real-life stress studies is the ability to examine stress over extended periods and explore its interactions with contextual factors. Despite these opportunities, we observed that most studies adopt a short-term approach to stress detection, where the input and output windows are closely aligned in time. Only a few recent studies have begun to explore forecasting methods that account for long-term temporal trends in psychological and physiological states.

Among the 4 forecasting-oriented papers, 2 adopt a conventional ML pipeline focused on next-day stress prediction. Paraschou et al [47] report an accuracy of 92.3% from a GB ML model, although the evaluation may be subject to data leakage concerns. Another study [50] systematically explores a wide range of input and output window configurations and finds that LSTM-based models generally achieve the strongest performance. In particular, the highest predictive accuracy is obtained when using data from the preceding 15 days (ie, input window=15 days) to predict next-day stress (ie, output window=1 day), although XGBoost (eXtreme Gradient Boosting) models show competitive performance under several configurations. In contrast, the remaining 2 papers adopt dynamic systems modeling approaches [40,57]. Hadjiantonis et al [40] fit a linear dynamical system model that characterizes next-day changes in emotional arousal as a linear function of the current day's perceived stress and emotional arousal, with model parameters estimated via linear regression. Li et al [57], however, model day-to-day perceived stress as a nonlinear dynamical system. The study follows a 2-step approach: first, chaos theory is used to identify the most reliable prediction horizon, which shows that an input window of 19 days maximizes predictability for forecasting stress over the subsequent 35 days. Using phase-space embedding and deep neural networks, the proposed method achieves accuracies of 74.4% for binary stress classification and 69.23% for 3-level stress classification under a person-wise 80/20 split.

We encourage future research to broaden the scope of stress modeling beyond momentary detection, incorporating longitudinal perspectives that capture the ebb and flow of stress over time. Such studies could also investigate the interplay between stress and mediating factors such as sleep, as well as coping strategies such as meditation, to provide a more comprehensive understanding of stress dynamics in daily life. Our review suggests that methodological innovations adopting multivariate and longitudinal perspectives are still emerging. Traditional ML pipelines provide a reasonable starting point by framing stress forecasting as a mapping between multimodal signal streams within predefined input windows and corresponding output windows. However, much of the existing work relies on black-box models that offer limited insight into the underlying mechanisms of stress-related dynamics. A complementary line of research draws on dynamical systems–inspired approaches, including both linear and nonlinear models. Within these frameworks, prediction targets often extend beyond a single future time point to a prediction horizon spanning multiple days or weeks. This shift enables more meaningful and theoretically grounded questions to be addressed, such as the evolution trajectory and long-term trends of stress dynamics over time. Chaos theory–based approaches, in particular, provide a useful lens for understanding the limits of predictability in forecasting future stress trajectories. Li et al [57] represent a promising first step in this direction, and future work could further advance this line of inquiry by incorporating richer, multivariate biosignals from wearable devices in both the input and output spaces.

For both ML-based and dynamical systems–based models, a key challenge in fitting highly complex models lies in data sparsity and limited transparency, as these approaches often require large amounts of high-quality longitudinal data while offering limited interpretability. One promising direction for addressing these challenges is the systematic integration of domain knowledge, such as insights from psychological theory, through principled frameworks such as neurosymbolic systems [60,61], which combine data-driven learning with theory-informed constraints and representations. Advancing such approaches will likely require close multidisciplinary collaboration between computing researchers and domain experts in fields such as psychology and health care.

Addressing Modeling Challenges in the Wild

Data collection in real-life settings, where participants are moving, poses significant challenges to the validity of physiological signals due to motion artifacts. Additionally, it remains unclear to what extent models trained on laboratory-controlled datasets generalize to real-world scenarios.

XSL•FO
RenderX

Our analysis found that only a few studies explicitly acknowledge and address these challenges. To address motion artifacts, a study [42] proposed subband HRV features in addition to traditional HRV benchmark features (time-domain and frequency-domain features). The proposed features were obtained by splitting the HRV tachogram into low-frequency (LF) and high-frequency (HF) bands and analyzing each band separately. From these bands, the authors computed nonlinear features, such as transfer entropy between LF and HF components, as well as spectral descriptor features, such as centroid, spread, skewness, kurtosis, crest, and spectral entropy. The study found that its Fuse-All model, which combined the traditional benchmark HRV features with the proposed subband features, gave better performance than the benchmark features alone. Another study [36] took a deliberate approach to compare the models developed in the lab versus those in the wild. They used a commercial off-the-shelf heart rate monitor in both laboratory and real-world settings on the same cohort of participants to ensure comparability. Stress labels collected in the wild were obtained through EMA-based self-reports. The results showed that the best-performing pipeline involved removing extreme values through trimming (ie, outlier removal), followed by data standardization using z-score normalization (trim_zscore). Furthermore, excluding periods of high physical activity further improved performance in real-world settings.

Model Transparency

In addition to evaluating model performance using common metrics such as accuracy, an equally important aspect of model quality is transparency. Transparent models not only allow for better diagnosis and refinement but also create opportunities for interdisciplinary collaboration with experts from fields such as psychology, who bring deep knowledge of stress and its mechanisms. However, many current modeling approaches rely on black-box methods—particularly those based on deep learning and, more recently, generative AI. While these models may improve performance in certain cases, they also make interpreting results more challenging [59]. Future research should explore modeling approaches that achieve a better balance between transparency and accuracy. By integrating domain knowledge from psychology and physiology, such models could not only predict stress but also explain why certain predictions are made—uncovering not just correlational relationships, but potentially causal ones that offer insights for designing effective stress interventions. Additionally, developing models and systems that facilitate clear communication of model decisions to end users could open a new line of inquiry focused on ensuring human-in-the-loop approaches in stress modeling as explored in the study by Paraschou [47].

LLMs in Wearable-Based Stress Detection

With the rise of LLMs, there is increasing interest in using them for mental health prediction tasks such as stress, anxiety, depression, and sleep disorders. One study included in this review demonstrated promising predictive performance using both larger LLMs, such as GPT-3.5 and GPT-4, and a smaller health-focused fine-tuned model, HealthAlpaca. The study suggested that performance depends not only on model size but also on prompting strategy, contextual information, and domain-specific fine-tuning, with smaller fine-tuned models performing comparably to or better than larger general-purpose LLMs. It also showed that the performance of larger models can be improved by providing examples through few-shot prompting or by adding contextual information to zero-shot prompts. However, several limitations remain. Wearable time-series data are high-dimensional, nonlinear, and continuous, making them more challenging for LLMs than conventional language inputs. In addition, the validity and interpretability of LLM-based predictions remain important concerns due to the lack of standardized evaluation benchmarks for nonlinguistic wearable data. These models also have substantial data and computational demands, as well as the risk of false-positive or hallucinated outputs in health-related settings. Future research should therefore examine explainability, validity, reliability, and whether LLM-based approaches provide meaningful advantages over more conventional models in wearable-based stress prediction.

Data Quality and Validity Considerations

Our review highlights several recurring data quality and validity challenges in wearable-based stress studies conducted in naturalistic settings. In particular, field-collected datasets are often shaped by study design constraints, resulting in nonuniform data distributions, limited sample sizes, short observation periods, and skewed participant characteristics (eg, gender, age, and other demographic attributes). These factors collectively constrain population representativeness and limit the external validity and generalizability of reported findings. In contrast, studies that rely on secondary or publicly available large datasets typically benefit from longer monitoring durations and more heterogeneous participant pools. While such datasets may offer improved statistical power and demographic coverage, they also introduce trade-offs, including reduced control over data collection protocols, labeling procedures, and contextual fidelity. Taken together, these differences underscore the importance of explicitly reporting dataset characteristics and carefully considering how data provenance and study design choices shape model validity and interpretability in real-world stress modeling. In our proposed model solution, we explicitly include sections on dataset characteristics to encourage robust study design, as well as transparency and standardization in reporting.

Limitations

Limitations of this scoping review include the challenge of ensuring that all relevant studies have been included and none have been overlooked due to language constraints, as well as the exclusion of unpublished or ongoing studies. Additionally, we focused on a limited range of databases, which restricts the scope of the studies retrieved. The search criteria and query string used may also limit the outcomes of the scoping review. Rather than implementing full parallel double-screening of all records, we adopted a variant of the screening approach in which one researcher conducted the initial screening, followed by a review by a second reviewer. As a result, interrater reliability metrics, such as Cohen κ or percentage agreement, were not calculated. The absence of formal double-screening and

XSL•FO
RenderX

corresponding reliability statistics may limit the reproducibility of the screening process.

Conclusion

Wearable devices offer valuable opportunities to measure and understand how stress manifests in real-world settings. ML and other advanced computational and statistical methods have increasingly been adopted to develop models that detect, characterize, and understand stress and related psychological constructs from physiological signals captured by wearables, as well as from self-reported data collected at increasingly fine temporal granularity using methods such as EMA. In this focused review, we examined recent studies that apply ML and advanced computational methods to model stress using data from wearable devices in the wild. This review provides an in-depth assessment of current modeling practices and reported performance in this domain and adds to existing reviews by focusing specifically on problem formulation, detailed analysis of model performance, and methodological rigor. In particular, we highlight key problem formulation decisions, such as input and output window configuration, and make the distinction between nowcasting and forecasting tasks, and conduct a detailed analysis of model performance across varied modeling approaches. Through this analysis, we observe a few general patterns of model performance as a function of modeling approaches. We also identify important methodological issues, such as potential data leakage, which may threaten the validity of reported results and inflate reported model performance. We also noted a lack of standardization in datasets, task definitions, and reporting practices, making cross-study comparisons challenging and potentially slowing progress in wearable-based stress detection research. In response to these findings, we propose a model card framework to guide modeling decisions, experimental design, and reporting practices, with the goal of promoting methodological rigor, enhancing transparency, and reproducibility. We hope this review serves as a roadmap for new researchers entering the field, while also offering a framework for researchers working on similar problems to share findings and collaboratively advance the field as a community.

Abstract

Background: As an established driver of hypertension, obstructive sleep apnea (OSA) generates a significant cardiovascular burden when both disorders are present. This intersection not only compromises nocturnal hemodynamics but also hampers long-term clinical management. Yet, current health care delivery rarely integrates the simultaneous and continuous tracking of these dual burdens. While wearable technology provides a noninvasive, pragmatic toolset for synchronized physiological monitoring, research remains largely siloed within single-disease frameworks. Consequently, clinical evidence supporting wearable applications specifically for comorbid populations remains sparse.

Objective: In this scoping review, we summarized the current applications of wearable technology for comorbid OSA and hypertension. The analysis primarily outlines device categories, monitored physiological indicators, prevalent clinical scenarios, and existing challenges.

Methods: The search for relevant literature spanned PubMed, Web of Science, Embase, and IEEE Xplore, covering the period from January 2015 to February 2026. Eligible studies included adults and used wearable or portable technologies to objectively track sleep- or respiratory-related indicators and cardiovascular/blood pressure metrics. Study selection, data charting, and evidence synthesis were conducted using a 2-reviewer process and descriptive and narrative approaches.

Results: Our initial search yielded 739 records. Following title and abstract screening, we reviewed 54 full texts, ultimately finalizing a cohort of 13 eligible studies. Published between 2015 and 2026 across 9 countries, these articles capture data from 5596 participants. Most were observational studies and device validation studies. Evaluated device types included wrist-worn devices, fingertip contact devices, patch and single-lead devices, and multiparameter portable monitoring systems. The clinical applications mainly focused on screening and risk stratification for comorbid OSA and hypertension, monitoring of abnormal nocturnal blood pressure and hemodynamic changes, and cardiovascular risk assessment and remote longitudinal management. However, research remains sparse, and different devices vary greatly in reference standards, diagnostic thresholds, and validation pathways; therefore, their clinical translational value still requires further validation.

Conclusions: Wearable devices may complement traditional assessment by providing continuous nocturnal and longitudinal data. However, at present, they are more suitable as auxiliary monitoring and risk warning tools in comorbidity management and cannot yet replace standard sleep studies or standard blood pressure monitoring. Future research should further shift from feasibility validation to large-sample, prospective, multicenter clinical studies in comorbid populations.

Introduction

Background

Obstructive sleep apnea (OSA) is one of the most common chronic respiratory diseases, affecting approximately 1 billion people worldwide, with the greatest management burden in China, the United States, Brazil, and India [1,2]. OSA has long been regarded as a disease that causes daytime sleepiness and reduced sleep quality. However, increasing evidence indicates that OSA is an independent risk factor for hypertension and a common cause of secondary hypertension [3]. The risk of incident hypertension is doubled in the population with OSA relative to healthy controls. OSA is also highly prevalent among patients with hypertension, particularly in more difficult-to-control cases [4,5]. These 2 conditions often coexist insidiously at night, and each apneic event is accompanied by marked hemodynamic fluctuations. This comorbid state is associated with a greater cardiovascular burden, abnormal nocturnal hemodynamics, and more complex long-term management, and it may also increase the lifetime risk of cardiovascular diseases such as coronary heart disease and stroke [6,7].

The link between OSA and hypertension may involve multiple interrelated mechanisms (Figure 1). The most central mechanism is recurrent nocturnal hypoxia-reoxygenation and hypercapnia. These nocturnal abnormalities can continuously activate the sympathetic nervous system, promote peripheral vasoconstriction, and increase blood pressure [8]. Neuroendocrine dysregulation may also be involved, as abnormal hypothalamic-pituitary-adrenal axis rhythms can lead to elevated cortisol levels and further increase blood pressure [9]. Vascular impairment is further characterized by endothelial dysfunction, which serves as a mechanistic link between the two disorders. Intermittent hypoxic events induce the expression of hypoxia-inducible factors, subsequently modulating downstream mediators such as vascular endothelial growth factor. These molecular events promote structural remodeling and compromise endothelial integrity, leading to an elevation in peripheral resistance [10]. Vascular alterations are exacerbated by inflammatory and oxidative stress pathways. Sleep fragmentation and intermittent hypoxia facilitate a systemic inflammatory response, which is characterized by elevated concentrations of interleukin-6, tumor necrosis factor-α, and C-reactive protein. These inflammatory mediators contribute to the progression of underlying vascular dysfunction [11,12]. Shifts in gut microbiota and metabolic processes can compromise intestinal epithelial integrity and elevate vascular tone [13]. Metabolic factors, including obesity, dyslipidemia, and insulin resistance, further contribute to cardiovascular impairment and reinforce the bidirectional relationship between OSA and hypertension [14,15]. Since these pathophysiological processes are predominantly nocturnal and dynamic, single-point outpatient measurements or assessments focused on a single disease often fail to represent the complete clinical profile of this comorbidity.

Figure 1. Proposed mechanisms linking obstructive sleep apnea and hypertension. CRP: C-reactive protein; HIF-1α: hypoxia-inducible factor 1 alpha; HPA: hypothalamic-pituitary-adrenal; IL-1β: interleukin 1 beta; IL-6: interleukin 6; RAAS: renin-angiotensin-aldosterone system; TNF-α: tumor necrosis factor alpha; VEGF: vascular endothelial growth factor.

At present, comorbid OSA and hypertension are still mostly managed separately across clinical specialties, with limited coordinated monitoring. Traditional data collection relies heavily on patient self-report or occasional in-hospital examinations

RenderX

and cannot provide real-time monitoring [16]. The lack of key continuous nocturnal data makes it difficult to capture the dynamic relationship between OSA and hypertension. In response to these clinical needs, wearable devices have provided new technologies for the continuous monitoring and management of comorbid OSA and hypertension. These devices usually integrate miniaturized sensors into watches, wristbands, skin patches, rings, and glasses, and can continuously and noninvasively collect multidimensional physiological signals such as electrocardiography, heart rate, heart rate variability (HRV), blood pressure, peripheral oxygen saturation, and sleep [16]. Wearable devices are designed for long-term wear and can measure changes in indicators during both daytime and sleep, thereby filling the gap in continuous nocturnal data acquisition in traditional assessment and better reflecting the dynamic relationship between OSA-related events and blood pressure fluctuations [17,18]. Wearable devices are expected to provide more timely and objective information for the screening, monitoring, and long-term management of this comorbid condition.

In recent years, reviews on the application of wearable devices in sleep monitoring, blood pressure monitoring, and chronic disease management have continued to increase. Most existing reviews have focused on a single-disease context of OSA or hypertension, or have only addressed devices, algorithms, and sensing signals [19-22]. There remains a lack of reviews that integrate devices, indicators, validation pathways, and clinical applications within the context of comorbidity management, which limits the overall understanding of their value, applicability, and current limitations among researchers and clinicians.

Aims

This gap in the literature has hindered researchers' understanding of the technology. Therefore, we conducted a scoping review to evaluate the current applications of wearable devices in the screening and management of comorbid OSA and hypertension, analyze recent developments and existing challenges, and inform future research directions.

We specifically addressed four aims: (1) to categorize wearable technologies used for the screening and management of concurrent OSA and hypertension, (2) to delineate the physiological parameters these tools monitor to evaluate respiratory and cardiovascular metrics, (3) to describe the clinical settings for device implementation and their reported practical use, and (4) to evaluate prevailing technical and methodological barriers, specifically regarding reference standards and clinical translation.

Methods

Overview

A scoping review approach was adopted in this study to address the substantial heterogeneity in device types, monitored indicators, and clinical application scenarios across the research questions, as well as the evidence gaps in previous reviews. The Arksey and O'Malley framework and the Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews (PRISMA-ScR) guidelines guided the methodological design and reporting of this scoping review. Related reporting checklists and structural details are available in Checklist 1 [23].

Inclusion and Exclusion Criteria

The inclusion criteria were as follows: (1) clinical studies involving adults (aged ≥18 years); (2) studies in which the included population was explicitly a comorbid OSA and hypertension population, or studies in which the population had a single disease but both sleep- or respiratory-related indicators and blood pressure/cardiovascular indicators were assessed to evaluate the relationship between the 2 conditions or their comorbidity-related clinical applications; (3) studies using noninvasive wearable or portable devices to obtain at least 1 type of objective physiological monitoring data; (4) original studies published in English; and (5) studies with accessible full text. The exclusion criteria were as follows: (1) reviews, systematic reviews, meta-analyses, study protocols, case reports, animal experiments, commentaries, conference abstracts, and articles without full text were excluded; (2) studies that focused only on OSA or only on hypertension without objectively assessing disease-related indicators of the other condition; (3) studies that used only traditional in-hospital or laboratory monitoring without wearable or portable monitoring data; and (4) studies that were not clinically or practically validated based on real human data were excluded.

Data Sources and Search Strategy

We comprehensively searched 4 databases, including PubMed, Web of Science, Embase, and IEEE Xplore. Original studies on wearable devices in the management of comorbid OSA and hypertension published between January 1, 2015, and February 28, 2026, were searched, and the final database search was completed on February 28, 2026. The search strategy included MeSH and free-text terms related to wearable devices and monitoring technologies (eg, "wearable electronics," "portable devices," "smartwatches," "actigraphs," "photoplethysmography," "remote monitoring," and "continuous monitoring"), OSA (eg, "obstructive sleep apnea," "sleep apnea," "sleep-disordered breathing," and "snoring"), and hypertension (eg, "hypertension" and "ambulatory blood pressure monitoring"); the full search strategy is provided in Multimedia Appendix 1. To ensure the comprehensiveness of the literature collection, we manually traced the reference lists of all finally included studies. All retrieved records were imported into EndNote 21 (Clarivate) for deduplication and screening, and duplicate records were manually checked.

Study Selection

Two researchers (HW and AC) independently conducted the initial screening of titles and abstracts to exclude records that did not meet the criteria. Following the preliminary screen, the remaining records underwent a complete full-text appraisal to confirm alignment with the predefined eligibility framework. Selection-related discrepancies were settled through consensus-based deliberation involving a third investigator (YL).

XSL•FO
RenderX

Data Extraction and Charting

Two authors (HW and AC) jointly developed a standardized data-extraction and charting form based on the aims of this review and the predefined research questions. Before full data extraction, the 2 authors piloted the form on 3 randomly selected included studies to calibrate the definitions of key variables and classification rules and to improve consistency between reviewers. Data charting was treated as an iterative process; during piloting and discussion, the categories and recording rules in the extraction form were refined and then applied consistently in the final form. Subsequently, both authors independently extracted and charted data from all included studies. Disagreements were first resolved through discussion and consensus between the 2 authors; if consensus could not be reached, a third researcher (YL) was consulted.

We extracted study-level information across 5 domains: (1) study characteristics, including author, publication year, country, study design, sample size, participant characteristics, and study setting; (2) device characteristics, including wearable device type, sensing modality, and continuous monitoring capability; (3) physiological monitoring parameters, including sleep- or respiratory-related indicators and cardiovascular or hemodynamic indicators; (4) methodological characteristics, including reference standards, diagnostic or stratification thresholds, and validation design; and (5) clinical characteristics, including clinical application scenarios and study limitations. For studies involving multiple monitoring targets or application scenarios, the research team determined the primary focus according to the study objective, main outcome, and emphasis of reported findings, while also recording secondary or supportive features. The charted data were used to develop Table 1, Figure 2 [24-36], and Multimedia Appendices 2-4.

Table . Summary of study characteristics. Categories are not mutually exclusive; individual studies may contribute to multiple rows. For studies involving multiple monitoring targets or clinical applications, classification was based on the primary study objective, main outcome, and emphasis of reported findings. Respiratory event frequency metrics included AHI[a], REI[b], ODI[c], or algorithm-estimated equivalents. Nocturnal BP[d] variables included mean BP, peak BP, morning BP surge, BP variability, beat-to-beat BP, and cuffless BP estimates. Reference standards and assessment pathways were recorded as reported in each study.

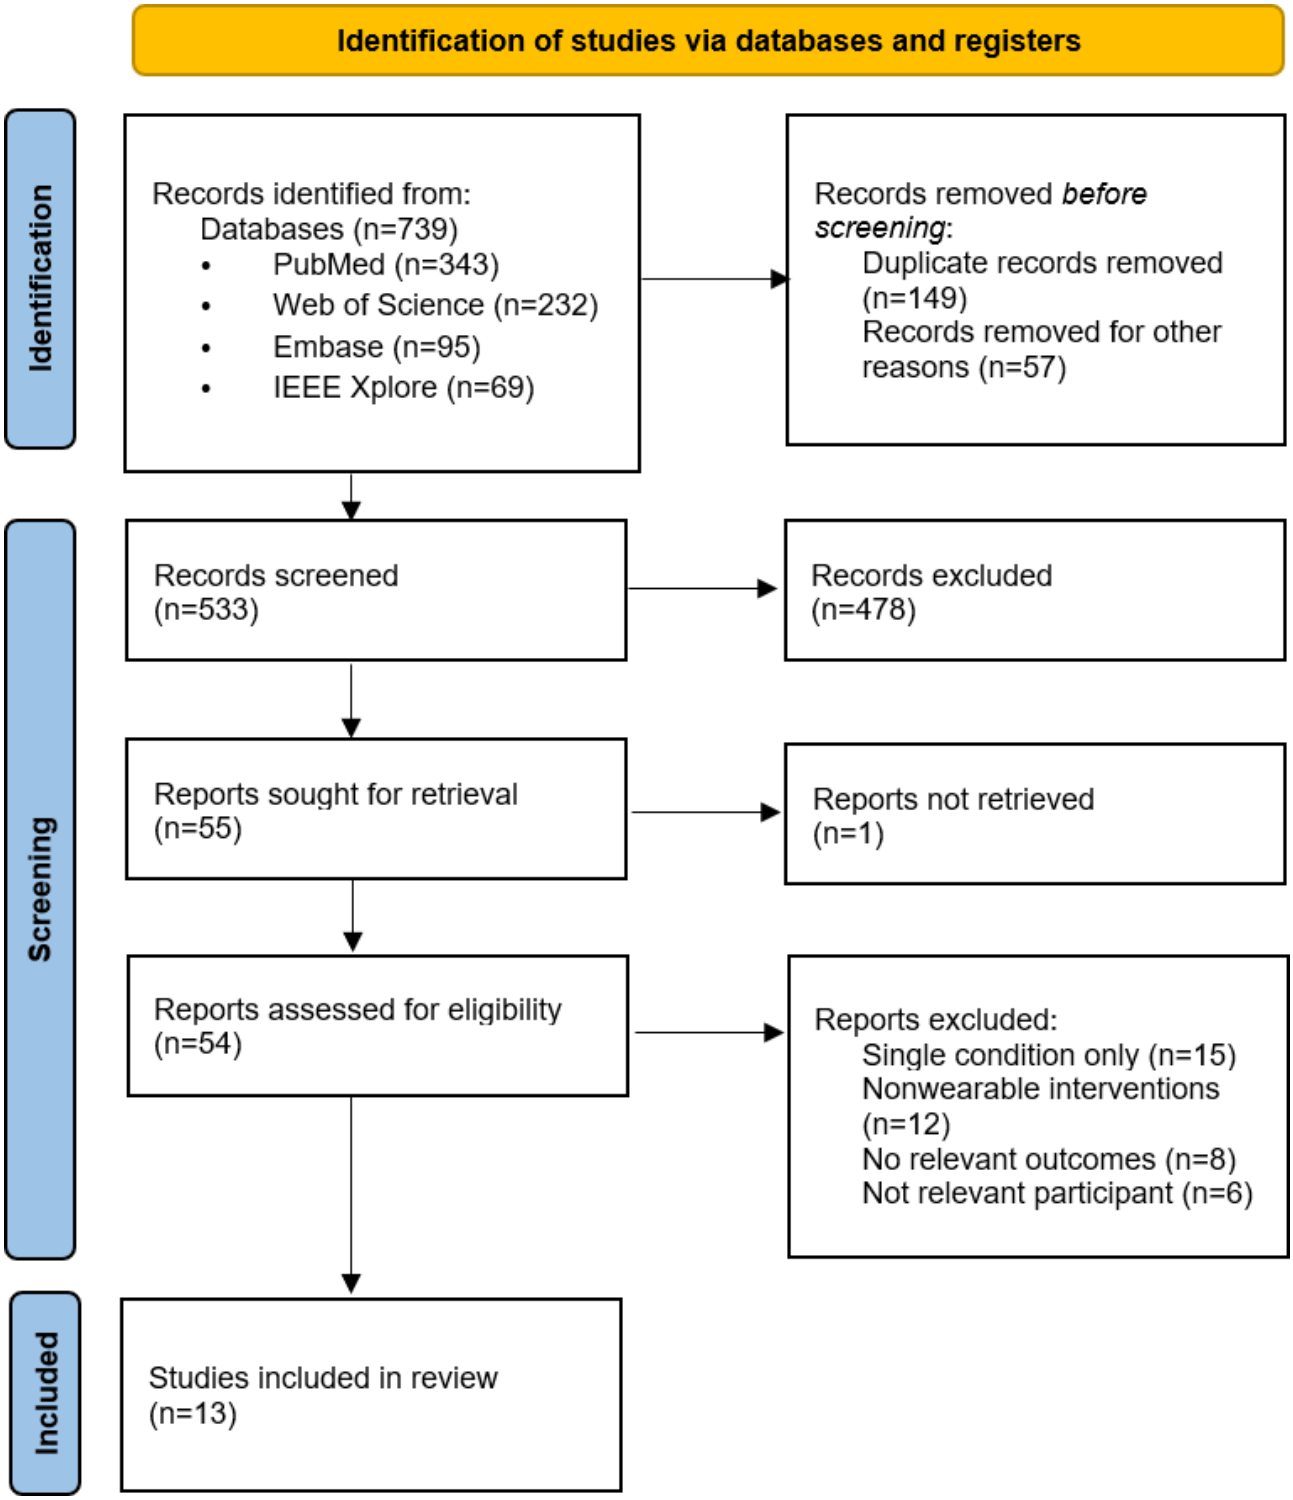
ABPM: ambulatory blood pressure monitoring; BP: blood pressure; CPAP: continuous positive airway pressure; CV: cardiovascular; ECG: electrocardiography; HRV: heart rate variability; HSAT: home sleep apnea test; PG: polygraphy; PSG: polysomnography.

Synthesis of Results

We synthesized the charted data using descriptive analysis and narrative synthesis. Using the charted data, we grouped similar findings into common themes. Information related to wearable device applications, sensing modalities, monitored indicators, reference standards, validation pathways, and clinical uses was described and organized. We did not prespecify the number of thematic categories or restrict the number of categories to which each study could contribute, in order to capture the diversity of the current evidence in terms of device types, monitoring targets, validation approaches, and clinical application scenarios. For each study, we reported the device characteristics, monitored variables, diagnostic or stratification thresholds, reference standards, and main findings as closely as possible to the original report, including information provided in supplementary materials where available. Similar content was then grouped into common themes without changing the meaning of the original studies.

Because the included studies were markedly heterogeneous in terms of wearable device types, sensing technologies, outcome assessment indicators, and measurement settings, we did not attempt to quantitatively pool the data or conduct a meta-analysis. Instead, the key study information, relevant findings, and methodological characteristics reported in each study were summarized and recorded. This approach was consistent with the purpose of a scoping review, which was to summarize study characteristics, identify evidence gaps, and clarify directions for future research rather than to estimate pooled effect sizes. Therefore, no formal risk-of-bias assessment or methodological quality appraisal was conducted for the included studies; relevant methodological and practical limitations were summarized in the Results and Discussion sections.



Results

Study Selection

The PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram (Figure 3) outlines the study selection process. A total of 739 studies were identified from the 4 databases. After removal of duplicates and records excluded for other reasons, 533 studies entered the title and abstract screening stage, and 478 articles were excluded after screening. Full texts of 55 articles were sought and assessed, of which 1 could not be retrieved. After full-text screening of the remaining 54 articles, 41 studies were excluded. Finally, 13 studies were considered eligible.

XSL•FO
RenderX

Figure 3. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram of study selection.

Characteristics of Included Studies

The 13 studies included in this scoping review were published between 2015 and 2026 and were conducted in 9 countries or regions, namely China, Japan, South Korea, Thailand, the United States, Canada, Brazil, Switzerland, and Germany/Sweden, involving a total of 5596 participants. Among them, 1 real-world study included initial screening data from more than 1 million users [24]. The included literature comprised 8 (62%) observational studies [24-31], 4 (31%) device validation studies [32-35], and 1 (8%) feasibility study [36]. The study populations were markedly heterogeneous and covered multiple clinical scenarios in the management of comorbid OSA and hypertension. Participants included patients with OSA at different stages, ranging from suspected screening and confirmed diagnosis to treatment with continuous positive airway pressure (CPAP), as well as patients with primary hypertension, older adults with hypertension, and obese adults at risk of abnormal nocturnal blood pressure. A summary of the characteristics of the included studies is shown in Table 1, and detailed information on the included studies is provided in Multimedia Appendix 2.

XSL•FO
RenderX

Wearable Device Types

The 13 included studies used various types of wearable devices, showing the characteristics of portability and continuous monitoring; detailed device information is provided in Multimedia Appendix 3. These included wrist-worn devices (n=3, 23%) [24,29,36], fingertip contact devices (n=4, 31%) [25,26,30,34], patch and single-lead devices (n=2, 15%) [28,31], and multiparameter portable monitoring systems (n=4, 31%) [27,32,33,35]. Wrist-worn devices mainly included smartwatches, wristbands, and activity trackers, and because of their greater convenience and practicality, they were mainly used for community screening, daily monitoring, and remote follow-up. Multiple studies used fingertip contact devices to collect nocturnal respiratory events and pulse wave signals in order to extract key characteristic parameters such as oxygen desaturation index (ODI), HRV, pulse propagation time (PPT), and pulse transit time (PTT). Patch and single-lead devices were used for the noninvasive continuous acquisition of acoustic or electrocardiographic signals. Some studies also applied multiparameter portable systems that combined sleep respiratory monitoring with continuous ambulatory blood pressure monitoring (ABPM) to synchronously assess nocturnal respiratory events and their related hemodynamic changes.

Sensor Technologies

The included studies used multiple sensing technologies for the noninvasive acquisition of sleep and cardiovascular parameters. Optical sensing was the most commonly used technology, and photoplethysmography and pulse oximetry were the most widely applied, mainly for recording hypoxic events, hemodynamic fluctuations, and assessing nocturnal cardiovascular risk [24,27,30,34,36]. Two studies further combined optical and electrical signal sensing and extracted PTT by acquiring electrocardiography and fingertip photoplethysmography signals to achieve cuffless blood pressure estimation, thereby extending monitoring from OSA to the preliminary assessment of nocturnal hypertension or masked hypertension [32,35]. Some studies also used peripheral arterial tonometry (PAT), acoustic sensing, and actigraphy-related sensing technologies. Cho et al [25] and Correa et al [26] used PAT-related signals to assess changes in peripheral vascular tone and sympathetic nervous activity associated with sleep-related respiratory events [25,26]. Accelerometers were commonly used for activity state identification, sleep staging, and variability analysis [29,36]. Kabir et al [28] collected tracheal breath sounds and heart sound signals using miniature microphones and accelerometers and analyzed them synchronously with polysomnography.

Monitored Parameters

Based on the multimodal sensing technologies described above, current evidence suggests that some wearable devices can simultaneously capture sleep-related respiratory parameters and hemodynamic parameters. In the sleep-respiratory domain, the devices were mainly used to assess OSA severity and nocturnal hypoxic burden. The monitored indicators included the apnea-hypopnea index (AHI) or respiratory event index (REI), ODI, minimum or mean peripheral oxygen saturation (SpO_2), sleep time with oxygen saturation below 90%, or other indicators of hypoxic exposure [24-27,30-33,35]. Some studies obtained sleep rhythm indicators through long-term monitoring, including total sleep time, sleep efficiency, and sleep variability [26,29,30]. Other studies focused on respiratory signal features such as nasal airflow, snoring, and thoracoabdominal respiratory effort [28,32]. In comparison, cardiovascular and hemodynamic parameters may better reflect the comorbidity characteristics of OSA and hypertension. Wearable devices were able not only to derive conventional indicators such as resting heart rate and HRV [29,31] but also to obtain continuous beat-to-beat blood pressure, PTT-based nocturnal ambulatory blood pressure [27,32,35], systolic blood pressure peaks triggered by hypoxic events [33], PAT amplitude attenuation caused by sympathetic activation [25,26], and PPT, which is related to vascular stiffness or nocturnal cardiovascular burden [30]. In addition, some studies also recorded changes in heart sound intensity and nocturnal abnormal arrhythmic events [24,28,31]. Overall, there was marked heterogeneity across the included studies in terms of reference standards, assessment pathways, and diagnostic or stratification thresholds, including different assessment methods such as polysomnography, home sleep apnea testing (HSAT), ABPM, and questionnaire tools. Blood pressure thresholds are reported as used in the original studies for diagnostic or stratification purposes; treatment targets were not synthesized because most included studies focused on screening and monitoring rather than treatment-goal attainment. Therefore, the reported device performance should be interpreted objectively in the context of specific study settings (Multimedia Appendix 4).

Clinical Applications

Overview

Evidence suggests that wearable technology for comorbid OSA and hypertension management largely focuses on three functional areas: initial comorbidity screening and risk stratification in community and home settings, continuous monitoring of abnormal nocturnal hemodynamics and changes in respiratory events, and multimodal cardiovascular risk assessment and exploration of remote management. Figure 2 summarizes the monitoring targets, validation approaches, and major clinical application scenarios across the included studies.

Screening and Risk Stratification for Comorbid OSA and Hypertension

Three studies involved the application of wearable devices in the screening and risk stratification of comorbid OSA and hypertension [24,29,31]. Existing evidence suggests that wearable devices have been increasingly applied to the early identification and risk stratification of this comorbidity. In a large real-world screening study, wrist-worn smart devices were used for initial screening in 1,056,494 users, identifying 19,563 individuals at high risk for OSA, and 1054 patients with OSA were confirmed among those who subsequently underwent HSAT or polysomnography evaluation; the devices could also simultaneously indicate the risk of arrhythmia [24]. A study including 2573 older adults with hypertension in primary care settings found that continuous monitoring based on wearable electrocardiography and the autocorrelated wave detection with adaptive threshold (ACAT) algorithm could be used for community-based initial screening of OSA and could help

XSL•FO
RenderX

improve the identification of individuals at high risk for moderate to severe OSA [31]. Another study analyzed long-term sleep data collected by wearable devices together with hypertension information and found that increased sleep variability was associated with higher OSA risk and increased hypertension risk, suggesting that wearable devices may be used for the preliminary identification of comorbidity risk [29]. The application of wearable devices is no longer limited to the detection of OSA alone but has extended to the preliminary identification of comorbidity risk. However, their role still lies in early identification and referral stratification, and they cannot replace standard sleep monitoring or the diagnostic pathway for OSA.

Monitoring of Abnormal Nocturnal Blood Pressure and Hemodynamic Changes

A total of 6 studies involved the monitoring of abnormal nocturnal blood pressure and respiratory event–related hemodynamic changes [25-27,32,33,35]. Wearable devices can not only monitor nocturnal blood pressure but also record the dynamic relationship between OSA-related hypoxic events and abnormal blood pressure fluctuations. Multiple studies found that the more severe the hypoxic events, the more pronounced the increase in nocturnal systolic blood pressure and blood pressure variability, suggesting that OSA-related hemodynamic changes are often event-triggered [27,33]. In a multicenter study of 330 patients with suspected sleep-disordered breathing, beat-to-beat PTT-estimated blood pressure was compared with fixed-interval PTT-estimated blood pressure. The results showed that the 2 methods were generally similar in mean blood pressure and blood pressure variability measures, but beat-to-beat monitoring was more sensitive in capturing maximum and minimum values [32]. Another study, using 24-hour ABPM as the reference, found that the PTT estimation method based on combined electrocardiography and photoplethysmography signals was only weakly correlated with nocturnal ABPM and tended to overestimate nocturnal blood pressure in patients with moderate to severe OSA, indicating that a gap in agreement with the gold-standard ABPM still remains [35].

Cardiovascular Risk Assessment and Remote Longitudinal Management

A total of 4 studies involved wearable devices in cardiovascular risk assessment and remote longitudinal management in this comorbidity [28,30,34,36]. In the assessment of hypertension and cardiovascular risk, 2 studies involving populations with suspected OSA showed that wearable devices could provide warning indicators such as the cardiac risk index, pulse wave attenuation index, and PPT. The studies reported that the cardiac risk index may be superior to conventional OSA severity indicators in identifying individuals at high cardiovascular risk, and that the derivation of these parameters may help identify high-risk cardiovascular phenotypes of OSA associated with increased arterial stiffness [30,34]. Another study found that heart sound intensity increased significantly after the termination of respiratory events and was closely associated with the degree of hypoxia and the concomitant fluctuations in blood pressure and heart rate, suggesting that patch-based devices may complement the assessment of the comorbid cardiovascular burden related to OSA from the perspective of cardiac mechanical load [28]. In terms of remote longitudinal management, a feasibility study including only 10 patients with OSA receiving CPAP treatment found that home monitoring using a multimodal wearable system could be used for the continuous observation of sleep, activity, and blood pressure changes and may support the remote management of intervention adherence and blood pressure fluctuations [36].

Technical Limitations and Challenges

Technical and translational obstacles persist in the application of wearables for managing comorbid OSA and hypertension. A total of 5 (38%) studies lacked adequate reference standard validation or used different assessment pathways, which limited the comparability of results across different devices and algorithms [25,29-32]. Selection biases attributable to voluntary enrollment, specific referral cohorts, and single-center designs were identified across multiple studies, restricting the generalizability of observations across diverse demographics and clinical outcomes. Methodological inconsistencies were observed in specific reports, such as the reliance on self-reported hypertension status (1/13, 8%) rather than clinical diagnostic verification [29]. Another study involved cardiovascular risk assessment derived from questionnaires and telephone-based follow-ups, a process susceptible to subjective bias compared to objective clinical measurements [24]. These observations support the use of wearables for risk stratification rather than as direct diagnostic substitutes. Data from Traiwannakij et al [35] indicated weak concordance between PTT-derived cuffless blood pressure monitoring and gold-standard ABPM; specifically, a systematic overestimation of nocturnal values was observed among patients with moderate to severe OSA. In addition, in remote or multimodal monitoring settings, obstacles such as reduced quality of nocturnal blood pressure data, difficulty in device calibration, and reliance on manual processing for cross-device data synchronization also remain, all of which limit the clinical application of wearable devices [36].

Discussion

Principal Findings

To our knowledge, this scoping review is the first review to systematically summarize the evidence on the application of wearable devices in the screening, monitoring, and management of OSA and hypertension from the perspective of this comorbidity. A total of 13 studies were included, involving 4 types of wearable devices, namely wrist-worn devices, fingertip contact devices, patch and single-lead devices, and multiparameter portable monitoring systems, covering a range of application scenarios from clinical validation to real home settings. Previous reviews have explored the feasibility of wearable devices in the monitoring of OSA or hypertension alone. From the perspective of comorbidity, this review further integrated the existing evidence on sleep-related respiratory signals and nocturnal hemodynamic information in the assessment of this comorbidity. The findings showed that wearable devices can simultaneously obtain sleep-related respiratory parameters and cardiovascular-related indicators,

XSL•FO
RenderX

and have shown preliminary application value in the identification of populations at high risk for OSA, the preliminary identification of abnormal nocturnal blood pressure, cardiovascular risk stratification, and remote follow-up. However, the current evidence remains limited and heterogeneous, particularly in terms of reference standards, diagnostic thresholds, and validation pathways. The following sections further discuss the clinical significance, technical boundaries, and future directions of current sleep and blood pressure monitoring.

Value of Sleep and Blood Pressure Monitoring From a Comorbidity Perspective

The clinical evaluation of OSA has long centered on AHI and the hypoxia and sleep architecture indicators obtained from conventional sleep monitoring. However, from the perspective of comorbid OSA and hypertension, sleep monitoring alone is insufficient to fully reflect the true clinical significance of OSA. AHI and REI mainly reflect the frequency of respiratory events and are less able to capture information more closely related to cardiovascular risk, such as nocturnal hypoxic burden, autonomic nervous responses, and abnormal circadian blood pressure patterns [6,8]. Comorbidity management does not simply mean adding more monitoring indicators, but rather incorporating the nocturnal cardiovascular burden underlying respiratory events into the overall assessment. Therefore, the focus of monitoring in comorbidity management should not be limited to AHI and ODI, but should also include indicators that better reflect the characteristics of OSA-related hypertension, such as hypoxic burden, respiratory effort burden, elevated nocturnal blood pressure, reduced nocturnal blood pressure dipping, abnormal morning blood pressure surge, and blood pressure variability. Traditional assessment mainly relies on patient recall or single in-hospital examinations and, in particular, lacks nocturnal data, making it difficult to effectively capture the dynamic relationship between OSA and hypertension [16]. The 24-hour ambulatory blood pressure and nocturnal blood pressure are closely associated with cardiovascular risk, and home morning blood pressure is closely associated with prognosis in patients with cardiovascular disease [37]. Traditional assessment may miss high-risk phenotypes such as masked hypertension, nondipper/riser blood pressure patterns, and morning blood pressure surge [5,38]. Reliance on a single sleep monitoring and routine outpatient assessment is therefore insufficient to fully identify the true risk of OSA-related hypertension. At the same time, OSA-related nocturnal hemodynamic changes may also manifest as autonomic dysfunction and increased blood pressure variability, suggesting that comorbidity management should further incorporate these related indicators [39]. Taken together, the assessment of comorbid OSA and hypertension should not remain limited to single examinations, but should further shift toward long-term dynamic monitoring.

The most direct clinical value of wearable devices lies in supporting long-term, longitudinal, and individualized monitoring in the management of comorbid OSA and hypertension. ABPM can monitor day-night blood pressure variability and detect masked hypertension, but it cannot assess daily and long-term blood pressure variability, including night-to-night variability; home blood pressure monitoring (HBPM) is suitable for tracking daily and long-term blood pressure trends, but measurements are mostly concentrated at fixed time points, such as in the morning and at night [40]. Single-night polysomnography is difficult to use to reflect OSA severity and its night-to-night variability, whereas ABPM and HBPM can provide blood pressure information, each still has limitations in long-term continuous dynamic tracking. Existing studies have shown through multinight sleep monitoring and repeated blood pressure measurements that the greater the night-to-night variability of OSA, the higher the risk of uncontrolled hypertension, and this association is independent of mean AHI [41]. Continuous monitoring may help more accurately identify hypertension risk and nocturnal vascular burden. For patients with OSA receiving CPAP treatment, wearable devices may support long-term adherence tracking and assist in evaluating posttreatment blood pressure improvement and cardiovascular benefit [36]. Consistent CPAP use correlates with lower rates of recurrent cardiovascular episodes, serving as an integral element of secondary prevention for the population with OSA [42]. For individuals presenting with both resistant hypertension and OSA, CPAP therapy facilitates reductions in 24-hour mean and nocturnal blood pressure and is more likely to correct nondipper/riser blood pressure patterns [43]. Therefore, the future value of wearable devices lies not only in improving the convenience of screening but also in providing continuous data support for treatment adherence tracking, blood pressure response assessment, and long-term cardiovascular risk stratification.

Clinical Limitations and Technical Boundaries of Wearable Monitoring

At present, the value of wearable technologies is reflected more in screening, dynamic monitoring, and long-term follow-up rather than in replacing standard diagnosis, and polysomnography remains the gold standard for OSA. The included studies found that wearable devices are feasible for identifying high-risk populations in large-scale real-world studies and primary care screening studies and are more suitable for initial screening and risk stratification [24,31]. Consistent with previous studies, most wearable devices lack complete electroencephalography channels, making full sleep staging difficult and limiting the accurate identification of microarousal-related hypopnea events, respiratory effort, and more complex respiratory events [44,45]. Signal fidelity frequently degrades due to postural shifts, ambient noise, and motion artifacts [28]. Proprietary algorithms differ across manufacturers, complicating their generalization to patients with complex comorbidities [31,45].

Continuous home-based blood pressure tracking via cuffless systems does not currently serve as a full replacement for standard ABPM or HBPM protocols [35]. Persistent technical limitations such as signal instability and mandatory calibration requirements, alongside sensitivity to postural changes and localized skin perfusion variations, affect the precision of these measurements [46,47]. The primary technical challenge involves the consistent recording of 24-hour blood pressure fluctuations rather than the accuracy of isolated measurement approximations [48]. Although certain cuffless tools demonstrate acceptable

XSL•FO
RenderX

performance during the day, their nocturnal estimates frequently lack precision and may fail to document transient pressure surges or circadian irregularities with sufficient reliability [27,48]. Inconsistencies in validation frameworks and algorithmic logic among manufacturers prevent data uniformity. Large-scale clinical datasets focused on blood pressure fluctuations specific to nocturnal OSA events also remain scarce. Therefore, cuffless blood pressure monitoring is currently better positioned as a tool for trend observation and risk warning than as a substitute for ABPM or HBPM.

Multimodal Sensing and Missing-Modality Handling

Recent studies have shown that intelligent OSA identification technologies are gradually shifting from single-signal analysis to multimodal sensing fusion. By integrating visual signals, snoring audio, body movement information, and multiple electrophysiological signals, related models have shown greater accuracy than single-modality approaches in OSA identification and stratification [49]. To address sensor detachment, motion artifacts, and modality missingness during long-term wearable monitoring, some studies have also begun to explore missing-modality reconstruction strategies to improve model robustness under incomplete input conditions. For example, the MIMAR-OSA model was able to maintain relatively high monitoring performance under partial signal loss through multimodal data integration and missing-modality reconstruction [50]. However, these advances are currently still limited to the automatic identification, severity stratification, and sleep staging of OSA itself, and are mainly focused on improvements in signal processing, feature extraction, and algorithm robustness. They have not yet been extended to the identification of abnormal nocturnal blood pressure or the long-term management of comorbid OSA and hypertension. Therefore, such studies may be more suitable as supporting technologies for future digital management of this comorbidity, but prospective clinical validation in the setting of comorbid OSA and hypertension is still lacking.

Exploration of a Sleep and Blood Pressure Closed-Loop Management Pathway

Existing studies have mainly involved digital care, wearable device monitoring, risk alert platforms, and long-term management, and a mature “sleep and blood pressure” closed-loop management model has not yet been established for comorbid OSA and hypertension [51,52]. Based on the included evidence, such a framework should at least involve 4 key components. At the input level, key information reflecting the comorbid state should be continuously acquired, including multinight sleep-related respiratory events, hypoxic burden, nocturnal blood pressure or blood pressure rhythm changes, HRV, and treatment adherence. At the output level, a more reasonable goal is not to directly generate an automated diagnosis, but to identify risk signals relevant to comorbidity management, such as suspected OSA-related nocturnal hypertension, persistent abnormal hypoxic burden, reduced CPAP adherence, or disordered nocturnal blood pressure rhythms. These risk alerts should primarily prompt clinicians to arrange polysomnography, supplement ABPM, or intensify remote follow-up, rather than delegating diagnostic or therapeutic decisions to autonomous algorithms. The safety boundaries of sleep and blood pressure management need to be clearly defined. Data outputs from wearable platforms operate as auxiliary indicators that do not replace gold-standard monitoring or bypass professional clinical appraisal. The use of wearables alongside CPAP remote monitoring is a feasible approach for home observation [36]. Future sleep and blood pressure closed-loop pathways are envisioned as auxiliary frameworks rather than fully autonomous diagnostic systems.

Barriers to Clinical Implementation

Practical obstacles persist in the clinical application of wearables for patients with concurrent OSA and hypertension. The existence of continuous data streams does not automatically translate into improved management efficiency. Clinical staff still have limited training in devices and related algorithms, and the interpretation of device data and verification of abnormal alerts may create an additional workload. In addition, there is still a lack of standardized clinical pathways, evaluation frameworks, and reimbursement systems applicable to the management of comorbid OSA and hypertension, making these technologies difficult to implement in routine clinical practice. Moreover, patient adherence, motion artifacts, and reduced nocturnal signal quality may further affect their application in clinical settings.

Therefore, in future clinical translation, it may be necessary to gradually establish a minimum necessary dataset for the management of comorbid OSA and hypertension, including core physiological indicators, device algorithm metadata, signal quality, and adherence information, in order to reduce the problem that outputs from different platforms are difficult to compare or cannot be incorporated into the clinical interpretation workflow [53,54]. On this basis, core indicators and quality control standards should also be standardized to improve the transferability and traceability of data across different systems. Responsibility for data quality should be further clarified. For example, synchronization, quality labeling, and abnormal alert generation could be completed at the device or platform level, while the clinical team would review the alert results, thereby reducing the data overload and additional interpretation burden caused by continuous monitoring [52,55].

Methodological Limitations

This scoping review has several methodological limitations. Only English-language studies were included, and gray literature and preprints were not included, which may have introduced language bias and publication bias. Second, because the current evidence on comorbid OSA and hypertension remains limited, this review included some studies conducted in single-disease populations that simultaneously assessed sleep- or respiratory-related indicators and blood pressure/cardiovascular indicators. Although this strategy expanded the scope of evidence covered, it also increased the heterogeneity across study populations, application scenarios, and outcome indicators. In addition, the number of included studies was limited, and some studies had small sample sizes, which restricted the robustness of the evidence. There was substantial heterogeneity across the included studies in terms of device types, reference standards, assessment pathways, and outcome definitions, and

XSL•FO
RenderX

no meta-analysis was performed in this review. Overall, the conclusions of this review are more suitable for informing subsequent validation studies and real-world research, and they should still be interpreted with caution in specific clinical implementations.

Future Directions

Based on the evidence gaps identified in this scoping review, future research should further shift from feasibility validation to clinically translational research in comorbidity management. Existing evidence mainly consists of observational studies and device validation studies and has focused primarily on whether devices can identify the risk of OSA and hypertension or record nocturnal physiological changes, with insufficient attention to the populations, indicators, and outcomes that are truly critical in comorbidity management. Future studies should more strongly emphasize large-sample, prospective, and multicenter research in clearly defined comorbid populations and should validate key nocturnal and long-term outcome indicators against reference standards such as polysomnography and ABPM. At the same time, the research focus should move beyond consistency with standard testing toward the effects of wearable devices on clinical outcomes such as blood pressure control, CPAP adherence, monitoring of nocturnal blood pressure patterns, and patient experience. Recent studies have also suggested that bedtime and circadian rhythm characteristics may be important additional factors for future comorbidity risk assessment [56]. Future comorbidity management should not be limited to the monitoring of apneic events alone, but should also incorporate sleep behavior, circadian rhythm characteristics, and hemodynamic changes into a comprehensive assessment. Finally, it will also be necessary to gradually establish core indicators, validation pathways, and reporting standards applicable to the management of comorbid OSA and hypertension, so that sleep and blood pressure data collected by wearable devices can better serve clinical care and be progressively integrated into standardized management pathways.

Conclusions

Wearable devices support the screening, nocturnal monitoring, and remote follow-up of comorbid OSA and hypertension. Specifically, they provide the continuous nocturnal data and longitudinal follow-up metrics that are often absent in conventional diagnostic workflows. Their clinical value is gradually extending from the identification of single sleep events to the continuous observation of comorbidity-related nocturnal cardiovascular burden. However, the existing evidence still mainly comes from observational studies and device validation studies, and there is marked heterogeneity across devices in terms of reference standards, diagnostic thresholds, and validation pathways. At the current stage, wearable devices are more suitable as auxiliary monitoring and risk warning tools in comorbidity management and cannot replace standard sleep testing or standard blood pressure monitoring.

Abstract

Background: Cancer poses a significant threat to children's health, and mobile health (mHealth) is emerging as a key tool for remote disease management, health education, and follow-up. However, evidence of its effectiveness remains limited.

Objective: This study aimed to summarize the effects of mHealth interventions for pediatric cancer compared with usual care, providing evidence-based support for optimizing intervention models and improving patient outcomes.

Methods: A systematic search of 14 databases identified randomized controlled trials (RCTs) on mHealth apps for pediatric patients with cancer from inception to August 1, 2025. Two reviewers independently screened studies, extracted data, assessed bias risk, and graded evidence quality. The meta-analysis was conducted using RevMan 5.4 and Stata 15.

Results: A total of 24 RCTs involving 2645 patients were included. This review found that mHealth interventions significantly reduced infection rates (odds ratio [OR] 0.25, 95% CI 0.10-0.60; *P*=.002) and the overall incidence of peripherally inserted central catheter (PICC) complications (OR 0.16, 95% CI 0.10-0.24; *P*<.001), while improving quality of life (standardized mean difference [SMD] 1.34, 95% CI 0.13-2.55; *P*=.03), self-management ability (SMD 6.39, 95% CI 1.26-11.53; *P*=.01), and treatment adherence (OR 2.83, 95% CI 1.41-5.66; *P*=.003). However, mHealth interventions had no significant effect on PICC catheter displacement (OR 0.44, 95% CI 0.15-1.29; *P*=.13) or health knowledge (SMD 4.44, 95% CI −2.40 to 11.29; *P*=.20). Further high-quality studies are needed to verify their impact in these areas. The intervention components covered 9 behavior change techniques: goals and planning, feedback and monitoring, social support, shaping knowledge, repetition and substitution, reward and threat, comparison of outcomes, natural consequences, and regulation.

Conclusions: This systematic review and meta-analysis synthesized evidence from RCTs. The findings support the use of mHealth to reduce infections and PICC-related complications among pediatric patients with cancer while improving quality of life, self-management capabilities, and treatment adherence. These results underscore the importance of incorporating mHealth strategies into pediatric cancer care and guide the development and enhancement of future mHealth interventions.

Introduction

Cancer remains a major threat to the health and survival of children [1]. While advances in medical technology have improved survival rates [2], children living with cancer continue to face considerable challenges. First, the disease itself compromises immune function and causes neutropenia, increasing susceptibility to bacterial, fungal, and viral infections [3], which is one of the leading causes of mortality in this population [4]. Second, following diagnosis, pediatric patients with cancer typically undergo intensive treatments. Chemotherapy, used in over 95% of pediatric cancer cases [5], is associated with adverse effects such as pain, vomiting, and fatigue, which substantially diminish quality of life (QoL) [6]. Additionally, pediatric patients typically require the placement and maintenance of a peripherally inserted central catheter (PICC) during chemotherapy, yet PICC-related complications—including bloodstream infections, venous thrombosis, and mechanical issues—remain frequent. These complications can delay antitumor therapy, prolong hospitalization, and increase mortality risk [7]. The complexity of disease management, coupled with limited access to routine care information [8] and frequent care transitions between hospital and home [9], places a heavy burden on pediatric patients and their families. Therefore, timely and effective health education and self-management support are crucial.

In this context, mobile health (mHealth) has emerged as a key tool in health care interventions due to its convenience, efficiency, accessibility, and low cost. mHealth has been shown to overcome barriers related to limited human resources and distance [10]. The World Health Organization defines mHealth as the use of mobile information technology devices, such as mobile phones, tablets, wearable devices, and wireless pedometers, in medical and public health practices [11]. It enables remote services, including symptom monitoring, health education, vital sign tracking, alerts, and medication guidance [12,13].

Previous reviews have examined mHealth apps in pediatric cancer care. Ramsey et al [14] found that mHealth can reduce pain and improve treatment adherence, though findings regarding health-related QoL were inconsistent. González-Díaz et al [15] observed that mobile apps effectively reduced the incidence and severity of symptoms, such as pain and nausea, with high usability and acceptance among patients and caregivers. Similarly, Upreti et al [16] noted that pain monitoring apps reduced pain intensity and decreased moderate-to-severe pain episodes, demonstrating good usability and satisfaction. Zhu et al [17] concluded that mHealth enables multidimensional pain assessment (intensity, frequency, location, and associated symptoms) with a favorable user experience. Delemere et al [18] found that incorporating high-frequency behavior change techniques (BCTs), such as feedback, monitoring, and social support, in pediatric cancer-related mHealth apps enhances treatment adherence and caregiving coping abilities. Mehdizadeh et al [19] further observed that smartphone apps improve symptom reporting adherence, health care communication, and medication compliance, with good user acceptance.

However, existing reviews have several limitations. First, most analyses included primarily pilot or small-sample exploratory studies, with no comprehensive synthesis of randomized controlled trials (RCTs) on mHealth apps for pediatric patients with cancer. Second, outcomes have often focused on mHealth device usability and pain management, lacking thorough evidence on clinical effectiveness in areas such as infection prevention and PICC care [18]. Third, some reviews combined children and adolescents in their analyses, resulting in high sample heterogeneity. These reviews also failed to distinguish between mHealth users (children or caregivers) and treatment stages (treatment or recovery phases) [20], making it difficult to rule out confounding factors influencing outcomes [15]. This limits the specificity and applicability of the evidence. Fourth, prior reviews have largely been restricted to English-language databases and evidence from high-income countries, offering limited insight into mHealth effectiveness in low-income and middle-income regions [15,19]. Furthermore, many existing mHealth platforms lack clinical and evidence-based input in their design, underscoring the need for high-quality evidence to guide development [21].

To address these limitations, this study conducted a systematic search of Chinese and English databases, aiming to synthesize the effects of mHealth interventions in children aged 0‐18 years undergoing cancer treatment by using meta-analyses based on RCTs. The primary outcomes are infection incidence, QoL, and PICC-related complications. Secondary outcomes include health knowledge, self-management ability, and treatment adherence. The BCT taxonomy was used to categorize intervention components across studies, thereby providing more practice-oriented evidence for mHealth apps in pediatric cancer care.

Methods

Ethical Considerations

This study did not involve the collection of primary data from human participants. All data were derived from previously published sources and are appropriately cited. Therefore, ethical approval was not required.

Study Registration

This review was registered with PROSPERO (registration number: CRD420251108938). During the review process, this study strictly adhered to the registered protocol. In the initial search strategy, broad telehealth-related terms were applied to comprehensively assess the multidimensional effects of telehealth interventions on pediatric patients with cancer. However, during the systematic search and screening process, it was observed that most (over 90%) of the studies meeting the original inclusion criteria used mHealth-based interventions—such as mobile apps, web-based platforms, or smart devices—rather than traditional telehealth approaches (eg, telephone follow-ups or video consultations) [22,23]. Meanwhile, a sufficient number of RCTs were identified. To enhance internal homogeneity and ensure that the review provides precise, high-quality evidence with clear practical implications, the scope of this review was refined to focus exclusively on RCTs of mHealth interventions. The registration

XSL•FO
RenderX

record has been updated accordingly, and the systematic review and meta-analysis were conducted in strict accordance with the most recent registration record [24].

Search Strategies

The systematic review and meta-analysis were conducted in accordance with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 statement [25] (Checklist 1). A comprehensive search was conducted across PubMed, Web of Science, Cochrane Library, Embase, CINAHL, Scopus, ScienceDirect, ProQuest, PsycINFO, OVID, Chinese National Knowledge Infrastructure, WanFang, Weip Database, and China Biology Medicine database, with each searched from inception to August 1, 2025. The search terms combined both Medical Subject Headings (MeSH) terms and free-text keywords: (cancer or oncology or tumor or neoplasm or leukemia) and (child or pediatric) and (mHealth or internet-based intervention or software application). The detailed search strategy is provided in Multimedia Appendix 1.

Study Selection and Data Extraction

Two researchers (HY and YX) first removed duplicates using EndNote X21 (Clarivate Analytics) and then screened the studies in 2 steps: first by title and abstract, and then by full text. Any discrepancies that arose during the screening process were resolved through discussion between the 2 researchers, or, if necessary, by consulting a third researcher (XM). The literature screening followed the participants, intervention, comparison, outcomes, and study design [26]. Inclusion criteria were as follows:

1. Participants: children aged 0 - 18 years diagnosed with cancer
2. Intervention: mobile-based or wireless-based tools such as apps, websites, wearables, or social media
3. Comparison: usual care (paper-based education or face-to-face monitoring)
4. Outcomes: infection incidence, QoL, PICC-related complications, health knowledge, self-management ability, and treatment adherence
5. Study design: RCTs

Exclusion criteria included (1) reviews, abstracts, theses, systematic reviews, meta-analyses, and case reports; (2) unavailable full texts; (3) interventions targeting only parents; (4) publications not in Chinese or English; and (5) interventions limited to calls or videos.

Two researchers (HW and YW) independently extracted the following data using a standardized form, including the first author, publication year, country, sample size, age, sex, cancer type, intervention duration and setting, mHealth platform, BCT clusters, intervention control groups, and outcome measurement tools.

Quality Assessment

Two researchers (HY and YW) independently assessed the methodological quality of the included studies using the revised Cochrane Risk of Bias 2 tool, evaluating selection, performance, attrition, detection, and reporting biases, each rated as low, some concerns, or high [27]. The Grading of Recommendations Assessment, Development, and Evaluation (GRADE) framework was applied to appraise the quality of evidence using GRADEpro. Results were categorized into 4 levels (high, moderate, low, and very low) according to predefined criteria. The assessment incorporated study design, risk of bias, inconsistency in population, heterogeneity of findings, statistical precision of effect estimates, and publication bias [28]. Discrepancies were resolved through discussion or, if needed, consultation with a third researcher (XM).

Statistical Analysis
