In conclusion, this study contributes to the growing body of evidence supporting the efficacy of mHealth exercise interventions in improving frailty phenotype and physical function among patients with MM. These findings have important implications for the development of accessible exercise interventions aimed at enhancing the functional capacity of individuals living with MM. Further research is needed to explore the long-term effects and potential mechanisms underlying the observed improvements, as well as to optimize the delivery and implementation of mHealth-based exercise programs in this population.

Abstract

Background: The effectiveness of a digital training (DT) system in which patients receive individually tailored physiotherapeutic elbow-specific training (PEST) delivered via a digital platform remains unclear.

Objective: This study determines the effectiveness of a DT system in which patients receive individually tailored PEST supervision and guidance via the Joymotion Intelligent Rehabilitation System and educational videos, compared with conventional training (CT) conducted by qualified physiotherapists at outpatient clinics and unsupervised home-based PEST in patients following arthroscopic release for posttraumatic elbow stiffness.

Methods: This single-center, noninferiority randomized controlled trial was conducted at the Rehabilitation Department of Shanghai Sixth People's Hospital between September 2020 and June 2024. Patients aged 16-65 years undergoing arthroscopic release for posttraumatic elbow stiffness were randomized to receive either a 12-week DT program or conventional outpatient clinic-based training. Outcome measures included elbow flexion-extension range of motion (primary outcome); forearm rotation; isometric and dynamic muscle strength; American Shoulder and Elbow Surgeons (ASES) and Disabilities of the Arm, Shoulder, and Hand (DASH) scores; EQ-5D-5L; cost-effectiveness; adherence; and adverse events, assessed at 4, 12, and 24 weeks postoperatively.

Results: At 12 weeks, the mean elbow flexion-extension range of motion improved similarly in the DT and CT groups (between-group difference –1.6°, 95% CI –8.2° to 4.9°; *P*=.53), confirming noninferiority. Forearm rotation gains were slightly greater with DT (difference 14.2°, 95% CI 2.9°-25.6°). Patient-reported outcomes were equivalent between groups: ASES function (difference 0.6, 95% CI –0.3 to 1.5; *P*=.39) and pain (difference 0, 95% CI –8.3 to 8.5; *P*=.68) subscores, DASH (difference 0.23, 95% CI –1.54 to 1.99; *P*=.68), and EQ-5D-5L index (difference 0.001, 95% CI –0.012 to 0.015; *P*=.56) showed no significant between-group differences. Nearly all patients completed the 12-week program in both arms (104/106, 98.1%, vs 101/102, 99%, adherence; odds ratio 0.52, 95% CI 0.05-5.77). Adverse events occurred in 29 out of 106 (27.4%) participants in the DT group and 32 out of 102 (31.4%) participants in the CT group (odds ratio 0.82, 95% CI 0.45-1.50). Total rehabilitation costs per patient were lower in the DT group by an average of CNY –7418.58, and incremental cost-effectiveness analysis indicated that DT provided comparable outcomes at lower cost.

XSL•FO
RenderX

Conclusions: Individually tailored PEST delivered via a DT system is a viable, cost-effective, and safe alternative to conventional outpatient clinic-based training following arthroscopic release for posttraumatic elbow stiffness. These findings support its integration into routine postsurgical care, particularly for patients facing barriers to traditional therapy.

Trial Registration: Chinese Clinical Trial Registry Chictr2400093415; https://www.chictr.org.cn/showprojEN.html?proj=240693

KEYWORDS

digital training system; noninferiority; elbow stiffness; arthroscopic release; cost-effectiveness

Introduction

Digital training (DT) systems, which involve the remote delivery of training services via digital technologies, have emerged as an attractive alternative or supplement to conventional in-hospital therapy. By using mobile apps and videoconferencing, DT enables patients to perform guided exercises at home, reducing the need for frequent hospital visits and overcoming geographic, logistical, and financial barriers. Studies have demonstrated that DT systems can yield outcomes comparable to those of traditional face-to-face interventions in postsurgical recovery settings [1-7].

In the United States and Europe, technological advances combined with supportive health care policies have accelerated the adoption of mobile-based DT. For instance, expanded telehealth coverage by Medicare in the United States and the integration of telemedicine within several European health care systems have facilitated timely, high-quality care delivered remotely [4,5,7]. These measures not only ease the burden of travel for patients but also promote adherence to training protocols through flexible scheduling and continuous monitoring. By contrast, DT systems in China are still in the developmental phase. Although major urban centers are beginning to deploy mobile health apps and telemedicine platforms, the supporting clinical evidence is less robust, and implementation practices vary widely.

Posttraumatic elbow stiffness, a condition marked by reduced range of motion (ROM) due to scar tissue formation following injury, can significantly impair daily activities [8]. Arthroscopic release is commonly used to surgically address elbow contracture by removing fibrotic tissue and improving joint mobility [9]. However, the success of this procedure relies heavily on effective postoperative rehabilitation. This typically involves intensive physiotherapeutic elbow-specific training (PEST) to restore elbow motion and function. Traditional in-hospital rehabilitation offers direct supervision and hands-on therapy; however, it presents several challenges. Frequent hospital visits can be particularly burdensome for patients in rural areas or those with limited mobility. Additionally, rigid scheduling and transportation difficulties may compromise patient adherence, thereby affecting the overall recovery process. DT systems address these challenges by bringing rehabilitation directly to the patient's home. DT programs provide daily exercise instructions, track adherence, and facilitate real-time, 2-way communication between patients and physical therapists. This model minimizes logistical hurdles and supports continuous, patient-centered care, which is crucial during the early postoperative period, when aggressive rehabilitation is needed to prevent recontracture. Furthermore, DT systems offer the flexibility to adjust exercise regimens in response to patient performance and feedback, closely mimicking the personalized care provided in traditional settings.

While DT systems have been extensively studied in lower limb surgeries, research on their use in upper extremity conditions, specifically posttraumatic elbow stiffness, remains relatively limited. Given the critical role of early and sustained rehabilitation in maintaining surgical gains and preventing recontracture, it is essential to evaluate whether DT systems can effectively replace traditional rehabilitation methods for elbow contracture. This study seeks to fill the current gap in the literature by rigorously comparing DT systems with conventional outpatient clinic-based training in patients following arthroscopic release for posttraumatic elbow stiffness.

The purpose of this study was to determine whether a DT system is noninferior to conventional outpatient clinic-based training in improving elbow ROM and other functional outcomes after arthroscopic release for posttraumatic elbow stiffness.

Methods

Study Setting and Design

This study was designed as a noninferiority randomized controlled trial with a 1:1 allocation ratio and was conducted at a single center, the Rehabilitation Department of Shanghai Sixth People's Hospital, from September 2020 to June 2024. The trial aimed to compare the efficacy of a DT system with that of conventional outpatient clinic-based training for patients undergoing arthroscopic release for posttraumatic elbow stiffness. This study was reported in accordance with the CONSORT (Consolidated Standards of Reporting Trials) extension for noninferiority and equivalence trials (CONSORT-NI), and the completed CONSORT checklist is provided in Multimedia Appendix 1.

Ethical Considerations

The study received ethical approval from the Ethics Committee of Shanghai Sixth People's Hospital (institutional review board approval number 2020-KY-089[K]) and was conducted in strict accordance with the principles outlined in the Declaration of Helsinki. All participants provided written informed consent before enrollment in the study. In addition, the study protocol was officially registered with the Chinese Clinical Trial Registry (identifier Chictr2400093415). To ensure privacy and confidentiality, all collected data were coded (deidentified) and securely stored using the hospital's electronic data capture system on local servers accessible only to the research team.

XSL•FO
RenderX

No financial compensation or other incentives were provided to participants for their involvement in this study.

Participants

Patients were recruited from the Department of Orthopedics at Shanghai Sixth People's Hospital between September 2020 and June 2024. The recruitment process involved 2 complementary approaches. First, orthopedic surgeons identified potentially eligible patients during routine preoperative evaluations and referred them to the research team. Second, the research team reviewed the weekly elective surgical schedule to identify patients scheduled for arthroscopic release of posttraumatic elbow contracture. All potentially eligible patients were approached by a member of the research team (YW), who explained the study objectives and procedures in detail. Those who expressed interest were formally screened using the predefined inclusion and exclusion criteria. Informed consent was obtained from patients who met the eligibility criteria and agreed to participate. Baseline data were collected before randomization. Participants were then consecutively allocated to either the DT system group or the conventional outpatient clinic-based training group (CT group) using a concealed randomization method. The assigned training protocol was initiated within the first postoperative week. The inclusion and exclusion criteria are listed in Textbox 1.

Textbox 1. Inclusion and exclusion criteria.

1. Inclusion criteria

- Patients who are 16 years of age or older.
- Patients who have a lack of elbow flexion or extension causing functional impairment that has been present for at least 6 months.
- Patients who have failed to respond to nonoperative treatment.
- Patients who are scheduled to undergo secondary arthroscopic capsulectomy or osteocapsular arthroplasty.

2. Exclusion criteria

- Patients with contraindications for rehabilitation or regional brachial plexus block use, such as those with bleeding diathesis, taking anticoagulants, or experiencing severe shoulder range of motion limitations.
- Patients with progressive or persistent neuropathy or neuritis.
- Those with preexisting conditions that might hinder their ability to fully participate in rehabilitation, including neuromuscular or psychosocial conditions.
- Patients with ongoing or recurrent contracture due to inflammatory diseases such as rheumatoid arthritis, juvenile idiopathic arthritis, or chondrolysis.
- Patients presenting with elbow joint infections or a history of previous joint infections.
- Patients with structural anomalies that could restrict elbow motion, unrelated to the condition being treated, such as dysplasia, malunion, osteonecrosis, or congenital deformities.
- Cases where a reasonable restoration of motion and function was not anticipated.
- Patients with insufficient postoperative regional anesthesia.
- Those experiencing intraoperative or postoperative complications that might impact the study's outcomes.
- Patients dealing with injuries or diseases during the postoperative period that could affect elbow function.
- Patients for whom arranging postoperative physical therapy appointments was not feasible.
- Cases where a significant portion of the procedure was performed in an open surgical manner.

Sample Size Calculation

A sample size of 73 patients was estimated to provide 80% power (2-sided α=.025) to detect a 10° difference in ROM at 12 weeks postoperatively. The 10° noninferiority margin was prespecified in the registered protocol and selected based on multiple lines of evidence. Sun et al [10] reported a distribution-based minimal clinically important difference (MCID) of 14.1° and an anchor-based MCID of 25.0° for the total elbow flexion-extension arc after arthrolysis, with a minimal detectable change at the 90% confidence level of 10.5°. In addition, O'Driscoll et al [11] observed a clinically meaningful between-group ROM difference of 9° in a trial comparing rehabilitation strategies after arthroscopic elbow contracture release. Our 10° margin was therefore more conservative than the published MCID estimates and approximated the MDC_{90} threshold, ensuring that any clinically important difference would be detected. To mitigate potential attrition, we increased the target enrollment to 122 patients, assuming a 40% dropout rate.

Intervention and Control Group

DT Group

Patients assigned to the DT group received individually tailored PEST through a mobile app (Joymotion R software; Shanghai Medmotion Medical Management Co, Ltd). On the day of discharge, a technician installed the app on each patient's mobile device, and patients used their home Wi-Fi to access the program. The app provided individually tailored PEST with detailed instructions, recorded exercise completion rates, and offered real-time feedback on training performance. In addition,

XSL•FO
RenderX

it enabled 2-way video and audio interactions with a physiotherapist (PT) at the rehabilitation center. Each week, the supervising PT initiated a scheduled conference with the patient to monitor progress, adjust the exercise regimen, and address any concerns. The PEST was individually prescribed by the supervising PT via the DT system and assigned as daily tasks to ensure continuity and adherence throughout the 12-week postoperative period.

CT Group

Patients in the control group received conventional outpatient clinic-based training (3-4 times per week), which consisted of scheduled training sessions and on-site PT supervision. This traditional approach involved direct, hands-on guidance and regular monitoring during therapy sessions at the Rehabilitation Department of Shanghai Sixth People's Hospital. Unlike the DT group, the control group did not use a mobile app or remote monitoring tools, and their rehabilitation was delivered entirely in a clinical setting.

Both groups followed a standardized 12-week PEST protocol (detailed in Multimedia Appendix 2). During weeks 1 and 2, patients performed pain-free passive and active-assisted ROM exercises hourly, along with grade I-III joint mobilizations and cryotherapy. Isometric strengthening was initiated at week 2. During weeks 3 and 4, light isotonic resistance exercises were introduced and progressed based on the achievement of near-functional ROM and tolerable pain (Visual Analog Scale score ≤4). During weeks 5-8, moderate-to-advanced resistance, eccentric loading, and sport- or work-specific functional training were added. During weeks 9-12, strengthening was maximized, and patients transitioned to self-managed maintenance programs. All exercises were performed within a pain-limited range; no absolute ROM ceilings were enforced. Outcome assessments were conducted at predetermined intervals to compare improvements in elbow function, ROM, and overall recovery.

Outcome Measures

Overview

Functional outcome measures were collected by physical therapists in outpatient clinics. Self-assessed outcome measures were also completed in the outpatient clinic using online questionnaires, with assistance from 2 physical therapists who were blinded to group allocation. Follow-up assessments were conducted at 4, 12, and 24 weeks after surgery.

Primary Outcome

The primary outcome was active elbow flexion-extension ROM (in degrees) measured at 12 weeks postoperatively. A standard handheld goniometer was used to measure the angle from full extension to maximum flexion of the affected elbow, providing an objective measure of motion.

Secondary Outcomes

Elbow flexion-extension ROM was measured in degrees using a goniometer at 4, 12, and 24 weeks after surgery. Forearm rotation ROM was also assessed at these same time points using a goniometer. All ROM measurements were performed with the patient's arm in a standardized position to ensure consistency, and greater angles indicated improved elbow joint flexibility.

Elbow flexor strength was evaluated at postoperative follow-up visits using a calibrated Baltimore Therapeutic Equipment (BTE) work simulator. Isometric strength was measured as the maximal voluntary contraction of the elbow flexor muscles maintained for 5 seconds with the elbow at a fixed angle. Dynamic strength was measured by having the patient perform repeated elbow flexion movements against a preset resistance on the BTE machine, simulating a functional lifting motion. Peak force or torque values obtained during each test were recorded. For standardization, strength outcomes were expressed as a percentage of the strength of the patient's unaffected contralateral elbow, allowing direct comparison with the healthy side (see Multimedia Appendix 2).

The American Shoulder and Elbow Surgeons (ASES) Shoulder Score Elbow Outcome questionnaire was administered at 4, 12, and 24 weeks to assess elbow function and pain from the patient's perspective. It yields 2 subcomponents: a pain score (typically assessed using a visual analog scale or pain rating, with 0 indicating no pain and higher values indicating worse pain) and a function score (based on the patient's ability to perform daily activities requiring elbow use). Each subscore contributes to an overall ASES elbow score (range 0-100 points), with higher scores indicating better function and less pain. For this study, the pain and function subscores were analyzed separately to assess improvements in each recovery domain.

Upper extremity disability and symptoms were evaluated using the Disabilities of the Arm, Shoulder, and Hand (DASH) questionnaire at 4, 12, and 24 weeks postoperatively. The DASH is a 30-item patient-reported outcome measure in which patients rate the difficulty of and interference with performing various physical activities involving the arm, shoulder, or hand. Scores range from 0 to 100, with 0 reflecting no disability and 100 indicating the most severe disability [12]. A decrease in the DASH score over time indicates improvement in arm function and reduction in disability [11].

General health-related quality of life was assessed at 4, 12, and 24 weeks using the EQ-5D-5L questionnaire. The EQ-5D-5L is a standardized instrument that covers 5 dimensions of health (mobility, self-care, usual activities, pain/discomfort, and anxiety/depression), each rated on 5 levels of severity [13]. Patients completed the questionnaire, and the responses were converted into a health utility index value and an EQ-5D Visual Analog Scale score for overall self-rated health. This provided a broad measure of patients' quality of life and well-being during recovery, with improvements in EQ-5D-5L scores indicating better overall health status as rehabilitation progressed.

Randomization, Allocation, and Blinding

A computer-generated randomization sequence was used to assign participants to either the DT or CT group. Block randomization with varying block sizes ensured balanced allocation over time. Allocation concealment was maintained using sealed, opaque, sequentially numbered envelopes prepared by an independent researcher (SY) who was not involved in patient recruitment or assessment. Following the initial

XSL•FO
RenderX

assessment, a volunteer PT distributed the envelopes according to the randomization sequence. These consecutively numbered, sealed, opaque envelopes were stored in a secure location accessible only to the unblinded lead researcher-PT (SL). This PT then scheduled the participants' postoperative training program and introduced the DT system.

Because of the nature of the interventions, blinding of patients and treating physical therapists was not feasible. However, outcome assessors responsible for measuring ROM and strength and administering standardized questionnaires (DASH, EQ-5D-5L, and ASES) were blinded to group allocation. Data analysts were also blinded to treatment assignments during statistical analysis to minimize potential bias. To support blinding during data collection, precoded data forms were used so that intervention group identity remained masked during data entry and evaluation.

Statistical Analysis

Patient data were securely coded and stored using the hospital's electronic data capture system on local servers. Baseline characteristics were summarized as mean (SD) for continuous variables and as frequencies and percentages for categorical variables. Between-group differences in baseline characteristics were assessed using independent 2-sample *t* tests (unpaired and 2-tailed) for continuous variables and chi-square tests for categorical variables. All hypothesis tests were 2-tailed, and a *P* value <.05 was considered statistically significant for these comparisons.

The primary efficacy analysis was performed on the intention-to-treat population in accordance with noninferiority trial guidelines. Cost-effectiveness and adverse event analyses were also conducted using the intention-to-treat population, with all randomized patients analyzed in their originally assigned groups.

The primary outcome was elbow flexion-extension ROM at 12 weeks postoperatively. Primary and secondary outcomes were analyzed using linear mixed-effects models to account for repeated-measures data collected over time. Fixed effects included group (DT vs CT), time (baseline, 4 weeks, 12 weeks, and 24 weeks), and their interaction (group × time), whereas age, sex, and the baseline value of each respective outcome were included as covariates. Specifically, for each outcome variable, the corresponding baseline measurement was entered as a covariate in the model, consistent with standard recommendations for controlling regression to the mean in randomized trials. Random effects were specified to account for within-participant variability, and least-squares means with 95% CIs were calculated for group comparisons at each time point. Noninferiority was established if the upper bound of the 95% CI for the between-group difference in 12-week ROM did not exceed 10°, indicating that the DT group was not more than 10° worse than the CT group. To account for rounding in range-of-motion measurements, we applied a *P* value correction method following the recommendation of Zdravkovic and Jost [14], setting the significance threshold at .03 for outcomes assessing mean differences in ROM. For all other outcomes, a *P* value <.05 was considered statistically significant.

Continuous secondary outcomes were also analyzed using linear mixed-effects models similar to those used for the primary outcome analysis, with adjustment for baseline values when available. Dichotomous outcomes were compared using Cochran-Mantel-Haenszel chi-square tests, controlling for baseline contracture severity.

For the multiple secondary end points, both the Bonferroni correction and the Holm step-down procedure were applied to adjust for multiple comparisons. Seven secondary efficacy outcomes were assessed at the 12-week primary end point: forearm rotation, isometric strength, dynamic strength, ASES function, ASES pain, DASH, and EQ-5D index. The Bonferroni correction set the significance threshold for each secondary outcome at α=.05/7. As the secondary outcomes were positively correlated, the standard Bonferroni approach was considered overly conservative. Therefore, the Holm step-down procedure was also applied because it controls the familywise error rate identically to the Bonferroni method while offering uniformly greater statistical power. Both methods yielded consistent conclusions. *P* values for secondary outcomes were interpreted against both adjusted thresholds. The primary outcome (noninferiority in ROM) was analyzed using a 1-sided alpha of .025 and was not subject to multiplicity adjustment.

The incremental cost-effectiveness ratio (ICER) was used to assess the cost-effectiveness of the DT group compared with the CT group. The ICER represents the difference in costs and outcomes between the groups. The numerator of the cost-effectiveness ratio was calculated as the monetary cost of the DT intervention minus the monetary cost of CT. Annual project costs were estimated by extrapolating the 12-week implementation costs. The denominator was calculated as the ROM gained in the DT group minus the ROM gained in the CT group at 12 weeks. Bootstrapping was used for pairwise comparisons of mean costs and effects between the DT and CT groups. CIs for mean differences in effects were obtained using bootstrapping with 1000 replications. The bootstrapped cost-effect pairs were also graphically represented on a cost-effectiveness plane [15].

Missing data in this study occurred exclusively at the visit level. If a patient missed a follow-up visit, all outcomes from that visit were missing; however, data from attended visits remained available. There was no item-level missingness within completed visits. Given this structure, mixed-effects models in the intention-to-treat analysis retained all available data for each participant. No imputation was applied to address missing values. As data loss occurred at the level of entire visits rather than within-visit fields, tests for data missing completely at random, such as Little missing completely at random test, were not performed. The analysis was repeated in the per-protocol population, which included only patients who completed all scheduled follow-up assessments. Missing outcome data were therefore addressed using both intention-to-treat and per-protocol analytical strategies.

Results

Participants

The DT group (n=106) and the CT group (n=102) were well matched at baseline (Table 1). The CONSORT flowchart for both the control and intervention groups, detailing exclusions and follow-up losses, is illustrated in Figure 1. The mean age was 47 years in the DT group and 48 years in the CT group, with males comprising 77 of 106 (72.6%) patients and 80 of 102 (78.4%) patients, respectively. The mean BMI was approximately 23 kg/m^2 in the DT group and 22 kg/m^2 in the CT group. Manual workers accounted for 59 of 106 (55.7%) patients in the DT group and 60 of 102 (58.8%) patients in the CT group, whereas 73 of 106 (68.9%) patients and 56 of 102 (54.9%) patients, respectively, had achieved at least a high school education. Most patients were covered by government insurance. The numbers of current smokers (*P*=.39), alcohol users (*P*=.28), and users of paracetamol and nonsteroidal anti-inflammatory drugs (*P*=.55) showed no significant between-group differences. Clinically, most patients had no prior history of significant elbow injuries, such as distal humerus, capitellum, olecranon, Monteggia, or radial head fractures, and only a small proportion had previously undergone surgical treatment for these conditions. No significant between-group differences were observed in records of previous operations (osteocapsular arthroplasty, *P*=.14; capsular release, *P*=.14; ulnar nerve management—limited decompression, *P*=.76; ulnar nerve management—subcutaneous transposition, *P*=.76; removal of heterotopic ossification, *P*=.61; radial head excision, *P*=.94; and hardware removal, *P*=.15). Baseline elbow function was comparable between groups, with mean flexion-extension ROMs of approximately 78°-79°, forearm rotation ROMs ranging from 76° to 91°, and isometric and dynamic flexion strength values of approximately 69%-70% and 77% of the contralateral side, respectively. Patient-reported outcomes, including ASES scores, DASH scores, and EQ-5D-5L indices, were also similar, reflecting moderate impairment and reduced quality of life in both groups.

Figure 1. Flowchart of the study from enrollment to analysis. CT: conventional training; DT: digital training; ROM: range of motion.

Primary and Secondary Outcomes

Using the linear mixed-effects model, the adjusted between-group difference in 12-week elbow flexion-extension ROM was –1.6° (95% CI –8.2° to 4.9%; Tables 2 and 3), indicating noninferiority of DT compared with CT. A complete-case analysis excluding 12 patients without ROM follow-up yielded a similar difference of –1.5° (95% CI –8.8° to 5.0°), confirming that the primary outcome was not sensitive to the handling of missing data. Thus, the conclusion of noninferiority remained unchanged when only observed cases were analyzed compared with multiply imputed data.

Secondary outcomes improved comparably in both groups, with no between-group differences meeting the adjusted significance criteria after Bonferroni correction for multiple end points. Forearm rotation ROM increased slightly more in the DT group, with an adjusted difference of 14.2° (95% CI 2.9°-25.6°). Isometric and dynamic flexion strength gains were nearly identical between groups, with differences of 0.04% (95% CI –2.1% to 2.2%) and 0.26% (95% CI –1.5% to 2.0%), respectively, when normalized to the contralateral side. Functional recovery, assessed using the ASES function subscore, showed a small difference of 0.6 points (95% CI –0.3 to 1.5), indicating similar functional improvement in both groups. Pain reduction, measured using the ASES pain subscore, was comparable, with a near-zero adjusted difference (95% CI –8.3 to 8.5). The DASH score, reflecting disability, improved similarly in both groups, with a minimal between-group difference of 0.23 points (95% CI –1.54 to 1.99). Lastly, health-related quality of life, measured using the EQ-5D-5L, showed no meaningful between-group difference, with an adjusted index difference of 0.001 (95% CI –0.012 to 0.015; Tables 2 and 3). Thus, forearm rotation (P<.001), ASES function (P<.001), and EQ-5D-5L (P=.003) showed statistically significant between-group differences, whereas isometric strength (P=.76), dynamic strength (P=.67), ASES pain (P=.18), and DASH (P=.87) showed no significant between-group differences. Sensitivity analyses using the per-protocol population showed similar results (Multimedia Appendices 3 and 4). Sensitivity analyses of secondary outcomes at 12 weeks using Bonferroni and Holm step-down adjustments for multiple comparisons are presented in Multimedia Appendix 5. An additional sensitivity analysis that included education level as a covariate in the primary mixed-effects model yielded an adjusted between-group difference of –1.7° (95% CI –8.4° to 5.0°), confirming that the noninferiority conclusion was robust to adjustment for this baseline imbalance.

[g]DASH: Disabilities of the Arm, Shoulder, and Hand.

[h]The EQ-5D-5L change of 0.00 (SD 0.00) at 4 weeks in both groups reflects the limited responsiveness of this generic health utility instrument in the early postoperative period. At 4 weeks after elbow surgery, improvements in joint-specific function are typically offset by ongoing postoperative recovery burden, resulting in negligible net change in global health utility. This pattern is consistent with published studies reporting limited EQ-5D sensitivity to change in upper extremity orthopedic populations during the early recovery phase.

[i]N/A: not applicable.

[a]Each coefficient represents the estimated between-group difference in the change from baseline (intervention group minus control group) for the specified outcome at that follow-up time point. Positive coefficients indicate higher scores in the intervention group compared with the control group, whereas negative values indicate lower scores in the intervention group. Each estimate is presented with its 95% CI and corresponding *P* value. All outcome measures were adjusted for baseline values in the model.

[b]Isometric flexion strength and dynamic flexion strength were measured and compared with the contralateral side using a BTE machine (Simulator II).

[c]ROM: range of motion.

[d]ASES: American Shoulder and Elbow Surgeons.

[e]DASH: Disabilities of the Arm, Shoulder, and Hand.

Cost-Effectiveness Outcomes

The economic evaluation is presented as a short-term cost-consequence analysis given the limited 12-24-week time horizon, with bootstrapped results presented in Tables 4 and 5 and Figures 2 and 3. We note that the incremental health effects were very close to 0 for most outcomes, rendering formal cost-per-quality-adjusted life year ratios unstable and difficult to interpret. The results should therefore be interpreted as descriptive cost-consequence findings rather than as a definitive cost-utility evaluation. Figure 2 illustrates the incremental cost-effectiveness plane. Across 1000 bootstrap resamples, the incremental cost of DT versus CT was almost always negative (median CNY –7400 [US $–1087]), whereas the incremental effects clustered near 0. The majority of bootstrap iterations fell within the southeast quadrant (negative Δcost, positive Δeffect), indicating that DT was cost-saving and at least as effective as CT in most resamples. A minority of points fell within the southwest quadrant (cost-saving but slightly less effective), and virtually none fell within the costly quadrants, underscoring the consistency of the cost-saving result. Figure 3 shows the cost-effectiveness acceptability curve. At a willingness-to-pay threshold of CNY 0 (US $0) per unit of effect, the probability that DT was cost-effective was 75%. This probability increased to 78% at a threshold of CNY 134,000 (US $19,677) per quality-adjusted life year and approached 80% as willingness-to-pay increased. These probabilistic findings suggest that DT was associated with lower costs in most bootstrap resamples. However, because incremental health effects clustered near 0, the cost-effectiveness acceptability curve should be interpreted with caution. The high probability of cost-effectiveness primarily reflects the cost-saving nature of the digital intervention rather than a meaningful differential in health effects. These short-term findings should not be extrapolated to longer time horizons without further study because downstream costs or savings associated with preventing recontracture or reoperation were not captured.

[a]DT: digital training.

[b]CT: conventional training.

[c]All relevant costs were captured from a societal perspective. This included direct medical costs (hospital stay, primary and secondary care, rehabilitation and physical therapy costs, and medication costs), direct nonmedical costs related to care (transportation for medical visits and any specialized nutritional support during recovery), and indirect costs due to productivity loss (lost wages for patients during recovery or disability, and lost income for family members/caregivers, if applicable). Costs were obtained from hospital billing records and patient self-reports where needed (wage losses). All costs are reported in 2024 Chinese Yuan, as 2024 was the end of the enrollment period; costs incurred in earlier years were adjusted to 2024 price levels using the consumer price index. Costs and outcomes occurring beyond the initial year were discounted at an annual rate of 3% to reflect time preference, consistent with standard practice in health economic evaluations.

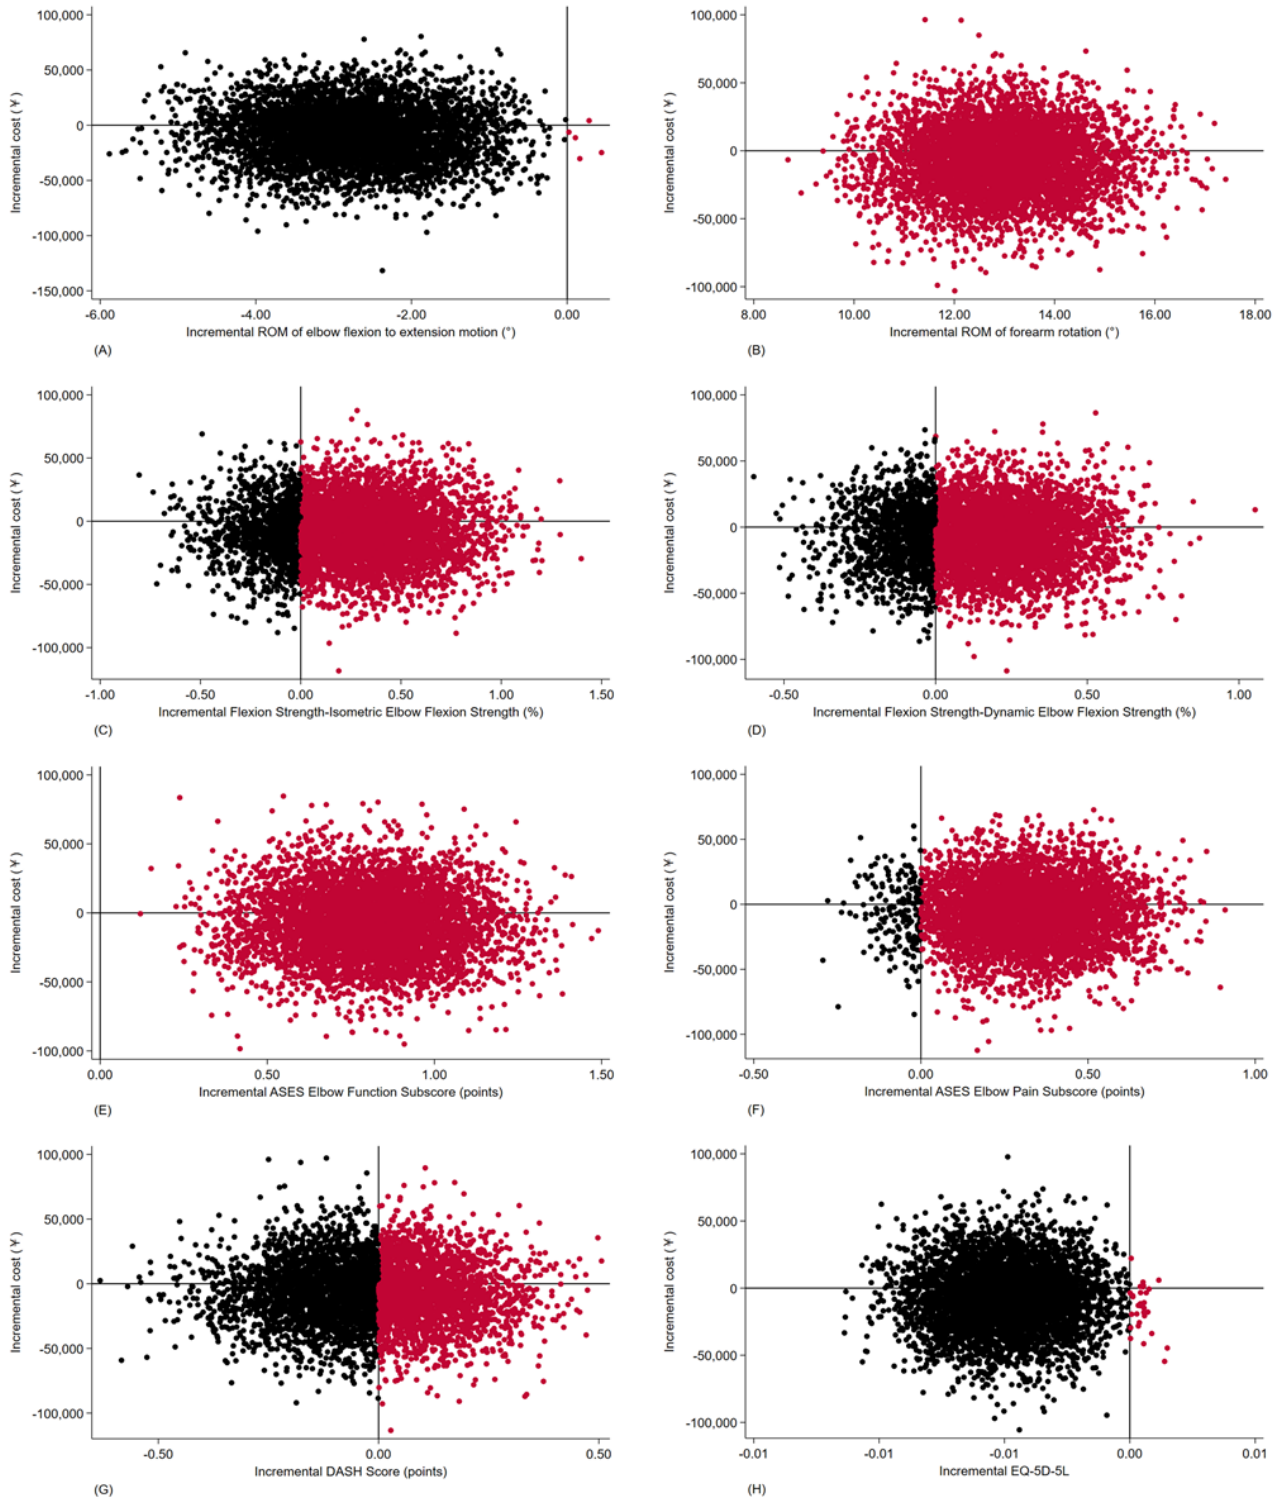
[a]ICER: incremental cost-effectiveness ratio.

[b]The table displays the incremental cost, incremental effect in primary outcome scores, and the resulting ICER. ICER is defined as the incremental cost divided by the incremental effect, representing the additional cost per unit improvement in outcome for the intervention group versus the control group. Incremental effects are given for all outcome measures. ICER values are presented for the 12-month follow-up under both the intention-to-treat and per-protocol analyses. A negative ICER indicates that the intervention group achieved equivalent or better outcomes at a lower cost compared with the control group.

[c]Values are reported as follows: incremental effects as coefficient (95% CI), and ICER values as point estimates computed from the ratio of incremental cost to incremental effect.

[d]CNY 1=US $0.15.



[e]ROM: range of motion.

[f]ASES: American Shoulder and Elbow Surgeons.

[g]DASH: Disabilities of the Arm, Shoulder, and Hand.

Figure 2. Bootstrapped cost-effectiveness planes (BCEPs) for the comparison of digital training (DT) vs conventional training (CT). Panels show the BCEPs for incremental outcomes of (A) elbow flexion-extension range of motion (ROM), (B) forearm rotation ROM, (C) isometric elbow flexion strength, (D) dynamic elbow flexion strength, (E) American Shoulder and Elbow Surgeons (ASES) function score, (F) ASES pain score, (G) Disabilities of the Arm, Shoulder, and Hand (DASH) score, and (H) EQ-5D-5L score. Each point represents an incremental cost-effect pair (ΔEffect on the horizontal axis and ΔCost on the vertical axis) derived from 1000 bootstrap replicates of the trial data. The origin (0,0) indicates no difference between groups. Points below the horizontal axis indicate that DT is less costly than CT, whereas points to the right of the vertical axis indicate that DT is more effective than CT. The cost-effectiveness acceptability curve illustrates the probability that DT is cost-effective compared with CT across a range of willingness-to-pay thresholds per unit of effect gained (per quality-adjusted life-year gained). The curve was generated from the same 1000 bootstrap replicates by calculating the proportion of simulations in which the net monetary benefit of DT compared with CT was positive at each willingness-to-pay threshold.

RenderX

Figure 3. Cost-effectiveness acceptability curves (CEACs) for the comparison of digital training (DT) vs conventional training (CT). Panels show the CEACs for (A) elbow flexion-extension range of motion (ROM), (B) forearm rotation ROM, (C) isometric elbow flexion strength, (D) dynamic elbow flexion strength, (E) American Shoulder and Elbow Surgeons (ASES) function score, (F) ASES pain score, (G) Disabilities of the Arm, Shoulder, and Hand (DASH) score, and (H) EQ-5D-5L score. Each curve illustrates the probability that DT is cost-effective compared with CT across a range of willingness-to-pay (WTP) thresholds per unit of effect gained (per quality-adjusted life-year gained). The curves were derived from 1000 bootstrap replicates by calculating the proportion of simulations in which the net monetary benefit of DT compared with CT was positive at each WTP threshold.

Adherence and Acceptability

Patients in both groups attended approximately 3.4-3.5 sessions per week. The DT group rated agreement with the assigned exercise plan at 8.2, compared with 8.4 in the CT group. Adherence to the recommended exercise program was high in both groups, with scores of 8.5 and 8.6, respectively. Similarly, ratings for pain relief were 8.7 versus 8.8, and ratings for functional improvement were 8.8 versus 8.9. Overall satisfaction with the exercise protocol was very high, at 9.5 in the DT group and 9.6 in the CT group. No significant between-group differences were observed, indicating excellent adherence and acceptability (Table 6).

Adverse Events

Adverse events occurred in 29 of 106 (27.4%) patients in the DT group and 32 of 102 (31.4%) patients in the CT group. Therapy-related events occurred in 4 patients in the DT group and 6 patients in the CT group, with common issues including pain, swelling, and tenosynovitis. Serious adverse events leading to study withdrawal occurred in 2 (2%) DT patients and 1 (1%) CT patient (Table 7).

XSL•FO

Waist fracture due to fall	1[e]	0
Spinal surgery	0	1[e]

[a]DT: digital training system.

[b]CT: conventional outpatient clinic-based training.

[c]One patient sustained a mild infection of the surgical site and healed with conservative treatment.

[d]Patients with serious adverse events were automatically withdrawn from the study.

[e]Two patients in the DT group sustained accidental falls during daily activities unrelated to the rehabilitation protocol. One patient sustained a hip fracture while walking outdoors (approximately 6 weeks postoperatively, not during or immediately after an exercise session) and underwent surgical fixation. Another patient sustained a lumbar vertebral fracture from a fall at home during routine household activities (approximately 8 weeks postoperatively) and was treated conservatively. Neither event was temporally associated with prescribed rehabilitation exercises, and the DT protocol did not include balance-challenging or weight-bearing lower extremity exercises. Both events were adjudicated as unrelated to the study intervention. Both patients were automatically withdrawn from the study.

Discussion

Principal Findings

This trial demonstrates that a DT system in which patients receive individually tailored PEST yields outcomes comparable to those of conventional outpatient clinic-based training after arthroscopic release for posttraumatic elbow stiffness. At 12 weeks, the DT group met the prespecified noninferiority criterion for elbow flexion-extension ROM relative to the CT group. The between-group difference was –1.6° (95% CI –8.2° to 4.9°), with the upper bound of the CI well within the 10° noninferiority margin. However, the lower bound of –8.2° approaches a magnitude that some clinicians may consider clinically relevant in a population with stiff elbows. Statistical noninferiority does not necessarily imply clinical interchangeability, and individual patient factors should inform treatment selection. Secondary outcomes, including pain relief and functional improvement, were also comparable between groups. Both interventions demonstrated high adherence, and no serious adverse events related to treatment were observed. The inclusion of bootstrap-based uncertainty analyses provides additional support for the economic advantage of the digital program. The scatter distribution on the cost-effectiveness plane suggests a robust trend favoring DT as a cost-saving intervention, and the cost-effectiveness acceptability curve indicates a high probability that DT is cost-effective under typical willingness-to-pay thresholds. However, the economic evaluation was limited to a 12-week postoperative horizon and was based on very small differences in quality-of-life indices.

XSL•FO
RenderX

Although DT appears cost-effective in the short term, a longer-term evaluation capturing downstream costs and quality-of-life changes would provide a more comprehensive assessment of its cost utility. Nevertheless, within the trial period, the probabilistic analysis suggests only a modest likelihood (20%-25%) that CT would be the more cost-effective option, reinforcing the conclusion that the DT system is an economically attractive alternative to standard care.

Comparison With Prior Work

Both the DT and CT groups in the RCT achieved substantial gains in elbow flexion-extension ROM. This finding aligns with previous studies showing that DT can restore joint mobility as effectively as CT. For example, a pilot trial involving patients with elbow fractures found significant ROM improvements in both digital rehabilitation and clinic-based therapy, with no between-group difference [6]. Similarly, an integrative review of digital rehabilitation after orthopedic surgeries (primarily knee and hip arthroplasties) concluded that internet-based training yields improvements in joint ROM and other outcomes comparable to those achieved with standard in-person rehabilitation [16]. In other words, DT systems do not appear to impede recovery of motion, and existing evidence suggests that they achieve ROM gains equivalent to those of traditional therapy, consistent with the findings of our elbow stiffness trial.

Baseline forearm rotation differed between groups (P=.01), with the DT group demonstrating higher baseline values. Although the mixed-effects model included baseline forearm rotation as a covariate, which is the recommended approach for addressing regression to the mean, residual confounding due to this baseline imbalance cannot be entirely excluded. The adjusted between-group difference of approximately 13° (Table 3), therefore, reflects the estimated treatment effect after baseline correction. Nevertheless, this finding should be interpreted as exploratory because the trial was powered only for the noninferiority comparison of the primary end point. No formal MCID has been established for forearm rotation ROM in the published literature. Normal forearm rotation encompasses a total arc of approximately 160°, meaning that a 13° difference represents roughly 8% of normal motion. Whether this magnitude translates into a clinically meaningful functional benefit for patients remains uncertain. In addition, as discussed above, baseline forearm rotation differed between groups, and some portion of the observed difference may reflect residual imbalance despite statistical adjustment. Confirmatory studies specifically powered for this end point are needed to establish the clinical significance of this finding.

Recovery of muscle strength in the DT group was comparable to that in the CT group. This finding is supported by previous research in orthopedic rehabilitation. For example, following knee surgery, patients undergoing digital rehabilitation achieved strength gains indistinguishable from those of patients receiving clinic-based therapy [16]. Systematic reviews across various musculoskeletal conditions have likewise reported no significant differences in strength outcomes between digitally supervised exercise and CT when exercise protocols are comparable [16].

For patient-reported outcome measures, improvements in the DT group were comparable to those in the CT group. Previous mobile-based rehabilitation studies have consistently demonstrated equivalent functional outcome scores [6]. In a pilot study of elbow rehabilitation, both groups achieved significant functional gains, and the mobile-based rehabilitation group even showed a trend toward slightly better DASH scores early in recovery, although the differences were not statistically significant [6]. More broadly, a 2017 meta-analysis confirmed that mobile-based rehabilitation is as effective as usual care for improving physical function and reducing disability in musculoskeletal disorders [5]. In our trial, both groups also demonstrated improvements in quality of life, and prior evidence suggests that DT performs comparably to traditional training in this domain. Systematic reviews have reported that improvements in health-related quality of life are similar between DT and in-person care among patients with musculoskeletal conditions [17].

Cost-Effectiveness

Our short-term cost-consequence analysis found that DT was associated with lower overall costs compared with conventional outpatient clinic-based training. The cost savings were driven primarily by reductions in primary care visits, secondary care costs, medication expenditures, and transportation expenses. These findings are strongly supported by previous cost-effectiveness studies [18-20]. A recent meta-analysis of 5 economic evaluations estimated that mobile-based rehabilitation was, on average, approximately US $90 less expensive per patient than standard rehabilitation for musculoskeletal conditions [18]. Another analysis of a mobile-based rehabilitation system after total knee arthroplasty reported cost savings of more than US $2400 per patient compared with traditional therapy, alongside equivalent or superior outcomes [19]. Our trial's findings of lower costs favoring mobile-based rehabilitation are therefore consistent with prior evidence. Overall, DT systems appear to be cost-effective, providing similar health outcomes at lower or comparable costs relative to conventional in-person training.

Adherence, Satisfaction, and Safety

Patient adherence to the DT system in the DT arm of the trial was high, reflecting a common trend reported in DT studies. Research indicates that patients often attend DT sessions and perform prescribed exercises as reliably as, or more reliably than, those receiving conventional therapy. A 2024 systematic review of RCTs found that patients undergoing mobile-based rehabilitation demonstrated approximately 9% higher exercise adherence on average compared with those receiving in-person care (95% CI 2%-16% higher) [21]. Attendance at scheduled sessions was also slightly better with DT systems, by as much as 8%, although the difference was not always statistically significant [21]. Likely contributing factors include convenience and flexibility, as patients can complete sessions from home, making adherence to the rehabilitation regimen easier. Patient satisfaction with the DT system in this trial was also very positive and may even have exceeded satisfaction with in-hospital therapy. This finding is consistent with previous studies reporting high acceptability of DT systems. In the elbow fracture pilot study, participants in the tele-rehabilitation group reported higher satisfaction with their care despite similar

XSL•FO
RenderX

clinical outcomes [6]. Patients often value the comfort and individualized attention made possible through video sessions, and the therapeutic alliance can be maintained remotely. Importantly, studies have shown that when DT systems are delivered synchronously through real-time video, the quality of patient-therapist interaction is preserved, resulting in satisfaction ratings comparable to those of in-person visits [17]. Overall, the high adherence and satisfaction observed in the DT group are well supported by previous research, indicating that mobile-based rehabilitation is generally well accepted and achieves patient engagement comparable to that of conventional rehabilitation.

Regarding safety, the DT system used in this trial proved to be safe, with no increase in adverse events compared with CT. This finding is strongly consistent with existing evidence indicating that DT systems do not pose an increased risk to patients. A recent scoping review encompassing more than 80 mobile-based training studies across diverse populations found that the incidence of adverse events during DT sessions was extremely low, approximately 0.3% across 84,534 total sessions [22]. Importantly, most reported incidents were determined to be unrelated to the DT intervention itself [22].

Clinical Implications

Within the context of this single-center trial, DT may be considered for integration into postsurgical rehabilitation pathways. Our study demonstrates that a DT system in which patients receive individually tailored PEST yields improvements in elbow ROM, strength, function, and quality of life comparable to those achieved with traditional outpatient clinic-based training, while also reducing overall costs. These findings support its use as a viable alternative, particularly for patients with limited access to specialized care or transportation challenges. The lower cost burden observed in our study, driven by reductions in primary care, secondary care, medication, and transportation expenses, further underscores its potential to reduce financial pressures on both patients and health care systems. In addition, the high levels of patient adherence and satisfaction, together with comparable safety profiles between the DT system and outpatient clinic-based training, suggest that digital interventions do not compromise treatment quality or clinical outcomes. Given these findings, clinicians may consider incorporating DT systems into standard postoperative rehabilitation protocols to enhance accessibility and optimize resource utilization. If validated in multicenter settings, DT systems may have broader applicability in musculoskeletal rehabilitation, although the generalizability of our single-center findings to other populations and health care systems requires further investigation [23-25]. Future efforts should focus on addressing barriers such as technology access and reimbursement policies to fully realize the benefits of DT systems in routine clinical practice.

Strengths and Limitations

This study's strengths include a rigorous randomized controlled design with an adequate sample size and comprehensive outcome measures encompassing clinical, functional, and economic end points. The noninferiority design allowed us to demonstrate that the DT system, in which patients receive individually tailored PEST, is as effective as conventional outpatient clinic-based training, while the inclusion of cost-effectiveness, adherence, and safety assessments provides a holistic view of the intervention's impact. Moreover, high patient adherence and satisfaction underscore the feasibility and acceptability of the DT system in a postsurgical setting. However, several limitations must be acknowledged. First, our trial was originally powered for the primary end point of elbow ROM noninferiority, with 73 patients per group expected to provide 80% power (1-sided α=.025) to detect a 10° margin. The final sample (106 and 102 patients per group) exceeded this target, yielding approximately 90% power for the noninferiority hypothesis. This ample sample size strengthens confidence in the primary finding that DT is not inferior to CT for ROM improvement. However, as is typical in RCTs, our study was not specifically powered to detect small between-group differences in secondary outcomes. We examined multiple secondary end points (functional scores, strength measures, etc) and applied a Bonferroni correction to control type I error. This stringent adjustment, while guarding against false positives, inevitably lowers statistical power for each secondary comparison. Consequently, the chance of type II error is increased for secondary outcomes under our analysis strategy. In practical terms, our negative secondary results should be interpreted with caution: the trial may not have been large enough to uncover subtle advantages of either intervention in secondary domains. For example, given our final sample, the detectable difference in DASH score with 80% power at an adjusted α≈.007 is several points; smaller improvements could have gone undetected. We opted for a conservative approach to multiple comparisons to prioritize confidence in any positive findings, but we acknowledge that this comes at the expense of sensitivity. We have now supplemented the original Bonferroni correction with the Holm step-down procedure, which is uniformly more powerful for positively correlated end points, as recommended by both the Food and Drug Administration and the European Medicines Agency guidance. Both methods yielded identical conclusions regarding the secondary outcomes. Future studies with larger samples or without such stringent correction might further explore secondary benefits of DT. In our data, no secondary outcome showed a trend large enough to approach the adjusted significance threshold, which provides some reassurance that we did not miss any clinically meaningful effects. Nonetheless, the possibility of type II error for modest effects, particularly in patient-reported outcomes, remains a limitation of this study.

Second, a notable limitation is that we relied on self-reported measures for exercise adherence and patient satisfaction. Such self-reports are susceptible to social desirability bias, whereby participants may portray themselves in a favorable light. Research using concealed accelerometers has shown that self-reported exercise diaries can overestimate adherence by approximately 20% compared with objectively measured activity. In our trial, patients might have overestimated their adherence to the exercise regimen or overstated their satisfaction. Although the Joymotion app recorded exercise completion rates and session frequency, thereby providing a partial digital log, we did not use dedicated motion sensors or video verification to confirm exercise quality or dosage. The

XSL•FO
RenderX

very high adherence scores should therefore be interpreted with caution. Future studies should incorporate wearable sensors or automated movement-quality assessment to complement patient reports. Consequently, although both groups reported excellent adherence (averaging 8.5/10) and satisfaction (9.5/10), these values should be interpreted with caution. It is possible that actual adherence was lower than reported, given evidence that individuals often overreport healthy behaviors. This limitation underscores the need for future studies to include objective monitoring of exercise completion to complement patient reports. Despite this caveat, the absence of between-group differences in self-reported adherence suggests that any social desirability bias was likely nondifferential between DT and CT and, thus, probably does not compromise the comparison of the 2 modalities, although absolute adherence levels may have been overestimated.

Third, the single-center design may limit the generalizability of our findings to other health care settings. Education level differed significantly between groups, and because education may correlate with digital literacy and comfort with technology, this imbalance could have influenced adherence and outcomes in the DT arm. A sensitivity analysis adjusting for education confirmed that the noninferiority conclusion was unchanged, but we cannot fully exclude residual confounding. The inability to blind participants and therapists introduces potential performance and expectation bias. This is particularly relevant for patient-reported outcomes such as ASES, DASH, and EQ-5D-5L scores, for which awareness of group assignment may have influenced response patterns. The small between-group differences observed in these measures may partly reflect equivalent patient expectations rather than purely equivalent treatment effects. Future trials should consider strategies to mitigate expectation bias, such as enhanced blinding of outcome assessors and the use of sham digital interfaces.

Conclusions

This study showed that individually tailored PEST delivered via a DT system was statistically noninferior to conventional outpatient clinic-based training following arthroscopic release for posttraumatic elbow stiffness. Although noninferiority does not necessarily imply clinical interchangeability, the digital approach may represent a viable option for patients facing barriers to traditional in-person rehabilitation, provided that clinicians consider individual patient factors when selecting a rehabilitation modality.

Acknowledgments

The authors acknowledge the Shanghai Medmotion Clinic for providing the necessary equipment for the study. We sincerely thank all the patients who participated in this study and the clinical staff who supported the trial. The authors also confirm that no generative artificial intelligence tools were used in the writing of this manuscript.

Abstract

Background: Non–small cell lung cancer (NSCLC) accounts for approximately 85% of primary pulmonary neoplasms. Complete surgical removal remains the cornerstone of curative therapy, yet it frequently diminishes residual lung function and exercise tolerance. Structured, center-based rehabilitation hastens physiological recovery, but conventional schemes rarely deliver continuous, patient-specific monitoring. Remote, digitally delivered exercise overcomes logistical obstacles; however, the lack of real-time quality assurance curtails effectiveness. Wearable motion capture platforms that provide millimeter-precise kinematic data and instantaneous biomechanical feedback can close this supervisory void by confirming movement accuracy and issuing immediate corrective prompts. Whether this technologically augmented telerehabilitation yields clinically relevant improvements in postoperative exercise capacity after NSCLC resection remains inadequately established.

Objective: This study aims to find out whether motion capture–enabled telerehabilitation can enhance exercise endurance and functional recovery following NSCLC resection, thereby filling a critical void in postoperative care pathways.

Methods: We performed a single-center, parallel-arm randomized trial in individuals who had completed curative lung resection for NSCLC and satisfied every enrollment criterion. Following randomization, eligible patients were assigned either to a technology-enhanced telerehabilitation protocol incorporating live motion sensing or to a WeChat-based regimen without that feedback layer. Each program spanned 4 weeks. Assessments—comprising exercise endurance, spirometric variables, health-related quality of life, and daily physical activity—were collected at discharge and repeated 4 weeks after intervention.

Results: No exercise-related adverse events occurred during the 4-week intervention. Compared with conventional video-guided training, the motion recognition group demonstrated significantly greater improvements in exercise tolerance, pulmonary function, selected functional mobility outcomes, and quality of life. The intervention group achieved a greater increase in 6-minute walk distance (mean difference 32 meters, 95% CI 5.40-58.60; *P*=.02). Significant between-group differences were also observed in forced vital capacity (mean difference 476.4 mL; *P*=.02), forced expiratory volume in 1 second (mean difference 346.0 mL; *P*=.04), FEV_1/FVC ratio (mean difference 12.8%; *P*=.03), and peak expiratory flow (mean difference 70.8 L/minute; *P*=.002). For functional mobility, the intervention group showed superior improvement in the Timed Up and Go test (mean difference −1.63 seconds; *P*=.04), whereas no significant between-group differences were found in other mobility measures. Quality of life

XSL•FO
RenderX

outcomes favored the motion recognition group, with greater improvements in physical well-being, functional well-being, additional concerns–lung subscale, and total Functional Assessment of Cancer Therapy–Lung score (mean difference 13.00; *P*<.001). Program adherence was higher in the intervention group (72% vs 40%; *P*=.02).

Conclusions: Four-week motion capture–guided telerehabilitation yielded clinically meaningful gains in aerobic endurance, spirometric indices, ambulatory capacity, and global health–related quality of life for patients recovering from NSCLC surgery, underscoring its usefulness as a safe and effective remote care strategy.

KEYWORDS

non–small cell lung cancer; artificial intelligence; motion recognition; telerehabilitation; exercise endurance

Introduction

Lung cancer continues to rank among the leading causes of malignant disease worldwide, exerting a disproportionate share of global oncological morbidity [1]. Global cancer statistics for 2022 recorded roughly 2.48 million incident cases—about 1 in 8 newly diagnosed tumors [2]. Non–small cell lung cancer (NSCLC) constitutes approximately 85% of this total [3]. Curative-intent surgical resection remains the primary therapeutic modality; yet, a substantial proportion of recipients subsequently experience pronounced reductions in aerobic capacity and ventilatory efficiency, translating into markedly lower health-related quality of life [4]. Exercise-based rehabilitation has repeatedly been demonstrated to augment cardiorespiratory fitness, elevate peak oxygen uptake, and enhance both muscular strength and endurance [5]. Physical training is therefore regarded as a cornerstone of postoperative recovery after NSCLC resection. Randomized evidence indicates that regimented exercise improves exertional tolerance, fortifies respiratory musculature [6], and confers psychological benefit [7,8]. Traditional, center-based programs—usually conducted in hospitals or specialized rehabilitation units—continue to confront entrenched barriers. Uneven geographic distribution of trained therapists leaves numerous primary care settings without access to specialist services, impeding timely intervention. Logistical burdens—lengthy travel, inflexible scheduling, and direct and indirect costs—further erode participation, while repeated clinic visits impose additional physical and psychosocial strain on patients and caregivers.

Digital telerehabilitation—encompassing videoconferencing, smartphone apps, and immersive virtual reality—overcomes spatial and temporal barriers to specialist care. Recent studies have suggested that eHealth-supported pulmonary rehabilitation may improve musculoskeletal symptoms and quality of life in patients with post–COVID-19 condition [9]. Furthermore, structured telemedicine-based pulmonary rehabilitation protocols have been developed for individuals with post–COVID-19 condition and persistent respiratory symptoms, reflecting ongoing efforts to establish remote rehabilitation approaches.[10]. In addition, recent systematic reviews and meta-analyses have confirmed that pulmonary rehabilitation significantly improves exercise capacity, pulmonary function, and quality of life in individuals with long COVID-19 syndrome, further reinforcing the clinical value of structured respiratory rehabilitation programs [11]. Evidence also links these remote interventions to prolonged survival, improved quality of life, and heightened self-efficacy in lung-cancer survivors [12]. Park et al [12] deployed the Smart Aftercare App to deliver postoperative exercise guidance and reported significantly fewer outpatient encounters among active users than among nonusers. Despite such benefits, conventional telerehabilitation platforms typically depend on asynchronous demonstration clips or synchronous verbal coaching, neither of which can supply real-time biomechanical feedback or quantitative motion assessment. This deficit jeopardizes movement fidelity and complicates the standardization of exercise execution.

Action recognition platforms integrate computer vision, wearable sensors, and machine learning classifiers to deliver millimeter-level appraisal of human kinematics. Over the past decade, this convergence has fueled growing interest in digitally mediated rehabilitation. He et al [13] reported that exercise regimens augmented by movement capture analytics yield gains in lean mass, functional capacity, and health-related quality of life that rival both center-based therapy and conventional tele-exercise. Chae and coworkers [14] created an artificial intelligence (AI)–driven fitness application that issues instantaneous postural cues during exercise. The participants who received algorithmic feedback improved their action accuracy by more than 32% and demonstrated higher execution consistency than those who followed the standard video instructions [14]. Extending this paradigm, our group previously conducted a randomized controlled trial in adults with chronic nonspecific low back pain. After allocation to either an AI-guided, real-time feedback group or a traditional video-only group, the AI cohort exhibited a pronounced reduction in pain intensity and a concomitant hypertrophic response in the deep core musculature within 4 weeks [15].

Based on this, this study aims to explore the application value of motion recognition technology in remote rehabilitation after NSCLC lung cancer surgery. By providing objective and quantifiable motion data, it enables precise evaluation of patients' rehabilitation progress, thereby filling the gap in existing research, promoting innovative development of postoperative rehabilitation models for lung cancer, and delivering higher-quality rehabilitation services to patients.

Methods

Study Design

This was a single-center, prospective, open-label, randomized controlled trial. We used an offline approach to screen adult patients who underwent radical lung cancer surgery in the Department of Thoracic Surgery at Zhujiang Hospital, Southern Medical University, between June 2024 and January 2025, and the study protocol adhered to the CONSORT-EHEALTH (V 1.6; Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and Online Telehealth) checklist (Multimedia Appendix 1). The study was prospectively registered in the Chinese Clinical Trial Registry (ChiCTR2500113139).

Sample Size Calculation

The sample size was determined based on the primary outcome—6-minute walk distance (6MWD). Previous studies have demonstrated that telerehabilitation can significantly improve 6MWD in patients following lung cancer surgery, and the minimal clinically important difference for 6MWD in this population has been reported to be 50 meters [16]. Accordingly, we hypothesized that the motion capture telerehabilitation intervention would yield a clinically meaningful improvement of 50 meters in 6MWD compared with the control group. Assuming a 2-sided α value of .05 and a power of 80%, the required sample size was calculated to be 23 participants per group. To account for an anticipated dropout rate of 20%, the sample size was inflated to 29 participants per group. Therefore, a total of 58 participants were required for this study.

Ethical Considerations

The clinical study was conducted in accordance with the Declaration of Helsinki and China regulations on clinical research and has been approved by the medical ethics committee. All participants signed informed consent forms. Prior to the formal initiation of this study, it was approved by the Ethics Committee of Zhujiang Hospital, Southern Medical University (approval 2024-KY-327-01, Medical Research Registration and Filing Information System Registration MR-44-24-052709). The study has been registered in the Chinese Clinical Trial Registry (ChiCTR2500113139). The study was conducted by trained investigators, who were responsible for patient recruitment, data collection, and test administration. The data collected included patients' basic information, clinical data, exercise tolerance, pulmonary function, quality of life scales, mobility, treatment adherence, and adverse event incidence. For patients capable of completing the paper-based questionnaire independently, the investigators provided standardized questionnaires and guided them through the completion process. For patients unable to complete the questionnaire independently due to physical conditions or other reasons, the investigators conducted oral inquiries and recorded responses accordingly. During the recording process, the investigators verified information with patients to ensure data accuracy and completeness, and completed the questionnaire after confirming no errors. Throughout the research process, the investigators strictly adhered to ethical guidelines, safeguarding patient privacy and data security. All collected data were processed anonymously and used solely for research purposes, with no disclosure to third parties without patient consent. Participants received complimentary health education resources and were granted access to the AI-driven telerehabilitation platform throughout the intervention phase, while no monetary incentives were offered to participants for taking part in the study.

Participant Selection and Recruitment

The study selected patients with NSCLC who underwent thoracic surgery and were hospitalized at Zhujiang Hospital of Southern Medical University from June 2024 to January 2025 as the research participants. A total of 58 eligible patients were enrolled. The research team provided comprehensive and detailed explanations to all enrolled patients and their families, covering the purpose, specific content, and significance of the study.

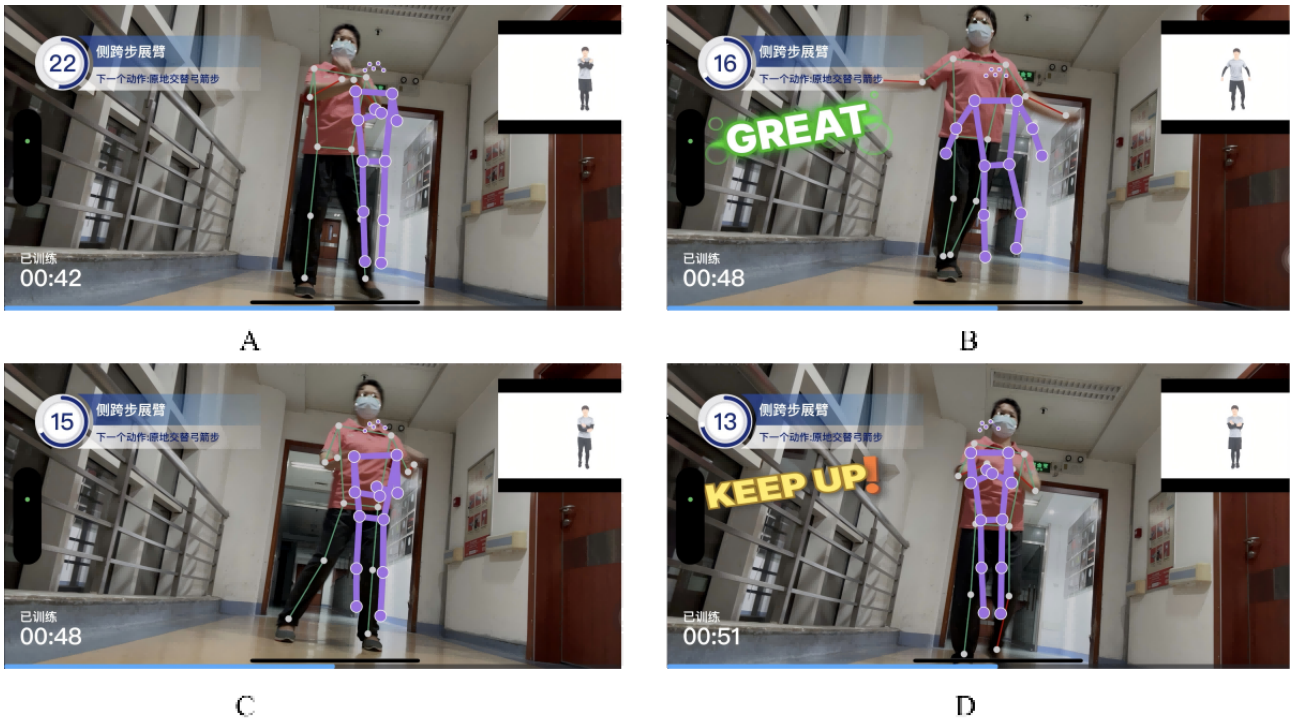
Eligibility Standards

Inclusion criteria included (1) histopathologic diagnosis of NSCLC per National Comprehensive Cancer Network Guidelines 2024.V4 [17], (2) age 18-75 years, (3) cognitive competence adequate for assessment and exercise adherence, and (4) completed radical resection (lobectomy, segmentectomy, or wedge) with stable postoperative vital signs. Exclusion criteria included (1) clinically significant impairment of cardiac, hepatic, or renal function precluding exercise; (2) uncontrolled postoperative complications such as pneumonia, atelectasis, pleural effusion, or respiratory failure; (3) concurrent malignancy likely to influence recovery; (4) enrollment in another interventional study within the preceding 90 days; (5) enrollment in another interventional study within the preceding 90 days; and (6) inability to use a smartphone or absence of reliable internet connectivity required for motion capture telerehabilitation.

Randomization and Blinding

Randomization was conducted using a computer-generated random number sequence in a 1:1 ratio. Simple randomization without blocking or stratification was applied. The allocation sequence was generated by an independent researcher (QZ) and concealed using sequentially numbered, opaque, and sealed envelopes to ensure allocation concealment. All researchers involved in patient recruitment or data collection will not be involved in the generation of the random sequence and the preparation and production of the random allocation concealment envelopes. The primary and all secondary outcome measures were collected offline through face-to-face interviews.

Interventions



Telerehabilitation App Incorporating Action Recognition Technology

The intervention group trained via the Rehabilitation Exercise Prescription app, whose core engine is a skeleton-driven motion recognition module. The software perpetually maps 3D coordinates of anatomical landmarks and then superimposes a chromatic skeletal overlay on the live video feed to log every trajectory. As depicted in Figure 1A-D, the user interface foregrounds the active exercise label together with a

XSL•FO
RenderX

decrementing timer; preparatory cues smooth transitions between successive movements.

Figure 1. Training diagram of experimental group. (A) The system demonstrates the “Running in Place” exercise, displaying real-time skeletal motion tracking, exercise guidance, and countdown timing. (B) The system demonstrates the “Side Steps with Arm Extension” exercise with posture recognition and movement feedback during training. (C) The system demonstrates the “Alternating Lunges in Place” exercise while continuously tracking joint trajectories and exercise performance. (D) The system demonstrates the “Chest Expansions With Heel Touches” exercise with synchronized skeletal overlay and live exercise instructions.

Instant textual feedback—both corrective and motivational—is pushed immediately after each repetition to sustain engagement. High fidelity is achieved through deep learning classifiers that pit the participant’s kinematic signature against a gold-standard template, flagging deviations and confirming when performance satisfies therapeutic thresholds.

Remote Rehabilitation Without Action Recognition

Members of the control group followed a home exercise protocol hosted on a WeChat mini program (Figure 2). The module provided only asynchronous video demonstrations; it lacked skeleton-tracking analytics, instantaneous correction, and any mechanism to log or verify completion.

XSL•FO
RenderX

Figure 2. Home page of WeChat mini program.

Assessment

All assessments and questionnaire surveys were conducted in person through face-to-face evaluation sessions. The assessment included the following:

1. *General data of patients*: sociodemographic variables: full name, age, sex, stature, body mass, BMI, education level, occupation, tobacco exposure, habitual physical activity patterns, medical insurance category, and habitual activity levels.
2. *Disease-specific metrics*: overall length of stay, postoperative inpatient days, adjuvant chemotherapy or radiotherapy use, histologic subtype, and tumor-node-metastasis stage according to the IASLC eighth edition guidelines and surgical approach.
3. *Exercise endurance*: 6-minute walk test (6MWT, Borg scale).

XSL•FO
RenderX

4. *Pulmonary function*: forced vital capacity (FVC), forced expiratory volume in 1 second (FEV_1), the FEV_1/FVC ratio, and peak expiratory flow (PEF).
5. *Quality of life indicators*: Functional Assessment of Cancer Therapy–Lung v4.0 (FACT-L) [18]: the core covers four dimensions [19]: physical well-being (PWB, 7 items)—energy, pain, and fatigue [20]; social/family well-being (SWB, 7 items)—relationships and perceived support [18]; emotional well-being (EWB, 6 items)—anxiety and depressive symptoms; functional well-being (FWB, 7 items)—daily activities and mobility [21].
6. *Measurement of functional mobility*: Five-times Sit-to-Stand Test (FTSST) [22], 30-second Chair-Stand Test (30-second CST) [23], Timed Up and Go (TUG) [24], Single-leg stance [25], and 2-minute step test [26].
7. *Exercise adherence*: individuals completing ≥3 sessions per week were deemed adherent; those completing <3 sessions per week were considered nonadherent.

The pulmonary function test graph and the 6MWT graph are shown in Multimedia Appendix 2.

Exercise Program Development and Implementation

Table 1 presents the structured components of the postoperative home rehabilitation program implemented in the experimental group. The intervention was organized according to specific time points, including discharge day, 4 weeks after discharge, and the follow-up assessment. It outlines the intervention items, detailed content, implementation methods, and prescribed frequency and duration.

Table 1. Contents of postoperative home rehabilitation of patients in the experimental group.

Intervention timing and item	Specific content	Implementation method	Frequency/duration
On the day of discharge			
Discharge assessment	• Assess exercise tolerance, pulmonary function, daily activity ability, and quality of life	In-hospital assessment	Single session, approximately 60 minutes
• From discharge to 4 weeks		Rehabilitation Exercise Prescription app (experimental)/WeChat mini-program (control)	3-5 times per week, 20-30 minutes per session
Aerobic training	• Stationary jogging • Jumping jacks • High-knee runs		
Strength training	• Side-leg raises • Body-weight squats • Step-ups • Prone planks		
Flexibility training	• Seated forward folds • Static bow stances		
From the day of discharge to 4 weeks after discharge			
Follow-up management	• A dedicated postdischarge support unit—consisting of thoracic surgeons, rehabilitation physicians, nurses, and therapists—monitored each participant through WeChat. The group sent session reminders, delivered immediate feedback, and addressed emerging questions. Outcome evaluations were scheduled 4 weeks (2 days) after discharge to gauge intervention efficacy.	WeChat + phone calls	2-3 times a week
4 weeks (2 days) after discharge			
Outcome assessment	• Assess all outcomes	Outpatient assessment	Single session, approximately 60 minutes

On the day of discharge, participants underwent an in-hospital discharge assessment to evaluate exercise tolerance, pulmonary function, activities of daily living, and quality of life. During the 4-week exercise after discharge, the intervention consisted of structured exercise training delivered through a digital platform, incorporating aerobic, strength, and flexibility exercises.

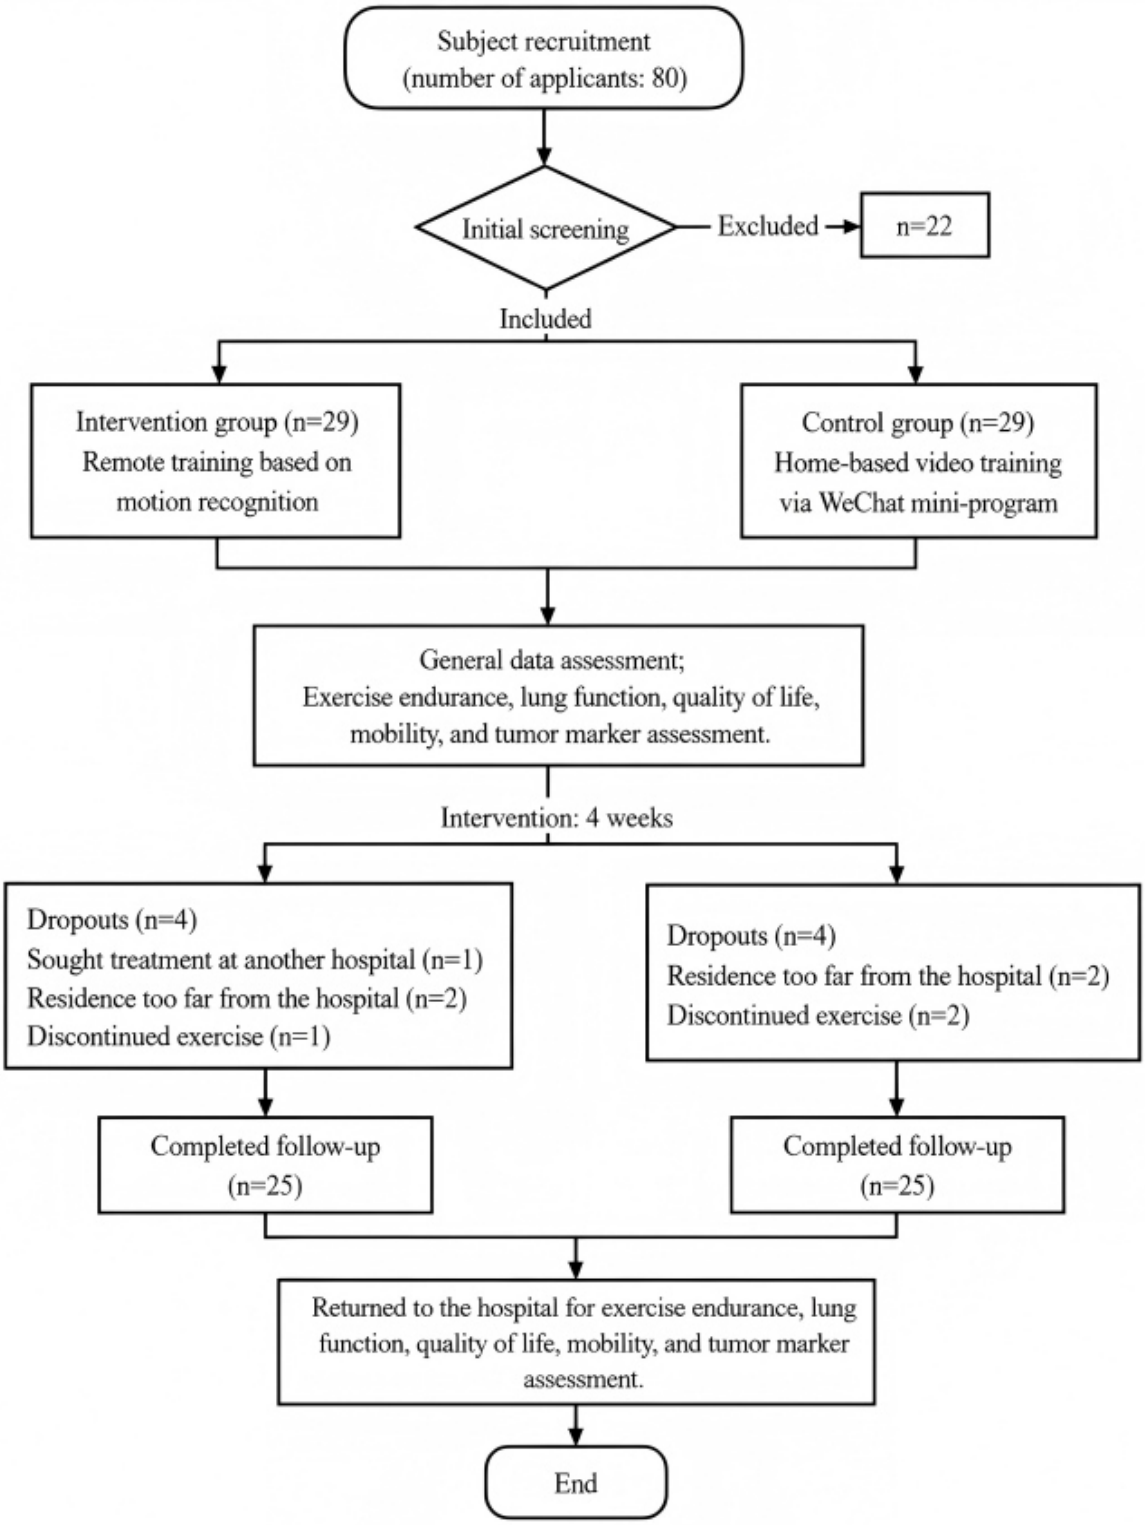
XSL•FO
RenderX

Follow-Up

Remote supervision and follow-up management were conducted by a multidisciplinary team via online communication tools such as the WeChat app and telephone contact to enhance adherence and provide timely feedback. At 4 weeks after discharge, outcome assessments were performed in the outpatient setting using the same evaluation domains as baseline.

Statistical Analyses

All analyses were performed in SPSS (version 26.0; IBM Corp). Normally distributed continuous data are presented as mean (SD); group differences and pre-to-post changes were examined with independent-samples and paired *t* tests, respectively. Non–normally distributed variables are summarized by medians; between-group contrasts were evaluated using the Mann-Whitney *U* test, and within-group shifts via Wilcoxon signed-rank tests. Categorical variables are described with counts and percentages, and baseline comparability was verified by chi-square analysis. The last available primary end point value was carried forward for withdrawals. Missing data mechanisms guided handling: missing completely at random observations were listwise-deleted, missing at random values were multiply imputed, and missing not at random scenarios were explored with sensitivity analyses using pattern mixture or selection models.



Results

Enrollment

A total of 80 applicants were initially recruited and underwent preliminary screening. Following the eligibility assessment, 22 individuals were excluded, and the remaining participants were included in the trial. Fifty-eight patients were randomized (29 per group). During follow-up, 4 participants in each group withdrew from the study. In the intervention group, reasons for dropout included seeking treatment at another hospital, residing too far from the hospital, and discontinuation of exercise. In the control group, dropouts were due to relocation far from the hospital or discontinuation of exercise. Ultimately, 25 participants in each group completed the follow-up assessment. Consequently, 50 participants (25 experimental and 25 control) provided complete data for the final analysis (Figure 3).

XSL•FO
RenderX

Figure 3. Flowchart of study process.

General Data of Patients

A total of 50 patients with lung cancer were enrolled and randomly allocated to the experimental group (n=25) and the control group (n=25). The mean age was 54.56 (SD 12.12) years in the experimental group and 56.96 (SD 11.02) years in the control group, with no statistically significant difference between groups (P=.62). In terms of sex distribution, 40% (10/25) of the participants in the experimental group and 48% (12/25) in the control group were male, and the difference was not statistically significant (P=.39). No significant differences were observed between the 2 groups with respect to height, body weight, or BMI (all P>.05). Similarly, baseline characteristics including educational attainment, occupational status, and exercise habits were evenly distributed between groups, with no significant between-group differences (all P>.05), suggesting comparability at baseline (Table 2).

XSL•FO
RenderX

Table 2. Comparison of demographic characteristics between the 2 groups.

Indicators	Experimental group (n=25)	Control group (n=25)	*t* test (*df*)	*P* value
Sex, n (%)			0.776 (1)	.39
Male	10 (40)	12 (48)		
Female	15 (60)	13 (52)		
Age (years), mean (SD)	54.56 (12.12)	56.96 (11.02)	–0.495 (48)	.62
Height (cm), mean (SD)	162.24 (7.03)	162.52 (5.83)	–0.153 (48)	.80
Body weight (kg), mean (SD)	60.04 (11.31)	58.5 (6.62)	–0.583 (48)	.56
BMI (kg/m^2), mean (SD)	22.77 (3.68)	22.19 (2.59)	0.646 (48)	.52
Degree of education, n (%)			5.219 (3)	.16
Primary school and below	9 (36)	5 (20)

No	19 (76)	21 (84)		

There were no significant differences between the 2 groups in smoking history, medical insurance type, history of chemoradiotherapy, pathological type, surgical method, length of hospital stay distribution, or postoperative hospital stay duration (all $P \geq .05$). The majority of participants in both groups had stage I lung cancer, and all patients were pathologically confirmed at stage I, indicating homogeneity in disease severity. Adenocarcinoma was the predominant pathological type, accounting for 92% in the experimental group and 100% in the control group. Regarding surgical procedures, most patients underwent wedge resection or segmentectomy, with comparable distributions between groups. Postoperative hospital stay was similar between the 2 groups, with a mean duration of 6.08 (SD 0.60) days in the experimental group and 4.84 (SD 0.48) days in the control group ($P=.10$). Overall, baseline clinical and perioperative characteristics were balanced between groups (Table 3).

Comparison of Outcome Index Results

Related Indexes of Exercise Endurance Compared Between 2 Groups

At baseline, 6MWD and Borg fatigue scores were comparable across groups (*P*>.05). After 4 weeks, both groups showed significant within-group improvements in the 6MWD. The experimental group increased from a mean of 399.00 (SD 67.92) to 507.00 (SD 62.23) meters (*T*=–7.40; *P*<.001). The control group also improved from 415.12 (SD 73.13) to 460.96 (SD 71.24) meters (*T*=–3.39; *P*<.001). The between-group comparison at 4 weeks revealed a statistically significant difference favoring the motion capture cohort (mean difference 32 meters, 95% CI 5.40- 58.60; *T*=2.43; *P*=.02). For perceived exertion, both groups demonstrated significant reductions in Borg scores following the intervention. The experimental group decreased from 2.12 (SD 0.93) to 0.96 (SD 0.87; *T*=3.63; *P*<.001), while the control group decreased from 2.32 (SD 0.80) to 1.36 (SD 0.94; *T*=3.67; *P*<.001). However, the between-group difference for the change in Borg-perceived exertion scores was not statistically significant (mean difference –0.40, 95% CI –0.88 to 0.08; *T*=–1.65; *P*=.10). Complete data are provided in Table 4.

Pulmonary Function Indexes of the 2 Groups Compared

At baseline, pulmonary function measures were comparable between groups ($P>.05$). After 4 weeks, every spirometric variable improved more in the motion capture cohort than in controls (all $P<.05$). The control group did not show significant within-group changes in any of these measures (all $P\geq.05$). For FVC, the experimental group increased from a mean of 1716.40 (SD 639.30) to 2576.80 (SD 629.54) mL ($T=–7.14$; $P<.001$), while the control group showed no significant change (2106.40, SD 823.67 mL to 2100.40, SD 742.77 mL; $T=0.96$; $P=.35$). The between-group comparison revealed a statistically significant difference favoring the motion capture cohort (mean difference 476.4 mL, 95% CI 85.2-867.6; $T=2.45$; $P=.02$). For FEV_1, the experimental group improved from 1294.80 (SD 413.62) to 2029.20 (SD 526.79) mL ($T=–8.74$; $P<.001$), compared with minimal change in the control group (1462.28, SD 629.17 mL to 1683.20, SD 647.47 mL; $T=–1.83$; $P=.08$). The between-group difference was statistically significant (mean difference 346.0 mL, 95% CI 9.8-682.2; $T=2.07$; $P=.04$). For the FEV_1/FVC ratio, the experimental group increased from 69.88% (SD 20.46) to 91.60% (SD 22.14; $T=–3.55$; $P<.001$), while the control group showed no significant improvement (72.04%, SD 18.30 to 78.80%, SD 18.01; $T=–1.31$; $P=.20$). The between-group comparison favored the experimental group (mean difference 12.8%, 95% CI 1.3-24.3; $T=–2.15$; $P=.03$). For PEF, the experimental group improved from 130.58 (SD 73.59) to 230.21 (SD 81.66) L/minute ($T=4.23$; $P<.001$), whereas the control group showed no significant change (170.04, SD 70.16 to 159.36, SD 62.26 L/minute [$T=0.48$; $P=.63$]). The between-group difference was statistically significant (mean difference 70.8 L/minute, 95% CI 26.4-115.2; $T=–3.15$; $P=.002$). Complete data are presented in Table 5.

Activity Ability Indexes of the 2 Groups Compared

At baseline, activity-capacity indices were comparable across groups (all $P>.05$). After 4 weeks, both groups demonstrated significant within-group improvements in most functional mobility measures, with the motion capture group showing superior gains in the TUG test. For the TUG test, the experimental group improved from a mean of 13.11 (SD 4.39) to 9.95 (SD 2.41) seconds ($T=3.46$; $P<.001$), while the control group improved from 12.78 (SD 3.35) to 11.58 (SD 3.04) seconds ($T=2.42$; $P=.02$). The between-group comparison revealed a statistically significant difference favoring the motion capture cohort (mean difference –1.63 seconds, 95% CI –3.19 to –0.07; $T=–2.11$; $P=.04$). For Stand on 1 foot, the experimental group improved from 24.79 (SD 19.71) to 43.72 (SD 31.59) seconds ($T=4.14$; $P<.001$), and the control group improved from 38.36 (SD 79.30) to 49.68 (SD 58.19) seconds ($T=2.52$; $P=.01$). However, the between-group difference was not statistically significant (mean difference –5.96 seconds, 95% CI –33.2 to 21.3; $T=–0.44$; $P=.66$). For the 30-second CST, the experimental group improved from 9.52 (SD 3.55) to 13.96 (SD 4.94) repetitions ($T=–5.73$; $P<.001$), and the control group improved from 11.16 (SD 3.88) to 12.68 (SD 3.00) repetitions ($T=–2.63$; $P=.02$). The between-group difference did not reach statistical significance (mean difference 1.28 repetitions, 95% CI –1.18 to 3.74; $T=0.78$; $P=.43$). For the FTSST, the experimental group improved from 13.56 (SD 6.78) to 9.32 (SD 2.90) seconds ($T=3.79$; $P<.001$), and the control group improved from 11.03 (SD 3.00) to 9.48 (SD 2.24) seconds ($T=2.35$; $P=.02$). The between-group difference was not statistically significant (mean difference–0.16 seconds, 95% CI –1.67 to 1.35; $T=–0.25$; $P=.80$). For the 2-minute step test, the experimental group improved from 1832.56 (SD 41.46) to 179.84 (SD 38.27) steps ($T=–6.10$; $P<.001$), and the control group improved from 143.88 (SD 33.74) to 177.48 (SD 30.25) steps ($T=–4.82$; $P<.001$). The between-group difference was not statistically significant (mean difference 2.36 steps, 95% CI –17.8 to 22.5; $T=0.24$; $P=.81$). Complete data are provided in Table 6.

Comparison of Quality of Life Indicators Between the 2 Groups of Patients

At baseline, there were no statistically significant differences between the experimental and control groups across all FACT-L subscales and total score (all *P*>.05), indicating good comparability before intervention. For PWB, the experimental group improved from 14.68 (SD 2.27) to 21.68 (SD 2.27; *T*=–4.55; *P*<.001), while the control group improved from 13.72 (SD 2.23) to 17.68 (SD 2.27; *T*=–4.52; *P*<.001). The between-group comparison revealed a statistically significant difference favoring the motion capture cohort (mean difference 4.00 points, 95% CI 2.66-5.34; *T*=6.24; *P*<.001). For SWB, the experimental group improved from 16.04 (SD 1.24) to 20.08 (SD 1.32; *T*=–4.33; *P*<.001), and the control group improved from 16.80 (SD 1.53) to 19.80 (SD 1.38; *T*=–4.40; *P*<.001). However, the between-group difference was not statistically significant (mean difference 0.28 points, 95% CI –0.76 to 1.32; *T*=–0.53; *P*=.60). For EWB, the experimental group improved from 13.48 (SD 1.16) to 15.80 (SD 1.19; *T*=–4.48; *P*<.001), and the control group improved from 13.72 (SD 1.49) to 15.92 (SD 1.38; *T*=–4.44; *P*<.001). The between-group difference did not reach statistical significance (mean difference –0.12 points, 95% CI –0.98 to 0.74; *T*=–0.27; *P*=.79). For FWB, the experimental group improved from 12.28 (SD 2.23) to 18.68 (SD 2.27; *T*=–4.55; *P*<.001), while the control group improved from 11.04 (SD 2.25) to 14.00 (SD 1.94; *T*=–4.44; *P*<.001). The between-group comparison revealed a statistically significant difference favoring the motion capture cohort (mean difference 4.68 points, 95% CI 3.44-5.92; *T*=7.85; *P*<.001). For

XSL•FO
RenderX

the Additional Concerns–Lung (ACL) subscale, the experimental group improved from 9.72 (SD 1.93) to 17.24 (SD 2.11; T=–4.41; P<.001), and the control group improved from 9.64 (SD 1.91) to 12.96 (SD 1.77; T=–4.41; P<.001). The between-group difference was statistically significant (mean difference 4.28 points, 95% CI 3.14-5.42; T=7.78; P<.001). For the total FACT-L score, the experimental group improved from 66.20 (SD 6.83) to 93.36 (SD 6.72; T=–51.12; P<.001), while the control group improved from 64.92 (SD 6.85) to 80.36 (SD 6.04; T=–33.94; P<.001). The between-group comparison revealed a statistically significant difference favoring the experimental group (mean difference 13.00 points, 95% CI 9.30-16.70; T=7.19; P<.001). Complete data are provided in Table 7.

Discussion

Principal Findings

This study demonstrated that motion recognition–based telerehabilitation was associated with greater improvements in postoperative recovery among patients with NSCLC compared with conventional home-based video-guided training. Specifically, participants in the intervention group showed superior gains in exercise tolerance, pulmonary function, selected aspects of functional mobility, and the physical and functional domains of quality of life. Rehabilitation adherence was also higher in the motion-guided group, and no intervention-related adverse events were observed in either group.

Taken together, these findings suggest that integrating real-time kinematic feedback into home-based pulmonary rehabilitation may enhance movement quality, functional recovery, and patient engagement beyond standard remote instruction. Importantly, these results are consistent with emerging evidence from recent systematic reviews and network meta-analyses [27] indicating that telerehabilitation can achieve improvements in physical function and quality of life comparable with, or in some contexts exceeding, conventional face-to-face pulmonary rehabilitation programs. This study extends this body of evidence by highlighting the potential added value of motion recognition–based feedback within a postoperative population with lung cancer.

Impact of Telerehabilitation Based on Motion Recognition Technology on Exercise Tolerance in Postoperative Patients With NSCLC

Exercise tolerance constitutes a primary indicator of postoperative functional recovery in patients undergoing NSCLC resection [28]. Baseline 6MWD did not differ between groups, confirming equivalent preintervention capacity. Although both cohorts achieved after-intervention gains—reflecting the efficacy of any structured training—the experimental group demonstrated a substantially larger increment, underscoring the supplementary value of motion capture–guided telerehabilitation. These observations align with prior evidence.

The superior improvement in the motion capture group can be attributed to several interconnected mechanisms. First, real-time kinematic feedback facilitates motor learning through augmented feedback loops. According to the guidance hypothesis ("Comparative Effects of Sensory Motor and Virtual Reality Interventions to Improve Gait, Balance, and Quality of Life MS Patients"), concurrent feedback enhances skill acquisition by providing immediate error information, allowing patients to correct aberrant movement patterns (eg, knee valgus and excessive trunk sway) before they become ingrained. This process engages the cerebellar-cortical circuit, promoting neuroplastic changes that optimize movement efficiency [29].

Second, real-time, AI-guided motion correction may augment walking economy by refining neuromuscular synchrony and dynamic stability. Earlier work documents that cancer survivors exhibit quadriceps weakness approximately one-third to two-fifths greater than healthy peers [30]. Instantaneous joint-angle feedback during tasks such as squats promptly redirects aberrant mechanics—knee valgus or excessive trunk sway—reducing metabolic cost per stride.

Third, patients in the experimental group covered more ground during the 6MWT without parallel rises in Borg ratings; superior gait efficiency and balance translated into greater distance with lower perceived exertion. Moreover, quantitative visual cues (eg, "posture accuracy: 92%") reinforced engagement and intensity, yielding a compliance rate of 72% (18/25) versus 40% (10/25) in controls. Sustained participation drove cumulative cardiopulmonary and musculoskeletal adaptations—the principal determinants of improved exercise capacity [31].

The Borg scale gauges perceived exertion and complements objective measures of exercise tolerance [32]. In our trial, Borg ratings did not differ between the motion capture and control groups. Nevertheless, instantaneous kinematic feedback appeared to bolster self-efficacy and refine movement efficiency, allowing the experimental cohort to increase walking distance without proportionate fatigue. Conversely, controls—hampered by suboptimal mechanics—covered shorter distances and yet reported greater perceived exertion per meter.

Impact of Telerehabilitation Based on Motion Recognition Technology on Pulmonary Function in Postoperative Patients With NSCLC

Enhancing pulmonary function represents a key objective in postoperative care for patients with lung cancer [33]. The superior improvements in FVC, FEV_1, and PEF observed in the motion capture group likely stem from the system's capacity to ensure optimal respiratory muscle synergy through real-time corrective feedback. While participants in both cohorts completed identical training protocols, only those in the intervention group received real-time monitoring of biomechanical parameters with prompt adjustments for aberrant movement patterns [34].

While participants in both cohorts completed identical exercise protocols, only those in the intervention group received

XSL•FO
RenderX

continuous monitoring of trunk alignment during core exercises. This distinction is critical because respiratory function is intimately linked to core stability. The diaphragm, the primary muscle of inspiration, shares fascial connections with the transversus abdominis and pelvic floor muscles, forming the thoracoabdominal pump [35]. Proper activation of this integrated system requires precise coordination—a skill that benefits from augmented feedback.

Consider the plank—an evidence-based core stabilization maneuver engaging key musculature including the transversus abdominis, rectus abdominis, and erector spinae. Regular plank training (3 times per week) enhances both respiratory function and general fitness in aging populations [36]. Yet, its benefits are substantially attenuated by technical errors such as hyperlordosis [37], which specifically impairs transversus abdominis recruitment [38]. Such deviations not only undermine therapeutic effects but also elevate spinal loading and injury potential.

The motion recognition system provided instantaneous proprioceptive feedback that helped patients maintain neutral spine alignment, thereby optimizing the feedforward control mechanism of core muscles. This feedforward activation—where trunk muscles contract in anticipation of limb movement—is essential for maintaining spinal stability during dynamic activities [39]. By reinforcing this mechanism during training, the intervention likely enhanced the neural drive to respiratory muscles, translating into improved spirometric outcomes. Furthermore, the observed improvements in PEF suggest enhanced expiratory muscle function, possibly through better recruitment of abdominal muscles during forced expiration.

Impact of Telerehabilitation Based on Motion Recognition Technology on Functional Mobility in Postoperative Patients With NSCLC

Functional mobility assessment serves as a critical component in evaluating rehabilitation success. Standardized tests such as the TUG [40], single-leg balance assessment [41], 30-second CST [42], FTSST [43], and 2-minute stepping task [44] collectively offer a comprehensive evaluation of movement capacity and functional performance. These validated measures enable clinicians to objectively determine patients' functional capacity for activities of daily living and community participation, while effectively tracking recovery milestones.

Among these assessments, the TUG represents a composite functional task requiring coordinated execution of multiple motor components, including sit-to-stand transition, gait initiation, turning, and resitting. Performance on this test reflects not only lower limb strength but also dynamic balance, motor sequencing, and intertask coordination [45]. The observed improvement in TUG performance in the motion recognition group may be related to enhanced movement precision and temporal coordination facilitated by real-time kinematic feedback. The motion recognition system provides continuous monitoring of joint angles and movement trajectories, potentially supporting more accurate sensorimotor integration during exercise execution—the process by which sensory feedback refines motor output [46]. Similar improvements in postural control and motor stability have been reported in neurological populations receiving telemedicine-based rehabilitation, including individuals with Parkinson disease, suggesting that remote feedback mechanisms may enhance movement regulation across different clinical conditions [47]. Real-time visual feedback of joint angles and movement trajectories may have facilitated implicit motor learning, whereby patients internalize correct movement patterns without extensive conscious processing. This contrasts with explicit learning approaches that rely primarily on verbal instruction and are more cognitively demanding and potentially less durable under stress [48]. The improved TUG performance in the experimental group likely reflects enhanced procedural memory for the sequence of movements involved in the test.

The lack of significant between-group differences in single-leg stance, 30-second CST, FTSST, and 2-minute step tests does not contradict this interpretation. These tests predominantly assess isolated components of physical function—static balance, lower extremity strength, and repetitive endurance—rather than the integrated motor control required for complex tasks. Both groups received identical exercise prescriptions targeting lower limb musculature, likely producing comparable gains in gross strength (as reflected in the similar improvements on these tests). The unique value of the motion-aware system lies in optimizing movement quality and interjoint coordination—domains captured by composite measures such as the TUG but not by simpler functional tests. This dissociation between strength gains and coordination improvements is consistent with the principle that motor skill acquisition and muscular adaptation are mediated by distinct neural and physiological mechanisms [49].

Impact of Telerehabilitation Based on Motion Recognition Technology on Quality of Life in Postoperative Patients With NSCLC

Quality of life represents a critical multidimensional end point in postsurgical NSCLC rehabilitation, encompassing physical, psychological, and social well-being as primary markers of recovery success [50]. Our intervention group showed statistically superior improvements in PWB, FWB, ACL, and the total FACT-L score relative to controls. This pattern implies that motion-aware telerehabilitation offers particular advantages for restoring physical and functional aspects of quality of life, potentially attributable to its capacity for optimizing functional recovery through millimeter-precise movement analysis and instantaneous form correction. Additionally, the system's ability to provide symptom-specific movement modifications and breathing technique guidance may explain this therapeutic advantage, empowering patients to better control their condition-related challenges.

The analysis revealed no statistically significant intergroup differences in either SWB or EWB domain. This observation may be explained by several key considerations. First, meaningful enhancement of social support systems and psychological state typically necessitates prolonged intervention durations and often benefits from dedicated mental health support, posing challenges for demonstrating immediate effects within a limited study period [51]. Second, the psychological

XSL•FO
RenderX

status of postsurgical patients with NSCLC is frequently influenced by complex psychosocial factors—particularly disease recurrence anxiety and treatment-related financial stress [52]—that extend beyond the scope of physical rehabilitation and may require targeted psychotherapeutic approaches combined with robust social services.

Impact of Telerehabilitation Based on Motion Recognition Technology on Exercise Adherence and Safety in Postoperative Patients With NSCLC

Program adherence represents a critical determinant of rehabilitation efficacy [53]. Our data revealed substantially better compliance rates in the intervention group than in controls, indicating that motion-aware telerehabilitation systems may optimize treatment engagement for postsurgical patients with NSCLC. This effect appears mediated by the platform's multimodal feedback mechanisms—including real-time performance metrics, achievement scoring, and graphical progress tracking—which collectively enhance treatment motivation through positive reinforcement. Contemporary research confirms that instantaneous performance feedback bolsters rehabilitation adherence by reinforcing patient self-confidence and perceived competence [54]. Furthermore, the system's interactive design elements convert conventional exercises into dynamic, goal-oriented tasks, offering superior psychological engagement compared with passive video demonstrations.

Regarding safety outcomes, neither study group reported intervention-related adverse events, confirming the acceptable risk profile of home-based motion capture rehabilitation. The technology's ability to continuously monitor and correct biomechanical execution helps ensure proper movement patterns, consequently minimizing injury risks associated with faulty technique [55].

Limitations

Despite the promising findings, several constraints warrant consideration. First, assessments were restricted to the 4-week end point, precluding insight into durability; subsequent studies should extend follow-up to 3, 6, and 12 months to chart longer-term recovery. Second, the modest sample size may limit both external validity and statistical power. Although significant between-group differences were observed for several primary outcomes, the study may have been underpowered to detect smaller yet clinically meaningful effects in some secondary measures. Accordingly, the absence of statistically significant differences for certain functional indicators should be interpreted cautiously, as the possibility of type II error cannot be excluded. Larger, adequately powered multicenter trials are required to validate and refine these findings. Third, the lack of preoperative functional baselines hampers delineation of the full perioperative trajectory; future protocols should incorporate presurgical assessments to construct comprehensive longitudinal recovery profiles.

Conclusions

To our knowledge, this is the first randomized controlled trial to integrate motion capture analytics into telerehabilitation following NSCLC surgery. Over 4 weeks, the approach proved both safe and superior to standard video-guided exercise, yielding larger gains in exercise tolerance, spirometry, functional mobility, and quality of life. These data establish a clinically viable strategy that can readily be scaled across telemedicine and postoperative care pathways.

Abstract

Background: Single-leg squat (SLS) performance is widely used to screen functional movement quality, but practical assessment often relies on expert visual grading or laboratory-based motion capture. In addition, conventional SLS criteria mainly focus on isolated joint deviations and may overlook coordination-related, multisegment movement patterns that characterize impaired performance.

Objective: This study aimed to examine the feasibility of an interpretable machine learning framework for classifying SLS performance into 3 levels (good, moderate, and poor) from single-smartphone, frontal-view videos based on trunk, pelvic, and knee kinematics, and to evaluate coordination-informed features and model explainability using Shapley additive explanations (SHAP) and local interpretable model-agnostic explanations (LIME).

Methods: A dataset of frontal-view SLS videos was labeled by physiotherapists into 3 functional categories (good, moderate, and poor). Videos were processed using 2D pose estimation, and models were trained on 17 engineered kinematic features derived from trunk, pelvic, and knee angles. Following the feature selection, 7 classifiers were trained and evaluated using the 8 selected features with stratified 5-fold cross-validation and a held-out test set. SHAP and LIME were applied for global and local interpretability.

Results: On the held-out test set, adaptive boosting classified SLS performance with an accuracy of 0.84, an F_1-score of 0.85, and an area under curve of 0.92. SHAP indicated that the summated angle (trunk + pelvis + knee), coordination-related features (knee × trunk interaction and knee-to-trunk ratio), and knee angle were key contributors to model predictions. LIME provided instance-level explanations that helped interpret individual classifications and decision boundaries.

Conclusions: This study presents an interpretable machine learning framework for classifying SLS performance into 3 levels using frontal-view videos acquired with a single smartphone. By leveraging coordination-informed engineered features and explainable artificial intelligence, the framework enables transparent interpretation of movement performance beyond isolated joint deviations. The proposed workflow uses smartphones for standardized video acquisition, while performance screening is achieved through machine learning. Given its lightweight feature design, this framework has potential for future implementation on modern smartphones and may support rehabilitation planning and injury-prevention strategies in sports and clinical settings.

Introduction

Knee function is a key factor in mobility, athletic performance, and quality of life in active young adults, and knee-related problems are common in this population [1]. In young physically active populations, functional performance tests provide meaningful evaluations of knee function by indirectly estimating muscle strength, joint stability, flexibility, balance, and proprioception, thereby offering insights that are not available through static radiographic imaging [2,3]. Among these, the single-leg squat (SLS) is widely used to assess dynamic lower extremity and trunk movement quality in both sports and clinical contexts, with movement quality rated on either a 2-point (good vs poor) or a 3-point ordinal scale (good vs moderate vs poor)

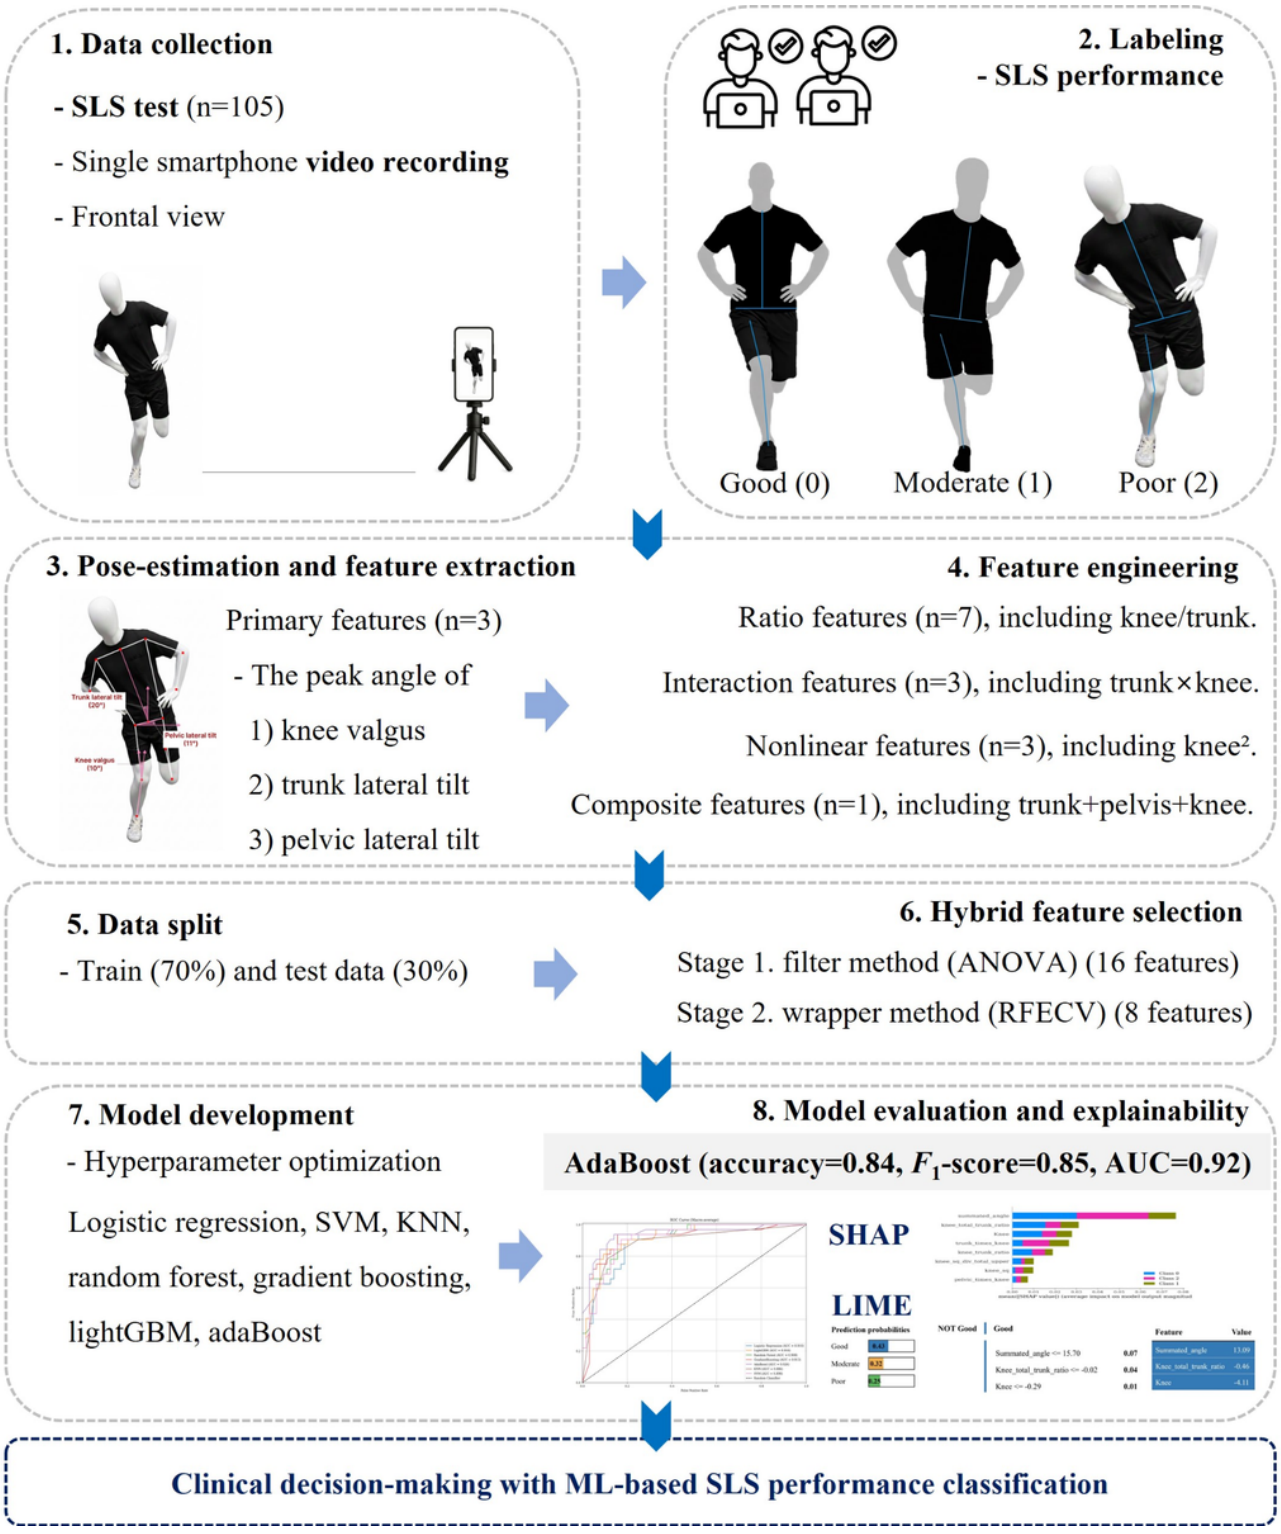
XSL•FO
RenderX

[4]. SLS performance is typically evaluated via expert visual observation of segmental alignment or using laboratory-based 3D motion capture to assess hip internal rotation, knee valgus, trunk lateral lean, and pelvic drop [5,6]. 3D motion capture can measure movement with high accuracy, but it requires costly equipment and substantial processing time compared to visual assessment [7]. Visual assessment, although less expensive, still necessitates expert analysis of recorded footage, making it time-consuming and susceptible to observer bias and limited reproducibility when classifying movement quality [5].

Recently, machine learning algorithms have been applied to evaluate and classify SLS performance without costly 3D motion capture systems or expert visual assessments, thereby reducing analysis time [7,8]. An inertial measurement unit (IMU)-based support vector machine (SVM) model using 3 sensors achieved 96% accuracy for binary classification (good vs poor) but decreased to 66% for 3-class classification (good vs moderate vs poor) based on hip and knee angles [9]. However, IMU accuracy depends on the number of sensors, and the requirement for multiple sensors limits clinical feasibility [9]. More recent approaches using consumer-grade cameras with pose estimation algorithms have achieved moderate-to-high accuracy in 3-class SLS classification, even with a single camera [7,10]. For example, pose-estimated SLS videos captured with a single camera achieved 53% - 77% agreement with expert assessments across 6 postural orientation errors, with knee valgus errors showing the highest agreement (77%) [7]. Similarly, a smartphone-based markerless motion capture study found that trunk, pelvic, and knee angles, together with the summated angle of these joints, enabled 3-class classification with 76.9% accuracy using a decision tree model [10]. However, these studies primarily extracted features based on expert-defined SLS guidelines, such as trunk lateral leaning and knee valgus, whereas SLS performance involves global, coordinated movement patterns of the trunk and lower limbs. It is necessary for future machine learning classification models to generate features that capture interjoint movement patterns, such as the knee-to-trunk ratio and joint interaction terms during the SLS test.

While recent machine learning approaches have demonstrated promising accuracy in SLS classification, the underlying decision-making mechanisms often remain unclear, which limits their adoption in clinical practice [11]. In rehabilitation and sports medicine, clinicians and other professionals need to understand which specific kinematic factors drive model predictions in order to design targeted interventions and maintain clinical confidence [12]. Explainable artificial intelligence (XAI) methods, such as Shapley additive explanations (SHAP) and local interpretable model-agnostic explanations (LIME), can provide feature-level explanations by quantifying the contribution of each joint movement or interaction to the model's decision [13]. Applying XAI to SLS performance assessment can both support movement quality classification and identify key movement patterns, bridging algorithmic predictions with clinical feedback and fostering trust and personalized rehabilitation planning.

In this study, we aim to examine the feasibility of an interpretable machine learning framework for classifying SLS performance based on trunk, pelvic, and knee kinematics into 3 levels (good, moderate, and poor) using frontal-view SLS videos recorded with a single smartphone. Using biomechanically informed feature engineering and hybrid feature selection, we further investigate whether coordination-related feature combinations (ratio, interaction, and summated features) involving trunk, pelvic, and knee angles provide clinically meaningful representations of movement quality beyond conventional single-joint angle metrics. In addition, we evaluate model interpretability using SHAP and LIME to support transparent functional grading and facilitate clinical translation in sports and rehabilitation screening.



Methods

Participants

An overview of the overall study workflow is presented in Figure 1. This study included a total of 105 young active adults (aged 19 - 30 y) who were recruited through university campus advertisements, social media, and local community bulletin boards. Participants were eligible for inclusion if they engaged in regular physical activity for at least 60 minutes per week. Exclusion criteria included a history of lower-extremity or low back pain within the previous 3 months, prior major knee injuries or surgeries, neurological disorders, or an inability to perform the SLS test [14]. Sample size adequacy for machine learning model development was evaluated using a prediction instability approach. Prediction instability was assessed across incremental proportions of the dataset (10%, 30%, 50%, 70%, and 90%), where instability was defined as the variability of model performance across resampled subsets [15]. The analysis showed a marked reduction in prediction instability with increasing sample size, with the final sample of 105 SLS videos yielding stable model performance across the evaluated machine learning models. Bootstrap resampling with 100 iterations indicated that using more than 70% of the dataset resulted in acceptable prediction stability, as reflected by low instability values, supporting the adequacy of the sample size for reliable machine learning performance (Figure 2).

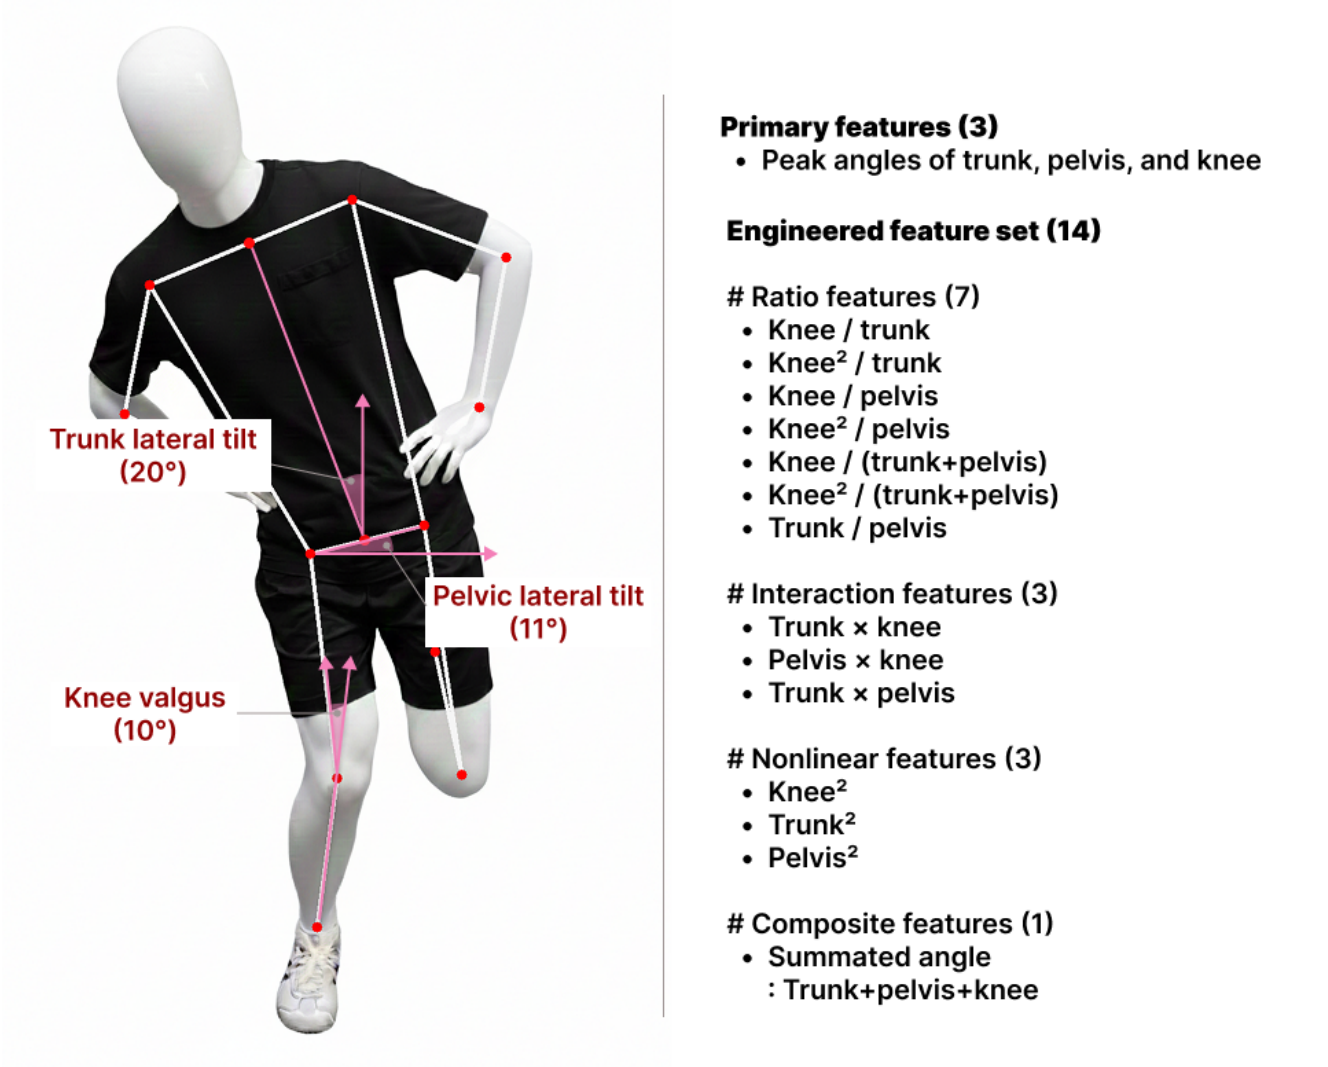
Data Collection



Videos were recorded using an iPhone, mounted on a tripod positioned 3 meters in front of the participant at pelvic height, capturing the entire body at 30 Hz and 1080 p resolution. Only the frontal view was recorded, as clinical evaluation of SLS performance primarily relies on frontal plane deviations including trunk lean, pelvic tilt, and medial knee displacement [7]. Additionally, this single-camera configuration reflects a practical and scalable approach for real-world clinical assessment settings, eliminating the need for multiple camera setups to capture additional views (side or top) [16].

Each participant performed the SLS on their dominant leg (defined as the leg used to kick a ball), wearing standard gym clothing (eg, shorts and t-shirts) to ensure full visibility of lower-limb motion. Participants were given a brief warm-up consisting of 5 minutes of stationary cycling and performed 3 practice trials under the supervision of a physiotherapist to ensure consistent technique. The SLS movement was performed at a comfortable, self-selected pace, avoiding excessively slow speed that might reduce compensatory kinematic deviations such as knee valgus [17]. The standardized SLS test procedure was as follows: (1) Participants stood with their feet shoulder-width apart and toes pointing forward; (2) Participants then placed their hands on the waist and extended the nondominant leg backward, maintaining approximately 90° of knee flexion; (3) From this position, participants descended into a squat as deeply as possible at a self-selected speed, bending the weight-bearing leg without losing balance, maintaining an upright posture, and facing the front camera (Figure 3); and (4) Finally, they fully extended the knee of the weight-bearing leg to return to the starting position [18].

Each participant performed 3 repetitions, with a 1-minute rest between attempts. A repetition was considered invalid if the participant lost balance, allowed the legs to touch, placed the nondominant foot on the ground, or failed to maintain an upright posture facing the camera. In such cases, an additional repetition was performed at the end of the trial. If 2 or more repetitions within a trial were invalid, the entire trial was repeated after a sufficient rest period [17].

Figure 3. Representative single-leg squat frame and interpretable kinematic features used for model training.

Labeling of Single-Leg Squat Movement Quality

Movement quality was evaluated independently by 2 licensed physiotherapists, each with over 10 years of clinical experience in musculoskeletal rehabilitation. Prior to labeling, the evaluators completed a structured 2-hour training session on SLS assessment criteria, which involved repeatedly reviewing and grading 5 representative SLS video recordings excluded from the main dataset [19]. During this session, a consensus discussion with one of the authors was conducted to standardize the interpretation of movement patterns and rating procedures, thereby ensuring consistent and objective classification.

Following training, the 2 evaluators independently assessed movement quality through visual observation while blinded to participant characteristics and not involved in other experimental procedures. Each participant's performance was reviewed no more than 2 times using full-length SLS videos played at normal speed on a personal computer, without pausing, rewinding, or slow-motion playback [19]. This approach was informed by previous findings indicating that even when raters are allowed unlimited repeated viewing in both real-time and slow-motion conditions, interrater reliability does not necessarily improve beyond fair to moderate levels for several movement components [20]. During each review, performance was assessed using a multisegmental approach, simultaneously evaluating the trunk, pelvic, and knee segments across 3 consecutive squats [19]. SLS performance was graded into 1 of 3 categories based on observable frontal-plane deviations [21]. Class 0 (good) was defined by no lateral trunk or pelvic tilt, absence of visible knee valgus, and a stable, straight knee trajectory throughout the squat. Class 1 (moderate) included mild lateral trunk or pelvic tilt with slight knee valgus and minor medial-lateral knee movement without notable instability. Class 2 (poor) was characterized by pronounced lateral trunk or pelvic tilt, obvious knee valgus, and clear mediolateral displacement or shaking of the knee.

Each repetition was independently and blindly assessed by 2 evaluators. Agreement scores were accepted when ratings matched. In cases of disagreement, the evaluators re-reviewed the video recording, shared their initial ratings, and discussed the observed movement patterns to reach agreement on a final score [7]. Before consensus, interrater agreement for the 3-level SLS performance grading was assessed using weighted Cohen Kappa, indicating a moderate level of agreement (κ=0.60).

The final class label for each participant was defined as the poorest performance observed across the 3 repetitions [7,21]. The poorest SLS repetition was used for machine learning

XSL•FO
RenderX

training to represent participant-level movement quality because clinical screening prioritizes detection of the most impaired movement pattern. In addition, when multiple repetitions from a single participant receive different labels, trial-level modeling can introduce ambiguity in participant-level classification. When multiple repetitions received the same label, the first valid repetition was used for pose estimation and feature extraction to ensure a deterministic and reproducible trial-selection rule and to minimize potential learning and fatigue effects across repeated trials [22].

Pose Estimation and Feature Extraction

For consistency between labeling and analysis, the same poorest-rated trial used for labeling was also selected for 2D pose estimation and feature extraction. Pose estimation of the SLS smartphone video was performed using the MediaPipe Pose library (v0.10.21) (Google), which detects 33 body landmarks from RGB frames in real time. MediaPipe Pose operates without the need for depth sensors, specialized hardware, or manual landmark initialization, making it well-suited for smartphone-based clinical assessments. Previous research has demonstrated that MediaPipe Pose provides highly valid estimates of lower-limb joint angles compared with gold-standard 3D motion capture (Pearson correlation=0.87) and exhibits excellent test-retest reliability (intraclass correlation coefficient=0.93 - 0.95), supporting its suitability for clinical biomechanics applications [23].

In accordance with established SLS test guidelines [21], trunk, pelvic, and knee angles were computed frame by frame across the entire SLS movement cycle. For each joint, the peak deviation from neutral alignment was extracted and used to quantify frontal-plane deviations during the SLS test. Knee valgus was computed as 180° minus the internal angle formed by the hip, knee, and ankle landmarks, representing frontal-plane knee alignment. Trunk lateral tilt was defined as the maximum deviation angle between the vertical axis and the line connecting the shoulder and hip midpoints, representing upper body lean. Pelvic lateral tilt was measured as the maximum angle between the line connecting the left and right hip landmarks and the horizontal axis, reflecting pelvic obliquity (Figure 3).

While the primary joint angles align with conventional SLS evaluation criteria [21], they may overlook complex inter-segmental relationships and compensatory movement strategies. To expand the feature representation beyond the primary measures, 3 frontal-plane joint angles (trunk, pelvic, and knee) were used to derive 14 engineered kinematic features. The engineered feature set included ratio features (knee/trunk, knee^2/trunk, knee/pelvis, knee^2/pelvis, knee/[trunk + pelvis], knee^2/[trunk + pelvis], and trunk/pelvis), interaction terms (trunk × knee, trunk × pelvis, and pelvis × knee), and nonlinear terms (trunk^2, pelvis^2, and knee^2). In addition, a composite feature (summated angle; trunk + pelvis + knee) was calculated. In total, 17 features (3 primary joint angles and 14 engineered variables) were used for subsequent model training. These ratios, interaction, nonlinear, and composite features were designed to capture coordination-related movement patterns beyond isolated joint deviations, potentially improving discrimination across knee-function levels and supporting clinical interpretability.

Feature Selection

The dataset was divided into training and test sets using stratified sampling, with 70% (n=73) allocated for training and 30% (n=32) for independent testing, ensuring proportional representation of the 3 movement quality classes (good, moderate, and poor). All models were trained and evaluated using the original class distribution without oversampling or synthetic data generation techniques.

Feature selection was performed using a 2-stage hybrid approach to identify features that exhibited significant between-class differences while preserving biomechanically meaningful feature diversity. First, a filter-based method using a 1-way ANOVA F_{df}-test with Benjamini-Hochberg false discovery rate correction was applied, resulting in the selection of 16 features that showed significant differences across the 3 movement quality classes (P<.05), with the trunk-to-pelvis ratio excluded because it did not show statistically significant between-class differences. Next, a wrapper-based method using recursive feature elimination with cross-validation and a random forest classifier was applied to the filtered feature set. Recursive feature elimination with cross-validation iteratively removed features that did not improve cross-validated classification performance, helping to mitigate functional redundancy among correlated variables derived from the same primary joint angles. Five-fold cross-validation was used with classification accuracy as the optimization metric. The final feature set was obtained by intersecting the results of both methods, resulting in 8 complementary features with reduced redundancy, including the knee valgus angle, ratio-based features (knee/trunk, knee/[trunk + pelvis], and knee^2/[trunk + pelvis]), interaction terms (trunk × knee and pelvis × knee), nonlinear knee-related features (knee^2), and a composite summated angle (trunk + pelvis + knee).

Classifiers

All implementations were conducted in Python 3.9 (Python Software Foundation) using standard machine learning libraries. For models that are sensitive to feature scaling, such as logistic regression, SVM, and *k*-nearest neighbors (KNN), *z*-score normalization was applied within a pipeline, while tree-based models were trained on raw feature values. Seven classifiers, including logistic regression, SVM, KNN, random forest, gradient boosting, light gradient boosting machine (LightGBM), and adaptive boosting (AdaBoost), were tuned via grid search with stratified 5-fold cross-validation using the macro-averaged F_1-score as the optimization metric. Hyperparameter search ranges included the regularization type and strength for logistic regression, the kernel type and penalty parameters for SVM, the number of neighbors and distance metrics for KNN, the tree depth and number of estimators for ensemble tree methods, and the learning rate for boosting algorithms.

Model Evaluation

Model performance was evaluated using stratified 5-fold cross-validation on the training set and an independent held-out test set. Three primary metrics were used to assess classification performance: accuracy, macro-averaged $F1$-score, and multiclass area under the receiver operating characteristic curve (AUC).

XSL•FO
RenderX

The macro-averaged F_1-score was computed as the unweighted mean of the class-specific F_1-scores, ensuring balanced evaluation across the 3 movement quality categories. Multiclass AUC was calculated using the one-vs-rest strategy, averaging the AUC scores obtained for each class.

Model Explainability

Both SHAP and LIME analyses were conducted exclusively on the final trained model, ensuring consistency between the interpretability results and the model used for evaluation. This dual approach enabled the identification of class-specific feature importance at the global level and the extraction of instance-specific decision patterns at the local level, supporting potential clinical and fitness applications [24,25]. Global interpretability was assessed using SHAP, applied to the final machine learning model. SHAP values were computed for each of the 8 selected features to quantify feature contributions to the model's class predictions. Class-wise SHAP value aggregation was used to identify the most influential features for each movement quality category.

Local interpretability was examined using LIME to generate instance-level explanations. LIME was applied to representative samples from each class in the test set, with the number of perturbed samples set to 5000 to ensure stability of the local surrogate models. The output from LIME was used to identify feature value ranges for each of the selected features that were most predictive of class membership. These thresholds were derived from the feature values at the decision boundaries learned by the model, providing interpretable biomechanical markers for distinguishing between "good," "moderate," and "poor" performance.

Computational Feasibility

Model training was performed offline as a 1-time procedure using a standard central processing unit-based environment (Google Colab) without graphics processing unit acceleration. Due to the use of lightweight classifiers and a limited set of interpretable features, training typically completed within a few seconds. Inference was conducted at the participant level, with each video processed independently. The inference pipeline, which included pose estimation, feature extraction, and classification, typically required only a few seconds per video on a central processing unit. In the proposed framework, the smartphone was used primarily for video acquisition, while pose estimation, feature computation, and classification were performed on a personal computer. These findings indicated that the proposed pipeline has modest computational requirements and is feasible for practical implementation.

Statistical Analysis

Descriptive statistics were computed for all participant characteristics and kinematic variables. Continuous data were reported as mean (SD), and categorical data were summarized as counts. Normality was assessed using the Shapiro-Wilk test. Differences among the 3 functional groups (good, moderate, and poor) were examined using 1-way ANOVA for continuous measures (age, BMI, weekly exercise duration, and peak frontal-plane angles). When a significant group effect was detected, Tukey honestly significant difference post hoc tests were conducted for pairwise comparisons. Statistical significance was defined as an α level of .05.

Ethical Considerations

The study protocol was reviewed and approved by the Institutional Review Board of Jeonju University (jjIRB-210315-HR-2021-03210) in accordance with the Declaration of Helsinki and relevant ethical guidelines. All participants were fully informed about the study's purpose, procedures, potential benefits, and rights prior to participation. Written informed consent was obtained from all participants prior to enrollment. All smartphone video data were collected solely for research purposes and were securely stored on an encrypted, password-protected server accessible only to the research team. To ensure privacy and confidentiality, all video and related data were deidentified; facial information and other personally identifiable details were neither analyzed nor disclosed. Participants were not asked to provide their real names; instead, each participant was assigned a unique anonymized code. Each participant received a small monetary incentive (approximately US $10) for participating in the study.

Results

Participant Characteristics

Participant characteristics are summarized in Table 1. The study included participants across the 3 SLS performance classification grades (good, moderate, and poor). While age, BMI, and weekly exercise duration did not significantly differ across groups, peak frontal-plane kinematics, including trunk lateral tilt, pelvic lateral tilt, and knee valgus, showed significant between-group differences (P<.05). Post hoc Tukey tests showed that trunk lateral tilt was significantly greater in the poor group than in the good and moderate groups, while no significant difference was observed between the good and moderate groups. Pelvic lateral tilt differed significantly between the good group and the other groups, whereas knee valgus increased stepwise across all 3 grades (P<.05).

[g]Post hoc showed a significant difference between good and moderate groups (P<.05).

[h]Negative values represent lateral deviation (knee varus) from neutral alignment, whereas positive values represent medial deviation (knee valgus).

Classification Performance of Machine Learning Models

Seven individual classifiers were evaluated using stratified 5-fold cross-validation, and final performance was assessed on a held-out test set (Table 2). AdaBoost demonstrated the best overall performance (AUC=0.92), comparable to LightGBM (AUC=0.92) and slightly higher than gradient boosting (AUC=0.91) (Figure 4). Accordingly, AdaBoost was selected as the final classifier for subsequent analysis. To confirm the value of feature selection, we compared AdaBoost performance using the full 17-feature pool versus the final 8 selected features. The AUC remained comparable (0.92 vs 0.92), indicating that the compact feature set retained most of the predictive information while improving model simplicity and interpretability.

The confusion matrices for AdaBoost, LightGBM, and gradient boosting are presented in Figure 5. Overall, AdaBoost showed more consistent class-wise discrimination, with reduced confusion between adjacent functional grades (particularly moderate and poor) compared with the other models, consistent with its overall performance metrics.

Table . Performance metrics of the evaluated classifiers.

Classifier	Accuracy	F_1-score	AUC[a]	Sensitivity	Specificity
Logistic regression	0.69	0.70	0.91	0.69	0.83
Support vector machine	0.75	0.76	0.90	0.75	0.83
k-nearest neighbors	0.78	0.79	0.89	0.79	0.88
Random forest	0.75	0.76	0.90	0.75	0.87
Gradient boosting	0.78	0.80	0.91	0.79	0.89
LightGBM[b]	0.81	0.82	0.92	0.81	0.90
AdaBoost[c]	0.84	0.85	0.92	0.84	0.92

Key Feature Analysis and Model Interpretability

To interpret the final classification model, we conducted both global and local interpretability analyses. SHAP identified the summated angle as the most influential feature, followed by the trunk × knee interaction, the knee-to-trunk ratio, and the knee angle (Figure 6). These results suggested that model predictions were influenced by both isolated knee deviations and intersegment coordination patterns, rather than conventional guideline-based single-joint criteria alone. For local interpretability, LIME provided case-specific explanations by visualizing how these features contributed to individual classifications across the 3 functional grades (Figure 7).

Discussion

Principal Findings

This study developed and evaluated an interpretable machine learning framework that classifies SLS performance into 3 levels (good, moderate, and poor) from single-smartphone, frontal-view SLS videos. Using a small set of biomechanically meaningful engineered features (summated angle, knee × trunk interaction, knee-to-trunk ratio, and knee angle), the AdaBoost classifier showed the best overall performance on a held-out

XSL•FO
RenderX

test set (accuracy=0.84, F_1-score=0.85, and AUC=0.92). SHAP and LIME enabled feature-based interpretation, allowing classification results to be translated into clinically interpretable feedback rather than labels alone. Importantly, the primary contribution of this study lies not in proposing a new algorithm but in demonstrating through a machine learning approach that impaired SLS performance is associated with coordination-related movement patterns rather than isolated joint deviations. By emphasizing the relative and interactive organization of trunk and knee movements, this coordination-based interpretation complements conventional guideline-driven SLS assessment and provides practical insights for rehabilitation decision-making and athletic screening.

Previous studies have reported that both wearable sensor-based and camera-based markerless models achieved moderate accuracy, typically ranging from 66% to 99% with an AUC of approximately 0.73, and often showed limited generalizability in 3-class SLS classification [9-11,26]. Notably, a recent study reported classification accuracies close to 99% using a single thigh-mounted IMU and a convolutional neural network-gated recurrent unit model trained on experimentally induced squat error patterns [26]. However, this IMU-based convolutional neural network-gated recurrent unit approach operates as a largely black-box model and relies on experimentally induced error motions (knee valgus/varus or excessive trunk flexion/extension), which may limit interpretability and ecological validity for clinical decision-making and real-world functional screening. In contrast, the present study emphasizes clinical translation by training the model on naturally performed SLS trials, with expert clinicians selecting representative videos that reflect real-world movement quality rather than artificially induced deviations. To move beyond guideline-based or composite measures, we generated ratio-, interaction-, and nonlinear-based features to capture interjoint coordination and identified summated angle, knee × trunk, knee-to-trunk ratio, and knee angle as the most informative predictors, thereby broadening the biomechanical basis for SLS assessment. By combining expert-labeled functional outcomes with interpretable feature representations learned from natural, nonexperimentally induced SLS performances, the proposed framework was designed to support clinical reasoning with transparent decision logic. Furthermore, machine learning models must be trained on data that are realistically obtainable in routine practice; otherwise, even high-performing algorithms remain difficult to translate when they depend on non-consumer sensors, multiple cameras, or specialized laboratory setups [27]. The present framework addresses this limitation by relying exclusively on a single, frontal smartphone video to extract interpretable kinematic features during standard SLS testing without specialized IMU sensor. This design enables automatic classification of SLS performance levels while maintaining practical feasibility, interpretability, and direct applicability in real-world sports and rehabilitation settings. Therefore, the key novelty lies not only in performance metrics but also in an ecologically valid and explainable approach that can be realistically implemented using smartphone video in routine screening workflows.

Beyond predictive accuracy, the explainability analyses provided additional biomechanical insights into SLS performance. SHAP highlighted the summated angle as the most influential feature, with additional contributions from knee-specific and coordination-related metrics, including the knee × trunk interaction, the knee-to-trunk ratio, and knee angle. These findings suggest that impaired performance is associated with multisegment movement patterns, rather than isolated joint deviation alone. Previous studies using individual joint or composite measures achieved only moderate accuracy (66% with an SVM and 76.9% with a decision tree) [9,10], without considering intersegmental interactions. In contrast, our approach explicitly incorporated coordination-related engineered features and combined them with an interpretable machine learning model, enabling biomechanically grounded explanations beyond conventional joint-by-joint criteria. This observation aligns with biomechanical evidence that interjoint coordination patterns are critical markers of movement quality during squatting and single-leg tasks [7], and supports the role of trunk-knee coupling as a central determinant of functional impairment [28]. Complementary LIME analyses further illustrated instance-specific decision boundaries, showing that case-level classifications were consistently explained by combinations of summated angle, coordination-related metrics, and knee angle supporting transparent subject-level interpretation. By clarifying why a patient is classified as having poor SLS performance, the XAI results may help clinicians and trainers gain confidence in machine learning-based SLS evaluation. Moreover, they can guide expert decisions on whether management strategies should focus solely on the knee or also address altered trunk-knee coordination, thereby supporting more personalized rehabilitation and remote monitoring.

Practical Implications

The practical meaning of this study is that it enables a low-cost, scalable, and explainable workflow for screening SLS performance using smartphone-recorded SLS videos, providing interpretable decision support rather than simple movement monitoring. In team sports, athletic trainers can apply this workflow for periodic screening, reducing the burden of manually reviewing large volumes of videos, grading SLS performance, and producing narrative reports for multiple athletes. Importantly, SHAP- and LIME-based explanations support interpretation beyond the final grade by clarifying whether impaired performance is driven primarily by knee deviation, altered trunk control, or their coordination-related interaction, thereby informing targeted preventive or corrective strategies. In physical therapy settings, clinicians can similarly use the framework during intake or follow-up visits to obtain an objective functional grade with interpretable feature-based rationale, supporting individualized rehabilitation planning and progress tracking. Compared with rule-based fitness screening applications, the proposed machine learning approach better captures coordination-related movement patterns and provides consistent decision logic with interpretable explanations, supporting standardized documentation and scalable musculoskeletal screening in sports and rehabilitation settings.

RenderX

Limitations

Despite these promising results, several limitations should be acknowledged. First, the dataset size was relatively small (n=105 participants). However, prediction instability analyses suggested that model performance stabilized with the available sample [15], and stratified cross-validation and systematic feature selection were applied to assess the stability of the results [13]. Nevertheless, future studies should validate the model in larger cohorts with external testing to quantify generalizability across populations and real-world settings. Second, all videos were recorded using the same smartphone under a standardized frontal-view setup with fixed camera distance and height, consistent with routine clinician-guided SLS screening protocols. While this standardized design improves reliability and reduces measurement variability, it may limit generalizability to home- or telehealth-based recordings where camera setup and recording conditions are less controlled. In particular, variations in smartphone camera specifications and video quality (resolution and frame rate), as well as real-world environmental factors such as lighting and background clutter, may affect pose estimation accuracy and introduce noise into extracted kinematic features. Future work should quantify sensitivity by systematically varying recording conditions (smartphone model, lighting, background, and camera distance or height) and examining the impact on pose estimation stability and final classification performance. Third, participants were limited to young healthy adults, which may restrict generalizability to clinical populations and athletic cohorts. Future studies should evaluate performance in more diverse groups, including older adults, patients with knee-related conditions, and injured athletes, to support clinical translation. Finally, because the dataset showed a right-skewed dominant-side distribution (Table 1), future studies should include more left-dominant participants and evaluate left-right normalization or symmetry-based augmentation strategies to improve model robustness.

Conclusion

This study developed an interpretable machine learning framework for classifying SLS performance into 3 levels (good, moderate, and poor) from frontal-view SLS videos recorded with a single smartphone. Using a small set of biomechanically meaningful engineered features (summated angle, knee × trunk interaction, knee-to-trunk ratio, and knee angle), the AdaBoost classifier achieved good overall performance on a held-out test set. SHAP and LIME provided consistent global and local explanations, enabling transparent interpretation of SLS performance classifications. Importantly, the proposed coordination-informed feature design provides a distinct contribution by reframing SLS assessment beyond isolated joint deviations, instead emphasizing intersegment movement patterns that align more closely with clinical reasoning and athletic screening. This workflow uses smartphones only for standardized video acquisition, while explainable SLS performance screening is achieved through an interpretable machine learning framework. Given the lightweight feature set and classical machine learning models used, the proposed framework is suitable for future on-device inference on modern smartphones, which may support rehabilitation planning and injury prevention strategies.

This work was supported by the Yonsei University Research Grant of 2024 (2024-22-0406).

Data Availability

The datasets generated or analyzed during this study are not publicly available due to privacy concerns but are available from the corresponding author on reasonable request.

Authors' Contributions

SK and KP conceptualized the study and jointly managed the project. Both authors developed the study methodology, curated the data, and contributed to the formal analysis. KP led the formal analysis and supervised the overall project. SK provided methodological support and contributed to data interpretation. Both authors were involved in visualization and drafting the original manuscript, as well as revising the manuscript at multiple stages. All authors reviewed and approved the final version of the manuscript.

Abstract

Background: Many frameworks and tools are available to evaluate the quality of mobile health apps (MHAs), which are increasingly used by health care professionals (HCPs) for accessing medical information, clinical decision support, and communication. However, existing tools are not well equipped to assess the quality of apps designed for HCPs from their perspectives.

Objective: We aimed to develop a new tool based on the Mobile App Rating Scale (MARS) to capture the unique perspectives of HCPs on MHAs. We then conducted a psychometric analysis of this new questionnaire to determine its effectiveness in assessing the quality of MHAs designed specifically for HCPs from their perspectives.

Methods: This study was conducted in 2 phases. In phase 1, the original MARS tool was adapted for HCPs through expert panel review and subsequent qualitative interviews, resulting in the development of the pMARS (MARS for health care professionals) tool. This phase focused on establishing face and content validity. Qualitative interviews were conducted with HCPs from a tertiary hospital in Singapore to gather their perspectives on the tool's structure, clarity, applicability, and usability. In phase 2, we invited HCP participants to complete pMARS based on their experience with the LabMed app, an mHealth tool designed to provide medical laboratory–related information to HCPs. We established the construct validity of pMARS through multiple psychometric techniques. Internal consistency reliability was measured using the Cronbach α, while structural equation modeling was used to examine the interrelationships among latent constructs. Additionally, we used item response theory (IRT) to evaluate each item's impact on latent constructs of interest, that is, discriminative performance of individual items within each domain.

Results: Based on the results from phase 1, the pMARS comprised 26 items across 5 domains: engagement, functionality, aesthetics, information, and subjective quality, refined through interviews with 10 HCPs. In phase 2 (n=218), pMARS demonstrated good internal consistency reliability across all domains (Cronbach α=0.855-0.931). Structural equation modeling demonstrated that functionality had the strongest influence on end-user willingness to use, recommend, and purchase the MHA (P<.001). IRT identified that customization and interactivity of the engagement domain had a weak impact on latent constructs, whereas entertainment had a higher impact. Ease of use and gestural design had a weak impact on the functionality domain, whereas arrangement and size of content and quantity and quality had a strong impact on the aesthetics and information domains, respectively.

Conclusions: This study reports the development and psychometric analysis of pMARS. Our findings demonstrate strong internal consistency reliability and construct validity, supporting its potential use in health care. Further research should validate pMARS across diverse MHAs and contexts and apply IRT to further refine its precision and efficiency.

Introduction

Mobile health (mHealth) apps (MHAs) offer the potential to deliver accessible, efficient, and cost-effective health care [1,2]. These apps are used not only by patients for health education and self-care but also by health care professionals (HCPs) [3]. HCPs rely on MHAs for many purposes, including consultations between HCPs, intersectoral communication, and access to information for HCPs at the point of health care delivery [3,4]. However, the quality of MHAs designed specifically for HCPs can vary significantly in terms of the accuracy of the information provided, functionality, data visualization effectiveness, credibility, and other key factors. Poor-quality or misleading content can pose serious risks to patient health and safety, underscoring the need for reliable quality assessment measures [1,5-7]. Although several frameworks and tools have been developed to evaluate the quality of MHAs, the Mobile Application Rating Scale (MARS) remains one of the most widely used and recognized tools for this purpose [8-10].

MARS is a multidimensional tool designed for experts to assess the quality of MHAs [10,11]. It consists of 23 questions or items, with 19 of these organized into 4 objective dimensions: engagement (5 items), functionality (4 items), aesthetics (3 items), and information (7 items) [10]. MARS has been widely applied in the evaluation of apps related to health, well-being, health care, and medicine [12-17]. Researchers have validated MARS across multiple languages, demonstrating that its psychometric properties are consistent with those of the original English version [11,17-20].

Given the expertise and training required to administer MARS, a simplified version, known as uMARS (user version of the MARS), has been developed for end users [21]. Items requiring expertise and complex terminology have been removed from uMARS. While uMARS has gained wide acceptance for its utility in assessing the quality of various MHAs [22-25] and has been translated into other languages [26], it has also faced criticism. Specifically, it has been noted that uMARS may inadequately capture end user perspectives on quality, and some have suggested that it should include emerging mHealth technologies to enhance its comprehensiveness [27].

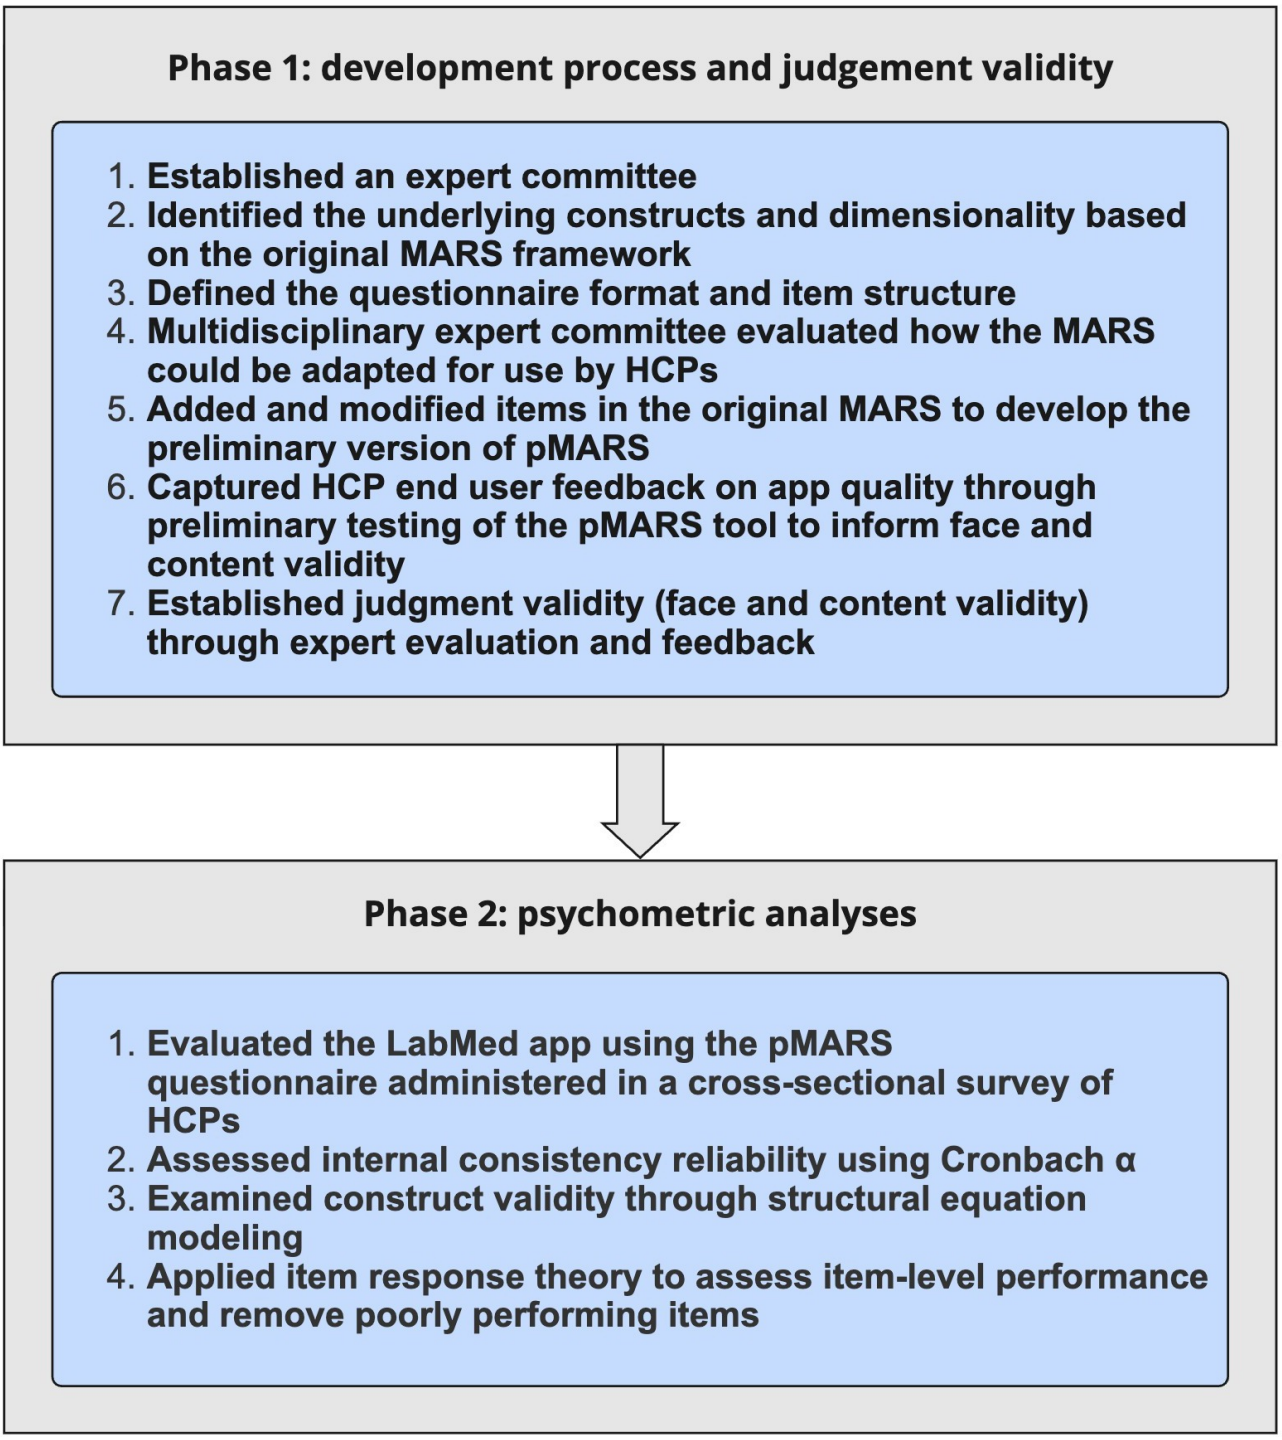
Despite the widespread use of tools for assessing the quality of MHAs, there have been only a few attempts to evaluate these tools from the perspective of HCPs as end users. This evaluation is crucial for several reasons. First, HCPs are reported to have unique requirements when assessing quality, including access to patient data, data security, and evidence-based clinical content [28]. Second, MHAs designed for HCPs must cater to clinical needs and other professional decision-making processes. Unlike MHAs for general users, these apps are also subject to professional and organizational policies that mandate specific security features. Third, HCPs often face demanding schedules, with limited time to thoroughly assess digital tools due to their primary responsibilities in patient care and clinical decision-making [29]. Finally, current assessment tools, such as MARS and uMARS, may not fully meet these specific functional requirements or accommodate the time constraints experienced by HCPs. Consequently, developing a new, specifically designed, and simplified questionnaire that can be administered quickly would effectively address these gaps and provide a more relevant evaluation tool for HCPs as end users.

Moreover, involving HCPs in the development of MHAs is widely recognized as a key factor in creating safe and effective apps [28,30,31]. A tailored assessment tool would enable MHA developers to address the unique priorities of HCPs. In addition, by capturing the distinct perspectives of HCPs using a dedicated tool, service providers can obtain more accurate and practical insights, ensuring that MHAs are suitable for professional use and health care delivery. Therefore, we aimed to (1) develop a new MHA rating scale tailored for HCPs based on the widely validated MARS framework and (2) conduct a psychometric analysis of this new questionnaire to determine its effectiveness in assessing the quality of MHAs designed specifically for HCPs.

This paper describes the development of the new rating scale and evaluates its initial application using the LabMed app, an mHealth tool designed to provide medical laboratory–related information to HCPs [29,32]. We present our Methods, Results, and Discussion sections in accordance with the "recommendations for instrument and scale development and testing" [33,34].

Methods

In this section, we discuss the specific methods and materials used in the study: (1) the process of adapting MARS for use by HCPs with the goal of establishing judgment validity and the qualitative methods used in this process (phase 1) and (2) the assessment of reliability and construct validity of the new tool, pMARS (MARS for health care professionals), through Cronbach α and structural equation modeling (SEM), respectively, followed by the utility of item response theory (IRT) in identifying weakly impacting or performing items (phase 2).



Phase 1: Development of the New Rating Scale (pMARS) and Establishment of Judgment Validity

Overview

Judgment validity was based on face and content validity [35]. Face validity is the degree to which respondents judge the questionnaire items to be valid. Content validity is the extent to which the observed variables in a questionnaire are representative of the theoretical constructs or latent variables (eg, entertainment, interest, customization, and interactivity) and latent constructs (eg, engagement, functionality, and aesthetics). A study outline is shown in Figure 1.

XSL•FO
RenderX

Figure 1. Study outline. HCP: health care professional; MARS: Mobile App Rating Scale. pMARS: Mobile App Rating Scale for health care professionals.

Expert Evaluation

Judgment validity as a whole was approached using the following steps: establishing an expert committee, identifying dimensionality of constructs, determining the questionnaire and item formats, adding items, determining length, reviewing results, and revising [35]. This step was guided by the anticipated clinical, informational, and workflow-related needs of HCPs when evaluating MHAs for professional use.

Data Collection

Data collection focused on systematically eliciting expert judgments on the relevance, suitability, clarity, and completeness of MARS items when assessing MHAs intended for HCP use. We assessed content validity with the following criteria: (1) questions were clear and easy to understand, (2) questions covered all the important aspects of each domain, (3) the questionnaire did not omit important questions regarding quality of MHAs, (4) the questionnaire was suitable for replication studies, and (5) there were no violations of privacy. A 3-member panel of multidisciplinary experts comprising a physician, a public health expert, and a human-computer interactions specialist evaluated the relevance and suitability of the original MARS domains and identified items for adaptation to HCP end users.

XSL•FO
RenderX

Data Analysis

The aim of this analysis was to identify key domains and constructs from HCP perspectives, eliminate multiconstruct items, ensure appropriate language for HCPs, and review questionnaire length. Feedback was synthesized through iterative review and consensus among the experts to determine item retention, modification, and/or removal. A draft tool with 23 items across 5 conceptually defined domains was developed. Items were not reverse scored. Domains were treated as conceptual groupings rather than independent subscales. Scoring of the tool was carried out by averaging the item scores within domains and across the full pMARS tool.

Interviews

To further establish face and content validity from an end-user perspective, qualitative interviews were conducted with HCPs.

Data Collection

To assess pMARS's ability to capture quality and other key characteristics, we recruited a sample of HCPs (n=10) through both convenience and purposive sampling for face-to-face interviews using a semistructured interview guide provided in Multimedia Appendix 1. A convenience sampling method was used to recruit HCPs who had recent contact with the clinical laboratory. A purposive sampling method was used to ensure that both physicians and nurses were represented in the sample. One researcher (AADNSS) was present for a week at the clinical laboratory to recruit participants.

Demographic details, excluding personal identifiers, were collected during the interview. Participants first completed version 1 of the pMARS tool, then were interviewed about their experiences and asked for suggestions for improvement. On average, the entire interview process lasted 25 to 30 minutes and was conducted in a private, quiet space within the hospital.

Interview Analysis

Audio recordings from the interviews were transcribed verbatim and handwritten notes were compiled without participant identifiers. Anonymized transcripts were analyzed using a deductive coding process [36]. One researcher (AS) conducted the initial coding, categorizing participant feedback based on the role pMARS played in assessing the app. Preliminary codes and emerging themes were discussed by the researcher and a collaborator until consensus was reached. The final coding scheme was subsequently reviewed and validated by a second researcher (AADNSS). Findings from this phase were used to refine item wording and enhance the content validity of the pMARS tool.

Phase 2: Evaluation of Reliability and Construct Validity of pMARS

Overview

To evaluate the pMARS questionnaire, a cross-sectional analysis was conducted with the users of the LabMed app between March and August 2019 at a tertiary care general hospital in Singapore.

Data Collection

The physicians, residents, nurse clinicians, and registered nurses in the hospital who used the clinical laboratory services and had experience using the LabMed app were eligible to take part in the study.

We used a simple sequential sampling approach to recruit participants. The questionnaire was administered using 2 parallel approaches. First, a researcher (AADNSS) systematically visited all hospital wards in person and distributed printed questionnaires, which were collected periodically during the data collection period. Second, the questionnaire was made available through the hospital intranet via the REDCap (Research Electronic Data Capture [37]) electronic data capture platform. The HCPs were informed of the online option through a single mass email campaign conducted by the hospital's marketing department. Response was voluntary.

REDCap is a secure, web-based software platform designed to support data capture for research studies. We aimed for a participant-to-questionnaire-item ratio of 8:1 to 10:1, resulting in an estimated sample size of 184 to 230 [35].

Data Analysis

All forms of questionnaires were transcribed into a Microsoft Excel file by 2 researchers working together to minimize transcription errors. STATA (version 17.0; StataCorp) was used for analysis [38]. The Cronbach α was used to show the internal consistency reliability of pMARS: 0.80 to 0.89 was considered good, and >0.90 was considered excellent [39]. A high α may indicate redundancy; however, it is not the sole determinant of item appropriateness [40]. Face and content validity, along with factor structure, were essential in determining the questionnaire's ability to accurately measure the intended construct.

SEM was used to evaluate the interrelationships between the latent constructs after adjusting for age, sex, and HCPs' role in the hospital [1]. SEM assumed a latent construct for the observed items of each subscale, and a higher order factor—subjective quality—accounted for correlations between the factors (Figure 2).

XSL•FO
RenderX

Figure 2. The model used in structural equation modeling.

Lastly, we used IRT to identify each question's impact on the latent constructs, that is, engagement, functionality, information, aesthetics, and subjective quality. Unlike classical test theory, which assumes all items contribute equally to the overall score, IRT allows for identifying items with varying discrimination, making it ideal for optimizing and shortening measurement tools without compromising validity and reliability. The primary purpose of using IRT was to refine the questionnaire, resulting in a precise, valid, and relatively brief pMARS that minimized the completion time and response burden [41].

Ethical Considerations

This research project received an ethics review exemption from the Projects Committee of the Department of Laboratory Medicine at Ng Teng Fong General Hospital, Singapore. The exemption was granted in accordance with the department's policy for minimal-risk research involving health care staff and was reviewed and approved by the head of the department. All participants were provided with an information sheet describing the study objectives, the voluntary nature of participation, and the commitment to data confidentiality. Informed consent was obtained before participation in each study phase. Participants who completed the qualitative interviews (phase 1) or paper-based questionnaires (phase 2) provided written consent, while those who completed the online survey via REDCap on the hospital intranet platform provided electronic consent.

Basic demographic data, including age, biological sex, and professional role, were collected. No personally identifiable data were collected. All files were stored on password-protected institutional drives accessible only to study investigators. In phase 2, participants were offered a Singapore $10 (S$1=US $0.78 as of June 17, 2026) voucher for a local coffee chain as compensation for their time spent completing the questionnaire. No other payments or incentives were provided.

Results

Phase 1, the qualitative study, included 10 participants. Phase 2 included 218 participants who responded and returned completed questionnaires. Selected sociodemographic characteristics of the participants are presented in Table 1.

XSL•FO
RenderX

Table . Demographic characteristics of the participants in phase 1 and phase 2.

Characteristics	Values
Phase 1	
Age (years), mean (SD)	28.4 (8.81)
Sex, n (%)	
Male	3 (30)
Female	7 (70)
Role in hospital, n (%)	
Nurse	8 (80)
Doctor	2 (20)
Phase 2	
Age (years), mean (SD)	30.4 (7.2)
Sex, n (%)	
Male	39 (17.9)
Female	176 (80.7)
Missing data	3 (0)
Role in hospital, n (%)	
Nurse	154 (70.6)
Doctor	47 (21.6)
Missing data	17 (7.8)
Specialty, n (%)	
Surgical specialties	26 (11.9)
Medical specialties (inpatient or acute care)	91 (41.7)
Community hospital	9 (4.1)
Unspecified	92 (42.2)

Phase 1: Development of pMARS and Assessment of Its Judgment Validity

The first version of the questionnaire consisted of a demographic data section and 5 domains. Certain question stems were reworded and/or split into 2 separate stems to ensure that there were no double-barreled questions, for example, item 1 of section A of MARS reads, “Is the app fun/entertaining to use? Does it use any strategies to increase engagement through entertainment?” This was broken into two separate question stems: (1) “Is the app fun/entertaining to use?” and (2) “Does the app use strategies to increase engagement through entertainment (e.g., strategies such as interactivity/gamification)?” This version of the questionnaire consisted of question stems presented in question form and shortened but descriptive answer stems presented as a Likert scale. Moreover, almost all the question stems had examples or descriptive statements to further elaborate or clarify the ideas.

Insights from the qualitative assessment, categorized into 4 key areas, guided the multidisciplinary panel in developing the second version of pMARS at the end of phase 1 (Table 2).

XSL•FO
RenderX

Table . Quotes from the qualitative interview participants (n=10) in relation to specific functionalities of the Mobile App Rating Scale for health care professionals.

Function	Quotes from participants	Action taken
Structure	• "Some questions are truncated in the paper." • "Takes a long time to read." • "Print all the stems on the same page." • "Shorten the questionnaire by reducing the length of the items."	• Shorten the questionnaire by reducing the length of the items. • Limit examples and descriptive statements in question stems. • Switch to landscape format to reduce the length of the survey to three pages.
Clarity	• "RCT, what does it mean? Only the abbreviation is given." • "Should have presented the answer stems in tables or using numbers instead of bullet points." • "I think only the options are quite long." • "Not sure or uncertain is the answer that I was looking for."	• Simplify the language and minimize jargon. • Revise question stems to statements to reduce length and increase clarity.
Applicability	• "The questionnaire is different to the context of this app." • "We usually use it when we need it, but the question is about entertainment. Not relevant." • "It is not about entertainment, it's whether I want it or not." • "Credibility is granted by hospital. Should not doubt it." • "App store description is not usually read by anyone. Therefore it is probably not important to assess."	• Reword item stems to better highlight app functionality and relevance. • Reduce descriptive statements to minimize assumptions about app use. • Remove irrelevant items such as app store description. • Reduce items on entertainment and gamification.
Usability	• "Likert scale should be reversed, as in 5 should be extremely satisfied." • "Should have presented the answer stems in tables or using numbers instead of bullet points." • "Introduce an additional option for those who do not know the answer."	• Change the answer stems to a simple 5-point Likert scale. • Add a new answer stem for "don't know." • Simplify design and remove Likert descriptors.

Findings from the qualitative assessment of the questionnaire (ie, interviews with HCPs) shed light on several areas of the questionnaire for focused improvement: (1) shorten the questionnaire by reducing the length of the answers, (2) further simplify the language and minimize jargon, and (3) introduce an additional option for those who do not know the answer to a specific question. It is noteworthy that no new items were proposed by the HCPs. Based on the findings, we changed the question stems from question forms to statements, for example, (1) "arrangement and size of buttons, icons, and menus on the screen is appropriate" and (2) "it uses strategies to increase engagement through entertainment (e.g., strategies such as interactivity/gamification)." Moreover, we limited examples and/or descriptive statements in question stems to a minimum. Simultaneously, we changed the answer stems to a simple 5-point Likert scale without embedded descriptive statements: strongly agree, agree, neutral, disagree, and strongly disagree. Finally, we added a new answer stem: "don't know."

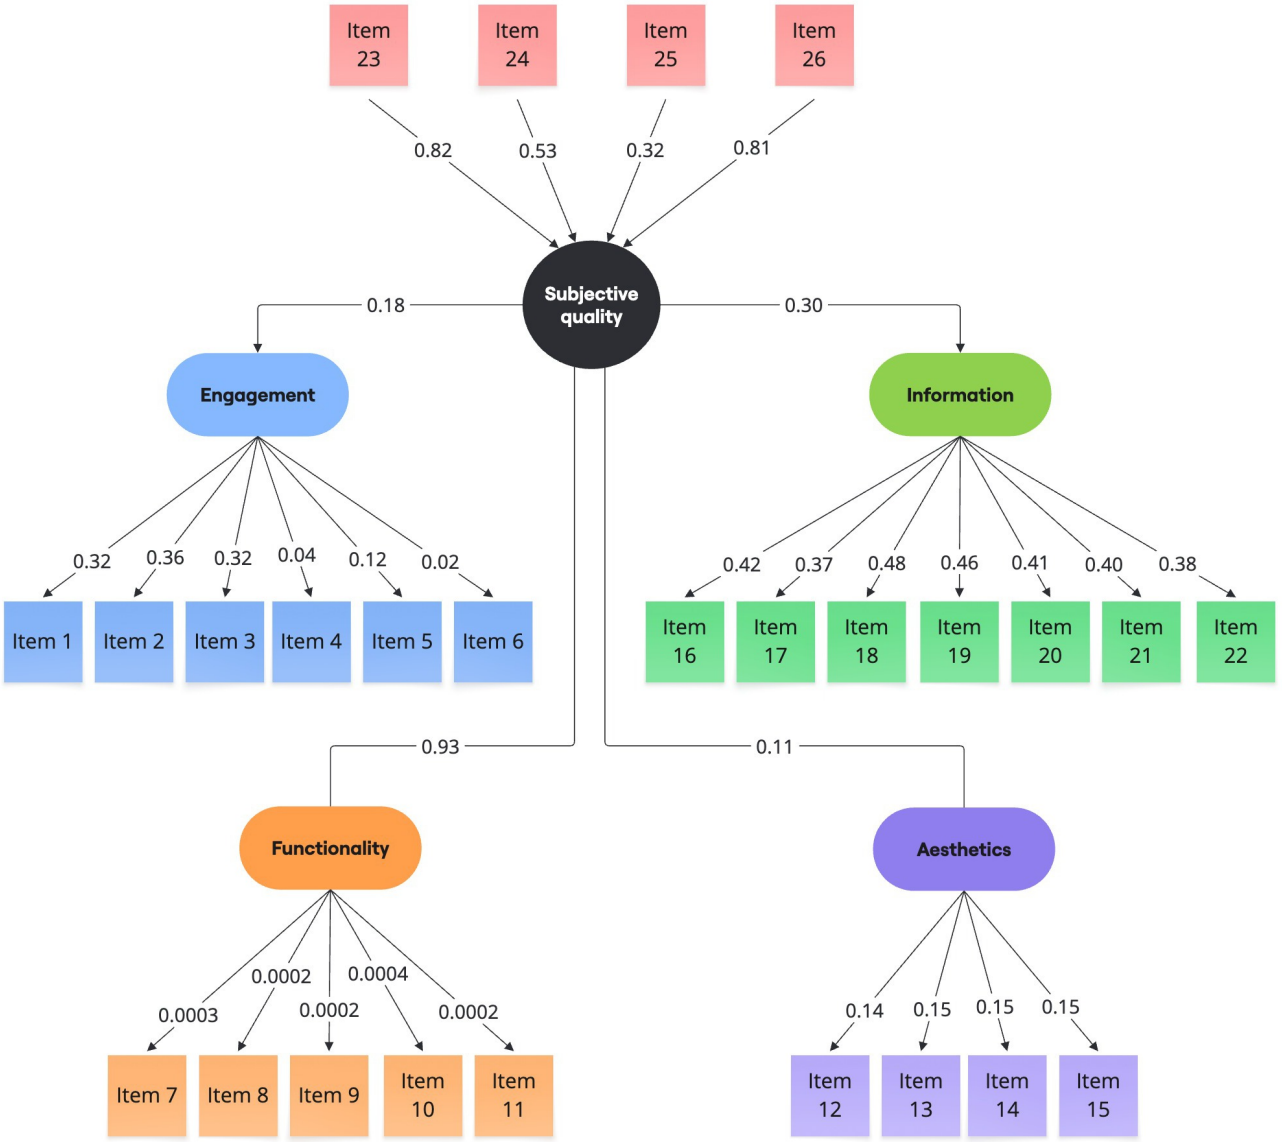
In addition, we redesigned the questionnaire by changing its orientation from portrait to landscape. The reasons for this change were to limit the length of the questionnaire to 3 pages despite including additional questions and to provide an easy-to-complete format. The final version of the questionnaire at the end of phase 1 consisted of 26 questions spread across 5 domains: engagement (6 items), functionality (5 items), aesthetics (4 items), information (7 items), and subjective quality (4 items). The length of the questionnaire was deemed appropriate by the committee (Multimedia Appendix 2).

Phase 2: Reliability and Construct Validity of pMARS

We distributed 197 printed questionnaires among HCPs in person, and 189 participated, resulting in a 95.9% response rate. Additionally, 29 HCPs accessed the survey through the hospital intranet, bringing the total number of responses to 218. A further 15 REDCap surveys were incomplete, resulting in a REDCap complete response rate of 65.9%. We were unable to calculate an overall response rate for REDCap as we could not track the reach through the hospital intranet. Among the in-person and intranet-administered questionnaires returned, the proportion of nonresponses per question item ranged from 0% to 13.3%, with the item "Would you pay for this app?" showing the highest nonresponse rate (n=29). Most items (29/30; 96.7%) had less than 5.1% missing responses. Detailed item-level missing data, including counts of "don't know" responses, are provided in Multimedia Appendix 3.

XSL•FO
RenderX

The Cronbach α (ranging from 0.855 to 0.931) showed that the internal consistency reliability of pMARS was good to excellent for all the domains (Table 3). SEM analysis demonstrated that functionality (P<.001) had the strongest influence on end-user willingness to use or recommend and purchase the MHA, after adjusting for age, sex, and the HCPs' role in the hospital (Figure 3).



For domains with Cronbach α values >0.90, we conducted a manual item review to assess potential redundancy. We examined item wording and conceptual distinctness within each domain. The review confirmed that, although some items were related, they measured complementary aspects of the construct and contributed meaningfully to the overall scale. All such items were therefore retained in the current version of pMARS.

Table . Cronbach α results for the Mobile App Rating Scale for health care professionals.

Domain and item	Scale mean if item deleted	Scale variance if item deleted	Corrected item–total correlation	Cronbach α if item deleted
Engagement: Cronbach α=0.855, number of items=6				
Item 1	17.936	8.080	0.671	0.825

Figure 3. Results of the structural equation modeling.

IRT (Table 4) identified that for the engagement domain, items 4 (customization) and 5 (interactivity) had a weak impact on latent constructs, whereas items 1 and 2 (both entertainment) had a higher impact on the domain. Similarly, items 9 (ease of use) and 11 (gestural design) had a weak impact on functionality, item 13 (arrangement and size of content) had a strong impact on aesthetics, and items 18 (quantity) and 19 (quality) had a strong impact on information. The engagement domain demonstrated the lowest reliability, and IRT highlighted weakly impacting items within the domain, enabling the researchers to shorten the questionnaire if required.

XSL•FO

Item 20	3.2
Item 21	4.1
Item 22	4.2

[a]Overall: engagement=4.0, functionality=11.3, aesthetics=24.5, and information=4.0.

Discussion

Principal Findings

Our study shows that the newly developed pMARS tool has strong internal consistency reliability (Cronbach α) across all domains, indicating its potential utility in assessing the quality of MHAs designed for HCPs from their perspective. Although most items performed well, item 22 of the information domain ("the app has been trialled/tested; verified by evidence") demonstrated weak correlations (Table 3). The item was retained in the final version of pMARS as it reflects a critical aspect of evidence-based practice in clinical settings and warrants further examination in future validation studies. Furthermore, SEM generated valuable insights into interrelationships between the latent constructs. Not all items were equally good indicators for the dimensions. The strongest influence was observed between subjective quality and functionality. Similarly, items 1 to 3 of the engagement domain, items 16 to 22 of the information domain, and items 23 and 26 of the subjective quality domain demonstrated relatively strong influence.

On the other hand, IRT revealed weakly impacting items such as items 4 and 5 of the engagement domain; items 9 and 11 of the functionality domain; and items 16, 17, and 20 of the information domain. These items provide an opportunity to further shorten the questionnaire. However, it should be evaluated within the theoretical factor model of the scale, and therefore, this is an area for future research. Overall, our findings suggest that pMARS is an MHA quality assessment tool of good metric quality considering the reliability and construct validity results.

Clinical Utility and Developmental Limitations

In the busy health care settings of Singapore, engaging HCPs in discussions unrelated to direct patient care can be challenging. With its brevity and standardized format, pMARS enables rapid assessment of MHA quality from the perspective of HCPs as clinical end users. Unlike MARS, which was designed for expert

XSL•FO
RenderX

evaluators to classify and assess general MHA quality, and uMARS, which targets general end users, pMARS fills a critical gap by capturing HCP-specific clinical usability and professional decision-making considerations that are not specifically addressed by existing tools [10,21]. The use of simplified language in pMARS ensures accessibility for HCPs without requiring specific training, including those who may be unfamiliar with MHA-related terminology. Consequently, pMARS provides a practical, contextually relevant, and adaptable tool for service providers and HCPs to evaluate the quality of MHAs within real-world clinical settings. Notably, pMARS is designed as a flexible framework that can be iteratively refined to incorporate emerging clinical-, workflow-, and patient safety–related quality considerations as digital health technologies evolve.

The direct use of MARS in developing pMARS, as described by Baptista et al [27], may eliminate certain aspects of MHAs that are important to end users. To overcome this limitation, we introduced a qualitative approach using interviews with HCPs; however, the inputs generated by this procedure were limited to a few aspects of the questionnaire, as discussed in the Results section. The qualitative component introduced changes to question stems by rewording, shortening, and simplifying them without adding or removing any items from the questionnaire. According to our observations during the interviews, the interview answers were brief and the discussions were limited, possibly as a result of time pressures.

Regulatory Challenges

Legislative frameworks such as the Health Insurance Portability and Accountability Act (HIPAA) in the United States and the Personal Data Protection Act (PDPA) in Singapore address crucial concerns for HCPs regarding MHAs, including data privacy, security, and patient confidentiality [42,43]. These regulations set important standards for protecting patient information and ensuring the reliability of MHAs. However, the adoption of such regulations varies globally, with many countries still developing or implementing their standards. As regulatory frameworks continue to evolve, the availability of a robust tool to evaluate the quality of MHAs from the perspective of HCPs remains essential to ensure these apps meet the necessary standards. Furthermore, health care organizations can use pMARS to evaluate and select suitable MHAs that comply with professional standards.

Considerations for the Future

As mHealth technology continues to evolve, several areas for potential improvement in future versions of the pMARS tool have emerged. First, interoperability between MHAs, health systems, and electronic health records is crucial for HCPs and health care organizations when integrating these technologies [44]. Second, evaluating the effectiveness and security of communications among HCPs, including end-to-end encryption, is important for ensuring coordinated care and protecting sensitive information [45]. Third, understanding potential patient safety concerns associated with MHAs is vital for maintaining high standards of care. Lastly, language barriers among HCPs should be addressed to enhance the app's quality, ethical considerations, and utility. Future versions of pMARS should take these evolving quality requirements into account. Additionally, with the growing integration of AI and large language models into mHealth apps, future versions of pMARS should also account for quality requirements specific to AI and AI-generated content [46,47].

Limitations

Our study has several methodological and participant-related limitations. There were 2 methodological limitations. First, the psychometric evaluation of pMARS was based on data from only 1 MHA. This focus may affect certain aspects of statistical analysis, particularly if the MHA had quality deficiencies in specific domains. To address this limitation, future validation studies should involve a broader range of MHAs across different medical fields. Second, the IRT depends on the accuracy of the underlying model. The utility of the IRT is contingent upon how well the model reflects the data, making further validation studies essential to evaluate the appropriateness of pMARS items.

Participant-related limitations include the potential influence of the questionnaire's ease of administration on construct validity. The simplicity and repetitive nature of the pMARS may lead to patterned responses, highlighting the need for negatively worded questions in future studies to counteract response biases. Second, the expert panel in phase 1, comprising a physician, public health expert, and human-computer interactions specialist, did not fully represent the demographics of the study participants or potential users, potentially limiting the generalizability of the pMARS tool. Further studies are necessary to assess and validate the pMARS tool across multiple MHAs. Finally, the disproportionate number of female participants should be noted as a limitation, as it may reduce the generalizability of findings to male HCPs. However, to some degree, this distribution reflects the gender composition of the hospital workforce rather than sampling bias.

Conclusions

To our knowledge, this study is the first to develop a tool to evaluate MHAs designed for HCPs from their perspective. Additionally, it is the first study to apply IRT to assess and identify the impact of each question on the latent constructs within MARS and its derivatives. Our findings demonstrate that pMARS is a robust and metrically sound tool for evaluating MHAs intended for HCPs. It has the potential to enable HCPs to assess and recommend high-quality MHAs. We recommend that future research on pMARS incorporate IRT to refine the questionnaire by identifying and removing less-effective items, thereby enhancing its utility and precision in assessing MHA quality.

Acknowledgments

The authors are grateful to all the staff who contributed to the project by taking part in the interviews and completing questionnaires despite their busy schedules in the hospital. This study would not have been possible without their tremendous support. We also thank Dr Leslie Lam, Ms Zeng Peizi, and Mr Andrew Goh for facilitating this study within the Department of Laboratory Medicine of Ng Teng Fong General Hospital.

Funding

This study was supported by the JurongHealth Internal Research & Development Grant Awards for fiscal years 2016 and 2017 (project code 16-55).

Authors' Contributions

AADNSS conceptualized and designed the study, co-designed the quantitative and qualitative methodologies, acquired the data, contributed to quantitative data analysis and interpretation of findings, drafted and critically revised the manuscript, and approved the final version for publication. YHC co-designed the quantitative methodology, performed the statistical analysis, critically reviewed the manuscript, and approved the final version for publication. AS co-designed the qualitative methodology, conducted the qualitative data analysis, critically reviewed the manuscript, and approved the final version for publication.

Abstract

Background: Mobile apps are being increasingly used to foster healthy lifestyles. There is a growing need for clear, standardized guidelines to help users select safe and effective health apps.

Objective: Our study aimed to highlight the importance of establishing a structured framework for quality evaluation in mobile health (mHealth) through a case study of mobile apps promoting healthy eating.

Methods: We conducted a systematic review of apps promoting healthy eating that had already been evaluated by one or more of 28 recognized health app certification bodies. Three rounds of app evaluations were conducted by experts in nutrition and behavior change. The first two rounds focused on the quality of the content of the recommendations and were performed pairwise using the Quality Evaluation Scoring Tool (QUEST), which has not been previously used by the certification bodies. In addition, in the second and third rounds, each reviewer answered the question “How probable is it that you would recommend this app?” using a subjective scale score from 0 to 10. In the third round, this score was weighed by usability (30%), content quality (40%), and promotion of behavior change (30%). Discussions were held to resolve scoring discrepancies and to identify the top-quality apps. We also assessed correlations among QUEST, Google Play Store, and certification body scores.

Results: Of the 41 apps identified by five certification bodies, 19 (46.3%) met the inclusion criteria and were examined. Only 16 (84.2%) of these remained accessible for the second round. Eight of these surpassed 20 points (out of a maximum of 28) on the QUEST scale and were evaluated by all six experts in the third round, and the top 5 (62.5%) apps were selected. No correlations were found among QUEST, Google Play Store, and certification body scores.

Conclusions: Despite numerous evaluations by various certification bodies, only 5 (12.2%) of the 41 apps met the quality standards set by our experts. Our results mark the importance of rigorous, transparent, and standardized app evaluation processes to guide users toward making informed decisions about health apps. Guidelines for developers for the design of evidence-based, unbiased, high-quality apps, as well as technological solutions for real-time monitoring of the health apps, would address these challenges and improve reliability.

apps; applications; mobile health; mHealth; nutrition; healthy eating; eHealth; digital health

Introduction

As our world becomes increasingly digital, the use of mobile apps for health-related purposes (health apps) is on the rise [1,2]. The World Health Organization's (WHO) Global Observatory of eHealth describes health apps as key components of the broader domain of mobile health (mHealth). The use of mobile devices (eg, smartphones, patient-monitoring tools, personal digital assistants, and other wireless devices) is instrumental to support medical and public health practices. eHealth encompasses the cost-effective and secure use of information and communication technologies for health care and related fields [3]. Since WHO's acknowledgment in 2016 [4], the market has expanded rapidly. There has been an exponential increase in health app availability from 325,000 in 2017 [5] to an estimated 255 billion app downloads in 2022 [1,2].

Despite this growth, health care professionals lack unified standards for evaluating health app quality, safety, and effectiveness [6]. Recent European Union regulations on medical devices, such as Regulation (EU) 2017/745 enacted in May 2021, represent significant development. These regulations classify certain health apps as medical devices, necessitating adherence to specific criteria for approval. Supplementary documents from the European Commission [7,8] complement these regulations. The regulations also establish a medical device database to enhance transparency for both patients and health care providers. However, despite mHealth apps being within the medical device framework and subject to all corresponding laws at the European level, there are pending challenges related to user data management. Commercial platforms typically do not provide reliable information regarding the efficacy or safety of the apps they offer. Health apps should be substantiated by scientific evidence, facilitating their endorsement by health care professionals and enabling end users to benefit from a validated certification system [9,10], which should include the assessment of not only the quality of the information provided but also other relevant factors associated with app quality, such as usability and behavior change promotion [11].

This case study proposed a robust process for the evaluation of health apps, using dietary intervention apps promoting healthy eating as an example, to illustrate both the evaluation method and the challenges faced by end users and health care prescribers. A particular focus was placed on the quality of the health information provided by the apps.

Methods

Study Design

Our approach was structured in two stages: first, the systematic identification of relevant apps and, second, their assessment based on predefined quality, usability, and evidence-based criteria. This sequence aims to be a realistic, reproducible way to support both health care professionals and end users in the navigation and evaluation of the growing mHealth landscape.

App Identification

An initial exploratory analysis was conducted to identify projects, initiatives, and organizations involved in the evaluation of health apps. Most of these resources have been catalogued in two documents by the Spanish Ministry of Health [12] and the European project mHealth-Hub [13,14]. Both include governmental and nongovernmental efforts. Each initiative was then individually reviewed to examine its content and structure. Notable heterogeneity among the initiatives was observed, allowing them to be classified into two main groups: (1) platforms offering pre-evaluated apps, used as databases for the search, and (2) those focused on normative aspects, standardization, and quality assessment. Given the diversity in the approaches and structures of these platforms, the search began with general terms related to the study's focus, such as healthy eating, staying healthy, diet, lifestyle, preventive medicine, weight or healthy habits, which were later adapted to the navigation logic, taxonomy, or filtering system of each initiative (for more details, see Multimedia Appendix 1).

From August to December 2021, we searched for health apps that met the following inclusion criteria: aimed at adults (over 18 years old), available in English or Spanish, and offering nutritional guidance (eg, recommendations for dietary changes or meal planning). Apps that solely functioned as food diaries, calorie counters, or barcode readers but did not include any specific recommendations were excluded. We examined app descriptions and features to confirm eligibility.

In the absence of established guidelines for health app evaluation, we followed the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) checklist (Multimedia Appendix 2) [15,16] adapted to our research objectives. We reviewed 28 certification bodies (see Table S1 in Multimedia Appendix 1), of which only 5 (17.9%) contained apps meeting our inclusion criteria (see Table 1 for additional details):

Table 1. Summary of certification/assessment bodies that included apps promoting healthy eating.

Name	Year it started	Country	Reviewers	Evaluation criteria	Public or private
MyHealthApps[a]	2013	United Kingdom	End users, associations, or caretakers	Scoring system	Private
Healthy Living Apps Guide	2018	Australia	Expert reviewers (at least two on behavior change/public health)	MARS[b] (functionality) and ABACUS[c] (behavior change)	Public (Government of Victoria)
ORCHA[d]	2018	United Kingdom	Experts and reviewers (end users considered)	A 7-step system	Private (cooperation with the NHS[e])
GGD[f] AppStore	2016	Netherlands	Experts and end users	A 4-step assessment based on questionnaires, including a final evaluation of behavior change techniques used	Public (GGD GHOR[g])
Health Navigator	2017	New Zealand	Experts, clinical reviewers, and end users	Internal revision by experts, clinical revision, and end-user revision.	Public Ministry of Health

[a]Closed on May 17, 2022.

[b]MARS: Mobile App Rating Scale.

[c]ABACUS: App Behavior Change Scale.

[d]ORCHA: Organization for the Review of Care and Health Applications.

[e]NHS: National Health Service.

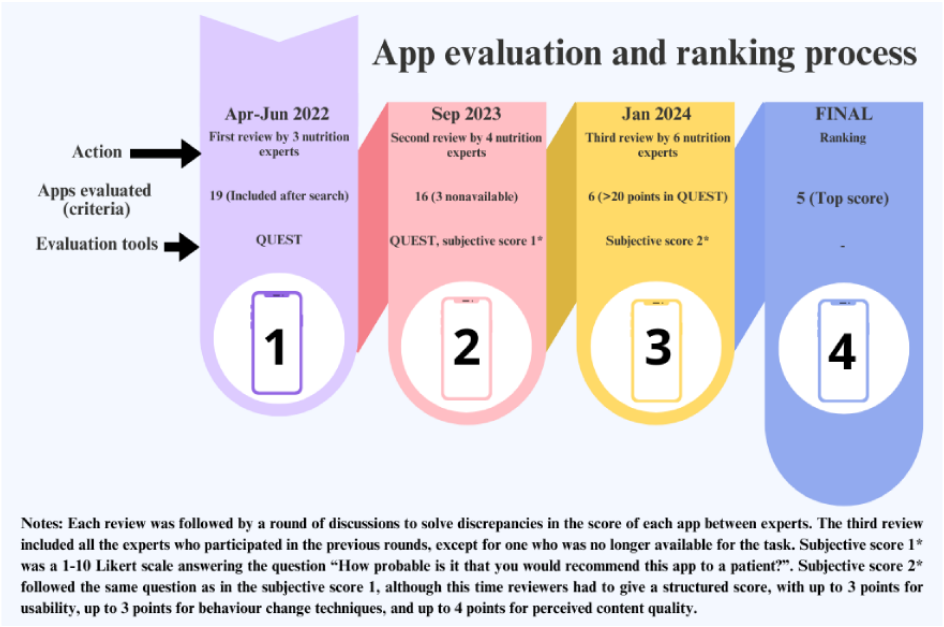
[f]GGD: *Gemeentelijke Gezondheidsdienst* (Municipal Health Service).

[g]GHOR: Geneeskundige Hulpverleningsorganisatie in de Regio (Regional Medical Emergency Preparedness and Planning).

Healthy Living AppsGuide [17] assesses app functionality using the Mobile App Rating Scale (MARS) [18] and behavior change using the App Behavior Change Scale (ABACUS) [19]. Each criterion is rated on a scale of 0-5 stars, with additional considerations, such as app cost and data export capabilities.

MyHealthApps [20] focused on user preferences and developer-related data. This resource operated as a catalog, rather than assigning individual scores to apps. It assessed transparency regarding pricing, contact details, geographical location, and security measures. Unfortunately, it closed in May 2022.

ORCHA (Organization for the Review of Care and Health Applications) [21] uses a seven-step evaluation system comprising three main domains: data, professional guarantee, and usability and accessibility. App functionalities and features are also considered. A maximum score of 100 points is attainable for each domain, with ratings above 65 considered good quality. Scores between 45 and 65 suggest areas for further investigation, and scores below 45 deem the app (or domain) potentially unsafe or ineffective.



Gemeentelijke Gezondheidsdienst (*GGD*) *AppStore* [22] follows an evaluation method considering app availability, pricing, compatibility with different operating systems, provider contact details, promotion of healthy behavior, data management, and goal setting. To enter evaluation, apps must focus on self-care and include at least two methods for behavior change. The apps are also assessed for usability, reliability, privacy, safety, and relevance, with each characteristic rated as good, sufficient, or inadequate. Apps are scored up to a maximum of 5 stars.

Health Navigator [23] is supported by the New Zealand Ministry of Health and provides a library of reliable apps. The evaluation process encompasses app features, functionalities, quality of information, and relevance to users. Apps must fulfil specific criteria, including evidence-based content and an evaluation of effectiveness, acceptability, and usability, and include a privacy statement. Clinicians with diverse expertise rate the apps from 1 (very poor, not recommended) to a maximum of 5 stars (excellent). End users also provide feedback. Finally, apps deemed clinically unsafe or potentially harmful are excluded.

As health apps are frequently updated, a follow-up search was performed in May 2022. By that time, *MyHealthApps* was no longer active. From this point on, three rounds of app evaluations followed (see Figure 1).

XSL•FO
RenderX

Figure 1. Diagram depicting the evaluation process of the apps.

App Assessment

The apps underwent three rounds of evaluation involving a total of seven reviewers who downloaded and assessed them on the devices described later. An endocrinologist (specialized in endocrinology and nutrition), one dietician, two psychologists, and three epidemiology and public health professionals participated. A second endocrinologist led the evaluation process and coordinated and summarized meetings.

Evaluation Round 1 (April-July 2022)

The content of each of the selected apps was evaluated by pairs from a panel of three nutrition experts (author AD-G, specialized in endocrinology and nutrition; author GZZ, a registered dietician; and Cristina Ruano Rodríguez, a lecturer in nutrition and public health). To facilitate comparison across the apps, we used the Quality Evaluation Scoring Tool (QUEST) [24], not used by any of the evaluating bodies that included the selected apps. QUEST was originally designed to assess the quality of health information in digital media and has been tested for reliability and validity. It offers a total score ranging from 0 to 28 points based on the following criteria: Authorship (0, 1, or 2 points) evaluates the ease of identifying the authors of the content; attribution (0, 3, 6, or 9 points) assesses whether health information is backed by scientific studies; type of study (0, 1, or 2 points, if at least 6 points have been given to *attribution*) evaluates the studies' quality; conflict of interest (0, 3, or 6 points) evaluates whether the information promotes purchase of products or services; complementarity (0 or 1 point) evaluates whether the information supports the health provider-patient relationship; and tone (0, 3, or 6 points) assesses language used as biased, neutral, or acknowledging the limits of knowledge.

The apps were downloaded by the reviewers to Android devices (two Galaxy Tab A7 Lite SM-T220 running on One UI Core 3.1 and Android 11 and a Redmi 9A M2006C3LG MIUI Global 12.0.20 mobile phone running on MIUI Global 12.0.20 Estable [QCDEUXM] and Android 10QP1A.190711.020). Whenever a premium version was available, it also was tested. A data extraction template was developed, including reviewer ID, date of the evaluation, name of the app, developer, version, device where it was downloaded, score for each item in QUEST, and comments. The mean total score was calculated to rank the apps, and inter-reviewer agreement for each QUEST item was measured using weighted κ coefficients. Concordance for the total score was evaluated using the intraclass correlation coefficient. We also explored potential correlations between the QUEST scores, Google Play Store ratings, and the scores from each assessment body (all three, nonnormally distributed quantitative continuous variables) using Spearman's coefficients. For these procedures, we used the *vcd* library in R software (RStudio version 1.3.1056, R Foundation for Statistical Computing). Following the analysis, discrepancies in the evaluation of QUEST items were discussed to identify their underlying causes.

Evaluation Round 2 (September 2023)

An expanded panel of four additional reviewers (authors AT-C and MLA-M, psychologists, experts in behavior change; author ITG, professor in epidemiology, expert in health promotion; and author GS, public health nutritionist, expert in prevention through diet) re-evaluated the apps (4-5 each) using the same methodology but limiting the time spent in the evaluation to a maximum of 45 minutes per app. Apps with a score average over 20 points (out of a maximum of 28) either in the initial evaluation or in the update were selected for further analysis. Although no given cutoff is recommended for the tool, this threshold was chosen to ensure the inclusion of apps that meet a fair-to-high standard. All evaluators were asked to subjectively score (0-10 points) their assigned apps by answering the question "How probable is it that you would recommend this app?" One of the reviewers (AD-G) scored all of them. Apps with a difference of 3 or more points in the initial and updated QUEST scores were discussed within the same reviewer pair (one of the reviewers involved in the first round and the new expert involved in the second round) to solve or explain this discrepancy. This process was documented, summarized, and

XSL•FO
RenderX

then discussed during a meeting involving all the authors, including author AMW (specialist in endocrinology, nutrition, and diabetes). The meeting was recorded, transcribed, and summarized in a document, which was shared with the participants for feedback.

Evaluation Round 3 (January 2024)

The last version of the selected apps was downloaded and assessed by six experts (GZZ, AD-G, AT-C, MLA-M, ITG, and GS), who had participated in the previous rounds. A subjective score was given again, this time assigning up to 4 points for content quality (this aspect being the most relevant for our research), 3 for usability, and 3 for promoting behavior change. The specific question to answer in this round was "How probable is it that you would recommend this app for someone to improve their healthy diet, based on the quality of the content (40%), usability (30%), and promotion of behavior change (30%)?"

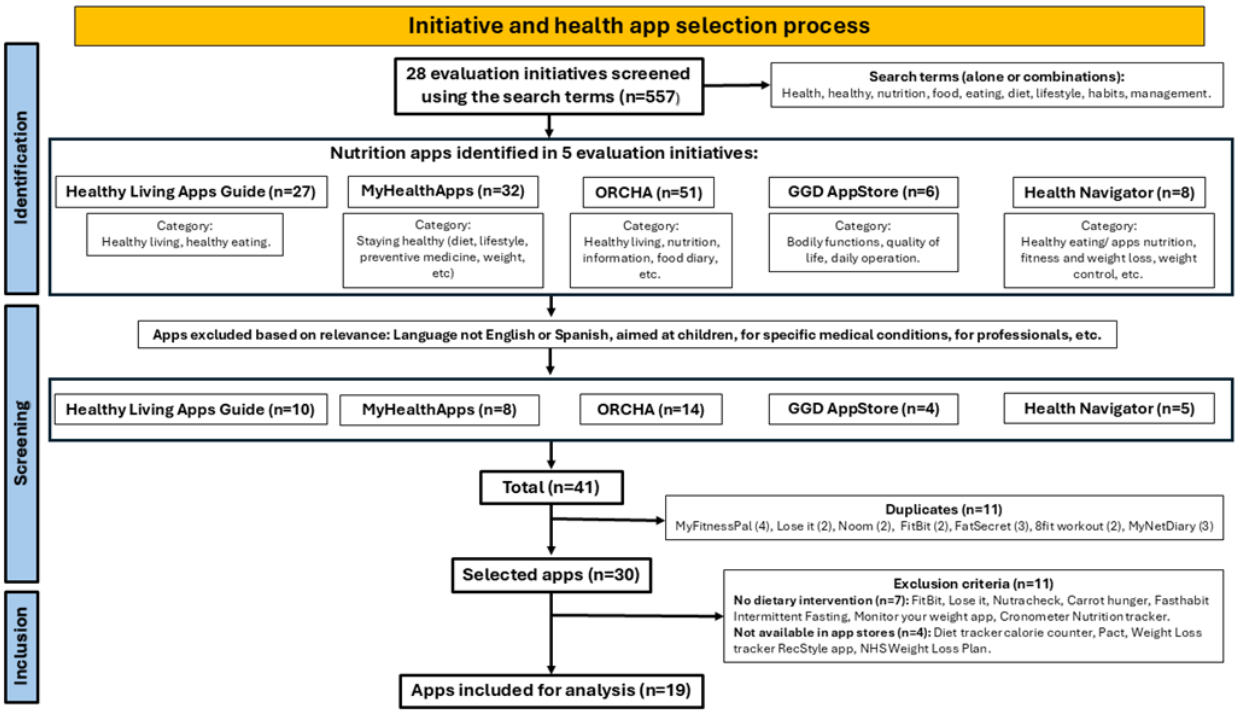
Further discussion among all the authors led to the final ranking and the selection of the top 5 apps.

Ethical Considerations

Given the nature of this study, no ethics committee approval or informed consent to participate was needed. All authors declared their consent for publication.

Results

App Details



Of the 28 certification bodies identified (see Table S1 in Multimedia Appendix 1), 14 (50%) catalogued a total of 557 apps across various categories, encompassing terms such as "healthy eating," "nutrition," "diet", "healthy practices," and "lifestyle". Only 5 (17.9%) included apps that fulfilled our inclusion criteria (see Table 1). These certification bodies used a variety of criteria in their evaluation processes, in terms of both the elements assessed and the tools used. Nevertheless, there was a significant overlap in the factors considered key for determining app quality, including functionality, usability, engagement, aesthetics, privacy, data protection, and effectiveness in promoting behavior change.

A total of 41 (7.4%) apps met the inclusion criteria. After eliminating duplicates, 30 (73.2%) apps remained, of which 11 (36.7%) met the exclusion criteria (see Figure 2).

The characteristics of the selected 19 (63.3%) apps are summarized in Table 2. Of these 19 apps, 5 (26.3%) were included in two or more of the certification bodies: *MyFitnessPal*, *FatSecret*, *MyNetDiary*, *Noom*, and *8fit Workout & Meal Planner*. Only the apps included in ORCHA had undergone formal evaluation of their content.

As per the definition, all apps included nutritional interventions, but most also combined different strategies or features, making their categorization challenging. Overall, 14 (73.7%) apps included weight control or tracking (numbered 1-6, 8, 11, 12, 14, 16-19 in Table 2), 12 (63.2%) allowed for calorie counting (numbered 1-4, 6-8, 11-13, 17, 19 in Table 2), and 13 (68.4%) facilitated the recording of physical activity (numbered 1-4, 6-9, 14-17, 19 in Table 2). Furthermore, 12 (63.2%) apps (numbered 1-8, 10, 11, 16, 18 in Table 2) incorporated behavior change techniques, such as motivational feedback, health education promotion, and goal setting.

Table 2. Main features of the 19 selected and evaluated health apps.

App number	App name; developer	Description
1	Noom; Noom Inc	It uses behavior change psychology to promote healthier habits, weight loss, and health goals. It can track meals and link to a pedometer.
2	YAZIO; YAZIO	It is a food diary and calorie counter that also offers diets and recipes, including vegan, vegetarian, and intermittent fasting options.
3	FatSecret; FatSecret	It is a food diary and calorie counter. It allows the user to scan products barcodes, tracking weight and keeping a record of meals and consumed food photos.
4	MyNetDiary; MyNetDiary Inc	It is a food log and calorie counter that also provides diets and recipes. It has a food database and a barcode scanner. It also provides motivational messages to achieve nutritional goals.
5	DietBet; WayBetter Inc	It aims to help the user achieve healthy weight loss and maintain motivation. It offers a support community, customer service, and expert-led games (coaches, nutritionists, etc).
6	MyFitnessPal; MyFitnessPal Inc	It offers recipes, a meal planner, a calorie counter, and workout plans. It also allows tracking progress and setting macronutrient goals.
7	MyPlate[a]; LIVESTRONG	It allows tracking calories and exercises. It also tracks the user's progress based on calorie and nutrient goals and provides motivation through support groups.
8	LIFESUM; Lifesum	It functions as a food diary and offers various types of diets and recipes. It also allows tracking exercise and water intake and setting weight goals and health data.
9	8fit Workout & Meal Planner; Urbanite Inc	It offers workout routines in different categories (boxing, yoga, high-intensity interval training, etc), along with meal plans.
10	Freeletics Nutrition; Freeletics GmbH	It acts as a nutrition coach to help the user achieve dietary goals. It guides the user toward healthy eating, recipes, etc, and helps them adapt nutrition to personal goals.
11	GetFit-Daily Meal Planner[a] App Prodakshn;OOO	It provides daily and weekly meal plans to lose, maintain, or gain weight based on the user's goals. It also calculates nutrients, calories, water intake, BMI, etc, and includes reminders.
12	HealthifyMe; HealthifyMe	It can act as a calorie counter, provides weight loss and exercise plans, guides sleep hygiene, etc.
13	Eat This Much-Meal Planner; Eat This Much Inc	It is a meal planner based on dietary preferences, budget, etc, and can be configured for different types of diets.
14	LIFE Extend[a]; LifeOmic	It is marketed as a precision health mobile app to help improve users' health using five pillars of health.
15	Fastic Fasting Ap; Fastic GmbH	It promotes intermittent fasting with different levels of intensity (gentle, moderate, intense).
16	Second Nature; Second Nature	It provides a lifestyle change program that helps lose weight and develop healthy habits. Nutritionists guide the user throughout the program. The app also includes a support group.
17	Uplyfe-Precision Nutrition[a]; Uplyfe AG	It is marketed as a customized nutrition and lifestyle change app-guided program based on scientific findings. It also provides personalized nutrition plans, activities, and symptom tracking.
18	Freshwell; Freshwell	Health care personnel promote a low-carb diet. The app provides informative weekly modules, a meal planner, etc.
19	Contador de calorías; Virtuagym	It provides a personalized nutrition plan according to the user's lifestyle and goals.

Evaluation Round 1

Table S2 in Multimedia Appendix 1 displays the score of each QUEST item in the first round of evaluations, categorized by reviewer, with apps ranked according to their mean total score. We explored potential correlations between the QUEST scores, Play Store ratings, and the scores of each certification body and found no significant correlations among any combination (data not shown). Agreement reached between reviewers was rather low, with most κ coefficient values below 0.6 and the intercorrelation coefficient between 0.50 and 0.67 (see Table S3 in Multimedia Appendix 1). The main reasons for discrepancy were attributed to the difficulty in finding the information needed to complete the QUEST scale.

Evaluation Round 2

Four additional experts were asked to update the app review on an Android device and were given a maximum of 45 minutes per app to find the information. At the time of this evaluation, 3 (15.8%) apps (*MyPlate*, *GetFit-Daily Meal Planner*, and *Uplyfe-Precision Nutrition*) were no longer available, and the remaining 16 (84.2%) apps were scored (see Table 3). One of the reviewers used an iOS device (Apple iPhone) due to unavailable Android devices. The 7 (43.8%) apps that received a score above 20 (out of a maximum of 28) either in the first evaluation or in the update were selected for further assessment.

Challenges were encountered assessing the items "authorship," "attribution," and "tone." Some apps (particularly *LIFESUM*, *Freeletics Nutrition*, *Eat This Much-Meal Planner*, *LIFE Extend*, and *Second Nature*) lacked clear indications regarding authors and sources, necessitating external web searches to retrieve these data, and even then, this took considerable time. Additionally, reviewers noted that the "attribution" item could be easily altered to achieve higher scores; for example, referencing a source, even if it was a low-quality source or irrelevant to the app's health information, could lead to a high rating, as long as it was a highly scored type of study. Subjectivity was also a significant factor in evaluating the "tone" item, leading to disparities in scores. Finally, some of the discrepancies were explained by the differences in app versions (eg, *Freeletics Nutrition*, *Fresh Well*, and *Second Nature* improved considerably between review rounds, coinciding with version changes, whereas the opposite was true for *HealthifyMe*). In the case of *HealthifyMe*, this (and the low subjective score) led to its exclusion from the third round, despite scoring above 20 points in the first round. Discussion about the subjective scores and the contribution by the reviewer scoring all the selected apps in this round led to a more structured scoring procedure in the third round.

Evaluation Round 3

All experts participating in the previous rounds of evaluation, except one who was no longer available for the task, took part in this round. At the time of this evaluation (early 2024), LIFE Extend was not available, so only 6 (31.6%) apps were included in the third round. Discrepancies in the scores were discussed among researchers.

Subjective scores were also given to the selected apps by all six reviewers (see Table S4 in Multimedia Appendix 1 and Table 3). The scores were discussed in a joint meeting, which led to the selection of the top 5 (8.3%) apps: *Second Nature*, *Freshwell*, *Yazio*,*LIFESUM*, and *MyNetDiary*. The scores given by each evaluator are included in Multimedia Appendix 1.

Second Nature was consistently the most highly scored app and is also endorsed by the National Health Service (NHS) of the United Kingdom. Its present version includes clear references to the evidence supporting its contents. Usability is good and improved by the inclusion in the update of interactive content, such as videos with advice and encouragement. There is a wide variety of dietary patterns to choose from, and recipes with visual backup are provided. Furthermore, most of the features are free to use. However, food registering is rather cumbersome, and the tone of the recommendations could be more cautious.

Freshwell was developed by two British general practitioners and is used by the NHS in the United Kingdom. Usability is good, with pictures, recipes, and explanations. Long-term goals are included, promoting behavior change. A classification of foods is included based on the type of dietary pattern that is promoted (low carb). Study references are provided to support this recommendation, and a disclaimer is provided stating that the app provides educational content and is not to be considered medical advice. People with chronic conditions are advised to ask their health care provider. Other health-promoting pieces of advice include reducing sugar intake, snacks, and alcohol. The subjective score penalized the low-carb type of dietary pattern on which the app is based, since reviewers considered that there is not sufficient evidence to promote it to the general public as the "default" dietary pattern [25].

Yazio has high usability due to likable aesthetics, ease of use, accessibility, and the challenges included in the app. The challenges, which promote behavior change, can be chosen by the user from a list, including quitting chocolate, sugar, sweets, fast food, etc. The app includes information about healthy eating, which is supported by scientific evidence, and the standard recommended diet is Mediterranean style. However, it also includes dietary patterns with less scientific evidence of benefit, such as intermittent fasting or the keto diet. In fact, intermittent fasting is a prominent feature of this app, including challenges on how long you can fast for. A disclaimer recommends not using this pattern in the long term and seeing a physician if that is the intention of the user.

LIFESUM has a visually pleasant interface and agile and intuitive navigation, both of which lead to good user experience. Different objectives can be set, and the app includes easy and

XSL•FO
RenderX

advanced recipes, which help with organization and motivation for healthier eating, although all this is only available in the premium version. The app includes a score for easy comparison and progress tracking, but the criteria for the score are not transparent. Studies supporting the contents were not easily found and were not there for all the recommendations. Once again, the latter included intermittent fasting and keto diets. Minor bugs were identified in the form of nonfunctioning links.

MyNetDiary offers an attractive design, easy navigation, and a variety of resources to engage users. It provides information about different types of diets and highlights their key aspects. Examples of recipes for each type of diet are included with detailed descriptions. The content is supported by a trained specialist in the nutritional management of diabetes and other health problems. A diary function to track daily food intake is included, and data can be entered via text, audio, or barcode scanning. The premium version offers daily advice and feedback. Users can also access a nutrition blog written by the same specialist behind the app. Professionals can subscribe to connect with users interested in weight loss.

Discussion

Principal Findings

In this paper, we highlighted the need for a common evaluation framework to assess the quality of health apps and proposed a robust approach to this end. Our use case focused on apps promoting healthy eating. A total of 19 apps were included, which had already been positively assessed by dedicated certification bodies. The latter used a variety of evaluation criteria, and most did not include content quality among them. Following a rigorous, three-step evaluation process by seven experts, only 5 apps were recommended. The selection was based on a comprehensive assessment of the quality of their contents (using QUEST), as well as their usability and the use of behavior change techniques.

Health apps have emerged as promising tools to promote healthier lifestyles, due to their widespread accessibility, user friendliness, and cost-effectiveness [26-28]. However, the app market's diversity and the lack of systematic evaluation processes leave consumers with limited tools to judge which apps are effective, safe, and suited to their needs.

To address this issue, several national and international actions have attempted to assess health app quality and safety [17,20-23]. Our investigation identified 28 initiatives dedicated to the evaluation of health apps, 5 including apps fulfilling our inclusion criteria. Although each of these initiatives uses distinct criteria for app evaluation, they all generally emphasize similar key factors, such as data security, privacy, ease of use, accessibility, usability, support for user-health care professional communication, personalization options, and capacity to induce behavior change. In a recent review, the importance of adherence to scientific evidence, as well as additional features (eg, gamification and cocreation of the app with health professionals and users), were supported [29]. Although a multitude of tools and scores have been proposed to evaluate different aspects of app quality, as of today, one single robust procedure or set of criteria does not exist [30-32], although some national and international evaluation efforts have been developed [33-35]. Additionally, all the certification bodies reviewed in this study have cautioned that they cannot guarantee the precision, quality, trustworthiness, and effectiveness of the health apps they assess, increasing uncertainty for the users.

Acknowledging these challenges, our study sought to evaluate nutrition-focused health apps using a tool aimed at the health information within the apps, assuming that health information based on evidence would support safety and effectiveness. We selected QUEST to assess the apps, since it has been specifically designed to evaluate health information and incorporates items such as attribution or study type to evaluate the quality of information sources. Additionally, it assesses items such as conflict of interest and tone to evaluate how information is presented to the user, where any sort of advertising is penalized. We found no significant correlations among the Play Store scores for the apps, the QUEST total mean score, or any of the certifier scores, probably because they assess different dimensions. QUEST is a robust tool for the assessment of content quality but does not address usability, engagement, or behavior change techniques, all factors known to influence the perceived quality of an app [11]. Therefore, the research team decided to complement this assessment with a subjective score, which also included these aspects. Such factors may influence the app store ratings, and many are directly evaluated by the certification bodies but are overlooked by QUEST. In contrast, Play Store scores are based on user opinions, which can be influenced not only by all these factors but also by popularity, endorsement by influencers, aesthetics, or alignment with their own nutritional preconceptions, which might not be backed by scientific evidence.

Furthermore, it is important to acknowledge that apps are dynamic and subject to constant updates. Although the latter can be beneficial if they enhance the quality of app contents, they also pose a challenge for app evaluation, as acknowledged by a recent consensus [36]. Thus, continuous reassessment would be necessary to account for the changes. Access to older app versions may not always be possible, and certain apps may become completely unavailable over time. Any app marketed as a health app should be subject to special scrutiny, particularly regarding collection of sensitive data and potential for harmful effects on users. Previously proposed improvements include establishing national lists of tested and trusted health apps, creating a catalog of health apps accessible to patients only if prescribed by professionals and guidelines for app developers toward evidence-based, unbiased, high-quality apps, with wider assessment requirements for higher-risk tools [14,33,36-39].

Strengths and Limitations

Our work has several strengths that contribute to the field of health app evaluation. First, the adoption of QUEST to assess all the apps constitutes a rigorous approach for the evaluation of content quality. This systematic assessment of the content was complemented by a subjective evaluation by the panel of usability and behavior change techniques. Additionally, the study's methodological approach, involving multiple, independent reviewers and the evaluation of a diverse range of

XSL•FO
RenderX

apps, strengthens the validity and comprehensiveness of the results. Finally, the study's alignment with the existing literature and national and international certification/assessment bodies highlights its relevance and potential impact on improving health app quality and user safety.

We acknowledge that the study also has some limitations. The small sample size of apps reviewed and their focus on nutrition-related interventions may limit the generalizability of our results, since they represent an incomplete picture of the overall quality and safety of available health apps. The decision to exclude apps that solely function as food diaries and calorie counters may be controversial. We chose apps offering recommendations, meal plans, and recipes, because we focused on the quality of the information provided. Nevertheless, we acknowledge that food diaries and calorie counting could also help the users become more aware of their eating habits and induce a change in behavior despite the lack of any other specific nutritional advice and therefore be considered a type of intervention. Another limitation is the subjective nature (eg, tone) or the scoring difficulty (eg, attribution) of some of the items in QUEST. Discrepancies in the first round of evaluations, reflected by rather low κ coefficient values, were mainly attributed to the fact that the information to score some items might be difficult to find in the app or might even be found behind a link and thus not be obvious. Hence, in the second round of evaluations using QUEST, we standardized the time spent on the assessment of each app. In addition, some aspects of app quality are overlooked by QUEST (eg, usability, engagement, and capacity to induce positive behavior changes). Thus, QUEST is not a comprehensive enough tool to judge app quality on its own, but it is complementary to other measures. Finally, to overcome these difficulties, several rounds of revision were made, which made the evaluation process longer than initially planned.

To summarize, during this review, we encountered several challenges. In the first place, numerous certification bodies were scanned for evaluated apps. Creating a common repository collecting their criteria and decisions would facilitate this task [40]. In addition, the rapid change in mHealth apps poses a challenge to the timeliness of evaluation. This might be mitigated by the development of living systematic reviews, which are continuously updated [39] or the use of rapid reviews [41] and evidence maps [42]. Lastly, there is currently no standardized procedure to evaluate app quality. To address this, we included what we considered a critical and often overlooked dimension in previous evaluation efforts: a thorough assessment of the quality of the health information provided by the apps using QUEST scoring.

Conclusion

In conclusion, despite their previous evaluations by various certification bodies, only 5 of 19 apps promoting healthy eating met the quality standards set by our experts. Our study calls for enhanced scrutiny and regulatory measures to ensure that health apps meet rigorous standards of accuracy, reliability, and user safety. Guidelines for developers for the design of evidence-based, unbiased, high-quality health apps, as well as technological solutions for real-time monitoring of the apps, would address these challenges and improve reliability.

Acknowledgments

We thank Cristina Ruano Rodríguez (University of Las Palmas de Gran Canaria) for participating in the first round of evaluations. We would also like to thank Lilisbeth Perestelo (Servicio de Evaluación, Servicio Canario de la Salud) for fruitful methodological discussions. Data Availability

All relevant data are available for direct review within the paper.

Authors' Contributions

AD-G, GZZ, and AMW designed the study and summarized and analyzed the results. AD-G and GZZ performed the search and first round of assessments and drafted the manuscript. ITG, GS, AT-C, and MLA-M performed the second round of assessments. All authors participated in the discussions and final ratings of the apps, participated in the revision of the paper, and approved the final version. During the preparation of this work, the authors did not use any artificial intelligence tools/services at any time. The authors are responsible for the entire content of this publication.

Abstract

Background: Accurate assessment of physical behaviors (PBs) and activity intensity is essential for public health research and digital health monitoring. Wearable accelerometers combined with machine learning (ML) or deep learning (DL) enable objective behavior assessment, but most existing models are trained on laboratory data, limiting generalizability to free-living conditions.

Objective: This study aimed to develop and evaluate multitask ML and DL models for PB classification across 7 categories (sitting, standing, walking, running, sports, cycling, and lying) and activity intensity categories (AIC) across 3 levels (sedentary, light, and moderate-to-vigorous physical activity) using thigh-worn (activPAL) and waist-worn (ActiGraph) wearable accelerometers. A second objective was to compare model-derived estimates of daily time spent in PB and AIC across single- and dual-sensor (activPAL + ActiGraph) configurations, and to evaluate agreement between the best-performing model and corresponding estimates obtained from the proprietary activPAL classification of real-world everyday activities (CREA) algorithm using free-living data collected over a 9-day monitoring period.

Methods: Data were obtained from 590 adults in the multicenter WEALTH study (627 recruited) and included up to 9 days of concurrent activPAL and ActiGraph free-living recordings. Sparse accelerometer-labeled data were obtained using ecological momentary assessment and refined by retaining instances with ≥75% agreement with the CREA algorithm. Resulting labeled data of 583 participants were used to develop ML models for single-sensor (activPAL or ActiGraph) and combined (dual-sensor) configurations. A random forest (RF) model using engineered features and a multihead convolutional neural network (MH-CNN) were trained within a multitask learning framework to jointly predict PB (task 1) and AIC (task 2) using a subject-independent hold-out split. The test subset (n=87) was used to estimate daily time spent in PB and AIC over 9 days, which were compared with CREA-derived estimates using Pearson coefficients and intraclass correlation coefficients (ICCs).

XSL•FO
RenderX

Results: The dual-sensor configuration consistently outperformed single-sensor models. For PB classification, the MH-CNN achieved the highest performance (F_1-score=0.750). For AIC, the RF model performed best (F_1-score=0.741). Dual-sensor free-living estimates showed epidemiologically plausible distributions across the 24-hour period, including sitting 37% (538/1440 min), lying 34% (496/1440 min), walking 9% (131/1440 min), and moderate-to-vigorous physical activity (MVPA) 2% (31/1440 min). Agreement with CREA was strongest for standing, walking, and cycling (r≥0.86; ICC ≥0.72), while lying showed modest reliability (ICC=0.48). For AIC, agreement was highest for light physical activity (LPA) and MVPA (ICC 0.72 - 0.75).

Conclusions: Multitask models combining thigh- and waist-worn accelerometers provide consistent estimates of PB and AIC under free-living conditions. The dual-sensor approach yielded more stable and epidemiologically coherent estimates than single-sensor methods, supporting its potential for large-scale population monitoring and mobile health apps.

KEYWORDS

accelerometers; convolutional neural networks; deep learning; human activity recognition; physical activity; sedentary behavior

Introduction

Robust assessment of movement and posture in free-living conditions is fundamental to population surveillance, behavioral interventions, and remote health monitoring. Recent advances in mobile health (mHealth) apps and wearable technologies have enabled more objective and scalable measurement beyond laboratory or clinical environments. However, variability in measurement approaches continues to limit comparability across studies and applications [1-3]. Consequently, there is a clear need for reliable, standardized methods capable of capturing physical behavior (PB) and activity intensity in real-world settings.

In this context, PB refers to posture- and movement-based activity types that describe how time is accumulated across the day, including sedentary postures (eg, sitting or lying), upright postures (eg, standing), and movement behaviors (eg, walking, running, or cycling) [4]. Activity intensity complements PB by characterizing the intensity associated with these behaviors. In population-based research, activity intensity is commonly operationalized using metabolic equivalents of task (METs), which can be used to estimate energy expenditure [5,6]. More commonly, METs are categorized into activity intensity categories (AIC), including sedentary behavior, light physical activity (LPA), and moderate-to-vigorous physical activity (MVPA), using established cut-points from the Compendium of Physical Activities [7] (eg, sedentary behavior 1.0 - 1.5 METs; LPA 1.6 - 2.9 METs; MVPA ≥3.0 METs), supported by consensus definitions in the sedentary behavior literature [8].

Wearable accelerometers have become central to mHealth research because they enable continuous monitoring of physical activity (PA) and sedentary behavior under free-living conditions [9]. Thigh-worn devices such as the activPAL have demonstrated strong validity for posture classification, including sitting, standing, stepping, and cycling, owing to their anatomical placement and compatibility with 24-hour wear protocols [4,10]. In contrast, waist-worn accelerometers such as the ActiGraph monitor are widely used in population-based studies and provide reliable estimates of ambulatory activity and overall activity volume [11]. ActiGraph devices are among the most widely adopted wearable accelerometers for device-based assessment of PB in free-living settings. However, consistent with previous validation studies, their ability to distinguish postures, particularly standing from sitting, is more limited, reflecting the reduced sensitivity of waist-mounted accelerometers to subtle changes in trunk orientation [12-14]. These limitations can result in systematic discrepancies in daily PB and AIC estimates, thereby complicating interpretation and comparability in mHealth apps.

Recent advances in machine learning (ML) and deep learning (DL) methods have substantially improved the accuracy and scalability of human activity recognition using wearables. These methods excel at learning complex temporal and biomechanical patterns that are difficult to capture with traditional rule-based algorithms [15,16]. Among these advances, multitask learning has emerged as a particularly promising framework [17]. By allowing a single model to learn shared representations across related outcomes, such as PB and AIC classification, multitask learning leverages complementary information embedded in accelerometer signals. This joint learning strategy can improve model stability, reduce overfitting, and enhance robustness in free-living environments, where movement patterns are highly variable, context-dependent, and often noisy [18]. Additionally, multihead convolutional neural networks (MH-CNNs) are increasingly used for accelerometer-based movement analysis, extending standard architectures through parallel processing heads that learn complementary representations and support the simultaneous modeling of heterogeneous signal characteristics, such as different temporal scales and movement patterns [19,20].

The limited availability of reliable, ecologically valid, and accurately labeled datasets remains a critical barrier to the development of robust ML models for population-level studies. Many existing approaches rely on data collected using laboratory-based protocols or short-duration recordings, which fail to capture the diversity and complexity of real-world behavior [21,22]. In this context, ecological momentary assessment (EMA) offers a scalable alternative by collecting self-reported behavioral information in real time, reducing recall bias and improving temporal alignment with sensor data [23]. When combined with wearable sensing, EMA enables the generation of labeled free-living datasets that more accurately

XSL•FO
RenderX

reflect naturalistic behavior patterns, supporting the development of models with improved ecological validity [24].

Despite these advances, relatively few studies have combined long-term free-living monitoring, multimodal wearable sensing, and subject-independent validation at scale. Large, labeled datasets such as CAPTURE-24 provide high-quality annotations but are limited in duration [25], while other resources offer contextual information but provide limited temporal resolution or constrained sensor configurations [26]. Moreover, the added value of combining posture-sensitive and movement-sensitive sensors for improving the stability and interpretability of daily PB and AIC estimates remains insufficiently quantified [27].

To address this gap, the wearable sensor assessment of physical and eating behaviors (WEALTH) project integrated standardized laboratory protocols with a 9-day free-living monitoring period across European populations, complemented by event-based (sensor-triggered) EMA delivered via the HealthReact mobile app [28]. These data enabled the generation of sparse (EMA) labeled accelerometer data, further refined using agreement with activPAL's proprietary classification of real-world everyday activities (CREA) algorithm, resulting in a large free-living dataset with quality-controlled labels [23].

Against this background, the main objective of this study was therefore to develop and evaluate multitask ML and DL models for simultaneous PB classification (task 1) and AIC classification (task 2) using thigh- and waist-worn accelerometry, both individually and in a combined (dual-sensor) configuration, under free-living conditions. In support of this objective, multimodal sensing and EMA-informed labels were integrated to facilitate robust behavioral monitoring in ecologically diverse settings. Subsequently, the best-performing models were used to estimate continuous PB and AIC over 9 days. These outputs were aggregated to derive daily time spent in each activity and AIC, enabling the comparison of behavioral patterns across sensor configurations (activPAL, actiGraph, and dual-sensor) and against CREA-derived daily estimates to assess agreement, stability, and ecological coherence. By focusing on ecological validity, scalable data collection, subject-independent validation, and real-world deployment considerations, this work aims to advance methodological foundations for population monitoring in free-living settings, while providing detailed estimates of daily PB and AIC profiles.

Methods

Study Design

This study used data from the WEALTH project, a large, multicenter cohort conducted in Czechia, France, Germany, and Ireland. The study supported the development of standardized methods for assessing daily PA, sedentary behavior, and eating behaviors by integrating structured laboratory assessments with free-living monitoring to ensure ecological validity.

Participants first attended a laboratory session involving a 75-minute semistructured activity protocol, during which well-defined movement patterns were recorded under controlled conditions using 4 different sensors including activPAL 3 micro (PAL Technologies), ActiGraph GT3X (ActiGraph LLC), Skagen Falster Gen 5 smartwatch (Skagen, Fossil Group Inc), and a Fitbit Charge 5 (Fitbit Inc., Google LLC). This was followed by a 9-day free-living phase, during which the 4 different sensor devices collected accelerometer data in combination with event-based EMA to capture contextual information about participants' behaviors in real-world settings [29].

Participants

A cohort of 627 adults was recruited across 4 European study sites using a convenience sampling strategy through university, community, and institutional advertisement channels, resulting in a selective but demographically diverse sample. Sample size was determined according to the WEALTH study protocol [29]. The target sample was selected to support machine-learning model development and to accommodate expected data loss arising from device noncompliance and data quality exclusions. Participants were required to have no mobility impairments and to be able to complete both the laboratory and free-living protocols. From the initial cohort, 32 participants did not provide concurrent activPAL and ActiGraph recordings, and an additional 5 participants were excluded due to significant temporal drift that precluded reliable sensor synchronization. The final sample consisted of 590 participants with valid and concurrent activPAL and ActiGraph data. Participant characteristics are summarized in Table 1 and reflect variability in age, sex, country, and BMI, including representation of individuals classified as obese (BMI ≥30 kg/m²).

Table . Demographic information of the participants included in this study (N=590).

Characteristics	Values
Age (years), mean (SD)	38.1 (14.3)
Height (cm), mean (SD)	171.2 (9.9)
Weight (kg), mean (SD)	72.0 (14.3)
BMI (kg/m²), mean (SD)	24.5 (4)
Obesity (BMI ≥30 kg/m²), n (%)	54 (9.2)
Country, n (%)	
Czechia	138 (23)
France	139 (24)
Germany	157 (27)
Ireland	156 (26)
Sex, n (%)	
Male	258 (44)
Female	332 (56)

Wearable Sensor Configuration and Data Acquisition

A combination of research-grade and consumer-grade wearable devices was used to capture movement patterns, posture, and activity-related events throughout both the laboratory session and the 9-day free-living period. As part of this multimodal setup, an activPAL 3 micro was placed on the midline of the anterior aspect of the right thigh using a hypoallergenic adhesive tegaderm dressing. The device recorded continuous triaxial acceleration at 20 Hz, provided estimates of activity intensity expressed as METs, and behavioral outputs through its proprietary CREA algorithm, classifying sedentary, standing, stepping, cycling, and nonwear, which offered a reference for refining EMA-derived annotations.

To complement the thigh-worn sensor, participants also wore an ActiGraph affixed to the right waist. This device provided higher-frequency (100 Hz) movement data, which contributed to the development of dual-sensor models by enabling an additional perspective on upper-limb and whole-body movement patterns.

Finally, participants wore a Fitbit Charge 5 on the nondominant wrist to trigger event-based EMA surveys. Although Fitbit data were not used as model input, step count and heart rate data were used to detect predefined behavioral conditions and automatically initiate EMA prompts. An overview of the body-worn wearables, data sources, and processing workflow used in this study is provided in Multimedia Appendix 1.

EMA

EMA assessments were implemented using the HealthReact mobile app [28], which delivered three types of surveys throughout the 9-day free-living period: (1) event-based (sensor-triggered) surveys, (2) time-based surveys, and (3) participant-initiated surveys. Only data from event-based surveys were used, as they were automatically triggered in response to specific sensor-detected activities relevant to this study.

Event-based survey prompts were generated automatically based on Fitbit-recorded data, triggering an EMA survey after ≥20 minutes of zero steps for sedentary behavior, ≥5 minutes of walking at 60 - 139 steps/minute, or ≥5 minutes of running at ≥140 steps/minute. Participants reported the activity and posture being performed, while timestamps were automatically logged by the HealthReact app. Prompt allocation rules were pilot-tested following Janek et al [23], with up to 4 daily prompts for sedentary behavior and up to 3 each for walking and running.

Data Synchronization and Preprocessing

The raw accelerometer data were processed using ActiLife (v6.8) for the ActiGraph devices and PAL Analysis (v9.1) for the activPAL devices. For activPAL, the activity annotations and MET-based activity intensity estimates (expressed in MET-seconds) were extracted using PAL Analysis software and the proprietary CREA algorithm. An epoch length of 60 seconds was applied to ensure consistency with prior studies and established protocols for MET-based activity intensity assessment [30,31].

To harmonize the recordings across devices, all acceleration signals were expressed in gravitational units (g). ActiGraph data (100 Hz) were resampled to 20 Hz to match activPAL's native frequency. Initial synchronization was performed using device timestamps and the recorded start of the laboratory session. A fine-grained alignment was subsequently performed and verified by visual inspection using MATLAB (R2020a). Temporal offsets attributable to internal clock drifts were compensated by inserting a small, fixed number of samples (80 samples per day) into the ActiGraph data at a daily interval. This correction accounted for systematic clock drift between activPAL and ActiGraph devices during prolonged free-living recordings, which can produce cumulative timing misalignment between posture and activity signals despite simultaneous initialization [32].

Following device-level synchronization, the CREA-derived MET estimates were temporally aligned with accelerometer

XSL•FO
RenderX

time-series. Activity intensity estimates were converted from MET-seconds to MET values and subsequently mapped to categorical intensity. In this study, AIC were operationalized using MET-derived categories rather than direct kcal-based energy expenditure estimates to enable standardized intensity classification for population-level free-living analyses. This enabled classification into sedentary behavior (1.0 - 1.5 MET), LPA (1.6 - 2.9 MET), and MVPA (≥ 3 MET) categories using standard MET-based cut-points [7,8].

EMA-Based Sparse Labeling and Quality-Controlled Segment Selection

Sparse free-living labeled data were generated following the EMA-based labeling framework proposed in Sigcha et al [24]. During the 9-day data collection period, 26,166 EMA activity surveys were recorded. After removing duplicates and surveys lacking valid posture or activity information, 16,907 surveys were retained for wearable data annotation. EMA triggers were used to segment the continuous accelerometer data streams, and each resulting data segment was labeled using the participant's response to the associated EMA prompt.

The resulting segments were annotated according to predefined PB categories established within the WEALTH study: sitting, standing, walking, running, sports, cycling, and lying, resulting in temporally sparse but highly specific annotations. This EMA-based approach prioritizes ecological validity and label specificity over label density, thereby providing high-quality annotations under free-living conditions.

To strengthen label reliability, only segments showing at least 75% sample-wise agreement with CREA were retained for model training and evaluation. In line with the findings reported in [24], this threshold was selected as an appropriate trade-off between data quality and quantity, reducing less confident segments while preserving sufficient free-living coverage across activity types, ensuring that the final labeled dataset was both ecologically valid and of high quality.

Following EMA-based annotation and quality control using a ≥75% agreement threshold with the CREA algorithm, 2108 hours of labeled free-living data from 583 participants were retained for model development and validation. The reduction in the number of participants from 590 to 583 was primarily due to EMA surveys that could not be synchronized with the corresponding accelerometer recordings because of time-stamp mismatches, which placed the EMA entries outside the valid recording range and prevented reliable segment construction. Detailed distributions of the EMA-labeled data before and after quality control are provided in Multimedia Appendix 2.

Generation of Unlabeled Dual-Sensor Datasets for Model-Derived PB and AIC Estimates

In addition to EMA-labeled data, the 9-day free-living (unlabeled) recordings from activPAL and ActiGraph devices were synchronized to enable the implementation and evaluation of a dual-sensor approach for generating model-derived daily PB and AIC estimates, as well as their corresponding 9-day averages. To ensure strict temporal correspondence between the 2 devices, each pair of recordings was then trimmed to match the sensor file with the lowest sample count and visually inspected using MATLAB.

Following this synchronization procedure, complete unlabeled free-living data were obtained from 590 participants (Table 1), representing the full 9-day monitoring period and providing the basis for subsequent analyses of daily PB and AIC profiles.

Data Segmentation and Feature Extraction

To prepare the data for model development, raw time-series signals were segmented using nonoverlapping windows. Multiple window lengths (5, 10, and 15 s) were evaluated to determine their influence on classification performance, reflecting common practices in human activity recognition [24,25]. For each window, a PB label (task 1) and AIC label (task 2) were assigned using 2 different approaches. The PB label was directly taken from the EMA-reported activity for the corresponding prompt, reflecting the participant's self-reported behavior within that data segment. In contrast, because MET-based estimates were available at a 60-second epoch resolution, a majority voting technique [33] was applied to assign a single AIC label to each window. Specifically, each window was labeled as Sedentary, LPA, or MVPA based on the AIC most frequently observed in the specific window.

Three feature-extraction strategies were implemented to support classical ML pipelines. First, a set of 40 features was computed following the CAPTURE-24 specification [25], capturing statistical, spectral, and temporal characteristics. Second, an adapted version of the HARTH feature set [34] was generated for single-sensor use, extending its applicability beyond the original dual-sensor design. Third, the original HARTH feature set [34] was extracted for dual-sensor configurations to leverage complementary information from thigh- and wrist-based measurements. A detailed description of the set of features extracted in this study is provided in the Multimedia Appendix 3.

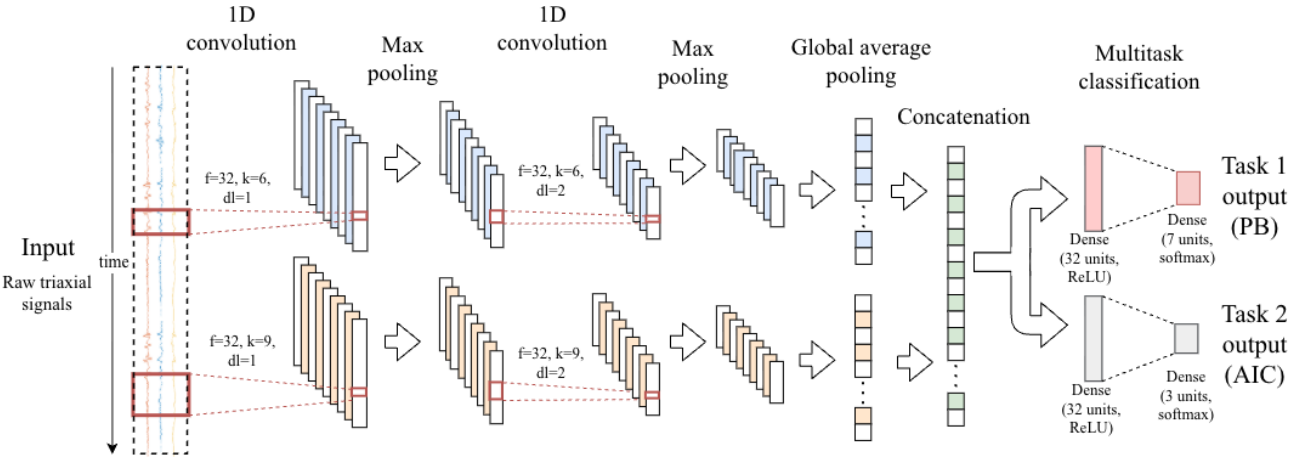
In parallel, raw accelerometer data were used to train a multihead convolutional neural network (MH-CNN), implemented in both single- and dual-sensor variants. This DL-based approach enabled the extraction of hierarchical temporal patterns directly from the raw signals, providing an alternative to feature-engineered models.

ML and DL Models

Overview

To evaluate both ML and DL methods, 2 multitask models were developed: a feature-based random forest (RF) model and the MH-CNN. These models were designed to jointly predict PB (task 1) and AIC (task 2) using triaxial accelerometer data.

RF



The RF model was selected for its robust performance in PA recognition tasks and its relatively small number of hyperparameters, which facilitates efficient optimization and reduces the risk of overfitting. Separate RF models were trained for each feature set described in the previous section, with each feature set providing a structured representation of the underlying accelerometer signals.

XSL•FO
RenderX

MH-CNN

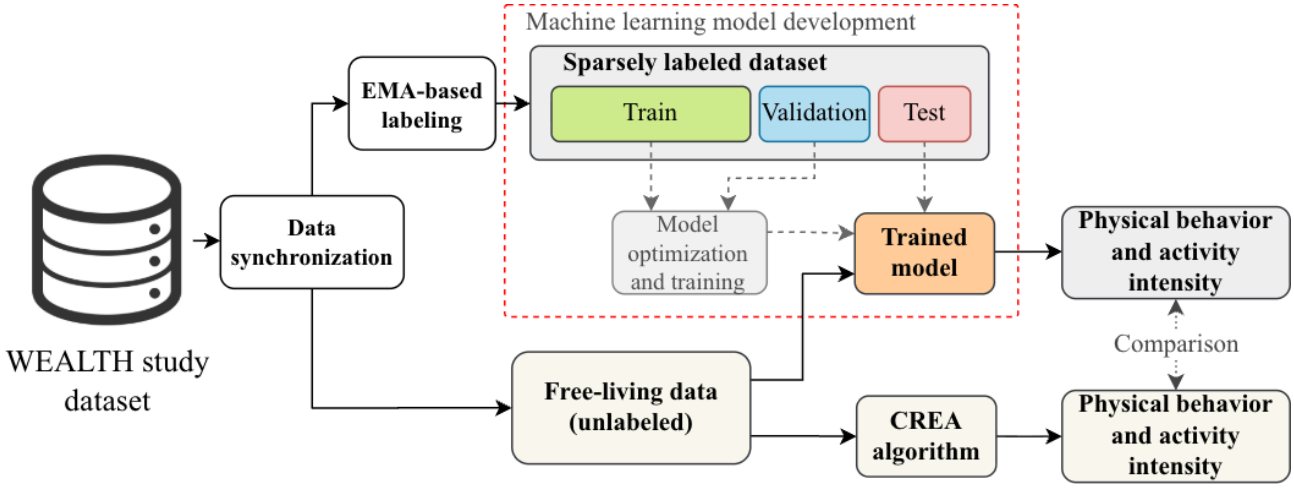
An adapted MH-CNN [19,20] was implemented to assess the performance of a DL-based approach trained directly on raw accelerometer data. The architecture was selected to balance classification performance, computational efficiency, and scalability for large-scale applications, while reducing the computational burden associated with more demanding sequential architectures. The network architecture comprised 2 parallel convolutional branches with distinct kernel sizes (eg, 9 for a large kernel and 6 for a medium-sized kernel), designed to capture both fine- and coarse-grained temporal dynamics. Each branch included 2 convolutional layers (32 filters each) with max pooling, followed by global average pooling. The extracted features were then passed to separate fully connected (dense) layer branches to support multitask classification. Figure 1 shows the architecture of the MH-CNN with 2 heads, with the output adapted for multitask learning.

Figure 1. Architecture of the multihead convolutional neural network adapted for multitask classification. AIC: activity intensity categories; dl: dilatation rate; f: number of filters; k: kernel size; PB: physical behavior; ReLU: rectified linear unit.

Hyperparameter optimization was performed for both models. For the RF classifier, optimization was carried out using grid search cross-validation, which enabled an exhaustive evaluation of key parameters while keeping computational demands manageable. For the MH-CNN, the Hyperband algorithm [35] was used to efficiently explore a broad space of architectural and training configurations. Details on the parameters and ranges used for the optimization of these models are included in the Multimedia Appendix 4.

To accelerate the optimization process, both procedures were conducted using laboratory data from a reduced subset of 100 participants, as prior work suggested limited performance gains beyond this sample size [25]. Laboratory data were used for model optimization, providing a controlled setting that allowed consistent tuning while avoiding the added variability inherent to free-living data during this stage of model development.

After the optimization, the RF model used for training had 150 decision trees, a maximum tree depth of 10, and a maximum of 16 features considered in each split. The resulting parameters for the MH-CNN are shown in Figure 1 and detailed in the Multimedia Appendix 5.



Model Training and Evaluation

To ensure a robust assessment of model performance, a subject-independent hold-out strategy was implemented using the EMA-labeled dataset. Of the original cohort (N=590) participants, data from 583 individuals were available for model training after excluding cases where EMA responses could not be synchronized with accelerometer data. The resulting participants were allocated to training (407/583, 70%), validation (87/583, 15%), and test (87/583, 15%) subsets, with each individual assigned to only 1 data subset to prevent information leakage across subsets. Stratification by age, gender, and country preserved demographic balance across subsets to support a reliable model evaluation. The number of participants and the characteristics of the data subsets used to train and evaluate the ML models are detailed in the Multimedia Appendix 6.

Model performance for both PB and AIC classification was quantified using classification metrics, including precision, recall, and F_1-score [36]. These complementary indicators allowed for a comprehensive evaluation across the imbalanced activity classes. Figure 2 presents the overall methodology for ML model development and agreement analysis.

XSL•FO
RenderX

Figure 2. Overall methodology for machine learning model development and agreement analysis. CREA: classification of real-world everyday activities; EMA: ecological momentary assessment.

ML and DL models were trained on a workstation equipped with an Intel Xeon 2.30 GHz processor, 25 GB RAM, and a 12 GB NVIDIA Tesla K80 GPU. ML models were implemented in Python (v3.12) using Pandas (v2.2), NumPy (2.0.2), and Scikit-learn (v1.6). To address class imbalance, the ML training subset was undersampled so that all activity classes matched the size of the smallest class. Undersampling was chosen because the dataset is highly skewed toward a single category; RF models can be biased by class imbalance; it also reduces training time, mitigates the risk of overfitting, and avoids potential artifacts introduced by synthetic data generation techniques such as the synthetic minority oversampling technique (SMOTE).

DL models were developed using Keras (3.10) and TensorFlow (2.19). Unlike the ML pipeline, undersampling for the DL model was applied selectively by reducing only the most frequent classes (sitting to 30,000 samples; lying to 25,000; walking to 20,000) to preserve the natural distribution of daily activities while controlling class dominance. As with ML, undersampling was performed exclusively on the training data subset.

The MH-CNN architecture was trained using a multitask learning framework with task-specific weighting prioritizing PB over AIC classification (ratio 10:1), together with class-weighted losses and early stopping to reduce overfitting. Optimization was performed using the adaptive moment estimation (ADAM) optimizer [37]. Additional details regarding training configuration and procedures are provided in Multimedia Appendix 5.

ML Experiments

Different experiments were conducted to evaluate the effects of window size, sensor type, and sensor configuration on PB and AIC classification.

The effect of window size was evaluated by segmenting synchronized accelerometer data into nonoverlapping windows of 5, 10, and 15 seconds. These analyses were performed using the dual-sensor configuration to identify an appropriate temporal resolution for subsequent experiments.

Single-sensor experiments were then carried out separately for activPAL and ActiGraph. For each device, RF models trained with hand-crafted features (CAPTURE-24 and an adapted single-sensor HARTH feature set) were compared with MH-CNN trained on raw accelerometer signals. This design allowed for a direct comparison between feature-engineered ML approaches and end-to-end DL models.

Finally, dual-sensor experiments were performed by combining activPAL and ActiGraph data. In this setting, RF models were trained using the original (dual-sensor) HARTH feature set and compared with the MH-CNN trained on synchronized raw data from both sensors.

In all experiments, PB and AIC classification were treated as separate outcomes but evaluated within the same experimental framework. Results of these experiments are reported as mean and SD across 5 repeated runs to identify the model stability during training. In addition, bootstrap resampling (n=100) was used to estimate 95% CIs for the F_1-scores across the evaluated window lengths following the methodology proposed by Efron [38].

Evaluation of Model-Derived Daily PB and AIC Profiles

Overview

Following ML development, the best-performing models were applied to unlabeled (free-living) data to estimate daily time spent in distinct PBs and AIC. The evaluation comprised two complementary analyses: (1) the derivation of model-based daily PB and AIC profiles across different sensor configurations, and (2) an agreement analysis between the best-performing model and the activPAL CREA algorithm. All analyses were conducted using free-living data from 87 participants not included in model training or optimization, ensuring an unbiased assessment of generalizability.

Model-Derived Daily PB and AIC Profiles Across Sensor Configurations

In the first analysis, model-derived daily PB and AIC profiles were generated separately for three sensor configurations: activPAL, ActiGraph, and the combined dual-sensor setup. Valid monitoring days were defined as those with ≥8 hours of wear time [39-41]. Participant-level summaries were calculated

XSL•FO
RenderX

using a weekday-weekend weighting scheme (5/7 weekdays, 2/7 weekend days) [42], and participants were included if they met the 3-day validity criterion (at least 2 valid weekdays and 1 valid weekend day).

For both PB and AIC, weighted participant-level estimates were subsequently summarized across participants to characterize population-level daily profiles. Variability in estimates across participants was quantified using 95% CIs, calculated via a normal approximation based on the sample mean, sample SD, and the number of participants contributing valid data to each estimate.

Comparison of Dual-Sensor Estimates With CREA

In the second analysis, the agreement between the best-performing model (dual-sensor configuration) and the activPAL CREA-derived estimates was evaluated. To ensure compatibility between the 2 systems, CREA activity labels "primary lying" and "secondary lying" were merged into a single lying category, enabling direct comparison of PB categories common to both approaches (eg, standing, walking, cycling, and lying). No additional harmonization was required for AIC, as both methods classify intensity using the same 3 categories (sedentary, LPA, and MVPA).

Unlike the sensor-configuration analysis described above, this comparison was performed at the daily level without applying weekday-weekend weighting to enable a direct, day-by-day comparison with CREA outputs. This approach preserved the original temporal structure of the CREA estimates and avoided introducing additional aggregation effects that could mask day-level agreement between methods.

Agreement was evaluated using correlation plots and Bland-Altman analyses to visually assess the relationship and systematic bias between methods. In addition, Pearson correlation coefficients (r; 2-sided α=.05) were used to quantify the strength of association, and intraclass correlation coefficients (ICC [1,2]) were computed and reported with 95% CIs to evaluate absolute agreement between methods at the daily level.

Ethical Considerations

Prior to the study's commencement, ethics committee approval was obtained from all participating institutions: The Education and Health Sciences Faculty Research Ethics Committee, University of Limerick (22_09_10_EHS); the Ethics Committee of the University of Bremen (2022 - 25); the Comité de Protection des Personnes CPP Île-de-France VI, Paris (2022-A02208-35); and the Committee for Research Ethics at the University of Hradec Králové, Czech Republic (11/2022). All participants provided written informed consent before data collection and were informed of their right to withdraw from the study at any time without providing justification. To acknowledge participants' time and contribution, monetary compensation was provided: €40 in Ireland and €20 in the other countries. All collected data were deidentified for analysis and stored securely to maintain participant confidentiality.

Results

Model Development and Classification Performance

PB and AIC Classification Performance Across Window Lengths

The impact of window size on model performance was evaluated using the dual-sensor configuration by combining the HARTH (dual-sensor) feature set with an RF algorithm. Table 2 shows the results of these experiments.

Table . Physical behavior and activity intensity categories classification performance across window lengths using the dual-sensor random forest model.

Window size (seconds)	Precision	Recall	F_1-score
PB[a], mean (SD)			
5	0.675 (0.005)	0.821 (0.004)	0.729 (0.004)
10	0.671 (0.002)	0.825 (0.002)	0.729 (0.002)
15	0.667 (0.007)	0.828 (0.005)	0.727 (0.006)
AIC[b], mean (SD)			
5	0.736 (0.0004)	0.737 (0.001)	0.728 (0.001)
10	0.743 (0.002)	0.749 (0.001)	0.741 (0.002)
15	0.744 (0.001)	0.754 (0.002)	0.742 (0.001)

[a]PB: physical behavior.

[b]AIC: activity intensity categories.

PB classification performance was comparable across window lengths, with similar F_1-scores for 5- and 10-second windows (both 0.729) and a marginal reduction for 15-second windows (0.727). AIC classification showed slightly higher performance with longer windows, reaching the highest F_1-score at 15 seconds (0.742). However, bootstrap-based CI results showed substantial overlap across window lengths for both PB and AIC outcomes, indicating limited practical differences between configurations (Multimedia Appendix 7). Although longer windows yielded marginally higher AIC performance, differences across window lengths were small; therefore, the 10-second window was selected for subsequent analyses as a compromise between classification performance and temporal resolution.

RenderX

Single-Sensor Model Performance Using activPAL Data

As shown in Table 3, for PB classification using activPAL data, the MH-CNN achieved the highest F_1-score (0.716), outperforming RF models trained with CAPTURE-24 and the adapted HARTH features. For AIC classification, the RF models showed the best performance, with F_1-scores of 0.736 (CAPTURE-24) and 0.738 (adapted HARTH), whereas the MH-CNN showed reduced performance (0.707).

Table . Physical behavior and activity intensity categories classification performance using activPAL data across machine learning and deep learning models.

ML[a]/DL[b] approach	Precision	Recall	F_1-score
PB[c], mean (SD)			
RF[d] and CAPTURE-24	0.646 (0.003)	0.775 (0.0004)	0.694 (0.002)
RF and HARTH (adapted)	0.639 (0.001)	0.777 (0.001)	0.690 (0.001)
MH-CNN[e]	0.698 (0.016)	0.744 (0.007)	0.716 (0.011)
AIC[f], mean (SD)			
RF and CAPTURE-24	0.740 (0.001)	0.741 (0.001)	0.736 (0.001)
RF and HARTH (adapted)	0.741 (0.001)	0.746 (0.0002)	0.738 (0.001)
MH-CNN	0.726 (0.002)	0.723 (0.005)	0.707 (0.008)

[a]ML: machine learning

[b]DL: deep learning.

[c]PB: physical behavior.

[d]RF: random forest.

[e]MH-CNN: multihead convolutional neural network.

[f]AIC: activity intensity categories.

Single-Sensor Model Performance Using ActiGraph Data

As shown in Table 4, using ActiGraph data alone, PB classification performance was lower than that observed with activPAL. The MH-CNN achieved the highest F_1-score (0.591), slightly outperforming RF models trained with CAPTURE-24 features and performing comparably to the RF model using adapted HARTH features.

Table . Physical behavior and activity intensity categories classification performance using ActiGraph data across machine learning and deep learning models.

ML[a]/DL[b] approach	Precision	Recall	F_1-score
PB[c], mean (SD)			
RF[d] and CAPTURE-24	0.535 (0.004)	0.688 (0.007)	0.553 (0.003)
RF and HARTH (adapted)	0.555 (0.002)	0.725 (0.002)	0.581 (0.002)
MH-CNN[e]	0.580 (0.006)	0.715 (0.008)	0.591 (0.004)
AIC[f], mean (SD)			
RF and CAPTURE-24	0.718 (0.001)	0.734 (0.001)	0.716 (0.001)
RF and HARTH (adapted)	0.721 (0.0003)	0.737 (0.001)	0.721 (0.001)
MH-CNN	0.717 (0.002)	0.718 (0.006)	0.697 (0.006)

[a]ML: machine learning.

[b]DL: deep learning.

[c]PB: physical behavior.

[d]RF: random forest.

[e]MH-CNN: multihead convolutional neural network.

[f]AIC: activity intensity categories.

For AIC classification, RF models outperformed the MH-CNN. The adapted HARTH feature set achieved the highest F_1-score (0.721), marginally above the CAPTURE-24 RF model. The MH-CNN yielded the lowest performance of the 3 approaches (F_1-score=0.697). To obtain comparable results with ActiGraph data, the MH-CNN architecture required an increase in the

XSL•FO
RenderX

number of CNN filters from 32 to 64, while all other hyperparameters were kept unchanged.

Dual-Sensor Model Performance

As shown in Table 5, when combining activPAL and ActiGraph data, performance improved for PB classification over single sensor configurations (Tables 3 and 4). The MH-CNN achieved the highest F_1-score (0.750), outperforming the RF model trained with the dual-sensor HARTH feature set (F_1-score=0.729). For AIC classification, the RF dual-sensor HARTH model achieved the highest and most stable performance (F_1-score=0.741).

Table . Physical behavior and activity intensity categories classification performance using the dual-sensor (activPAL + ActiGraph) configuration.

ML[a]/DL[b] approach	Precision	Recall	F_1-score
PB[c], mean (SD)			
RF[d] and HARTH (dual-sensor)	0.671 (0.002)	0.825 (0.002)	0.729 (0.002)
MH-CNN[e]	0.720 (0.015)	0.797 (0.011)	0.750 (0.008)
AIC[f], mean (SD)			
RF and HARTH (dual-sensor)	0.743 (0.002)	0.749 (0.001)	0.741 (0.002)
MH-CNN	0.734 (0.003)	0.734 (0.005)	0.722 (0.006)

[a]ML: machine learning.

[b]DL: deep learning.

[c]PB: physical behavior.

[d]RF: random forest.

[e]MH-CNN: multihead convolutional neural network.

[f]AIC: activity intensity categories.

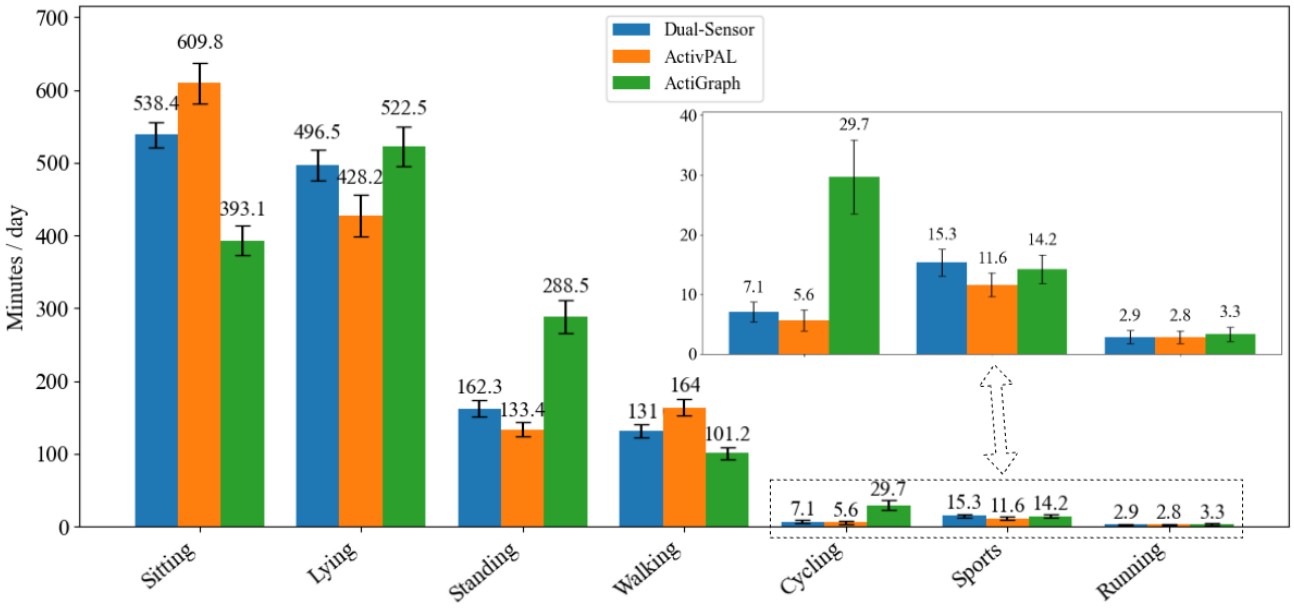
Overall, dual-sensor configurations consistently outperformed single-sensor setups for PB classification, while variability across the 5 repeated runs remained low, indicating robust and stable model behavior. Although the RF model achieved the highest AIC classification performance, the overall multitask performance of the RF and MH-CNN models was comparable (mean F_1-score between PB and AIC: 0.736 for MH-CNN and 0.735 for RF). To maintain a unified multitask framework across both outcomes, the MH-CNN was selected for subsequent analyses.

Free-Living Daily PB and AIC Estimates

Model-Derived Daily PB Profiles Across Sensor Configurations

Following model development and results, the selected MH-CNN models were applied to the test subset data (n=87) to generate a (weekday-weekend) weighted average of daily PB estimates across the 9-day free-living monitoring period for the 3 sensor configurations (activPAL, ActiGraph, and dual-sensor).

As shown in Figure 3, sedentary behaviors, particularly sitting and lying, accounted for the highest proportion of daily time in all sensor modalities. The dual-sensor approach estimated 37% (538.4/1440 min) of the day as sitting and 34% (496.5/1440 min) as lying.



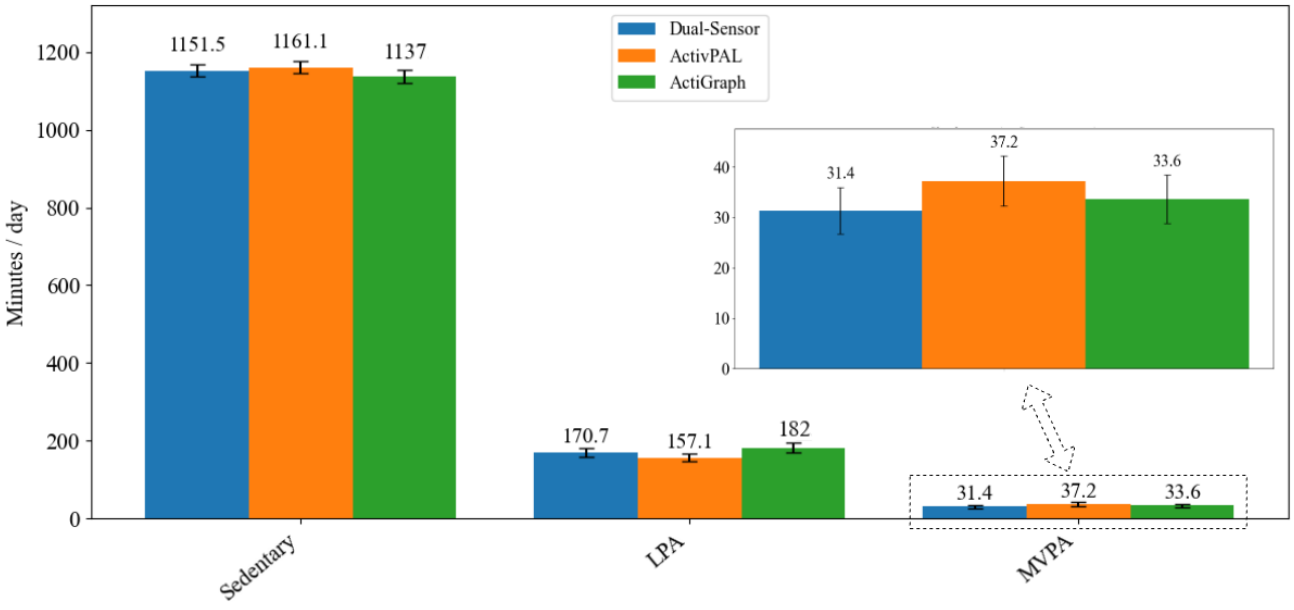
In comparison, our activPAL ML algorithm estimated 42% (609.8/1440 min) of the day as sitting and 30% (428.2/1440 min) as lying, while ActiGraph showed the opposite pattern, with 27% (393.1/1440 min) as sitting and 36% (522.5/1440 min) as lying. For standing time, the dual-sensor configuration estimated 11% (162.3/1440 min) of the day, yielding values intermediate between those obtained with the single-sensor devices. Specifically, activPAL estimated a lower standing time of 9% (133.4/1440 min), whereas ActiGraph produced higher estimates of 20% (288.5/1440 min).

A similar pattern was observed for walking. The dual-sensor model estimated 9% (131/1440 min) of the day, with values falling between those obtained from the single-sensor devices. ActivPAL yielded higher estimates (164/1440 min, 11%), while ActiGraph provided lower estimates (101.2/1440 min, 7%).

PB with low expected temporal prevalence under free-living conditions such as cycling (6–30/1440 min, <2%), sports (12–15/1440 min, ~1%), and running (~3/1440 min, <1%) accounted for only a small proportion of the daily activity profile. Among the single-sensor modalities, ActiGraph yielded higher estimates for these infrequent behaviors, most notably cycling (29.7/1440 min, 2%), whereas the dual-sensor approach produced lower estimates.

XSL•FO
RenderX

Figure 3. Weighted average daily distribution of time spent in physical behavior estimated using activPAL, ActiGraph, and dual-sensor configurations over 9 days. Error bars represent 95% CIs across participants.



Model-Derived Daily AIC Profiles Across Sensor Configurations

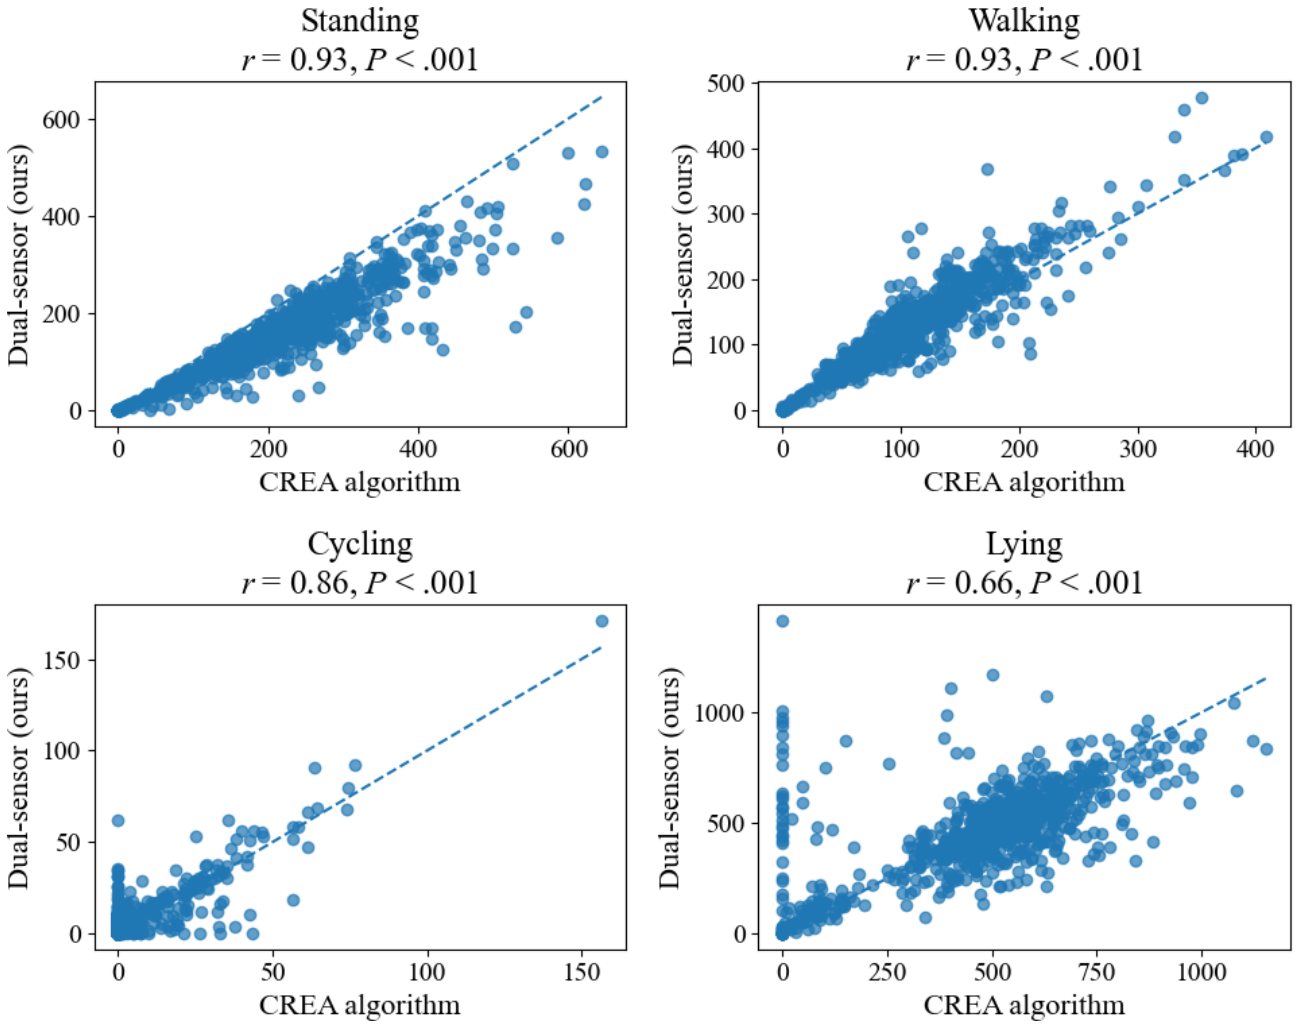
Similarly, the selected MH-CNN models were applied to the test subset data to generate weighted average daily AIC estimates across the 9-day free-living monitoring period.

As shown in Figure 4, estimated weighted average daily AIC exhibited the expected gradient across intensity categories, with sedentary time comprising most of the day across all sensor modalities.

Figure 4. Weighted average daily distribution of time spent in activity intensity categories estimated using activPAL, ActiGraph, and dual-sensor configurations over 9 days. Error bars represent 95% CIs across participants. LPA: light physical activity; MVPA: moderate-to-vigorous physical activity.

The dual-sensor approach estimated 80% (1151.5/1440 min) of the day as sedentary behavior, with comparable values from activPAL (1161.1/1440 min, 81%) and ActiGraph (1137/1440 min, 79%). These higher totals reflect that waking sedentary time and sleep were merged into a single sedentary category.

For LPA, daily estimates ranged from 11% - 13% (157.1 - 182.0/1440 min), with ActiGraph reporting the highest values (182/1440 min, 13%), activPAL the lowest (157.1/1440 min, 11%), and the dual-sensor configuration producing an intermediate estimate of 12% (170.7/1440 min).



MVPA contributed only a small portion of the daily time. The dual-sensor approach estimated 2% (31.4/1440 min), compared with 3% (37.2/1440 min) for activPAL, and 2% (33.6/1440 min) for ActiGraph.

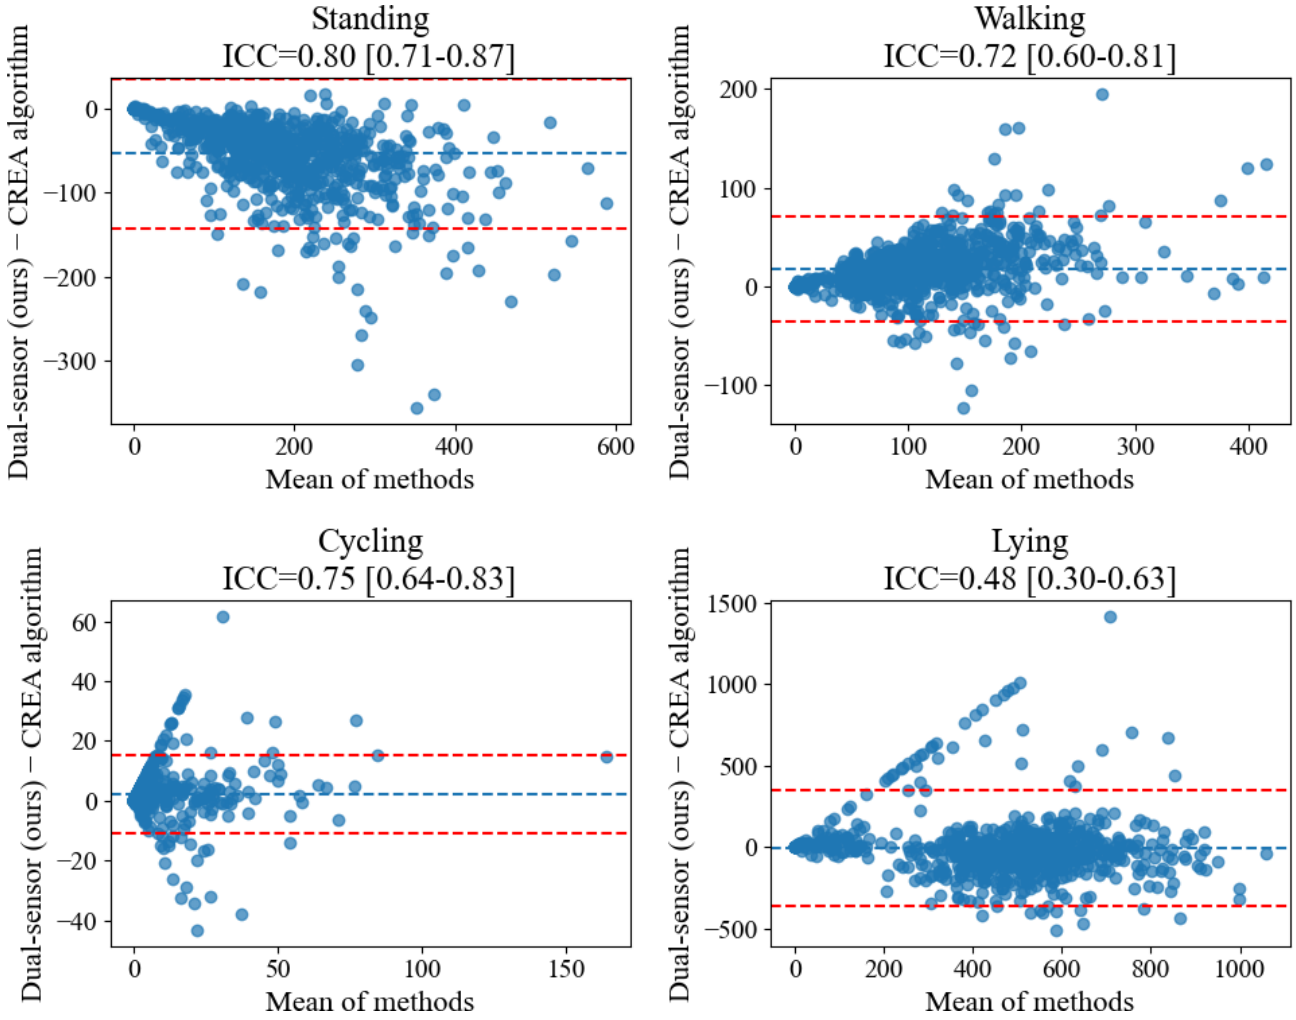
Agreement Between Dual-Sensor Estimates and CREA for PBs



The dual-sensor configuration demonstrated varying levels of agreement with the CREA algorithm across the 4 PB categories, as illustrated in the correlation analyses (Figure 5) and Bland-Altman results (Figure 6). These analyses were based on participant-specific daily estimates, with each data point representing a direct day-by-day comparison between the 2 methods.

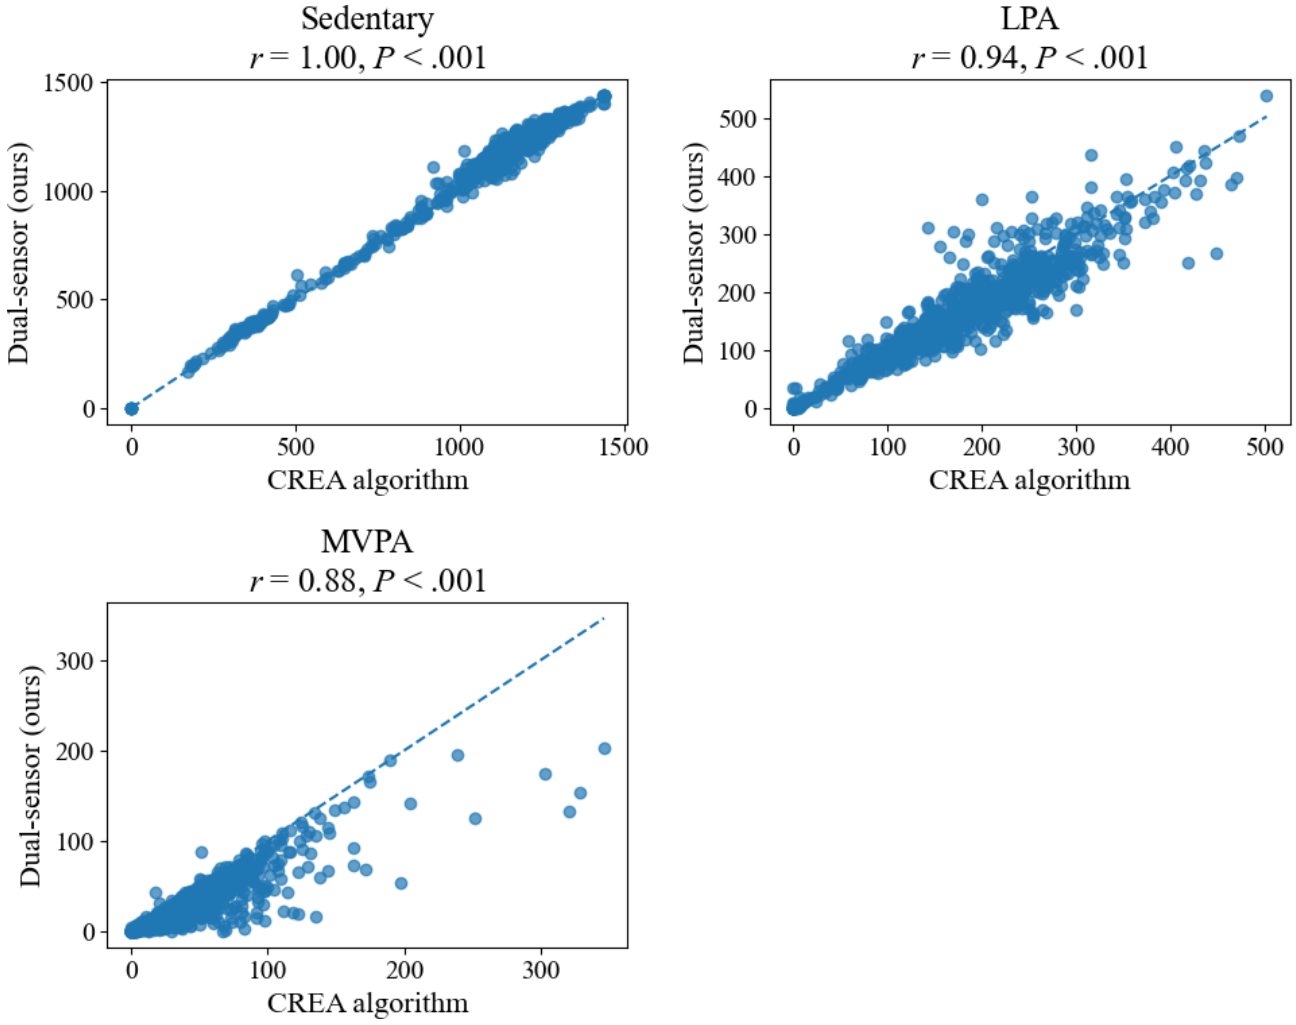
Figure 5. Correlations between classification of real-world everyday activities and dual-sensor estimates of daily time spent in physical behavior categories. Each point represents one participant-day, showing the daily duration (minutes/day) estimated by the classification of real-world everyday activities algorithm (x-axis) and the dual-sensor model (y-axis). Pearson coefficients (*r*) and *P* values are shown for each physical behavior. CREA: classification of real-world everyday activities.

XSL•FO
RenderX

Figure 6. Bland-Altman plots showing agreement between classification of real-world everyday activities and dual-sensor estimates of daily time spent in physical behavior categories. Each point represents the difference between dual-sensor and classification of real-world everyday activities daily estimates plotted against their mean at daily level. Intraclass correlation coefficients with 95% CIs are reported for each physical behavior. CREA: classification of real-world everyday activities; ICC: intraclass correlation coefficients.

Standing and walking showed the strongest correspondence, with high correlations (r=0.93, P<.001 for both) and substantial ICC values (standing: ICC=0.80, 95% CI 0.71 - 0.87; walking: ICC=0.72, 95% CI 0.60 - 0.81). Bland-Altman plots indicated relatively narrow limits of agreement and minimal systematic bias.

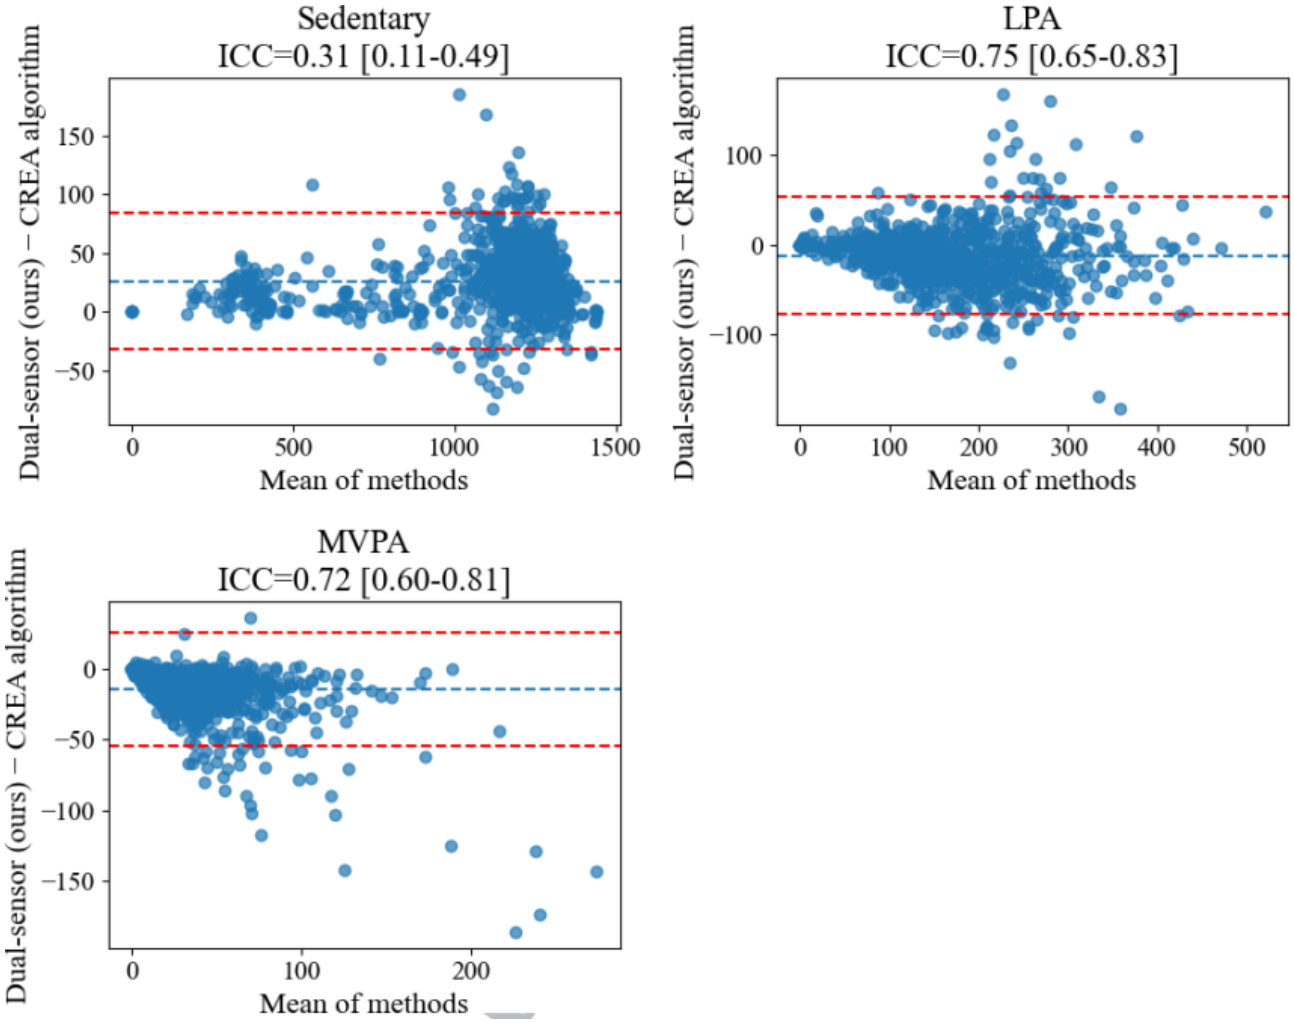
Cycling also showed a strong correlation (r=0.86, P<.001) and good reliability (ICC=0.75, 95% CI 0.64 - 0.83), although the Bland-Altman plot revealed greater dispersion at longer cycling durations.



Lying exhibited a similar pattern, with moderate correlation (r=0.66, P<.001) and fair reliability (ICC=0.48, 95% CI 0.30 - 0.63) with increased dispersion at higher daily durations.

Agreement Between Dual-Sensor Estimates and CREA for AIC

The agreement between the dual-sensor configuration and the CREA algorithm varied among AIC, as illustrated in the correlation (Figure 7) and Bland-Altman plots (Figure 8).



XSL•FO
RenderX

Figure 7. Correlations between classification of real-world everyday activities and dual-sensor estimates of daily time spent in AIC. Each point represents one participant-day, showing the daily duration (minutes/day) estimated by the classification of real-world everyday activities algorithm (x-axis) and the dual-sensor model (y-axis). Pearson coefficients (*r*) and *P* values are shown for each activity intensity category. CREA: classification of real-world everyday activities; LPA: light physical activity; MVPA: moderate-to-vigorous physical activity.

XSL•FO
RenderX

Figure 8. Bland-Altman plots showing agreement between classification of real-world everyday activities and dual-sensor estimates of daily time spent in activity intensity categories. Each point represents the difference between dual-sensor and classification of real-world everyday activities daily estimates plotted against their mean at the daily level. Intraclass correlation coefficients with 95% CIs are reported for each activity intensity category. CREA: classification of real-world everyday activities; ICC: intraclass correlation coefficient; LPA: light physical activity; MVPA: moderate-to-vigorous physical activity.

Sedentary showed a near-perfect correlation (r=1.00, P<.001; Figure 7). However, the Bland-Altman analysis (Figure 8) revealed a wide dispersion at higher sedentary levels, resulting in poor reliability (ICC=0.31, 95% CI 0.11 - 0.49), with increased disagreement above approximately 1000 minutes/day.

For LPA, a strong correlation (r=0.94, P<.001) and good reliability (ICC=0.75, 95% CI 0.65 - 0.83) were observed. MVPA also showed strong agreement (r=0.88, P<.001; ICC=0.72, 95% CI 0.60 - 0.81), with Bland-Altman plots indicating an increasing negative bias at longer MVPA durations.

Discussion

Overview of Key Findings

This study provides a comprehensive development and evaluation of multitask ML models for simultaneous PB and AIC classification using multisensor accelerometry under free-living conditions. Leveraging data from 590 adults across 4 European countries monitored over a 9-day period, the findings demonstrate that integrating thigh- and waist-worn sensors within a multitask learning framework improves model performance and the stability of daily behavioral profiles compared with single-sensor approaches. Collectively, these results support the feasibility of scalable long-term wearable monitoring under real-world conditions, thereby providing ecologically valid evidence at a scale rarely reported in prior free-living wearable studies.

When applied to free-living data, the dual-sensor configuration produced PB distributions characterized by high sedentary time and comparatively limited engagement in ambulatory and vigorous behaviors. These estimates fall within ranges commonly reported in adult populations, where sedentary behaviors account for approximately 60% - 70% of daily time [31,43] and walking typically averages 1 - 2 hours per day [44]. Similarly, low-prevalence behaviors such as running, sports, and cycling contributed minimally to daily activity, consistent with epidemiological observations that vigorous or sport-related activities occupy only a small fraction of daily time in adults [43,45].

For AIC, the dominance of sedentary time and the relative contributions of LPA and MVPA were consistent with population-based accelerometer studies reporting 8 - 10

hours/day of sedentary behavior [46,47], 10% - 20% of time in LPA [48], and 20 - 40 minutes/day of MVPA [39]. The dual-sensor configuration consistently produced intermediate estimates between single-sensor approaches, suggesting reduced sensor-specific bias and improved behavioral characterization across heterogeneous activity patterns. Similarly, the inclusion of participants with a broad range of BMI values, including individuals classified as obese, supported the representation of diverse PB and AIC patterns under free-living conditions.

Agreement analyses further showed that the dual-sensor approach aligned most closely with CREA for ambulatory behaviors (standing, walking, and cycling), while greater discrepancies were observed for prolonged sedentary behaviors, particularly lying. This pattern suggests that multimodal sensing enhances recognition of dynamic behaviors under free-living conditions but remains challenged by extended low-movement postures, a limitation also reported in prior work [49].

Implications for Remote Monitoring

From a monitoring perspective, these findings have important implications for real-world implementation of wearable-based monitoring systems. First, they demonstrated that dual-sensor wearable monitoring could reduce modality-specific biases inherent to single-sensor approaches, particularly for posture-related behaviors. The dual-sensor configuration mitigated systematic over- and underestimation observed with activPAL-only and ActiGraph-only models, producing more balanced and interpretable daily PB profiles that are better suited for longitudinal monitoring and population-level analyses. The scalability of the dual-sensor approach warrants consideration for large-scale deployment. Although the use of 2 devices may increase participant burden, it proved feasible and was well accepted in our sample [50]. Furthermore, jointly labeled thigh- and hip-worn data enable the development of more accurate and generalizable models that can subsequently be applied in single-sensor configurations, supporting scalable mHealth apps [27].

Second, the integration of EMA-informed labeling provided a scalable and pragmatic solution to overcome the scarcity of reliable free-living training data. Event-based EMA enabled the collection of relevant behavior labels at the moment of occurrence, thereby improving ecological validity, supporting the development of models that generalize beyond controlled laboratory environments [23,24,26]. This approach is particularly relevant for mHealth studies requiring extended monitoring periods, where intensive manual annotation is not feasible.

Third, the relative stability of AIC estimates across sensor configurations suggests that multitask learning may be especially valuable for digital health apps focused on energy balance, PA guidelines, and surveillance of activity intensity distributions. Even when discrepancies were observed in PB classification, aggregated AIC estimates remained consistent with epidemiological norms reported in large cohort studies [39,46-48], supporting their use in public health monitoring and evaluation of intervention outcomes.

Comparison With Prior Work

Previous studies on wearable-based activity recognition have frequently relied on laboratory-based protocols, short-term recordings, or single-sensor configurations, which may limit generalizability to free-living settings [22,25,26]. Although datasets such as CAPTURE-24 have advanced free-living activity recognition using video-based behavioral labels [16], reliance on wearable cameras and manual annotation may reduce scalability and raise privacy concerns for longer-term monitoring. In contrast, this study uses 9-day free-living data and EMA-informed labeling from a multicenter cohort, providing a rigorous assessment of model performance under realistic conditions.

Previous research has demonstrated the feasibility of EMA for behavioral annotation and the potential of multitask learning for activity recognition [17,18]. Extending this work, this study combined multitask learning with multisensor accelerometry in a large multicenter dataset, offering empirical evidence of their combined value for mHealth monitoring in real-world settings.

The findings are consistent with previous studies reporting that feature-engineered ML models can remain competitive with DL approaches for free-living activity recognition [21]. In this study, the MH-CNN achieved the highest PB classification performance, whereas the RF model achieved the highest AIC classification performance, suggesting that engineered temporal and statistical features remain informative for AIC classification under free-living conditions [25]. Although more complex sequential architectures may further improve temporal modeling, the selected MH-CNN offered a balanced compromise between predictive performance, complexity, and scalability for long-term monitoring.

Limitations

Several limitations should be acknowledged. AIC estimates were derived from the activPAL CREA algorithm and operationalized using MET-derived categories rather than direct kcal-based energy expenditure, thereby limiting the assessment of continuous energy expenditure. In addition, the CREA algorithm contributed to the label-refinement procedure and was subsequently used as a comparator for daily estimates; therefore, comparisons with CREA-derived estimates represent assessments of agreement rather than independent validation. Although gold-standard methods such as doubly labeled water or other forms of indirect calorimetry would provide stronger absolute validation of the AIC estimates [3], these approaches were beyond the scope of this study and warrant further investigation within multitask wearable monitoring frameworks.

The behavioral taxonomy was limited to 7 PB categories and 3 activity intensity levels, which, although appropriate for large-scale monitoring, do not capture the full diversity of real-world activities. In addition, the EMA-labeled dataset was imbalanced, with low-frequency behaviors such as running and sports remaining underrepresented despite mitigation strategies including selective undersampling and class-weighted losses. Future research may benefit from data augmentation, self-supervised learning, or transfer learning approaches trained

XSL•FO
RenderX

on large unlabeled datasets to improve recognition of infrequent behaviors [15].

Furthermore, although the MH-CNN improved PB classification performance, the comparatively smaller gains observed for AIC classification may reflect class imbalance and limitations in CNN-based temporal modeling under free-living conditions. Future work should evaluate sequential architectures such as LSTM- or Transformer-based models using larger (real-world) datasets. Finally, although the dual-sensor configuration improved performance, practical deployment in some mHealth contexts may require adaptation to single-sensor or consumer-grade devices, which warrants further investigation.

Conclusions

This study demonstrates that multitask ML models combining thigh- and waist-worn accelerometry can provide consistent estimates of PB and AIC under free-living conditions. The dual-sensor approach produced stable, epidemiologically coherent daily profiles and reduced modality-specific biases observed in single-sensor methods. By integrating multimodal wearable sensing with EMA-informed labeling at scale, this work advances methodological foundations for real-world mHealth monitoring and supports more consistent and comparable assessment of PB in population and public health research.

Acknowledgments

We would like to express our sincere appreciation to the volunteers and field staff in Czechia, France, Germany, and Ireland for their invaluable participation. We are deeply grateful to the WEALTH Advisory Panel for their essential guidance and unwavering support throughout this study.

Collaborators: The WEALTH consortium members and affiliations: Alan Donnelly, Catherine Woods, Luis Sigcha, Gráinne Hayes, Pepijn Van de Ven, Daniels Stahovskis (University of Limerick, Ireland), Janas Harrington (School of Public Health, University College Cork, Ireland), Antje Hebestreit, Christoph Buck, Maike Wolters, Annika Swenne, Chandra Gowsiga Loganathan (Leibniz Institute for Prevention Research and Epidemiology—BIPS, Bremen, Germany), Jean-Michel Oppert, Leopold K. Fezeu, Jérôme Bouchan, Fabienne Delestre, Junko Kose (Sorbonne Paris Nord University, France), Hélène Charreire (Inrae, France), Greet Cardon (Department of Movement and Sports Sciences, Ghent University, Belgium), Tomas Vetrovsky, Richard Cimler, Jitka Kuhnova, Alena Faltysova (Faculty of Science, University of Hradec Kralove, Czechia), Steriani Elavsky, Veronika Horká, Michal Sebera (Department of Human Movement Studies, University of Ostrava, Czechia), Michael Janek, Dan Omcirk (Faculty of Physical Education and Sport, Charles University, Prague, Czechia).

OpenAI's ChatGPT was used to refine the language and improve clarity of the manuscript. All content was reviewed and edited by the authors to ensure accuracy and integrity.

Funding

The WEALTH project is funded by the Joint Programming Initiative a Healthy Diet for a Healthy Life, a research and innovation initiative of European Union member states and associated countries under Grant Agreement No 727565, under STAMIFY (Standardized measurement, monitoring and/or biomarkers to study food intake, physical activity, and health). The funding agencies supporting this work are (in alphabetical order of participating countries): Belgium: Research Foundation—Flanders; Czechia: Ministry of Education, Youth, and Sports; France: French National Research Agency; Germany: Federal Ministry of Research, Technology and Space; and Ireland: Health Research Board (HRB).

Data Availability

The data used in this study are not publicly available at this time, as they are subject to an embargo period under the WEALTH project. Access to the data may be granted upon reasonable request and subject to approval by the WEALTH Steering Group.

The trained models, along with example analysis workflows implemented as Python notebooks, are publicly available on the GitHub repository [51].

Conflicts of Interest

LS, AS, GH, CB, GC, SE, LFK, JH, AH, JK, JMO, PVV, TV, and AD declare that they have no known competing financial interests or personal relationships that could have appeared to influence the work reported in this study. RC reports a potential conflict of interest. RC is the owner of a company that holds a license to use HealthReact, a software developed by the University of Hradec Králové. However, this did not influence the data analysis, interpretation, or manuscript preparation.

Abstract

Background: Over the past decade, wearable activity monitoring (WAM) devices have become prevalent to improve quality of life and support the prevention and management of a wide range of health disorders. WAM devices based on the Internet of Medical Things (IoMT) paradigm provide a practical means of tracking physical activity, but their widespread adoption raises sustainability concerns. Meanwhile, health technology assessment and life cycle assessment are typically applied at advanced development stages, when empirical certainty about the final design and operating conditions is available, leaving little room for further improvements.

Objective: This exploratory work provides the empirical foundations for an information-driven approach addressing this paradox in the early evaluation and conception of wrist-worn step counters, for which evidence suggests overdimensioned and unsustainable electronic designs. Specifically, we identify optimal resource-performance trade-offs in critical electronic components of frugal smartbands based on the data they collect and the information they preserve for step counting. This approach accounts for uncertainties in device reliability, users' gait speeds, and material and energy consumption in final products.

Methods: We conducted a secondary analysis of an accelerometer dataset characterizing wrist motion in healthy individuals walking at different speeds. The original x-, y-, and z-axis signals were progressively downsampled using cubic spline interpolation and discretized to quantify the information preserved, first across sampling frequencies and then with respect to changes in motion velocity. We also preliminarily assessed the viability of the downsampled signals for step detection by estimating percentage errors in peak and valley counts. Based on this, we constructed and evaluated 4 frugal smartband design archetypes, linking energy consumption and sampling frequency for 4 widely used accelerometers and combining essential electronic components, implementing a suboptimal asynchronous first-in-first-out (FIFO) algorithm at different sampling rates. Finally, we evaluated the environmental impact and circularity of these components through a streamlined analysis focused on raw materials.

Results: About 70% - 90% of the information is lost in signals downsampled at very low frequencies (2 - 5 Hz), whereas losses remain below 24% from 20 Hz onward. Substantial information loss also occurs when individuals walk briskly or jog (≥8 km/h), or walk below 8 km/h with sampling frequencies below 7 Hz or above 25 Hz. Step-counting accuracy is expected to be acceptable from approximately 11 Hz onward. Conversely, higher sampling rates rapidly saturate FIFO buffers and increase energy overhead, particularly when implemented in memory-dense components handling both processing and data transfer. Finally, gold and silver in transceivers and microcontrollers contribute substantially to resource depletion, while copper remains relevant for material recovery.

Conclusions: These findings provide preliminary insights into the concurrent assessment and development of frugal WAM devices. This work extends the understanding of step detection under knowledge-constrained conditions and provides mechanisms to reduce uncertainty during early health technology assessment and eco-design.

Introduction

Wearable activity monitoring (WAM) devices, such as smartwatches, fitness bands, and pedometers, are widely endorsed for promoting physical activity (PA) [1,2] and well-being [3]. Consequently, the WAM market is projected to grow significantly, from reported sales of US $71 billion in 2023 to more than US $186 billion by 2030 [4]. This rapid market expansion raises critical medium-term sustainability concerns. Under current trends, WAM devices are estimated to generate 3.4 Mt CO_2-equivalent emissions by 2050, while also exacerbating challenges related to ecotoxicity, resource depletion, and e-waste management [5].

Yet, evidence also shows that the environmental impacts of wearables vary considerably. For instance, official sustainability reports for Samsung smartwatches reveal that resource depletion differs markedly across product families and models [6]. Moreover, the production of a midtier smartwatch accounts for approximately 5 kg CO_2-eq of global warming potential [7], whereas this impact can increase by as much as 6-fold for a high-end model [8].

Different product families and premium devices undoubtedly offer a range of benefits. However, regarding PA monitoring performance, several works suggest that low-complexity devices are generally sufficient for approximate movement tracking [9,10], which appears adequate to encourage and sustain PA over the long term [11]. Furthermore, clinical studies have shown that accelerometer data collected over only a few days are sufficient to provide a reliable daily step count in people with neurodegenerative diseases [12]. Likewise, specific research has demonstrated that low data resolution does not significantly impair the detection of complex gait-related motor symptoms [13]. Taken together, this evidence suggests that limited resources and information can still be used effectively to monitor simple ambulation patterns.

From the perspective of national health authorities responsible for assessing and approving WAM devices, this insight is particularly important because a primary public health objective is to reduce disease morbidity through resource-efficient strategies that promote long-term PA. While health technology assessment (HTA) [14] and life cycle assessment (LCA) [15] are widely accepted methodologies for supporting this objective, their analytical reach is severely constrained during early product development due to limited empirical evidence [16]. Paradoxically, this stage also offers considerable freedom to make critical decisions that can positively influence not only the sustainability of final devices [17] but also their efficiency and ethical characteristics [18-20]. As a result, 2 related challenges emerge: an “eco-design paradox” [21,22], in which opportunities for environmental improvement decrease as product knowledge increases [23], and an early HTA paradox, in which the imbalance between uncertainty and evidence complicates decision-making in health care technology design and development [24].

In this exploratory work, we address these challenges by building on evidence suggesting (1) that low-complexity devices can effectively support approximate PA tracking [9-11] and (2) that limited information may still be sufficient to monitor simple ambulation patterns [12,13]. Specifically, this study investigates how the degradation of intrinsic information contained in accelerometer data influences the acquisition and use of knowledge and the management of uncertainty during the early-stage design and preliminary sustainability assessment of frugal WAM devices. To answer this research question, we analyze how sensor data availability affects the development and environmental evaluation of lightweight prototypes. In particular, we quantify the effects of incremental information loss on early design and on the energy consumption of basic algorithms operating under different motion velocities.

The aim of this exploratory research is therefore to examine the potential of a novel information-driven approach for addressing the difficulties and paradoxes associated with the early assessment and design of frugal WAM devices. In doing so, we contribute to the state of the art by providing knowledge relevant to the early design and preliminary environmental assessment of frugal archetypes, together with empirical evidence regarding the performance of final devices operating under specific and uncertain conditions. The remainder of this paper is organized as follows. The Methods section details our research approach applied to the specific case of smartbands, followed by the Results section presenting our preliminary findings. The Discussion section contextualizes the novelty and contributions of this work, addresses its limitations, and concludes with directions for future research.

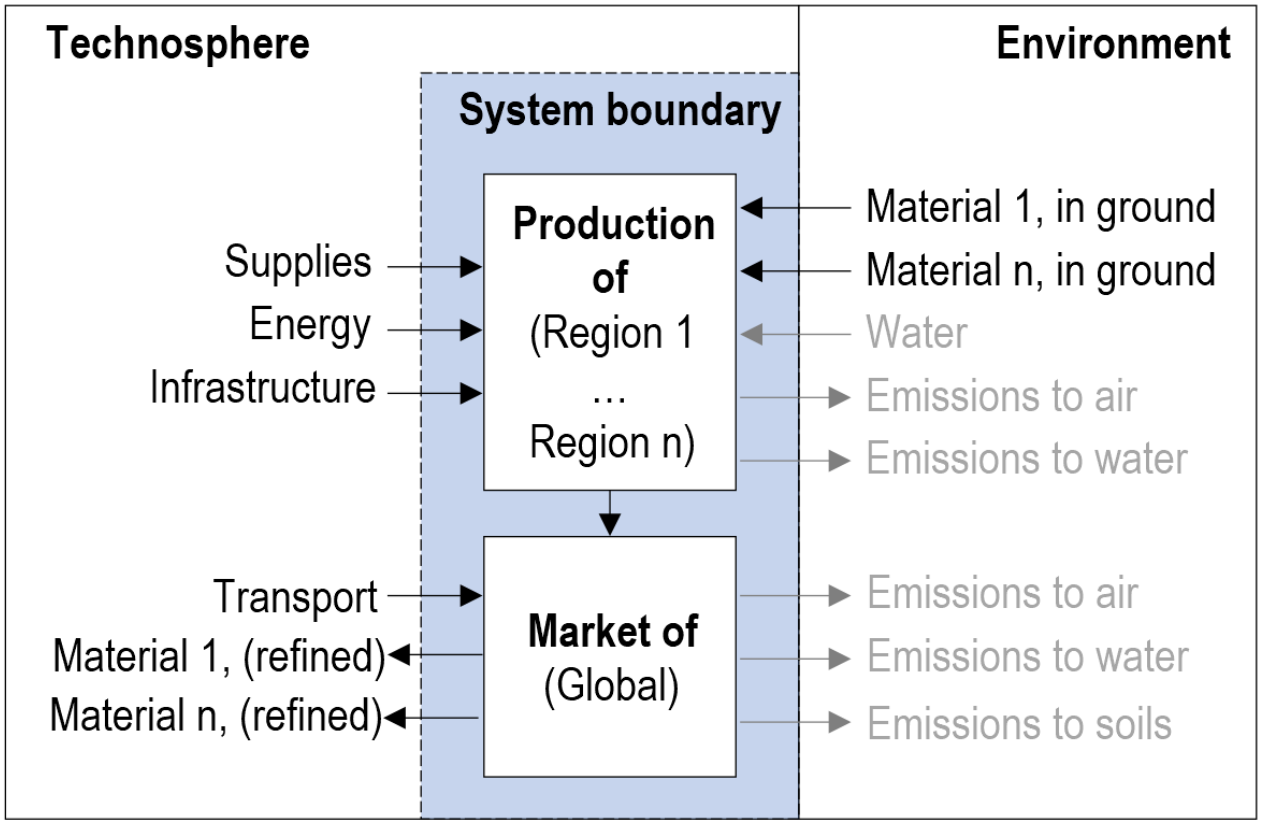
Methods

Methodology Overview

Our research methodology consists of 3 successive steps: a secondary analysis of an existing accelerometer dataset, the construction of design archetypes for frugal smartbands, and a streamlined assessment of their environmental impact.

The first step is grounded in the principles of information theory and follows a data-information-knowledge process adapted for the ecological design and evaluation of Internet of Medical Things (IoMT) systems [25]. Its objective is to quantify how much information is preserved in signals describing the wrist movements of individuals walking at different speeds as the initial sampling rate is progressively reduced across the x-, y-, and z-axes. By doing so, we generate and use the knowledge required to manage critical uncertainties encountered during the early design and performance evaluation of archetypes, particularly those related to the movement speed of users and the energy consumption of final devices. We focus on energy consumption because it represents a major source of uncertainty in wearable design, as it is influenced by numerous stochastic factors, including usage context [26] and data acquisition, processing, and communication conditions [27].

The second step focuses on constructing electronic design archetypes for frugal smartbands based on the primary functions and capacities of their essential components, following the approach proposed by Quisbert-Trujillo and Morfouli [28]. Its objective is to support a worst-case analysis that addresses the



XSL•FO
RenderX

uncertainty and limited knowledge regarding users' walking speeds and the energy consumption of final devices. To achieve this, we evaluate the extent to which different design archetypes can support the acquisition, processing, storage, and transmission of raw accelerometer data under demanding operating conditions and at different sampling rates, independently of software-level optimizations.

The third step provides a high-level estimate of the environmental impact associated with the production of the essential components identified in the previous step and incorporated into the design archetypes. For conciseness and due to space limitations, this analysis was intentionally conceived as a lightweight environmental screening approach focused on the scarcity and potential recovery of raw materials. Its purpose is to provide rapid and pragmatic insights during early-stage product development and eco-design, where knowledge of final devices is typically limited. Specifically, the assessment is based on the identification and quantification of constituent refined materials using official manufacturer-declared material composition data. For simplicity, we focus exclusively on the contributions of gold, silver, and copper to abiotic resource depletion (according to the Environmental Footprint 3.1 impact assessment methodology and antimony-equivalent characterization factors expressed in kg Sb-eq). These materials were selected because of their documented prevalence in electronic devices [29-31] and their relevance to other environmental impact categories, including global warming [32].

Figure 1 illustrates the boundaries and limitations of this streamlined analysis, which accounts for all extractions involved in the global production and commercialization processes available in Ecoinvent 3.10 for the materials considered in this study.

Figure 1. System boundary of the streamlined analysis conducted in this study. Only abiotic resource depletion (kg Sb-eq) was assessed; water consumption and emissions to air, water, and soil (shown in gray) were excluded from the system boundary.

In this sense, this streamlined analysis should not be interpreted as a comprehensive LCA study. Several standardized elements were intentionally excluded from the scope. Specifically, we did not include comprehensive life cycle inventory modeling of manufacturing processes of the electronic components of the design archetypes. Likewise, we did not model the technosphere and the environmental inputs and outputs associated with the use, transportation, maintenance, or waste treatment of final devices. In addition, no sensitivity analysis was conducted to support advanced interpretations of results.

Despite these limitations, the proposed streamlined approach provides a transparent, reproducible, and operationally practical method for integrating preliminary environmental considerations into early design-oriented analyses. As part of this step, we also conducted a conservative assessment of the recovery potential of gold, silver, and copper contained in the electronic components of the design archetypes. The objective was to establish a worst-case scenario for evaluating the minimum recyclability threshold of the final smartbands. This analysis is based on the respective material proportions and their corresponding functional recycling rates, according to Graedel et al [33].

Secondary Analysis of the Accelerometer Data

The information theory concepts used in this part of the research methodology are marginal entropy, conditional entropy, and mutual information. Marginal entropy quantifies the uncertainty associated with a variable independently of another variable [34]. In contrast, conditional entropy quantifies the amount of uncertainty that remains about a variable when the value of another variable is known [35]. Mutual information quantifies the amount of information shared between two variables [34]. For two variables X and Y, the mutual information $MI(X;Y)$ is mathematically defined as the difference between the marginal entropy of X ($H(X)$) and the conditional entropy of X given Y ($H(X|Y)$), as shown in Equation 1.

Equation 1: Mutual information formula

$$MI(X;Y)=H(X)-H(X|Y)$$

When the variables X and Y represent measurements of the same phenomenon, the mutual information $MI(X;Y)$ can be interpreted as the amount of information about X that is also provided by Y [36]. This interpretation follows from the fact that $H(X)$ quantifies the total uncertainty associated with the measurements represented by X, whereas $H(X|Y)$ quantifies the uncertainty that remains after observing the measurements represented by Y.

In this work, X represents the original accelerometer data describing users' movements at a reference sampling rate along the x-, y-, and z-axes, whereas Y represents the corresponding accelerometer data after downsampling. Therefore, if the downsampled signal Y preserves most of the measurements describing the relevant motion patterns of a specific PA, observing Y substantially reduces the uncertainty associated with the original signal X that describes this PA fully, resulting in a high value of $MI(X;Y)$. Conversely, if the downsampled signal Y removes measurements that capture critical details of these motion patterns, the information provided by Y about the original signal becomes limited, and the mutual information decreases accordingly. In practical terms, this means that the downsampled signal no longer retains enough information from the original signal to adequately characterize the PA being monitored.

Following Kvålseth [37], we define the preserved information $PI(X;Y)$ as the fraction of uncertainty in the original signal X that is resolved by observing the transformed signal Y or, equivalently, as the fraction of information contained in the original signal that remains after downsampling (Equation 2).

Equation 2: Preserved information formula

$$PI(X;Y)=MI(X;Y)H(X)$$

So that

$$PI(X;Y)=\{\text{No information loss},PI(X;Y)=1,\text{Partial preservation},0<PI(X;Y)<1,\text{Complete information loss},PI(X;Y)=0.$$

Data Preparation

The secondary analysis was conducted using a previously published dataset of treadmill walking tests performed by healthy participants at speeds ranging from 1.4 to 10 km/h [38]. In this exploratory study, only wrist accelerometer recordings collected with ActiGraph GT9X devices were analyzed, using the original triaxial signals sampled at 30 Hz as the reference data.

The original signals were progressively downsampled from 29 to 1 Hz using cubic spline interpolation. This approach was selected for its computational simplicity and suitability for benchmarking purposes, while remaining consistent with the Nyquist-Shannon theorem [39,40] given the frequency range associated with human walking [41]. In addition, previous studies have shown that spline interpolation can preserve the structural characteristics of a signal when generating lower-frequency representations from known data points [42].

After downsampling, both the original and downsampled signals were discretized using identical binning schemes and organized according to participant, walking speed, and signal axis. This procedure enabled direct comparisons between the reference and modified time series, as illustrated in Rashkovska et al [43]. Additional details regarding data preparation are provided in Multimedia Appendix 1.

Preservation of Information

To quantify the preservation of information in the downsampled signals, the mutual information $MI(X;Y)$ and the preserved information $PI(X;Y)$ were computed using Equations 1 and 2 for each 1-second interval throughout the walking period. Mean values were then calculated for each signal axis and sampling frequency across all walking speeds. Subsequently, a deviation analysis was performed to evaluate the consistency of these results in accordance with conventional statistical methods [44].

In addition, changes in preserved information with respect to variations in walking speed and sampling frequency were quantified through $PI'(X;Y)$ for each participant and signal axis, according to Equation 3.

Equation 3: Changes in the preserved information

$$PI`(X;Y)=|PI(X;Y)s-PI(X;Y)s`PI(X;Y)f-PI(X;Y)f`|$$

where

PI(X;Y)s=PI for a given walking speed

PI(X;Y)s′=PI for a walking speed lower than the given speed

PI(X;Y)f=PI for a given sampling frequency

PI(X;Y)f′=PI for a sampling frequency lower than the given frequency

More specifically, PI′(X;Y) is the derivative that systematically models the instantaneous rate of change of the preserved information variable. It quantifies how rapidly preserved information changes as a participant transitions from a given walking speed (PI(X;Y)s) to a higher walking speed (PI(X;Y)s`), while the accelerometer of the WMA device simultaneously transitions from a given sampling frequency (PI(X;Y)f) to a lower sampling frequency (PI(X;Y)f`).

Evaluation of the Downsampled Signals

To estimate the viability of the downsampled signals for step detection, the procedure adopted in this exploratory study was

XSL•FO
RenderX

divided into two stages and repeated across the x-, y-, and z-axes.

First, we identified and counted peaks and valleys in both the original and downsampled signals. This approach was selected because step-counting methods commonly rely on the detection of peaks and valleys in accelerometer data. Specifically, gray literature suggests that peak detection constitutes the basis of pedometer software implemented in widely used commercial sensors [45], while academic studies identify the detection of peaks [46] or peak-valley pairs [47] as standard approaches for step-counting algorithms.

In our study, peaks were identified using the find_peaks algorithm from the scipy.signal Python library. Detection was based on local extrema and constrained by a topographic prominence of 0.2 and a height threshold equal to the mean acceleration value plus half of its standard deviation for each axis. Valleys were identified using the same procedure applied to the inverted signals.

Second, we computed the percentage error of peak counts (PEpeaksi,j) and valley counts (PEvalleysi,j) for the downsampled signals at each walking speed *i* and sampling frequency *j*. The corresponding peak and valley counts obtained from the original signals were used as reference values, according to Equations 4 and 5.

Equation 4: Percentage error of peaks formula

$$PEpeaks_{i,j} = \frac{|PC_{i,j} - PC_{i,j'}|}{PC_{i,j}} \times 100\%, \forall i \in \{1,\ldots,29\}, j \in \{1.4,\ldots,10\}$$

Equation 5: Percentage error of valleys formula

$$PEvalleys_{i,j} = \frac{|VC_{i,j} - VC_{i,j'}|}{VC_{i,j}} \times 100\%, \forall i \in \{1,\ldots,29\}, j \in \{1.4,\ldots,10\}$$

where

$PC_{i,j}$ = Peak Counting ∈ the original signal for walking speed $i \wedge$ frequency j

$PC_{i,j'}$ = Peak Counting ∈ a downsampled signal for walking speed $i \wedge$ frequency j

$VC_{i,j}$ = Valley Counting ∈ the original signal for walking speed $i \wedge$ frequency j

$VC_{i,j'}$ = Valley Counting ∈ a downsampled signal for walking speed $i \wedge$ frequency j

In this manner, the results of this evaluation complement those of the previous section from a functional perspective. Specifically, they make it possible to assess the extent to which the information retained in the downsampled signals remains suitable for step-detection and step-counting applications.

Ethical Considerations

This study did not involve any direct experimentation with human participants or patients. The analyses were conducted exclusively using secondary data derived from a previously published study. All data sources were appropriately cited, and data use complied with the conditions and guidelines specified in the original publication. The original study that generated the dataset used in our secondary analysis is part of a broader body of work executed under the European Union's Horizon 2020 research and innovation program under the Marie Sklodowska-Curie grant agreement no. 823871 (iGame), and it was approved by the Ethics Committee of the Malaga Provincial Research of the Andalusian Health Service (RTC-iGAME 24092020). As reported by the authors of the original study, all participants accepted and signed the informed consent following the principles established in the Declaration of Helsinki.

Results

Preserved Information

Table 1 presents the mean preserved information values of the downsampled signals across all participants, grouped by sampling frequency.

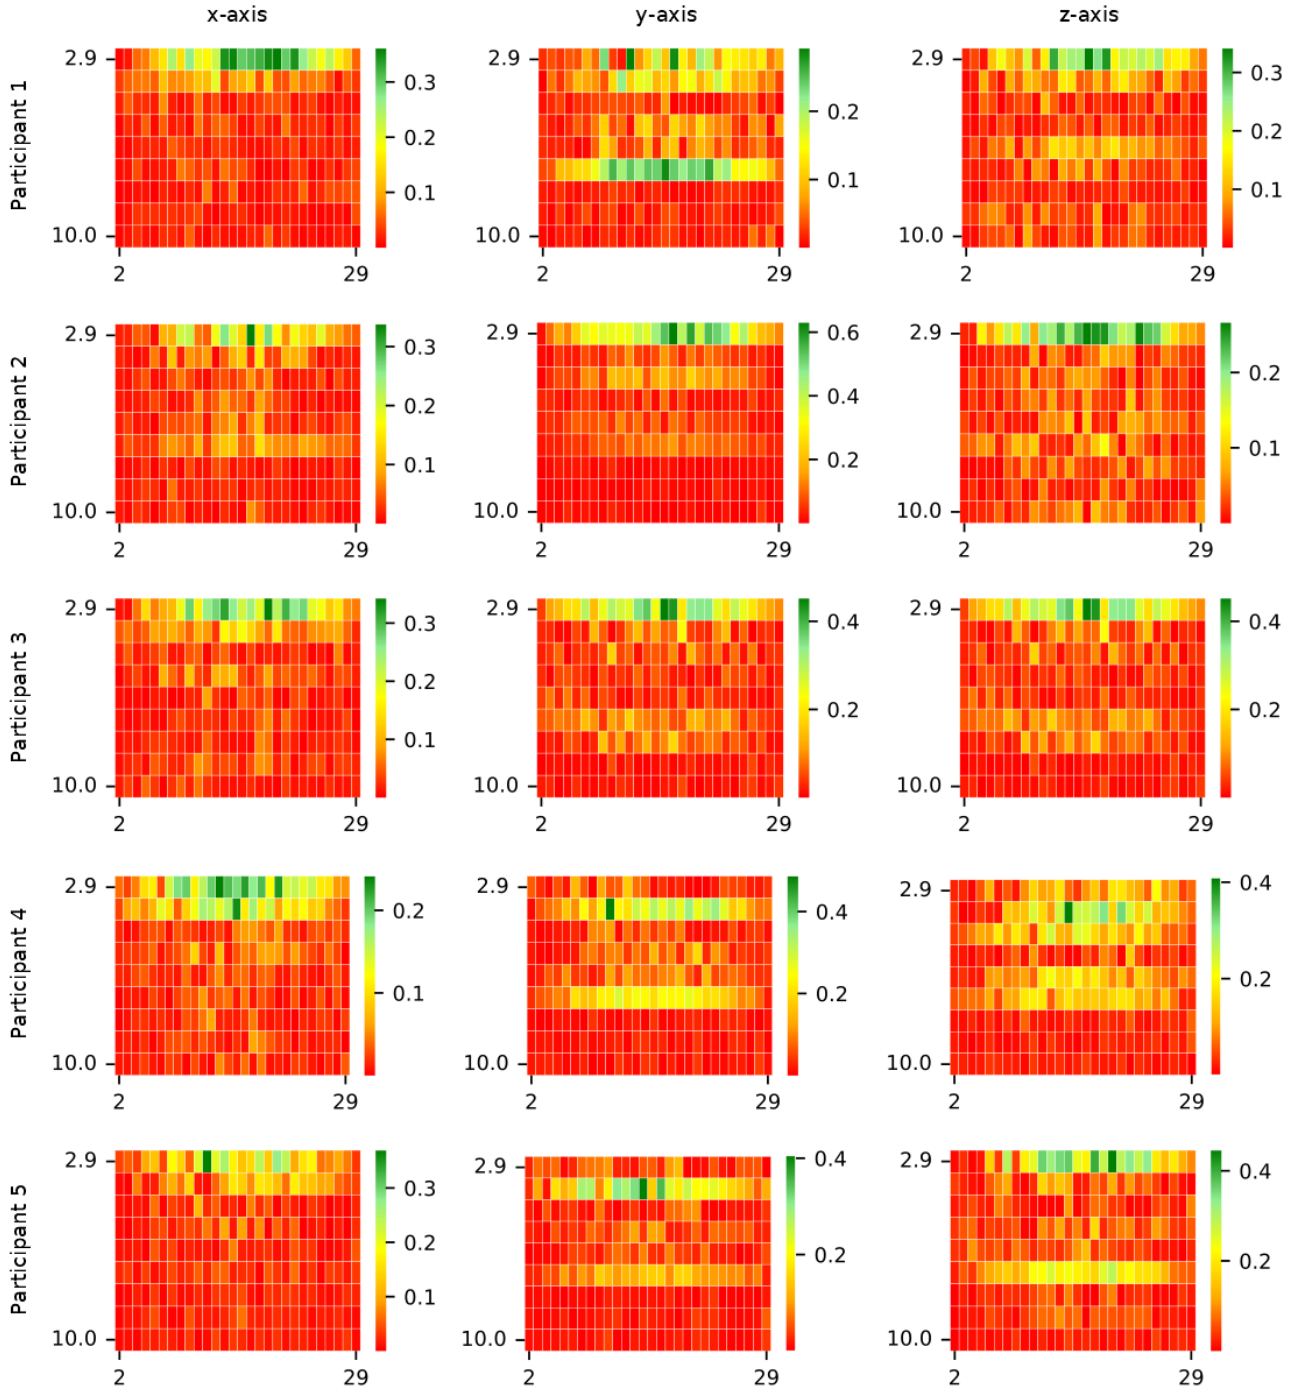
[a]Full visualization and detailed results of the deviation analysis validating these tendencies are available in Multimedia Appendix 2.



The results reveal a consistent decrease in $PI(X;Y)$ as the sampling frequency decreases. Specifically, the downsampled signals exhibit substantial information losses exceeding 91% at 2 Hz and 79% at 5 Hz. In contrast, information loss remains below 24% at 20 Hz, indicating a more moderate degradation of information.

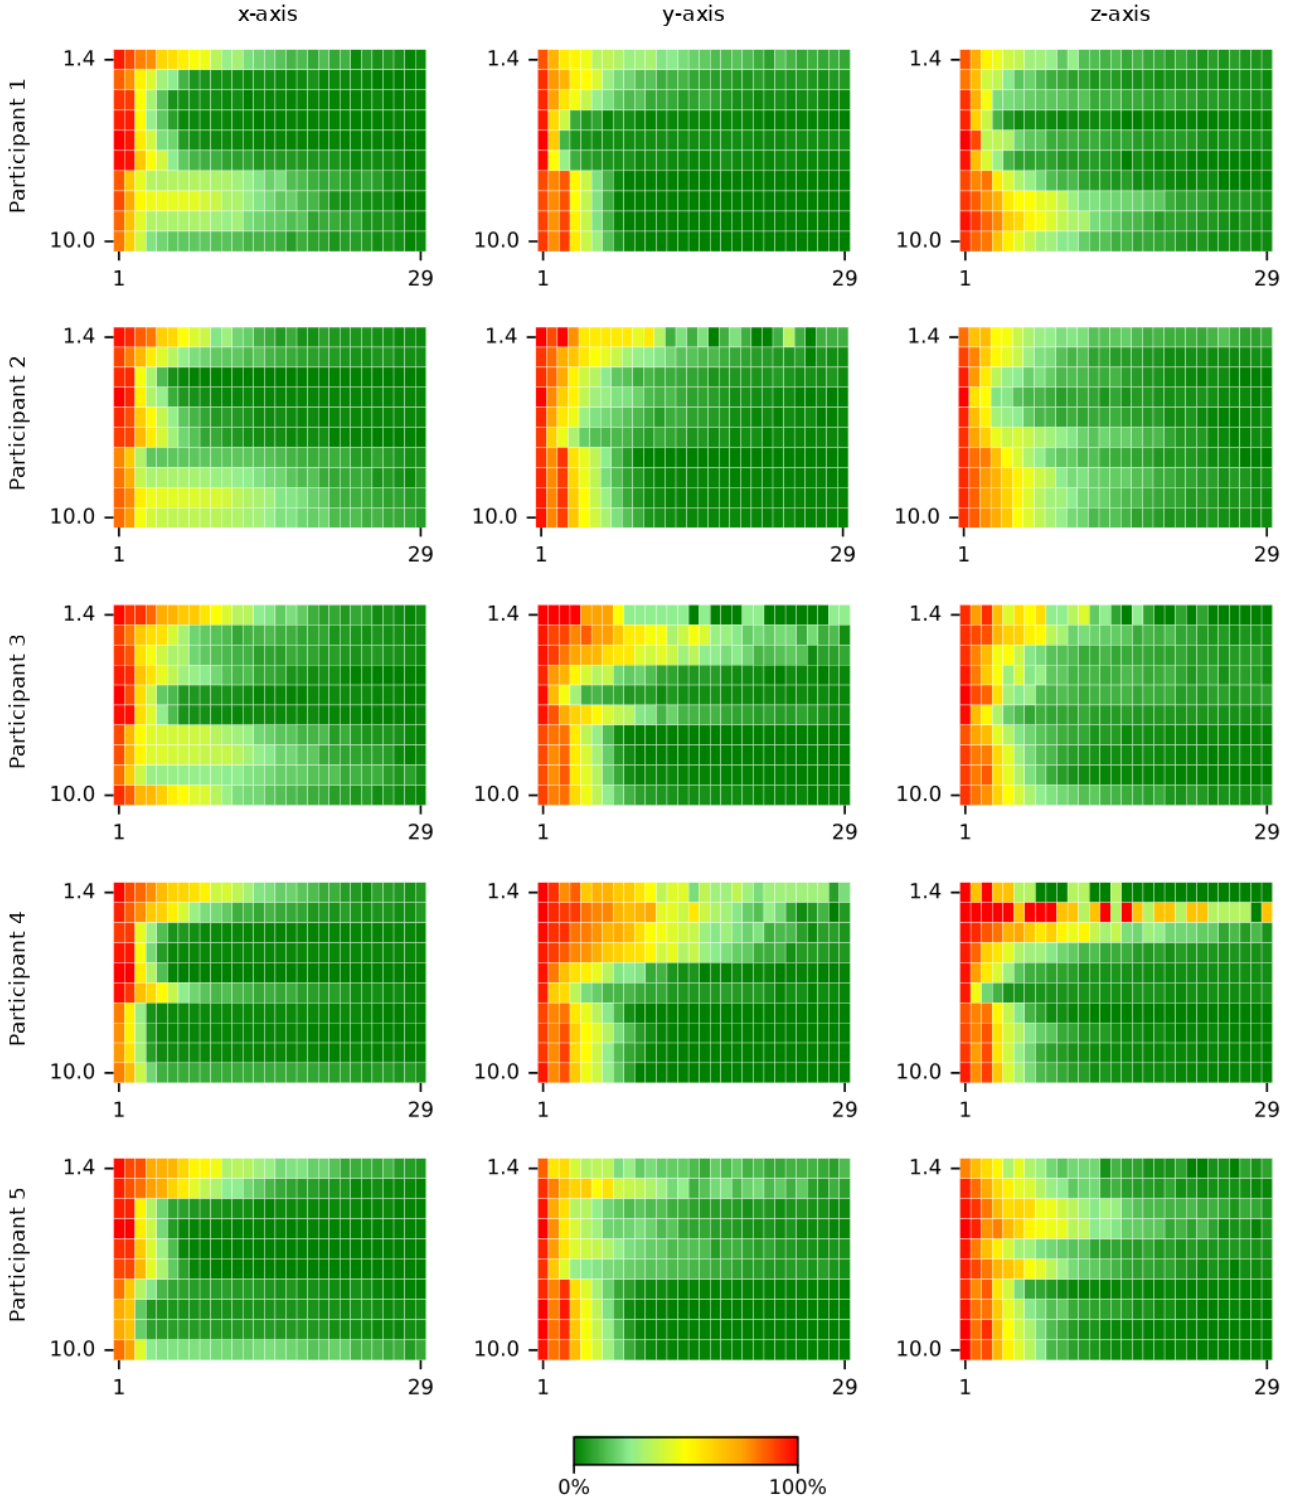
Changes in the Preserved Information

Figure 2 summarizes our preliminary findings regarding how preserved information varies with changes in walking speed and sampling frequency ($PI'(X;Y)$). Specifically, each cell within each heatmap represents the ratio between the changes in $PI(X;Y)$ associated with a stepwise increase in walking speed and the corresponding changes in $PI(X;Y)$ associated with a stepwise reduction in the accelerometer sampling frequency.

XSL•FO
RenderX

Figure 2. PI′(X;Y) values showing changes in preserved information as walking speed increases (from 1.4 to 2.9 km/h in the first row, from 2.9 to 4.3 km/h in the second row, and so forth) and sampling frequency decreases (from 30 to 29 Hz in the last column, from 29 to 28 Hz in the penultimate column, and so forth).

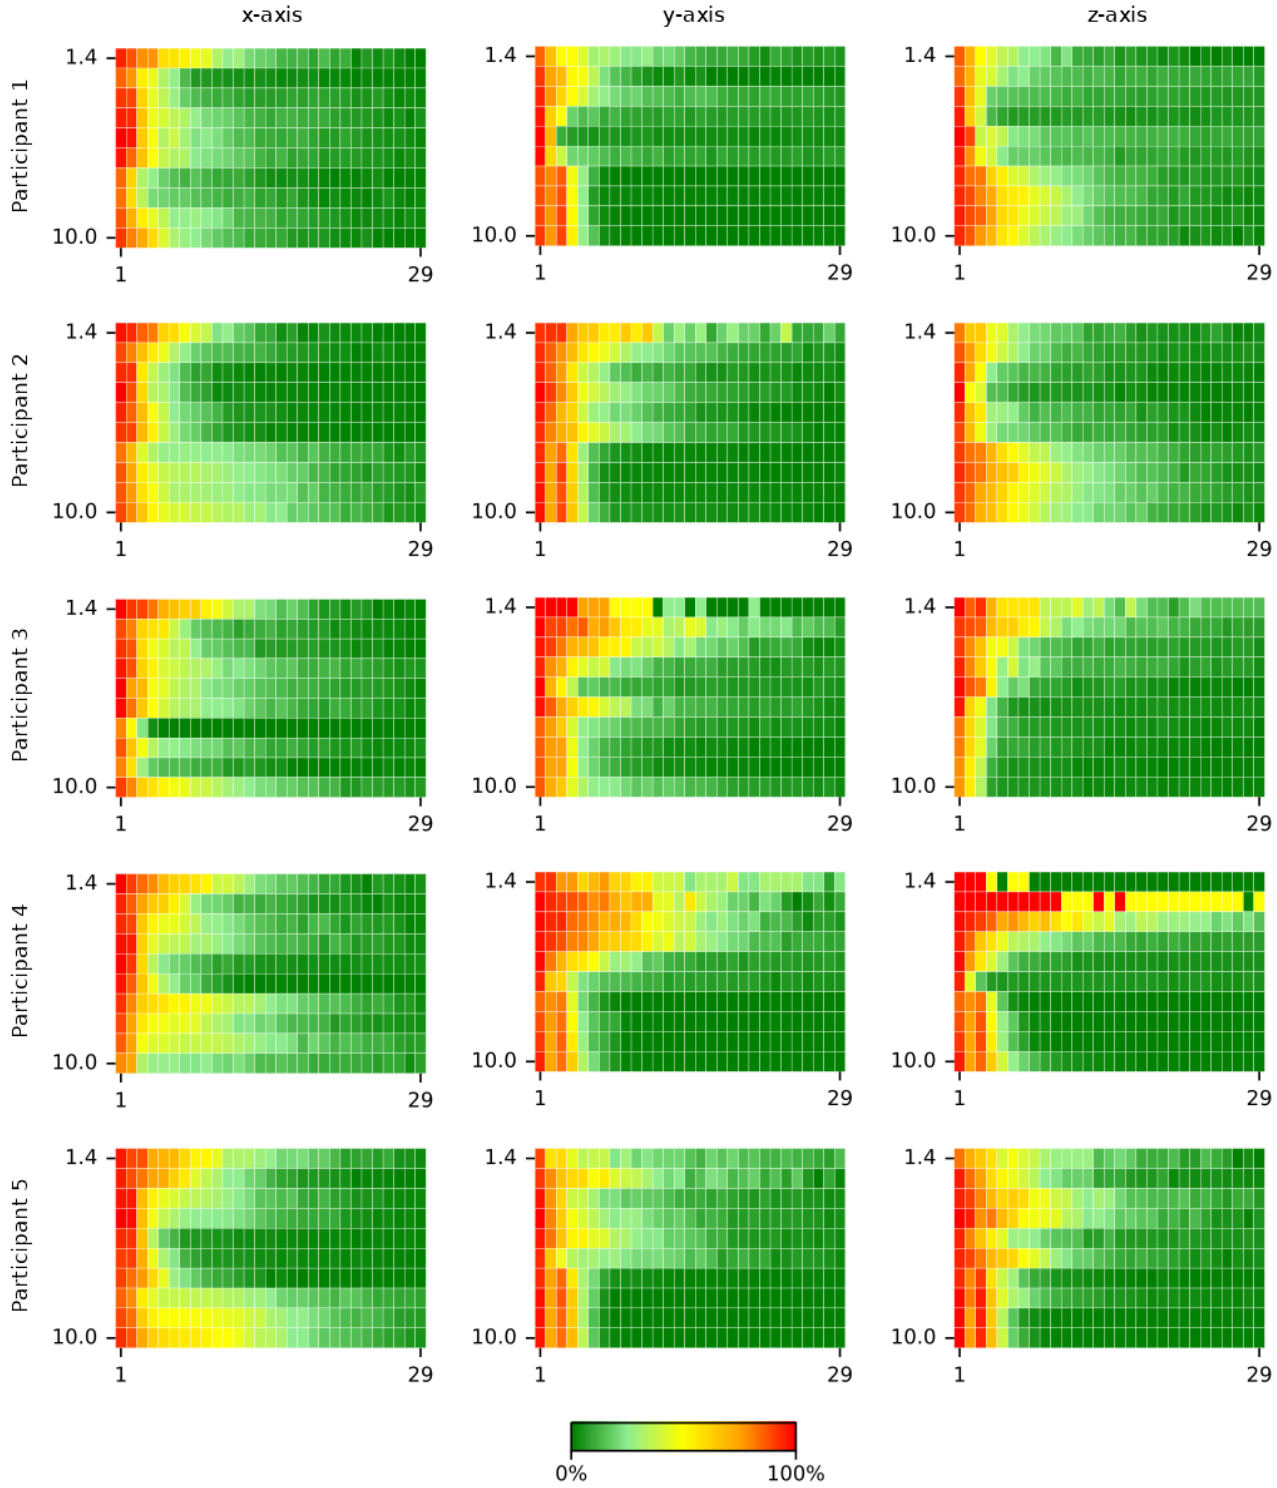
Across all participants and signal axes, substantial information losses are observed at both very low and very high sampling frequencies. However, no consistent pattern emerges when participants walk at speeds between 8 and 10 km/h.



In general, when participants walk at speeds between 1.4 and 2.9 km/h, information is preserved in all downsampled signals with only limited degradation at sampling frequencies between 7 and 25 Hz. However, this window progressively contracts as walking speed increases up to 6.5 km/h. For the y-axis, a noticeable increase in preserved information is observed for participants 1, 3, 4, and 5 when walking speed increases from 6.5 to 7.0 km/h. Although the cause of this behavior remains unclear, it does not alter the overall trends identified in this analysis.

Results From the Evaluation of the Downsampled Signals

Figures 3 and 4 present our preliminary findings on the percentage error calculated from the peaks and valleys detected in the original and downsampled signals of all participants.



XSL•FO
RenderX

Figure 3. Percentage error (PE) of peak counts in the original and downsampled signals across all participants, sampling frequencies, and walking speeds. In each heatmap, gait speed (km/h) is shown on the vertical axis and sampling frequency (Hz) on the horizontal axis.

XSL•FO
RenderX

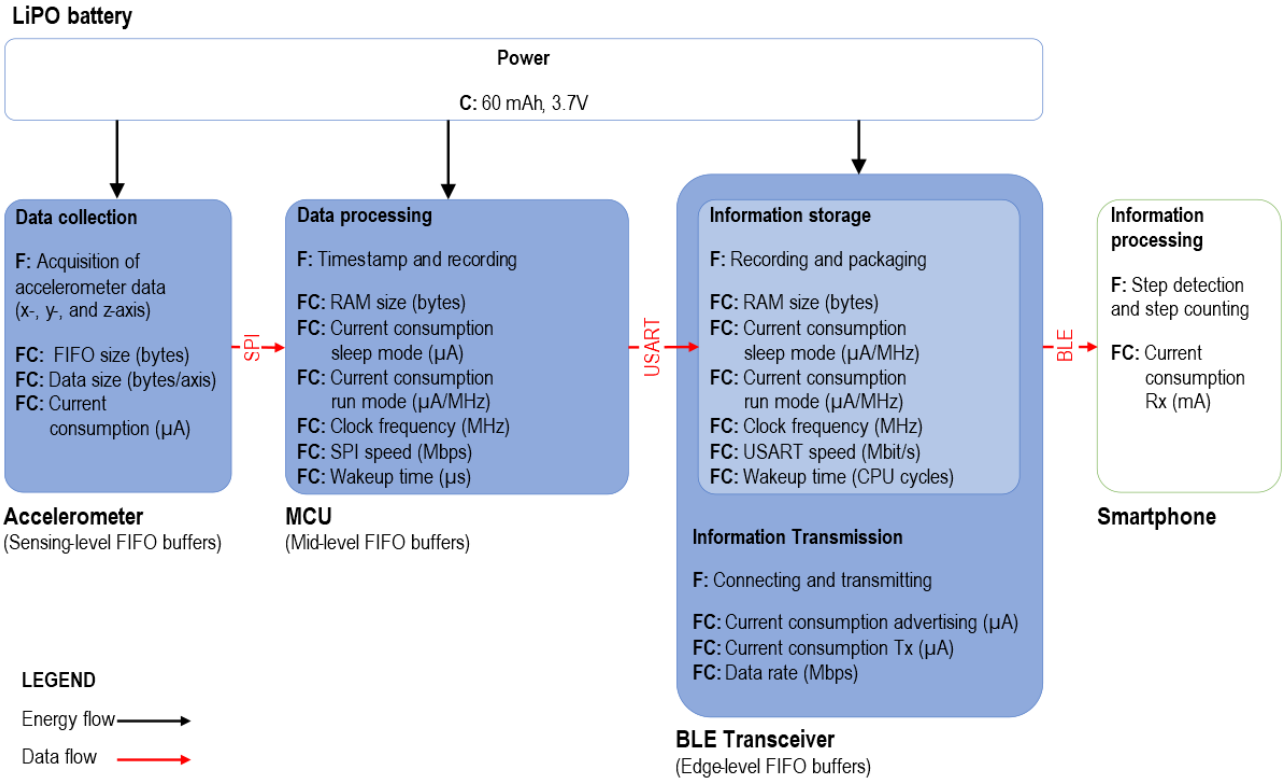
Figure 4. Percentage error (PE) of valley counts in the original and downsampled signals across all participants, sampling frequencies, and walking speeds. In each heatmap, gait speed (km/h) is shown on the vertical axis and sampling frequency (Hz) on the horizontal axis.

Across all participants and signal axes, the percentage error associated with peak and valley counts remains very high for downsampled signals sampled at very low frequencies (below 3 Hz). This result suggests that such signals are unlikely to support reliable step detection, regardless of walking speed.

In addition, the suitability of downsampled signals for step detection on the y-axis appears to deteriorate at walking speeds below 6 km/h when sampling frequencies fall below approximately 11 Hz. Under these conditions, the percentage error approaches 80%, suggesting a substantial reduction in detection performance.

Design Delineation of Frugal Smartbands

The preliminary results presented in Figures 2-4 suggest that sampling frequencies around 15 Hz are likely sufficient to preserve the information for step detection during normal walking (ie, between 4.3 and 7 km/h). In addition, a broader frequency range (approximately 11 - 25 Hz) may remain



XSL•FO
RenderX

suitable when individuals walk at very slow speeds (below 3 km/h).

In practice, these relationships between sampling frequency, walking speed, and information preservation for effective step detection are often difficult to determine during the design of WAM devices. As a result, research and development efforts frequently rely on resource-intensive dynamic sampling strategies, including optimized duty-cycling approaches, on-chip processing, and advanced computing components. In this exploratory work, we use the findings from our secondary data analysis to examine how variations in sampling frequency and walking speed may influence the design of frugal smartbands. Specifically, we establish a set of hardware archetypes capable of supporting a suboptimal algorithm operating under different sampling rates. This approach allows us to define a worst-case scenario for energy consumption and user-behavior uncertainty, thereby providing insight into the robustness of the resulting devices.

To support this analysis, we adopt a simple asynchronous first-in-first-out (FIFO) strategy as the basis for communication between 3 essential hardware components. We then relate the data acquisition, processing, and transmission functions of these components to their respective capacities to model and estimate energy consumption and battery autonomy across different design archetypes and sampling frequencies, according to the framework presented in Figure 5.

Figure 5. Framework for constructing design archetypes of frugal smartbands based on a simple asynchronous first-in-first-out (FIFO) strategy and a mapping of the capacities (C), functions (F), and function-capacities (FC) of their essential electronic components (adapted from the sustainable IoT design framework proposed by Quisbert-Trujillo and Morfouli [28]). BLE: Bluetooth Low Energy; MCU: microcontroller; SPI: serial peripheral interface; USART: universal synchronous/asynchronous receiver transmitter.

Each archetype consists of 3 core elements: an accelerometer, an ARM-based microcontroller (MCU), and a Bluetooth Low Energy (BLE) transceiver powered by a 60 mAh LiPo battery and organized as an asynchronous FIFO-based system. The accelerometer continuously acquires triaxial samples, which are transferred in bursts through the MCU and BLE transceiver before being transmitted to a smartphone. The energy model incorporates the current consumption and operating duration of each component in low-power, run, and sleep modes, including wake-up, processing, and data transmission functions (*F*).

Battery autonomy is estimated from the available battery capacity and the energy required to fill and transmit a complete BLE FIFO buffer, following the approach described by Tarkoma et al [48]. Because the FIFO filling time is determined by the accelerometer sampling frequency, this parameter directly influences the run and sleep durations of the remaining components and, consequently, the overall energy consumption of the system. Other factors affecting battery autonomy include communication throughput, processor clock frequency, workload, and FIFO/RAM capacities.

Using the component configurations and unfavorable operating conditions summarized in Tables 2 and 3, we evaluated all combinations of 4 accelerometers, 3 MCUs, and 3 BLE transceivers across multiple sampling frequencies. The objective was to identify the configurations capable of achieving at least 10 days of battery autonomy, a benchmark representative of current commercial wearable devices [49].

Accordingly, and considering the capacities and parameters summarized in Tables 2 and 3, our preliminary results suggest that midlevel FIFO buffers should not be implemented across the full memory capacity of microcontrollers with moderate or relatively large storage capacities (such as the MCU L053C8). Under these conditions, transferring and writing large amounts of buffered data would prolong the active periods of other components, particularly BLE transceivers, thereby increasing energy overhead and potentially reducing battery autonomy below 10 days. This effect may become more pronounced at higher accelerometer sampling frequencies (above 20 Hz), which accelerates FIFO saturation throughout the system.

Conversely, this limitation could be mitigated when FIFO buffers are implemented across the full memory capacity of edge-level components, particularly the WB55CC BLE transceiver, provided that efficient radio communication capacities are available.

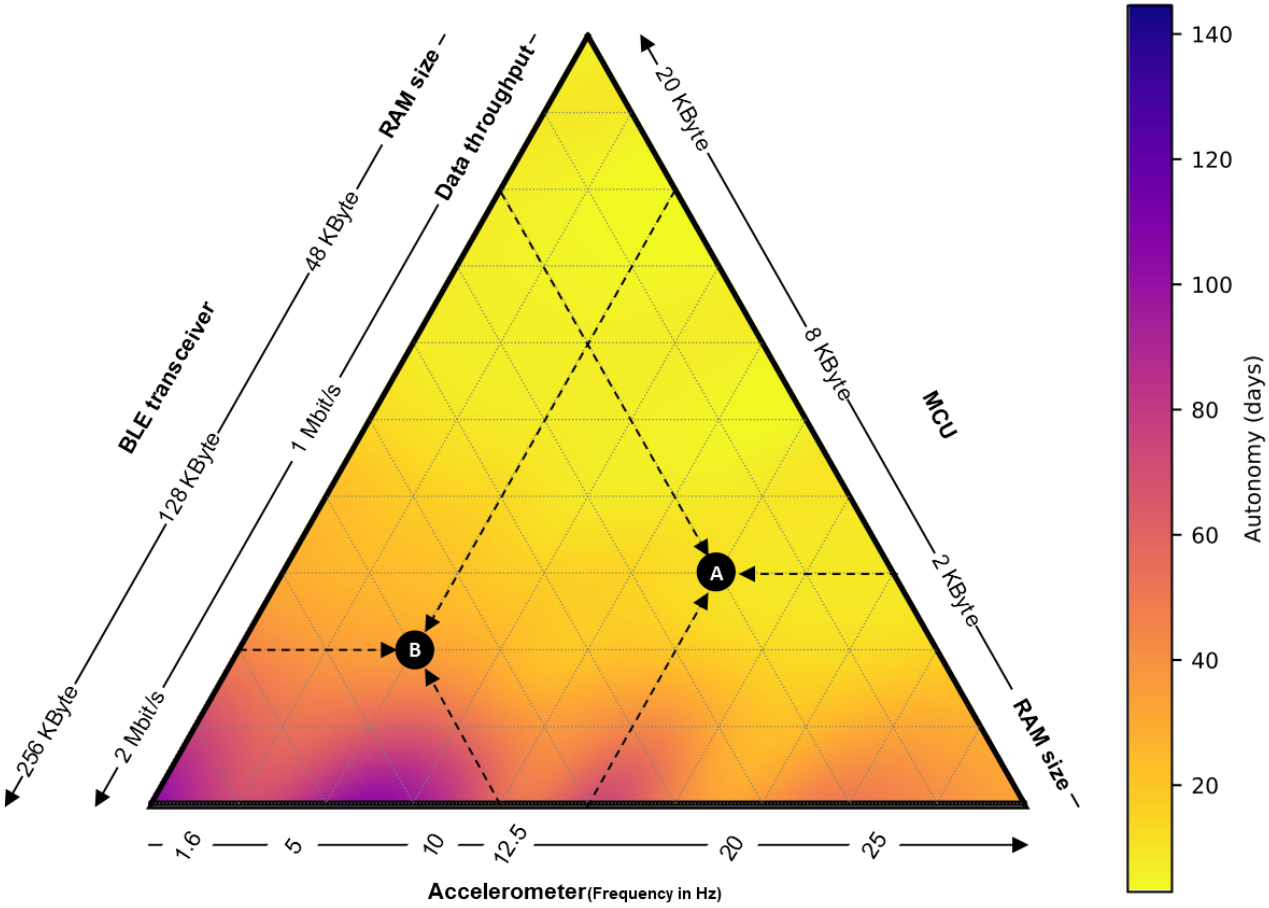

Figure 6 summarizes these findings in a practical framework intended to support the design of frugal yet robust smartbands for walking monitoring. The framework is based on the sensing, processing, storage, and transmission function-capacities (FC) of the electronic components that constitute the design archetypes evaluated in this study.

This preliminary framework helps visualize hardware trade-offs and the flexibility available for distributing computational workloads across system components. For example, point A suggests that designers should restrict MCUs to lightweight temporary storage functions and resource-constrained transceivers to simple data retransmission tasks. Such a configuration would support smartbands intended to operate primarily around 15 Hz while remaining close to a common commercial benchmark of approximately 10 days of battery autonomy.

In contrast, Point B indicates greater flexibility for implementing dynamic sampling strategies within the microprocessors of accelerometers, MCUs, or BLE transceivers. This configuration may be advantageous when supporting adaptive sampling frequencies below 12.5 Hz (but above 11 Hz), which correspond to situations in which users walk at very slow speeds. Under these conditions, a larger proportion of the available energy budget could potentially be allocated to onboard preprocessing or step-detection functions, as suggested by the estimated battery autonomy of 20 - 40 days, even under the unfavorable operating conditions considered in this analysis.

XSL•FO
RenderX

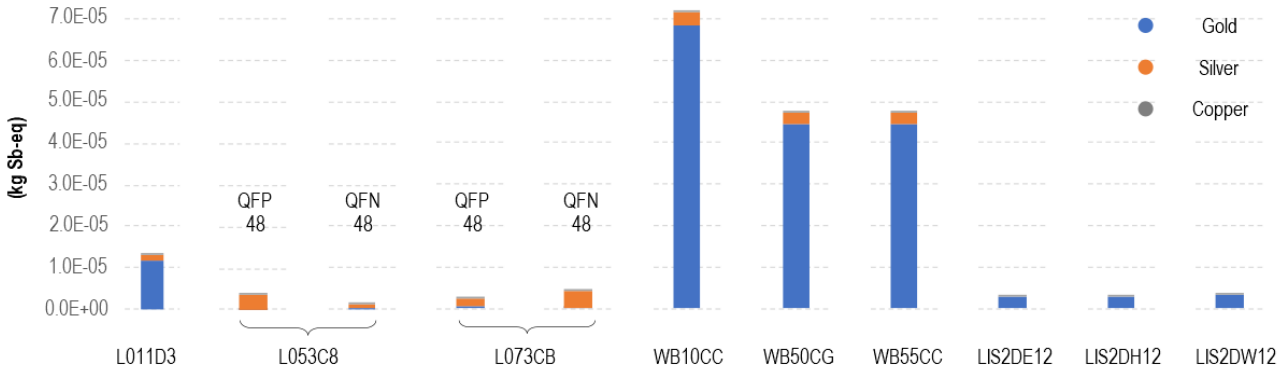

Figure 6. Practical design framework for frugal and efficient smartbands, according to the studied capacities of the electronic components that constitute the design archetypes. The scales on the right and left sides of the isosceles triangle show the RAM sizes of the studied microcontrollers (MCUs) and Bluetooth Low Energy (BLE) transceivers, as described in Table 3. The left scale also displays the data throughput of the BLE transceivers. The scale at the base shows the frequency range studied in our secondary data analysis, while the color scale on the rightmost side shows the battery autonomy range calculated from all combined function-capacities (FC) of the electronic components summarized in Figure 5, and the corresponding values and current consumptions reported in Tables 2 and 3. Each intersection within the triangle indicates the maximum battery autonomy (in days) associated with our worst-case use scenario, based on a suboptimal first-in-first-out (FIFO) strategy and on specific combinations of RAM capacity, communication throughput, and sampling frequency. For example, point A indicates that a battery autonomy below 20 days could be expected when combining a 2-Kbyte MCU RAM capacity (eg, provided by the L011D3 MCU) with a BLE transceiver offering less than 48 Kbytes of RAM and a data throughput below 1 Mbit/s (eg, the WB10CC transceiver) at an accelerometer sampling frequency of 15 Hz.

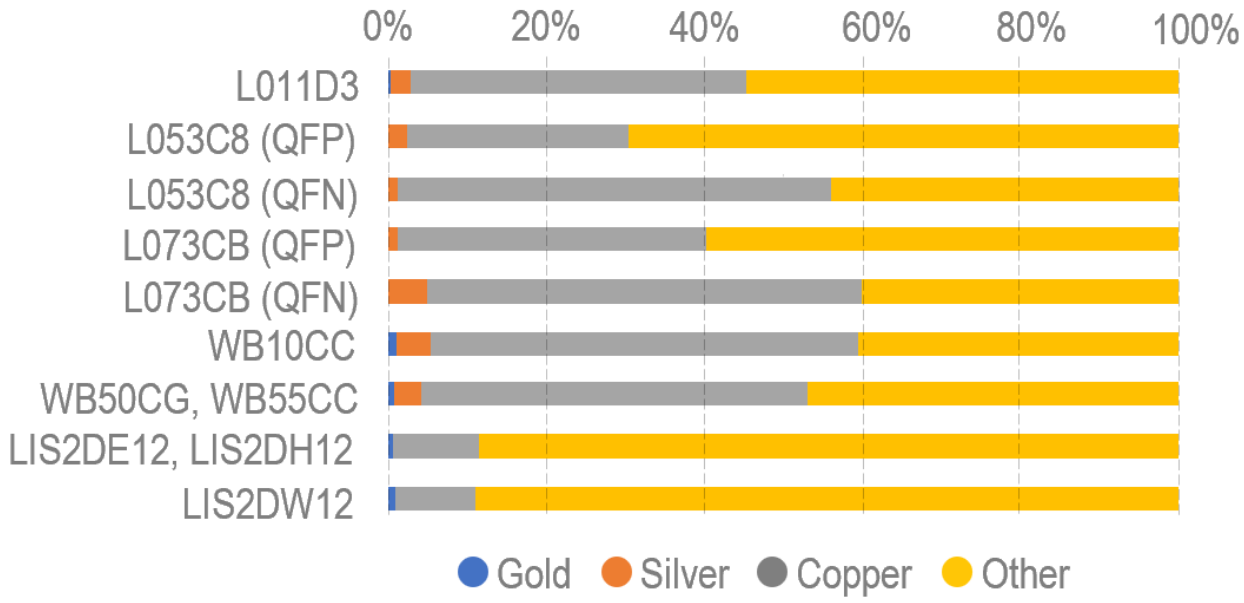
Environmental Impact Overview

Figure 7 presents the estimated resource depletion associated with the extraction of gold, silver, and copper required to manufacture the electronic components included in the design archetypes. Results for the MPU6000 accelerometer are unavailable because the manufacturer does not provide a material declaration.

Figure 7. Preliminary results showing the resource depletion incurred in the production of the electronic components of the design archetypes, according to the Environmental Footprint 3.1 assessment method [60], expressed in kg Sb-eq.



XSL•FO
RenderX

According to our preliminary estimates, BLE transceivers contribute the most to resource scarcity, primarily because of the relatively large amount of gold used in their bonding wires. A similar pattern is observed for the L011D3 microcontroller and for all accelerometers included in this analysis. Silver also contributes noticeably to the impacts associated with BLE transceivers and with all variants of the L053C8 and L073CB microcontrollers.

In contrast, copper contributes only marginally to the resource depletion results. However, its relatively high concentration in BLE transceivers and QFN-packaged microcontrollers suggests a considerable recovery potential under functional recycling scenarios, as illustrated in Figure 8.

Figure 8. Proportions of gold, silver, and copper in the electronic components that comprise the design archetypes.

Indeed, assuming a maximal functional recycling rate of 50% for gold, silver, and copper (as reported by Graedel [33]), substantial quantities of secondary copper could potentially be recovered and reintegrated into broader metallurgical production streams, as summarized in Table 8. Such material could also be reused in equivalent electronic applications following appropriate alloy adjustment processes, thereby establishing a defined lower bound for the recyclability potential of the resulting smartbands.

Table . Recovery yields of gold, silver, and copper in the studied electronic components that constitute the design archetypes (in mg).

Electronic component	Gold	Silver	Copper
L011D3	9.15E-02	6.67E-01	1.15E+01
L053C8 (QFP)	1.00E-03	2.21E+00	2.57E+01
L053C8 (QFN)	1.00E-03	5.69E-01	2.81E+01
L073CB (QFP)	6.50E-03	1.10E+00	3.65E+01
L073CB (QFN)	1.00E-03	2.53E+00	2.83E+01
WB10CC	5.27E-01	2.23E+00	2.76E+01
WB50CG, WB55CC	3.45E-01	1.70E+00	2.44E+01
LIS2DE12, LIS2DH12	2.20E-02	0.00E+00	4.34E-01
LIS2DW12	2.50E-02	0.00E+00	3.04E-01

However, realizing this recovery potential would depend on the effective implementation of closed-loop recycling strategies, as well as on the selective dismantling and segregated treatment of these components rather than their disposal within mixed electronic waste streams.

Discussion

Comparison With Prior Work

Various authors have successfully developed high-performing algorithms for wearables that maintain high accuracy even at very low sampling frequencies. For example, Straczkiewicz et al [61] developed a walking-recognition algorithm for smartwatches and wearable accelerometers capable of detecting

XSL•FO
RenderX

and tracking activity periods with high sensitivity while operating at a sampling rate of 10 Hz. Likewise, other researchers have reported advanced step-counting algorithms achieving accuracies above 90% at sampling rates of at least 8 Hz, regardless of the device's orientation [47].

The novelty of this exploratory work lies in moving beyond these algorithm-centered perspectives by focusing on the information content of the signals themselves. Specifically, we systematically quantify both the information preserved in downsampled accelerometer signals and their potential viability for step detection. By doing so, we provide designers and researchers with practical insights into how these two related aspects may influence not only the development of step-counting algorithms but also the early design and preliminary environmental assessment of frugal PA monitoring devices operating under baseline commercial constraints (ie, battery autonomy).

Our preliminary findings, based on the analysis of signals originally sampled at 30 Hz, reinforce the idea that triaxial accelerometer information remains useful for step detection during normal walking even at relatively low sampling frequencies (eg, below 15 Hz).

At the same time, our estimates suggest that signals sampled at very low frequencies (eg, below 3 Hz) retain limited information for reliable step detection and counting. Interestingly, our preliminary analysis also indicates that high frequencies (ie, above 26 Hz) may present limitations under certain conditions, particularly when individuals walk at low speeds, a tendency consistent with the observations of Fokkema et al [62]. Furthermore, when participants walk at very low speeds (2.9 or 4.3 km/h), information appears to be preserved and used more effectively within an intermediate frequency range between 11 and 25 Hz. Nevertheless, these observations should be interpreted with caution. Rather than generalizing the results across all signal axes, each axis should be considered separately, as evidenced by the percentage errors exceeding 80% for peak and valley detection along the y-axis.

Beyond signal analysis, the framework presented in Figure 6 extends previous research on medical-device design by providing an initial tool for delineating frugal smartband architectures during the early stages of product development, as recommended by Smith et al [63]. More specifically, it establishes a set of design archetypes that clarify how minimal hardware resources can be allocated according to different smartband usage requirements, consistent with the recommendations of Seva et al [64] regarding early Medical Device Readiness Levels.

From the perspective of environmental assessment within early HTA, our exploratory work offers an overview of several factors that influence the lifecycle of frugal devices. In particular, the environmental screening of the raw materials present in the electronic components that constitute the design archetypes identifies gold as a major contributor to resource depletion during production while simultaneously highlighting the potential importance of copper recovery during end-of-life management.

In addition, the framework presented in Figure 6 supports the initial formulation of preliminary operational scenarios for WAM devices based on component-level technical constraints. This capability helps reduce uncertainty regarding energy consumption, device performance, and user behavior during the early Technology Readiness Levels of new products, thereby addressing the well-recognized challenge of identifying pivotal parameters in early prototype assessments [24].

Overall, the proposed information-driven approach complements existing perspectives on the environmental assessment and design of wearable devices by providing both empirical quantification and practical decision-support tools. Specifically, the present work operationalizes the laboratory-scale assessment and use-scenario modeling activities described by Wentz et al [65] to estimate resource depletion and energy consumption at the prototype stage, thereby supporting the design of frugal smartbands through worst-case performance analyses. Similarly, this exploratory work provides an early-design instrument that facilitates the practical implementation of the broad recommendations synthesized by Gurova et al [66], particularly those related to energy efficiency and the allocation of computational and storage resources.

Limitations

It is important to acknowledge the limitations of this exploratory study, as they directly affect the interpretation and generalizability of our preliminary findings.

First, our streamlined sustainability analysis of the electronic components included in the design archetypes was limited to a single environmental impact category. As a result, this analysis provides only a partial environmental perspective on WAM devices and should not be used in isolation as a substitute for a complete LCA or HTA.

Second, the secondary data analysis used to identify the "edge zones" associated with substantial information loss in accelerometer signals was based on a relatively small dataset comprising gait tests from only 5 healthy participants, each recorded for a maximum of 120 seconds. In addition, all data considered in this exploratory study were collected using a specific research-grade WAM device worn exclusively on the wrist. Consequently, both our preliminary findings and the resulting design recommendations should be interpreted with caution, particularly when considering applications beyond the specific population, device configuration, and experimental conditions examined in this study.

Third, several important dimensions typically considered within HTA were outside the scope of this work. These include broader socioeconomic aspects such as cost-effectiveness, robustness, and ease of repair. Accordingly, our objective was not to perform a complete HTA, but rather to provide a preliminary evaluation instrument for use during the early stages of device design.

Finally, caution is warranted when relating the results of our secondary data analysis to studies that compare accelerometer signals obtained from different devices. At present, no evidence supports the use of cubic spline interpolation to resample distinct signals prior to rigorous comparative analyses. Therefore, the

XSL•FO
RenderX

findings reported here should not be interpreted as validation of such an approach in cross-device comparison studies.

Conclusions and Perspectives

This exploratory study investigated how the degradation of intrinsic information contained in accelerometer data influences the acquisition and use of knowledge and the management of uncertainty during the early-stage design and preliminary sustainability assessment of frugal WAM devices. To answer this research question, we quantified both the preservation and practical utility of information contained in degraded accelerometer signals collected at different motion velocities. This knowledge was subsequently used to examine uncertainties related to user behavior and energy consumption during the early design of WAM device archetypes.

Overall, our preliminary findings suggest that both sampling frequency and gait speed play a critical role in determining how much information can be preserved and effectively used when individuals move at normal walking speeds. Based on the patterns identified in these variables, we observed the existence of "edge zones" in which information loss negatively influences the basic mechanisms used to detect gait-related PA (ie, peak and valley counting). These zones also influence hardware trade-offs, computational load allocation, and environmental screening activities performed during the early stages of device conception.

In this manner, this exploratory study provides initial tools and practical insights that may help address some of the challenges and paradoxes that complicate HTA and LCA during the early design and development of WAM devices. Through our secondary data analysis, we extend current knowledge regarding the minimum data requirements that researchers and designers should consider when developing gait-recognition solutions under different sampling conditions.

Furthermore, the application of the design framework presented in Figure 6 provides preliminary evidence that austere hardware architectures combined with limited data inputs may still achieve acceptable operational performance, offering a potential alternative to unnecessarily complex electronic designs. Finally, the integrative framework and environmental screening proposed in this work may assist HTA practitioners and regulatory bodies in developing an initial understanding of some factors contributing to the ecological burden of WAM devices, particularly those associated with raw materials during production and end-of-life stages within a usage-oriented context.

Nevertheless, these tools and insights should be interpreted and applied cautiously. The findings of this exploratory study remain constrained by two main factors: (1) the limited scope of the environmental overview, which focused exclusively on a single environmental impact category, and (2) the relatively small dataset used in the secondary data analysis.

More broadly, this work illustrates the application of part I of our previous methodology for the sustainability assessment and development of IoMT [25]. In the present study, this methodology was applied to the specific context of wearable devices, with particular emphasis on how uncertainty and information influence the early assessment and sustainable design of smartband prototypes. The applicability of our preliminary findings to final products will be examined in part II of the methodology, which will be detailed in a forthcoming study. This future work will benefit from richer proprietary datasets generated through our ongoing investigations of unsupervised mobility, involving the assessment of average daily steps in large cohorts of participants with motor impairments (ie, more than 100 individuals) monitored through consumer-grade wearables under free-living conditions [67,68]. These datasets will enable a more robust evaluation of the preliminary observations derived from the secondary data analysis presented here. Likewise, the clinical outcomes and socioeconomic implications of frugal devices derived from the proposed design archetypes remain important topics for future investigation.

Finally, extending this line of research to other domains, such as medical imaging, represents a promising opportunity to further investigate how information influences both clinical accuracy and the environmental impact of medical devices. This is particularly relevant in fields where these outcomes depend directly on the quantity and quality of the underlying data.

Through these future investigations, we aim to gather additional evidence to examine one of the central hypotheses underpinning our broader research program that "information is the message from which a sustainable digital-based health service or paradigm can exist, and with which specific barriers for integral assessment and eco design can be surpassed" [25].

Funding

This work was partially supported by funding from the French government, managed by the National Research Agency (ANR) under the France 2030 program MIAI Cluster (ANR-23-IACL-0006) and under the "Investissements d'avenir" program (ANR-10-AIRT-05 and ANR-15-IDEX-02). This work also forms part of a broader translational and interdisciplinary GaitAlps research program (to NV).

Abstract

Background: Continuous glucose monitoring (CGM) can facilitate weight management and lower the risk of metabolic diseases by providing real-time feedback on glycemic responses, thereby enabling more informed lifestyle decisions. However, current CGM systems remain constrained by invasiveness, cost, and short sensor lifespan, limiting their practicality for guiding individualized postprandial low-glycemic diets.

Objective: Extending earlier proof-of-concept findings, this study aimed to validate an interstitial glucose (IG) machine learning algorithm in real-world environments using multimodal, continuous data collected from wearable sensors and smartwatches. In the long term, we aim to embed a noninvasive, sensor-based algorithm for estimating tissue glucose within mobile health apps and postprandial low-glycemic diet frameworks to enable scalable, personalized prevention strategies.

Methods: We conducted a 2-week study phase during which participants continuously wore 2 noninvasive sensor devices: a scientific sensor wristband (Empatica EmbracePlus) and a commercially available smartwatch (Fitbit Sense 2). As a reference measurement, an invasive CGM sensor (Abbott FreeStyle Libre 3) measured IG levels. For metabolic characterization, 1-point fasting blood and urine samples were collected, and deep phenotyping using state-of-the-art nuclear magnetic resonance spectroscopy and bioelectrical impedance analysis was performed. For participants with overweight and obesity, clinical standard parameters focusing on glucose metabolism were analyzed.

Results: A total of 74 participants, 34 (46%) healthy controls and 40 (54%) metabolically at-risk (MR) individuals, simultaneously used an invasive CGM device together with 2 noninvasive wristbands over 2 weeks. Healthy controls were characterized by a mean age of 24.53 (SD 3.68) years and a mean BMI of 22.36 (SD 2.16) kg/m². In contrast, the MR cohort had a mean age of 55.38 (SD 15.08) years and a mean BMI of 35.38 (SD 4.91) kg/m². Furthermore, the MR cohort showed elevated fasting glucose levels (mean 107.56, SD 19.26 mg/dL), hemoglobin A_{1c} levels (mean 5.67%, SD 0.63%), and an increased homeostatic model assessment of insulin resistance index (mean 4.34, SD 3.49), indicating a disturbed glucose metabolism. The proposed long short-term memory network based on feature vectors obtained the best IG prediction performance, with an average root-mean-squared error of 21.04 (SD 8.32) mg/dL and 98.3% of predictions in zones A and B of the Clarke error grid analysis, representing a high level of predictive accuracy. In addition, based on data from a smartwatch, we achieved a comparable average root-mean-squared error of 23.49 (SD 11.46) mg/dL for the overall cohort.

Conclusions: This study demonstrates that IG levels can be predicted from multimodal, noninvasive wearable sensor data using a machine learning approach under real-world conditions. While further validation in larger and more diverse cohorts is warranted,

continuous glucose monitoring; wearables; interstitial glucose; machine learning algorithm; personalized nutrition

Introduction

Maintaining glucose homeostasis is beneficial not only for patients with type 2 diabetes (T2D) but also for healthy individuals. Stable blood glucose (BG) levels are crucial for body weight control and preventing risks such as metaflammation, insulin resistance, and associated conditions such as cardiovascular diseases, cancer, acne, migraine, and neurodegenerative diseases, indicating a wide range of applications [1-3].

A high postprandial glucose response (PPGR) can lead to postprandial hyperinsulinemia, glucotoxicity, lipogenesis, and visceral obesity [4]. Although diet is a major determinant of PPGR, standardized dietary recommendations frequently fail in practice, as eating behavior is strongly influenced by individual preferences, taste, cultural patterns, and daily routines. These factors make dietary responses and adherence highly variable. Personalized nutrition addresses this challenge by tailoring guidance to each individual's unique habits and preferences rather than imposing a uniform diet. Previous studies have shown promising results for personalized diets in avoiding glucose spikes, thereby addressing the individual nature of PPGRs [5,6]. As an example, digital postprandial low-glycemic diets (PLGD) based on continuous glucose monitoring (CGM) have shown effectiveness for individuals with prediabetes or diabetes and migraine [7,8].

While CGM is commonly used to measure interstitial glucose (IG) levels [9], it has limitations, including invasiveness, inconvenience, high cost, limited sensor lifespan, and environmental impact [10]. Noninvasive sensor technologies offer a potential solution for real-time calculation of glucose levels through longitudinal monitoring of physiological parameters, thereby providing a foundation of individualized, adaptive, and dynamic day-to-day recommendations. Early research has examined the influence of physiological parameters on food intake and the associated development of obesity [11]. Some approaches focus on the development of noninvasive continuous glucose monitors based on optoacoustic signals [12] or microwave technology [13,14], while others seek to use existing sensor systems. Nowadays, a wide variety of wearable devices capable of continuously monitoring diverse biosignals are commonly used in everyday life (eg, smartphones, smartwatches, and fitness trackers). When combined with modern machine learning (ML) algorithms, these technologies offer the potential to elucidate relationships between physiological parameters and food intake [15], thereby enabling personalized dietary guidance. Initial data demonstrate the ability to predict IG values in real time using physiological parameters and dietary information [16-18]. However, these algorithms depend on the manual entry of daily dietary information, a process that demands considerable user adherence and is inherently time-consuming, subjective, and susceptible to error. In prior research, we demonstrated the feasibility of predicting IG levels using data from noninvasive sensors coupled with ML algorithms without using food logs. This approach yielded robust results in young, healthy individuals when assessed in controlled settings using standardized test meals, including oral glucose tolerance tests and mixed-meal tests [19].

Given the current constraints of invasive CGM and food diary–based PPGR prediction models, there is a significant opportunity to expand the availability of digital PLGD solutions. Particularly in the context of mobile health (mHealth), calculating BG levels based on noninvasive sensor data using ML algorithms represents a significant milestone. The availability of wearables such as smartwatches, smart rings, and wristbands is steadily increasing, and using these data, BG levels and trends could be calculated in the future. In combination with low-level, user-friendly documentation tools based on photos and voice recordings, individual dietary habits could be easily tracked. A corresponding mHealth tool could then provide PLGD recommendations based on individual predictions of food reactions. This scalable mHealth tool could make PLGD accessible to the global population and, therefore, become a key application for prevention and health management in the future.

To establish the foundation of this mHealth app, address the challenges of current CGM devices, and adapt our algorithm to realistic, real-world use, we conducted a 2-week study under everyday conditions with a habitual diet. During this study, we analyzed CGM data of both healthy individuals and metabolically at-risk (MR) individuals (with overweight or obesity). We included MR participants with disturbances in glucose metabolism and insulin resistance, potentially generating aberrant IG signals, to challenge our algorithm and evaluate its performance with more complex data. For noninvasive data collection, we used 2 devices: a clinically designed sensor wristband and a commercially available smartwatch. The study had 3 aims. First, we evaluated the ML algorithm to calculate IG values under real-world conditions involving complex, mixed meals. Second, we examined its generalizability across healthy and MR individuals based on the assumption that insulin resistance may alter physiological signals and reduce predictive accuracy. Third, we assessed device independence by implementing a proof-of-concept version on a commercially available smartwatch to determine whether the algorithm maintains its performance across different wearable platforms.

Methods

Ethical Considerations

The study examined healthy adults and adults with overweight. The study was approved by the Ethics Committee of the University of Luebeck (Az 2022 - 550 and 2024 - 363) according to Good Clinical Practice. Potential participants were recruited through posters, social media, and newspaper articles in northern Germany. The inclusion and exclusion criteria were deliberately broad, encompassing adults with sufficient German language proficiency to comprehend the study materials and able to operate a smartphone. Participants in the MR cohort were either overweight with at least one known metabolic comorbidity, such as hypertension, dyslipidemia, atherosclerosis, insulin resistance, gout, stroke, or heart failure, or classified as obese. All participants provided written informed consent prior to their inclusion in the study. As part of the consent process, the participants were informed about the data protection measures, the voluntary nature of study participation, and their right to withdraw from the study at any time without giving a reason and without any disadvantages. In accordance with applicable data protection regulations, the participants' data were deidentified. The data were analyzed in pseudonymized form solely for the purposes of the study. No compensation was paid for participating in this study.

Study Cohort and Design

In total, 74 adults (women: n=54, 73%; and men: n=20, 27%), aged between 19 and 84 years, participated in this pilot study using an observational cohort study design. Participants were asked to wear 2 sensor wristbands as well as a CGM sensor on the upper arm continuously for 14 days. Otherwise, participants were expected to behave as usual and received no further instructions other than being asked to charge their wristbands regularly. During a clinic visit, blood and urine samples were collected, and a bioelectrical impedance analysis (BIA) measurement was performed.

In more detail, noninvasive wearable data from a scientific high-end device (Empatica EmbracePlus) and a commercially available smartwatch (Fitbit Sense 2) as well as IG data from an invasive CGM device (Abbott FreeStyle Libre 3) were collected over 14 days. First, Food and Drug Administration–confirmed noninvasive Empatica EmbracePlus measured skin temperature (STEMP) at 1 Hz, electrodermal activity (EDA) at 4 Hz, triaxial acceleration (taACC) at 32 Hz, sleep assessment (Sleep) at 0.017 Hz, and photoplethysmography (PPG), which produces a blood volume pulse (BVP) to calculate the interbeat interval in seconds and the pulse rate (Plr=60 seconds/interbeat interval) at 0.017 Hz. Second, Fitbit Sense 2 (Fitbit) quantified Plr at 0.2 Hz. Third, as reference values for our algorithm, continuous IG levels were measured by Food and Drug Administration–approved CGM devices every 5 minutes with a mean absolute relative difference of 7.8% [20]. In addition, participants kept a self-guided food diary with the help of an app (Perfood) to document their normal eating habits, activity, and sleep. However, these data were not included in this study, as the primary objective was to develop and optimize the algorithm itself, while the derivation of personalized nutritional recommendations will be addressed in a subsequent step in the future. Furthermore, study participants were deeply phenotyped. First, body composition was determined using BIA (Seca). Second, 1-point fasting blood and urine samples were collected to analyze individual metabolic profiles using nuclear magnetic resonance (NMR) spectroscopy. Third, for MR participants, characterized by overweight and obesity, clinical standard parameters were quantified, including complete blood count, lipid profiles, and liver parameters (glutamate-oxaloacetate transaminase, glutamate-pyruvate transaminase, and gamma-glutamyl transferase). Furthermore, glucose metabolism was characterized in detail by analyzing fasting glucose, insulin, homeostatic model assessment of insulin resistance, and hemoglobin A_{1c} (HbA_{1c}) levels to identify potential disorders indicating a prediabetic or diabetic status of the individuals.

NMR Spectroscopy

Serum samples were thawed at room temperature and prepared according to the standard operating procedure described by Dona et al [21]. In brief, samples were homogenized 1:1 (v/v) with a phosphate buffer (75 mM, pH 7.4) and cooled to 279 K in 5 mm NMR tubes prior to measurement. Following daily quality control procedures, including water suppression, quantification, and temperature checking, the samples were analyzed according to Bruker's in vitro diagnostic research protocol using a 600 MHz Avance III HD NMR spectrometer at 310 K. A 1D nuclear Overhauser effect spectroscopy experiment (pulse program: noesygppr1d) and a 1D Carr-Purcell-Meiboom-Gill spin-echo experiment (pulse program: cpmgpr1d) were acquired for each sample, and 39 metabolites (plus 2 technical additives) as well as 112 lipoproteins were quantified using Bruker's Quantification in Plasma/Serum (B.I.Quant-PS 2.0.0) and Bruker's in vitro diagnostic research Lipoprotein Subclass Analysis (B.I.-LISA) software. For lipid profiling, triglycerides, phospholipids, cholesterol, free cholesterol, and apolipoproteins were analyzed in very-low-density lipoprotein (VLDL), intermediate-density lipoprotein (IDL), low-density lipoprotein, and high-density lipoprotein (HDL; Tables S1 and S2 in Multimedia Appendix 1). Although urine samples were collected and analyzed according to standard procedures [21], these findings are not discussed further because the focus of this study is on BG outcomes.

Data Preprocessing

To facilitate rapid processing by the ML model, 4 essential preprocessing steps were implemented.

Data Formatting

In this study, 3 data formats were obtained from the different wearables: AVRO, CSV, and JSON. The CGM device provided IG responses (in mg/dL) in CSV format. EmbracePlus recorded daily physiological data in AVRO and CSV formats, including sensor recordings, time stamps, and frequency rates. To ensure accurate time information during preprocessing, Unix time stamps in GMT were computed and saved with each recording. The recorded value time stamps were calculated using frequency conversion from the initial sensor time stamp. Data collection

XSL•FO
RenderX

temporal variations were observed when daily recording start and end times were 15 minutes outside the midnight to 11:59 PM range. Fitbit sensor data were stored in JSON files containing GMT time stamps. Weight, height, age, sex, and BMI were used as demographic variables. The files were merged and converted to NumPy files for data analysis.

Data Cleaning

In accordance with standard procedures, the first and last days of CGM data collection were excluded to ensure proper sensor calibration and stabilization. Additionally, variations between participants were observed due to differences in the timing of the initial application and removal of the devices. As a result, our subsequent analyses were conducted using a dataset that comprised 12 of the 14 study days. In consideration of the temporal variability in data collection commencement and conclusion times, we opted to commence our analysis at 1 AM on the second day of the study and conclude it at 11 AM on the 13th day of the study. Afterward, we applied participant-specific outlier detection for artifact removal, that is, values more than 4 SDs from the individual mean were marked as invalid and substituted with the local mean, resulting in the removal of less than 0.2% of data points while preserving physiological validity and temporal continuity.

Data Alignment

To properly align the data, missing values, a fluctuating timespan between timesteps, and varying recording frequencies from the sensors had to be compensated for. To address this issue, an artificial timestep array was created. The sampling rate for the features or the prediction horizon (PH) for the labels determined the equidistant timesteps between the fixed start and end times that constrained this array. The primary objective of this approach was to standardize the temporal representation of available data and establish a coherent representation spanning from the start to the end. The next step was to select the data from the sensors that fell within the predefined period. The sensor modality data were then interpolated with a common sampling rate and their respective time information to match the predefined timesteps.

To accommodate the data characteristics of each sensor modality, a customized interpolation approach was adopted. For sensor signals that capture continuous numerical data, such as EDA, taACC, temperature, and plr, linear interpolation (LI) was implemented, with its mathematical formulation provided in equation 1. It estimates intermediate values by constructing a linear polynomial that passes through 2 consecutive known data points, denoted as (x_0, y_0) and (x_1, y_1). This process yields a piecewise linear representation that approximates the inherent continuous trend of the signal. In this context, ξLI(x) is the first-order polynomial interpolation operator. Given its modest computational overhead, LI remains a prevalent choice for inferring missing intermediate data points in the dataset.

(1)ξLI(x)=y0(x−x1x0−x1)+y1(x−x0x1−x0)

Notably, LI exhibits discontinuities in smoothness at subinterval boundaries, primarily due to its nondifferentiable nature at these junction points. To address this limitation, we evaluated alternative interpolation techniques for glucose-labeled datasets, where PH was used to define the interval between consecutive data points. One such method tested was nearest neighbor interpolation provided in equation 2. This approach assigns each new data point the value of its nearest existing data point, eliminating the need to compute intermediate values or derivatives. As a result, it retains the step-wise characteristic inherent to the original glucose data.d=argmini|x - xi|

(2)εNNI(x)=yd, d=arg mini|x−xi|

Here, (xi,yi) is a set of discrete data points for i=0, 1, 2, ... , n. ξNNI(x) represents the interpolated value at any point x. argmini|x-xi| denotes the index d for which the distance |x-xi| is the smallest.

Data Segmentation

We used a nonoverlapping window segmentation to segment the continuous multivariate time series into samples aligned with the PH, denoted as p. The source data were collected from multiple smartwatch sensors S = [s0, s1, ... , sn-1] with associated time stamps T = [t0, t1, ... , ti-1], which were divided into contiguous windows of length p minutes. Each window kx is constructed to encompass the sensor readings from the time interval [tωx-p, tωx] that immediately precedes the corresponding label ωx. This yields a set of windows K = [k0, k1, ..., kl-1] equal in number to the labels Ω=[ω0,ω1,...,ωl-1]. Consequently, for a fixed observation period, the number of training samples |K| decreases as p increases. This segmentation provides the foundational structure for subsequent supervised learning. All segmentation procedures were executed independently for each participant, ensuring that window construction and temporal indexing remained confined to each individual's sensor stream and label trajectory.

Feature Engineering

The complex physiological processes underlying glucose dynamics present a challenge for predicting BG levels [22]. Nevertheless, previous research identified correlations associated with specific extracted features and established the impact of personal demographics on BG responses [23,24]. For each nonoverlapped PH (PH=30 min), handcrafted features were extracted for all sensor modalities, considering their temporal characteristics [25]. In respect thereof, the sensor data were segmented into consecutive 1-minute windows. For every subwindow, a rich set of handcrafted features was computed for each available sensor signal as detailed in Table S3 in Multimedia Appendix 1. These included statistical and time domain descriptors, frequency and amplitude domain measures, and morphological indicators. Temporal context features were added to capture circadian and seasonal regularities. Demographic and anthropometric variables were incorporated to account for interindividual physiological variability. After feature extraction, all variables were concatenated across modalities and time windows to form the final multivariate input representation for the long short-term memory (LSTM) model. In total, 5 contextual and demographic features and 22 features per sensor modality were retained after preprocessing, yielding 159 features per minute per 30-minute observation window for the Empatica dataset and 27 features for the Fitbit dataset. No dimensionality reduction, embedding, or feature selection was applied, as the LSTM architecture was designed to learn

XSL•FO
RenderX

hierarchical temporal representations directly from the complete feature space. For more details on the feature engineering standards, see a study by Huang et al [19].

Model Characteristics

After data preprocessing and feature engineering, we fed the reformulated sensor data (feature vectors) to the LSTM network, which is an enhanced type of recurrent neural network designed to overcome issues such as vanishing gradients and gradient explosions in traditional recurrent neural networks. Using recurrent connections over time, LSTM is capable of capturing and maintaining dynamic temporal information. A key feature of LSTM cells is the use of 3 gating mechanisms, called input gate, forget gate, and output gate, which collectively regulate the flow of information. They use adaptive weights and activation functions to control whether information is retained, updated, or discarded. Specifically, the forget gate uses a sigmoid function to determine whether information from the previous hidden state should be dropped. The input gate, which combines both sigmoid and *tanh* functions, drives which parts of the new input should be stored in the cell state. The output gate then generates the new hidden state based on the updated cell state. In such a manner, the cell state functions as long-term memory, carrying stable information across time steps, while the hidden state serves as short-term memory.

In our implementation, the input to the LSTM consists of 2D sensor data (timesteps×features). The model architecture comprises 4 stacked LSTM layers with progressively decreasing hidden sizes, allowing the network to hierarchically extract temporal representations at different levels of abstraction. After the recurrent layers, the output of the last time step is passed through 2 fully connected layers with a nonlinear *tanh* activation in between, before being projected to the final scalar prediction. This architecture was determined empirically based on preliminary experiments and prior work on glucose forecasting tasks using physiological sensor data [19,26]. Hyperparameters, including the learning rate and hidden layer dimensions, were selected via a grid search performed on the validation partition of each leave-one-subject-out (LOSO) fold to optimize regression performance. This design enables the model to capture complex sequential dependencies while maintaining a compact representation for the final regression output.

Normalization and Data Leakage Prevention

The prediction task was modeled as a continuous regression problem. To stabilize training and ensure comparability across participants, both the input features and the target glucose values were standardized using fold-specific StandardScaler objects, which were fitted exclusively on the training participants within each LOSO fold. For the target variable, the mean and SD were estimated from the training participants and subsequently applied to the held-out participant. Likewise, each feature dimension was scaled using a StandardScaler fitted on the training data, with the resulting transformation applied to the test participant without incorporating any statistics from the held-out participant. All preprocessing operations that depend on the underlying data distributions, including feature and label standardization, were strictly confined to the training partition of each fold, thereby eliminating any risk of leakage of global statistics into the test data. This procedure ensures that both the features and labels of the held-out participant remain completely independent of the training data, while maintaining stable distributions for LSTM model training and subsequent regression performance evaluation.

Training Setup

The model was trained for 70 epochs with a batch size of 32 using PyTorch 2.7.1+cu128 in Python 3.11.13 on an NVIDIA RTX 5090 GPU with 32 GB RAM. The optimizer used was Adam (learning rate=0.001), while model optimization was guided by the mean absolute error (MAE; L1 loss), chosen for its stability and robustness to non-Gaussian error distributions in continuous glucose regression. During training, the model output remained in standardized units. Before evaluation, predictions (and targets when required) were transformed back to the original glucose scale using the inverse StandardScaler parameters of the respective LOSO fold to ensure clinically interpretable metrics.

Quantitative and Qualitative Evaluation

Clinical characteristics were compared between groups using nonparametric Mann-Whitney *U* tests. For BIA measurement and metabolic profiling, a correction for multiple testing using the method of Benjamini et al [27] with a false discovery rate of 1% was performed. Furthermore, linear and multiple linear regression analyses were conducted.

To properly evaluate performance, model effectiveness was examined across different PHs (15, 30, and 60 min) using the proposed LSTM and inverted transformer (iTransformer) models, based on the combined dataset from Empatica and Fitbit wearables. As a benchmark baseline, the iTransformer inverts the architecture by embedding the entire historical time series of each individual variable into an independent token. In detail, the model leverages a multilayer perceptron to transform the temporal sequence of each sensor modality into a high-dimensional vector. The self-attention mechanism is then applied across these variable tokens to capture multivariate correlations, while layer normalization and feed-forward networks characterize the temporal dynamics of each individual variable. This design allows the iTransformer to effectively learn complex intervariable dependencies from heterogeneous multisource wearable data, making it a highly robust benchmark for our study [28]. Algorithm model performance was evaluated using commonly used metrics: MAE, mean absolute percentage error (MAPE), and root-mean-squared error (RMSE). MAE quantifies the average absolute magnitude of errors to reflect overall accuracy, while MAPE measures the percentage deviation to provide a scale-independent metric for relative accuracy. To heavily penalize larger outliers, the mean squared error was computed to assess the average of squared differences. Finally, its square root, RMSE, was reported to express this error in the original measurement units for a more intuitive clinical interpretation. To qualitatively evaluate the model predictions, we performed Clarke error grid analysis (CEGA) [29], in which predefined zone A as clinically accurate predictions that would lead to correct treatment decisions, zone B as deviations that would not result in harmful clinical actions, zones C and D as errors potentially leading to unnecessary

XSL•FO
RenderX

overtreatment and failure to treat, respectively, and zone E as misguidance that could cause completely opposite and dangerous interventions.

CI Calculation

To ensure consistency in statistical comparisons across different cohorts and model conditions, we calculated 95% CIs for all RMSE and MAE metrics. These were derived using a nonparametric bootstrapping method with 1000 resamples. For each cross-validation fold, bootstrap samples were generated by conducting with-replacement random sampling from the model predictions and true glucose values, while maintaining independence at the individual level. In general, SE was calculated as SD/n with n as the number of LOSO folds to reflect the precision of the mean estimate, while 95% CI for RMSE and MAE means were derived from 1000 nonparametric bootstrap resampling, that is, 2.5th and 97.5th percentiles of bootstrap mean distributions. Thereby, narrow CI widths (consistent with SE×2) confirm robust mean performance estimates, even with moderate within-cohort variability. This procedure was consistently applied across all cohorts to ensure statistical comparability.

Ablation Study of Sensor Modalities

To quantify the individual and combined contribution of each sensor modality to IG prediction performance, a systematic ablation study was implemented. The study was performed on the combined cohort of healthy control (HC) and MR participants using the same preprocessed dataset, LSTM model architecture, training protocol, and LOSO cross-validation strategy as the primary analysis. First, single-modality ablation was conducted by independently removing EDA, PPG, STEMP, and taACC from the feature space. Second, combinatorial ablation tests were performed by removing pairs of sensor modalities to evaluate correlations between modalities. All other features, including demographic variables, temporal context features, and the remaining sensor modalities, were retained without modification. Model performance was evaluated using RMSE, MAE, MAPE, and CEGA to quantify the degradation in predictive accuracy caused by the exclusion of each modality or modality combination, relative to the full-feature model containing all sensor inputs. This approach allowed us to isolate the unique and synergistic predictive value of each physiological signal source for glucose estimation.

Shapley Additive Explanations Analysis

Shapley Additive Explanations (SHAP) analysis can be used to estimate the marginal importance of input features across all sensor modalities by implementing statistical analysis on the contributions of features, thereby identifying the key physiological mechanisms influencing model predictions. Within the proposed LOSO cross-validation framework, local SHAP values for all features extracted from PPG, EDA, STEMP, and taACC were calculated for each test sample. Following this, the local attribution findings were integrated to generate a global feature importance ranking, demonstrating the impact of each sensor-derived feature on IG prediction. By validating the physiological significance of the hypotheses in the model, we demonstrate the dominant and complementary roles of each modality and ensure that all predictions are based on clinically relevant signal patterns.

Results

Study Participant Characteristics

A total of 74 participants participated in our study, including 54 (73%) women and 20 (27%) men. Of these, 34 (46%) individuals were assigned to the HC cohort and 40 (54%) to the MR cohort. The MR cohort comprised individuals who were either overweight and exhibited at least one comorbidity or who were classified as obese. In more detail, individuals with a BMI between 25 and 29.9 kg/m^2 (overweight) were only included in the MR group if they presented with at least one known metabolic comorbidity, such as hypertension, dyslipidemia, atherosclerosis, insulin resistance, gout, stroke, or heart failure. In contrast, individuals with obesity (BMI ≥30 kg/m^2) were assigned to the MR cohort regardless of comorbid conditions. As a result, 2 cohorts were formed that exhibited significant differences in their physiological parameters (Table 1).

The HC cohort comprised 34 individuals, of whom 25 (74%) were women, with a mean age of 24.53 (SD 3.68) years and a BMI within the normal range (mean 22.36, SD 2.16 kg/m²). In contrast, the MR cohort consisted of 40 individuals, including 29 (73%) women, with a mean age of 55.38 (SD 15.08) years and an average BMI in the obese range (mean 35.38, SD 4.91 kg/m²), resulting in significant differences in age and BMI between the 2 cohorts. Within the MR cohort, 8 (20%) participants were overweight with at least one known comorbidity, 12 (30%) presented with obesity class I, 14 (35%) with class II, and 6 (15%) with class III. Both cohorts underwent BIA as well as deep metabolic profiling of blood and urine samples (urine data not shown; Table 1 and Figure 1A). Detailed results of the BIA measurements are presented in Table 1 and Figure 1B. Key parameters linked to metabolic syndrome and disruption in glucose metabolism, including fat-free mass, fat mass, and visceral fat, are highlighted in Figure 1C. Compared to HC, individuals in the MR cohort showed significantly increased fat mass and visceral fat, whereas relative fat-free mass was decreased.

Figure 1. Study design and metabolic markers. (A) Study cohort included 74 participants performing a bioelectric impedance analysis (BIA), deep metabolic profiling, and 2-week sensor phase, during which they wore an invasive device for continuous glucose monitoring (CGM) and 2 noninvasive sensor wristbands. (B) Overall cohort was separated into healthy controls (HC) and metabolically at-risk (MR) individuals based on BMI and comorbidities. (C) BIA results indicate alterations in lipid profiles in the MR cohort (n=35) compared to HC (n=33). (D) Blood metabolic phenotyping showed changes in amino acid, glucose, energy, as well as lipid metabolism between MR (n=39) and HC cohorts (n=33). (E) Detailed analysis of glucose metabolism revealed differences among MR individuals with overweight (n=8) and obesity (n=31). Multiple Mann-Whitney *U* test with false discovery rate of 1% for BIA measurement and metabolic profiling as well as 10% for clinical analysis of glucose metabolism were applied with *$q \leq .1$, **$q \leq .01$, ***$q \leq .001$, and ****$q < .0001$. HDL: high-density lipoprotein; HOMA-IR: homeostatic model assessment of insulin resistance; IDL: intermediate-density lipoprotein; LDL: low-density lipoprotein; VLDL: very-low-density lipoprotein.

Furthermore, deep metabolic profiling of blood samples revealed alterations in amino acid, glucose, energy, as well as lipid metabolism. Elevated levels of amino acids alanine, phenylalanine, tyrosine, and valine were detected in MR compared to HC, along with increased concentrations of lactic and pyruvic acid as well as glucose. In line with the results of the BIA measurement, increased lipid levels (triglycerides, VLDL, and IDL) were observed in MR, whereas HDL was reduced in MR. Furthermore, an increased apolipoprotein ratio (ApoB100/ApoA1) was observed in the MR cohort, serving as a marker for elevated cardiovascular risk (Figure 1D).

To further characterize the overall health status of the MR cohort, additional parameters, including complete blood count, glucose metabolism, liver function, and blood lipids, were assessed by routine clinical laboratory testing (Table 2). Within the MR group, glucose metabolism was analyzed in detail across overweight and obese subgroups, revealing that individuals with obesity exhibited significantly higher insulin concentrations and increased insulin resistance, as indicated by homeostatic model assessment of insulin resistance (Figure 1E). However, no differences were observed between groups for fasting glucose and HbA_{1c}.

Calculation of IG Values

The aim of the study was to expand our algorithm for the calculation of IG values using noninvasive sensor data and to validate the generalizability of the proposed algorithm under healthy and MR conditions. Therefore, we pursued 2 approaches. First, we implemented 2 cohort-specific algorithms trained and tested for the HC and MR cohorts, respectively. Second, we developed an algorithm using the overall population, consisting of the HC and MR cohorts. For the HC cohort, we achieved a strong performance, indicated by a mean MAE of 13.23 (SD 1.86) mg/dL, a mean MAPE of 0.14 (SD 0.02), a mean RMSE of 17.41 (SD 2.38) mg/dL, and 2.0% of data points in zone D of the CEGA. A total of 33 healthy individuals were included in this dataset, as 1 (3%) participant had to be excluded due to his frequent sauna visits and the resulting errors in data collection. Our MR cohort–specific algorithm also performed well, including 40 individuals, with a mean MAE of 19.75 (SD 8.11) mg/dL, a mean MAPE of 0.18 (SD 0.06), and a mean RMSE of 25.53 (SD 9.28) mg/dL. However, only 1.4% of data points fell in zone D of the CEGA. Furthermore, a cohort-independent algorithm including the HC and MR dataset was developed with a mean MAE of 15.98 (SD 7.19) mg/dL, a mean MAPE of 0.15 (SD 0.05), a mean RMSE of 21.04 (SD 8.32) mg/dL, and 1.7% in zone D of the CEGA (Figure 2A). Model performance characteristics of the overall analysis were stratified by the HC and MR cohorts (Figure 2B), yielding MAE, MAPE, mean squared error, and RMSE values comparable to the cohort-specific analyses. These findings support the assumption that the algorithm is capable of abstracting across the different datasets underscoring its generalizability between various datasets. In addition, we identified a linear association between the RMSE and the HbA_{1c} of the MR cohort (R^2=0.5842; P<.001). The simple linear regression analysis remained highly significant (P<.001) after the exclusion of the outlier exhibiting an HbA_{1c} value above 7.0%. To further investigate the influence of intersubject variability, we performed a multivariate linear regression analysis with RMSE as the dependent variable and both age and HbA_{1c} as independent variables, indicating that age is not significantly associated with RMSE (β_1=−0.0146; P=.10), while HbA_{1c} shows a strong and statistically significant association with the RMSE (β_2=12.57; P<.001), even after adjusting for age. In line with a previous study by Bent et al [17], we categorized the HbA_{1c} into normal (<5.2%), high normal (5.2% - 5.6%), prediabetic (5.7% - 6.4%), and diabetic (>6.4%), resulting in 82% (n=28 of 33 known values) of individuals with high HbA_{1c} levels and potential disruptions in glucose metabolism (Figure 2C).

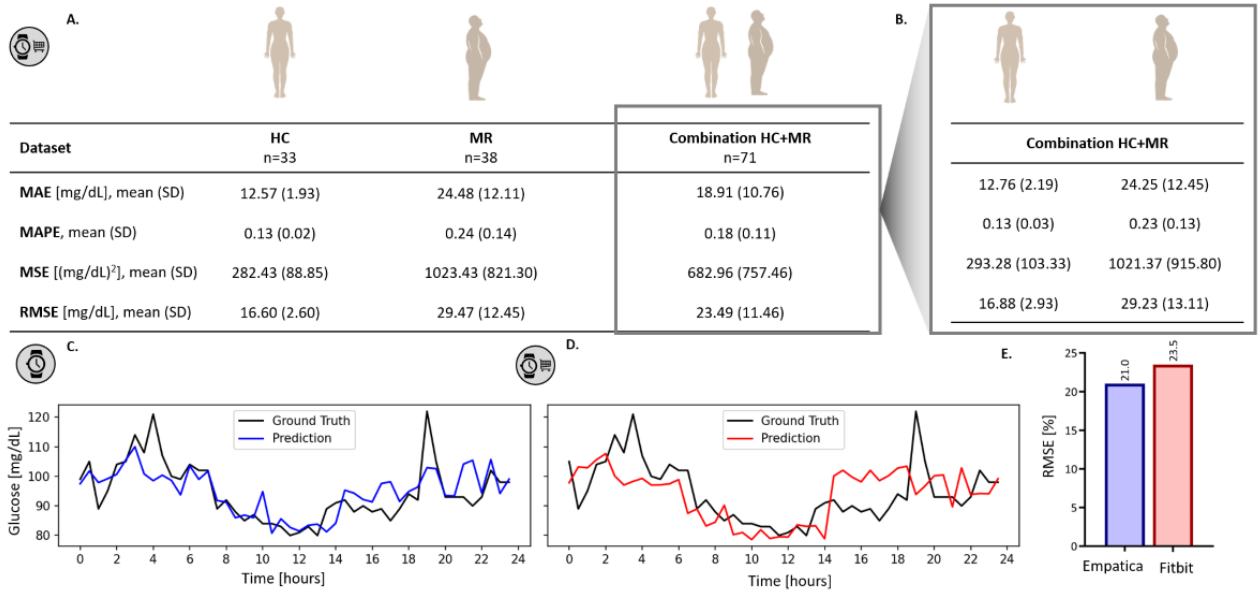
RenderX

Figure 2. Performance of the algorithm for interstitial blood glucose calculation. (A) Model performance was evaluated by mean absolute error (MAE), mean absolute percentage error (MAPE), mean squared error (MSE), root-mean-squared error (RMSE), and Clarke error grid analysis (CEGA) for cohort-specific algorithms of the healthy control (HC) and metabolically at-risk (MR) groups as well as for the combined dataset model. (B) Stratification of the combined model demonstrated its potential for generalizability across different datasets. (C) Linear regression analysis indicated a relationship between the RMSE of the algorithm and abnormalities in blood glucose metabolism, characterized by hemoglobin A_{1c} (HbA_{1c}). Furthermore, HbA_{1c} levels of the MR cohort were divided into normal (<5.2%), high normal (5.2% - 5.6%), prediabetic (5.7% - 6.4%), and diabetic (>6.4%).



Dataset	HC n=33	MR n=40	Combination HC+MR n=73
MAE [mg/dL], mean (SD)	13.23 (1.86)	19.75 (8.11)	15.98 (7.19)
MAP, mean (SD)	0.14 (0.02)	0.18 (0.06)	0.15 (0.05)
MSE [(mg/dL)^2], mean (SD)	308.75 (82.41)	737.67 (606.10)	511.80 (520.88)

To evaluate the practical applicability and broad usability of noninvasive IG estimation, the use of a commercially available smartwatch (Fitbit Sense 2) was investigated. Analogous to the evaluation of the sensor data generated by the scientific wristband from Empatica, 3 models were trained: 2 cohort-specific models for the HC and MR groups and 1 combined model. The combined model achieved a mean MAE of 18.91 (SD 10.76) mg/dL, a mean MAPE of 0.18 (SD 0.11), and a mean RMSE of 23.49 (SD 11.46) mg/dL (Figures 3A and 3B). The Fitbit dataset comprised 33 (46%) HC and 38 (54%) participants from the MR cohort, as data from 2 (5% of the overall MR cohort) MR individuals were unavailable due to missing recordings. In line with the Empatica combined model, the combined model based on Fitbit data demonstrated the capability to generalize across different datasets. Furthermore, measured IG values based on CGM as well as the calculated parameters derived from sensor data over a 24-hour period were illustrated for Empatica (Figure 3C) and Fitbit (Figure 3D), showing a high overlap despite visible dynamics in IG values. In summary, the Empatica and Fitbit models exhibited comparable RMSE values, although the commercially available smartwatch showed a slightly reduced performance (Figure 3E).

XSL•FO
RenderX

Figure 3. Algorithm performance based on smartwatch data. (A) Model performance was evaluated by mean absolute error (MAE), mean absolute percentage error (MAPE), mean squared error (MSE), and root-mean-squared error (RMSE) for the cohort-specific algorithms of the healthy control (HC) and metabolically at-risk (MR) groups as well as characteristics of the combined dataset model. (B) Stratification of the combined model showed the potential for abstraction across different datasets. (C) Interstitial glucose levels measured by a continuous glucose monitoring (CGM) device (black) were compared with values calculated from noninvasive wearable data obtained with the Empatica EmbracePlus (blue) for 1 participant over time. (D) Analogous to C, calculated glucose values were derived from data collected using a commercially available smartwatch (Fitbit Sense 2) (red). (E) Comparison of RMSE between algorithms based on Empatica and Fitbit data for the combined model.

Dataset	HC n=33	MR n=38	Combination HC+MR n=71
MAE [mg/dL], mean (SD)	12.57 (1.93)	24.48 (12.11)	18.91 (10.76)
MAPE, mean (SD)	0.13 (0.02)	0.24 (0.14)	0.18 (0.11)
MSE [(mg/dL)^2], mean (SD)	282.43 (88.85)	1023.43 (821.30)	682.96 (757.46)
RMSE [mg/dL], mean (SD)	16.60 (2.60)	29.47 (12.45)	23.49 (11.46)

Combination HC+MR	
12.76 (2.19)	24.25 (12.45)
0.13 (0.03)	0.23 (0.13)
293.28 (103.33)	1021.37 (915.80)
16.88 (2.93)	29.23 (13.11)

Moreover, to provide additional statistical validation and strengthen comparative claims, SE and 95% CI for both RMSE and MAE were computed using nonparametric bootstrapping with 1000 resamples under the LOSO cross-validation framework for the main cohort analyses, including HC and MR cohorts, as well as the combined cohort, using the proposed LSTM model based on either Empatica or Fitbit data. As shown in Table S4 in Multimedia Appendix 1, the 95% CI for RMSE was 16.34 to 18.48 mg/dL in the HC cohort, 22.65 to 28.41 mg/dL in the MR cohort, 19.12 to 22.96 mg/dL for the combined cohort with Empatica, and 20.81 to 26.17 mg/dL for the combined cohort with Fitbit. Corresponding 95% CIs for MAE were 12.45 to 14.01 mg/dL, 18.12 to 21.38 mg/dL, 14.57 to 17.39 mg/dL, and 17.03 to 20.79 mg/dL, respectively. Despite relatively large SDs across LOSO folds, especially in the MR and combined cohorts, all derived 95% CIs remained narrow, indicating robust and consistent central estimates of model performance. These intervals explicitly quantify statistical uncertainty in overall performance and reinforce that observed between-cohort performance differences are reproducible and not driven by random estimation variability.

To address the influence of PH on IG prediction, we evaluated model performance at 15, 30, and 60 minutes using both Empatica EmbracePlus and Fitbit Sense 2 records (Table S5 in Multimedia Appendix 1). For the Empatica device, the proposed LSTM achieved the lowest RMSE (mean 21.04, SD 8.32 mg/dL) and MAE (mean 15.98, SD 7.19 mg/dL) at a 30-minute PH, with slightly higher errors at 15 minutes (RMSE: mean 21.69, SD 8.30 mg/dL) and 60 minutes (RMSE: mean 22.68, SD 9.01 mg/dL). A similar pattern was observed for the Fitbit device. The 30-minute PH yielded the optimal RMSE (mean 23.49, SD 11.46 mg/dL) compared to 15 minutes (mean 26.10, SD 15.30 mg/dL) and 60 minutes (mean 24.50, SD 11.75 mg/dL). The 30-minute interval was selected as the primary PH because it balances temporal resolution and physiological relevance for PPGR, while minimizing prediction error across both wearable platforms. To validate the LSTM architecture, we further compared it with the iTransformer model at the optimal 30-minute PH (Table S5 in Multimedia Appendix 1). For Empatica data, the LSTM model outperformed iTransformer. For Fitbit, LSTM remained competitive (RMSE: mean 23.49, SD 11.46 vs mean 22.68, SD 8.40 mg/dL) with lower MAE in real-world wearable signals. These results confirm that the LSTM network is better suited for capturing sequential physiological dependencies from continuous wearable data than the transformer-based architecture in this task.

The ablation study confirmed the differential individual and combined contributions of each sensor modality to IG prediction (Table S6 in Multimedia Appendix 1). Single-modality removal showed that PPG and taACC were the most impactful individual features, with their exclusion increasing RMSE by 5.82 and 8.43 mg/dL, respectively, followed by EDA, which led to an RMSE increase of 4.17 mg/dL. STEMP contributed moderately, with an RMSE degradation of 2.35 mg/dL upon elimination. Combinatorial ablation further revealed strong synergistic interactions between modalities. Simultaneous removal of EDA and PPG caused the largest performance drop (RMSE of 9.13 mg/dL), while removing STEMP and taACC resulted in a substantial decline of 7.61 mg/dL, consistent with the high importance of accelerometer-derived motion information. Similarly, excluding PPG and taACC together led to the most severe degradation (RMSE of 10.25 mg/dL), underscoring their dominant and complementary roles. Other combined ablations (EDA+STEMP) also yielded notable accuracy reductions. These findings demonstrate that cardiovascular dynamics from PPG, physical activity patterns from taACC, and autonomic arousal

XSL•FO
RenderX

from EDA provide the strongest predictive signals for glucose fluctuations, whereas STEMP acts as a supplementary but meaningful contributor.

To identify the dominant physiological and contextual drivers of glucose prediction, we performed a SHAP analysis on the full dataset (n=39,314), quantifying the magnitude and direction of each feature's impact on the model's glucose prediction output, with results visualized in the SHAP beeswarm plot (Figure S1 in Multimedia Appendix 1). It ranks features by the overall magnitude of their SHAP values, revealing that demographic and temporal features were the most influential predictors at the top of the ranking, followed closely by wearable physiological sensor modalities. Focusing on the top 30 most impactful features, we categorized them by sensor modality to quantify their relative contributions, that is, 3 (10%) of the top 30 features were demographic variables, 2 (6.7%) of 30 were temporal metadata, and the remaining 25 (83.3%) of 30 were derived from wearable sensors, encompassing BVP (Plr), EDA, STEMP, and taACC. Within the wearable sensor modalities, accelerometer-derived features were the most abundant, with 12 features (40% of the top 30), followed by 6 (20%) BVP-related features, 4 (13.3%) STEMP features, and 3 (10%) EDA features. The SHAP beeswarm plot further reveals biologically plausible directional effects for these top-ranked features, consistent with well-documented age-related metabolic changes and glucose dysregulation risk. The temporal feature also exhibited a strong directional impact, with high values linked to elevated glucose predictions, reflecting long-term temporal trends in metabolic health and study population dynamics. Wearable physiological features demonstrated consistent dose-response relationships, with high feature values driving predictable shifts in model output, validating their direct physiological relevance to glucose regulation as key complementary functions. In general, these results confirm that demographic and temporal features are the most dominant predictors of glucose levels in our model, with wearable sensor modalities providing critical, physiologically meaningful contributions that enhance predictive accuracy by capturing real-time physiological dynamics.

Discussion

Principal Findings

Our study demonstrates the feasibility of predicting IG levels exclusively using noninvasive sensor data and ML techniques. The proposed algorithm achieved high performance across healthy and MR individuals, confirming our previous results [19], even in MR participants with higher glucose levels and dynamics. We implemented cohort-specific algorithms focusing on the HC and MR dataset, respectively, as well as an overall algorithm trained and tested for all individuals together. Furthermore, we identified a potential linear relationship between the error of our algorithms and participants' glucose metabolism, as characterized by HbA_{1c}. This approach may in the future allow for the estimation of HbA_{1c} levels from algorithmic outputs, thereby offering individuals an early indication of possible metabolic dysregulation. In addition, we investigated the potential of using data from commercially available smartwatches for IG prediction. Despite the limited availability of continuous raw data compared with research-grade sensors, we achieved promising results.

Taken together, our IG predictive performance was in line with other state-of-the-art studies, but outperformed these studies in three significant points: (1) to the best of our knowledge, this is the first study using an equal number of healthy and MR individuals resulting in the largest continuous observation with 74 individuals so far; (2) in contrast to other studies, our study exclusively used data collected by wearable smart devices without using manually recorded food logs. Consequently, participants were not required to engage in an additional time-consuming self-reporting, which is prone to data errors; and (3) in addition to sensor wristbands designed for scientific studies, we also tested a commercially available smartwatch in parallel to demonstrate scalability of our proposed solution.

Comparison to the Literature

Like others, we emphasize the potential of wearable devices for noninvasive glucose prediction. For example, Aziz et al [30] used an open-source dataset consisting of 13 participants aged between 9 and 77 years with a nondiabetic-to-diabetic ratio of 4:6. Various physiological measurements were collected over 3 months, resulting in linear and nonlinear models with high accuracy, specifically an MAE ranging from 0.093 to 0.142 and an RMSE ranging from 0.186 to 0.271. However, the generalizability of this study is limited by the participant-dependent allocation of training and testing as well as the small sample size. Similarly, van den Brink et al [16] conducted a 2-week study with 24 participants without diabetes, using handcrafted features from diet, physical activity, and sleep data to predict glucose levels. They developed a participant-specific Extreme Gradient Boosting model to predict glucose levels with an average MAE of 11.17 mg/dL (reported 0.62, SD 0.15 mmol/L) for the test data. However, this model is also restricted due to the limited generalizability by the personalized training and test strategy. Furthermore, a study by Bent et al [17] involved 16 participants with high normal BG (HbA_{1c}=5.2 - 5.6) or prediabetes (HbA_{1c}=5.7 - 6.4) using a CGM sensor, a wristband, and self-reported food logs for 8 to 10 days. They extracted various features and created 2 Extreme Gradient Boosting models—one participant-specific and one population-based—to predict IG levels, achieving an average MAPE of 14.33% (SD 3.25%) and a mean RMSE of 21.22 (SD 4.14) mg/dL for the population model validated with leave-one-person-out cross-validation. Nevertheless, the model is restricted due to the use of self-reported food logs and the limited sample size. Recently, a study published by Zeynali et al [31] demonstrated an RMSE of 19.7 mg/dL using PPG signals of a diverse dataset during surgery and anesthesia. However, although this study included 6388 participants, it comprised only 35,358 BG measurements, corresponding to an average of 5.5 values per participant. In contrast, our longitudinal 2-week dataset comprises 900,606 IG measurements from 74 individuals, providing the potential to capture the temporal dynamics of IG values. Moreover, the glucose data in the study by Zeynali et al were collected during surgical procedures and anesthesia, thus reflecting a highly specific clinical context. A study by Geng et al [32] developed a multisensor-based,

XSL•FO
RenderX

noninvasive continuous glucometer with a normalized RMSE of 14.61 mg/dL. However, this study aimed to develop a new sensor device and therefore only 6 healthy individuals and 3 individuals with diabetes were examined for the accuracy of the model. In a study by Zahedani et al [18], an app was developed to identify food types and metabolic factors from images, aiding in glucose prediction. Although this method reduces the burden of self-reporting, it still requires participant involvement, making it unsuitable for long-term monitoring, and its accuracy in complex dietary situations remains unverified. In conclusion, these studies have some limitations in small sample sizes, data processing, and validation and necessitate detailed dietary intake data, requiring significant participant commitment. Without qualitative assessment, the reliability of these ML models for glucose prediction based on clinical validation criteria is challenging.

Technical Discussion

From the technical point of view, the supplementary 95% CIs derived from nonparametric bootstrapping further validate the stability and generalizability of our prediction model across HC and MR populations. The narrow CIs for RMSE and MAE in all cohorts confirm low between-participant variability and high reproducibility of model performance, rather than reflecting random or spurious estimation. The nonoverlapping tendency of CIs between the HC and MR groups also quantitatively supports the genuine difference in predictive accuracy related to underlying metabolic status, rather than chance variation. Collectively, these statistical estimates strengthen the physiological interpretability of our wearable-based glucose prediction model and reinforce its reliability for real-world mHealth apps in personalized nutrition and metabolic health monitoring.

The optimal performance at a 30-minute PH aligns with the typical time course of postprandial IG excursions, which peak approximately 30 to 60 minutes after meal ingestion. Shorter horizons may lack sufficient physiological signal for robust prediction, while longer horizons (PH=60 min) introduce greater uncertainty due to accumulating variability in lifestyle and metabolic state. Thus, the 30-minute PH provides the best trade-off between predictive accuracy and clinical utility for real-time glycemic monitoring and personalized dietary guidance. Benchmarking against an iTransformer further validates the choice of LSTM for noninvasive IG prediction. While transformers excel at long-range dependencies in static datasets, LSTM networks are more efficient at modeling continuous, noisy physiological time series from wearables, where local temporal dynamics dominate glucose fluctuations. The consistent superiority of LSTM across both research-grade and commercial wearable devices supports its suitability for real-world mHealth apps requiring low latency and robust sequential learning.

Additionally, the findings from ablation tests further strengthen the implied perspectives of the predictive signals underlying noninvasive IG estimation. Individual modality removal revealed that PPG and taACC were the dominant contributors to model accuracy, consistent with the close coupling between cardiovascular tone, physical activity–related metabolic demand, and IG dynamics. EDA also contributed substantially, reflecting the role of autonomic arousal in glucose fluctuation prediction. In contrast, STEMP exerted a more modest effect, supporting its role as a complementary rather than primary predictive feature. Combinatorial ablation confirmed strong synergistic interactions across key modalities. Notably, simultaneous removal of PPG and taACC caused the most severe performance deterioration, while the combined exclusion of EDA and PPG also led to a marked decline, underscoring the value of multimodal integration for robust real-world glucose prediction. These results clarify the relative importance of each wearable signal and validate that our model relies on physiologically meaningful inputs rather than spurious correlations, reinforcing the translational potential of the proposed approach.

Metabolomics

As a secondary outcome, deep phenotyping of HC and MR individuals was performed. In line with other studies, we identified elevated fat mass and visceral fat in our MR cohort [33,34]. In particular, visceral fat is a well-known biomarker for T2D and cardiovascular risk. Furthermore, blood metabolic profiling revealed alterations in amino acid, energy, and glucose, as well as lipid metabolism. Previous studies showed altered amino acid profiles in T2D compared to HC. For example, a study by Chen et al [35], published in 2019, confirmed our results, highlighting that elevated concentrations of alanine, phenylalanine, tyrosine, and valine increased the risk of T2D. Furthermore, disruptions in glucose metabolism, indicated by increased BG levels, are common biomarkers for the development of insulin resistance, T2D, and metabolic syndrome [36]. Abnormalities in lipid profiles identified by BIA measurement were confirmed by NMR spectroscopy, which indicated increased concentrations of VLDL and IDL, as well as the ratio of ApoA1/ApoA100, a well-known biomarker for cardiovascular risk [37]. In contrast, HDL, commonly referred to as “good cholesterol,” was reduced in MR [38]. Within the MR cohort, individuals with obesity exhibited higher insulin resistance compared to those with overweight, underscoring the association between increased body weight and impaired metabolism [1,2]. This, in turn, may contribute to an elevated risk of insulin resistance, T2D, and metabolic syndrome. Taken together, our deep phenotyping confirms the disruptions in glucose metabolism in the MR cohort and thereby strengthens the validity of our algorithm, which was tested both in healthy individuals and in participants with metabolic impairment.

Limitations

Nevertheless, further research is needed to validate the IG prediction algorithm. In our study, we examined only a limited cohort consisting of 2 substudies with different study populations, including differences in demographic characteristics such as age and BMI. Furthermore, we were able to test only one commercial smartwatch and did not cover other wearables and smartwatches on the market. Therefore, it is appropriate to evaluate the efficacy in larger and more diverse cohorts, as well as testing the model on distinct sensor data collected from various smart devices is essential for detailed fine-tuning to reduce the impact of data diversity on IG prediction outcomes. This includes validating the algorithm in different clinical

XSL•FO
RenderX

scenarios following the V3 [39] principle and adapting it for predicting IG response in metabolic diseases such as obesity and T2D. Furthermore, the role of confounding factors such as age, gender, BMI, dietary intake, physical activity, stress, sleep, and medication should be evaluated. In particular, the observed relationship between RMSE and HbA_{1c} levels, as well as a possible association with other confounders, warrants further consideration. On the one hand, this observation may indicate reduced model performance in persons with strong fluctuations in IG levels, while on the other hand, it may suggest a potential for noninvasive estimation of HbA_{1c} levels, which could be of interest for prevention and early detection of abnormalities in glucose metabolism. It is also critical to rigorously validate the extracted features to ensure that predictive signals reflect true physiological responses rather than artifacts or spurious correlations. In particular, when using smartwatch data with limited output parameters, it is important to verify that physiological signals actually reflect the IG values. A limitation of this study is that the model was evaluated primarily in terms of pointwise glucose prediction accuracy. Dynamic characteristics such as trend direction, rate of change, and peak timing were not explicitly assessed. These aspects are important for clinical decision-making and should be investigated in future work. From the technical point, exploring AI learning strategies with promising potential in processing physiological signals, including updated Neural Hierarchical Interpolation for Time Series [40], transfer learning [41], or federated learning [42], is warranted. Moreover, combining multimodal data sources such as continuous activity, sleep, and heart rate metrics could further enhance feature validity and predictive accuracy across diverse populations. In the long term, systematic assessment of the algorithm's sensitivity to lifestyle and dietary variations is necessary to ensure its robustness for real-world mHealth apps and PLGD recommendations.

Conclusions

In conclusion, we predicted continuous IG values using wearable technologies and ML approaches, resulting in an algorithm obtaining strong performance with an average MAE of 15.98 (SD 7.19) mg/dL, a mean MAPE of 0.15 (SD 0.05), a mean RMSE of 21.04 (SD 8.32) mg/dL, and 1.7% of predictive points in zone D of the CEGA. Notably, this performance was achieved using one of the largest datasets consisting of HC and MR individuals without relying on food logs, which sets our study apart from others. The widespread availability of wearables and smartwatches offers a scalable and cost-efficient path toward broad CGM-based monitoring, supporting PLGD strategies and enabling early risk detection. Leveraging longitudinal multimodal data may further enhance predictive accuracy and extend the applicability of PLGD approaches to other conditions associated with metabolic dysregulation, including neurodegenerative diseases.

Abstract

Background: Low anterior resection syndrome (LARS) is a common postoperative complication in patients with low rectal cancer, presenting with a spectrum of bowel dysfunction symptoms, including urgency, incontinence, evacuation disorders, and changes in stool frequency. Pelvic floor muscle training (PFMT) can alleviate LARS, but its effectiveness may be limited by poor accuracy of technique and low adherence during home-based training due to a lack of real-time feedback and monitoring devices.

Objective: This study aimed to evaluate the effects of a novel integrated balloon biofeedback device for home-based PFMT on accuracy of technique, adherence, quality of life, and LARS reduction in patients after sphincter-preserving surgery for low rectal cancer.

Methods: A nonrandomized controlled trial was conducted among 164 patients with low rectal cancer who underwent temporary ileostomy without neoadjuvant therapy. Participants were assigned by surgical date to an intervention group (n=82) using an adjustable-pressure balloon device with real-time waveform feedback via a mobile app or a control group (n=82) performing PFMT without equipment. PFMT was initiated within 72 hours after temporary ileostomy and continued throughout the stoma period until 1 month after ileostomy reversal. Outcomes including PFMT accuracy of technique, adherence, LARS score and incidence, and quality of life (European Organisation for Research and Treatment of Cancer Quality of Life Questionnaire Core 30) were assessed 1 month after stoma reversal.

Results: At baseline, major LARS was present in 47.6% (39/82) of patients in the intervention group and 62.2% (51/82) of patients in the control group. Compared with the control group, the intervention group showed significantly higher PFMT training accuracy and adherence (P<.001 in both cases). LARS scores were significantly lower in the intervention group (median 16.00, IQR 11.00-29.00 vs 32.00, IQR 13.75-36.00), with a markedly reduced proportion of major LARS (17/82, 20.7% vs 45/82, 54.9%; P<.001). Global health/quality of life scores were significantly higher in the intervention group (P<.001).

Conclusions: The integrated balloon biofeedback device improved the accuracy of technique and adherence to home-based PFMT, reduced the incidence and severity of LARS, and enhanced quality of life in patients after low rectal cancer surgery. These findings support further development and clinical implementation of the device. However, the nonrandomized, time-sequenced study design and baseline differences between groups may limit causal interpretation of the results, and randomized controlled trials with longer follow-ups are needed to confirm long-term efficacy.

KEYWORDS

pelvic floor muscle training; rectal cancer surgery; low anterior resection syndrome; quality of life; biofeedback device

Introduction

Rectal cancer is one of the most common malignancies [1], with low rectal cancer accounting for approximately 75% of rectal cancers. In recent years, with the continuous improvement in surgical techniques, preserving the anal sphincter to avoid permanent ostomy has become the primary choice for more patients with low rectal cancer [2]. However, the reality is that approximately 90% of patients face a series of intestinal dysfunctions after surgery, known as low anterior resection

XSL•FO
RenderX

syndrome (LARS), characterized by unpredictable features such as frequent bowel movements, urgency, and fecal incontinence [3,4], which seriously affect patients' social and quality of life [5]. Currently, the incidence of major LARS is close to 50%, with half of the patients experiencing symptoms for up to 15 years [6].

Pelvic floor muscle training (PFMT), as one of the important interventions for postoperative pelvic floor rehabilitation in patients with rectal cancer, works through bidirectional regulation of pelvic floor muscle function. PFMT works by increasing the voluntary contractile capacity of the external anal sphincter and levator ani muscles. PFMT improves fecal incontinence symptoms in patients with LARS; conversely, in cases of pelvic floor hypertonicity or spasm, PFMT alleviates symptoms by relaxing the pelvic floor muscles, effectively reducing urgency and spasmodic bowel symptoms [7]. By restoring mechanical balance to the pelvic floor muscles and optimizing anatomical structures such as the anorectal angle, PFMT improves postoperative LARS symptoms and quality of life in patients with rectal cancer [8-10]. PFMT is recommended by many scholars for its advantages of being noninvasive, requiring no additional equipment, being low cost, and allowing patients to exercise at home [9,11]. However, studies have found that PFMT adherence is relatively low [12]. Moreover, research indicates that many individuals struggle to correctly perform pelvic floor muscle contractions. In a study on postmenopausal women, 32% were unable to correctly perform their first pelvic floor muscle contraction without guidance [13]. Similarly, a study of 82 women found that, although 98.8% believed that they could voluntarily contract their pelvic floor muscles, only 33% accurately estimated their contraction when assessed by a physiotherapist [14]. Even in women with no or mild pelvic floor disorders, 14% to 31% could not correctly contract on first attempt, particularly those with pelvic organ prolapse [15]. For patients who have undergone low anterior resection—where pelvic floor anatomy and innervation may be compromised—these challenges are likely even more pronounced. The lack of effective and objective real-time feedback may be a key bottleneck restricting the efficacy of home-based PFMT.

To address this bottleneck, we have developed a novel home-use integrated pelvic floor balloon biofeedback training device. Its design is based on a clear physiological rationale: active contraction of the pelvic floor muscles increases anal canal pressure, which is a key mechanism for maintaining fecal continence [16]. In addition to improving voluntary contraction during training, PFMT may induce muscle hypertrophy, increasing the bulk of the muscles around the anal canal and providing greater structural support even at rest [17]. The device places a balloon sensor in the anorectal ring region to directly capture the specific pressure signals generated through pelvic floor muscle contraction. Through real-time pressure-waveform conversion and intelligent algorithm analysis, it provides users with immediate, objective feedback on the accuracy of technique of their contractions. This process establishes a complete biofeedback loop, and research has confirmed that transforming intrinsic physiological signals into intuitive visual cues can effectively guide patients in identifying and regulating pelvic floor muscle function [18]. On the basis of this, we hypothesized that this device, through targeted biomechanical signal-based precise biofeedback, could guide patients in performing correct home-based PFMT; improve the accuracy of technique of movements and training adherence; and, ultimately, enhance the neuromuscular control capacity of the pelvic floor muscles to improve postoperative bowel function and reduce the incidence and severity of LARS. This study aimed to evaluate the effects of this device on PFMT outcomes and the occurrence and progression of LARS at 1 month postoperatively in patients who have undergone sphincter-preserving surgery for low rectal cancer.

Methods

Participants

Patients with rectal cancer admitted to the Department of Gastrointestinal Surgery at the First Hospital of Jilin University from October 2022 to March 2023 were enrolled as the control group, whereas patients admitted from April 2023 to September 2023 were enrolled as the intervention group. Inclusion criteria were (1) age of 18 years or above, (2) pathological diagnosis of low rectal cancer (tumor edge located ≤5 cm from the dentate line) and confirmed through pelvic magnetic resonance imaging; (3) having undergone temporary ileostomy at the time of rectal surgery, followed by ileostomy reversal surgery 3 months postoperatively; (4) consciousness and ability to communicate without barriers; and (5) independence in daily living and ability to understand and consent to participate in the study. Exclusion criteria were (1) distant metastasis; (2) concurrent tumors in other organs; (3) preoperative presence of severe conditions such as severe hemorrhoids, anal fissures, anal fistulas, rectal prolapse, irritable bowel syndrome, Crohn disease, and ulcerative colitis; (4) having received preoperative neoadjuvant therapy; (5) unfeasibility of temporary ileostomy reversal; (6) postoperative complications related to anastomotic leakage; and (7) voluntary withdrawal from treatment, death during the study, or loss to follow-up. The eligibility criteria above were applied uniformly to both the control and intervention groups prior to allocation.

Intervention Methods

All PFMT guidance and follow-up in both groups were provided by specialized pelvic floor rehabilitation nurses with postgraduate qualifications in pelvic floor rehabilitation and a mean of 13 (SD 8) years of clinical experience in this field.

Control Group

The control group received routine PFMT guidance and follow-up. First, during the preoperative stage of temporary ileostomy surgery, specialized pelvic floor rehabilitation nurses explained the potential hazards of LARS to patients and introduced PFMT methods; PFMT was initiated within 72 hours after temporary ileostomy and continued throughout the stoma period until 1 month after ileostomy reversal. Patients also received lifestyle advice, including regarding adequate fluid intake, a high-fiber diet to prevent constipation, and avoidance of straining during bowel movements. Second, personalized PFMT guidance was provided to patients through educational

XSL•FO
RenderX

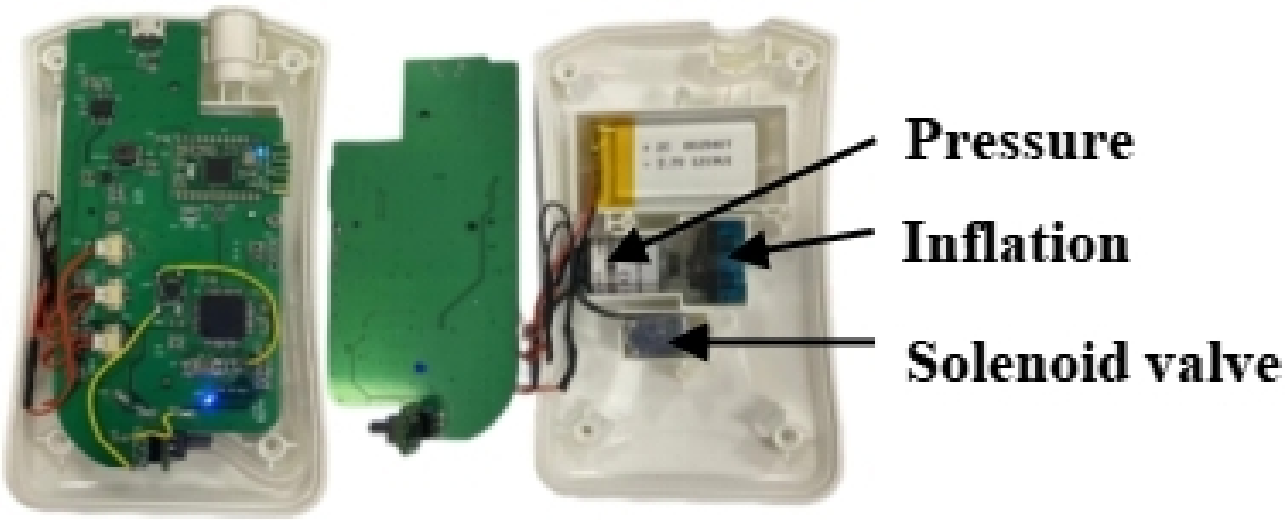
videos, manuals, and classes. Patients were instructed to contract the pelvic floor muscles as if "stopping the passage of stool" or "holding in gas," lifting the muscles upward and inward. Each contraction was held for 3 to 10 seconds (initially based on patients' self-reported ability and subsequently adjusted based on the 1-month biofeedback assessment), followed by complete relaxation for an equal period. Patients were advised to avoid holding their breath or contracting abdominal muscles and were registered for an electronic training diary. Third, during the period from discharge to 1 month after temporary ileostomy reversal surgery, follow-up nurses sent training voice messages and videos to patients daily through individual WeChat groups, requiring patients to complete 30 minutes of PFMT daily, which could be done multiple times to achieve the target volume. Follow-up nurses were responsible for supervising patients in filling out the electronic training diary. Motivation strategies included daily reminders and goal setting (completing 30 minutes daily). Fourth, during the outpatient review 1 month postoperatively, specialized pelvic floor rehabilitation nurses assessed patients' pelvic floor muscle function using a biofeedback device (SA9800; Thought Technology Ltd; see the section PFMT Accuracy of Technique for a detailed device description) to determine each patient's baseline maximum voluntary contraction, which informed the starting level for ongoing training; provided targeted PFMT re-education based on the assessment results; and emphasized once again that the training duration was until 1 month after temporary ileostomy reversal surgery. Patients were instructed to progress their training by (1) increasing hold duration from 3 to 10 seconds as tolerated, (2) increasing repetitions, (3) changing positions (lying, sitting, and standing), and (4) incorporating functional activities (eg, contracting during coughing). Progression was based on perceived ability and successful completion of the current level. Fifth, 1 month after temporary ileostomy reversal surgery, specialized pelvic floor rehabilitation nurses assessed patients' training adherence, accuracy of technique, occurrence of LARS, and quality of life in the outpatient setting. Sixth, based on the assessment results, further training and treatment recommendations were provided to patients.

Intervention Group

The intervention group received the following additional care beyond the control protocol: pelvic floor rehabilitation specialist nurses provided 2 guidance sessions. The first session was conducted preoperatively, introducing the concept and importance of PFMT. The second session occurred during hospitalization after temporary ileostomy surgery on home-based pelvic floor intra-anal balloon training and the operation of the integrated reminder device. Before initiation of balloon-assisted training, participants in the intervention group underwent a 1-month postoperative digital rectal examination (DRE) as a safety prerequisite for device use. This assessment was not part of the baseline eligibility criteria.

The intervention was implemented in 2 distinct phases. Phase 1 was early PFMT (noninvasive). Patients commenced standard, noninvasive pelvic floor muscle contractions and relaxation exercises (ie, Kegel exercises) within 72 hours after temporary ileostomy surgery. This phase aimed to prevent muscle disuse atrophy and promote neuromuscular re-education without any device insertion or mechanical contact with the nascent anastomosis. Phase 2 was intra-anal balloon training (device assisted). The initiation of this phase was strictly contingent upon passing a safety assessment conducted during the 1-month postoperative outpatient follow-up. Physicians assessed anastomotic healing status through (1) DRE to confirm anastomotic patency (defined as the passage of the distal phalanx of the index finger); (2) endoscopic evaluation to exclude mucosal erythema, ulceration, or fibrotic stenosis; and (3) pain assessment using a visual analog scale (score of <4) induced via contact with the anastomosis during DRE. This safety assessment was performed only for patients in the intervention group to determine their eligibility to begin balloon-assisted training and did not influence participant allocation, which had already been completed prior to the assessment. Only patients demonstrating satisfactory healing based on all the criteria above received reinforced guidance on home-based pelvic floor intra-anal balloon training and device use, officially initiating the intra-anal balloon training regimen. Patients were instructed to progress their training by (1) increasing hold duration from 3 to 10 seconds as tolerated, (2) increasing repetitions, (3) changing positions (lying to sitting to standing), and (4) incorporating functional activities (eg, contracting during coughing). Progression was based on perceived ability and successful completion of the current level.

The development of the intra-anal balloon training and reminder integrated device was based on 2 previously approved patents: one for a PFMT device inserted anally (patent ZL 2017 2 1594601.5) and another for a PFMT device displaying pressure values (patent ZL 2021 2 0383459.X). The device consists of 2 main components: an adjustable-pressure intra-anal balloon training device, with hardware including a cylindrical balloon and an inflation handle (as shown in Figure 1). The cylindrical balloon is made of medical-grade silicone material, has passed biocompatibility testing, and is designed to be soft and comfortable and conform to the intestinal wall. It is adaptable and retractable, with a diameter of 2.5 cm and a cylindrical length of 8 cm. Health care providers set the inflation threshold not exceeding 50 mm Hg based on the patient's initial sensation threshold determined through anorectal manometry. The inflation handle contains an inflation pump, solenoid valve, and pressure sensor (as shown in Figure 2). The device uses pressure exchange and solenoid valve control principles to monitor pressure, control inflation, and compress the balloon. The second component of the device is the companion app, which connects to the intra-anal balloon training device via Bluetooth. Upon log-in, the app automatically switches to the inflation interface, followed by the training interface after inflation, displaying real-time pressure waveforms during training (as shown in Figure 3). It should be emphasized that the pressure signals recorded by this device possess a clear physiological origin and specificity. When the balloon is positioned in the anorectal ring region, the perceived pressure changes mainly originate from the active contraction of the pelvic floor muscle complex, particularly the direct radial compression exerted by the external anal sphincter and the synergistic upward traction provided by the puborectalis muscle. A correct and coordinated pelvic floor muscle contraction is manifested on the waveform as a pressure curve characterized by a gentle rise, stable maintenance, and



XSL•FO
RenderX

gradual decline, reflecting effective force generation by the pelvic floor muscles themselves. Conversely, if the waveform exhibits a sharp rise and fall, lacks a stable plateau, or displays jagged fluctuations, it suggests possible compensatory contractions such as those of the abdominal muscles leading to intra-abdominal pressure transmission, which represents an erroneous pattern to be avoided. Our hypothesis is that this device not only provides real-time pressure monitoring but also, through the recognition and feedback of waveform characteristics, guides patients to achieve precise, pelvic floor muscle–dominated contractions that are independent of abdominal pressure interference during training, thereby enhancing neuromuscular coordination between pelvic floor muscle contraction and abdominal pressure regulation.

Figure 1. Intra-anal balloon training device.

Figure 2. Internal structure of the inflation handle.

XSL•FO
RenderX

Figure 3. (A) App log-in screen, (B) inflation interface, and (C) training interface.

(A) (B) (C)

The specific instructions for using the device were as follows. Initially, the specialized pelvic floor rehabilitation nurse adjusted the training inflation threshold for each patient based on preoperative anorectal manometry results obtained using a clinical anorectal manometry system (Hefei Aoyuan Technology Development Co, Ltd; model ZGJ-D3), and guided the patient to install the training software and enter the training interface. The patient was then placed in the left lateral position. After lubricating the balloon with liquid paraffin, it was gently and slowly inserted through the anus until the end of the cylindrical balloon was positioned within the anal canal region (approximately 1-2 cm from the anal verge). The patient then assumed a supine position in preparation for training. To start the training, the patient clicked the Inflate button, and the balloon inflated to the set pressure threshold. After inflation stopped, clicking Start prompted the patient to perform pelvic floor muscle contractions and relaxations following voice prompts. During the Train and Hold process, the patient contracted the anus forcefully for 10 seconds, mimicking the act of holding in a bowel movement. The pressure exerted by the wall of the anal canal on the balloon during this contraction was monitored, and when the pressure exceeded the inflation threshold, the device emitted a beep to indicate successful training. Throughout the training, the pressure sensor provided feedback to the mobile app, displaying real-time pressure values and waveform trends during the contraction and relaxation phases. The patient could adjust the training intensity based on the numerical and waveform prompts. After the voice prompt indicated “training complete,” the balloon was deflated and then slowly withdrawn from the anus. Additionally, it is important to note that the intra-anal balloon training and reminder integrated device used in this study is a self-designed prototype. This device is not a commercially available product and has not been approved by the Food and Drug Administration for any purpose. Its use in this study was investigational and specifically designed to evaluate its potential in guiding and monitoring PFMT for patients with low rectal cancer.

The research team monitored protocol adherence through regular review of electronic training diaries and WeChat communication records. No major protocol deviations were reported.

Evaluation Indicators

PFMT Accuracy of Technique

At the 1-month follow-up after temporary ileostomy reversal surgery, the accuracy of technique of the patients’ training was assessed using a biofeedback device (SA9800 by Thought Technology Ltd). The biofeedback device was connected to the patients’ abdominal electrodes to collect electromyographic signals and display them in real time on a computer screen. The waveform moved upward with abdominal exertion and downward with relaxation. If the patient exerted excessive abdominal force beyond the threshold, a blue threshold line appeared on the waveform. During the 10-minute training session, the total time the blue threshold line was present represented incorrect training time, whereas the rest indicated correct training time (accuracy of technique = correct training time/10 minutes × 100%).

Adherence to PFMT

The daily training time of patients in both groups was obtained through self-recorded electronic training diaries. The daily training target duration was 30 minutes (daily training adherence = total training time on a given day/30 minutes × 100%). If the training duration exceeded 30 minutes, adherence was set at 100%. The highest adherence value was 100%. The average adherence during the 3-month training period following temporary ileostomy was calculated based on daily adherence records.

XSL•FO
RenderX

LARS Score

The LARS score developed by Emmertsen and Laurberg [19] in 2012 was used for evaluation. This score is specifically designed to assess bowel function in patients after low anterior resection surgery, identifying the occurrence and severity of LARS. The LARS score consists of 5 items: incontinence to gas, incontinence to liquid stool, bowel frequency, repeated defecation within 1 hour (clustering of stool), and fecal urgency. The total score is 42, with higher scores indicating worse bowel function. LARS is classified as major (score of ≥30), minor (score of 21-29), and no LARS (score of ≤20).

Quality of Life

The European Organisation for Research and Treatment of Cancer Quality of Life Questionnaire Core 30 [20] was used to assess the quality of life of the 2 groups of patients at 1 month postoperatively. This questionnaire includes 5 subscales for physical, role, cognitive, emotional, and social functioning; 3 symptom subscales for pain, fatigue, and nausea or vomiting; 6 single-item scales for dyspnea, appetite loss, insomnia, constipation, financial difficulties, and diarrhea; and 1 overall quality of life scale. Each item is scored from 0 to 100, with higher scores indicating a higher level of quality of life.

Adverse Events

Adverse events were defined as any device-related complications, including but not limited to anal pain, bleeding, mucosal injury, or infection. Patients in both groups were instructed to report any discomfort, pain, or unusual symptoms during the training period at each follow-up contact (including daily WeChat follow-ups and outpatient visits). All reported events were recorded and assessed by the research team for severity and causality.

Sample Size Calculation

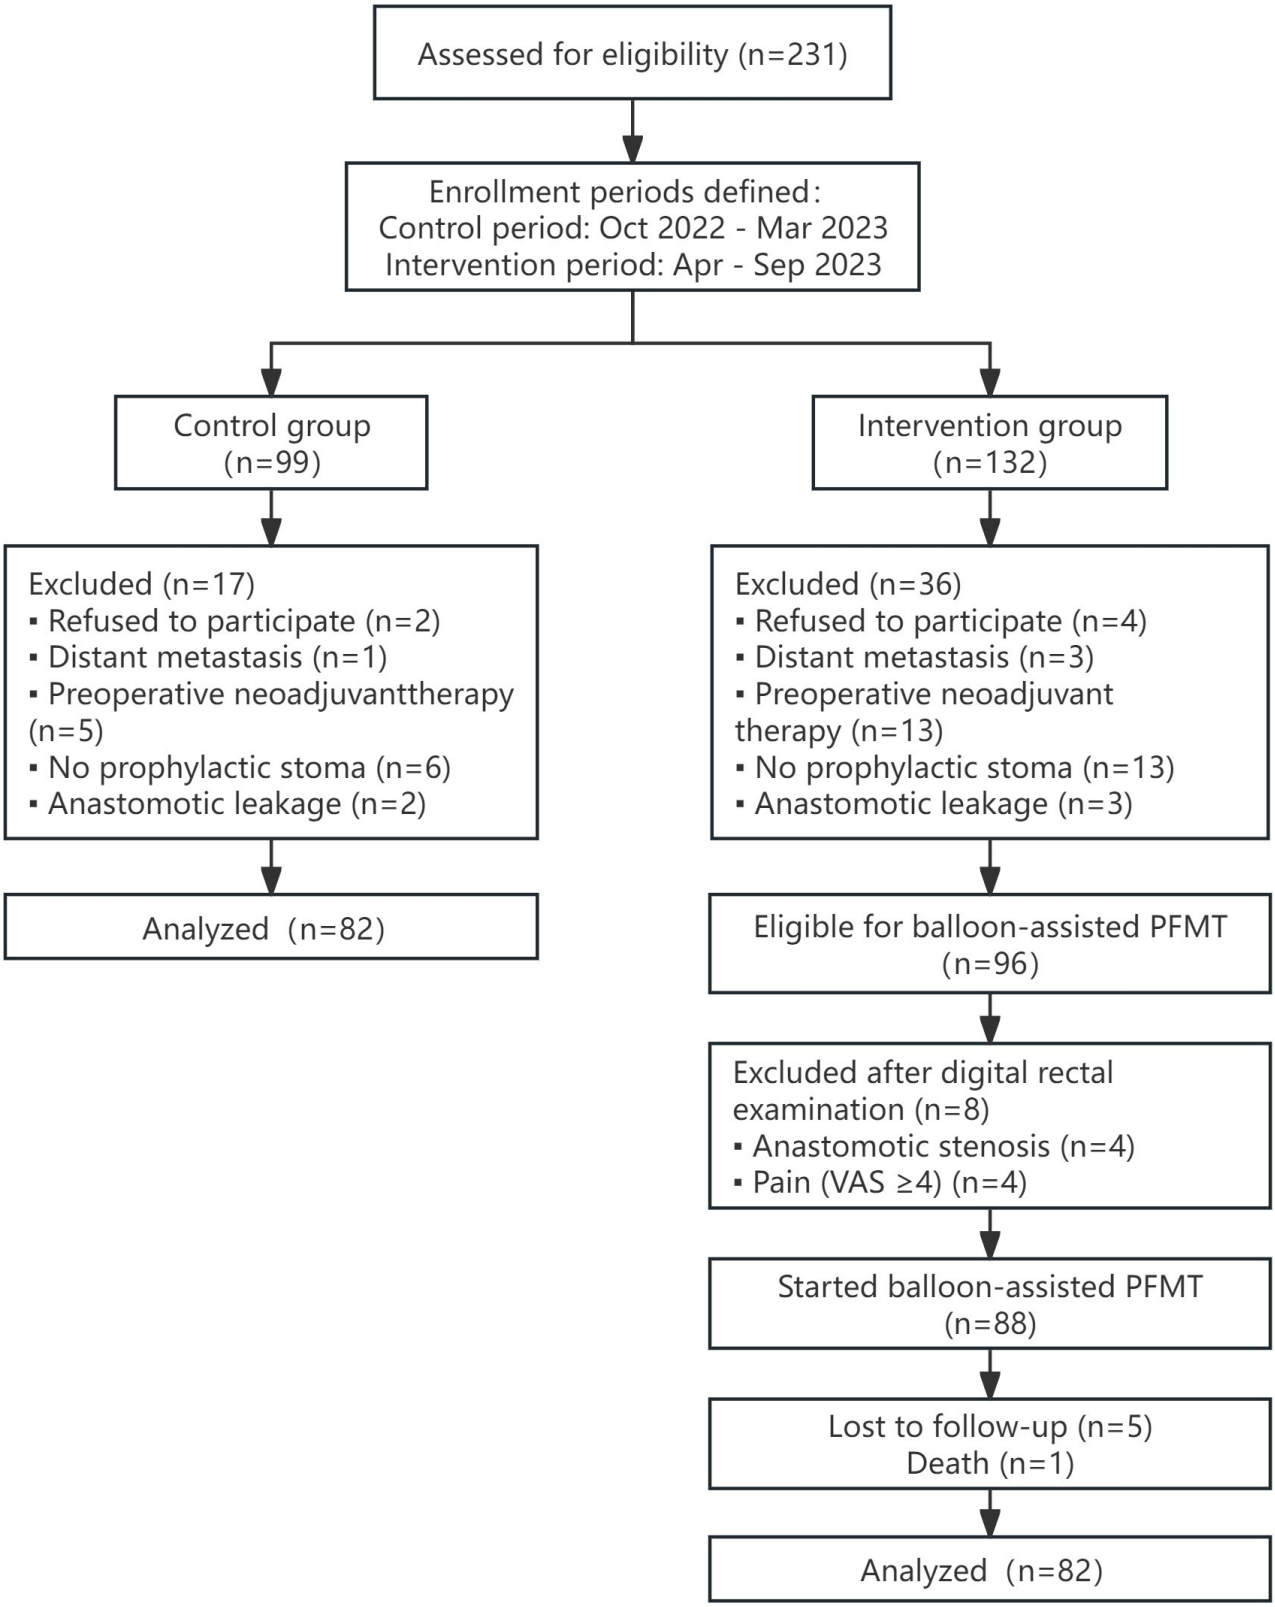
This study was a nonrandomized controlled trial. The intervention group underwent PFMT using the intra-anal balloon training and reminder integrated device, whereas the control group received routine PFMT. The primary outcome measure was the LARS incidence rate at 1 month postoperatively. On the basis of prior experimental results, the LARS incidence rate in the control group was approximately 75%. We expected the LARS incidence rate in the intervention group to decrease to 50%. With a 2-sided α of .05 and a power of 90%, using the PASS software (version 15; NCSS LLC), the calculated sample size was 74 patients for the treatment group and 74 patients for the control group. Considering a 10% attrition and refusal rate, the final required sample size was at least 82 participants in each group, totaling at least 164 study participants.

Statistical Methods

Statistical analyses were performed using SPSS (version 21.0; IBM Corp). Categorical variables are presented as frequencies and percentages and were compared between groups using the chi-square test. Continuous variables were assessed for normality using the Shapiro-Wilk test. Normally distributed data are expressed as means and SDs and were compared using the independent-sample 2-tailed *t* tests, whereas nonnormally distributed data are presented as medians and IQRs and were compared using the Mann-Whitney *U* test. For the comparison of postoperative LARS scores between groups, the Mann-Whitney *U* test was used because both baseline and postoperative LARS scores were not normally distributed (Shapiro-Wilk test; $P<.001$). For the comparison of LARS severity categories (no LARS, minor, or major), a multivariable ordinal logistic regression model was applied with adjustment for baseline LARS scores. The proportional odds assumption was assessed using the parallel lines test. A 2-sided *P* value of less than .05 was considered statistically significant.

Ethical Considerations

This study was reviewed and formally approved by the ethics committee of the First Hospital of Jilin University (21K028-001). Written informed consent was obtained from all individual participants included in this study. All participant data were anonymized and handled confidentially in accordance with institutional and ethical guidelines. No financial compensation was provided to participants for their involvement in this study.



Results

Comparison of General Data Between the Two Groups of Patients

From October 2022 to September 2023, a total of 231 patients with low rectal cancer were recruited and assessed for eligibility in this study. The participant enrollment process is detailed in Figure 4. In the control group, a total of 99 patients were screened, with 17 (17.2%) excluded, whereas in the intervention group, of the 132 patients screened, 36 (27.3%) were excluded based on baseline eligibility criteria. Of the remaining 96 patients eligible for balloon-assisted PFMT in the intervention group, 8 (8.3%) did not meet the postoperative safety criteria prior to intervention initiation. During follow-up, of the remaining 88 patients, 5 (5.7%) were lost to follow-up, and 1 (1.1%) died. Ultimately, 82 patients were included in the final analysis in the intervention group. Overall, 164 eligible patients were included in the study, with 82 (50%) in the intervention group and 82 (50%) in the control group. The 2 groups demonstrated comparable baseline characteristics, with no significant differences in demographic or clinical data ($P>.05$ in all cases). Additionally, baseline LARS scores prior to temporary stoma surgery showed no statistically significant intergroup discrepancy ($P=.09$). Detailed baseline data are shown in Table 1.

[a]LARS: low anterior resection syndrome.

Adverse Events

No device-related adverse events were reported in either group throughout the study period. Specifically, no patients experienced anal bleeding, severe pain (visual analog scale score of ≥4), mucosal injury, or infection associated with PFMT. All patients in both groups completed the training protocol without premature discontinuation due to adverse effects.

Comparison of PFMT Accuracy of Technique, Adherence, and LARS Scores Between the Two Groups of Patients

Patients in the intervention group demonstrated significantly superior training accuracy and adherence compared to the control group (*P*<.001 in both cases; Table 2). Postoperative LARS scores were significantly lower in the intervention group than in the control group as assessed using the Mann-Whitney *U* test (*Z*=−3.491; *P*<.001). Furthermore, the distribution of LARS severity differed significantly between the 2 groups (χ^2_2=20.8; *P*<.001), with a higher proportion of patients without LARS and a lower proportion of severe LARS observed in the intervention group (Table 2). In addition, a multivariable-adjusted ordinal logistic regression model (accounting for baseline LARS scores) revealed that the intervention group had a markedly reduced risk of developing major LARS (odds ratio 0.27, 95% CI 0.15 - 0.50; *P*<.001), as detailed in Table 3.

Comparison of Quality of Life Scores Between the Two Groups of Patients

At 1 month after temporary ileostomy reversal surgery, patients in the intervention group had significantly higher scores in physical functioning, role functioning, social functioning, and overall quality of life than the control group. Scores for insomnia, constipation, and diarrhea were significantly lower in the intervention group than in the control group, and the score on the economic difficulties dimension in the intervention group was notably lower than in the control group, as shown in Table 4.

Table . Comparison of European Organisation for Research and Treatment of Cancer Quality of Life Questionnaire Core 30 scores between the control and intervention groups at 1 month after stoma reversal surgery[a].

Variable (0-100)	Control group (n=82), median (IQR)	Intervention group (n=82), median (IQR)	*Z* score	*P* value
Physical functioning	80 (73.33-86.67)	93.33 (86.67-100)	−6.303	<.001
Role functioning	66.67 (66.67-83.33)	83.33 (66.67-100)	−2.234	.03

Discussion

Principal Findings

This study aimed to investigate the impact of a novel home-based integrated device for pelvic floor intra-anal balloon training and reminders on postoperative LARS in patients with low rectal cancer. The results showed that using this device to guide and monitor patients in home-based PFMT significantly improved the accuracy of technique and adherence to patient training, thereby reducing the incidence and severity of LARS at 1 month after temporary ileostomy reversal surgery and improving patients' quality of life.

PFMT involves consciously and autonomously contracting the levator ani and anal sphincter muscles to increase the stiffness of the pelvic floor muscle group and reduce anal descent. This approach helps improve bowel control by enhancing voluntary sphincter contraction, which may indirectly improve rectal reservoir function and is beneficial in repairing injuries to the internal and external anal sphincters and perianal nerves following surgery [9,21]. PFMT is simple to learn and not limited by time or location and does not increase patient discomfort. Several studies have demonstrated the effectiveness of PFMT in improving symptoms of LARS in patients after rectal cancer surgery [22].

Intra-anal balloon training, as an auxiliary method for PFMT, can help patients better perceive and exercise the pelvic floor muscles, providing real-time feedback that allows patients to perform muscle contractions and relaxations more accurately, thus achieving better exercise results. However, research on the use of intra-anal balloon training in PFMT is still relatively limited [23], and there is currently a lack of commercially available balloon devices that can be widely used.

In this study, the design and use of the intra-anal balloon training and reminder integrated device provided an innovative approach to the rehabilitation of patients with low rectal cancer. By combining an adjustable-pressure balloon device with a dynamic monitoring device, patients can perform PFMT at home and ensure the accuracy of technique and adherence to the training through real-time monitoring and feedback. In this study, comprehensive and rich health education content related to LARS prevention for patients with mid-low rectal cancer was provided, and postoperative daily follow-ups and PFMT were widely and meticulously promoted. The results showed that adherence was higher in the intervention group than in the control group (median 87.68%, IQR 83.33%-100.00% vs 65.08%, IQR 50.00%-84.17%; $P<.001$) and much higher than previously reported rates [12]. After adjusting for baseline LARS scores, the intervention was associated with a 73% reduction in the risk of major LARS (odds ratio 0.27, 95% CI 0.15 - 0.50), suggesting that the device has significant clinical implications for improving postoperative bowel function.

In summary, the results of this study suggest that the self-designed intra-anal balloon training and reminder integrated device enables self-management of home-based PFMT and has potential clinical applications in preventing and improving LARS in patients with low rectal cancer, warranting widespread clinical promotion.

Limitations

This study is the first nonrandomized controlled trial integrating intra-anal balloon training with a reminder device for the prevention of LARS. To minimize group contamination caused by cross-contact between concurrent patients, a temporal isolation strategy was adopted. In addition, the interventions were standardized through systematic training by the same nursing team. Nevertheless, several potential biases should be considered. First, the nonrandomized, time-sequenced design may introduce unmeasured time-related confounding (eg, potential differences in surgical techniques or perioperative care over the recruitment period). In addition, the exclusion rate differed between the 2 recruitment periods, which may have contributed to baseline differences in functional status between groups. Second, although the analysis of baseline characteristics and intensive follow-up management in the control group suggested comparability between groups, the biofeedback devices used in the intervention group may introduce a slight Hawthorne effect bias by objectively quantifying training parameters. Third, training adherence in both groups was manually recorded via self-reported electronic diaries, which may have introduced self-reporting bias. The combination of this self-reporting bias and the Hawthorne effect from intensive follow-up and device feedback may have led to overestimation of adherence in the intervention group, potentially exaggerating the observed differences between groups. Fourth, this study did not perform a strict intention-to-treat analysis as participants who were lost to follow-up were excluded from the final analysis. Although the overall attrition rate was low, this may introduce potential attrition bias and should be considered when interpreting the results.

Additionally, the single-center sample source and the relatively short follow-up period represent important limitations of this study. Outcomes were assessed only 1 month after temporary ileostomy reversal, which mainly reflects early postoperative bowel function recovery rather than long-term functional outcomes. Previous randomized controlled trials have reported inconsistent evidence regarding the long-term effectiveness of PFMT for LARS, with some studies showing only transient benefits over time. Therefore, the findings of this study should primarily be interpreted as indicating a potential benefit in early functional recovery rather than definitive long-term improvement. Furthermore, given that neoadjuvant therapy (particularly radiotherapy) may lead to anastomotic tissue fibrosis, reduced blood supply, delayed healing, and potential complications (eg, bleeding or dehiscence) when initiating intra-anal balloon training 1 month after stoma reversal, we prioritized validating the device's efficacy in low-risk patients who did not receive neoadjuvant radiotherapy to ensure intervention safety, and therefore, the results cannot be generalized to higher-risk patient groups. Future phase 2 studies will expand to high-risk populations undergoing neoadjuvant therapy. To address these limitations, we plan to conduct a multicenter stepped-wedge cluster randomized controlled trial that includes patients receiving neoadjuvant therapy, analyzes

XSL•FO

the association between radiotherapy dose and type and LARS, and further evaluates the device's clinical utility.

Abstract

Background: Asthma remains one of the most serious chronic diseases of childhood. Individuals with severe asthma experience sudden episodes of breathlessness due to acute airflow obstruction, leading to recurrent pediatric intensive care unit (PICU) admissions that often result in mechanical ventilation and even death. Existing clinical assessments lack temporal resolution to effectively track the rapidly changing physiology.

Objective: This study aimed to evaluate the feasibility of quantifying respiratory health during acute asthma in children using wearable multimodal sensing.

Methods: Wearable-based impedance pneumography (IP) and multichannel lung sounds (LSs) were measured on 17 children admitted to the PICU with an acute asthma attack and on 9 healthy controls. Short-term multimodal measurements were obtained throughout hospitalization, specifically at PICU admission (T1) and discharge (T2). Measurements were also obtained from controls without any signs of acute asthma or otherwise healthy. Statistical and clustering analyses were performed to identify trends in IP- and LS-derived respiratory markers from T1 to T2 across all patients with paired time points (n=13), as well as across the matched cohort (T1: n=10 and T2: n=7), who were compared against controls (n=9). Five features were computed from the IP signal: respiratory rate, inspiration time (Ti), expiration time (Te), expiration-to-inspiration time ratio (Te:Ti), and the normalized Ti by interbreath interval (Ti/IBI). Leveraging the breathing context provided by the IP signal, 4 spectral integrated intensity (SI) acoustic features were computed in 4 different subbands for the inspiration and expiration phases.

Results: Within the patient group (n=13), we found that respiratory rate decreased ($W(12)=79$; $P=.02$), whereas Te ($W(12)=12$; $P=.02$) and Ti ($W(12)=13$; $P=.02$) lengthened. Meanwhile, the SIs for the lowest subband (100-300 Hz) decreased for both inspiration and expiration phases ($P<.01$), while they increased for the highest subband (800-1000 Hz) for both inspiration and expiration phases ($P<.01$). Significant differences also existed between T1 and control and T2 and control of the matched cohort. We found that all features were significantly different between T1 and control ($P<.05$), and all SIs together with Te:Ti and Ti/IBI were significantly different between T2 and control ($P<.05$), all exhibiting trends toward normalcy.

Conclusions: These results demonstrate the feasibility of quantifying and tracking respiratory health in children with acute asthma using wearable multimodal sensing, specifically with the fusion of IP- and LS-derived markers. Such technology may provide a new adjunctive clinical tool for real-time respiratory monitoring and enable timely titration of care, thereby improving patient outcomes.

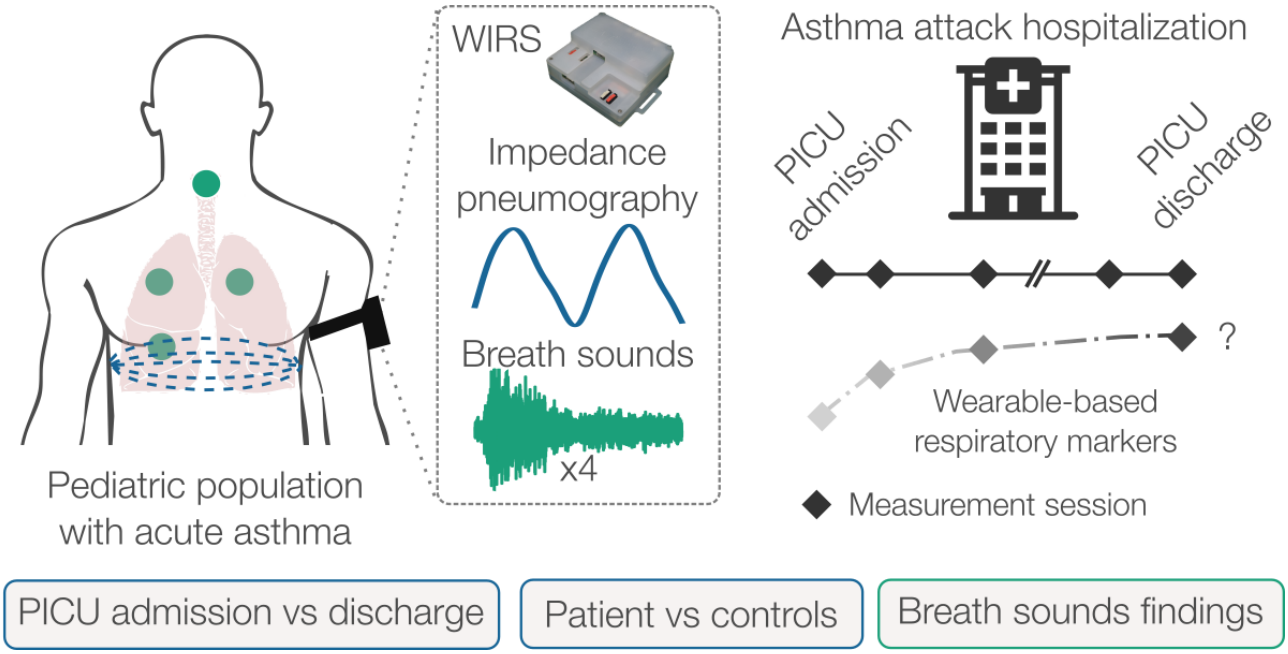
Introduction

Asthma affects more than 4.6 million (6.5%) of US children, resulting in more than 270,000 emergency department visits and 27,000 hospitalizations for status asthmaticus annually [1,2]. Individuals with asthma experience recurrent episodes of reversible airflow obstruction, resulting in breathlessness, chest tightness, wheezing, and coughing. Severe asthma is characterized by the sudden worsening of these symptoms (asthma attacks) and trapping of air inside the lungs (air trapping) due to bronchoconstriction [3]. While many children respond to emergency treatment with bronchodilators and systemic corticosteroids, others progress to respiratory failure and require admission to a pediatric intensive care unit (PICU). PICU admissions for respiratory failure have increased in proportion to general hospital admissions for asthma [4] for reasons that are unclear. Children with severe asthma can have recurrent PICU admissions due to exacerbations that may require mechanical ventilation and even result in death.

Management of asthma involves, among other strategies, the use of inhaled corticosteroids and β-agonist therapy to reduce airway inflammation and promote bronchodilation, thereby reversing airflow obstruction and improving symptoms [5]. Titration of care commonly relies on symptom reporting, physical examination, and pulmonary function tests [3,5]. However, these assessments are often highly subjective and lack the temporal resolution needed to capture the rapidly evolving physiology of a disease characterized by substantial interindividual variability in treatment response [6,7]. On physical examination, the hallmark of asthma monitoring is the manual evaluation of lung sounds (LSs) via auscultation with a stethoscope [3,8]. Unfortunately, this technique is limited by its manual, qualitative, and subjective nature [8]. Digital auscultation enables the quantitative acoustic analysis of LSs, but commercially available electronic stethoscopes do not provide breathing-phase context for post hoc analysis and only record for a short amount of time at a single location. Pulmonary function test via spirometry, on the other hand, requires patient cooperation for performing respiratory maneuvers, which may not be feasible in young children [9], and these diagnostic maneuvers cannot be performed during an acute exacerbation. Hence, there is a need for noninvasive sensing technologies that can consistently quantify asthma signs continuously and conveniently.



Wearable noninvasive sensing systems have emerged as promising technological approaches for the continuous monitoring of the physiological manifestations of asthma [10,11]. These include vital sign monitoring via electrocardiogram, photoplethysmogram [12], LSs [13], chest movement [14], and electrical bioimpedance (BioZ) signals [15,16]. Yet, demonstrations of these technologies in pediatric populations are scarce. Specifically for children with asthma, van der Kamp et al [17] proposed a suite of sensors for at-home monitoring that leveraged an electrocardiogram for heart rate and respiratory rate (RR) estimation. An at-home sensing suite was also proposed by Hosseini et al [18], including a portable spirometer and heart rate derived from a smartwatch. Despite the promising results, these technologies only capture a limited number of markers that may not fully capture the complex physiological manifestations of asthma.

Recent studies have proposed the use of impedance pneumography (IP) as a promising noninvasive sensing modality for respiratory flow and volume signal measurement in children with asthma [19-21]. Prior work has demonstrated the accurate estimation of respiratory markers such as RR, breathing-phase timings, tidal volume and flow, among others, in both laboratory and clinical settings [15,19,20,22-25]. Notably, we recently demonstrated the feasibility of measuring IP simultaneously with multichannel respiratory sounds in a clinical setting and studied their joint application for continuous breathing-phase contextualization in computerized respiratory sound analysis [26,27]. Given the critical role of auscultation and lung function assessment in asthma management, the joint application of such technologies for the continuous monitoring of severe asthma signs in children warrants further investigation.

This study aimed (1) to evaluate the feasibility of using respiratory markers derived from wearable-based transthoracic BioZ and LSs to quantify the physiological manifestations of life-threatening asthma from peak to resolution of signs and (2) to compare their trajectory against healthy controls, as illustrated in Figure 1. To this end, we evaluated multimodal measurements from 17 children admitted to the PICU with an acute asthma attack, as well as 9 healthy controls. We took measurements up to twice daily during hospitalization and carried out several statistical analyses to assess trends in the wearable-based multimodal respiratory markers from PICU admission to discharge and compared them against controls. Ultimately, the combination of BioZ-derived respiratory markers and acoustic signatures derived from the LSs in a wearable form factor may provide clinicians with a new adjunctive clinical tool for real-time respiratory monitoring and enable timely titration of care, thereby improving patient outcomes.

XSL•FO
RenderX

Figure 1. Overview of the study. Transthoracic electrical bioimpedance and multichannel breath sounds were simultaneously measured on children admitted to the PICU with an asthma attack using our WIRS. Measurements were taken after PICU admission and before discharge. The feasibility of using these signals for monitoring asthma symptoms was evaluated by comparing admission-to-discharge feature trends, differences between patients and controls, and breath sound findings. PICU: pediatric intensive care unit; WIRS: wearable impedance pneumography and respiratory sound system.

Methods

Human Subjects Study

Eligible participants for the patient group were participants admitted to the PICU at the Children's Healthcare of Atlanta (CHOA), Atlanta, Georgia, with a severe asthma attack. Exclusion criteria included substantial comorbidity (eg, cystic fibrosis, bronchiectasis, and pulmonary aspiration). Children were enrolled irrespective of a prior diagnosis of asthma because there are some children whose first presentation of symptoms requires hospitalization, sometimes in the PICU [28]. Eligible participants for the control group were participants with no prior history of respiratory illness as the cause of intensive care admission and without wheezing or otherwise healthy, nonhospitalized individuals. All participants were in the age range of 1-17 years. Measurements took place between April 2023 and April 2024.

Ethical Considerations

The human subject study was carried out with the approval from the Emory University School Institutional Review Board (STUDY0004316) and the Georgia Institute of Technology (IRB #H22329). Informed consent was obtained from the participants' parents or legal guardians prior to any study procedures by trained pediatric research coordinators. Additionally, per institutional review board requirements, children aged 6-11 years provided oral assent and those aged 12-17 years provided written assent, when feasible, given their medical condition. All metadata and physiological signals collected at the CHOA site were properly deidentified before sharing for further processing. No compensation was provided to the participants of this study.

Experimental Protocol

Following enrollment, noninvasive physiological measurements were obtained in the morning (AM) or afternoon (PM), whenever possible, while the participants remained hospitalized in the PICU. The first and last measurements in the PICU are hereafter referred to as T1 and T2, respectively. For healthy participants in the control group, a single measurement took place in a hospital staff room within the PICU, with the participants in the sitting position. For participants in the control group who were hospitalized without signs and symptoms of acute asthma, 2 measurements were taken, and only the first one was used for further analysis. Recordings lasted up to 15 minutes, determined by the cooperativeness of the participants, following which all sensors were detached from the participant, and the recordings were saved for further analysis. No instructions were provided to any of the participants to modulate or control their breathing patterns for the recordings. Clinical data from the electronic medical record were also collected in each recording.

Physiological Measurement

Our custom wearable impedance pneumography and respiratory sound system (WIRS) was used in this study to simultaneously measure transthoracic BioZ and LSs [26]. Transthoracic BioZ was measured at 4 excitation frequencies (5, 50, 100, and 150 kHz). Each frequency was sampled at 16 Hz and calibrated to form complex impedance vectors [29]. A tetrapolar electrode configuration was used, with a pair of current-injecting electrodes placed along the mid-axillary line approximately at the fifth intercostal space and the voltage-measuring electrodes in the same vertical plane and separated by 5 cm approximately. Standard 3M Ag/AgCl gel electrodes were used. This BioZ sensing module was previously validated in prior work [22,23,26].

XSL•FO
RenderX

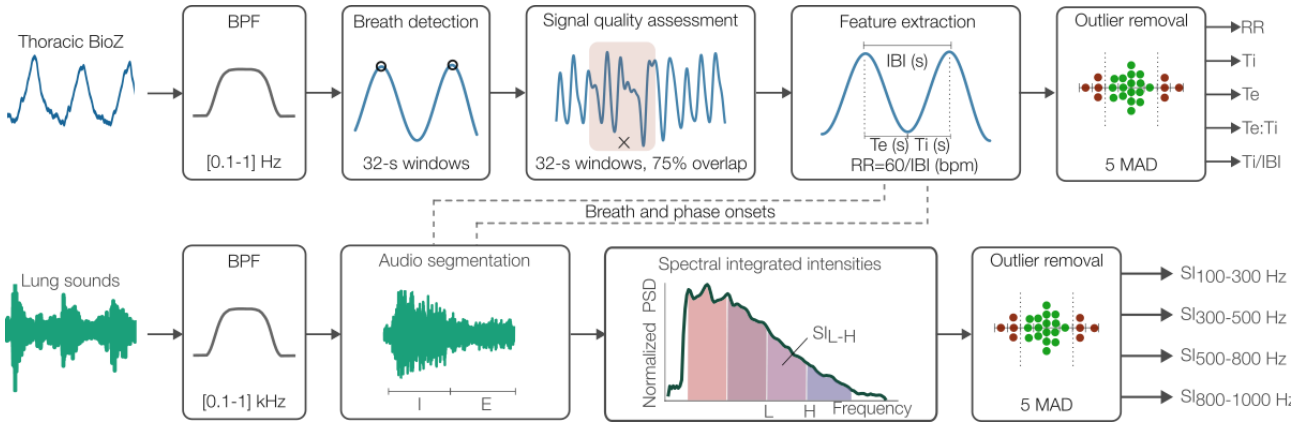
LSs were measured at 4 locations simultaneously using WIRS. Three locations were used to measure LSs: the anterior right and left upper chest and the posterior right lower chest. The fourth channel was moved from the posterior left lower chest to the suprasternal notch or neck for some participants to measure tracheal sounds. As in prior work, the accelerometer contact microphones (BU-23173-000, Knowles Electronics LLC) were enclosed in our previously reported acoustic enclosure and secured with surgical tape [26]. For the youngest participants, due to their small thorax sizes and for tracheal sound measurements, a more compact acoustic enclosure was used. These consisted of the same overmolded microphones used in Sanchez-Perez et al [26], but only a 3D-printed hollow backing piece was used to prevent loading of the sensor when external forces are exerted on it. Lying over the sensors for posterior chest auscultation while in the supine position is a notable example of such a case. The effectiveness of this acoustic solution was validated in prior work [30].

To validate the recordings against a commercial stethoscope, simultaneous recordings were taken with the Eko CORE digital stethoscope (Eko Devices). The recordings were manually aligned with WIRS following the simultaneous tapping of the Eko CORE diaphragm and the proximal WIRS channel. All measurements were performed by clinical staff at CHOA.

Signal Processing

Impedance Pneumography

The IP signal processing pipeline used in this work is shown in Figure 2. IP is a noninvasive signal that measures the respiratory-mediated changes in thoracic BioZ and has demonstrated excellent correlation to spirometric airflow and volume measures [31,32]. The pipeline follows a similar structure to our previously published version [26] but was modified for this dataset, which took place in an acute-care setting with a pediatric population in the awake state. BioZ-based respiratory monitoring in children with asthma has been previously performed during sleep due to their notorious lack of cooperation, which represents a challenge for physiological measurements [19,20].



The multifrequency thoracic BioZ signals were first linearly resampled to 100 Hz using a finite impulse response (FIR) antialiasing low-pass filter [26]. An amplitude-based removal stage was then applied to the signals to remove transient events with abnormally high thoracic BioZ values. These events were observed in some participants, likely due to abrupt movements loosening the BioZ wire connection. In this stage, portions of the signal were flagged for removal if they were 1.5 above or 0.5 below the median BioZ. Finally, the removed values were filled via linear interpolation.

As shown in Figure 2, the BioZ signals (150 kHz excitation frequency) were bandpass filtered with a Kaiser window FIR filter in a nominal frequency range of 0.1-1 Hz (6-60 bpm), resulting in IP 150 kHz. The upper end was increased up to 1.4 Hz for some participants with clear dominant frequencies above 1 Hz to ensure accurate processing of the signals. Following filtering, interbreath intervals (IBIs), hereafter referred to as “breaths,” were detected on 32-second windows (2-second overlap) with a minimum distance between peaks set to 0.67 seconds (RR<89.55 bpm), using prior work methodology [33,34]. An RR of 90 bpm has been used as an extreme upper end in previous work [35]. A signal quality index was then assessed using the Charlton et al [36] method. The method was applied using 32-second windows with 75% overlap [15], wherein a breath was considered good if it was labeled as such in any of the windows it belonged to [26]. The normalized SD threshold (ie, coefficient of variation) of the signal quality index method was set to 0.3 to avoid excessive rejection with the original threshold of 0.25, as reported by Blanco-Almazan et al [15], while controlling for the high intraparticipant variability expected in the recordings. Further, a window was considered of good quality if the mean correlation to the window breath template was above 0.7 and at least 60% of the window contained valid breaths.

After signal quality assessment, 3 features were extracted on a breath-by-breath basis: RR, expiration time (Te), and inspiration time (Ti). A feature-based outlier removal stage was then performed to remove breaths if any of these features laid 5 median absolute deviation (MAD) away from the median, over a window of 30 breaths [26,34]. Following this stage, the final set of features was RR, Te, Ti, expiration-to-inspiration time ratio (Te:Ti), and the inspiration time normalized by the IBI duration (Ti/IBI). These respiratory markers have been widely studied for monitoring obstructive pulmonary diseases using BioZ [15,19,20] and spirometry [37].

RenderX

Figure 2. Multimodal signal processing pipeline used to compute breath-by-breath and phase-by-phase respiratory features. BioZ: electrical bioimpedance; BPF: bandpass filter; E: expiration; I: inspiration; IBI: interbreath interval; MAD: median absolute deviation; RR: respiratory rate; SI: spectral integrated intensity; Te: expiration time; Te:Ti: expiration-to-inspiration time ratio; Ti: inspiration time.

Lung Sounds

The multichannel breath sounds were linearly resampled from 46.875 to 4 kHz to match Eko CORE sampling frequency using a FIR antialiasing low-pass filter. All LS signals were then filtered in the passband 100 to 1000 Hz using a zero-phase minimum-order FIR bandpass filter [27]. The low-frequency cutoff was chosen to suppress heart sound interference [38]. The upper cutoff frequency, on the other hand, suppressed high-frequency noise (eg, speech and hospital room noises) while preserving the parts of the spectrum occupied by normal and adventitious sounds (eg, wheezes) [39,40]. As in prior work, the IBI and phase (ie, inspiration and expiration) onset timings derived from the IP signal were used to index and segment the breath sounds [27]. Figure 2 shows an example of the process of fusing IP-derived timings with LS to segment the phases and extract features on them from prior work.

Following phase and breath segmentation, the normalized spectral integrated intensity (SI) described in Nabi et al [39] was computed across 4 different bands: 100-300, 300-500, 500-800, and 800-1000 Hz. These acoustic features capture the SI at frequency bands that have been found by prior airway obstruction modeling work [41] to be informative within the known LS frequency spectrum [40,42]. First, power spectral density (PSD) estimates were obtained using a 64-ms Hamming window [39] with 75% overlap. These were then normalized to 1 using their respective maximum PSD value to obtain PSD_{norm} [39]. The normalized SIs were then computed as the integrated PSD_{norm} in the specified ranges divided by total cumulative spectral intensity from 100 to 1000 Hz, as described in Nabi et al [39]. This was necessary to obtain comparable intensities regardless of the loudness of the sound, which depends on the airflow rate, auscultation location, and breathing phase [40,42]. The final SI values were defined as the average SIs across all windows within a given breathing-phase segment, resulting in SI100-300, SI300-500, SI500-800, SI800-1000, and for each range described earlier, respectively.

To assess outliers, the cumulative sum in the frequency range 100-1000 Hz of the unnormalized PSD of each breath segment and phase was used, namely, SI, SI_I, and SI_E. Specifically, a feature-based outlier removal stage was applied to remove breaths if any of these 3 features laid 4 MAD away from the median, over a window of 30 breaths. The final set of breaths used in this study consisted of the simultaneous good breaths following the processing procedures for IP and those described in this section for the LS data. In this way, the final breath instances had both IP and audio features. Hence, the final multimodal feature vector consisted of 5 IP features and 8 SI features across both breathing phases, yielding a total of 13 features.

Feature Time Series Generation

The final feature time series was generated after averaging the features over 32-second windows, 75% overlap to mitigate breath-by-breath variability due to physiology or phase-onset variability. A final outlier removal stage was performed by removing window averages lying 5 MAD from the median. Removed values were filled using linear interpolation. All signal processing was done in MATLAB R2020b (MathWorks).

Statistical Analysis

Two separate statistical analyses were carried out to assess differences in respiratory timing features across time and between patient and control groups. In the former, differences in the features within participants with both T1 and T2 time points available were assessed using Wilcoxon signed rank paired statistical tests. In the latter, features from the control group were compared against T1 and T2 of the matched participants using Wilcoxon rank sum tests with Benjamini-Hochberg correction for 2 comparisons (ie, T2-control and T1-control). Comparisons against the control group were conducted to highlight a trend in improvement in respiratory features. Participants were retrospectively matched to controls based on BMI and weight. Before conducting statistical tests, the feature time series of each participant was first aggregated with their mean across any given time point. R5 kHz was excluded from the statistical analysis since the values may not be directly comparable between participants due to differences in electrode locations, posture, and thorax sizes. Differences in demographic data between matched participants and controls were also assessed using Wilcoxon rank sum tests. All statistical analyses were carried out in R (R Foundation for Statistical Computing). A 2-tailed *P* value <.05

XSL•FO
RenderX

was considered significant. Numerical data are shown as median and IQR, unless specified otherwise.

Principal Component Analysis

The multidimensional feature matrix composed of IP- and LS-derived features was projected to 2 dimensions using principal component analysis (PCA) to elucidate any clustering between T1, T2, and control of the matched cohort. The first principal component (PC) was evaluated as a synthetic multimodal feature that maximally captures the variance in the data while retaining explainability. This analysis was carried out in Python (version 3.9; Python Software Foundation) using the scikit-learn library [43].

Results

Dataset Characteristics

Multimodal measurements were obtained from a total of 28 participants. The data from 2 participants were discarded due to measurement errors, resulting in 26 usable datasets (17 participants and 9 controls). Of the 9 controls, 7 were healthy participants, and 2 were patients hospitalized with no signs and symptoms of acute asthma. Table 1 shows detailed demographics for these participants, including the matched participants. No significant differences existed in the demographic data between matched participants and controls. Table 2 shows expanded demographic details for the participants, including the matched cohort, for T1 and T2. The variables include the type of respiratory support, albuterol administration (intermittent or continuous), terbutaline administration, aminophylline administration, time from the last albuterol administration, albuterol dosing interval, time to discharge from PICU, and time to discharge from hospital per recording (T1 and T2). A total of 48 multimodal recordings were obtained from 26 participants, from which 3 recordings were discarded due to poor data quality or measurement errors. The mean recording durations were 748 (SD 117), 661 (SD 86), and 688 (SD 111) seconds for T1, T2, and control, respectively. The mean proportion of raw BioZ data interpolated was 0.235% (SD 0.930%), 1.62% (SD 3.78%), and 0.146% (SD 0.327%) for T1, T2, and control, respectively. The mean final acceptable breaths retained for analysis were 76.1% (SD 23.4%) after applying our processing pipeline. The mean outlier removal proportion at the final feature time series level was 1.17% (SD 0.703%), 0.668% (1.06%), and 0.474% (SD 0.430%) for T1, T2, and control, respectively.

Analysis of Multimodal Respiratory Features

Three exemplary multimodal recording segments are shown in Figure 3. The segments show the annotated IP signal along with spectrograms of LSs measured with the Eko CORE and the proximal WIRS channel. A transition from wheezing at T1 to normal LSs at T2 for a 3-year-old patient is shown in Figure 3B and 3C. The more compact acoustic enclosures described in the Physiological Measurement section were used due to the small thorax size. An exemplary full-length recording is illustrated in Multimedia Appendix 1. The recording shows the annotated IP signal providing respiratory context and a sharp transition in the phase-specific sound intensities computed for CH_3 from strongly expiratory breath sounds shortly after the 150-second mark and back to normal-like strongly inspiratory sounds after 550 seconds. Exemplary spectrograms from all 4 channels during the segments with normal-like sounds and continuous strongly expiratory sounds are also illustrated.

The results for the paired time points of the participants are shown in Figure 4 and Table 3. Compared to T1, the IP-derived respiratory timings revealed a significant decrease in RR, while Ti and Te increased significantly. Te:Ti and Ti/IBI increased but did not reach statistical significance. The results for the LS-derived SIs revealed a decreasing trend for SI100-300 and an increasing trend for other subbands across both breathing phases. Significant differences were observed for SI100-300 in inspiration, SI500-800 in inspiration, and SI800-1000 in inspiration and expiration.

The results for the comparison between patients and controls for the matched cohort are shown in Figure 5 and Table 4. Significant differences existed between T1 and control for all features. Further, all features except RR, Ti, and Te resulted in significant differences between T2 and control. For the respiratory timings, a decreasing trend toward the control distribution was observed in RR and Ti/IBI, while an increasing trend was observed for Ti, Te, and Te:Ti. For the LS features, a decreasing trend toward the control distribution was observed for SI100-300, while increasing trends were observed for the rest of the subbands. Further, for all groups (T1, T2, and control) and phases (inspiration and expiration), a decreasing trend from the first subband's intensity (SI100-300) to the last (SI800-1000) was also observed (Table 4). Comparing T1 and control, the greatest change was observed for the inspiratory phase across all subbands, and the change magnitude increased as the frequency increased: SI100-300 (inspiration: –17.3% vs expiration: –13.77%), SI300-500 (inspiration: +55% vs expiration: +38.4%), SI500-800 (inspiration: +95.2% vs expiration: +84.1%), and SI800-1000 (inspiration: +114.3% vs expiration: +83.3%).

The PCA results for the matched cohort are shown in Figure 6. PC1 vs PC2 clustering and PC1's loadings ranked in order of importance are shown in Figures 6A and 6C. The aggregated PC1 values per participant in the matched cohort (Figure 6B) resulted in significant differences between T1-control (P<.001) and T2-control (P=.003).

Discussion

Principal Findings

In this study, we evaluated the feasibility of quantifying the physiological manifestations of acute asthma in children using a wearable multimodal sensing device. Leveraging the fusion of respiratory timings derived from the IP signal to index breathing cycles and phases, together with simultaneously obtained LSs, we found that phase-contextualized respiratory markers and acoustic signatures exhibited changes that correlated with the transition of patients from an acute asthma attack to a compensated respiratory status state that warranted hospital discharge. In particular, the respiratory timings showed that the breathing pattern trended toward normalcy, while the phase-contextualized acoustic signatures exhibited a change toward normal LSs by T2. We further show the value of fusing these modalities for enhancing the physiological interpretation of LS spectrogram images and for enabling a simple, interpretable proof-of-concept machine learning model for risk stratification of asthma. Hence, these results highlight the feasibility of combining wearable-based respiratory acoustic features derived from LS and respiratory pattern features derived from IP for quantifying and tracking the physiological manifestations of asthma in children.

IP and LS Features Can Quantify and Track the Resolution of Acute Asthma Signs

As the participants transitioned to a compensated respiratory status state—evidenced by the improvement in their signs enabling discharge from the PICU (Table 2)—we found that their breathing pattern changed substantially. In particular, RR decreased, and the duration of both breathing phases increased significantly. The significant reduction in RR indicates a progression toward reversing the airflow obstruction as the children were able to breathe easier. Although Te lengthening has been previously associated with airway narrowing [37], only 3 of the 13 participants showed longer Te at T1, with 2 of them also experiencing lower RR compared to T2. Furthermore, compared to T1 of the matched participants, participants in the control group exhibited significantly lower RR, longer Te, and higher Te:Ti. Hence, our phase and phase-ratio timing results seem to be largely influenced by RR. Previous studies have found strong correlations between RR and tidal breathing timings [44].

Similarly, the transition to a compensated respiratory state correlated with the LS-derived SI markers. Specifically, we found that as the participants transitioned to a more compensated state, SI100-300 decreased, while other higher-frequency subbands increased. This shift in spectral energy from low to high frequencies indicates an overall transition to a flatter and more spread-out spectrum, as we have observed on healthy participants in prior validation studies [26,27]. Notably, we recently studied forced-expiratory (FE) breathing maneuvers on healthy participants, some of which generated expiratory wheezes and found an increase in the mean roll-off frequency f95 (ie, the frequency containing 95% of the spectral energy) from 565 (SD 180) Hz in FE breaths to 929 (SD 130) Hz in normal deep breaths [27]. In addition, we observed the greatest change in the inspiratory features, particularly in the 2 uppermost frequency bands, which suggests a progressive increase in the inspiratory intensity for healthier respiratory states and supports the interpretation of a transition toward normal LS whose strongly inspiratory nature is well-known [42].

Compared to prior work, the finding that changes in spectral power between the groups did not alter the relative distribution of power within the spectral bands (ie, SI100-300>SI300-500>SI800-1000 for all groups) is in agreement with reports using this subband decomposition and normalized SIs, where the SIs were found to decrease as frequency increases regardless of the asthma severity level [39]. The SI trends from T1 found herein, however, disagree with those found by Nabi et al [39] if wheezing is assumed to be present at T1, decreased or resolved by T2, and absent in control. Comparing mild and severe asthma groups, Nabi et al [39] found that SI100-300 was reduced while the rest of the bands were increased with severity level. This discrepancy may be explained by important differences in study design and measurement conditions. First, the work by Nabi et al [39] only included high-quality segments with wheezes, while the production of wheezes, or lack thereof, was not part of the inclusion criteria in this work, nor was it used to define sign severity or disease progression. Second, prior work has used commercially available digital stethoscopes with noise-cancelling capabilities and transducers designed to aggressively filter out high frequencies [45], as illustrated in Figure 3, with the sharp drop in spectral energy after 500 Hz for the sounds measured with the Eko CORE.

In the context of asthma, the generation of wheezes is related to changes in airway thickness [46,47] and the narrowing of the air caliber leading to fluttering of the airway walls and fluids [47]. This leads to sounds exhibiting greater acoustic energy at frequencies higher than 300 Hz compared to normal LS [40,48-50]. A transition from wheezes to normal sounds would then be expected to result in SI100-300 increasing and the other SIs decreasing when using a digital stethoscope since the normal LS spectra will be inherently concentrated below 300 Hz by the sensor itself. In our case, however, the passive nature of the acoustic measurements leads to normal LS becoming flatter, compared to wheezes, rather than more concentrated at lower frequencies, with the ultimate result of decreasing SI100-300 and increasing the other subband's SIs, as the spectral energy becomes spread out between the other bands. Supporting this argument are the opposing trends in f75 and f95 (ie, the frequencies containing 75% and 95% of the total spectral energy, respectively) observed between the Eko CORE and WIRS when comparing normal deep breaths and FE breaths, wherein normal deep breaths resulted in both f75 and f95 increasing for WIRS but decreasing for Eko CORE [27].

Finally, the matched cohort analysis further confirmed the above observations, highlighting that the direction of change in all IP and LS markers across T1 and T2 was toward a compensated respiratory status (control). This suggests the progressive resolution of the acute asthma signs, wherein participants at T2 are physiologically closer to healthy individuals (ie, control group). However, the differences in RR, Te:Ti, and Ti/IBI

XSL•FO
RenderX

between T2 and control indicate that such a transition was not complete before PICU discharge. This may be explained by participants transitioning from the PICU to a regular hospital room before going home for further monitoring until recovery. Hence, their respiratory status at T2 may not have reached normalcy. In all, these results suggest that parameters derived from wearable-based IP and LS may be effectively used to quantify and track respiratory status from peak to resolution of an acute asthma attack.

Wearable-Based Multimodal Respiratory Features May Enable Robust Machine Learning Models for Risk Stratification of Asthma

In the proof-of-concept PCA, we found that PC1 captured close to 61% of the total variance in the data and was significantly higher for control compared to T1 and T2 for the matched cohort. The ranking further reveals that the transition toward a compensated respiratory status was most strongly influenced by increased intensity in the 500-800 Hz subband, decreased intensity in the 100-300 Hz subband, increased intensity in the 800-1000 Hz subband, and finally, increased intensity in the 300-500 Hz subband. Expiratory features showed higher ranks compared to their inspiratory counterparts, but the differences were marginal. This finding is consistent with those reported in Nabi et al [39], wherein inspiratory and expiratory phases were found to be equally informative for discriminating severity levels. Indeed, airway obstruction in asthma may lead to both inspiratory and expiratory LS abnormalities [40]. In the context of children with asthma, inspiratory and expiratory wheezes may be equally informative for characterizing asthma severity levels [51]. Nevertheless, the ability to segment wearable-based LS recordings into phases was enabled by the simultaneously measured IP signal, which motivates further investigation into their utility for monitoring children with asthma. Overall, the feature ranking revealed that the LS-derived phase-specific SI features were more important than the IP-derived features. This highlights the importance of quantifying and tracking respiratory acoustic features in combination with respiratory pattern features for monitoring asthma in children.

The Combination of IP and Multichannel Breath Sounds Holds Promise for Continuous Monitoring of Asthma Signs

Although the IP-derived features ranked lower in importance in our PCA, these results nevertheless highlight the potential of combining both sensing modalities for continuous monitoring of asthma. IP enables the respiratory contextualization of the sounds while also enabling the calculation of well-known tidal breathing parameters, many of which have shown promise for monitoring children with asthma [19-21,25,52]. Furthermore, the combination may not only enhance the discriminatory power of ML models but also the physiological interpretation of the results [27]. Examples of this are our findings of polyphonic expiratory wheezes (Figure 3) and the abrupt transitions in SI in 2 of the sickest participants of the cohort (Multimedia Appendix 1). In the former, the finding indicates that the patient was likely obstructed at T1 and that the reversal of the obstruction resulted in normal LSs at T2 [40,53]. Indeed, the clinical records indicate that this 3-year-old patient transitioned from high-flow nasal cannula at T1 to no ventilatory support at T2 and was discharged home at the same time as PICU discharge. Similarly, the albuterol dosing interval increased from 3.4 to 4.3 hours. Hence, the resolution of expiratory wheezes observed in this patient is consistent with the transition to a normal, compensated respiratory state. In the latter, the expiratory sounds found therein are consistent with snoring or rhonchi that likely resolved after awakening and repositioning. Notably, expiratory snoring and rhonchi may be indicative of airflow obstruction [40,53,54]. In these cases, tidal breathing parameters derived from the IP signal together with phase-specific SI features provide a more holistic and interpretable picture of the physiologic manifestations of asthma in children.

Limitations and Future Work

This study has several limitations. First, the sample size is small and may not capture the well-known disease heterogeneity and severity in asthma [3,6] and limits the assessment of correlations between physiological markers and clinical variables. Second, high intersubject variability in the respiratory markers' response throughout hospitalization was expected in this dataset because the measurement period was different between patients, as well as their relative recovery before PICU discharge. Third, the higher variability in RRs observed in this sample required subject-specific processing parameters to ensure signal quality. This may have introduced a minor bias in the final feature matrix. Fourth, due to the inability to use a regular patient room in the PICU for healthy controls, their measurement took place in a different setting. Although measurements were equally uncontrolled, these participants were naturally freer to move and talk. Furthermore, despite our efforts to maintain the same sensor positions throughout the recordings and across participants, changes in measurement conditions from recording to recording may have resulted in sensing location variability. Likewise, measurements likely took place in slightly different postures due to variations in head-of-bed angles and participants leaning forward for auscultation on the posterior chest. Ultimately, however, this study aimed to evaluate the feasibility of recording multimodal physiological signals with a wearable with the least amount of interference to the regular hospital workflows. Hence, the measured signals captured the natural variability that occurs in realistic continuous monitoring scenarios.

We only analyzed 1 of the 4 locations measured by WIRS. Including additional channels in the analysis will provide regional information, which may improve the results further because LS intensity is known to be a function of auscultation location [40,42]. The LS signal quality evaluation consisted of removing breaths with outlying intensities after rejecting breaths based on the LS signal quality. This may have resulted in the inclusion of low acoustic-quality breaths in the analysis. Yet, there are currently no validated methods for LS signal quality assessment that can be broadly applied to any type of sounds within the vast dictionary of LS described in the literature. Moreover, notable efforts along this direction have developed features to characterize noise based on recordings measured with sensors that integrate active noise-cancellation strategies, which may be different from those obtained with custom

XSL•FO
RenderX

wearable systems such as WIRS, as previously discussed. These observations underscore the need for novel signal quality assessment algorithms that not only incorporate LS data measured with wearable systems but also other wearable-based sensing modalities correlated to the generation of the sounds (ie, IP, IP-derived flow, and chest motion) [26,27,40,42,55]. The successful application of such a method may enable a robust and continuous monitoring of breath sounds at home and in otherwise uncontrolled settings.

Future work will evaluate ML models trained on more complex feature vectors that combine LS and IP data to elucidate their ability to predict sign severity in children hospitalized with asthma. Other auxiliary information obtained from multiple sensors (eg, kinematics and posture) will be evaluated to contextualize the recordings and increase robustness. Chest kinematics via an inertial measurement unit were measured by WIRS and may thus be studied in the future, given the promise shown in recent work to contextualize multimodal recordings [55,56]. Longer tidal-breathing recordings may be studied to enable the incorporation of respiratory pattern variability metrics [15]. Tidal flow variability metrics derived from tidal flow-volume loops may also be studied to assess lung function variability in children with asthma [19,20,24,52]. Furthermore, correlations to clinical outcomes will be studied on larger and more diverse datasets to elucidate the value of wearable technologies such as the one used in this work for supporting clinical decisions.

Conclusions

We evaluated the feasibility of monitoring children from peak to resolution of acute severe asthma signs using wearable-based BioZ and multichannel breath sounds. We found that respiratory timings derived from the IP signal and breathing phase–contextualized SIs derived from the LS signal were significantly altered from peak to resolution of asthma signs, and the changes trended toward the distributions observed in healthy participants. Their combination further enhanced the separation of groups in a low-dimensional subspace. These results highlight the potential of wearable multimodal sensing systems such as WIRS for monitoring the physiologic manifestations of acute asthma in children.

Abstract

Background: Falls among older adults are a growing and costly public health problem that often leads to mobility decline and loss of independence. Although clinical frameworks such as the Centers for Disease Control and Prevention's (CDC) Stopping Elderly Accidents, Deaths, and Injuries (STEADI) initiative recommend multifactor screening (gait, balance, strength, fear of falling, and fall history), most wearable fall risk assessment systems rely on a small set of risk factors (typically gait), which creates a gap between clinical practice and automated wearable assessment.

Objective: This study aims to evaluate the importance of STEADI-based fall risk factors and provide design guidance for clinically compatible wearable fall risk assessment systems.

Methods: We created a dataset of 24 older adults (10 low fall risk and 14 high fall risk) from a publicly available plantar pressure dataset of 48 participants by retaining only those with consistent fall risk labels based on both the Berg Balance Scale and the Timed Up and Go test. A total of 18 features were extracted to quantify gait, strength, balance, fear of falling, and fall history. Random forest (RF) models were trained with leave-one-subject-out cross-validation to assess fall risk. Importance of STEADI-based factors was assessed by two methods: (1) estimating Shapley Additive Explanations values based on a single RF model trained on all features; and (2) training 5 separate RF models, each on 1 STEADI factor category, and comparing their fall risk classification accuracies.

Results: In this secondary analysis, the RF model trained on all features achieved a subject-level accuracy of 87.53% (95% CI 75%-100%). Shapley Additive Explanations analysis identified the right foot flat phase ratio (fear of falling feature) as the highest-ranked feature, followed by maximum right forefoot ground reaction force (strength feature), whereas traditional gait features did not appear in the top 10. The 5 separate RF models trained on individual STEADI-based factor categories showed a similar trend in mean participant-level accuracy: fear of falling, 87.59% (95% CI 75%-100%); strength, 79.18% (95% CI 62.5%-95.83%); balance, 70.5% (95% CI 50%-87.5%); gait 70.81% (95% CI 54.17%-87.5%); and fall history 62.37% (95% CI 50%-75.1%). However, paired comparisons did not show statistically significant differences in accuracy between the gait model and the models trained on other factors.

Conclusions: These preliminary results show that commonly overlooked nongait factors are potentially as informative as gait, although clear superiority was not demonstrated in this dataset. The novel foot flat phase ratio ranked higher than all other evaluated features, which showed the value of domain knowledge–informed feature engineering. These preliminary findings indicate that nongait STEADI factors merit consideration in the design of wearable fall risk assessment systems.

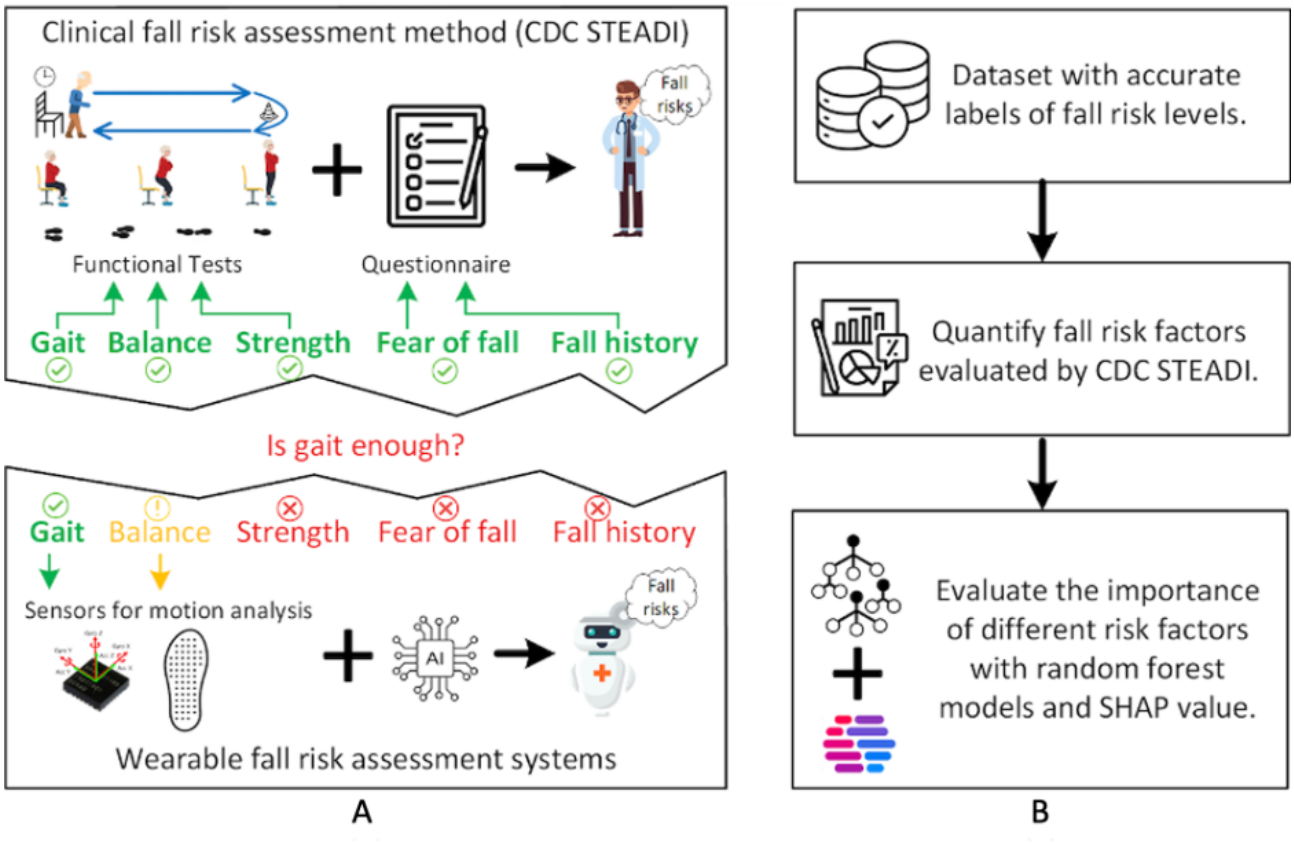
Introduction

Falls are the leading cause of fatal and nonfatal injuries among older adults in the United States [1]. In 2022, falls accounted for approximately 48% of all injury-related deaths among adults aged 65 years or older [1,2]. Each year, falls lead to nearly 3 million emergency department visits and 1 million hospitalizations among older adults [2]. Many older adults who experience falls develop a fear of falling, which can reduce their independence, restrict their mobility, and limit their social interaction [3]. The annual cost of treating nonfatal fall-related injuries among older adults has increased from US $50 billion in 2015 to US $80 billion in 2020 [4] and is projected to exceed US $101 billion by 2030 [5].

To avoid the serious consequences of falls, proactive detection and mitigation of fall risks have been recognized as effective measures and recommended by the Centers for Disease Control and Prevention (CDC). Different from fall prediction or fall detection, fall risk assessment identifies an individual's risk of falling and helps guide targeted interventions to reduce future falls. The Stopping Elderly Accidents, Deaths, and Injuries (STEADI) initiative, developed by the CDC, is one of the most widely used tools for fall risk assessment. It begins with 3 key screening questions related to history of falls, fear of falling, and unsteadiness, followed by further assessment of gait, strength, and balance. Although the STEADI enables a comprehensive fall risk assessment, its practical application is limited because it is time consuming [6-11] and is typically conducted in clinical settings that may not fully reflect everyday behavior [12-14].



To address the limitations of clinical assessments, new technologies, especially wearable systems, have been proposed to enable automatic fall risk assessment in free-living environments. However, most existing wearable systems mainly rely on gait-related features, which creates a disconnect from clinical practice. As shown in Figure 1A, clinical methods such as STEADI rely on a comprehensive evaluation of gait, balance, strength, fear of falling, and fall history to assess fall risk. However, existing wearable assessment systems rely on an incomplete set of risk factors (typically gait) extracted from sensor data. For example, inertial measurement unit (IMU)–based wearable technologies have been widely explored for fall risk assessment using measured gait parameters. However, their limitations in measuring strength-related factors prevent them from achieving a comprehensive fall risk assessment required by clinical standards [15,16].

This mismatch between wearable systems and clinical tools raises a research question: "Is gait enough?" To answer this question, this study conducted a comprehensive evaluation of the importance of STEADI-based factors for wearable fall risk assessment. As shown in Figure 1B, this study built a dataset with accurate fall risk labels, quantified fall risk factors evaluated by STEADI, and evaluated the importance of different risk factors using random forest (RF models and Shapley Additive Explanations (SHAP) values.

The contributions of this paper are as follows: first, a new dataset with clinically aligned fall risk labels was built to enable reliable evaluation of the importance of STEADI-based fall risk factors. The Timed Up and Go (TUG) test and the Berg Balance Scale (BBS) are 2 frequently used clinical tests for fall risk assessment. Although neither test alone provides a comprehensive evaluation, their combination covers most of the assessments used by STEADI. This study proposed a new labeling standard that combines TUG and BBS scores to identify participants with high and low fall risk from a public dataset. Second, a comprehensive set of risk factors evaluated by STEADI was quantified. In addition to commonly used features to quantify gait, balance, strength, and history of falls, a novel feature, the foot flat phase ratio (the ratio of the foot flat phase duration to the stance phase duration), was extracted to quantify fear of falling. This feature is informed by cautious gait patterns associated with fear of falling and was found to be the highest-ranked feature in this study. Third, the importance of STEADI-based fall risk factors was comprehensively evaluated to guide the development of wearable fall risk assessment systems. An explainable framework was developed with RF models and SHAP values to quantify the contribution of each factor to fall risk assessment.

Methods

Ethical Considerations

The PlantPre dataset used in this study is deidentified and has been released under the Apache-2.0 license. Ethical approval for the collection of the PlantPre dataset was obtained by Hu et al [17] from the Medical Aircraft Ethics Committee of the First Affiliated Hospital of Jinan University (approval number: KY-2020-099).

Preparing the Dataset With Accurate Fall Risk Labels

To reliably evaluate the importance of different factors for fall risk assessment, a dataset with accurate labels of participants with high and low fall risk is essential. In this study, a new dataset was prepared based on a publicly available dataset (PlantPre) that includes plantar pressure, fall history, TUG test score, BBS score, body weight (BW), and other variables collected from 48 older adults [17]. The plantar pressure data were collected with smart insoles during 2-3 minutes of normal level-ground walking. As shown in Figure 2, each smart insole has 8 sensors for measuring pressure under the foot.

The TUG test and BBS are widely used for fall risk assessment [18,19]. During the TUG test, the patient is observed and timed while rising from an armchair, walking 3 m, turning, walking back, and sitting down again. A TUG score exceeding a threshold (eg, 13.5 seconds) is used to identify individuals at higher risk of falling [20]. The BBS is a widely used clinical test comprising 14 tasks to assess both dynamic and static balance [21]. A BBS score below a specific threshold (eg, 36) usually indicates high fall risk [22]. However, neither the TUG test nor the BBS alone is sufficient to reliably identify older adults with high risks of falls [23,24].

To enhance the accuracy of identifying participants with high or low fall risk, reduce noisy fall risk labels, and provide a more reliable basis for the evaluating the importance of STEADI-based factors, a new labeling method that integrates both the BBS and TUG scores was introduced. Firstly, participants were independently labeled based on the BBS and TUG score. Participants with a BBS score ≤36 were classified as high risk, whereas those with a BBS score >36 were classified as low risk [22]. Similarly, participants with a TUG score ≥13.5 seconds were labeled as high fall risk, whereas those with TUG score <13.5 seconds were labeled as low fall risk [20]. Previous research has shown the effectiveness of these thresholds for reliable fall risk assessment [20,22]. Participants whose labels agreed across both tests were then retained, whereas those with conflicting labels were excluded. This approach addressed the limitations of labeling based on a single test and provided a more reliable fall risk labeling. The flowchart of the proposed participant labeling method is illustrated in Figure 3.

Because 1 participant did not have a recorded history of falls, which was 1 of the fall risk factors evaluated in this study, that participant was excluded from this study. Therefore, the total number of participants shown in Figure 3 was reduced to 47.

XSL•FO
RenderX

As shown in Figure 3, a total of 23 participants were excluded, and the final dataset prepared for this study comprised 24 participants, with 10 labeled as low fall risk and 14 as high fall risk. As shown in Table 1, the TUG score, BBS score, and fall history of each selected participant were listed. The final dataset of 24 participants had no missing values for any variable used in this study.

Quantifying STEADI-Based Fall Risk Factors

Overview

According to the STEADI initiative, gait, balance, strength, fall history, and fear of falling are critical factors for fall risk assessment. In this study, a comprehensive set of features was extracted from the prepared dataset to quantify gait, balance, strength, fall history, and fear of falling. The strength and fear of falling features used in this study are pressure-derived proxies rather than direct clinical measures such as dynamometry-measured strength. Table 2 summarizes all the extracted features and their definitions. The total ground reaction force (GRF) was computed as the sum of the pressure measured by all sensors. Subregional (ie, hindfoot, midfoot, and forefoot) GRFs were obtained by summing the pressure readings from sensors within each specific foot region. To account for differences in BW, each participant's GRF was normalized to BW. The normalized total GRF was then segmented into individual gait cycles using an adaptive threshold method [25]. In total, 3556 gait cycles were detected across 24 participants and were used to extract features to quantify fall risk factors.

RenderX

Table 2. Extracted features for quantifying Stopping Elderly Accidents, Deaths, and Injuries (STEADI)–based fall risk factors.

Category and gait parameters	Description
Gait features	
Gait cycle time (s)	Time duration between 2 consecutive occurrences of any gait event (eg, heel strike) for the same foot. This parameter was calculated for both feet.
Step time (s)	Time duration from the heel strike of one foot to that of the other foot. This parameter was calculated for both feet.
Stance time ratio (%)	Length of the interval from heel strike to toe off of the foot in a stride divided by the gait cycle time of the same stride. This parameter was calculated for both feet.
Swing time ratio (%)	Length of the interval from toe off in a stride to heel strike of the next stride of the foot divided by the gait cycle time of the same stride. This parameter was calculated for both feet.
Single support time ratio (%)	Length of the interval during which only one foot is in contact with the ground divided by the gait cycle time. This parameter was calculated for both feet.
Double support time ratio (%)	Length of the interval during which both feet are in contact with the ground divided by the gait cycle time. This parameter was calculated for both feet.
Strength-related features	
Median weight acceptance rate (BW/s[a])	Median rate of change of the GRF[b] from heel strike to the weight acceptance peak of the GRF. This parameter was calculated for both feet.
Median push-off rate (BW/s)	Median rate of change of the GRF from the push-off peak to toe off. This parameter was calculated for both feet.
Maximum hindfoot GRF (BW[c])	Maximum force measured by all sensors in the hindfoot region. This parameter was calculated for both feet.
Maximum midfoot GRF (in BW)	Maximum force measured by all sensors in the midfoot region. This parameter was calculated for both feet.
Maximum forefoot GRF (in BW)	Maximum force measured by all sensors in the forefoot region. This parameter was calculated for both feet.
Balance-related features	
Absolute CoP[d] range (cm)	Absolute difference between the maximum and minimum CoP during a gait cycle. This parameter was calculated for the ML[e] direction and the AP[f] direction of both feet.
Average CoP rate of change (cm/s)	Average CoP change during a gait cycle. This parameter was calculated for the ML direction and the AP direction of both feet.
Maximum CoP rate of change (in cm/s)	Maximum CoP changes during a gait cycle. This parameter is calculated for the ML direction and the AP direction of both feet.
Fear-of-falling–related features	
Foot flat phase ratio (%)	Length of the interval when both hindfoot and forefoot are in contact with the ground, divided by the length of the interval from the heel strike to toe off of the foot during a gait cycle. This parameter was calculated for both feet.
Heel strike to foot flat phase start (s)	Length of the interval between heel strike and foot flat start within a gait cycle. This parameter was calculated for both feet.
Foot flat phase end to toe off (s)	Length of the interval between foot flat end and toe off within a gait cycle. This parameter was calculated for both feet.
History-of-falls–related features	
Fall History	A binary variable indicating whether the individual experienced a fall within 1 year before data collection. A value of 1 denotes a history of falling, and a value of 0 denotes no fall history.

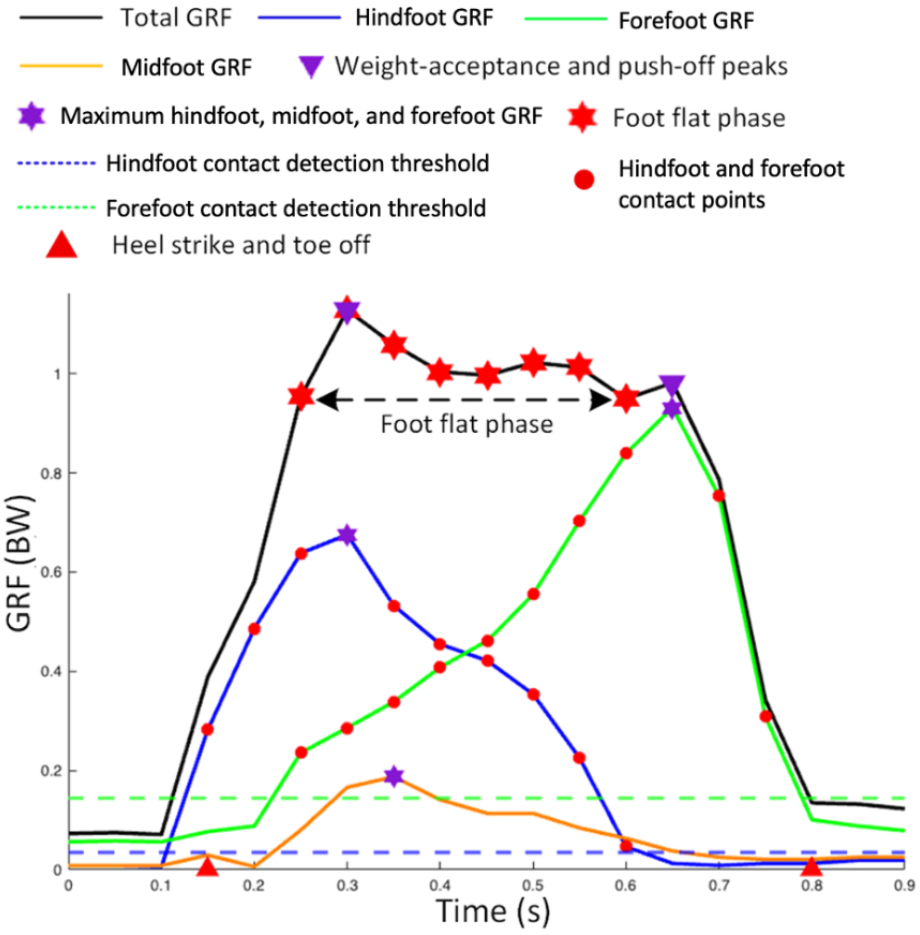
Gait Features

Gait is recognized as a major fall risk factor among older adults [26]. To quantify gait-related fall risk factors, a total of 6 features (gait cycle time, step time, stance time ratio, swing time ratio, single support time ratio, and double support time ratio) were extracted from each gait cycle. Swing and stance phases were identified using a dynamic threshold proposed in previous research [25]. Figure 4 and Table 2 show the gait features extracted from each gait cycle.

Figure 4. Gait features extracted for a right foot gait cycle. BW: body weight; GRF: ground reaction force.



Strength-Related Features

Strength-related features extracted from plantar pressure during walking are strong indicators of fall risk [27]. In this study, as shown in Figure 5 and Table 2, a total of 5 strength-related features were extracted from plantar pressure [28,29]. In addition to the maximum GRF in the hindfoot, midfoot, and forefoot (purple stars in Figure 5), the median rate of change of the GRF was calculated over 2 intervals: from heel strike to the weight acceptance peak (median weight acceptance rate), and from the push-off peak to toe off (median push-off rate). Zero crossings of the GRF rate-of-change signal were used to identify these peaks. The peaks closest to heel strike and toe off were designated as the weight acceptance and push-off peaks (purple triangles in Figure 5), respectively. In gait cycles with only 1 detected peak, the peak was used to calculate both parameters.

XSL•FO
RenderX

Figure 5. Illustration of key parameters for extraction of strength-related and fear-of-falling–related features. BW: body weight; GRF: ground reaction force.

Fear-of-Falling–Related Features

Older adults who experience fear of falling often adopt a cautious gait pattern with significant reductions in various parameters [30,31]. While most studies used conventional gait parameters such as stance time and double-support time to quantify fear of falling, these features have not shown significant contributions to fall risk assessment [31]. To more accurately quantify the cautious gait pattern, the stance phase was divided into 3 subphases: heel strike, foot flat, and toe off. People with cautious gait tend to adopt a flat-foot landing strategy that is characterized by a longer foot flat phase duration but shorter intervals from heel strike to foot flat and from foot flat to toe off [32]. Therefore, 3 features were extracted: the ratio of foot flat phase duration to stance phase duration, the time interval from heel strike to the start of the foot flat phase, and the time interval from the end of the foot flat phase to toe off.

The foot flat phase within each gait cycle is defined as the interval during which both hindfoot and forefoot subregions are in contact with the ground [33]. Inspired by previous studies, dynamic GRF thresholds (blue and green dashed lines in Figure 5) were used to detect ground contact of both hindfoot and forefoot regions [25]. As shown in Figure 5, samples in the foot flat phase are marked with red stars, and the times of heel strike and toe off are marked with red triangles on the left and right, respectively.

Balance-Related Features

In this study, features extracted from the center of pressure (CoP) were used to quantify balance because of their high reliability and accuracy [34]. The CoP is defined as the location at which pressure is concentrated and is calculated by multiplying each sensor's coordinates by its respective pressure reading and normalizing by the total GRF. The CoP in the anteroposterior (AP) and mediolateral (ML) directions was calculated in equation 1.

In this equation, CoP_{AP} and CoP_{ML} indicate the CoP in the AP and ML directions, respectively. x_i and y_i and p_i are the coordinates and the pressure readings of sensor i, respectively. CoP variations and rate of change have been shown to be effective for assessing balance [35,36]. In this study, absolute variations in CoP and the mean and maximum rate of change of CoP were extracted for each gait cycle in the ML and AP directions. CoP variations in the ML direction provide information about lateral sway during each gait cycle, whereas AP CoP changes provide information about weight-transfer patterns throughout each gait cycle.

History of Fall Feature

History of fall is a binary variable indicating whether the individual experienced 1 or more falls in the past 12 months.

XSL•FO
RenderX

A value of 0 indicates no fall history, whereas a value of 1 indicates at least 1 fall during this period.

Evaluating Importance of Different Fall Risk Factors

To evaluate the importance of different fall risk factors, two methods were implemented (1) training a single RF model using all quantified fall risk factors and evaluating the importance of individual risk factor using SHAP values; and (2) training 5 separate RF models, each using 1 of the 5 types of risk factors, with achieved fall risk classification accuracy used to determine the relative importance of each type of risk factors [37]. Each RF model consisted of 100 decision trees and used the Gini impurity criterion for node splitting. The minimum number of samples required to split an internal node and to form a leaf node was set to 2 and 1, respectively. Following standard RF practice, trees were grown to full depth without a maximum depth constraint. No feature selection was performed. Because class imbalance in the dataset was modest, no explicit class weighting or resampling was applied during training.

To avoid participant-specific overfitting and ensure the achieved accuracy generalizes to unseen individuals, we implemented a leave-one-subject-out cross-validation (LOSO-CV), in which the model was trained on 23 participants and tested on the remaining 1 participant. Traditional validation approaches that shuffle and split samples across all participants can place data from the same participant in both training and testing sets. This can cause the model to rely on memorized participant-specific feature patterns rather than fall-related feature patterns, leading to overestimated testing accuracy. By excluding the testing participant's data from the training process, LOSO-CV evaluates the true performance of the model in fall risk assessment. Within each LOSO-CV fold, the training and testing data were standardized using the mean and SD computed from the training set only, which prevented information leakage.

To quantify individual feature contributions, SHAP values were used [38]. This method uses a game-theoretic approach to estimate each feature's impact on the model's output. SHAP values were first computed for each gait cycle of the held-out test participant of each LOSO-CV fold. For each feature, absolute SHAP values were then averaged across all gait cycles of the held-out participant in that fold to obtain 1 fold-level feature importance value. Finally, these fold-level values were summarized across the 24 LOSO-CV folds using the mean and SD.

Results

Overview

This section presents the performance of the RF model for classifying individuals with low and high fall risks, analyzes feature contributions using SHAP values, and evaluates the importance of different types of STEADI-based factors for fall risk assessment.

Performance of RF Model With all STEADI-Based Features for Fall Risk Assessment

Table 3 summarizes the model's classification accuracy for each participant in the dataset. Using all extracted features as inputs, the RF model achieved an overall accuracy of 84.93% in fall risk classification across all gait cycles. Although 3556 gait cycles were available in the dataset, cycles within a participant are not independent. Therefore, the participant was treated as the primary unit for performance analysis. To determine each older adult's final risk of falling, majority voting across all their gait-cycle classifications was used. A participant was considered correctly classified if at least 50% of their gait-cycle classifications matched the ground-truth fall risk label. The RF model achieved a participant-level accuracy of 87.5% in identifying older adults' risk of falling.

To quantify the uncertainty of model performance, we generated 2000 stratified participant-level bootstrap resamples with replacement from the full LOSO-CV predictions to estimate the mean and 95% CI of the model's accuracy, sensitivity, specificity, receiver operating characteristic area under the curve, and Brier score, as shown in Table 4.

Metrics	Values, mean (95% CI)
Accuracy, %	87.53 (75-100)
Sensitivity, %	79.10 (57.14-100)
Specificity, %	100 (100-100)
ROC-AUC	0.99 (0.96-1.00)
Brier score	0.07 (0.02-0.12)

Importance of Different Types of Fall Risk Factors Based on SHAP Values

Figure 6 summarizes the top 10 features in predicting the risk of falls based on SHAP values. Mean and SD of absolute SHAP values are presented in Figure 6. Among all STEADI-based features, the “right foot flat phase ratio” has the highest rank. According to Figure 6, a higher foot flat phase ratio leads to the prediction of high fall risk, which aligns with clinical findings that longer foot flat phases characterize cautious gait patterns associated with fear of falling and high fall risk [32]. The “maximum right forefoot GRF” ranked second, with higher values predicting lower fall risk. This is consistent with clinical knowledge, as a higher maximum forefoot GRF indicates greater lower-limb strength, which contributes to better gait stability and balance and consequently a lower risk of falls. Fall history ranked third, with more previous falls predicting higher fall risk. This is consistent with clinical practice, where fall history is recognized as an indicator of risk of falls. However, because the dataset includes only 24 participants, the relative ordering should be interpreted as preliminary.

Importance of Different Types of Fall Risk Factors Based on Classification Accuracy

To further illustrate the importance of different types of STEADI-based factors for fall risk assessment, 5 separate RF models were trained, each using features from only 1 type of factor listed in Table 2. The classification accuracy achieved by each model was used to determine the importance of the corresponding type of fall risk factor.

Table 5 shows the classification accuracy achieved by each category of fall risk factor. Overall, fear-of-falling–related features, strength-related features, balance-related features, gait features, and the history-of-fall feature achieved accuracies of 75.68%, 72.44%, 68.34%, 66.31%, and 62.5%, respectively. This ranking is mostly consistent with the result in the previous section "Importance of Different Types of Fall Risk Factors Based on SHAP Values." However, because the dataset includes only 24 participants, the relative ordering should be interpreted as preliminary.

To quantify the uncertainty of model performance, we generated 2000 stratified participant-level bootstrap resamples with replacement from the full LOSO-CV predictions to estimate the mean and 95% CI of the model's accuracy, sensitivity, specificity, receiver operating characteristic area under the curve, and Brier score, as shown in Table 6.

To further evaluate the significance of differences between gait features and other fall risk factor features, a paired bootstrap comparison was performed. The mean and 95% CI of the accuracy differences between the model trained on gait features and the models trained on other fall risk factor features were calculated across 2000 stratified participant-level bootstrap resamples. As shown in Table 7, the mean paired accuracy differences for "fear of falling–gait," "strength–gait," and "balance–gait" are all positive. Since the corresponding 95% CIs indicate that these paired differences were not statistically significant, the results indicate that nongait factors are potentially as informative as gait, although clear superiority was not demonstrated in this dataset.

To provide more insight into the importance of individual features within each category of fall risk factors, SHAP values for the features are shown in Figure 7. According to Figure 7A, older adults with a higher risk of falling showed a longer foot flat phase ratio. This aligns well with clinical findings that older adults with a fear of falling adopt a cautious gait with longer period for the foot flat phase [32].

As shown in Figure 7B, maximum GRF of the forefoot and hindfoot were identified as the most important strength features, with higher maximum GRF indicating a lower risk of fall. This is consistent with clinical findings, as maximum forefoot and hindfoot GRF correspond to peak forces during toe off and heel strike, respectively, and higher forces reflect greater lower-limb strength for controlling walking posture and maintaining stability. Similarly, the weight acceptance rate, which correlates with the hindfoot GRF, was also ranked highly in the list. The lower ranking of maximum midfoot GRF is expected, as it reflects forces during the relatively static foot flat phase rather than the critical dynamic heel strike and push-off phases. The low ranking of "median push-off rate" was unexpected. The reason for this may be the hysteresis effect of the pressure sensor during the push-off phase, which potentially leads to an underestimation of this feature.

Additionally, among the balance-related features (Figure 7C), the maximum CoP velocity in the AP direction was identified as the most important feature for fall risk assessment. As indicated by the SHAP values, older adults at higher risk of falling exhibited lower maximum COP velocities in the AP direction, which reflects a reduced walking speed. This is consistent with clinical findings that older adults at high risk of fall are associated with slower walking speeds.

Finally, as shown in Figure 7D, step time and double-support time were the most important gait features for fall risk assessment. Based on the SHAP analysis, a higher double-support time and step time indicate a higher risk of falling. This result is consistent with clinical studies, where older adults at a higher risk of falling have prolonged double-support and step time [31].

AP: anteroposterior; CoP: center of pressure; GRF: ground reaction force; ML: mediolateral.

Discussion

Overview

This paper presented a comprehensive study to quantify the importance of STEADI-based factors for wearable fall risk assessment. Based on a newly developed dataset with accurate fall risk labels and a comprehensive feature set that quantifies STEADI-based fall risk factors, the importance of different STEADI-based factors was evaluated using RF models and SHAP analysis. This section discussed the new knowledge generated from this study, provides design guidance for the development of wearable fall risk assessment systems, and specifies the limitations of this study and plans for future work.

STEADI-Based Factors Other Than Gait Are Also Important for Wearable Fall Risk Assessment

Although clinical studies have shown that gait, balance, strength, fear of falling, and history of falling are important for fall risk assessment [39-41], most wearable systems still mainly rely on gait features for fall risk assessment [42-44]. The importance of nongait fall risk factors in wearable fall risk assessment has not been comprehensively evaluated.

Choi et al [43] developed a model to predict the TUG score using gait features extracted from 3D acceleration data collected from pelvis and both feet during normal walking, and then used the predicted TUG scores for fall risk assessment. Maiora et al [42] used IMU sensors to collect motion data during the TUG test and built convolutional neural networks and recurrent neural network models based on gait features extracted from the IMU data for fall risk assessment. Agrawal et al [44] proposed a smart insole–based system for fall risk assessment. They used a commercial smart insole with 5 force-sensitive resistance sensors to collect dynamic plantar pressures from 5 foot locations: big toe, medial forefoot, lateral forefoot, midfoot, and heel. The fall risk labels were generated using the TUG score with a threshold of 13.5, and the RF model achieved an accuracy of 81% in fall risk classification. Although the smart insole has the potential to quantify a comprehensive set of fall risk factors, this study focused on gait and balance features only without exploring the importance of different types of factors for fall risk assessment.

This study provides preliminary evidence to address this gap by comprehensively evaluating the importance of STEADI-based factors for wearable fall risk assessment. The results show that nongait factors are potentially as informative as gait, although clear superiority was not demonstrated in this dataset. The exclusion of these important factors may lead to unreliable fall risk assessment results. This finding provides preliminary design guidance on the necessary factors that should be considered when developing wearable fall risk assessment systems.

Effective Features Can Be Generated From Domain Knowledge

To build the connection between clinical practice and wearable fall risk assessment systems, it is important that the outputs of wearable systems are explainable using clinical knowledge. One solution is to ensure that predicted fall risks are described using clinically meaningful features. This requires developing features based on domain knowledge.

This study showed that effective features can be generated from domain knowledge. For example, based on the domain knowledge that older adults with fear of falling usually adopt a cautious gait with a flat-foot walking pattern, new features specifically focused on the foot flat phase were extracted. The foot flat phase ratio feature was shown to be the most effective feature for fall risk assessment, as shown in Figure 6. This new feature was more effective than many widely used fear-of-falling features, such as stance time and double-support time, which were not ranked in the top 10 features in Figure 6. Compared with stance time and double-support time, the foot flat phase ratio captures how the stance phase is redistributed around foot contact and push-off, rather than simply prolonged duration. This makes it more sensitive to changes in landing strategy and weight-transfer behavior, which may reflect a cautious walking pattern associated with fear of falling. This finding contributes to the knowledge base on effective features to quantify fear of falling and shows the value of domain knowledge in developing new features for fall risk assessment.

Limitations and Future Work

Although this study quantified different fall risk factors and presented a preliminary evaluation of their importance in fall risk assessment, its scope is limited by the existing dataset, which will be addressed by future studies.

First, although the analysis included 3556 gait cycles, these gait cycles were collected from only 24 participants. Therefore, the effective independent sample size is determined by the number of participants rather than the number of gait cycles. The limited number of participants may affect the stability of feature-importance rankings when generalizing to a broader population. Therefore, the main contribution of this preliminary study is not the feature-importance ranking but the finding that STEADI-based factors beyond gait features may also contribute meaningfully to fall risk assessment. Given the limited participant-level sample size and wide CIs, the findings should be interpreted as preliminary. Additionally, although the class imbalance in the dataset was modest (14 high-risk vs 10 low-risk participants), it may still bias the model toward the majority class and influence feature-importance estimates. In future work, we will build a new more balanced dataset with more participants to further explore the relative importance of STEADI-based factors.

Second, the gait, strength, balance, and fear-of-falling–related features were extracted only from the plantar pressure data collected using a smart insole with 8 pressure sensors. One potential shortage is that 8 sensors may not provide enough spatial resolution to quantify different risk factors with optimal accuracy. Additionally, although temporal gait parameters were extracted from plantar pressure data, spatial gait parameters such as stride length and gait speed could not be extracted for analysis. This may lead to an underestimation of the contribution of gait-related features. In the future, we plan to address these limitations by using the smart insole developed in our laboratory. This insole has 96 pressure sensors uniformly distributed across the insole, and an accurate IMU sensor integrated into it. It has been comprehensively validated and successfully applied in various research projects [25,33,45-52]. With this smart insole, we will build a new dataset by collecting comprehensive data from more older adults, enabling a more accurate and comprehensive evaluation of the importance of different fall risk factors.

Third, to reliably evaluate the importance of different factors for fall risk assessment, the dataset used in this study was built by excluding participants whose TUG and BBS labels disagreed. Although this method reduces label noise, the resulting dataset may not fully reflect the heterogeneity of real clinical populations and may reduce ecological validity. Therefore, the reported model performance may overestimate the accuracy achievable in a heterogeneous clinical population. Additionally, the estimated importance of STEADI-based factors may not fully generalize to participants whose BBS and TUG assessments disagree. Validation in a larger and more heterogeneous cohort, including discordant cases, is an important direction for future work.

Participant-level classification was obtained by majority voting across all gait cycles of each participant. A participant was considered correctly classified if at least 50% of their gait-cycle classifications matched the ground-truth fall risk label. However, the stability of this approach depends on the number of gait cycles available for each participant and may be reduced when the number of cycles is relatively small or when the proportion of positive classifications is close to 50%. Therefore, participant-level classifications near the decision boundary should be interpreted with caution.

Conclusion

This study provides a preliminary evaluation of the importance of STEADI-based factors for wearable fall risk assessment. The study quantified a comprehensive set of STEADI-based factors and introduced a novel domain-knowledge–informed feature, the foot flat phase ratio. The key finding is that commonly overlooked nongait factors are potentially as informative as gait, although clear superiority was not demonstrated in this dataset. These preliminary findings indicate that nongait STEADI factors merit consideration in the design of wearable fall risk assessment systems.

Abstract

Background: Wearable fitness trackers have become a valuable tool in public health research due to their ability to collect large-scale, individual-level data at a low cost. Because of this, wearables have the potential to mitigate the urgent need for health research in low-resource settings. However, their use has been largely limited to high-income settings, and a major challenge remains: high rates of missing data. This problem may be exacerbated in low-resource environments where logistical and operational barriers further complicate data collection. Wearable sleep data collected in an urban informal settlement in Uganda during The Onward Project on Well-being and Adversity project revealed substantial challenges related to missingness in low-resource research settings.

Objective: The study aimed to characterize the patterns and frequency of missing data and to demonstrate the use of analytical methods to determine the underlying missingness mechanism.

Methods: For this study, 300 women in slum communities in Kampala were equipped with Garmin smartwatches that collected data over 5 days. The nature of missingness was assessed through four methods: pattern analysis, the Little test, a random forest classification model, and a logistic regression classification model. Pattern analysis is an established method of identifying missing data patterns, while the Little test is used specifically to identify missing completely at random data. Random forest and logistic regression models are more recent methods proposed to identify the mechanism of missingness; both were used to examine agreement between the 2 methods and to ensure a thorough examination of missingness patterns.

Results: Approximately 30% of nighttime data were missing. Three patterns were identified that occurred in over 10% of participants' data: no data missing, fifth night of data missing, and all nights of data missing. Pattern analysis and the Little test (P<.001) indicated that the data were not missing completely at random. Both the random forest (area under the curve=0.7) and logistic regression models suggested that the data were missing at random (MAR).

Conclusions: Evidence of missingness in this dataset was consistent with MAR. Potential causes of missingness include device removal, battery failure, and technical malfunctions. These findings have important implications for both wearable device users and future research. Understanding the mechanisms behind missingness can inform strategies to improve data quality, particularly in low-resource settings, and allow researchers to manage missingness using appropriate strategies designed to handle MAR data without introducing bias into the results.

Introduction

Wearable Fitness Trackers in Health Research

Originally intended for personal health and fitness tracking, wearable fitness trackers have gained traction in research due to their ability to collect large-scale, real-world data from participants in natural settings [1]. According to Fitabase, a platform monitoring research applications of Fitbit devices, over 1300 studies incorporated Fitbit devices between 2012 and 2025 [2] and that number increases when factoring in the studies that have used other fitness trackers. Wearable fitness trackers provide real-time data collection, including physical activity, heart rate metrics, biometric and health indicators, location, behavior, and sleep. These data are critical for identifying risk factors for various health conditions, tracking health outcomes over time, evaluating interventions, and advancing personalized medicine. Wearable device data, when limitations are managed, have the potential to advance understanding of how lifestyle behaviors interact with physical and mental health across diverse populations, supporting more effective, data-driven public health strategies and clinical practices. Despite their growing adoption in research, these technologies remain disproportionately used in high-income countries and among wealthier populations [1,3,4].

Research in Urban Slum Communities

Wearable devices hold significant promise for research, particularly in low-resource settings such as urban slums [4,5]. These settings, defined by constraints across finances, health care, infrastructure, knowledge, research capacity, social resources, environmental factors, human resources, and cultural practices [6], pose unique challenges for data collection. Furthermore, over 1 billion people, or 24% of the world's urban population, currently live in slums, with this figure rising to 56% in sub-Saharan Africa [7]. Wearables offer a practical solution to the need for health research in these settings with large populations and disproportionately high risks of physical and mental health conditions [8-10]. They are cost-effective, scalable, minimally intrusive, and capable of gathering individual-level data for multiple days without reliance on external power or additional technology. These advantages make them especially valuable for research in resource-limited environments [4,5]. Understanding missingness in sleep data from wearable fitness trackers can provide important foundational information for this research.

Understanding the physical and mental health challenges in urban slums and other low-resource settings is a critical public health priority, and sleep serves as a key indicator of overall well-being. Sleep problems, including poor sleep quality and short sleep duration, are common among residents of slum communities and have been linked to mental illness, but this topic is still understudied, especially so in low- and middle-income countries [4]. Wearable technology presents a transformative opportunity for such studies, offering cost-effective, minimally intrusive methods to collect longitudinal health data in challenging urban environments. For instance, while poor sleep is a documented issue in slums, existing research has relied primarily on subjective and unreliable self-reports rather than objective sensor-based measurements [4].

However, while missing data is an issue present in all research involving wearable fitness trackers, the difficulties associated with doing research in low-resource settings like urban slums can contribute to higher rates of missing data [11]. Residents of urban slums often have unreliable electricity access, are unfamiliar with wearable fitness tracker technologies, and face logistical barriers to implementing these technologies [12,13]. Additionally, many wearable fitness trackers are reliant on connection to a smartphone or the internet, and rates of internet access and smartphone usage are low in urban slums [4,14]. Because of these challenges associated with low-resource settings like urban slums, rates of missing data can be higher when wearable fitness trackers are used in these settings. Though wearable studies in slums remain limited and are often clinic-based, there is potential for scalable, real-world data collection using wearable devices [15-17]. To realize this potential, understanding critical challenges like missing data must become a priority.

Missing Data

Missing data remains a pervasive challenge in human research, arising from diverse sources. Participant-related factors, such as missed study visits or attrition, and researcher limitations in follow-up capacity are well-documented contributors [18,19]. The growing integration of digital devices and sensors in research has introduced additional technical sources of missingness, including equipment malfunctions, battery failures, and connectivity issues [20]. Longitudinal studies, which require sustained data collection across multiple timepoints, face compounded risks of missing data, making this issue particularly acute in such designs [21].

Missing data in wearable device studies typically stems from two primary sources: device-related factors and wearer-related behaviors [22,23]. Technical issues such as battery failure, sensor displacement, software malfunctions, connectivity problems, or synchronization errors frequently contribute to device-related missingness [22-24]. Wearer-related missingness most commonly results from nonadherence, including device removal or improper wear [23]. There has been some study of missing data in wearable data, but very little in low-resource settings where wearables have only been used in a small number of studies outside of clinical settings, where conditions are much more controlled. Researchers in low-resource settings have theorized that a higher prevalence of manual labor in these settings results in exposure to extreme conditions, contributing to both device- and wearer-related challenges, which may contribute to the deterioration of wearable devices and increased missingness [5]. Wearables also differ widely in the types of data they collect, and only a few studies have considered missingness in wearable sleep data specifically [23,25]. Despite the growing use of wearable devices to collect sleep data, limited research has examined patterns and mechanisms of missingness, particularly in low-resource settings, where contextual challenges may further exacerbate missing data [11].

The prevalence of missing data significantly impacts data quality and poses substantial analytical challenges [26]. Effective

XSL•FO
RenderX

handling of missing data through methods like imputation becomes crucial for ensuring accurate analyses [24]. A comprehensive review of wearable studies in biomedical research confirms that data missingness remains among the most significant obstacles researchers face [26,27]. Few researchers have used wearables in low-resource settings, but among those who have, numerous studies have found data missingness to be a substantial issue, underscoring the need to understand the mechanisms of missingness and to find robust solutions to this persistent issue [5,28].

Missing data can be categorized into three primary mechanisms: missing completely at random (MCAR), missing at random (MAR), and missing not at random (MNAR). When data are MCAR, the probability of missingness is entirely independent of both observed and unobserved data [29,30]. In contrast, MAR occurs when missingness depends only on observed variables, not the missing values themselves [30]. The most challenging scenario, MNAR, arises when missingness is related to the unobserved data [18,31]. Understanding these common classifications of missing data is necessary, as these distinctions depend on whether missingness is related to observed or unobserved information and has important implications for analysis and interpretation [29-31].

Analytical Methods for Determining the Mechanism of Missingness

Determining the exact mechanism of missingness is challenging, but several methods can provide evidence for specific patterns. Visualization techniques offer a preliminary approach to identifying missingness patterns through graphical exploration [32]. For formal testing, the Little test, a well-established method, assesses whether data are MCAR [33]. To explore whether data are MAR, two analytical approaches are commonly used: random forest and logistic regression. Both methods model relationships between observed variables and a binary indicator of missingness. If significant associations exist between observed variables and missingness, this supports the MAR mechanism [34,35]. However, in longitudinal studies, where observations within participants are correlated, these methods require modifications to account for dependencies. In addition to contributing to the body of knowledge on missingness in wearable sleep data, this study demonstrates the use of these analytical methods on wearable sleep data, and on repeated measures data, where adjustments are necessary to preserve the dependencies between observations from the same person.

Wearable Fitness Trackers in Sleep Research

Since around 2017, consumer wearable fitness trackers have measured time spent in each sleep stage using a combination of motion detection, heart rate variability, and respiratory rate monitoring [36]. While questions remain about the absolute accuracy of sleep-stage classification, the devices' ability to detect sleep-wake patterns has significantly improved [37,38]. Importantly, wearable fitness trackers provide more objective sleep data than self-reports, as individuals often cannot accurately recall specific sleep metrics like sleep onset time or nighttime awakenings [36]. Although wearable sleep tracking technology still has limitations, it represents a substantial improvement over subjective reporting for research purposes, with accuracy continuing to advance through technological innovations [37-39].

Garmin devices like the ones used in this study have been assessed for the validity of their measurements. Existing studies indicate that they provide highly valid step count measurements, though their accuracy for distance, energy expenditure, and heart rate data remains more variable [40]. Garmin devices demonstrate reasonable agreement with polysomnography for measuring sleep duration and staging [41], and they more accurately identify deep sleep stages than some other wearable fitness trackers [42]. Manufacturers release new models frequently, and different models from the same brand can vary. Therefore, the comprehensive evaluation of wearable devices across all models and brands, including validity, reliability, proprietary algorithms, cost differences, and feature variability, remains challenging. Overall, however, modern wearable technologies that combine heart rate and motion tracking demonstrate comparable effectiveness for sleep monitoring, despite some variation in specific metrics across models and brands.

Wearable Sleep Data Missingness

While the problem of missingness in wearables data, including sleep data, has been well documented, only 2 studies were identified that considered how to address this problem in sleep data [23,25]. However, these studies differed substantially from this work. First, both studies used sleep and wakefulness data collected every few seconds for up to 50 days, so that missingness was determined by measuring the length of time during the data collection period that no data was collected (a method typically referred to as measuring data completeness). Additionally, one of these studies used data from individuals with very irregular sleep patterns so that the results may be used by those studying sleep disorders, while the other removed participants who had removed the device at any point, a common cause of missing data [23,25]. Neither study used data from low-resource settings where missingness is likely to be even higher than in data from high-income populations.

Study Purpose

The limited research on missing data in wearable sleep data that has been conducted so far uses sleep data that is in a significantly different format from that used in this study. To the authors' knowledge, this is the first study to examine missingness in wearable sleep data aggregated by night within a low-resource setting. This innovative approach to analyzing missingness in wearable sleep data is closely aligned with the typical use and analysis of this type of data.

Wearable fitness trackers offer a promising tool for collecting sleep data in diverse environments, which can allow for further study of sleep and the impact of poor sleep on health. However, missing data remain a significant limitation, and the unique logistical challenges of conducting research in low-resource settings, where sleep and health research is urgently needed, may exacerbate this issue. Addressing the patterns of missingness is essential not only for improving data quality but also for advancing research on sleep's role in health in all settings. This study has two primary objectives: (1) to

XSL•FO
RenderX

characterize the patterns and frequency of missing data and (2) to determine the underlying missingness mechanism using analytical techniques appropriate for longitudinal repeated measures data. Enders [43] comprehensive work on missing data argues that MAR is the most reasonable assumption for the mechanism of missing data in most cases of research, and this assumption should be adopted unless there is evidence to the contrary. Therefore, this study will focus on evidence that the missingness is MCAR or MAR.

Methods

The TOPOWA Project

The data for this study were collected through The Onward Project on Wellbeing and Adversity (TOPOWA), a mixed methods investigation examining the social determinants of mental health among women in Kampala, Uganda's urban slums. Details of the study have been reported previously [4,44]. Participant recruitment was conducted across 3 slum communities (Banda, Bwaise, and Makindye) in collaboration with the local community leaders and Uganda Youth Development Link, a nongovernmental organization serving youth in Kampala's informal settlements.

TOPOWA project used multiple research components, including focus group discussions, Photovoice methodology, and a longitudinal cohort study which includes the collection of sleep data via wearable fitness trackers to study the prevalence of sleep disturbance and its association with mental health in this population.

Ethical Considerations

All study procedures were designed in compliance with the Declaration of Helsinki and received ethical approval from both the Makerere University School of Social Sciences Research Ethics Committee (MAKSSREC MUSSS-2022 - 172) and the Uganda National Council of Science and Technology (SS1560ES).

Uganda Youth Development Link staff at each study site described the TOPOWA study including risks, benefits, and expectations regarding follow-up assessments to interested participants. Informed consent in writing was obtained from those who agreed to participate in the study. Participants were compensated in the local currency for each component of the study that they participated in, including wearing and returning the wearable device and completing the survey, as well as being provided with food and transportation on the days that they traveled to the research hub to complete assessments. All research assistants involved in participant enrollment and data collection were trained in participant privacy, confidentiality, and safety measures. Data were deidentified before being uploaded to REDCap (Research Electronic Data Capture) for storage and shared with members of the research team for analysis.

Data Collection and Processing

The TOPOWA project enrolled 300 women from Kampala's urban slums, equipping each participant with a Garmin vívoactive 3 device to wear continuously for 5 days and nights. These devices were specifically selected for their field suitability: they operate independently without smartphone connectivity, feature a 5-day battery life, and automatically collect sleep data each night. During data collection, 299 devices were successfully returned, with only 1 unit lost. The vívoactive 3 devices record heart rate, heart rate variability, and movement data, which Garmin's proprietary algorithms analyze to classify sleep into 4 stages (rapid eye movement [REM], deep, light, and awake) plus an "unmeasurable" category for periods that cannot be classified [45]. For each sleep session, the devices generate detailed outputs including the duration (in seconds) spent in each sleep stage and precise timestamps marking the beginning and end of the primary sleep period. Notably, when multiple sleep periods occur within a day, the system prioritizes and reports only the longest continuous sleep bout, overriding shorter naps. This design ensures researchers obtain standardized, comparable metrics for a person's main sleep period, which will be discussed as nightly sleep for simplicity, while maintaining the practicality required for field studies in low-resource settings.

During the compilation of baseline sleep data, specific criteria were established for identifying missing data. These criteria focused on total sleep duration, treating nights with no sleep information as missing while retaining nights with vague or low-quality data. Notably, the absence of data for a particular sleep stage on nights when other stages were recorded was not classified as missing data. This pattern could indicate either that the participant genuinely did not enter that sleep stage or that the device failed to detect it—a distinction that cannot be determined from the available data. Consequently, 0 values for specific stages on otherwise recorded nights were treated as valid observations rather than missing data. No nights with data had a 0 recorded for light sleep, but there were nights that contained 0 for the deep sleep, REM sleep, and awake categories. Less than 2.5% of nights with data had a 0 recorded for multiple sleep stages. Similarly, "unmeasurable" sleep seconds were considered (periods the device could not classify into any stage) as legitimate data points and included in total sleep duration calculations, rather than being treated as missing values. Zeros were common in the "unmeasurable" category, indicating that there were no seconds of sleep that the device was unable to classify into one of the other sleep stage categories during those nights. This approach ensured that the analysis reflected the complete sleep architecture as captured by the device while maintaining methodological consistency.

The presence or absence of heart rate and activity data was also recorded. If heart rate data were present for the prior day, then a 1 was recorded, and if heart rate data were not present for the day before the night in question, then a 0 was recorded. If at least 1 activity was recorded during the 5 days that the participant wore the device, then a 1 was recorded for activity data, and if no activity was recorded over the 5 days, then a 0 was recorded. The presence or absence of heart rate data was used in the statistical analysis to determine the likely mechanism of missingness; however, since activity data was only collected during prolonged periods of physical activity and was therefore much less frequent, they were not included in the statistical models. While the Garmin sleep stage classification algorithm

XSL•FO
RenderX

uses concurrently collected heart rate data, the missing data definition used in this study allowed for inclusion of nights with unclassified stages—therefore, the presence of heart rate data was not perfectly correlated with missingness.

Statistical Analysis

The analysis of missing data followed a systematic approach. First, a pattern analysis was conducted using the *naniar* (version 1.1.0; Nicholas Tierney and Dianne Cook) package in R to visually examine the structure of missingness in the dataset [46]. Next, the Little test, a likelihood ratio-based test that compares the expected means for each variable across different missingness patterns [33], was applied to evaluate whether the data were MCAR. For the Little test, the data were converted to wide format, and the 5 sleep category variables (deep, light, REM, awake, and unmeasurable) were included as well as the variables for marital status, household size, education level, and employment status. This test was conducted first because the MCAR criteria are more restrictive than the MAR criteria.

Following this initial assessment, 2 distinct classification methods, a random forest model and a generalized estimating equations (GEE) model with a logit link function, were used to explore whether the missingness pattern was consistent with MAR. For both models, a binary dependent variable indicating whether data were present or missing for each night was created. Both models incorporated six predictor variables: (1) night sequence number (1-5), (2) household size, (3) education level, (4) employment status (binary), (5) marital status (binary), and (6) presence of heart rate data for the day before the night of sleep (binary). These covariates were selected based on established relationships between socioeconomic factors and sleep behaviors in prior research [47,48]. The results from both models were then used to strengthen the conclusions about the nature of the missing data mechanism.

The dataset included participants with complete missingness across all 5 nights of sleep monitoring, represented by NA (not available) values for all sleep stages. While standard practice might suggest listwise deletion for such cases, these participants were retained in this analysis for three key reasons: (1) they provided complete data for all independent variables (household size, marital status, education level, employment status, and heart rate data availability), (2) this study specifically aimed to develop alternatives to conventional listwise deletion approaches, and (3) missingness, even complete missingness, can be informative when evaluating the mechanism and patterns behind the missingness.

While the random forest classification and GEE modeling with logit link functions serve similar analytical purposes for MAR assessment, their concurrent application provides methodological robustness, given that (1) each approach has distinct strengths in handling different data characteristics and (2) their use for MAR determination remains relatively novel in the literature, with foundational publications emerging only in the early 2000s [34,35,49]. This dual-method approach strengthened the conclusions by assessing consistency across complementary analytical frameworks.

Random Forest Classification Model

A random forest classification model was used using the *randomForest* R package (version 4.7.1.1; Andy Liaw and Matthew Wiener) to assess whether the data were consistent with MAR, as this approach can effectively capture complex, nonlinear relationships among observed variables [35]. Model performance was evaluated using the area under the receiver operating characteristic curve. An area under the curve (AUC) value significantly greater than 0.5 provided evidence for MAR, as this indicates that the missingness pattern was systematically related to the observed variables in the dataset [35]. Low AUC values (less than 0.5) indicate that the model performs no better than random guessing and would be expected if the data were MCAR. AUC values above 0.5 can occur if the data are MNAR but are more likely to occur if the data are MAR [35].

A critical consideration in the analysis was that standard random forest classification assumes independence between observations, an assumption violated in longitudinal data where multiple measurements come from the same individual. To address this dependency, a cluster-adjusted bootstrap sampling approach [50] was implemented, which resampled participants (rather than individual nights) to preserve within-subject correlations. While the use of a random forest model to assess evidence of MAR is not novel, modifying that model to account for dependencies between observations in repeated measures data is not a standard use of the method. For this reason, a second method of modeling patterns between observed variables was used.

GEE Model With Logit Link Function

The second approach implemented for exploring a MAR mechanism was a logistic regression model. This method tests whether observed variables can systematically predict missingness patterns—a key criterion for MAR. While several logistic regression-based approaches exist for MAR assessment (including Ridout's method for dropout analysis in longitudinal studies [34] and Fairclough's method for missingness prediction), Fairclough's framework [34] was adapted for this analysis since its purpose was closely aligned with the goal of this study. Independent variables were entered sequentially into the model to assess their association with missingness. A variable's contribution was evaluated based on the regression coefficient estimates, with statistical significance determined using robust standard errors derived from the GEE, to characterize predictors of missingness. Five total models were created with an additional variable added in each model. This iterative approach using forward selection allowed for assessing how different participant characteristics and study factors influenced the probability of data being missing for a given night.

While traditional logistic regression assumes independence between observations, this assumption is violated in repeated measures designs where observations from the same participant are inherently correlated [51]. To address this dependency, a GEE model with a logit link function was used using the *geepack* package in R (version 1.3.12; Søren Højsgaard, Ulrich Halekoh, Jun Yan, and Claus Thorn Ekstrøm), which extends generalized linear models by incorporating specified covariance

XSL•FO
RenderX

structures [52]. Working correlation structures were assessed for fit, including the unstructured, exchangeable, and autoregressive (1). The quasi-likelihood under the independence model information criterion was used to assess which working correlation structure was most suitable [52]. For this analysis, an exchangeable working correlation structure was selected, which assumes that the correlations between observations from the same participant are equally correlated [52]. This selection is appropriate because the data were collected over just 5 consecutive days, so significant correlation decay is not expected in such a short time period. The GEE framework allowed for properly accounting for within-participant correlations while examining how various factors predicted missingness patterns.

While the GEE model with a logit link function and the random forest model perform similarly in that they both model relationships between observed variables, neither is a standard method of assessing the mechanism of missingness that has been well documented in previous publications, as is the case for the Little test. Literature was identified that supported the validity of these methods, but no prior studies using these methods were identified. For these reasons, both modeling methods were performed so that their results could be compared.

Results

Participant Characteristics

All women who participated in the TOPOWA project were aged between 18 and 24 years old. All participants had completed some primary school and could read and write, but only 8% (24/300) had completed secondary school. Over half, 62% (186/300), had given birth and 82% (152/186) of those who had given birth lived with her child(ren). Only 15% (45/300) of the women lived in a single generation household, while the remaining 85% (255/300) lived in households with 2 or more generations. Women who had a job represented 32% (97/300) while the remaining 68% (203/300) of the women were unemployed.

Missing Data in the TOPOWA Baseline Sleep Data

Participants wore Garmin devices continuously for 5 days and nights, yielding sleep data from 299 individuals. However, 37 (12%) devices recorded no sleep data across all 5 nights (complete missingness). The dataset exhibited a notable missing data pattern: nights were either fully observed (all sleep stages recorded) or fully missing (no data for any sleep stage). Consequently, missingness proportions were identical across all sleep metrics (deep, light, REM, awake, and unmeasurable seconds), with an overall missing data rate of 30% (455 nights missing out of 1495 total nights). The rate of missingness was similar across the 3 study sites (Banda, Bwaise, and Makindye) with Banda having a slightly higher rate of missingness than Bwaise and Makindye (Table 1). The rate of missingness in the sleep data remained consistent as household size increased but increased slightly with each additional child a woman had, so that participants with no children had the lowest rate of missingness (155/570 nights of data, 27%) and participants with 3 children had the highest rate of missingness (18/25 nights of data, 72%) (Table 1). The rate of missingness in the sleep data was approximately equal across changes in income, employment status, education level, and marital status. Notably, 58% (173/299) of participants experienced at least 1 night of missing data, demonstrating the pervasiveness of this issue.

Table . Proportion of missing data by study site, night of data collection, and number of children.

Rate and number of nights of data missing	Nights of data (n=495) missing from Banda participants, n/N (%)	Nights of data (n=500) missing from Bwaise participants, n/N (%)	Nights of data (n=500) missing from Makindye participants, n/N (%)	Total nights of data (n=1495) missing from all participants, n/N (%)
Night of data collection				
1	22/99 (22)	25/100 (25)	20/100 (20)	67/299 (22)
2	32/99 (32)	26/100 (26)	21/100 (21)	79/299 (26)
3	32/99 (32)	25/100 (25)	24/100 (24)	81/299 (27)
4	35/99 (35)	21/100 (21)	32/100 (32)	88/299 (29)
5	49/99 (49)	44/100 (44)	47/100 (47)	140/299 (47)
Number of children				
0	34/155 (22)	65/155 (42)	56/155 (36)	155/570 (27)
1	89/188 (47)	45/188 (24)	54/188 (29)	188/625 (30)
2	35/94 (37)	26/94 (28)	33/94 (35)	94/275 (34)
3	11/18 (61)	7/18 (39)	N/A[a]	18/25 (72)

[a]N/A: not available.

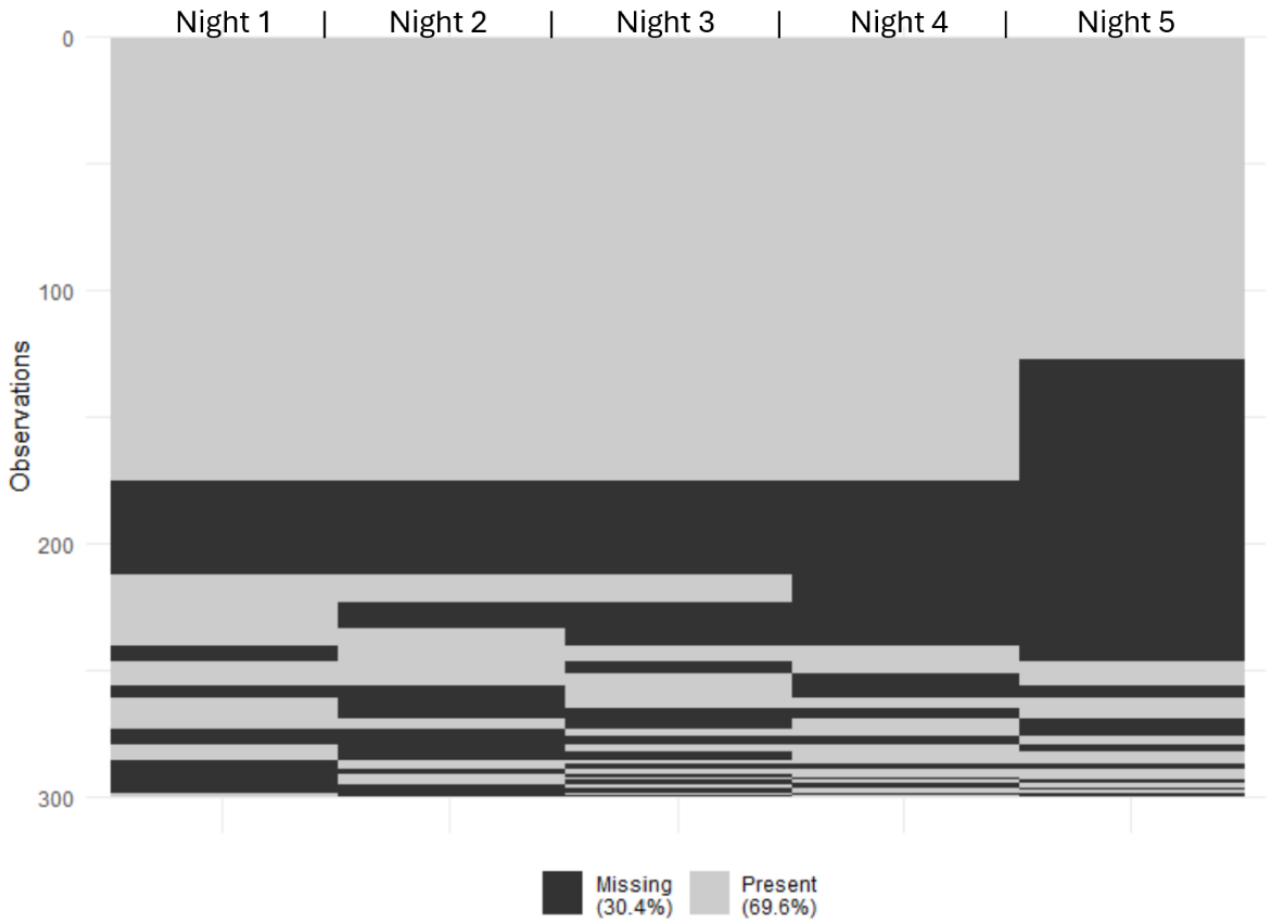
The 37 cases of complete missingness for all 5 nights of sleep data can be categorized into 3 distinct scenarios with varying probable causes, detailed in Table 2.

XSL•FO
RenderX

Table . Categorization of the 37 cases of complete sleep data missingness.

Status of sleep and heart rate data	Number of cases
No sleep or heart rate data collected	1 device
Partial data collection—either heart rate or activity (but not both) data collected for at least 1 day	8 devices
Selective sleep data missingness—devices collected both heart rate and activity data for at least 1 day, but no sleep data	28 devices

Data Exploration



The distributions of time spent in each sleep stage and total time asleep were examined to determine if the distributions differed based on the day of the data collection (1-5). For each sleep stage, as well as total time asleep, the distribution was the same both when the 5 nights of data were considered together and when the data were grouped by night. There were no changes in the distribution of sleep times over the course of the 5 days of data collection.

There were some outliers in the total sleep durations. For 1 participant, less than 1 hour of sleep was recorded in 1 night, and for another participant, just over 12.5 hours of sleep was recorded on 1 night. Because the outlier values present in the data are not outside the realm of possibility, these observations were retained when assessing the missing data mechanism.

Missingness Patterns

The first night of data collection has the least amount of missing data, with 22% (66/300) of nights missing data. The rate of missing data increases for each subsequent night, and the fifth and final night of data collection has 47% (141/300) of data missing (Table 1). There were 29 missingness patterns identified in the data (Figure 1), with no nights missing being the most common (126 cases), followed by missing only the last night of data (48 cases) and then missing all nights of data (37 cases).

Figure 1. Patterns of missingness in the sleep data. Missingness patterns are ordered from most common at the top (no missing nights of data) to the least common (bottom).

The Little Test

When running the Little test, the null hypothesis is that the data are MCAR while the alternative hypothesis is that the data are not MCAR and are therefore either MAR or MNAR. The χ^2 statistic was 969 and the degrees of freedom was 587, which resulted in a P value for the Little test of P<.001. Therefore,

XSL•FO
RenderX

the null hypothesis is rejected. This suggests that the data were not MCAR.

Random Forest Classification Model

The AUC value of 0.70 for the random forest classification model indicated that the model was generally able to distinguish missingness, which is consistent with data MAR. The sensitivity, a measure of how well true positives (ie, missing data) are predicted, was 0.30 and the specificity, a measure of how well true negatives (ie, data present) are identified, was 0.94. The overall accuracy for the model was 0.75. Table 3 shows the confusion matrix for the random forest classification model.

Table . Random forest classification model confusion matrix.

Predicted values	True values	
	0 (data present)	1 (data missing)
0 (data present)	978	319
1 (data missing)	62	136

GEE Model With Logit Link Function

The results of the GEE model with a logit link function also yielded results that were consistent with a MAR assumption. The independent variables were added to the model in an iterative process to determine the extent to which each of the variables was able to predict missingness. The final model (Table 4) contained only 2 predictor variables that were statistically significant, number of night in the 5-night sequence (1-5) and whether the participant had a job. The model had an accuracy of 0.70. The sensitivity was 0.12, while the specificity was 0.96. The confusion matrix for the model is displayed in Table 5.

Table . Results of generalized estimating equations model with logit link function.

	Parameter estimate	SE	Odds ratio (95% CI)	*P* value
Intercept	–1.8546	0.1850	0.156 (0.109 - 0.225)	<.001
Number of night in the 5-night sequence	0.2554	0.0357	1.291 (1.204 - 1.384)	<.001
Job	0.6671	0.2016	1.948 (1.312 - 2.893)	.001

Table . Confusion matrix for the generalized estimating equations model with logit link function.

Predicted values	True values	
	0 (data present)	1 (data missing)
0 (data present)	996	402
1 (data missing)	44	53

Comparing the Results of the 2 Classification Models

The random forest model and the logistic regression model agreed in 90% (1346) of cases. Table 6 contains the confusion matrix showing how often the 2 models agreed and how often they disagreed in their classifications.

Table . Confusion matrix comparing the random forest and logistic regression models.

Logistic regression predictions	Random forest predictions	
	0 (data present)	1 (data missing)
0 (data present)	1281	117
1 (data missing)	32	65

Discussion

Principal Results

Our comprehensive analysis provides evidence that the missing sleep data in the TOPOWA study follows a MAR pattern, thereby permitting the use of imputation and likelihood-based methods that would be inappropriate under an MNAR mechanism. Furthermore, Enders [43] recommends adopting MAR as the default assumption in most realistic research scenarios. The findings in this study indicate that missingness was systematically related to observable variables rather than unobserved sleep characteristics [21,53]. Both the random forest model and the GEE model with a logit link function had high specificity values, indicating that the models identified true negatives well (present data values), but the values for sensitivity were low, indicating that the models performed worse at identifying true positives (missing data values). The classification models more accurately identified when data

XSL•FO
RenderX

values were present than when data values were missing. However, previous researchers who have used this method to check for evidence that missing data are MAR have focused on the AUC value and did not report sensitivity and specificity [35].

While additional studies using varying types of data, such as supplementary self-reported sleep data, are necessary to further validate the methodology used in this study, the results suggest that a GEE model with a logit link function and a random forest classification model can be used to identify evidence that missing data are MAR in repeated measures data when modifications are made to account for the dependencies between observations from the same person. This finding has the potential to improve researchers' handling of missing data in longitudinal data, common in health research, by providing a way to empirically determine the likely mechanism of missingness prior to analysis and decide how best to handle the missing data based on that mechanism of missingness.

Possible Explanations for Missing Data

Several key observations support the conclusion that the missingness is MAR. First, the temporal pattern of missingness showed a clear progression, with later nights (particularly night 5) having higher rates of missingness than earlier nights. Second, known explanations for missingness—including device failure (n=1 likely case), nonadherence (n=3 self-reported cases), or improper device fit—would generally qualify as MAR mechanisms. While 37 participants had no sleep data for any of the 5 nights, the available evidence suggests these cases resulted from technical or behavioral factors rather than being related to the missing sleep values themselves.

Missing data in the baseline sleep dataset likely stemmed from multiple sources, each with distinct implications for analysis. Battery depletion emerged as a primary factor, with some devices failing to maintain charge through all 5 nights, according to reports from the research assistants. This explanation aligns with the observed increase in missingness across successive nights and qualifies as MAR, as battery failure was unrelated to participants' sleep patterns. The most common missingness pattern in the data was data missing on the fifth night only, which likely occurred because the battery was depleted before the fifth night. The third most common missingness pattern was data present for the first 3 nights and missing for the fourth and fifth nights, which also likely occurred due to a depleted battery. A subset of cases involved unpredictable device malfunctions (MCAR), where hardware failures caused complete data loss independent of user behavior or sleep characteristics. This was likely the case for the 1 participant for which no heart rate, activity, or sleep data was collected, and may have been the case for the 8 participants for whom either heart rate data or activity data was collected (but not both) and no sleep data was collected. Another possibility is that the missing data in the underlying raw data (heart rate variability and motion data) resulted in insufficient physiological data for sleep algorithm processing. This pattern highlights the technical and behavioral challenges inherent in wearable research, where algorithm-derived outcomes (like sleep duration and stages) depend on sensor data.

Participant-related issues also contributed: some women reported removing devices due to social discomfort (eg, partner or child concerns) [14], while improper fit (eg, loose wrist placement) prevented sensor contact, mimicking nonwear. In the case of the 8 participants for whom no sleep data was collected but either heart rate or activity data was collected, and the 28 participants for which heart rate and activity data was collected but sleep data was not, intermittent device removal (ie, at night) may have been a factor contributing to sleep data missingness. The coexistence of these mechanisms, and the potential for both technical and behavioral reasons for missingness, highlights the complexity of missingness in wearable research and underscores the need for robust analytical approaches to mitigate bias.

While only 3 women reported removing the device for any period of time during the 5-day data collection period, the missingness patterns in the data from considerably more devices suggested that device removal was a possible factor. The second most common missingness pattern in the data was data missing for all 5 nights, which could indicate the participants removed the device. Notably, the discrepancy between self-reported and probable nonwear suggests possible social desirability bias, as participants received compensation for participation.

Limitations

Several important limitations should be considered when interpreting this study's findings. The presence or absence of other physiological or behavioral metrics that wearable devices can capture (eg, activity levels, heart rate variability) was examined, but only the presence or absence of this data was tracked. Detailed information on heart rate or activity was not analyzed. Low-quality data may also mask data that should have been marked as missing. Some extreme sleep duration values (both small and large) were identified that could represent either genuine biological variation or measurement artifacts. Wearable devices may misclassify wakefulness as sleep during prolonged sedentary periods or conversely interpret restless sleep as wakefulness. While these devices generally provide more objective sleep measurements than self-reports, such classification errors underscore the importance of interpreting extreme values cautiously. Future studies could benefit from incorporating complementary data sources such as self-reported sleep to validate these outlier observations.

While it is possible that the day of the week may impact missingness, this was not explored in this analysis for 2 reasons. The women in this study were issued Garmin devices for 5-day periods on a rolling basis, meaning that not all women wore the devices over the weekend. The second reason that considering weekday versus weekend missingness is not ideal using this data is that the lifestyle and employment status of these women are very different from those of middle- and working-class populations, as well as Western assumptions of a structured 5-day work week, who typically have consistent and differing routines on weekdays and weekends. Most of these women did not have jobs with regular Monday-Friday hours.

Lastly, questions regarding the validity and reliability of consumer-grade wearable devices remain and should be further researched, especially because validity can vary between different device models from the same brand using similar

XSL•FO
RenderX

technology. As health research using wearable devices continues and expands, the study of the validity of these devices should continue as well, especially as new models and technology that have not been previously studied are released. Additionally, self-reported sleep data has long been used for sleep research and can be a valuable tool when used as complementary data for validating sleep data from wearable technology.

Conclusion

This work demonstrates the process researchers can undertake when assessing missing data assumptions prior to the analysis of wearable data. Taken together, these findings suggest that a MAR mechanism can be assumed for sleep data in the TOPOWA study, with missingness driven primarily by observable technical and behavioral factors rather than unobserved sleep characteristics. This distinction is critical for selecting appropriate imputation strategies and ensuring valid inferences in future analyses. As wearable methods expand in global health research, especially in urban informal settlements, addressing the practical and ethical complexities of data missingness will be essential for advancing equity, rigor, and reproducibility. In addition to considering data collected in a low-resource setting, where research faces additional challenges, this study contributes meaningful information on missingness in wearable sleep data aggregated by night, closely aligning it with the common use and analysis of this type of data.

Abstract

Background: Previous research has attempted to determine the minimum number of days of accelerometry required to reliably reflect an individual's physical activity. However, human behaviors on a day-to-day basis can be highly variable. As a consequence, the number of days required to reliably predict habitual physical activity is dependent on the variability that exists within an individual. There is a concern that adopting generic recommendations from previous research could provide unreliable estimates by failing to represent individuals with specific physical activity patterns.

Objective: The main aim of this study was to identify clusters of individuals with distinct physical activity patterns and to determine if the number of days of accelerometry data required to reliably estimate short- (7 days) and medium-term (28 days) physical activity differed between each unique cluster.

Methods: Accelerometry data were retrieved from 2 independent research studies. Participants during each study had their physical activity recorded using a Withings Scanwatch (Withings Health Solutions). Following a data eligibility process, agglomerative hierarchical clustering was used to identify clusters of individuals based on their physical activity. The clusters were determined using 4 dimensions; mean, SD, skewness, and kurtosis of the step count data. Intraclass correlation coefficients (ICCs) of step count were then calculated within each physical activity cluster. A series of ICCs were computed by separately comparing the average step count across the full periods (7 and 28, for the short- and medium-term analysis, respectively) to a series of averaged subsamples (ranging from 1-6 days and 1-27 days, for the short- and medium-term analysis, respectively). For each subsample, 500 random combinations were generated and compared, providing a distribution of ICCs for each subsample. An ICC of ≥0.80 identified when the subsample of days was sufficient to achieve appropriate reliability.

Results: Of 258 participant datasets, 149 were eligible for the short-term analysis and 64 were eligible for the medium-term analysis. Following agglomerative hierarchical clustering, 4 and 3 clusters of sufficient size (n≥12) were identified in the short-term and medium-term analyses, respectively. When considering the short-term analysis, to achieve a mean ICC score greater than or equal to 0.80, using all randomized combinations, the number of days ranged from 2 to 6 days depending on the physical activity cluster. For the medium-term analysis, the number of days required to achieve a mean ICC score greater than or equal to 0.80 ranged from 6 to 11 days. The short-term analysis clusters displayed more diversity in physical activity patterns than the medium-term analysis.

Conclusions: Physical activity patterns influence the number of days required to estimate habitual physical activity. Thus, to avoid unreliable estimates of physical activity, which could significantly impact the interpretation of results, researchers should be mindful of the physical activity patterns of their sample before adopting generic recommendations.

Introduction

Accelerometers are wearable devices that measure the acceleration of the body region to which the device is secured. Commercially, the signals are then processed and transformed into physical activity metrics that are relatable to the consumer, such as daily step count. The popularity of accelerometry as a method to quantify physical activity is growing due to the objectivity and availability of such devices. Importantly, the use of accelerometry provides an alternative option to self-reporting questionnaires, which can lack strong reliability and validity [1].

The field is rapidly developing with the advancement of new technology and the commercialization of devices. As a consequence, the approaches used to interpret collected data can vary and lack a consensus [2]. An area of importance relates to the minimum number of valid days required to reliably reflect a person's habitual level of physical activity [3]. Unfortunately, many studies with important implications, such as those linking physical activity to health outcomes, have used varying criteria to define a participant's habitual level of physical activity. For example, the United Kingdom biobank guidelines advise researchers to exclude participants from their accelerometry dataset who have fewer than 3 valid days of data [4], which has been adopted in many impactful studies [5-7]. In contrast, the National Center for Health Statistics, which administers the National Health and Nutrition Examination Survey in the United States, does not advise on the number of valid days that should be available to validate inclusion when using their accelerometry datasets. As a consequence, researchers have adopted various inclusion criteria ranging from 1 to 5 days [8-10].

From a research perspective, the fewer days required could help relieve the study burden on the participant and better support the use of study resources. Past reviews have suggested 4 days would suffice to achieve sufficient reliability [2,11]. Furthermore, a more recent comprehensive study using a large Singaporean sample recommended that at least 3 and 5 measurement days of step count data were needed to predict weekly and monthly time windows, respectively [12]. Despite the existing recommendations, providing a consensus for the minimum number of days required to predict habitual physical activity can be challenging and fraught with error if the uniqueness of the sample in question is not considered. Human behaviors on a day-to-day basis can be highly variable; thus, the number of days required to reliably predict habitual physical activity is dependent on the variability that exists within an individual [13]. Intuitively, individuals with high consistency or limited variability in physical activity may be predicted with fewer days than an individual with low consistency and high variability. As a consequence, the identification of an optimal number of days could be problematic. Another source of consideration relates to the formula used to calculate reliability. In the physical activity literature, the intraclass correlation coefficient (ICC) is commonly used to grade the reliability of physical activity and a common standard used to indicate acceptable reliability is an ICC of 0.8 [13,14]. However, broadly, this formula approximates the within-subject variability by comparing its magnitude to the between-subject variability. Thus, an increase in diversity between individuals will inherently reduce the reliability score without any change in variability within individuals. This situation poses a potential concern that predictions from large heterogenic samples may not translate to groups of individuals with specific physical activity patterns.

Therefore, the main aim of this study was to identify clusters of individuals with distinct physical activity patterns and to determine if the number of days of accelerometry data required to reliably estimate short- (7 days) and medium-term (28 days) physical activity differed between each unique cluster. This study used clustering analysis to allocate individuals from a heterogenic population into distinct physical activity clusters. Subsequently, reliability estimates were derived for each cluster and compared. The hypothesis was that the number of days to reliably predict (1) short- and (2) medium-term physical activity differs between clusters.

Methods

Study Design

This is a secondary, longitudinal analysis using combined data from 2 independent studies. Only the objectively measured physical activity data (daily step counts) and demographic descriptors were used from each dataset. All other variables from the original studies were excluded from the current analysis. The analysis was conducted at Reykjavik University in Iceland as part of the European Union Horizon 2020-funded Sleep Revolution research project [15].

Setting

Study 1 was an observational study conducted at the Reykjavik University Sleep Institute, aimed at exploring the associations between physical activity and markers of obstructive sleep apnea (OSA) severity [16]. A total of 66 adults were recruited, representing a broad range of sleepers, including healthy individuals, snorers, and those with suspected or diagnosed OSA. Each participant underwent a 3-night, self-applied somnography study at home, along with assessments of anthropometry, body composition, and both subjective and objective physical activity. Importantly, for the purpose of this analysis, objective physical activity was measured using a smartwatch device (Withings Scanwatch, Withings Health Solutions) worn on the nondominant wrist for a 3-month period.

Study 2 was a 12-week, 3-arm randomized controlled trial conducted at the Reykjavik University Sleep Institute [17]. The study was registered in ISRCTN 16974764. It aimed to evaluate

XSL•FO
RenderX

the effects of an exercise program and a lifestyle app on OSA, physical health, and quality of life in adults with mild-to-moderate OSA or habitual snoring. A total of 192 eligible participants were randomized into exercise, app, or control groups. Randomization was stratified using an algorithm to ensure balance across age, gender, BMI, and apnea-hypopnea index (AHI). Participants completed baseline assessments, including a one-night type 3 sleep study, body composition, and physical activity measures. The exercise group attended structured sessions 3 times per week, and the app group engaged in daily behavioral tasks via a health app (Sidekick Health, Reykjavík). Objective physical activity was assessed via a smartwatch device (Withings Scanwatch, Withings Health Solutions) worn on the nondominant wrist over the 12-week study period.

Participants

Participants from each study, who are described in the subsequent paragraphs, were pooled to explore habitual physical activity patterns. Study 1 recruited a heterogeneous sample from the general adult population (≥18 years) with the goal of reflecting natural variation in age, sex, and body morphology. Participants were not excluded based on sleep health status. Study 2 was a randomized controlled trial targeting adults aged 18–50 years of age that were categorized as overweight or obese (BMI ≥25<42 kg/m²), who were physically inactive and had either mild-to-moderate OSA (AHI ≥5 and <30) or habitual snoring (≥10%). Shift workers and individuals undergoing OSA treatment were excluded. Eligible participants underwent a one-night type 3 sleep study to confirm OSA.

Variables

The primary variable analyzed was daily step count, measured objectively using accelerometry-based methodology. Step count served as the key indicator of physical activity throughout the study period.

Data Measurements

Demographics

Data were collected using a custom-developed questionnaire. REDCap (Research Electronic Data Capture) survey software version 9.3.1 (Vanderbilt University) was used to collect participant responses [18,19].

BMI

Height and weight (digital scale; TANITA MC-780, Tanita Corporation) were measured and used to calculate BMI.

Smartwatch

Participants were instructed to wear a smartwatch (Withings Scanwatch, Withings Health Solutions) for the study period. The smartwatch generated physiological and physical activity parameters that included step count, distance covered, elevation, sleep, heart rate, oxygen saturation, passive calories, and active calories. Due to the substantial correlations between the physical activity parameters, step count was selected as the parameter of primary interest. The generated data were available in two forms: (1) timestamped data and (2) daily aggregated data. Additional details of the smartwatch are described by [20].

Bias

Several potential sources of bias were considered in the study design and analysis. First, selection bias was likely present in Study 2, as participants were specifically recruited based on specific inclusion criteria around OSA. However, Study 1 reflected a broader segment of the general adult population and may have helped offset this limitation by introducing more heterogeneity in age, sex, BMI, and physical activity profiles. Nonetheless, the combined sample remains somewhat weighted toward individuals with OSA. Measurement bias was addressed by using objective step count data from smartwatches rather than self-reported physical activity, reducing recall and reporting biases. However, inaccuracies could arise from nonwear time or device limitations; to mitigate this, systematic methods were used to exclude days with insufficient wear time [2,21]. Similarly, to address potential bias from missing days, nonconsecutive valid days were allowed but only within specified windows described in more detail in the Sample Size section.

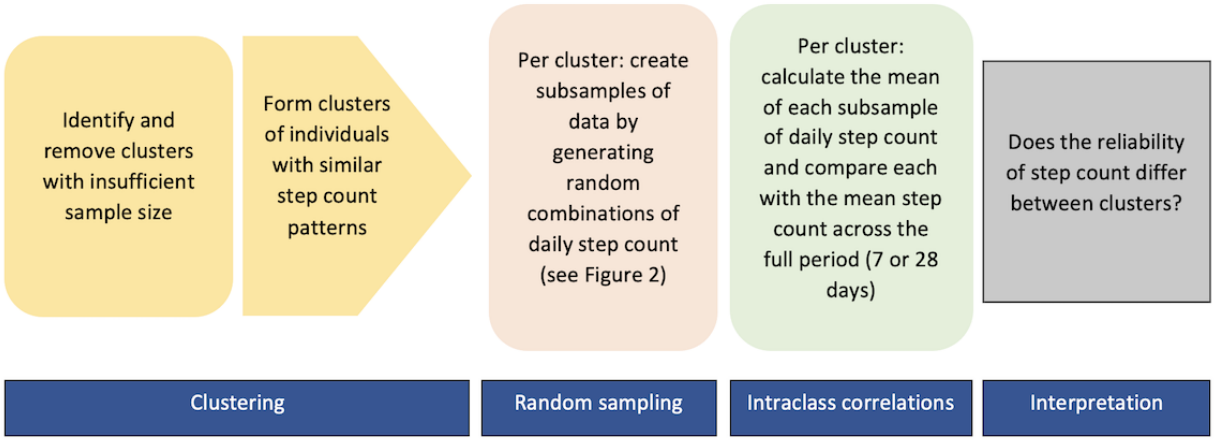
Sample Size

All participants from Study 1 and Study 2 were considered eligible for analysis, but their inclusion depended on passing specific wear-time criteria.

Valid Day

Given the longitudinal nature of the study, participants were not required to report nonwear time, which influenced the accuracy of step count data. Therefore, a systematic approach to identify nonwear periods was established. Gaps in the timestamped “calories earned” data exceeding 60 minutes were classified as nonwear periods. Summing the nonwear periods that occurred between consecutive sleep periods permitted the calculation of wear time during waking hours. In line with previous approaches and retaining statistical power [2,21], days with less than 10 hours of wear time during waking hours were considered insufficient to accurately estimate step count and excluded.

Valid Period



Using the step count data filtered for valid days, one period of 7 days and another of 28 days were selected for each participant in the short- and medium-term analyses, respectively. Periods with nonconsecutive days were allowed if there were (1) 7 valid days within a 10-day period in the short-term analysis or (2) 28 valid days within a 40-day period in the medium-term analysis. Periods with full consecutive sequences or with the fewest days skipped were preferentially chosen, but if more than one of these sequences existed, then the selection was randomized. Nonconsecutive days were permitted due to the difficulty of achieving full consecutive sequences of data, particularly when considering the medium-term analysis. For the inspection of data, the chosen periods of 10 and 40 days were chosen to allow us to retain a sufficient sample size without compromising the representation of physical activity for the given period.

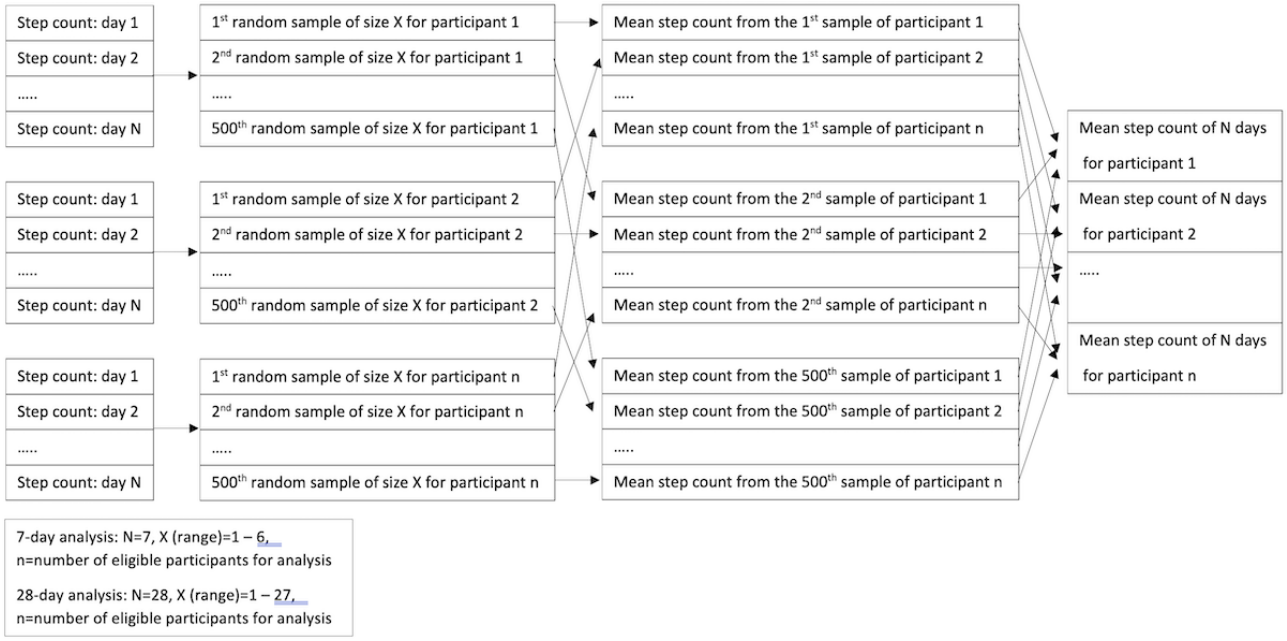
XSL•FO
RenderX

Data Analysis of Quantitative Variables

The methodological approach to the analysis of the daily step count variable is displayed in a visual format in Figure 1. Using unsupervised machine learning, we identified clusters of individuals that shared more similar physical activity patterns than those in the other identified clusters. Agglomerative hierarchical clustering with complete-linkage, a distance-based algorithm, was used to identify clusters [22]. This form of clustering was chosen because it can be used to identify outliers and does not require a predetermined number of clusters. The clustering analysis was conducted for both short- and medium-term physical activity patterns, separately. The clustering analysis first involved running the algorithm to identify sufficiently sized clusters. Given that the calculated reliability metrics are influenced by between-subject variability, smaller clusters may be more prone to an underestimation or overestimation of reliability depending on participant similarities. Thus, if any clusters with less than 12 participants were identified, they were removed, and the remaining clusters were retained for the full analysis. The clusters were determined based on their similarities across 4 dimensions, those being the scaled and centered mean, SD, skewness, and kurtosis of the step count data. These dimensions represent the 4 moments of distribution, which quantitatively reflect each participant's physical activity patterns in the context of an average, day-to-day variability and range of values.

Figure 1. Methodological approach to study analysis.

Statistical Analysis



Following the identification of clusters, the reliability of step count within each cluster was determined, along with a baseline comparison (unclustered data). ICCs were derived using linear mixed models with one-way random effects. A series of ICCs were computed by separately comparing the average step count across the full period (7 and 28 days for the short- and medium-term analysis, respectively) to a series of averaged subsamples (ranging from 1 to 6 days and 1 to 27 days for short- and medium-term analysis, respectively). As the subsamples could include any combination of days from the full period, for each participant, resampling methods without replacement were used to ensure an appropriate number of combinations were tested. For each subsample, 500 random combinations were generated and compared to the average step count across the full period (see Figure 2). Prior testing of the data showed that when 500 combinations were used for ICC predictions, the results remained stable when repeated. Thus, the range of ICC values possible for each subsample comparison was produced. In line with previous research, a threshold value of 0.80 was used to infer "acceptable" reliability [13,14].

It is necessary to point out the benefits of the Monte Carlo resampling approach used. This approach reduces the influence of nonnormality and heterogeneity of within-subject variances by using aggregated participant-level means and repeated ICC estimations. Given that ICCs were computed from mean step counts, assumptions of normality and homogeneity of variance are less probable, as justified by the Central Limit Theorem. Additionally, using 500 iterations per subset further enhances the robustness of the reliability estimates by reducing the influence of a typical combinations.

All the analyses were conducted in R (version 4.3.2; R Core Team). Specifically, the "ICC" package was used to extract the ICCs.

Figure 2. Data randomization of subsamples.

Ethical Considerations

Both studies received ethical approval from the National Bioethics Committee of Iceland and the Icelandic Data Protection Agency (21-170; 22-082). Participants provided written informed consent to participate, which also extended consent to secondary analysis. All data were stored anonymously and processed on a secure high-performance computing cluster to ensure efficient handling while maintaining data security and integrity. Finally, participants did not receive any compensation for their participation.

Results

Participants and Descriptive Data

Of the 258 original participants available from Study 1 and Study 2, a total of 149 participants possessed 7 valid days (>10 hour wear time during wake) across a 10-day period and were included in the short-term analysis, and 64 participants possessed 28 valid days across a 40-day period and were included in the medium-term analysis.

In the short-term analysis, 76 of the participants were male, and 73 were female. On average, the participants were 41 (SD 5) years of age and were categorized in the obese category (BMI: mean 31, SD 4). Age ranged from 19 to 76 years old, while BMI ranged from 19 to 42. In the medium-term analysis, half of the participants were male (n=37) and half of the participants were female (n=37). On average, the participants were 45 (SD 9) years of age and were categorized in the obese category (BMI: mean 31, SD 5). Age ranged from 23 to 65 years old, while BMI ranged from 20 to 41. The participants that were eligible for both analyses did not have any missing data.

Outcome Data

Clustering in Short-Term Analysis

Following agglomerative hierarchical clustering, 4 clusters of sufficient size (n≥12) were identified from a visual inspection of the dendrogram. The clusters were chosen by attempting to achieve a balance between appropriate sample sizes and within-cluster cohesion. The 4 dimensions of daily step count used to form each cluster are reported in Table 1.

In comparison to the other clusters, Cluster 1 displayed moderate physical activity levels and day-to-day variability. However, Cluster 1 had a highly skewed physical activity pattern and high kurtosis, suggesting these participants tended to have days that, when compared to their habitual physical activity levels, were considered extremely low or high. In contrast, the other clusters had kurtosis values below or slightly above 3, suggesting the number of days classed as outliers (extreme high or low physical activity) was similar to or less than that seen in a normal distribution pattern. Cluster 2 displayed the lowest relative variability in physical activity levels, while participants in Cluster 3 had the lowest overall physical activity levels, with habitual levels of 4391 (SD 1058) steps per day. Cluster 4 displayed the highest physical activity levels (mean 7179, SD 1028 steps per day), but also the highest day-to-day variability. Given the low kurtosis and moderate skewness, this would suggest the participants in Cluster 4 displayed a mixture of physical activity days.

XSL•FO
RenderX

Table 1. Dimensions of daily step count used to isolate clusters of individuals in the short-term analysis.

Short-term Cluster (n)	Mean steps, mean (SD)	SD steps, mean (SD)	Skewness, mean (SD)	Kurtosis, mean (SD)
1 (n=36)	5883 (1298)	2192 (727)	1.28 (0.48)	5.34 (1.08)
2 (n=22)	5980 (1538)	1619 (685)	0.82 (0.26)	3.67 (0.99)
3 (n=42)	4391 (1058)	1467 (586)	0.50 (0.35)	2.20 (0.83)
4 (n=30)	7179 (1028)	3068 (1132)	0.55 (0.37)	1.96 (0.70)

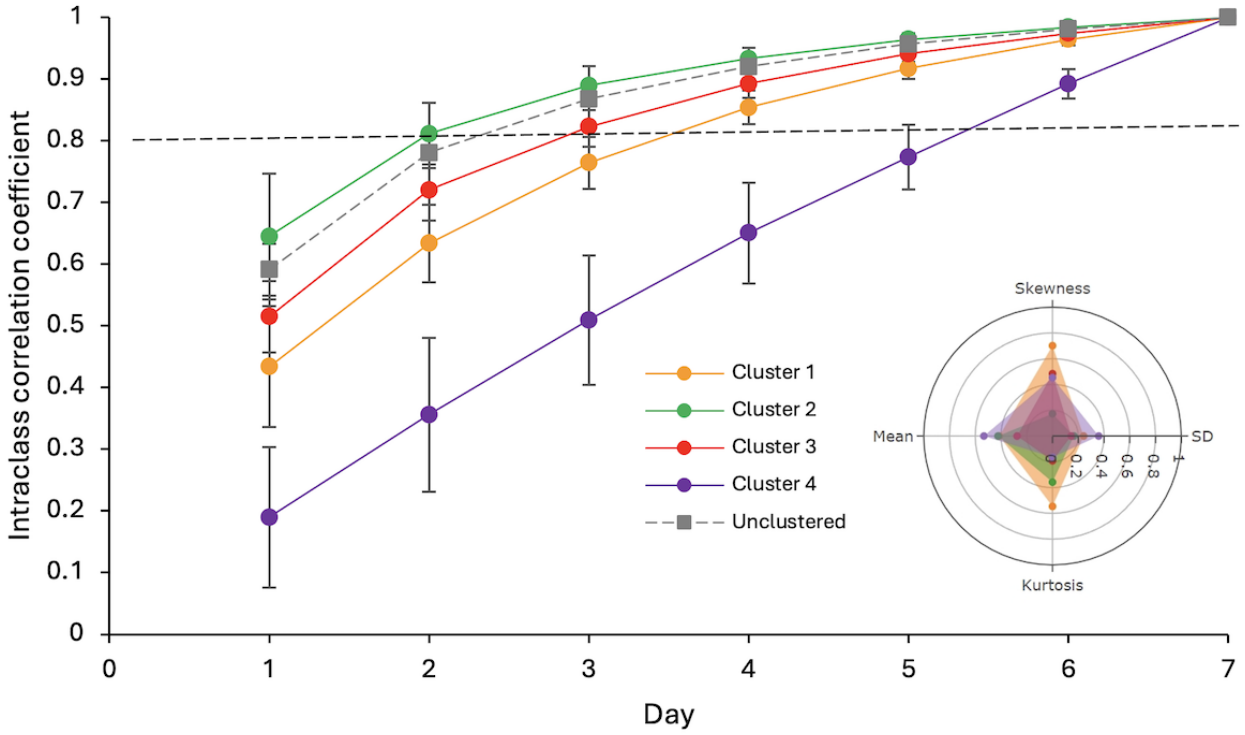
Clustering in Medium-Term Analysis

Following agglomerative hierarchical clustering, three clusters of sufficient size (n≥12) were retained by visually inspecting the dendrogram. The four dimensions of daily step count used to form each cluster are reported in Table 2.

Compared to the short-term analysis, the clusters within the medium-term analysis displayed less diversity. Modest day-to-day variability in physical activity was found in Cluster 1, but the participants in this cluster had the highest physical activity levels (mean 7671, SD 1052 steps per day). In contrast, participants in Cluster 2 displayed the lowest levels of physical activity (mean 4746, SD 947 steps per day) with the highest relative variability in physical activity. Cluster 3 displayed the least relative variability in physical activity and a low degree of skewness. This suggests that the physical activity levels for these participants were usually around the mean alongside an expected number of higher and lower physical activity days (normal distribution). The number of extremes in physical activity was small in all clusters and did not display distinctly different tails to a normal distribution pattern.

Table 2. Dimensions of daily step count used to isolate clusters of individuals in the medium-term analysis.

Medium-term Cluster (n)	Mean steps, mean (SD)	SD steps, mean (SD)	Skewness, mean (SD)	Kurtosis, mean (SD)
1 (n=23)	7671 (1052)	2955 (655)	0.66 (0.45)	3.65 (1.11)
2 (n=14)	4746 (947)	2265 (381)	0.87 (0.24)	3.31 (0.58)
3 (n=16)	5775 (988)	1764 (398)	0.31 (0.28)	2.87 (0.72)



Main Results

Intraclass Correlations in Short-Term Analysis

To achieve a mean ICC score above 0.80, calculated using all randomized combinations for each day subset, Cluster 2 required 2 days, Cluster 3 required 3 days, Cluster 1 required 4 days, and Cluster 4 required 6 days (Figure 3). The minimum number of days needed to achieve an ICC score above 0.80 in all 500 random combinations was 4 in Clusters 2 and 3, 5 in Cluster 1, and 7 in Cluster 4. As a baseline comparison, when the data were unclustered, 3 days were required to achieve a mean ICC score above 0.80 in all 500 random combinations.

XSL•FO
RenderX

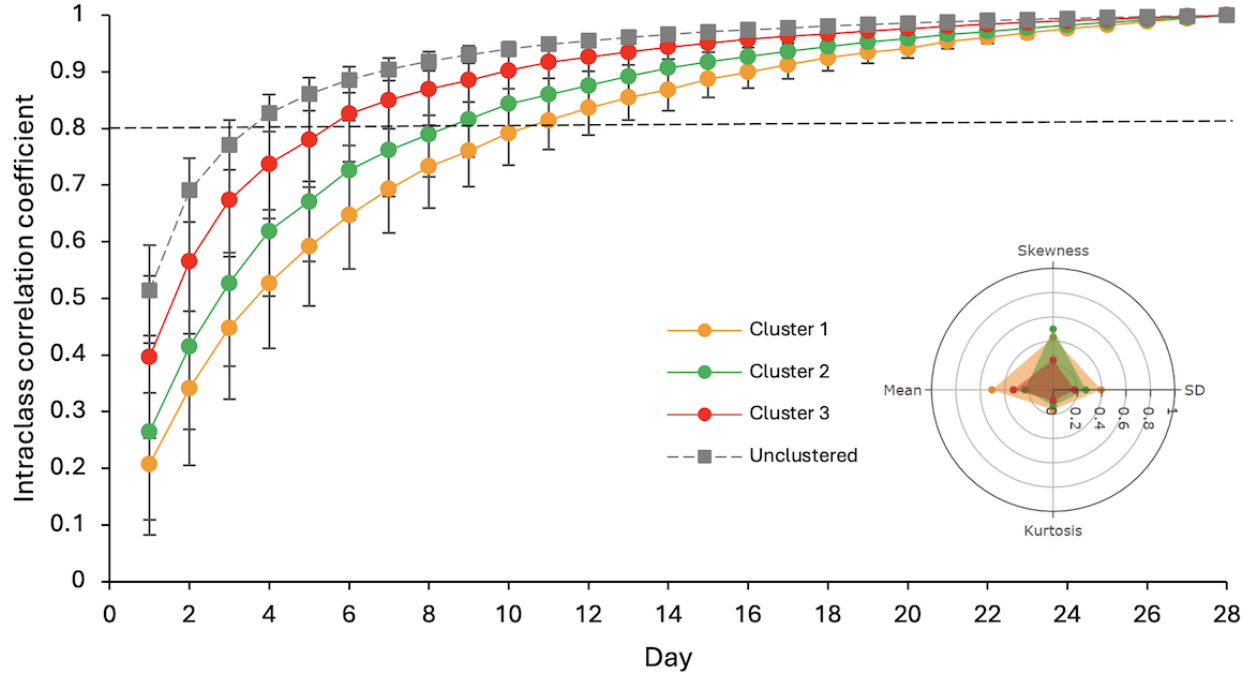


Figure 3. Range of intraclass correlation coefficients across all randomized combinations for each cluster from short-term analysis. Scores ≥ 0.80 are classed as "acceptable" agreement. Data are mean (SD).

Intraclass Correlations in Medium-Term Analysis

In order to achieve a mean ICC score greater than 0.80, calculated using all randomized combinations for each day subset, Cluster 3 required 6 days, Cluster 2 required 9 days, and Cluster 1 required 11 days (Figure 4). The minimum number of days needed to achieve an ICC score above 0.80 in all 500 random combinations was 11 in Cluster 3, 18 in Cluster 2, and 17 in Cluster 1. As a baseline comparison, when the data were unclustered, 4 days were required to achieve a mean ICC score above 0.80 in all 500 random combinations.

Figure 4. Range of intraclass correlation coefficients across all randomized combinations for each cluster from medium-term analysis. Scores ≥ 0.80 are classed as "acceptable" agreement. Data are mean (SD).

Discussion

Principal Findings

The main aim of this study was to identify clusters of individuals with distinct physical activity patterns and to determine if the number of days of accelerometry data required to reliably estimate short- (7 days) and medium-term (28 days) physical activity differed between each unique cluster. Clustering analysis confirmed that, in a heterogenic sample, clusters of individuals could be identified based on their physical activity patterns. In agreement with our hypothesis, the physical activity patterns of different individuals were highly relevant to the number of days needed to reliably predict both short- (7 days) and medium-term (28 days) physical activity, ranging from 2 to 6 days and 6 to 11 days, respectively, by cluster. Therefore, the minimum number of days should be assessed within a particular study cohort, instead of relying on generic recommendations.

One major consideration of using accelerometry for longitudinal physical activity research is that participant monitoring is a continuous process, which can require significant study resources and can challenge participant adherence. Therefore, having the flexibility to monitor less or lose more days, without compromising the validity of the data, is of significant benefit. However, the results from the current study show that, while this is possible, it can be erroneous to use a generic number of days across all participants. This supports the need to be cautious when considering a one-size-fits-all approach when it comes to collecting accelerometry data. For example, past reviews have suggested 4 days would suffice to achieve sufficient reliability in physical activity [2,11]. However, based on the results from the current study, this will be highly dependent on the physical activity patterns that exist within the specific research sample being studied. Another potential limitation of previous recommendations is the use of the Spearman-Brown prophecy formula to estimate reliability [23-25]. This statistical method depends on achieving homogeneity of variances, which may be unrealistic to achieve in many datasets. The resampling approach in this study helped address this problem, as it does not rely on this formula and is less sensitive to violations of homogeneity of variance. By repeatedly calculating ICCs from randomly selected combinations of days, the method reduces the influence of unequal within-subject variances on individual ICC estimates, resulting in a more robust overall estimate of reliability. Similarly, a nonclustered ICC may violate the assumption of homogeneity of variance if the physical activity patterns of the sample are diverse. Clustering can help group individuals with similar within-subject variance, improving the likelihood that model assumptions are satisfied.

The results from both the short- and medium-term analyses highlighted that clusters with relatively low variability in their physical activity required fewer days to reliably estimate physical activity. In contrast, clusters with high variability required significantly more days. Referring specifically to the data, depending on the cluster, the mean number of days required ranged from 2 to 6 for the short-term analysis and 6 to 11 for the medium-term analysis. This makes generalized recommendations as reported in previous research [26-28] difficult to provide. Interestingly, within this study's sample, the physical activity patterns of clusters in the medium-term analysis were more similar to each other than those observed in the short-term analysis. This implies reduced variability as participants settle into comparable daily activity patterns with larger measurement windows. Nonetheless, it is important to mention that, for one cluster, the minimum number of days needed to achieve sufficient reliability in all 500 random combinations was still noteworthy (17 days).

To an extent, these results agree with the work by [12] that recommended at least 3 and 5 measurements days of step count data were needed to predict weekly and monthly time windows, respectively. However, it highlights the risk of adopting the minimum limit of these recommendations for all participants. Instead, an approach that first attempts to understand the sample that is being studied could be beneficial. For example, if pilot testing is being conducted, this could provide an opportunity to collect prior accelerometer data on the group of participants. Depending on whether the physical activity patterns are expected to be similar or not, a cluster analysis could be used to determine the minimum number of days needed for each subset of participants. Alternatively, while physical activity questionnaires may provide an inexpensive and less-demanding method to group individuals, they can be prone to recall bias, as we have previously shown [16].

Practically, this research demonstrated that a heterogeneous sample can be divided into subgroups with distinct physical activity patterns. As a consequence, these clusters can influence the reliability of predicting habitual physical activity and, thus, the broader interpretation of the results. Previous research linking physical activity to health outcomes has estimated a participant's habitual level of physical activity using subsamples ranging from 1 to 5 days [8-10]. Unfortunately, the validity of such results is tied to the accuracy of this physical activity estimation. Researchers who do not fully consider the potential heterogeneity in their sample may be at potential risk of underestimating within-subject variability, which could potentially influence their interpretation of the results. Therefore, safeguards should be considered to improve physical activity estimates that include clustering, using appropriate ICC methods, and including complementary reliability metrics (standard error of measurement, coefficient of variation, etc).

Another point of consideration is that, in research studies, accelerometry is often used to quantify the rest-activity cycle of participants, which spans physical activity, sedentary time, and sleep. While this research focused on physical activity, the reliability of sedentary time and sleep will also display different levels of within-subject variability. Therefore, if researchers intend to quantify all 3 components of the rest-activity cycle, it is important to consider whether the number of days chosen is sufficient to capture the variability across all 3 components. For example, before individual sleep behaviors become stable, they require many more days of data than the general recommendation of 14 days [3]. However, more research exploring clustered samples is required because results from grouped data have reported differing results [29-31], which is likely a reflection of the level of heterogeneity across the sample in each analysis.

XSL•FO
RenderX

The current study is not without its limitations. First, the specific results of the current study reflect the discrete physical activity patterns of the analyzed sample. Nonetheless, the core concepts are universal and generalizable to other research samples in this area. With a larger sample size, more clusters may have been identified, or rather, a greater number of participants may have been placed within each identified cluster. For example, a number of clusters that were identified had insufficient sample sizes to conduct the analysis on and thus were excluded. It is plausible that the individuals with these excluded physical activity patterns may have required even more or fewer days to reliably estimate their physical activity over time, compared to those seen in the reported results. Importantly, while the physical activity patterns of the excluded individuals were uncommon in this study, they may better reflect physical activity patterns seen in a different study. Notably, while our sample was relatively heterogeneous, there was a higher percentage of individuals with large BMIs, which may have contributed to a small bias, as BMI has been shown to be associated with lower physical activity patterns [32]. Nonetheless, if the sample in this study had more variance, it likely would have strengthened the results while also improving the study's generalizability. In the current study, 10 or more hours of wear time during waking hours for a given day was considered sufficient for inclusion. Therefore, certain days with missing physical activity data will inherently be included and can influence reliability predictions [24]. Nonetheless, this decision was made to align with previous approaches [2,21], and to balance accuracy with the retention of information. Finally, ICCs are based on the proportion of between-to within-subject variance; thus, results from separate samples can differ based on within-subject variance (day-to-day variability of steps within a participant) but also, between-subject variance (variability of steps between participants). As alluded to in the introduction, this poses a potential concern that recommendations from large heterogeneous samples may misrepresent research samples that are more homogenous in nature. Unfortunately, while widely used, this is the limitation of using ICCs in the context of estimating physical activity. Importantly, our clustering analysis attempted to limit the between-subject variance by identifying clusters of individuals with similar physical activity patterns based on the 4 moments of distribution.

Conclusion

In conclusion, the number of days required to reliably estimate physical activity differs between clusters of individuals characterized by distinct physical activity patterns across both the short- and medium-term. To avoid unreliable estimates of physical activity, researchers should be mindful of the sample they are studying and how this may influence the minimum number of days required to reliably reflect physical activity. This study showcases that one-size, indeed, does not fit all when it comes to collecting accelerometry data.

Acknowledgments

The authors are grateful to all the participants for their involvement. The authors would like to thank the Sports Science Department for providing the Facility of Social Sciences at Reykjavík University, Reykjavík (Iceland) to carry out Study 2. We would also like to thank Birta Sóley, Steinunn Svansdóttir, Karitas Kjartansdóttir, and Katrín Gústafsdóttir for their work regarding recruiting participants, the preliminary Study 1 and Study 2. Also, the authors would like to thank Kristín Anna Ólafsdóttir for her extensive contribution to ethical applications and personnel management. We used the generative AI tool ChatGPT by OpenAI to support with code generation, which was reviewed and corrected by the study group, and to restructure writing.

Funding

The authors declare that financial support was received for the research, authorship, and/or publication of this article. The authors of this paper have received funding to perform this work and write this paper from the European Union's Horizon 2020 research and innovation program (grant agreement 965417). The Sleep Revolution project has received funding from the European Union's Horizon 2020 research and innovation program under grant agreement No. 965417.

Authors' Contributions

Conceptualization was done by CJM, GMJ, JMS, MO, and ESA. Data curation and formal analysis were performed by CJM and GMJ. Funding acquisition was secured by JMS, ESA. Investigation was carried out by CJM and KYF. Methodology was developed by CJM, GMJ, JMS, MO, and ESA. Project administration was managed by CJM. Resources were provided by ASI. Software development was completed by CJM and GMJ. Supervision was provided by ASI, JMS, MO, and ESA. Validation was conducted by CJM and GMJ. Visualization was done by CJM and GMJ. Writing of the original draft was performed by CJM, while review and editing were carried out by CJM, GMJ, KYF, ASI, JMS, MO, and ESA.

Conflicts of Interest

The Sleep Revolution pays KYF PhD students' salaries and CJM, GMJ postdoctoral researchers' salaries. ESA reports honoraria from Nox Medical, ResMed, Jazz Pharmaceuticals, Linde Healthcare, Wink Sleep, Apnimed, and Vistor. A former member of Philips Sleep Medicine, Innovation Medical Advisory Board, and Lilly Medical Advisory Board. As well as currently being the President of the European Sleep Research Society. None for other authors.

Abstract

Shoulder pain is prevalent in people living with spinal cord injury. Technology and digital rehabilitation tools are increasingly available, but this has not yet included the provision of a self-guided exercise intervention focused on managing shoulder pain for people living with spinal cord injury. We drew on the person-based approach (PBA) to intervention development to design a Shoulder Pain Intervention delivered over the interNet (SPIN) to address this gap. However, in preparation for the design process, we found very few published examples of how the PBA had been operationalized. The aim of this paper is to provide a detailed explanation of our approach and how we operationalized the PBA in the design of SPIN to maximize relevance and engagement. Our design process followed the key PBA steps, combining additional evidence and theoretical components. Each step ensured that guiding principles were formulated and followed to maximize the probability that SPIN would be fit for purpose. We followed 3 steps: (1) we drew on themes from preparatory research (existing and primary) to identify the key behavioral issues, needs and challenges, and existing features to form the basis of SPIN design; (2) we formatted guiding principles that included articulating specific design objectives to provide a framework to identify system requirements; and (3) we selected and refined intervention features using existing literature, behavioral theory, and tools such as the "Behaviour Change Wheel." We have designed SPIN by incorporating a deep understanding of the users' needs and best available evidence to maximize engagement and positive outcomes. In this paper, we have made clear how we operationalized the PBA phases, including how existing evidence, theory, tools, and methods were leveraged to support the PBA process. In explicating our process, we have provided a blueprint to guide future researchers using this approach.

Background

Overview

Shoulder pain is common in wheelchair users living with spinal cord injury (SCI) [1,2]. A lesion to the spinal cord can result in loss of innervation to muscles of the trunk and lower limbs. Consequently, many people living with SCI (pwSCI) rely on their upper extremities not only for performance of daily activities but also for locomotion. Shoulder pain can have a significant impact on their activity, reducing mobility, independence, and quality of life [1-5]. Digital and web-based interventions have increasingly been offered to pwSCI to promote exercise and physical activity [6-9]. These interventions minimize barriers to rehabilitation to address many health concerns, including managing their shoulder pain. Previous authors have found that in the general population, digital or web-based interventions can produce positive effects in various outcomes, such as physical activity [10,11].

Technology-supported exercise interventions for pwSCI with persistent shoulder pain are currently available, but they have some limitations. They either require ongoing input and monitoring from a clinician [12-15] or provide general self-management advice [13] but without enough guidance to allow for clear and structured exercise progression specifically for shoulder pain. Self-guided digital exercise interventions have been successfully implemented for people with knee osteoarthritis [16,17], dizziness [18,19], and breast cancer [20] and may be a viable option for pwSCI. Our recent systematic

XSL•FO
RenderX

review and meta-analysis of self-guided digital physical activity and exercise interventions demonstrated positive effects on physical activity at both short- and longer-term follow-up, in people living with chronic conditions [21]. We also found that interventions that used behavioral strategies and were underpinned by a theoretical framework were more effective. This suggests that self-guided digital interventions have the potential to support pwSCI to manage their shoulder pain, but that the intervention would need to be designed systematically and intentionally.

We have designed Shoulder Pain Intervention delivered over the interNet (SPIN) as a self-guided digital intervention to give pwSCI who experience shoulder pain the ability to access and progress evidence-based exercises. The intervention guides pwSCI to monitor symptoms and improvement [22] to promote autonomy in the management of their condition. The aim of SPIN is to be an engaging program that is responsive to the needs of pwSCI who have shoulder pain.

To achieve this, we were guided by the person-based approach (PBA) in the design of SPIN [23]. The PBA follows 4 iterative phases of intervention development that include (1) planning which seeks a deep understanding of the perspectives and psychosocial context of potential users through iterative qualitative research, (2) design based on guiding principles that have been created from insights from the first phase, (3) development and refinements which are made through iterative user feedback, and (4) trialing to evaluate the effectiveness on outcomes and impact on behavior change to make any necessary adjustments. Due to its focus on the development of digital behavior change interventions, the intent and purpose of PBA align well with adjacent behavior change theory and tools such as the COM-B [24], "Behaviour Change Wheel" [25], and behavioral analysis [26]. Furthermore, the PBA process is sufficiently flexible to enable the use of these (and other) tools to achieve the aims and purpose of a given phase. Integrating behavioral science theory and evidence while keeping users' needs and contexts in focus has been found to maximize engagement and effectiveness of interventions [18,25,27-31]. This tutorial focuses on the first 2 PBA phases of planning and design. See Table 1 for an example of how our study was mapped onto the PBA.

Table . Mapping of person-based approach phases onto Shoulder Pain Intervention delivered over the Internet design.

PBA[a] description	Phase	This study	
		Purpose	Planned outcome
Use of primary and secondary *qualitative evidence* to understand users' behavioral and psychosocial needs and challenges in using the intervention		To determine *factors that need to be included* to *encourage or facilitate engagement* with this self-guided web-based exercise intervention	• A rich description of key *needs, challenges, and facilitators* of engagement in web-based tools and exercise for people living with SCI[b] who experience shoulder pain to *underpin the design phase's guiding principles and features*
Formulation of *key guiding principles* that capture the main intervention objectives as identified in the planning phase and that are continuously referred to throughout the development of the intervention		To design an *evidence-based, self-guided, web-based* intervention Exercise, behavioral support, and self-guided components to be included within the intervention features	• Intervention design objectives • Intervention features • First iteration of SPIN[c] prototype

[a]PBA: person-based approach.

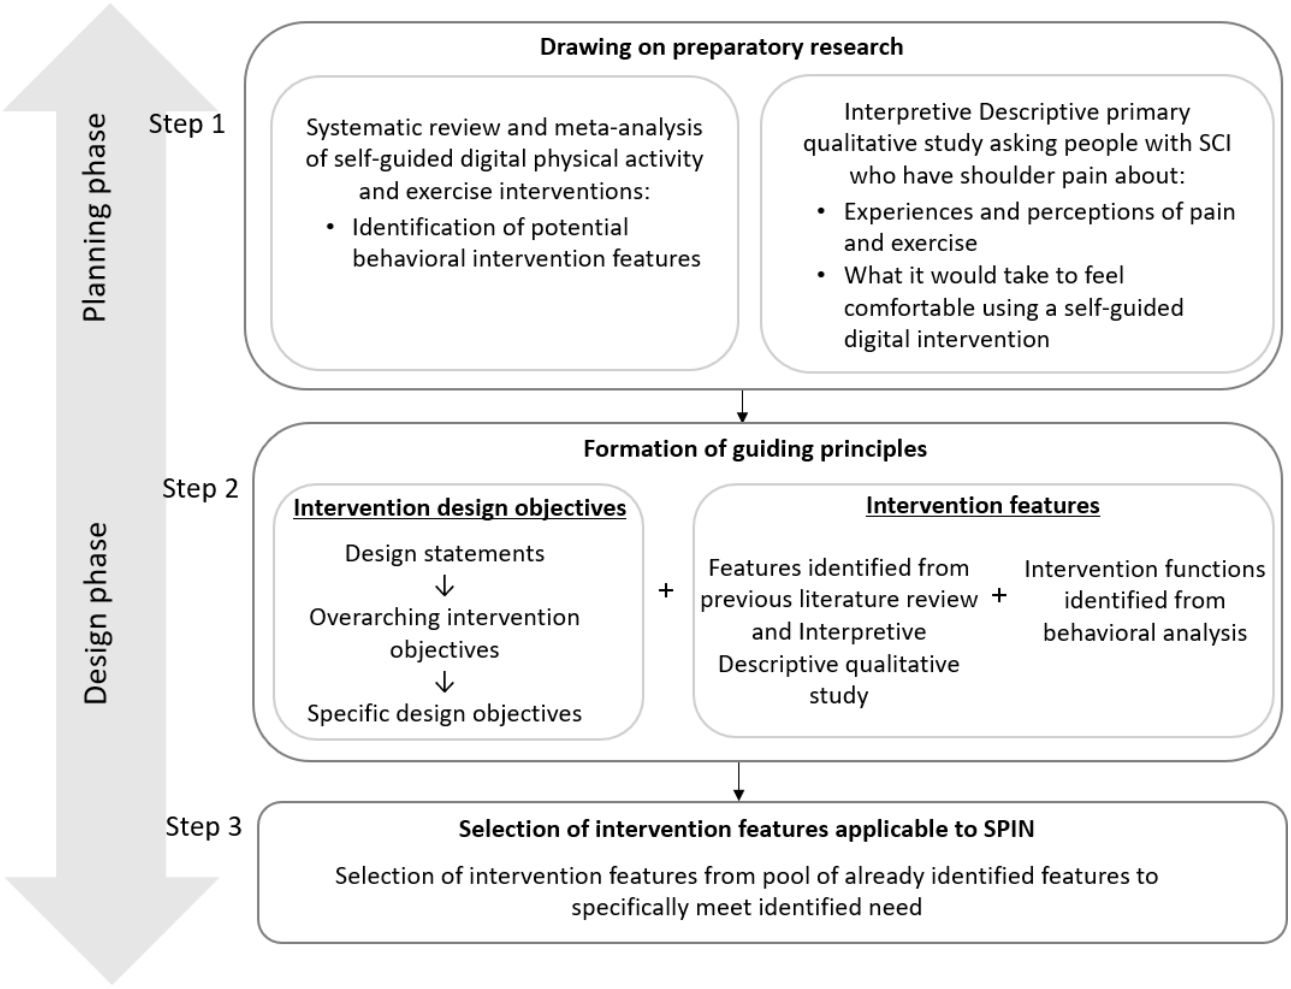
[b]SCI: spinal cord injury.

[c]SPIN: Shoulder Pain Intervention delivered over the interNet.

We drew heavily on the existing PBA literature during the planning and designing stages of SPIN. However, the lack of access to detailed examples of how the PBA has been operationalized in practice made it challenging to translate the principles of this approach into reality. This is not a unique problem. Duncan and colleagues [32] noted that published work on the development of an intervention is frequently sparse because it is often included in the same publication as the reporting of a pilot or feasibility study.

Aim

The aim of this paper is to make clear how the principles of the PBA were operationalized in intervention design and the development of SPIN. We have illustrated our use of the PBA framework by outlining the detailed and explicit steps involved in the translation of the evidence, theory, and person-based recommendations into intervention design. In doing so, we have built on the existing methodological framework and enabled others to draw on this approach in future intervention design and development.



Methods and Outcomes

Overview

The planning and design phases of the PBA are described below, along with an overview of how they were operationalized in the design of SPIN. Figure 1 provides an overview of the SPIN design process and the components involved. Each step and its subsequent outcome have been described in detail in the sections that follow.

RenderX

Figure 1. Overview of Shoulder Pain Intervention delivered over the Internet design steps and components. SCI: spinal cord injury; SPIN: Shoulder Pain Intervention delivered over the interNet.

Step 1: Drawing on Preparatory Research

Methods

This initial phase of the PBA draws on qualitative research, including interviews and focus groups, to gather in-depth insights into the psychological, social, and emotional factors that influence the users' behavior. The goal is to identify the underlying motivations, beliefs, and barriers that may affect engagement with health interventions [23]. In the context of SPIN, this preparatory research included: (1) a systematic review and meta-analysis investigating the effectiveness of self-guided digital physical activity and exercise interventions [21] and (2) an Interpretive Descriptive qualitative study exploring the perceptions of pwSCI who have shoulder pain, on the use of a self-guided digital intervention to help them manage their shoulder pain [33].

Outcome

The review identified several self-guided digital physical activity and exercise interventions. Data extraction included identifying discrete intervention features and categorizing them using a purpose-built template (Multimedia Appendix 1), based on a synthesis of key literature [27,34-40]. Using this template, we extracted possible behavioral intervention features relating to qualities such as customizability, the provision of instruction, feedback and monitoring, tailoring, reminders and prompts, goals and planning, social support, and rewards and threats. We also noted the success of interventions using features that supported behavior, particularly self-regulation. This informed an initial pool of possible intervention features for SPIN that were reviewed later in Step 2.

The Interpretive Descriptive qualitative study identified themes that represented an evaluative process pwSCI go through when considering using a self-guided digital exercise intervention: *Should I use it?*, whether I believe it will work for me right now; *Can I use it?*, whether I can operate the intervention competently and confidently; and *Will I use it?*, whether it will be responsive to my unique needs and keep me coming back. These formed the basis of the design statements in Step 2.

Conceptual representations of possible behavioral intervention features identified from the review were used as probes and images during data collection in the Interpretive Descriptive qualitative study. These were used to prompt discussion about what could help pwSCI to engage in a self-guided digital intervention. The pwSCI discussed ways in which these concepts and specific features may support them. These perspectives were extracted from the audio recordings and tabulated to support the identification of behavioral intervention features in Step 2.

XSL•FO
RenderX

Step 2: Formation of Guiding Principles

Overview

The guiding principles in the PBA are formulated by synthesizing key insights from the planning phase (Step 1) into intervention design objectives and corresponding intervention features that address users' specific needs, preferences, and behavioral barriers [23]. Yardley and colleagues [23] contend that staying true to the identified needs of the people who will use the intervention, throughout the design process, increases intervention relevance, engagement, and effectiveness. In our design of SPIN, we followed several stages to ensure the key context-specific behavioral needs and challenges identified in the Interpretive Descriptive qualitative study remained the focal point during intervention design.

Intervention Design Objectives

Yardley et al [23] suggest generating intervention design objectives to support the creation of the guiding principles but do not expand on how these may be identified. Below, we describe the method we followed to produce intervention design objectives through the creation of design statements, overarching intervention objectives, and specific intervention design objectives.

Design Statements

Methods

We created design statements by using the 3 themes constructed in the Interpretive Descriptive qualitative study. We first reframed each theme into a design statement, giving consideration to how each could be reflected in the design of the intervention. To do this, we reworded the themes to move from a question (*Should I use it?*) into a design statement (*I should use it if…*) and then added conditions applicable to each design statement. Each condition reflected key elements from the qualitative findings, resulting in person-centered conditions to be met in the design process. This process provided depth and context to inform the design of SPIN and ensured the next step would be underpinned by the perspectives of the future users of the intervention, in this case, pwSCI.

Outcome

The Interpretive Descriptive qualitative study themes, design statements, and key conditions for success are presented in Table 2.

Table . Translation of themes to design statements and conditions of success.

Interpretive Descriptive qualitative study theme	Reframed to: design statements	Conditions for success
Should I use it?	I should use it if:	• I believe it will work for me • There is evidence of credibility • There is a clear indication that it is suitable for me • It resonates with my current attitude toward exercise, support situation
Can I use it?	I can use it if:	• I can use it competently • I can use it confidently • It can be tailored and adapted to my unique needs • I can use it safely, without causing more harm • I have the belief that I could use it, given the resources and capacity I have • I have the right support to use it
Will I use it?	I will use it if:	• It is responsive to my unique needs • It encourages me to progress when I am ready • I feel supported to use it • I can see progress as a consequence of using it • It keeps me coming back

Overarching Intervention Objectives

Methods

Next, we articulated the overarching intervention objectives. Succinctly describing the intervention objectives allows a snapshot of the key characteristics of the intervention [23]. We, therefore, clearly articulated how SPIN is distinctive and different from other interventions, reflecting the specific behavioral issues, needs, and challenges it must address.

We developed the intervention objectives iteratively, repeatedly revising the wording with reference to the original research question and design statements, and with input from the research team and stakeholders. Stakeholders included pwSCI, a clinician with experience in SCI rehabilitation, a clinician who was also a pwSCI and a representative of a relevant nongovernmental organization. Each iteration strived to reflect the essence of the needs expressed by the participants with wording that represented what ideal uptake and use of this self-guided digital exercise intervention could look like. The overarching

XSL•FO
RenderX

intervention objectives were then used as a reference point for later design and development phases.

Outcome

Referring to the design statements and overall research aim, the overarching intervention objectives for SPIN were to:

1. Be tailored to users' specific and unique needs so they can relate to it and trust it and so that it can be responsive to their changing needs while using SPIN; and
2. Enable users to use it competently and confidently within their capabilities and support systems in a way that is safe and motivating.

Specific Design Objectives

Methods

Once the overarching intervention objectives were formulated, we created the specific design objectives underpinned by the design statements. We developed a working definition, incorporating the key conditions for success for each specific design objective, to ensure clarity in interpretation. These were then reviewed against the overarching intervention objectives, making sure they supported the overall objectives of SPIN. We continued to refine them as the design process progressed, during our planned discussion forums.

Outcome

Tables 3-5 each refer to a different theme. Specific design objectives and working definitions are presented in the first 2 columns; intervention functions and features are discussed in later sections.

Table . Guiding principles from the theme *Should I use it?*.

Design objectives that address identified needs, issues, and challenges	Working definition	Intervention functions	Intervention features that address the design objectives
To help users relate to and trust the program	The program will give users confidence in the source, message, and value of the program. The program is credible and legitimate and promotes trust.	• Education • Training • Modeling • Enablement • Persuasion	• Development team details (names, credentials, and contact info) • Endorsements • *Testimonials* (source matching for social comparison) • Evidence for shoulder pain exercises • How user data will be used or stored • Professional polished interface and function
To reassure users it will be clear who the program is suitable for, giving users confidence that the program is right for them and at what stage it is right for them	The program will guide users through a process to be able to screen for and identify if they are suitable to use the intervention and to promote trust and confidence that this is a safe and robust process.	• Education • Training • Modeling • Enablement • Persuasion	• Screening questionnaire/questions (that will exclude those unsuitable) • Monitoring questions at each exercise event and tracking this information • *FAQ*[a] *section* • Contact information for the team
To provide a sense of potential that it will work for them	The program will help users identify with it and the potential that it may have for them, in their current situation.	• Education • Training • Modeling • Enablement • Persuasion	• *Testimonials* (image with text, video, and quotes) of people in different "stages" of readiness or different situations. • FAQ section addressing suitability of different situations "Is this right for me?" or "How do I know this is right for me?" or "Questions I can ask to make sure this is right for me?"

Design objectives that address identified needs, issues, and challenges	Working definition	Intervention functions	Intervention features that address the design objectives
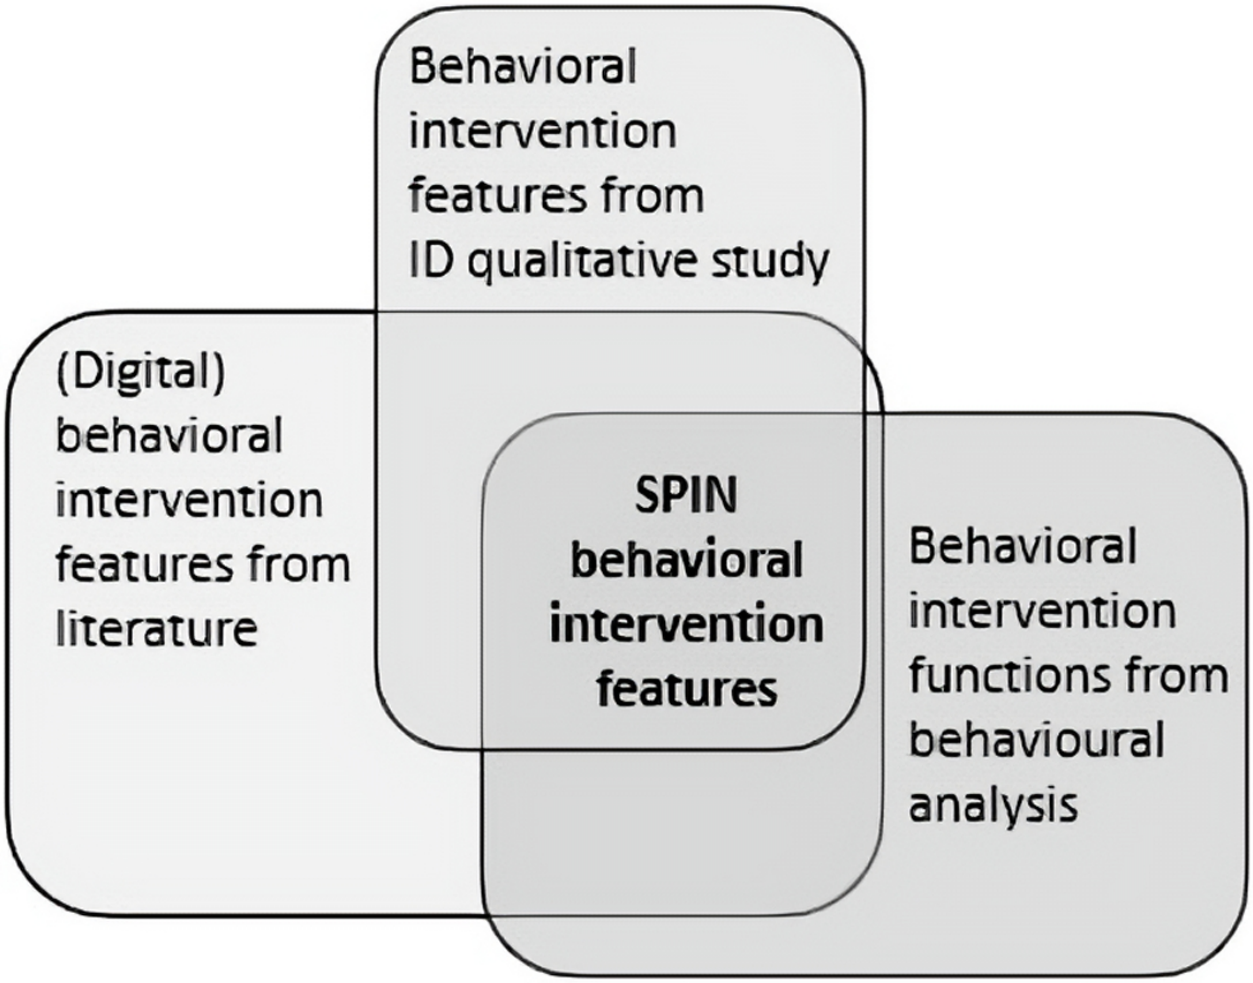
To promote a sense of accountability	The program will provide features that encourage the user to return to the program and to continue with the exercises.	• Training • Environmental restructuring • Enablement • Modeling • Education • Persuasion • Incentivization	• Competition with others or with self • Support from others • Communication that is *positive*, immediate, and useful and *tailored* • Communication that is personalized • Rewards that are only released upon completion of a certain amount of exercise
To promote a sense of progree and engagement	The program will enable the user to understand their progress through a clear and simple tracking feature. This will be done in a way that encourages further progress and ongoing engagement with the exercise intervention	• Training • Environmental restructuring • Enablement • Modeling • Education • Persuasion • Incentivization	• Feedback and tracking • Choice in exercise selection • Personalization • *Tailoring*



[a]FAQ: frequently asked question.

Intervention Features

In the PBA, the guiding principles inform the intervention features by providing a framework for selecting and shaping features that directly support the specific design objectives, and to improve resonance, engagement, and acceptability of an intervention [23]. A range of evidence informed the selection of behavioral intervention features: (1) in our review, we identified a range of features used in digital interventions that have been associated with better health-related outcomes [27,34-36]; (2) we identified possible behavioral intervention design features from our Interpretive Descriptive qualitative study [33]; and (3) we identified behavioral "intervention functions" we were trying to achieve using a behavioral analysis as per Michie and colleagues' framework [26]. We then mapped these to the most relevant intervention features. Figure 2 represents the layers of evidence that informed SPIN's intervention features. We will describe each of these in detail below.

XSL•FO
RenderX

Figure 2. Layers of evidence that informed Shoulder Pain Intervention delivered over the Interjet's intervention features. ID: Interpretive Descriptive; SPIN: Shoulder Pain Intervention delivered over the interNet.

Identifying Behavioral Intervention Features From Previous Literature Review and the Interpretive Descriptive Qualitative Study

Methods

In Step 1, we had earlier identified potential behavioral intervention features for self-guided interventions that were identified from our systematic review and meta-analysis, using the specifically developed template, drawing from the CONSORT-EHEALTH checklist (V.1.6.1) [38]. See Multimedia Appendix 1 for a sample of our template showing sections used to record behavioral intervention features. For this current stage of the SPIN design, we also reviewed intervention features of publications that missed the strict inclusion criteria of the systematic review and meta-analysis but addressed digital delivery of physical activity or exercise intervention for possible relevant behavioral intervention features. We then integrated the data on specific features collected from our Interpretive Descriptive qualitative study. These data were categorized by proposed purpose and function and then mapped against the specific design objectives.

Outcome

There was overlap, resulting in some features identified as addressing more than one design objective. Many of the studies in the systematic review included digital behavioral intervention features that involved instruction on exercise or physical activity performance, self-monitoring of the exercise or physical activity behavior, goals and planning, and prompting. The results of the Interpretive Descriptive qualitative study and other reviewed literature suggested additional behavioral intervention features. Table 6 presents a summary of the behavioral intervention feature categories that we considered for SPIN, the design objective(s) they are related to, and the supporting evidence.

XSL•FO
RenderX

Table . Behavioral intervention feature categories supported by systematic review, Interpretive Descriptive qualitative study, and existing literature.

Design objectives	Behavioral intervention feature	Proportion of studies identified in systematic review and meta-analysis (out of 16 studies)	Identified in Interpretive Descriptive qualitative study	Identified in other literature not included in meta-analysis
Should I use it?	Ensuring personal relevance	16	✓	Horsch et al [41]

Identifying Intervention Functions From a Behavioral Analysis

Methods

We included a behavioral analysis using the "Behaviour Change Wheel" and COM-B model as outlined by Michie and colleagues [26]. This is a theoretical framework that provides a systematic way of identifying the problem and analyzing the behavioral needs of a target behavior. The "Behaviour Change Wheel" can support intervention design by linking the identified behavioral needs to "intervention functions" through a mechanism of action.

Consistent with the guiding principles and specific design objectives, and for the purpose of this behavioral analysis, we reframed the 3 themes from the Interpretive Descriptive qualitative study into target behaviors: *Should I use it?*—Signing up to SPIN (Table 7); *Can I use it?*—Using SPIN (Table 8); and *Will I use it*?—Returning to SPIN over the 12 weeks (Table 9). The COM-B Model was then used to identify the capability (C), opportunity (O), and motivational (M) components required for each of these behaviors (B) to occur, referring to the specific design objectives. The questions "*what needs to happen for the target behavior to occur?"* and "*is there a need to change?"* facilitated the analysis process [26]. We used this process to identify (or "diagnose") the relevant COM-B components that need to be addressed for the target behavior to occur (see the Behavioral diagnosis of the relevant COM-B components in Tables 7-9).

XSL•FO
RenderX

Table . Behavioral analysis of target behavior: signing up to SPIN[a] (*Should I use it?*) for people living with spinal cord injury who have shoulder pain.

COM-B components[b]	What needs to happen for the target behavior to occur?	Is there a need for change?
Physical capability	Have the physical ability to access SPIN features and functions and use it	No change needed as SPIN will only be suitable for people who can physically access and use it
Psychological capability	Believe they have the capability to use SPIN	*Change* needed as pwSCI[c] will want reassurance that they have sufficient physical capability to use SPIN and/or that it is suitable for people with their level of physical ability
Psychological capability	Know that exercise can improve pain symptoms (or not make the condition worse)	*Change* may be needed as there may be fears or concerns that exercise could worsen pain symptoms
Physical opportunity	Have a device that can access SPIN	No change needed as SPIN will only be suitable for those people who have devices that can access SPIN
Social opportunity	Know about other pwSCI who have either benefitted from exercise for shoulder pain or are using SPIN	*Change* needed as pwSCI may not know about others who have benefitted from exercise to improve shoulder pain symptoms or who are using SPIN
Reflective motivation	Hold beliefs that exercising will reduce pain symptoms and/or improve activity	*Change* needed as pwSCI may be fearful that exercise may worsen pain symptoms
Reflective motivation	Believe that SPIN has been developed by a credible and trustworthy source	*Change* needed as pwSCI will want to assure themselves that SPIN has been developed by knowledgeable personnel who have experience in SCI[d] rehabilitation
Automatic motivation	Believe that SPIN will identify those that are suitable (and unsuitable) to use it	*Change* needed as pwSCI will want assurance that SPIN is appropriate for their circumstances and can be tailored for their needs
Automatic motivation	Need to feel that SPIN resonates (with current attitude toward exercise, support situation)	*Change* needed as pwSCI need to feel comfortable that SPIN is right for them at this time
Behavioral diagnosis of the relevant COM-B components	Psychological capability, social opportunity, reflective and automatic motivation need to change for the target behavior to occur	—[e]
Likely ”intervention functions” that link to COM-B	Education (psychological capability, reflective motivation), Training (physical opportunity), Modelling (social opportunity), and Persuasion (reflective motivation, automatic motivation)	—

[a]SPIN: Shoulder Pain Intervention delivered over the interNet.

[b]Behavioral diagnosis of the relevant COM-B components: physical and psychological capability, physical and social opportunity, and reflective motivation need to changefor the target behavior to occur.

[c]pwSCI: people living with spinal cord injury.

[d]not applicable.

Next, we mapped these components to established 'intervention functions,' using the "Behaviour Change Wheel." Most relevant "intervention functions" were then identified from the matrix of links between COM-B and intervention functions [26]. The "Behaviour Change Wheel" uses the term "intervention function" in lieu of intervention "type" or "category" since the same intervention feature may address more than 1 function [26].

Outcome

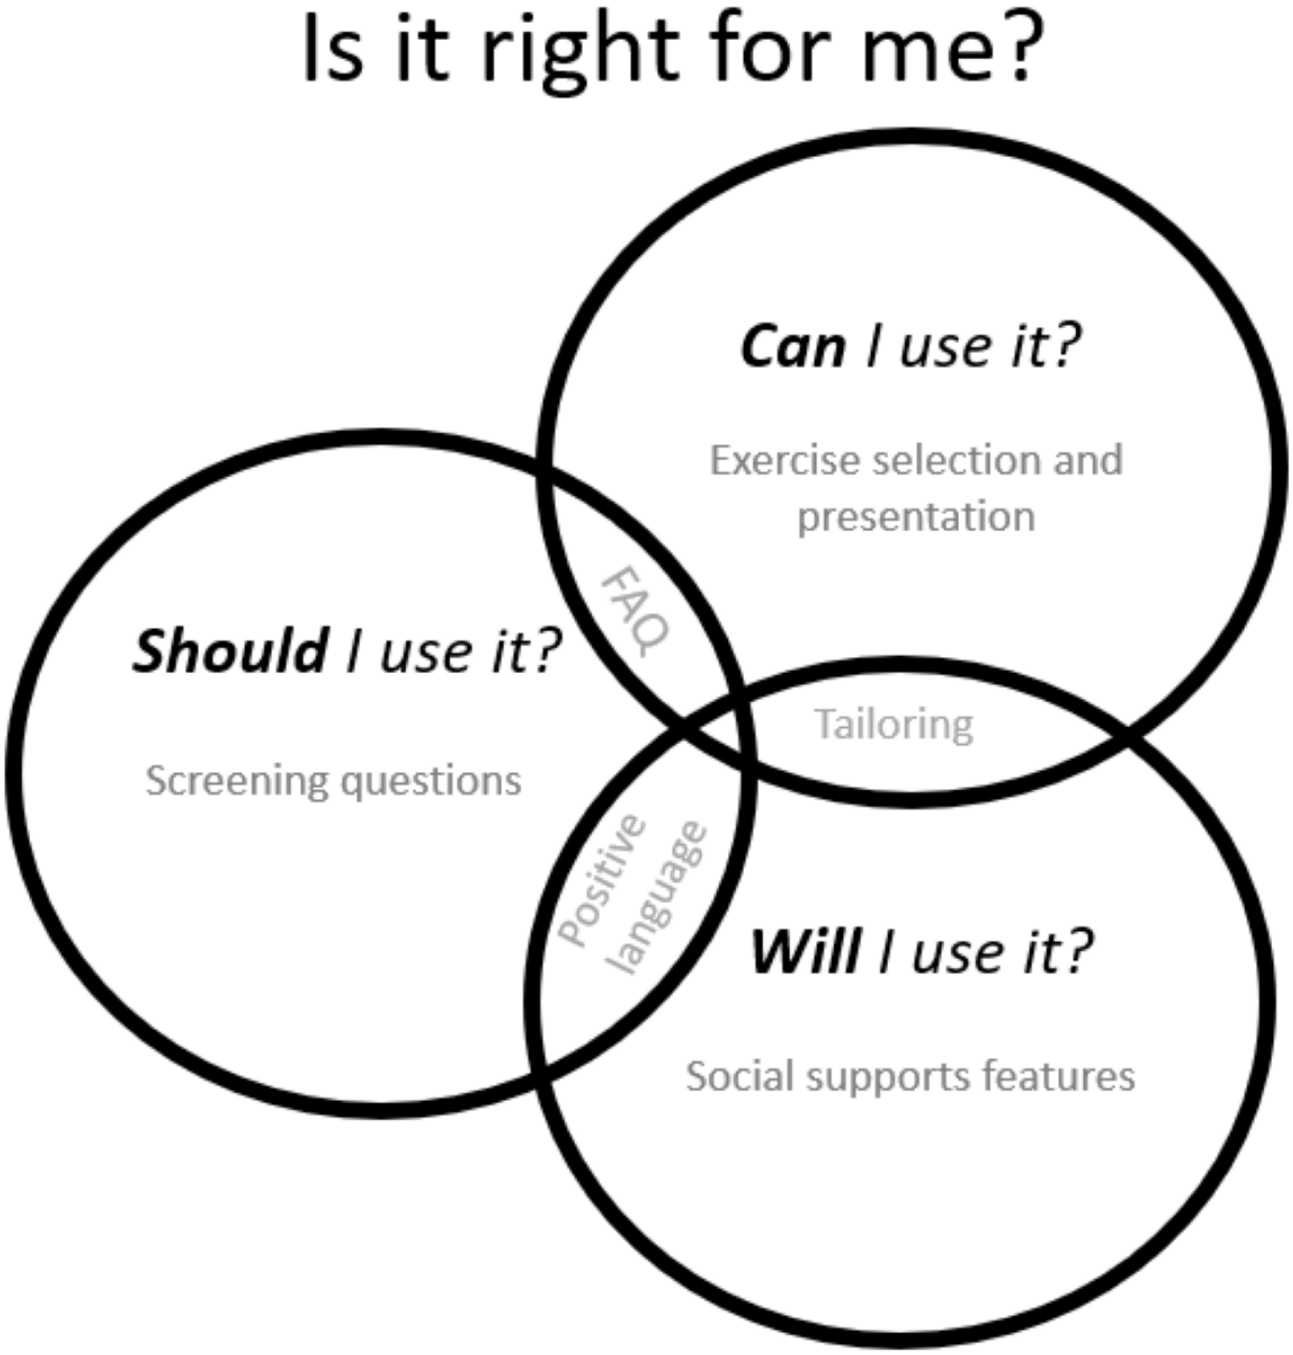
Tables 7-9 present the target behavior for each design objective and what (if any) change is needed to occur based on the COM-B components. "Intervention functions" most likely to support behavior change have also been identified. For example, testimonials about positive experiences of using exercise to help with shoulder pain could be a form of modeling (providing an example for people to aspire to) and persuasion (using communication to induce positive feelings or stimulate action). This mapping process allowed each specific design objective to be checked to ensure it was supported by an appropriate "intervention function" and corresponding intervention feature. "Intervention functions" linked to the target behavior have been included in Likely "intervention functions" that link to the COM-B in each of the tables (Tables 7-9). The guiding principles tables (Tables 3-5) provide an overview of how these

XSL•FO
RenderX

"intervention functions" map to the design objectives ("Intervention functions" column).

Step 3: Selection of Intervention Features Applicable to SPIN

Methods



The design phase of the PBA involves identifying intervention features and content, guided by the previously formulated guiding principles, to ensure alignment with users' psychosocial contexts and to enhance relevance, acceptability, and engagement through iterative user feedback [23]. We were able to begin selecting specific SPIN intervention features once the behavioral analysis was complete. The behavioral intervention features previously identified (Table 6) were reviewed. We mapped those that we felt were contextually appropriate against the "intervention functions." Each was checked to ensure it supported the specific design objectives and the overarching intervention objective. VS completed this process in consultation with coauthors.

Outcome

Collectively, Tables 3-5 demonstrate a complete representation of the guiding principles of SPIN's proposed intervention features and functions, mapped back to the design objectives. Some intervention features address more than 1 intervention design objective. These features have been italicized in Tables 3-5. For example, having a forum for frequently asked questions may reduce barriers to starting the intervention and give users the information they need to progress. Having positive, encouraging language can attract users to start using the intervention and motivate them to continue with it. Other intervention features more clearly support only one of the intervention design objectives. Figure 3 schematically presents an example of how overlapping intervention features cohesively support SPIN's identified design objectives.

XSL•FO
RenderX

Figure 3. Schematic representation of overlapping intervention features.

Application of Our Design Steps to Future Intervention Design

We believe that by explicating how we used the PBA in the development of SPIN, we can support others to use the PBA in the design of interventions. Table 10 provides a summary view of our process and includes some questions that we hope will prompt other researchers to consider how they might operationalize the use of PBA in their work. The table provides an overview of key phases of PBA and possible timelines (column 1) and examples from SPIN (column 2), including tools and methods we drew on as complementary to PBA and which we found useful in operationalizing the approach. In column 3, we have included our reflections on the benefits of our approach. The final column has questions that we hope will serve as prompts for researchers and designers when using this approach.

XSL•FO
RenderX

Table . Operationalizing the person-based approach: our experience and future applications.

1. Key steps in the person-based approach	2. Methods we used to operationalize PBA[a] steps in the development of SPIN[b]	3. Strengths and opportunities of our approach	4. Questions to consider when planning this step
Step 1 (months 3 - 6) Identify key behavioral issues (access), needs (not feeling competent), and challenges the intervention must address	Interpretive Descriptive qualitative study to explore user perspectives of self-guided exercise intervention and what would help or hinder uptake of a self-guided digital exercise intervention. Used probes and images during data collection to help users visualize and provide feedback on possible intervention features.	Drawing on Interpretive Descriptive as a nested study within the PBA process helped to provide a robust framework to capture and make sense of user needs and preferences. Interpretive Descriptive is congruent with the goals of PBA and has the benefit of (1) being oriented toward translation from the outset, (2) prioritizing the production of clinically relevant insights, and (3) flexibility in methods so data collection and analysis could be tailored to the intended use of findings for intervention development.	Who are the users? What is the best way to understand their unique context and specific needs? Are there existing tools and methods available that would be fit for purpose to capture user needs and preferences? How is the information going to be used? How might your approach to capturing needs and preferences be optimized for this intended use? Does data already exist (systematic reviews and qualitative research) that can help inform this step?
Step 2 (months 6-9-12) Creating intervention design objectives that capture what is unique about your intervention and reflect the specifically identified user needs and challenges the intervention needs to address.	Translate themes from the Interpretive Descriptive study into design statements and conditions for success, drawing on the data from each theme.	Helped to reframe the themes into actionable statements. Provided an evidence-based framework to underpin intervention design objectives. Ensured that user needs and preferences will continue to be reflected in the design process.	How are user needs and preferences currently expressed? Can they be used to underpin design objectives in their current form, or do they need some further refinement/transformation?
Step 2 (months 6-9-12) Creating intervention design objectives that capture what is unique about your intervention and reflect the specifically identified user needs and challenges the intervention needs to address.	Two overarching objectives for SPIN were developed from the design statements and conditions of success. It was repeatedly revised, referring to the original research question and design statements, and with input from stakeholders.	Developing 2 overarching objectives, rather than 1, helped to make explicit 2 interrelated but distinct objectives. The intermediary step of developing design objectives from the qualitative study themes ensured that the objectives represent the essence of the needs expressed by the users. Refining with input from stakeholders helped to ensure the objectives remained resonant with the SCI[c] community. Articulating these objectives at the outset was a useful reference point to keep coming back to for all later design and development phases.	What is(are) the overarching intervention objective(s)? How will you ensure your overarching objective(s) remain(s) grounded by user needs and preferences? Who might need to be involved in the development of intervention objective(s)? How will you know if your intervention objective(s) adequately capture(s) the perspectives of future users?
Step 2 (months 6-9-12) Creating intervention design objectives that capture what is unique about your intervention and reflect the specifically identified user needs and challenges the intervention needs to address.	Specific design objective were identified, drawing on the design statements and overarching intervention objectives. Working definitions were formulated with reference to original data sources and in collaborative discussions as a research team.	The development of specific design statements provided a framework to identify design requirements (system requirements) and intervention features. Investing time to develop the working definitions as a team, with reference to original data sources, was important for clarity and shared understanding.	What process will you use to generate specific design objectives from your overarching design objective(s)? Who might need to be involved in that process? What data sources do you have that you can refer to so you can refine your specific design objectives?

1. Key steps in the person-based approach	2. Methods we used to operationalize PBA[a] steps in the development of SPIN[b]	3. Strengths and opportunities of our approach	4. Questions to consider when planning this step
Step 3 (months 6 - 12) Select and refine intervention features that support the specific design objectives.	Several methods were used to support the selection and refinement of intervention features for SPIN including: (1) extracting data on intervention features from a previous systematic review on self-guided exercise interventions, (2) reviewing relevant behavioral theory, (3) undertaking a behavioral analysis, and (4) drawing on persuasive system design.	Drawing on a multiplicity of methods in this step (1) ensured an evidence-based and theoretically informed approach and (2) enabled a systematic approach to ensure intervention features were those best suited to the behavioral needs of the SPIN user. A systematic approach to identifying intervention features and mapping them back to design objectives helps to imrove the credibility of intervention design. The outcome was a clear framework for SPIN intervention design that was a useful tool to support communication with design colleagues or software developers who were then bringing SPIN to form.	What data sources are available that can help you identify potential intervention features? What midrange theories are available that can help you identify potential intervention features? Are there existing tools and methods available that would be fit for purpose to help you identify intervention features which respond to user needs and preferences? Of all the potential intervention features, which are most likely to meet the design objective(s)? Who else should be involved in this process? How might you ensure that the outcome of this process can be an accessible and usable framework for others involved in intervention development?

[a]PBA: person-based approach.

[b]SPIN: Shoulder Pain Intervention delivered over the interNet.

[c]SCI: spinal cord injury.

Ethical Considerations

Ethics approval (Auckland University of Technology Ethics Committee-AUTEC 18/263) and participant consent were received for the earlier work [33] that informed this work.

Discussion

Principal Findings

This paper has described how we applied evidence, theory, and person-based approaches in the design of a self-guided digital intervention to help pwSCI manage their shoulder pain. We have detailed the processes of applying the PBA to the design of SPIN.

This builds on Yardley and colleagues' [23] collection of work. The PBA emphasizes a detailed, qualitative understanding of users' psychosocial contexts to inform intervention design. It adds value to user-centered design by addressing factors that influence behavior change, beyond just usability. The PBA complements theory- and evidence-based frameworks, such as the "Behaviour Change Wheel" [25] by tailoring interventions to the needs and preferences of specific populations. Despite growing evidence for the use of the PBA framework in intervention design [29-31,62,63], there is little available on its operationalization. To our knowledge, the detailed reporting of each step has not been available before.

In a recent systematic review on the effectiveness of self-guided digital exercise interventions, Stavric et al [21] found that interventions with theoretical underpinning had increased congruence with the intervention features leading to significant positive results. This is supported by findings from McEwan [64] who found that theory-based interventions resulted in more consistent significant improvements in physical activity. The pwSCI and shoulder pain who will use SPIN are likely to have minimal contact with a health care professional. Therefore, successful design required an understanding of how SPIN would meet their needs and how pwSCI would use it in daily life in a self-directed way. Engaging people and evidence in intervention design is supported by a range of researchers and designers [23,34,65]. Using a person-based approach, drawing on evidence from the people who will use the intervention, to derive the behavioral strategies has been shown to be effective in a variety of settings and methods of delivery [18,29,30,66,67].

Despite acknowledgment that interventions supported by theory and evidence maximize outcomes [68,69], there remains a paucity of full intervention description or design disclosure [70-73], making it challenging to explicate the link between theory and evidence and intervention features. A key tension we encountered was the limited availability of detailed examples of how the PBA had been operationalized in practice. This required us to make interpretive decisions when translating PBA principles into design elements, often without clear guidance. Additionally, balancing adherence to the PBA's iterative, user-focused process with practical constraints such as time, resources, and access to participants posed challenges. These limitations were compounded by the fact that we were largely self-taught in the application of both the PBA and behavioral analysis frameworks.

Michie and colleagues [74] recognized the challenges and lack of clarity around the purported mechanisms by which digital interventions work during an international workshop on developing and evaluating digital interventions to promote behavior change in health. DiLiberto and colleagues [75] support the importance of "insider accounts" of intervention implementation and argue that the same transparent reporting practice should apply to intervention design. Of the 16 self-guided interventions included in our systematic review and meta-analysis conducted in the planning phase [21], only 6

XSL•FO
RenderX

provided any reference to methods used to plan, design, and develop them [19,76-81]. Of these, there was little supporting detail on how the design was carried out and none of the included studies reported exploring the behavioral needs of the users before designing the intervention. Future researchers might benefit from greater transparency and reporting of the design phase, including more practical examples of operationalizing person-based and behavioral approaches. Considerations for mitigating these challenges include allocating sufficient time and resources for user involvement beyond the planning stage, documenting key design decisions, and seeking opportunities for peer collaboration to support methodological alignment and confidence.

Strengths

We have shown commitment to providing a robust and transparent process in the operationalization of the design phase of SPIN drawing on the PBA approach. This process included explicitly addressing the identified behavioral needs of the users and kept these central throughout the entire design process. The design of SPIN has demonstrated how we used evidence (from existing literature and from a previous Interpretive Descriptive qualitative study) and theory (from behavioral analysis, "Behaviour Change Wheel," and COM-B) to enhance the person-based process. This explicit and thorough process of planning and designing SPIN has provided a blueprint for intervention development when using PBA. It also addresses many of the limitations in the reporting on the development processes for existing self-guided digital exercise and physical activity-related interventions.

Limitations

Our operationalization of the PBA design phase reflects our interpretation of the PBA steps through available readings. We acknowledge there may be other perspectives and understandings. However, we believe that it is important to make our experiences visible to build on previous work and support future intervention design. Similarly, we relied on literature and online course instruction for support when we conducted the behavioral analysis using the COM-B. Being self-taught in both the PBA and behavioral analyses may mean that some aspects of our approach are not consistent with the original intent of these approaches. However, this is perhaps an artifact of the knowledge mobilization process, where the application of knowledge can change as knowledge changes hands. By offering transparency in our process, we hope that people can draw their own conclusions regarding the robustness of our approach. The design of SPIN did not include a logic model. Logic models typically include the main intervention components, how they relate to one another, which are meant to produce which effect, and include processes and expected outcomes. However, we did not believe a logic model would have been pragmatically useful as they assume causal relationships which may have restricted our thinking about solutions [82]. Our development process was underpinned by relationship building and community interaction, both of which are complex and require flexibility [83,84].

Future Steps of SPIN Using the PBA

With the proposed intervention features selected, SPIN wireframes have been constructed. Wireframes are images or screenshots that show how screens of a website or app are structured and how content is arranged. These have provided a visual representation of the product and an opportunity to comment on content, features, and organization without getting distracted by aesthetics. Further participant consultation and design refinement have occurred. Frontend and backend software programming will occur at a later phase. Reporting of these stages will follow in a subsequent publication.

Conclusion

The design of SPIN has incorporated a deep understanding of the users' needs and best available evidence by drawing on the PBA design process to maximize chances of engagement and outcomes. This paper has made visible the operationalization of each of the phases and can act as a blueprint to provide guidance to future researchers when using this approach.

Abstract

Intensive longitudinal data (ILD) include frequent and dense repeated measures captured over acute timescales (eg, every second, hour, or day) that are used to investigate within-person processes both within and across days. ILD are collected via wearable sensor data, ecological momentary assessments, or daily diaries and provide unique insights into within-person processes under ecologically valid conditions that can strengthen understanding of temporal relationships among variables and potential causal processes, while also informing the development of just-in-time adaptive interventions. Advancements in mobile and sensor technology have facilitated an explosion of ILD studies that have outpaced formal training in ILD study design. When designing ILD studies, researchers need to make careful decisions about the frequency (ie, how often) and timing (ie, when) of measurements. Decisions about the frequency and timing of measurement are influenced by issues such as variability across individuals and constructs, the purpose of the assessment, concerns about recall biases, saliency, or missing information, and participant needs. The interpretation of study results, causal inferences, and the predictive value of ILD are also impacted by decisions related to the timing of assessments, temporal lags between measures, how a “day” is defined, and data aggregation choices. Due to the increased interest in and adoption of ILD studies, and a lack of formal training, researchers can benefit from guidance on how to design ILD studies. Therefore, this paper aims to provide practical guidance to researchers on how to plan ILD studies using a step-by-step decision-making tutorial with applied health behavior research examples examining phenomena (eg, physical activity and alcohol use) that vary over acute time scales.

KEYWORDS

intensive longitudinal data; ecological momentary assessment; daily diaries; study design; wearable electronic devices

Introduction

Advancements in mobile and sensor technologies have facilitated an explosion of real-time data capture strategies in health behavior research to collect intensive longitudinal data (ILD) of time-varying phenomena [1-5]. ILD include frequent and dense repeated measures captured across acute timescales (eg, every second, hour, or day) [6,7]. ILD are collected via multiple methods, including wearable sensors, ambulatory assessments, experience sampling methods (ESMs), ecological momentary assessments (EMAs), and daily diaries [6,8-11]. These advanced methodologies reflect the increased interest and need for strategies to capture health behavior phenomena that change in intensity or direction across time scales as short as minutes, hours, or days. For example, engagement in health behaviors that impact chronic disease risk, such as unhealthy food intake, alcohol and tobacco use, physical inactivity, and lack of sleep [12,13], varies from day to day. Similarly, psychological and contextual factors that influence health behavior engagement, such as affect, intentions, and social context, can fluctuate rapidly over time. As a result, studies in health behavior and prevention research are increasingly using strategies to capture these types of psychological and contextual factors and behavioral outcomes. Such studies often aim to describe these phenomena, but may also inform the design and implementation of just-in-time adaptive interventions (JITAIs) [14,15].

When using ILD to examine health behavior phenomena that vary across short time scales, researchers often ask questions about temporal dynamics (eg, how variables change over time) to inform intervention and treatment approaches. First, researchers may ask whether these phenomena change as a

XSL•FO
RenderX

function of time itself, such as increasing linearly during treatment or demonstrating a curvilinear pattern across the day. Second, researchers may examine within-person effects of time-varying predictors, such as whether greater perceived stress compared with their usual stress level leads to greater consumption of saturated fat in the next few hours. Third, researchers may investigate the extent to which these within-person effects of time-varying predictors change over time or across situations, such as whether a person's positive affective response during physical activity depends on being alone or with others.

Up until recently, methods to capture the dynamic nature of how these time-varying phenomena change over time were not available. Previously, research on health behavior phenomena typically relied upon cross-sectional, longitudinal, or experimental designs where exposures and outcomes were assessed infrequently (eg, monthly or yearly) across few occasions. These studies used retrospective measures to capture an individual's usual level of a behavior or indicator such as average daily minutes of physical activity or past month frequency of depressive symptoms. Such approaches are not only vulnerable to recall biases, but they may lack ecological validity because they are not captured in real-world contexts, and they are not conducive to assessing phenomena that vary frequently over time or space or exhibit dynamic patterns of change and fluctuation [16].

Advancements in methods for collecting ILD have overcome many limitations of previous approaches, enabling researchers to capture time-varying phenomena in people's daily lives. ILD data collection methods, which collect data through wearable sensors, EMAs, and daily diaries, among others, differ from previous methods in how frequently variables are measured and participants' degree of active engagement with data collection. Wearable sensors can passively collect continuous or semicontinuous ILD every minute or several times per minute about time-varying phenomena such as heart rate, physical activity (eg, acceleration and step counts), location, or alcohol use, and require minimal participant engagement with data collection [17-25]. For example, participants may wear a physical activity sensor while awake, with their engagement limited to removing the sensor while sleeping or charging [21,23,24].

Another common approach to collecting ILD is through ESMs and EMAs (referred to throughout as "EMA"), which require active participant input through multiple self-reports per day of time-varying psychosocial or contextual variables, such as a participant's emotional states, cognitions, or social or physical contexts [2,4,6,8,10,11,16,26-33]. EMAs can capture time-varying measures before, during, or after specific events, such as during a physical activity bout or while drinking alcohol [26,28]. EMAs may be initiated by researchers (eg, signal- or interval-contingent EMA) or by participants' behavior (eg, event-contingent EMA), with the goal of capturing time-varying, ecologically valid information about participants' real-world experiences [4,6,10,11,26,33].

Daily diaries are also an active data collection strategy that includes a single self-report per day of variables, behaviors, or events that are expected to vary from day to day, rather than within a day [6,9,32,34,35]. Daily diaries may ask about a participant's stress experiences or physical activity or alcohol use behaviors on a given day, as these typically occur only once per day [9,34-36]. Daily diaries may include morning reports of the participant's previous night's experiences (eg, sleep quality) or evening reports of the participant's current day experiences (eg, soda intake) [37,38]. Like EMA, daily diaries also aim to capture participants' real-world experiences in near real time.

A Decision-Making Tutorial for Designing a Study Using ILD

These advancements in mobile and sensor technology have outpaced formal training in ILD study design. A recent concept paper partially addressed this need by developing a list of ten topics specific to the design and implementation of experience sampling studies, providing guidance on how to select ESM items, ESM sampling schemes, and practical considerations for real-world implementation of ESM studies [39]. A recently published special issue on ILD designs includes a series of articles addressing ILD considerations related to statistical power, sampling designs, participant experiences, and psychometrics or data quality [40]. The special issue dives deeply into specific features of ILD, providing practical guidance for researchers who are experienced in designing and implementing ILD studies [40]. However, there is a need for an ILD tutorial developed for researchers who are new to or have limited experience with ILD studies, such as graduate students and early career researchers. Additionally, guidance on ILD study design that simultaneously addresses the use of sensors, EMA, and daily diary methods is warranted, as many ILD studies rely on a combination of these methods to answer health behavior research questions. When designing ILD studies, researchers need to make careful decisions about the method used to capture health-behavior phenomena, as well as the frequency (ie, how often) and timing (ie, when) of measurements. These decisions should be based on the a priori research question and consider the characteristics and preferences of the target population. To address these needs for training and guidance, we present a decision-making tutorial for designing ILD studies. Multimedia Appendix 1 provides a detailed, step-by-step guide for navigating the decision-making process.

The tutorial is informed by a synthesis of the authors' applied experience in designing, implementing, and analyzing ILD studies, their didactic and consulting work with researchers new to ILD study designs, and relevant empirical and methodological literature. Recommendations were developed using an iterative, practice-oriented process that integrates published guidance with common challenges encountered in applied research. The recommendations and examples reflect the authors' applied research backgrounds, which have shaped the selection of illustrative health behaviors, populations, and design considerations emphasized in the tutorial. As such, the tutorial may not represent the full range of possible ILD applications (eg, clinical or patient populations [41-44]). The tutorial is

XSL•FO
RenderX

intended for beginning- to intermediate-level researchers who are interested in examining health behavior phenomena that vary over acute time scales such as minutes, hours, and days. The tutorial provides a step-by-step approach to 10 decisions that need to be made when selecting measures and developing a sampling protocol to collect ILD. The tutorial poses these decisions (in the form of questions) about the nature and timing of the variables and associations involved in the research of interest. Depending on the answers to those questions, the tutorial provides specific study design recommendations that are based on answering the research question of interest. The end of the tutorial provides data processing and analysis recommendations that can facilitate answering the research question based on the study design but should not dictate study design decisions. Although this tutorial and the applied examples emphasize health behavior research, the decisions and methods apply to a wide range of psychological, behavioral, and biological phenomena that may vary dynamically within persons. To facilitate readers' understanding of how to use the tutorial for investigating health behavior research questions, the design decisions are described with 2 working examples based on the authors' applied research experiences that represent some of the common research questions about temporal dynamics described above. The dependent variables (DVs) in the examples are health behaviors that vary over acute timescales (minutes, hours, or days) and are commonly investigated in ILD studies – physical activity and alcohol use [45-52]. The independent variables (IVs), momentary affective states, and daily drinking intentions, similarly vary across minutes or days, respectively, and are associated with physical activity and alcohol use behaviors [46-48,50,53-55].

In this study, we propose the following two research questions:

1. In children, are momentary affective states associated with moderate-to-vigorous physical activity (MVPA) levels in subsequent 30 minutes?
2. Do the effects of drinking intentions on same-day drinking behaviors differ based on the experience of daily stressors?

Decision 1: Determine Whether the IV and DV Change Over Time Within People

The first step is for the researcher to define their primary research question, which will serve as the basis for subsequent design decisions (question 1 in Multimedia Appendix 1). There may be several research questions within a single study, and each question may require different measurement or sampling protocol considerations; therefore, for simplicity, the researcher should start with a primary research question for which decisions about measures and a sampling protocol are made. For secondary research questions, the researcher can repeat the steps in the tutorial and attempt to integrate the design recommendations when possible. Once the primary research question is articulated, the researcher should define their IV and DV with as much specificity as possible (questions 2 - 3). Then, the researcher should determine whether the IV and DV change over time within people (eg, whether these are time-varying variables that change within people). If either the IV or DV change over time within people, then the research question may be suitable for an ILD design, and the researcher may proceed with the next part of the tutorial.

Application to research examples: For the first research example, both affective states (DV) and MVPA (IV) change over time within people. Similarly, for the second research example, drinking intentions (IV), daily stressors (moderator), and drinking behaviors (DV) change over time within people, making both research questions suitable for an ILD design.

Decision 2: Identify the Timescale of Within-Person Changes

The second decision is to identify the timescale of within-person change for the primary DV (question 4), which may be short, such as minute-to-minute changes in heart rate [56], or long, such as changes in disease risk factors (eg, hemoglobin $A1_c$) across months or years [57]. ILD studies are most appropriate for examining IVs and DVs that change across minutes, hours, or days. This is reflected by the frequency of ILD measures, with sensors measuring variables several times per minute or hour (eg, heart rate, blood glucose, or bodily movement), EMAs measuring variables several times per day (eg, affect, cognition, or tobacco use), and daily diaries measuring variables once each day (eg, intentions or alcohol use) [58,59]. If the IV and/or DV are expected to show within-person change over timescales of a day or shorter, then an ILD design is likely an appropriate choice. If the IV and/or DV changes over a longer timescale (such as monthly), an ILD study may result in collecting data more frequently or intensely than necessary, which may be costly for researchers and unnecessarily burdensome for participants. Some researchers may choose to use an ILD study design when the DV changes over longer timescales (eg, weeks and months) if they are interested in examining within-person change or variability in the IV as a predictor. However, this type of ILD study design requires slightly different design considerations and statistical methods than traditional ILD studies focused on within-person change in the DV. Therefore, discussion of this type of ILD study is beyond the scope of this paper. For IVs or DVs expected to show within-person change from day to day, a daily diary (ie, once a day) design may be appropriate. For IVs or DVs expected to change over a few hours within a day, wearable sensors or EMA may be appropriate. Finally, for IVs or DVs expected to change over minutes or seconds, wearable sensors may be the best measurement method. If the timescale of within-person change is unknown, it may be more efficient to start with EMAs rather than daily diaries, because data can always be aggregated up to a longer timescale from the EMA measures (eg, day-to-day). In contrast, data cannot be broken down into timescales shorter than the original measure, meaning that starting with daily diaries may be less efficient for identifying the timescale of change when it is unknown.

Application to research examples: For the first research example, investigating associations between momentary affective states and MVPA in the subsequent 30 minutes in children, affective states (ie, a subjective feeling state that a person experiences at a given moment, including both how positive or negative the feeling is ["affective valence"] and how energized the person

XSL•FO
RenderX

feels ["affective arousal"]) change within-person over minutes or hours—suggesting that either wearable sensors (eg, affect derived from galvanic skin response or heart rate variability) or EMA (eg, self-reported affect) may be appropriate design choices. MVPA changes over minutes, suggesting that wearable sensors are an appropriate design choice. For the second research example, investigating whether daily stressors moderate the effects of drinking intentions on behaviors, daily stressors (moderator) change from day to day, and daily drinking intentions (IV) may change from day to day—suggesting that daily diaries may be appropriate to measure both variables [47,60-63]. Drinking behaviors (DV) change across minutes or hours, suggesting that sensors or EMAs may be appropriate. In the next design decision, we will select the specific ILD measurement approach to use.

Decision 3: Determine Whether There Are Valid and Reliable Sensor-Based, EMA, or Daily Diary Measures

The next decision is whether reliable and valid sensor, EMA, or daily diary measures exist to assess the IV and DV of interest. Researchers should first consider whether sensor measures (ie, portable or wearable devices that use mechanical, electronic, or digital hardware and software) are available (question 5). Sensor measures can passively collect objective data (eg, heart rate, skin temperature, blood sugar, blood alcohol, body movement, sun exposure, or geographic location) [17,19,21,22,25] and may generate less participant burden [64] because they do not require manual user input.

If valid and reliable sensor measures are available, then researchers should consider the extent to which using the sensor will result in participant reactivity (ie, when awareness of being measured leads to changes in phenomena of interest; Table 1; question 5a) [65]. To manage participant reactivity, researchers could reduce participant access to information or data generated by the sensor (eg, do not provide access to the accompanying smartphone app, put tape over the sensor's display).

Table . Key concepts explained.

Concept	Explanation
Within-person change over time	How much an individual person in a sample or population tends to change over a specific timescale (eg, hours, days, weeks) regarding a given behavior or value of a construct. In the case of ILD[a] studies, within-person change is typically expected to occur within minutes, hours, or days, making the construct appropriate to study via ILD.
Passive assessment	ILD assessments that consist of collecting continuous or semicontinuous measures of body movements, physiology, location, device use, etc, without active participant engagement, that are often considered "objective" measures and are collected via wearable sensors or smartphones.
Active assessment	ILD assessments that consist of collecting participant self-reported measures of psychological constructs (eg, stress, affect), cognitive constructs (eg, thought processes), or context (eg, social, environmental), that are often considered "subjective" measures and are collected via surveys completed via smartphones or computers once or multiple times per day.
Participant reactivity	When a participant's behavior or subjective responses alter because they know they're being studied. Also referred to as a measurement or assessment effect, participant reactivity can also occur because responding to assessments provides a form of self-monitoring or feedback that changes participants' subjective responses, such that their responses are more reflective of their reaction to the assessment rather than to true naturalistic experiences or changes.
Expectancy effects	A form of participant reactivity in which a participant anticipates an upcoming assessment and changes their behavior or context to provide the expected response or outcome, to appear more favorable to researchers or to provide researchers with an "ideal" response, or to improve their ability to respond to the assessment.
Participant burden	When the effort required by the participant exceeds their abilities or motivation, impacting participant compliance and data quality. In ILD studies, wearable sensor-related burden may be related to the requirement to remove or replace, charge, or sync a device. EMA[b] and daily diary-related burden may be due to the length of the study protocol, frequency or timing of assessments, length of assessments, or length or complexity of individual items.
Naturalistic processes	Processes, such as behaviors, experiences, or cognitions that occur in people's real-world environments and that would occur naturally whether or not the research study is taking place. ILD studies often attempt to collect data in people's real-world contexts to maximize the ecological validity of findings.
Recall bias	Type of response bias in which a participant fails to accurately remember a past event or experience or to leave out relevant details when reporting them. In ILD, recall bias is influenced by design features, such as the timeframe across which participants are asked to recall data in EMAs (eg, "currently," "past 10 min") or daily diaries (eg, "today," "since waking")
Availability heuristic	A type of mental shortcut participants use when responding to questions, in which they rely on immediate or easily accessible information to inform their responses, which can be influenced by the timeframe for recall or item wording in ILD studies.
Saliency bias	A type of response bias in which more personally relevant or more intense experiences are more likely to be recalled, which is related to the availability heuristic. In ILD studies, daily diary items may be particularly impacted by saliency biases because participants are asked to recall constructs across the entire day, such as stressful events.
Peak effect	A type of response bias in which the most intense experience (ie, "peak") disproportionately influences a participant's response. For example, an extreme moment of anger unduly influencing the report of negative affect.
End effect	A type of response bias in which the most recent experience in time (ie, "end") disproportionately influences a participant's response. For example, the last social interaction of the day influencing the participant's report of social connectedness.

XSL•FO
RenderX

Concept	Explanation
Sampling window	The timeframe a researcher is interested in investigating. In ILD studies, this may be the entire 24-hour period, waking hours, sleeping hours, or a discrete event, such as a physical activity bout or a drinking event.
Participant schedules	The typical timing of daily behaviors being investigated among participants, such as sleep and wake times, class times, or work start and stop times. In ILD, participant schedules may be similar or different between participants and may be consistent or inconsistent from day to day within participants, which influences how sampling windows are specified for a study.
Between-person differences	When the association between the IV[c] and DV[d] reflects a difference between individuals in a sample. For example, when examining the association between stress and physical activity, a between-person effect could be that people who experience higher stress on average compared to other people are less physically active.
Within-person differences	When the association between the IV and DV reflects a difference between moments or days in an individual participant. For example, when examining the association between stress and physical activity, a within-person effect could be when a person experiences more stress than usual when they are more physically active than their average amount.
Concurrent effects	These are associations in which the IV and DV are expected to cooccur in time, also referred to as synchronicity. For example, it may be hypothesized that a mother's stress level will concurrently impact their child's stress level.
Lagged effects	These are associations in which the IV is expected to impact a DV that occurs at a later point in time, also referred to as sequentiality. For example, it may be hypothesized that a mother's stress level will impact her parenting behavior later in the day, which may in turn influence a child's subsequent behaviors.
Observation	The lowest level "unit" of analysis that will be used in hypothesis testing, statistical analyses, or the interpretation of results. This may be the momentary assessment, a discrete occasion or event, a given timeframe (eg, every 2 h), or the entire day.
24-hour day or Calendar day	A traditional 24-hour day based on a calendar date that begins at midnight and ends at 11:59 PM.
Study-centric day	A 24-hour cycle that is based on a study design feature or phenomenon of interest. For example, a researcher interested in studying a person's alcohol use behaviors may choose to align the day start with a 9 AM morning assessment about past day drinking and end the day at 8:59 AM on day n+1 to ensure that all drinking behaviors are consequences are attributed to the correct functional day.
Person-centric day	A "day" that is based on an individual's sleep-wake cycle and does not follow a 24-hour cycle, with each day differing between and/or within participants. This may include entire days or person-centric waking or sleeping periods. For example, each person-centric day may start when they wake up on day n and end when they wake up on day n+1, such that some "days" may be longer or shorter than 24 hours.

RenderX

Concept	Explanation
Measurement burst design	A type of intensive longitudinal design consisting of repeated clusters ("bursts") of high-frequency assessments separated by intervals in between the bursts without any assessment occurring. This design allows researchers to capture short-term dynamics within bursts while also examining longer-term change between bursts. It is particularly useful when the DV changes over longer timescales, when within-person variability in a time-varying variable changes over longer timescales, when associations between time-varying variables vary over longer time scales, when key variables reflect relatively rare or time-bound events (eg, weekend alcohol use or phases of the menstrual cycle), or when it is necessary to balance temporal resolution with participant burden.

[a]ILD: intensive longitudinal data.

[b]EMA: ecological momentary assessments.

[c]IV: independent variable.

[d]DV: dependent variable.

Next, researchers should ask whether the sensor is cost-effective and whether there are resources (including personnel and software) to support using it (question 5b-c). Some sensors cost hundreds of dollars, which can be prohibitive for studies with smaller budgets or those requiring large samples. Also, sensors may require substantial research personnel resources to provide instructions on use and troubleshoot technical problems [66]. They may also require technological expertise to program, fix, and process data [22,66].

Finally, researchers should consider participant burden imposed by the sensor. Participant burden occurs when the effort (time, physical, and attention) required exceeds the ability or motivation to engage with or use a measure, which impacts data quantity and quality (question 5d) [67]. When burden from a sensor is higher than participants can handle, researchers may choose to use a less burdensome self-report measure instead, such as EMA or a daily diary, or they may consider a design with less frequent assessments (eg, every other week). Characteristics of the target population are also related to participant burden. For example, people who are less comfortable with technology may find EMAs more burdensome than tech-savvy populations [68], although well-designed study protocol, participant training, and user-friendly smartphone apps can address issues of participant burden and enhance compliance [52,68,69].

Some constructs may be too subjective in nature (eg, perceptions, motivations, intentions, and cognitions) to be assessed through a sensor, requiring self-reports via EMAs or daily diaries instead. In this case, researchers should determine whether there are acceptable or widely used items and/or instruments to assess those constructs (question 6). Ideally, researchers will select measures that were developed and validated using within-person longitudinal data, as measures developed from between-person cross-sectional data may not have the same factor structure at the within-person level, making it unclear whether shifts in variables reflect true within-person changes or measurement error [70-73]. While within-person validated measures are not yet available for all constructs, in recent years, freely available repositories have emerged where researchers can share EMA tools, measures, and reliability and validity information such as the Experience Sampling Method item repository [74]. If a within-person validated measure is not available, researchers may adapt an existing between-person cross-sectional measure (using appropriate recall time frames), while acknowledging that the measure was not validated for within-person use. If feasible, researchers could simultaneously conduct a psychometric study evaluating the reliability, validity, internal consistency, and/or factor structure of the items adapted from the between-person instrument (eg, using multilevel factor analysis to explore within- and between-person measurement model differences [72,73,75]), contributing to the ongoing need for psychometrically sound EMA measures [70,71,76]. An important point to consider is whether variability captured by EMA or daily diary measures represents true changes in an underlying construct or instead is indicative of poor reliability of the measure [70,71,76]. In contrast, it is necessary to understand whether lack of variability in EMA or daily diary measures is an artifact of careless responding (ie, participant not using the full range of response options due to lack of interest or fatigue) or true stability in a construct. It is possible to investigate these concerns by determining whether changes in EMA and daily diary measures correspond to changes in monitor-based or biologically-based indicators captured across the same timeframe (eg, accelerometry, cortisol, heart rate, and galvanic skin response) [77]. Other strategies to limit measurement error are to use a larger number of items to assess a construct, ensure adequate sampling frequency, avoid unreliable measures, and use appropriate statistical analytic strategies (eg, multilevel modeling or latent variable modeling) to differentiate measurement error from true variability [78].

If researchers find an acceptable EMA measure, they should consider whether answering EMAs will result in participant reactivity to a sufficient degree that it could alter study outcomes (question 6a).

Researchers should also consider whether actively responding to a real-time EMA prompt interrupts a naturalistic process that a participant is experiencing such as a romantic encounter, conversation, physical activity session, or emotional moment (question 6b). If so, researchers could consider measuring the construct passively using a sensor or retrospectively via an end-of-day daily diary [34]. Researchers should additionally ask whether the naturalistic process impacts the participant's

XSL•FO
RenderX

ability to provide valid and/or reliable EMA responses (eg, being intoxicated while responding to questions about drinking alcohol; question 6c). Finally, similar to using a sensor, researchers should ask whether the study has the financial, personnel, and informational resources to support implementing EMAs. If not, a sensor or daily diary measures could be considered (question 6d).

Finally, if researchers are contemplating using daily diary measures, they should seek out reliable and valid items and instruments to use (question 7). In some cases, items originally designed for EMA can be easily adapted for a daily diary by adding, "Over the past day." However, in some circumstances, memory errors and biases including peak and end effects can be introduced by asking participants to retrospectively report constructs up to 24 hours later [79]. If reliable and valid daily diary instruments are available, then researchers should consider whether these measures are likely to be impacted by expectancy effects, which occur when a participant has knowledge that a survey is about to occur and changes their mood, location, or behavior in preparation for the survey.

Regardless of the method selected for an ILD study (ie, wearable sensor, EMA, or daily diary), researchers should carefully consider privacy and data security implications. Many commercially available smartphone apps and wearable sensors require participants to agree to user terms and privacy policies that are outside of researchers' control, which may allow data sharing with developers or third-party entities [80]. This can introduce risks related to confidentiality, data ownership, and secondary data use [80,81]. Additionally, mobile sensing and EMA approaches often involve the collection of highly sensitive, potentially identifiable data (eg, location or health information), increasing the risk of unintended disclosure or reidentification. Participants may also also be required to accept app-specific data use agreements, which the researcher has no control over [80-82]. Researchers should clearly communicate data access rights and potential confidentiality risks during the informed consent process [81].

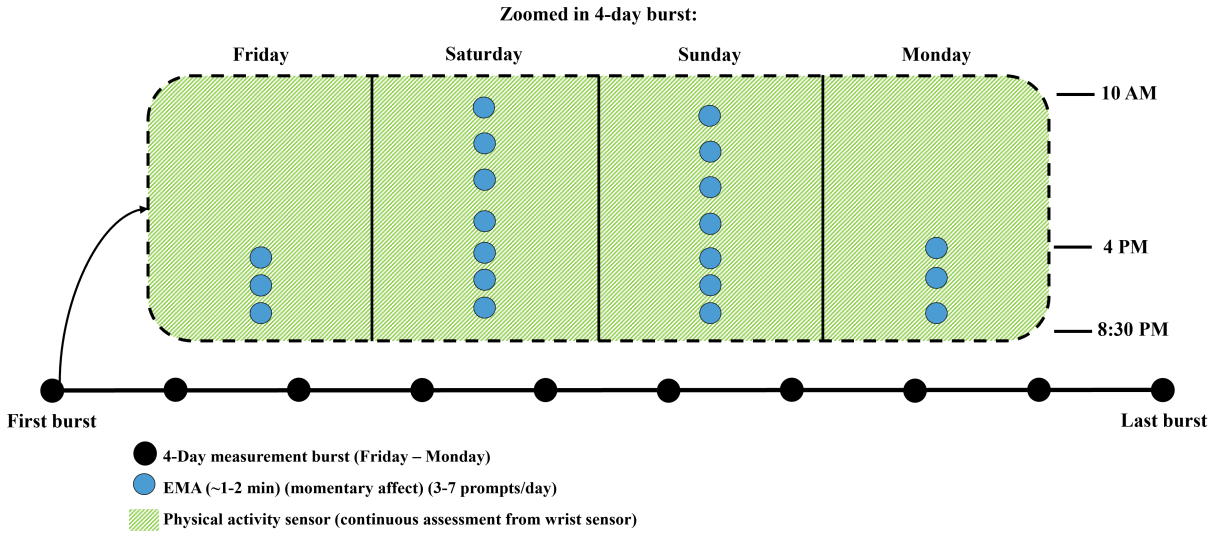
Application to research examples: When studying associations between affective states and MVPA in the subsequent 30 minutes in children, wearable sensors are ideal to measure MVPA due to the timescale of change (seconds or minutes), the time frame under investigation (30 min), and minimal concern about participant burden and reactivity to sensors. The population of interest (children) also warrants the decision to use wearable sensors, as self-reports of past 30-minute MVPA via EMAs may be too cognitively burdensome for children to complete—resulting in unreliable data. To measure affective states, EMAs were selected due to the timescale of change (hours), minimal concern about participant reactivity and expectancy effects, and acceptable participant burden, and having resources to support personnel and software costs.

When investigating daily stressors moderating the effects of drinking intentions on drinking behaviors in adults, alcohol use can be measured via sensors, EMAs, or daily diaries. However, EMAs are subject to expectancy effects and biases due to alcohol consumption, and daily diaries are subject to recall biases and miss key features of drinking that often occur while people are sleeping (ie, descending limb of drinking or alcohol elimination). Therefore, passive wearable sensor measures were deemed most appropriate. In contrast, there are reliable and valid daily diary measures of stressful experiences that are not subject to expectancy effects and capture psychological stress experiences and responses, leading to the selection of daily diaries to measure stressors. Similarly, although drinking intentions could vary within a day, the research question was specifically investigating daily intentions. Additionally, drinking intentions are subjective, warranting the use of daily diaries.

Decision 4: Determine Timing and Frequency of Sampling (EMA Studies Only)

The next decision when using EMAs is determining when and how frequently to collect data. If asking participants about their "current" state or "the past 10 minutes," recall biases will be minimal. However, as the recall time frame increases, participants are more likely to use mental shortcuts to inform their responses, such as relying on the most easily accessible information (ie, availability heuristic) or being influenced by personally relevant or intense experiences (ie, saliency bias, peak and end effects) [83]. The wording of EMA items may also change participants' recall, how they interpret questions, or how they respond [83]. Researchers should aim to select an EMA sampling schedule that minimizes these types of biases. To do so, they need to identify the time frame across which participants can reasonably recall the construct, when the construct occurs throughout the day, whether it is susceptible to expectancy effects, and whether it occurs during specific events or in specific contexts. For example, if the construct occurs at the same time each day (question 8), such as a regular morning physical activity bout, or if it has low susceptibility to expectancy effects, then an interval-contingent design (ie, same time each day) with EMAs close to when the construct occurs may be appropriate. An interval-contingent design is also appropriate when a researcher is interested in measuring the level of a construct at the same time each day (question 8a). If the construct occurs at different times each day, such as a stressor, or if it has higher susceptibility to expectancy effects (question 9) [3,84], then a signal-contingent design (ie, random times throughout each day) is likely a better choice. Finally, if researchers are interested in measuring the construct during a specific event or behavior (question 10), such as measuring affect during a drinking event, then an event-contingent design is most appropriate. Selecting a particular type of EMA sampling schedule in turn influences EMA item wording, recall windows and, for signal-contingent designs, the frequency of EMA measures.

When designing an EMA sampling protocol, researchers should determine the frequency and length of the recall period. If using a signal-contingent design, then researchers should consider how frequently the construct changes across the day (question 11). Depending on the frequency (eg, every 2 - 4 h), researchers may consider sampling 2 to 16+ times per day for 7 to 14 days, for example. However, if more frequent sampling is necessary to capture natural variation in the construct (eg, every hour),



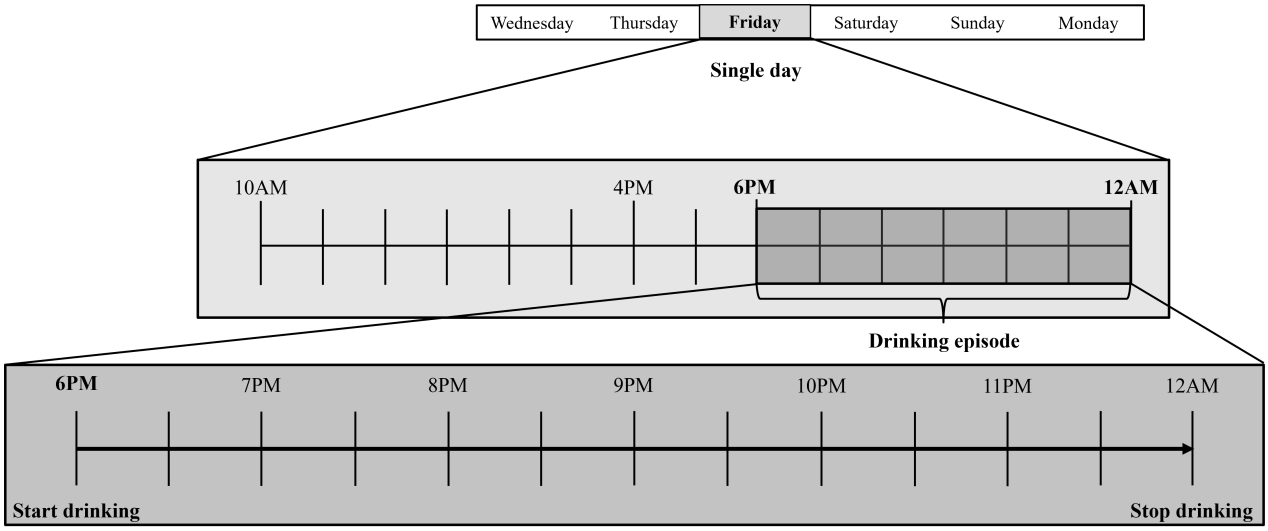
XSL•FO
RenderX

then researchers may need to consider a shorter study period (eg, 2 - 4 days) to minimize burden and maximize data quality [85]. For example, in the TIME (Temporal Influences on Movement and Exercise) study, a signal-contingent EMA protocol prompted once during every waking hour of the day for 4 days during each bimonthly measurement burst [86].

Researchers should also consider how long after a behavior or experience a participant can reliably recall the phenomena (question 12). If the construct becomes more vulnerable to recall biases over elapsed time (such as intensity of affective valence), the length of the EMA recall window should be short (eg, "Right now, how are you feeling?" or "In the past 15 min, how have you been feeling?") [48]. In contrast, some constructs such as concrete behavior, social encounters, or locations visited may be reliably reported across longer EMA recall windows (eg, "In the past 4 hours, have you spent any time with your child?") [87,88]. The ideal recall window may differ between participants. For example, children may find it more difficult than adults to report feelings across the past 15 minutes. It is important to note, however, that the EMA recall window should not be longer in duration than the spacing between adjacent EMA measures of the same construct to avoid overlapping or double assessments. For example, if EMA surveys are prompted every 2 hours, then the recall window should not be longer than 2 hours.

Application to research examples: For investigating affective feeling states in children, we selected EMAs as the most appropriate measure. The EMA sampling design needed to minimize burden on children and account for times of day when they cannot or should not receive prompts. Therefore, a hybrid design with interval and signal-contingent EMAs was selected (Figure 1). During each 2-hour window (interval-contingent component), an EMA survey was prompted at a random time (signal-contingent component). The recall time frame was momentary, asking children about their affect at the given moment (eg, "How happy do you feel right now?"), to avoid issues of recall bias, such as peak and end effects that could occur if asking children about their daily affect at the end of the day.

Figure 1. Decision 4: Example intensive longitudinal data protocol using a hybrid interval-signal-contingent ecological momentary assessment design with continuous sensor measures of physical activity via multiple assessment bursts with intensive sampling across four days to balance reliability and power while minimizing participant burden. Random prompts sent between 4 PM-8:30 PM on Friday and Monday and 10AM -8:30 PM on Saturday and Sunday. EMA: ecological momentary assessments; ILD: intensive longitudinal data.



Decision 5: Select Sampling Windows and Time(s) of Day When Assessments Occur (Sensor and EMA Studies Only)

The next decisions involve selecting the sampling windows and time(s) of day that assessments should occur (question 13). For example, a researcher may only be interested in social interactions when the participant is at work or screen time in 2 hours leading up to bedtime. In these situations, collecting data outside of these sampling windows may be unnecessarily costly and burdensome. If a researcher is interested in a specific event, such as a high-intensity drinking episode, then they should use an event-contingent design with participants completing EMAs and wearing an alcohol sensor during the drinking episode [46,49] (Figure 2). Additionally, if the research question is about eating behaviors, the researcher may choose to use an interval-contingent design that triggers EMAs 3 times per day immediately after known mealtimes.

XSL•FO
RenderX

Figure 2. Decision 4: Example Intensive longitudinal data (ILD) protocol using event-contingent ecological momentary assessments (EMAs) during drinking episodes (Courtney and Russell [47]).

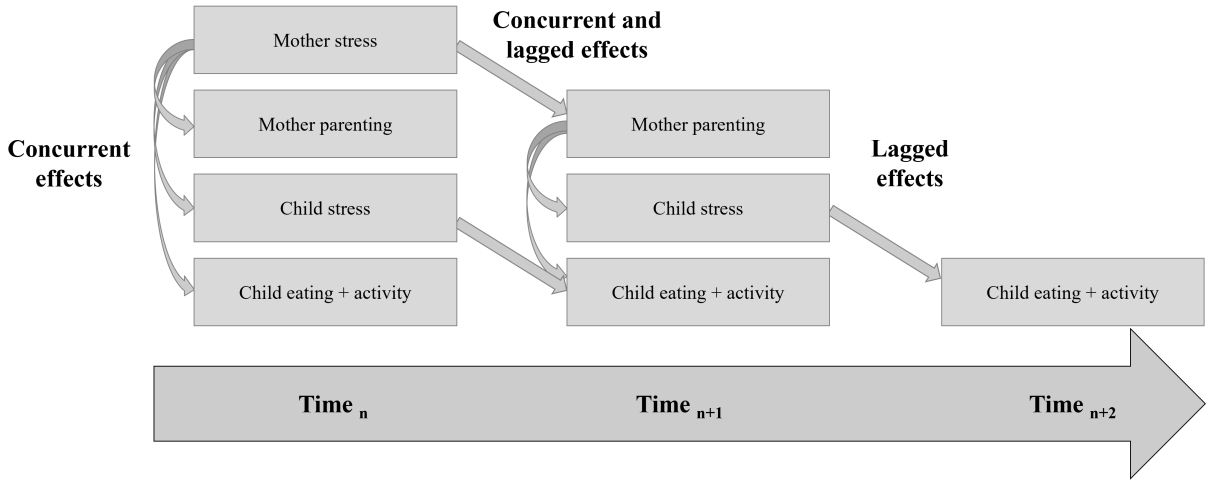
Next, researchers need to address whether to use the same EMA sampling window for all participants and/or for each day of the week. If participants' sleep-wake schedules differ, such as for shift versus nonshift workers [89], then each participant may need a personalized EMA daily sampling window [87]. Researchers also need to determine whether a given participant or all participants have a similar sleep-wake schedule for each day of the week (question 15). If participants have very different schedules, such as going to sleep later and waking up later on weekend days, then sampling windows should be tailored for each day of the week or weekends versus weekdays. Real-time customization of prompting schedules is also possible, such that each day participants are asked when they anticipate going to sleep that night and waking up the next day [86]. Customized schedules can increase compliance by reducing burden and unpleasant sleep interruptions; however, they may be impractical, too costly to program, or create data processing challenges. If customization is too costly or burdensome, then the researchers may want to consider screening out participants with unusual sleep-wake schedules (eg, screen out shift workers), using a sampling schedule that does not include early morning or late evening assessments, or using only event-contingent EMAs.

When making design decisions about sampling windows and schedules, considering the needs and preferences of the target population can help reduce participant burden and missingness. In some cases, surveying members of the target population before making design decisions can help researchers identify ideal sampling windows or the need for tailored or real-time customized schedules. For example, the ideal time of day for asking participants to complete morning diaries of past-day behaviors is likely to differ between college students versus older adult populations. College students may require a later sampling window time (eg, 10 AM-2 PM) whereas the older adults may require an early sampling window time (eg, 7 AM-11 AM).

Application to research examples: For studying affect and subsequent 30-minute MVPA in children, EMAs were triggered on weekday afternoons and evenings and throughout the day on weekend days to avoid interrupting school and sleep time. Using the same schedule across all participants was appropriate given that school schedules are fixed (eg, classes end at 3 PM each day) and the sampling windows were narrow enough to avoid interrupting sleep time, thereby not requiring customized windows.

For investigating daily stressors and drinking intentions and behaviors, there were 2 daily diaries per day, with the sampling windows selected to go from 9 AM-11 AM and 8 PM-10 PM across all weekdays and weekend days. The 9 AM schedule for the morning diary ensured that intentions were reported before drinking behavior, as participants are unlikely to drink that early in the morning. The 8 PM schedule for the evening diary of stressful events avoided interrupting sleep time while reducing recall biases about the day's stressors. Due to the nature of alcohol metabolism, with alcohol elimination occurring for many hours, often while individuals are sleeping, the decision was made for participants to wear the sensor 24 hours/day. Similarly, inter- and intraindividual variability in timing of alcohol use across weekends and weekdays also warranted the use of continuous sensor wear. As the timing of daily diaries were selected with consideration of late-rising and early bedtimes, and since diaries were available for completion for 2 hours after each prompt, the decision was to use the same schedule for all participants.

Decision 6: Delineating Temporality of the Associations



The next decision involves researchers specifying the nature of temporal associations that they are hypothesizing, which is a useful step toward better understanding potential causal processes. Whether the associations are thought to be primarily within- or between-persons and concurrent or lagged in time have design implications in terms of statistical power and the sampling timing. Researchers should first determine what type of association they are interested in testing (question 16). If they are examining whether within-person changes in the IV (eg,

XSL•FO
RenderX

positive affect assessed every 2 h through EMA) are associated with within-person changes in the DV (eg, MVPA min in 30-min window after the EMA), then the study should include enough observations nested within enough people to detect within-person effects [90,91].

If a researcher is examining whether within-person changes in the IV are associated with within-person changes in the DV, then researchers should first consider whether the IV is hypothesized to be associated with the DV at the same point in time (ie, cooccurring effect) or a later point in time (ie, lagged effect; question 17). For the cooccurring effect, the design would need to ensure that affect and physical activity are assessed concurrently (eg, participants respond to EMA while doing physical activity) whereas the latter hypotheses would require a design that captured physical activity after each EMA prompt and linking data through date-time stamps (Figure 3).

Figure 3. Decision 6: Example of concurrent and lagged effects for examining the causal associations (Redrawn from Dunton et al [87]).

Second, if the researcher hypothesizes that the IV is associated with the DV at the same point in time (ie, cooccurring effect), then they need to specify the "duration" of that point in time (question 18). For example, one could hypothesize they are associated with each other during the same 1-hour period (eg, types of social interactions over the past hour are associated with level of positive affect over the past hour). If using EMA, the item wording would need to specify the duration of the recall period (ie, "In the past hour…").

Third, if the researcher hypothesizes that the IV is associated with a DV occurring at a later point in time (ie, lagged effect), then it is necessary to specify how much later (eg, in minutes, hours, or days; question 19). For example, if a researcher is interested in understanding whether perceived stress at any point of the day (IV) is associated with asthma symptoms occurring over the next 4 hours (DV), then the sampling frequency and item wording need to reflect these temporal associations [30].

Application to research examples: The first research example explicitly asks whether momentary affect is associated with MVPA in the subsequent 30 minutes. This requires linking sensor data to EMA survey responses and then calculating time spent in MVPA during the subsequent 30 minutes (leading observations). In the second research example, the question is investigating within-person, daily associations between intentions and drinking behaviors, with daily stress as a moderator. The design includes morning diaries about drinking intentions and evening diaries about daily stressors, including reports of the time of day the stressor occurred. This type of design requires linking morning and evening diaries by study day and linking sensor data to the diary data. To ensure temporal precedence, time stamps for when morning diaries were completed and for when stressors occurred must be linked to the sensor data so that (1) only drinking data which occurs after the morning assessment of intentions are included and (2) only stressors that occurred after the morning assessment of intentions and before drinking onset are included. Multimedia Appendix 2 provides example R code using timestamps from the morning diary and stressor occurrences to establish temporal precedence, followed by removing all stressors that occurred before the morning diary.

Decision 7: Select Number and Type of Days to Assess

Once the temporal and causal associations are specified, the next decision is determining the number and types of days across which the ILD sampling protocol should be implemented. The key challenge is balancing the need for adequate representation across time and statistical power (more observations are typically better) with the potential response burden (fewer observations are typically better). If the research question concerns between-person differences and conceptualizes either the target IV or DV at person level (ie, their usual level of a behavior), researchers should consider how many days will provide adequate representation or between-person reliability (ie, internal consistency) for the target IV and DV (question 20), with reliability meaning the extent to which any given set of assessments approximates the typical level of the construct [92]. For constructs that are generally stable for a person across time, such as the time of the day that someone starts work, only a few days may be needed. However, for constructs that fluctuate from day to day, such as dietary intake, many more days may be needed to obtain adequate representation of one's

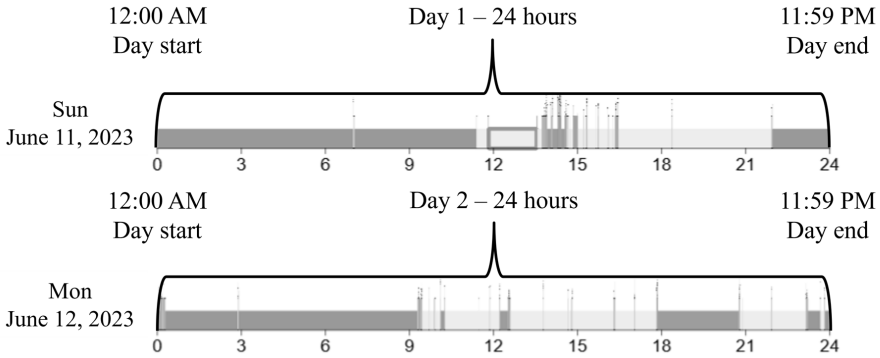
XSL•FO
RenderX

typical daily nutrient intake [93]. A different but associated concept is within-person (ie, idiographic) reliability, which addresses how reliably one can detect fluctuations within an individual over time (ie, time-varying states) beyond measurement error as described in decision 3 [78].

Related to the total number of days are questions about whether weekend and/or weekdays are needed (question 21) and the total number of observations per person (question 22). Some questions, such as those pertaining to children's social interactions at school, may only require weekday assessment whereas other questions, such as those related to overall sleep patterns, would require weeknight and weekend night assessments. Which days to sample for a given phenomenon may also differ depending on the target population. For example, among college students, drinking is more likely to occur on Thursday-Saturday, the "social weekend"; therefore, researchers studying college student drinking may only need to sample those days. However, if studying alcohol use in other adult populations or individuals with an alcohol use disorder, it may be appropriate to sample all days of the week. Finally, if a researcher is using EMA as the primary measurement modality with multiple assessments per day, then they need to consider how many observations per person are needed to ensure adequate statistical power. It is beyond the scope of this tutorial to provide in-depth guidance for power analyses in ILD studies; however, we will briefly state that multiple approaches can be used for estimating power in ILD (eg, simulation or summary-statistics based approaches) and, as in all power analyses, the sample size and number of observations needed depend on the primary effect researchers aim to detect (eg, within-person, between-person effects, and cross-level interactions) [94-97]. Due to the multilevel nature of ILD, power analyses should also account for the estimated intraclass correlation coefficient, which reflects the proportion of variance attributable to between-person differences and influences the amount of independent information contributed by repeated observations [94-97]. For example, a Monte Carlo simulation study found that, with 70 observations per person, a sample size of 15 participants yields 99% power to detect within-person (level 1) effects [94]. More participants were needed to detect between-person (level 2) effects; specifically, 30 participants with 70 observations yield over 80% power to detect between-person effects [94]. Given the complexity of power analyses for ILD, we recommend that readers consult a biostatistician and refer them to the PowerAnalysisIL Shiny app (Ginette Lafit) on GitHub to aid their research team in conducting power analyses for their ILD studies [94].

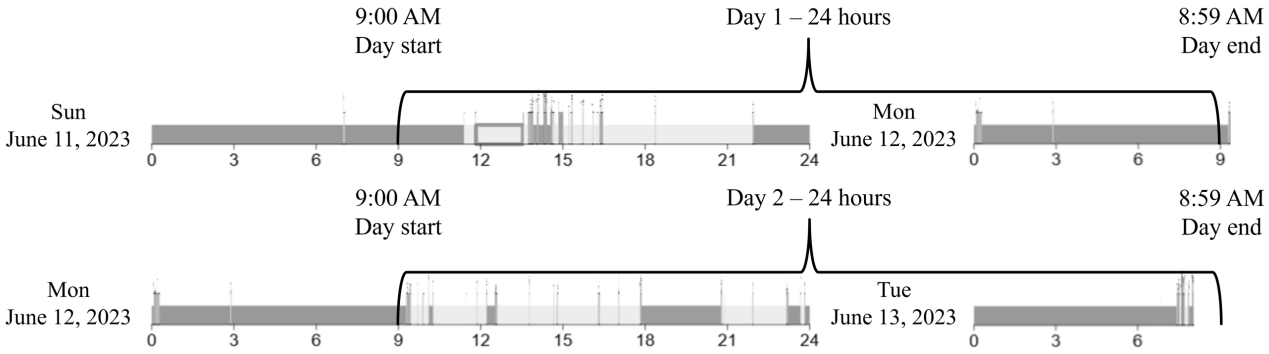
The next questions relate to balancing reliability and power requirements while minimizing participant burden. When participants experience greater burden due to the behavioral or cognitive effort involved in responding, the quality and/or quantity of data can be reduced [98,99]. If the number of days or assessments per day appear to be too burdensome (questions 23 and 24), then the researcher could consider altering the study design such as having assessments occur on random days with no-assessment days in between (eg, one day on followed by one day off) or multiple assessment bursts with a short string of continuous days (eg, 5 d) separated by multiday breaks (eg, 5 d; Table 1).

Finally, researchers should consider whether they expect the strength of within-person associations to change or remain stable over time (question 25). If they anticipate that a within-person association (eg, whether stress leads to increased hunger in the next hour) remains stable across weeks, months, and years, then they may choose to use a single measurement burst design (eg, a single period of continuous days). However, if they expect that the within-person association changes in strength over longer periods of time (eg, due to exposure to an intervention or historical events), then a multiple measurement burst design with bouts of continuous assessment days separated by the time interval of expected change (eg, weeks, months, or years) should be considered.



Application to research examples: For investigating affect and MVPA in children, the decision to only assess Fridays-Mondays necessitated a measurement burst design to collect sufficient observations. For example, 10 measurement bursts, separated by at least 14 no-assessment days, with 4 days of data collection during each burst permits collecting sufficient observations without undue burden (Figure 1). For investigating daily drinking intentions, stress, and behaviors, at least 30 sequential days of observation are warranted, as the research question is about day-level associations in adults.

Decision 8: Define What a "Day" Means in the Study



After selecting the number and types of days to assess, the next decision is determining how a "day" is defined. For example, if a researcher is examining participants' daytime behaviors, such as activities during work or school [48,89,100] or studying discrete events during the day, such as physical activity or drinking events [46,49,87], then defining the day based on a calendar day, which reflects the traditional 24-hour day or calendar date (eg, starting at midnight and ending at 11:59 PM) is appropriate (Figure 4). In general, a "calendar day" is appropriate when most participants go to bed before midnight or for studies examining daytime behaviors.

XSL•FO
RenderX

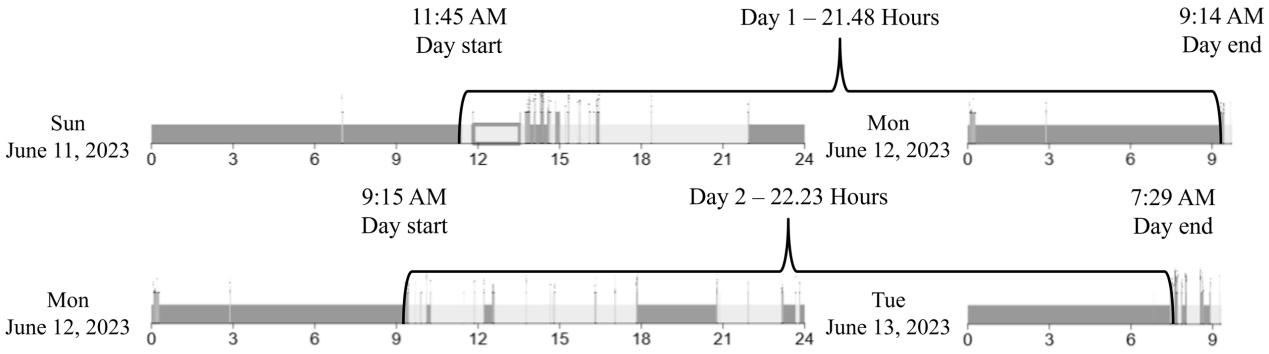


Figure 4. Decision 8: Scenarios for how to define a "day" might be defined for a given study. (A) Defining a day based on "calendar day," or a traditional 24-hour day/calendar date from midnight on day *n* to 11:59 PM on day *n*. (B) Defining a day based on a "study-centric" day with 24 hours from 9 AM on day *n* to 8:59 AM on day *n*+1. (C) Defining a day based on a "person-centric" day with each day starting upon waking on day *n* and continuing until waking on day *n*+1, resulting in a varying number of total hours (ie, <24 h or >24 h) per day.

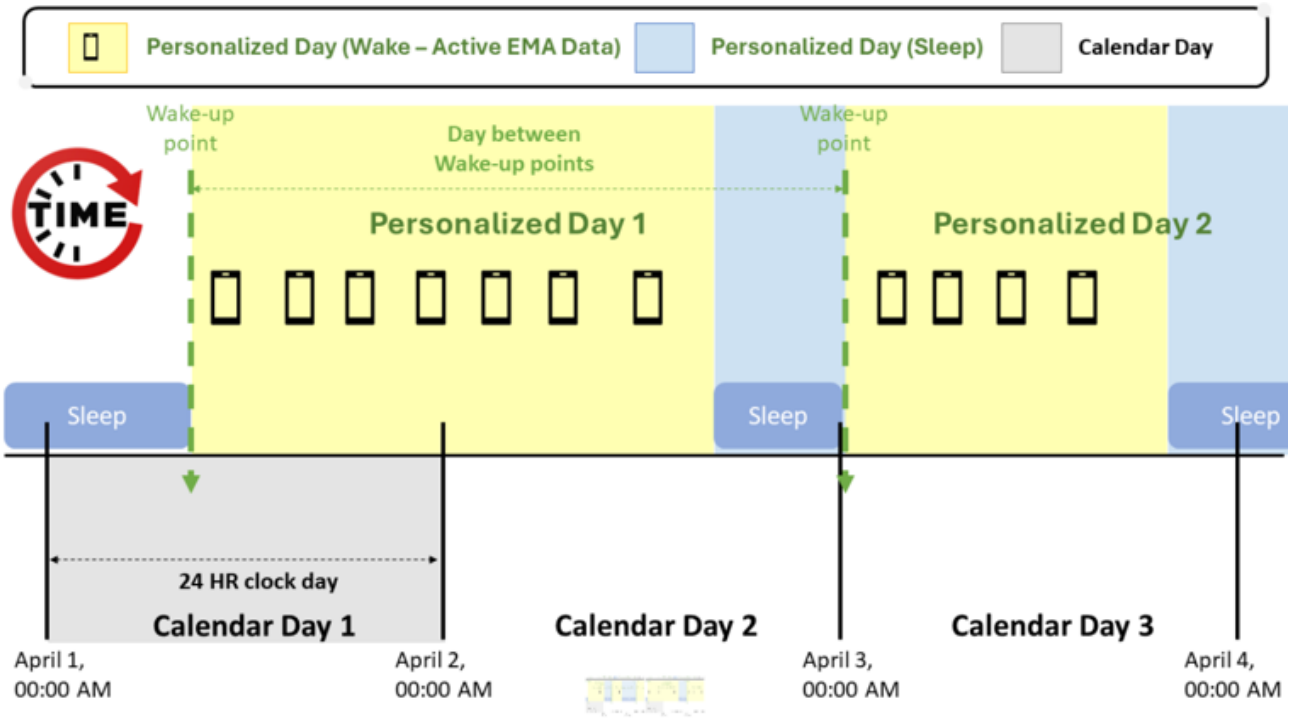
A: defining a day based on a 'calendar day', or a traditional 24-hour day/calendar date from 12:00 AM on day *n* to 11:59 PM on day *n*.

B: defining a day based on a 'study-centric' day with 24-hours from 9:00 AM on day *n* to 8:59 AM on day *n* + 1.



C: defining a day based on a 'person-centric' day with each day starting upon waking on day *n* and continuing until waking on day *n* + 1, resulting in a varying number of total hours (i.e., <24 hours or >24 hours) per day.

If a researcher is studying phenomena that are not contained within a calendar day, influence each other across the sleep-wake cycle, or have spillover effects across calendar days, then defining a "study-centric" day based on a key study feature, such as a morning EMA, is appropriate. For example, drinking events often occur after midnight and alcohol metabolism continues into the next calendar day. Using a study-centric day ensures these constructs are correctly attributed to the day when they practically occurred. For example, studies by Courtney and Russell [47] and Russell et al [51] used a 10 AM EMA as the daybreak when examining daily drinking intentions and outcomes.

Finally, if a researcher is investigating variability in a person's daily lived experiences or circadian rhythms, then a "person-centric" day based on an individual's sleep-wake cycle (eg, not following a 24-h cycle) is appropriate. With a person-centric day, each day may differ between and/or within participants, and a "day" may include entire days or person-centric waking or sleeping periods. For example, Wang et al [86] were interested in within-person predictors of physical activity engagement and maintenance; therefore, they used person-centric days based on a participant's sleep-wake cycle to examine these within-person processes (resulting in some "days" having more than 24 h and some less than 24 h; Figure 5). Researchers should decide a priori about how to define a "day" because it has important implications for sensor wear protocol, timing of measures, data processing, and results interpretation.

RenderX

Figure 5. Decision 8: Example ecological momentary assessment sampling strategy when using a "person-centric" study day (reproduced from Wang et al [86]). EMA: ecological momentary assessments.

Application to research examples: In the first research example investigating affect and MVPA in children, the EMA sampling schedule was limited to 10 AM-8:30 PM; therefore, the design decision was to use a 24-hour calendar day. In the second research example investigating drinking intentions and behaviors, the design decision was to use a study-centric day. This was more appropriate than a 24-hour day because alcohol use often occurs after midnight and, even if a person is done drinking before midnight, alcohol metabolism continues throughout the sleeping period (ie, after midnight). By using a study-centric day, we avoid the problem of attributing sensor-detected alcohol use to the incorrect "lived" day, which would cause problems related to temporality and causality. The study-centric day was defined based on the start time of the morning daily diary, with the day running from 9 AM to 8:59 AM the following day. To further avoid issues of misattributing alcohol use to the incorrect data, it was also necessary to remove any residual alcohol detected after 9 AM when processing the sensor data.

Decision 9: Determine Whether to Aggregate Data and, if Applicable, Which Assessments to Aggregate

After making the previous design decisions, researchers need to make data processing decisions related to aggregating assessments and temporally aligning variables based on whether the hypothesized associations are concurrent or lagged. These decisions are critical, because variation in decisions regarding which variables to include in analyses, which items to cluster with one another (eg, calculate average positive affect from several items), the handling of missing data, and the use of contemporaneous versus lagged variables all may impact final model results [101]. If there are multiple assessments per day (eg, EMAs), then the researcher needs to decide the timeframe and duration of time they are interested in studying (questions 32a and 32b). If a researcher is interested in all observations of the IV that occurred before DV, then they would aggregate all of those IV assessments during the specific time frame (taking the total, average, or variance value). If a researcher is interested in a duration of time shorter than 1 day, then they need to specify whether concurrent or lagged effects are of interest (questions 17 - 19).

Data aggregation refers to combining multiple observations via summary measures, such as calculating average daily affect using multiple EMA responses within a day. There are two decisions underlying aggregation: (1) how to aggregate data (ie, which summary measures to use, such as mean, total, maximum, or variance), and (2) across which time frame (ie, measurement windows) to aggregate data (eg, hour or day). Both decisions can be informed by top-down (a priori) or bottom-up (data-driven) approaches. Top-down decisions may be preferable when guided by a specific research question. For example, if researchers are interested in the range of emotions children experience, they may aggregate using within-day variability (eg, variance) or the number of unique emotions reported, rather than mean levels of affect. Similarly, if researchers hypothesize that negative social interactions throughout the school day, but not after school, are most relevant for children's emotion regulation, a top-down approach would support aggregating observations specifically within the school-day window. To facilitate implementation, Multimedia Appendix 2 includes example code for leading and lagging variables, data aggregation (ie, day-level mean, within-day variability, or number of unique emotions), and multilevel models. This code is intended as a starting point rather than a prescriptive template; researchers should carefully adapt all steps to their specific study design, research question,

XSL•FO
RenderX

measurement structure, and analytic goals, particularly with respect to decisions about disaggregation (ie, within- vs between-person effects) and model specification (eg, inclusion of random slopes).

In contrast to top-down approaches, bottom-up, data-driven approaches (eg, machine learning methods) may be useful when there is limited theoretical guidance or when researchers aim to use empirical data for identifying optimal aggregation strategies. For example, researchers could compare multiple summary metrics (eg, mean, total, and variability) or time windows (eg, hourly vs daily) in terms of their predictive utility for an outcome, allowing the data to inform both the aggregation metric and time frame. Such an approach could reveal, for instance, that the total number of negative social interactions experienced in the morning has the largest impact on children's emotion regulation.

Application to research examples: Research example 1 requires aggregating accelerometer data from the 30 minutes before and after the EMA prompts. Research example 2 requires aggregating alcohol sensor data across the study-centric day (9 AM-8:59 AM) so that only alcohol use after morning intentions is included in the models investigating day-level within-person associations.

Limitations and Future Directions

Overall, this tutorial is meant to be a practical, step-by-step, decision-making tool to help beginning-to-intermediate ILD researchers design an ILD study. As such, it does not include advanced considerations needed for more complex research questions. The tutorial also does not address sophisticated ILD study designs that are needed to test time-varying effects (eg, within-person effects that vary across the day), time-varying moderating effects (eg, within-person effects that vary across contexts), multilevel mediation, idiographic effects, or N of 1 studies [102-105]. It also does not address research questions that examine within-person variability as a predictor, mediating, or moderating variable [106]. For example, a researcher may be interested in understanding how mood variability predicts changes in physical activity levels across childhood. The tutorial does not address some novel ILD measurement selection strategies, such as using computerized classification based on measurement error or mean and variability in previous EMA item responses to determine when and how often those items should be assessed [107,108]. Furthermore, the overall purpose of the tutorial is to inform the development of assessment protocols for observational studies, or as the evaluation component of intervention studies. It does not address considerations needed for the design and delivery of mobile or digital intervention strategies, such as when and how to provide intervention notifications that are part of microrandomized trials or JITAIs [14,15]. While the tutorial does provide some guidance on lagged versus leading observations and data aggregation, which is essential given that these choices can influence model outcomes and require transparency on the part of researchers [101], it does not address in depth the data processing and analysis needs inherent to ILD studies. For example, merging EMA data with sensor data based on time stamps and creating lagged or leading variables may require programming skills not typically taught in graduate training. Researchers may need to develop advanced data analytic skills or consult with data scientists and biostatisticians to ensure that data processing and analytic approaches are appropriately aligned with the a priori research question. The advent of AI systems provides another potential resource for researchers to use when encountering the data processing and aggregation challenges common to ILD. Furthermore, although the tutorial discusses selective data-processing decisions that have direct implications for study design (eg, temporal alignment and aggregation of observations), it does not provide detailed guidance on handling missing EMA responses, participant attrition, or incomplete sensor data. These issues are important considerations in ILD research and can have important implications for data quality and validity but were considered beyond the scope of the current design-focused tutorial [109]. Finally, the scope and emphasis of the tutorial are informed by the authors' own research experiences and areas of applied work, which have influenced the selection of examples, populations, and design priorities. As a result, some ILD applications, research domains, or methodological perspectives may be underrepresented. While many of the principles discussed are broadly applicable, the tutorial primarily draws on examples from student and community populations and does not provide detailed guidance tailored to clinical or patient populations (eg, individuals with chronic conditions or older adults), for whom additional feasibility, burden, and adherence considerations may be especially important [41-44].

Further research in several key areas is needed to help researchers make better decisions about selecting measures and designing protocols for ILD studies. First, more comprehensive and systematic psychometric testing of daily diary and EMA items that compare different recall windows (eg, in the past hour vs 2 hours) and sampling densities (eg, 3 vs 10 prompts per day) can inform decisions about when and how often items should be assessed. Additionally, more thorough evaluations of the reliability and validity of EMA and sensor methods compared with established standards are needed. It would be helpful to develop an open-source repository that provides example items and detailed information about their timing, variability, and assessment burden within specific subgroups. Second, studies are needed to systematically test accessibility and usability of mobile, digital, and wearable assessment devices across vulnerable populations. For example, with older adult populations, the font on a smartwatch may be more difficult to see and vibrations on a sensor may be less detectable due to decreased skin sensitivity. Finally, future research directions include substantial opportunities to apply recent advancements in computational modeling, machine learning, and AI to predict the most opportune time to deliver the most useful type of ILD assessments to specific participants to reduce response burden and maximize the quantity and quality of the data.

Conclusions

Advances in mobile technology and statistical methods have increased the accessibility and feasibility of collecting and analyzing ILD in health behavior research studies. However, a

XSL•FO
RenderX

lack of readily available information and training on how to select measures and design the sampling protocol for ILD studies has hampered progress and the application of these methods. The tutorial provided here is intended to make it easier for researchers to implement rigorous ILD studies to enable scientific advancement and understanding of the nature of time-varying phenomena in health.

Abstract

Background: Remote patient management (RPM) that supports patient self-monitoring of vital parameters and lifestyle factors may improve cardiovascular risk management (CVRM) in primary care. However, large-scale implementation remains limited, partly due to insufficient evidence on long-term value for money, budget impact, and implications for health care professionals' workload.

Objective: This study aimed to estimate the long-term cost-effectiveness, 5-year health care budget impact, and expected changes in general practitioner (GP) and practice nurse (PN) workload associated with the CVRM-Box intervention in the Netherlands.

Methods: We conducted a model-based economic evaluation comparing CVRM-Box with care as usual in Dutch primary care integrated CVRM programs. CVRM-Box is a multicomponent RPM intervention comprising a digital blood pressure (BP) monitor, digital weight scale, step counter/activity tracker, and a mobile app, with measurements transferred to the GP practice for periodic review. A time-inhomogeneous cohort Markov model simulated lifetime transitions among health states, including at-risk, post–myocardial infarction (MI), poststroke, recurrent events, cardiovascular death, and noncardiovascular death. Cardiovascular risks were modeled using prediction equations (SCORE2, SCORE2-OP, and SMART2) populated with subgroup-specific risk factor profiles. Intervention effects were modeled as changes in systolic BP derived from a matched cohort study of CVRM-Box. Other key parameters (costs and utilities) were similarly obtained from the matched cohort study, or routine primary care data, and published sources. Outcomes included incremental cost-effectiveness ratios (ICERs, indicating cost per quality-adjusted life year [QALY] gained), cost-effectiveness probabilities, 5-year health care budget impact, and an exploratory workload analysis estimating annual changes in visit time and remote consultation frequency for GPs and PNs. Probabilistic and scenario uncertainty analyses were performed.

Results: In the overall population, CVRM-Box increased costs and QALYs versus care as usual, yielding an ICER of €17,340/QALY gained (EUR €1=US $1.11 as of 29 December 2023) and a 60% probability of cost-effectiveness at a willingness-to-pay threshold of €20,000/QALY. Cost-effectiveness was more favorable in higher-risk subgroups (uncontrolled BP and/or prior MI/stroke), with ≥70% probability of cost-effectiveness at €20,000/QALY, whereas in the lower-risk subgroup with controlled BP and no prior MI/stroke, the intervention is unlikely to be cost-effective (ICER: €42,384/QALY). The 5-year health care budget impact was €2.9 million and €662.2 million for regional and national rollout, respectively. In a typical Dutch

XSL•FO
RenderX

primary care practice, the CVRM-Box reduced PN workload by 25.9 h and 44.7 remote consultations annually, while the change in GP workload was negligible (0.5 h; 3.3 remote consultations).

Conclusions: The CVRM-Box multicomponent RPM intervention is likely to be cost-effective among high-risk subgroups but not in lower-risk groups. The intervention further reduces PN workload but not GP workload. Results primarily apply to the Dutch context and may not generalize to health care systems with different payment/incentive arrangements. Additionally, long-term outcomes were modeled using prediction models rather than observed cardiovascular events. Nonetheless, our findings provide an argument for implementation in primary care for higher-risk subgroups.

patient management; preventive cardiology; primary care; cost-effectiveness; budget impact

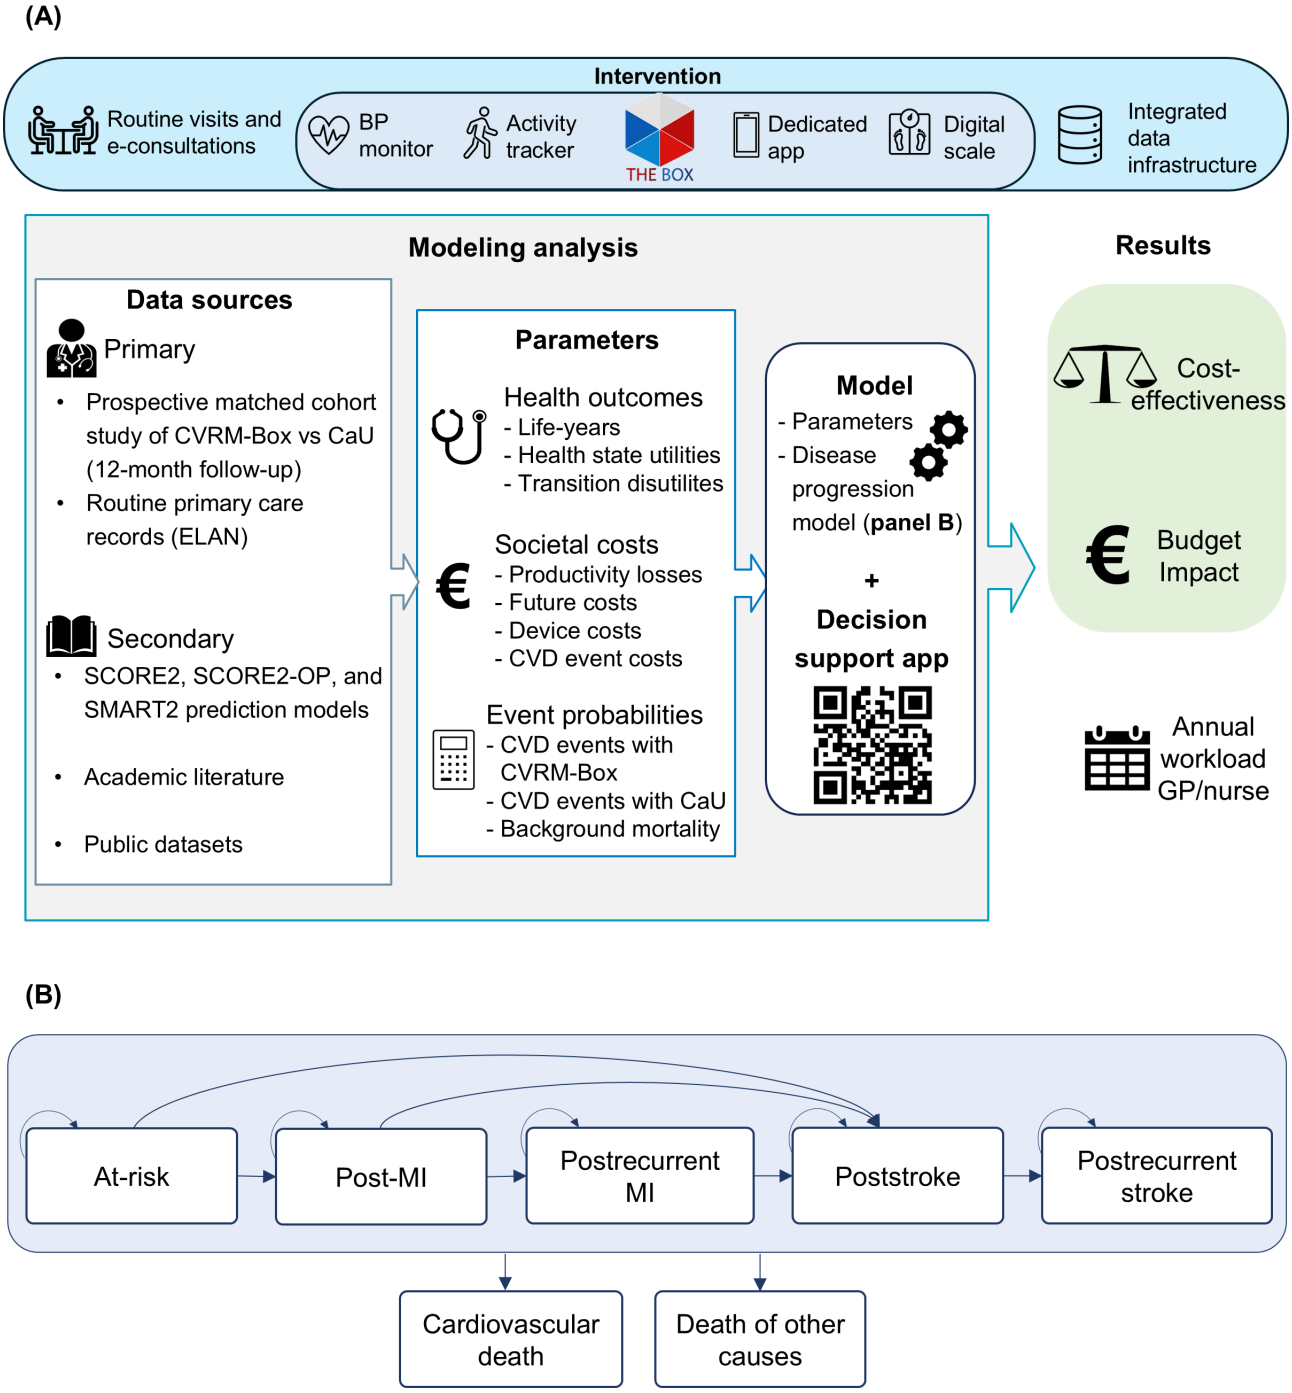
Introduction

Cardiovascular disease (CVD) is a leading cause of death globally, contributing to substantial illness, mortality, and an economic burden on health care and society [1,2]. With aging populations and the increased prevalence of chronic diseases, primary care is strained due to a shortage of general practitioners (GPs) and practice nurses (PNs) and an increased workload [3-5]. Remote patient management (RPM) for preventive care is a relatively new approach that can improve reaching blood pressure (BP) targets, aid weight loss, and facilitate lifestyle change [6-10]. However, a significant gap remains in the large-scale implementation of RPM within integrated care [11,12].

In the Netherlands, a matched cohort study of a multicomponent RPM intervention, "cardiovascular risk management (CVRM)-Box," has been conducted to evaluate the effect of RPM within primary care settings for enhancing BP control, weight, and consultation frequency [13]. Patients at a high risk of major adverse cardiovascular events (MACEs), including myocardial infarction (MI), stroke, or transient ischemic attack, were recruited across 6 primary care practices [13]. Previous implementation studies of the CVRM-Box intervention, guided by the RE-AIM (Reach, Effectiveness, Adoption, Implementation and Maintenance) framework and the Consolidated Framework for Implementation Research, have shown that successful implementation depends on factors such as compatibility with routine practice, perceived workload for health care professionals, technical feasibility, and organizational support [14,15]. In addition to these implementation determinants, the cost-effectiveness of RPM interventions is a key consideration for their adoption, long-term sustainability, and large-scale implementation in routine primary care.

Health economic assessments have traditionally been tailored for pharmacological studies and medical devices and may not adequately capture the multifaceted nature of RPM interventions. Capturing the broader benefits of RPM interventions, such as enhancing health care professional efficiency through increasing patient self-management, is important for informed decision-making [16-18]. Effective implementation and scaling of RPM involves new value propositions shared among different stakeholders and capturing these different values that arise from RPM-supported care [19,20]. Waiting for numerous studies with larger time horizons and sample sizes is impractical and costly, as information is essential for upfront investment to achieve large-scale adoption. More insight into realistic scenarios of upscaling is crucial for informed decision-making [21].

Therefore, this study aimed to model the long-term cost-effectiveness, budget impact, and reduction in required visits to assess the potential scale-up of a multicomponent RPM intervention for the high-risk CVD population in primary care.



Methods

Study Design

The current study constitutes a model-based evaluation of CVRM-Box versus care as usual (CaU) [22]. This approach enables the transparent combination of multiple data sources in one modeling framework to estimate long-term health and economic outcomes under each care pathway (Figure 1A). Patients at risk of first or recurrent MACE were simulated throughout their remaining lifetime according to each care pathway. Our model input parameters incorporated data from 3 main sources: (1) primary data from the prospective propensity score-matched CVRM-Box cohort study [13], which informed the intervention effect on systolic blood pressure (SBP) and intervention-related resource use and costs; (2) primary data from the Extramural Leiden University Medical Center (LUMC) Academic Network (ELAN) database [23,24], which informed baseline risk factor profiles and CaU costs for at-risk patients; and (3) published literature, public datasets, and published Dutch costing guidance, which informed calculations of event probabilities, event and postevent costs, and health utilities. Table 1 summarizes key parameters and sources, while Multimedia Appendices 1 and 2 provide full parameterization and transition-probability calculations. Figure 1A presents a general schematic of our study design.

[k]Incremental cost or disutility relative to the at-risk state and post-MI/poststroke state.

The cost-effectiveness of CVRM-Box was described using incremental cost-effectiveness ratios (ICERs) and cost-effectiveness acceptability curves [50]. We additionally conducted 2 budget impact analyses (BIAs) and estimated annual reductions in workload for GPs and PNs. Reporting followed the CHEERS (Consolidated Health Economic Evaluation Reporting Standards; the completed CHEERS reporting checklist is available as Checklist 1) [51]. Finally, a user-friendly R Shiny app was developed [52] to facilitate interaction with and modifications to the model by decision-makers and researchers, such as assuming different values for key model parameters (eg, higher costs, lower intervention effects) to represent alternative scenarios or assumptions. The web-based app is accessible at jmheij.shinyapps.io/CVRM-Box-model.

Ethical Considerations

The present study was a model-based secondary analysis and involved no new participant recruitment or data collection. The prospective CVRM-Box study [13], which informed various model input parameters, was approved by the Medical Ethics Committee of Leiden University Medical Center (N21.126), and participants provided written online informed consent. The same committee determined that the ELAN data resource was not subject to the Dutch Medical Research Involving Human Subjects Act (reference G18.070); individual informed consent was therefore waived, and individuals could withdraw through an informed opt-out procedure [24]. Analyses were conducted using deidentified CVRM-Box data and anonymized ELAN data, with access restricted to authorized personnel. Participants in the CVRM-Box study received no financial or other compensation.

Population and Setting

The modeled cohort represents primary care patients who are part of the Dutch integrated care programs for increased risk or history of CVD. For the main analysis, we assumed the population receives the intervention at age 50. In line with the prospective study of CVRM-Box, the cohort was 53% male and had a moderate to high risk (10%-15%) of 10-year CVD mortality [53] or a history of MI or stroke.

To account for patient and effect heterogeneity, 4 subgroup-specific analyses were conducted by BP status (ie, controlled/uncontrolled) and history of MI or stroke (ie, history/no history). The proportions of patients in each subgroup (Table 1) were consistent with the prospective study of CVRM-Box [13].

Interventions

CVRM-Box

The modeled CVRM-Box intervention reflects the multicomponent RPM program evaluated in van Hattem et al [13], which was a 12-month matched cohort study across 6 Dutch primary care practices. Because the present model is stratified by BP-control status, the BP-effect parameters used here (Table 1) were taken from the subgroup-specific estimates of that study: an adjusted office-measured SBP difference of –1.3 (95% CI –4.1 to 0.5) mm Hg in patients with controlled BP at baseline and –3.5 (95% CI –7.5 to 0.5) mm Hg in patients with uncontrolled BP, neither reaching conventional statistical significance. Despite the modest office-based effect, the intervention significantly increased the proportion of patients achieving controlled BP (<140 mm Hg) over follow-up, and home (CVRM-Box) BP measurements showed a larger reduction than office measurements (SBP –5.5 mm Hg, P<.001). The intervention was also associated with statistically significant reductions in body weight (–0.9 kg) and BMI (–0.3 kg/m²) and a lower overall consultation frequency (rate ratio 0.82, P=.002). These primary-data estimates, particularly the subgroup-specific SBP differences and the consultation-frequency reduction, directly informed the intervention effect sizes and resource-use parameters used in the present model.

XSL•FO
RenderX

Eligible patients underwent a consultation with an assistant who introduced "The CVRM-Box." The CVRM-Box was developed within a regional multistakeholder innovation environment, "Gezonde Zorg, Gezonde Regio" [14,54], a multistakeholder initiative involving health care providers and a major regional health insurer. This collaboration included long-term funding agreements, in which efficiency gains were redistributed between providers and the insurer. This structure aimed to align financial incentives and support sustainable implementation of digital care [55]. The intervention included a digital health infrastructure comprising a BP monitor (Wireless Blood Pressure Monitor; Withings), weighing scale (Smart Body Scale Analyzer; Withings), activity tracker (Move, Withings), and a dedicated mobile-based lifestyle app (LUMC Care) integrated in hospital and primary care electronic health records (Medicom, PharmaPartners) (Figure 1A). To facilitate effective use of the CVRM-Box at home, patients were supported by a GP assistant (a student) during dedicated consultations. These sessions included assistance with pairing the monitoring devices to the patient's smartphone, guidance on navigating the CVRM-Box app, and time to address questions or concerns. Patients were instructed to perform weekly BP and weight measurements and were provided with practical advice via the mobile-based lifestyle app on interpreting their results. In addition, individualized targets for weight and daily steps were defined. Patients were instructed to contact the PN in case of very high BP readings (>180 mm Hg), repeated elevated measurements (>140 mm Hg on 3 consecutive occasions), persistently increased values, or the occurrence of symptoms such as dizziness, headache, or chest pain. A follow-up appointment within 6 weeks was scheduled to resolve potential technical problems. The GP assistant also managed a help desk service that patients could reach for technical issues with their devices.

Measurement results were stored locally on the patient's smartphone and subsequently transmitted to the servers of the respective app providers (Withings). To safeguard participant privacy, each patient was assigned an @hlc.nl email address consisting of a randomly generated identifier and password, which was used solely for study-related logins. The @hlc.nl domain was managed by the LUMC, and all associated data were stored on secure LUMC servers. Data from Withings devices were retrieved through the Withings Application Programming Interface. The Withings Application Programming Interface enabled automatic transfer of device data into the hospital and GP electronic medical record system using a secure OAuth2 authentication process.

All transmitted measurements were reviewed at least weekly by the PN using a built-in dashboard within the electronic patient record. Because this dashboard was embedded within the existing workflow, PNs did not need to review incoming measurements through a parallel/separate monitoring system, limiting additional cognitive burden and disruption. Automated alerts flagged abnormal values, prompting the nurse to contact patients when needed. Depending on the findings, medication adjustments could be made or follow-up appointments scheduled. If no mobile health measurements were received for 3 consecutive weeks, GP assistants contacted patients by phone to emphasize the importance of continued monitoring. Further details about the CVRM-Box intervention are described elsewhere [13].

CaU

CaU was defined as the current CVRM practice within the primary integrated care programs for individuals with increased cardiovascular risk or a history of CVD. This protocolized program focused on lifestyle modifications and the treatment of BP and cholesterol levels and was primarily conducted by the PN [56]. Yearly check-ups at the GP included a local BP measurement and laboratory examination. Most visits (95%) were assumed to be with the PN, while the other visits (5%) took place with the GP when necessary. Thus, routine cardiovascular monitoring in both care pathways was predominantly PN-led, with limited direct GP involvement.

Model Structure

We developed a cohort Markov model with 1-year cycles to compare CVRM-Box versus CaU over a lifetime horizon. The underlying disease-progression structure (health states and allowed transitions) was identical between arms (Figure 1B), but the disease progression rates differed by arm. Specifically, baseline risk-factor profiles and CaU costs were informed by ELAN routine primary care data [23,24], while CVRM-Box intervention effects on SBP (by BP-control subgroup) and intervention-related costs were sourced from the prospective matched cohort study [13]. Cardiovascular event risks for the transitions shown in Figure 1B were generated using SCORE2/SCORE2-OP [57,58] and SMART2 [59] risk prediction equations populated with subgroup-specific mean risk factors and applying CVRM-Box–related changes in SBP in the intervention arm (more details in Transition probabilities subsection).

The Markov model (Figure 1B) simulated 3 cardiovascular events: nonfatal MI, nonfatal stroke, or fatal cardiovascular event. Additionally, the "Postrecurrent" states were included to account for the greater risk and consequences of recurrent nonfatal events. As the costs and burden of stroke are generally greater than those of MI [25,27,41,49,60], the model does not allow for transitions from stroke to MI states. Finally, patients could experience a fatal cardiovascular event or die of other causes. Patients with no CVD history entered the model in the "At risk" state, while patients with a CVD history entered the model in the post-MI (64%) and poststroke (36%) states, in line with the proportions observed in ELAN data [23,24].

Model Input Parameters

Probabilistic Approach

The main analysis was probabilistic, whereby parameter estimates were resampled 1000 times based on their SEs and assumed posterior distributions [50]. This probabilistic approach enabled us to reflect uncertainty in the available evidence (eg, the uncertainty surrounding key parameters) by running the model many times with plausible alternative input values, so results could be reported as ranges and the probability that CVRM-Box represents good value for money. All model parameters with corresponding sources [10,25-49] and

XSL•FO
RenderX

uncertainty ranges are summarized in Table 1 (details in Table S1 of Multimedia Appendix 1).

Transition Probabilities

The transitions in Figure 1B were simulated using age- and subgroup-specific transition probability matrices. Transitions from the "At-risk" state to post-MI/stroke or cardiovascular death were parameterized using the SCORE2 and SCORE2-OP prediction equations, including the appropriate recalibration scales for the Netherlands (ie, corresponding to the "low risk" region) [57,58]. Transitions between post-MI/stroke states and from post-MI/stroke to cardiovascular death were parameterized using the SMART2 prediction equations, including the appropriate recalibration ratio for the Netherlands (ie, corresponding to the "low risk" region) [59]. All prediction equations were populated with subgroup-specific mean risk factor values (ie, cholesterol, BP, etc, reported in Tables S2-S7 of Multimedia Appendix 1) obtained from ELAN data [23,24] (representative of CaU). All-cause mortality followed population life tables corrected for CVD-related mortality [61,62]. Transition probability calculations are detailed in Multimedia Appendix 2.

The effect of CVRM-Box was modeled as a reduction in the absolute risk of MACE (ie, lower transition probabilities) resulting from an expected reduction in BP and smoking with the intervention (Table 1). The reduction in BP was equivalent to the adjusted difference in BP estimated in the matched prospective study of CVRM-Box (Table 1). Specifically, the intervention study of CVRM-Box reported an adjusted mean reduction in SBP of −1.3 mm Hg among patients with controlled BP and a −3.5 mm Hg reduction among patients with uncontrolled BP [13]. Smoking cessation was assumed at 13% of patients with a wide credible interval of 2% to 18% [10].

Costs

In line with Dutch guidelines for economic evaluations, we followed a societal perspective and discounted costs at 3.5% per yearly cycle [63].

Annual intervention and CaU costs for at-risk patients were estimated from the prospective study of CVRM-Box [13] and ELAN data [23,24], respectively, while the incremental annual costs for nondeath states were sourced from literature (Table 1). The literature sources informing the incremental annual costs for stroke states included a Dutch 2-year analysis of health care use and costs among stroke survivors in the Restore4Stroke Cohort [27], and a German lifetime cost analysis of stroke survivors [28]. For the incremental annual costs in MI states, sources included a 6-year cohort study among MI patients that reported annual health care use [25], and parameters used in a previous Dutch economic evaluation [26]. Nonhealth care costs included work productivity losses (ie, reduced working and/or work leave), estimated using the friction cost method [64] and accrued only while the cohort was younger than 67 years (Table 1). The degree and duration of work productivity loss was informed by ranges reported in various studies, most of which showed that work leave after a nonfatal CVD event lasts approximately 120 days and high proportions of early retirements [27,32,36-40].

Our modeling approach integrated state-specific and transition-specific costs (Table 1). State-specific costs represent the aforementioned annual/recurring costs associated with each health state, while transition-specific costs account for any one-time/short-term costs associated with the cardiovascular events themselves [65]. Existing literature that reported on transition-specific costs, such as initial hospitalization and treatment after a stroke [27,28,32-35] or MI event [25,26,29-31], were used to inform those parameters (Table 1 and Multimedia Appendix 1).

Finally, to avoid overestimating the economic benefits of preventing fatal cardiovascular events, we used the PAID 3.0 tool [63,66] to include future unrelated medical costs attributable to any increases in life expectancy with the intervention. The PAID 3.0 tool was developed to provide standardized, age- and sex-specific estimates of health care expenditures unrelated to the index condition that accrue in additional life-years following (preventive) interventions [63,66]. Incorporating these costs is recommended in economic evaluations to avoid overstating an intervention's net benefits [63].

Outcomes

Total quality-adjusted life years (QALYs) were calculated as the sum of utilities over all cycles, applying a discount rate of 1.5% per cycle [63]. Similarly to costs, our model accounts for state-specific utilities and transition-specific disutilities (all reported in Table 1). State-specific utilities represent the annual utility of patients *excluding* any acute, short-term burden associated with the acute transition events themselves (which were modeled as transition-specific disutilities).

The baseline annual utility of 0.83 for patients in the "At-risk, controlled BP" state was estimated using primary data from the matched prospective CVRM-Box cohort study [13]. From that baseline value, annual disutilities for uncontrolled BP and all postevent (stroke and MI) states were informed by published national catalogs of preference-based utility values across multiple chronic conditions (including CVD) [41-43], evidence from longitudinal studies on cardiovascular populations [32,44,48], population-based health-related quality of life analyses [45,47], and a systematic review/meta-analysis of utility weights in stroke patients [46]. Four of these studies also reported utility values that were used to derive our model's transition-specific disutility parameter estimates (Table 1) [32,43,44,48], as well as an additional vignette study [49].

Assumptions

As with every model, ours is subject to simplifying assumptions (details in Multimedia Appendix 2). First, there is no waning in effect nor change in adherence to the intervention, although this is addressed in later scenario analyses. Second, patients can only experience 1 recurrent event of the same type. Although third/fourth events occur in practice, these are much less frequent, and evidence to inform corresponding parameters is lacking. Third, the costs of a fatal event are equivalent to the lowest of the nonfatal events to avoid overestimating the benefit of preventing cardiovascular deaths.

XSL•FO
RenderX

Model Validation

The Technical Verification (TECH-VER) checklist was used to test our model's credibility and technical implementation [67]. The checklist consists of white-box and black-box tests designed to identify errors/inconsistencies in model implementation. The completed TECH-VER checklist is reported in Table S8 of Multimedia Appendix 1.

Uncertainty Analyses

Deterministic Sensitivity Analysis

To describe the influence of each model parameter on our results, we performed deterministic sensitivity analyses (DSAs) on all parameters assuming alternative (ie, 25% lower or 25% higher) point estimates.

Scenario Analyses

To explore the sensitivity of results to more general assumptions, 4 scenarios were explored: (1) starting age of 40 years, to explore how earlier receipt of the intervention influences cost-effectiveness; (2) the effectiveness of CVRM-Box decreases by 40% after 5 years, reflecting a reasonable reduction in adherence/discontinuation; (3) health care perspective (excluding nonhealth care costs) [63]; and (4) no discounting of costs and utilities [63].

BIA

To estimate the short- or medium-term budgetary requirements for rolling out CVRM-Box, we conducted 2 BIAs assuming rollout at the regional (South-Holland-North region) and national levels, with a time horizon of 5 years. The methodological approach and assumptions for both BIAs are detailed in Multimedia Appendix 2. Briefly, the South-Holland-North region has 10,256 patients eligible to receive the intervention over 5 years (8344 in the first year) [68]. For the national-level BIA, the corresponding eligible population was estimated at 2,177,350 (with 1,917,812 in the first year) based on publicly available data [69].

Workload Reduction in Care Delivery

RPM interventions may by design result in lower provider workload, an outcome not completely captured by cost-effectiveness analyses or BIAs. Therefore, we conducted an additional exploratory workload analysis to estimate potential savings in time and resource utilization with the intervention. We estimated the annual reduction/change in (1) time spent on patient contacts (short and long visits) and (2) number of e-consultations per GP and PN in a reference Dutch primary care practice (in Dutch, a "normpraktijk"). A reference primary care practice in the Netherlands has on average 1 GP, 0.83 PNs, and 2100 registered patients [70], of which 420 have a history or high risk of CVD [68].

To estimate the amount of time spent on care by GPs and PNs annually, we used data from the CVRM-Box prospective study [13] about the frequency of e-consultations, short visits, and long visits with GPs and PNs (by subgroups of controlled and uncontrolled BP). These per-patient frequencies were converted to expected practice-level annual volumes by multiplying (for each BP-control subgroup and contact type) the relevant per-patient frequency by the expected number of eligible patients with CVD in a reference primary care practice: 2100 registered patients × 420/2100 patients with CVD × 55% assumed eligible=231 eligible patients per practice. This eligible practice population was then split into controlled and uncontrolled BP according to our main analysis proportions. Annual time requirements (hours) per provider were calculated by multiplying expected annual visit counts by standard scheduled visit durations and dividing by the number of practitioners per reference primary care practice (1 GP; 0.83 PN), while remote consultations were reported as annual counts per provider. Consistent with current practice in the Netherlands, a short visit was calculated to last 10 minutes (with the GP) and 15 minutes (with a PN), while long visits lasted 20 minutes (with a GP) and 30 minutes (with a PN), respectively. The complete formulas and assumptions are provided in Multimedia Appendix 2.

Results

Main Analysis

Overall, CVRM-Box was €924 (95% CrI –467 to 2238) more costly and yielded 0.05 (95% CrI –0.02 to 0.12) more QALYs than CaU, resulting in an ICER of €17,340 per QALY gained (Table 2) from a societal perspective (EUR €1=US $1.11 as of 29 December 2023). At the commonly applied willingness-to-pay threshold of €20,000/QALY for prevention in the Netherlands, the overall probability of CVRM-Box being cost-effective over CaU was 60% (Figure 2A).

In terms of subgroup-specific results, CVRM-Box was ≥70% likely to be cost-effective and had ICERs below €20,000/QALY in all subgroups except for patients with controlled BP and no history of MI/stroke (Table 2 and Figure 2A). For the latter subgroup, the higher ICER of €42,384/QALY was mainly explained by the fact that CVRM-Box did not meaningfully influence MACE rates in this group of patients, in which BP levels were already within target range.

Figure 2. Cost-effectiveness acceptability curves (A) and deterministic sensitivity analysis results (B). (A) The curves represent the probability that CVRM-Box is cost-effective compared to CaU for each willingness to pay on the x-axis. (B) The "Base" values are the parameter values used in the main analysis (Table 1), while the "Lower" and "Upper" values are plausible alternative values. BP: blood pressure (systolic); CaU: care as usual; ICER: incremental cost-effectiveness ratio; SBP: systolic blood pressure.

(B)

Parameter	Base	Lower	Upper
Annual cost intervention, controlled BP	88	67	112
Annual cost intervention, uncontrolled BP	94	71	119
Annual cost under CaU, controlled BP	61	46	77
Annual cost under CaU, uncontrolled BP	77	57	96
Baseline utility (at−risk, no hypertension)	0.83	0.73	0.93
SBP reduction intervention, uncontrolled BP	3.5	2.7	4.5
SBP reduction intervention, controlled BP	1.36	1.02	1.71
Initial intervention cost	213	160	266
Smoking cessation proportion, intervention	0.11	0.08	0.14
Incremental state cost, poststroke	9609	7207	12011

DSA

The most influential model parameters were the annual costs of CVRM-Box and CaU (Figure 2B). The model's sensitivity to these parameters was largely due to the fact that QALY gains with the intervention were small, making differences in costs more influential (especially costs that apply to the entire cohort). All other parameters had a much lower influence on the estimated ICERs.

Scenario Analyses

The scenario assuming no discounting and the scenario assuming a waning effect of the intervention resulted in ICERs above €20,000/QALY, while a starting age of 40 decreased the overall ICER to €15,087/QALY (Table 2). Subgroup-specific scenario analysis results (Table S9 of Multimedia Appendix 1) showed that the ICERs for CVRM-Box were consistently below €20,000/QALY, with few exceptions in the subgroups with no history of MI/stroke, in line with our main analysis.

Budget Impact

The pooled budget impact of CVRM-Box was €2.9 million assuming regional rollout (10,256 patients) and €662.2 million assuming national rollout (1,917,812 patients) over 5 years. Nearly 60% of the overall budget impact was attributable to patients with controlled BP and no history of MI/stroke (Figure S1 of Multimedia Appendix 1), due to the fact that the higher intervention costs were not compensated by the (few) prevented events in this subgroup. Conversely, the budget impact was much lower in other subgroups, ranging from €0.26 to €1.01 million at the regional level and €59.3 to €232.5 million at the national level (Figure S1 of Multimedia Appendix 1). This was

XSL•FO
RenderX

especially the case in the subgroup with uncontrolled BP and a history of MI/stroke, where the 5-year budget impact was slightly negative.

Workload Reduction

Assuming a reference Dutch primary care practice, CVRM-Box would be expected to require more time spent on long visits with patients and less time spent on short visits each year (Table 3). The reduction in time spent on short visits compensated for the additional workload on long visits, resulting in a net annual reduction in workload that was substantial for PNs but negligible for GPs. Annually, PNs would spend 25.9 fewer hours on patient contacts and handle 44.7 fewer remote consultations, whereas the corresponding change for GPs was small (0.5 h and 3.3 fewer remote consultations). The greatest workload reductions were among PNs treating patients with uncontrolled BP (Table S10 of Multimedia Appendix 1).

Table . Annual expected reductions in workload with the intervention, per general practitioner and practice nurse in a reference Dutch primary care practice[a].

Care activity	CVRM[b]-Box, annual workload	Care as usual, annual workload	Annual increase (+) or reduction (−) with intervention
Per practice nurse			
Long patient contacts[c]	157.7 hours	147.2 hours	+10.5 hours
Short patient contacts[d]	94.7 hours	131.1 hours	–36.4 hours
All patient contacts (sum)	252.4 hours	278.3 hours	–25.9 hours
Remote consultations	167.0 consultations	211.7 consultations	–44.7 consultations
Per general practitioner			
Long patient contacts[c]	4.6 hours	4.2 hours	+0.4 hours
Short patient contacts[d]	2.8 hours	3.7 hours	–0.9 hours
All patient contacts (sum)	7.4 hours	7.9 hours	–0.5 hours
Remote consultations	6.9 consultations	10.2 consultations	–3.3 consultations

[a]"Hours" and "consultations" refer to annual amounts per general practitioner or practice nurse in a reference primary care practice assuming an eligible cardiovascular population of N=231 patients per practice (Multimedia Appendix 2).

[b]CVRM: cardiovascular remote management.

[c]Duration of 20 minutes with general practitioner and 30 minutes with practice nurse.

[d]Duration of 10 minutes with general practitioner and 15 minutes with practice nurse.

Discussion

Principal Findings

In this study, the long-term cost-effectiveness, budget impact, and workload reductions associated with the CVRM-Box implemented in primary care were assessed using a model-based evaluation. The CVRM-Box was highly likely to be cost-effective among patients with uncontrolled BP and/or a history of CVD, but not in patients with controlled BP and no history of CVD. Our BIA showed a similar pattern, where most of the incremental costs were attributable to this healthier subgroup. Together, these findings support considering the CVRM-Box primarily for high-risk subgroups, whereas broader adoption for lower-risk patients would require significant financial investment with insufficient QALY gains. Another key finding was that the CVRM-Box was expected to reduce the annual workload of PNs, who deliver the large majority of routine cardiovascular contacts in Dutch primary care. The corresponding change in GP workload was negligible, and because it is of a similar order to the one-off training and set-up required to adopt the intervention, we do not interpret it as a saving in GP time; the workload benefit is therefore essentially a PN benefit, which is where workforce pressure in Dutch primary care is greatest.

Our results were generally robust to extensive uncertainty analyses. Our DSA showed that the annual intervention costs were highly influential, suggesting that reducing the intervention costs would yield the greatest increase in cost-effectiveness. Our scenario analyses showed that delivering the intervention at a younger age (ie, 40 instead of 50 y) would improve cost-effectiveness, and that a 40% reduction in effectiveness/adherence after 5 years would not compromise cost-effectiveness in the 3 highest-risk subgroups (Table S9 of Multimedia Appendix 1).

Comparison With the Literature

Model-based evaluations of RPM interventions for CVD vary in methodology, making comparisons difficult. However, most studies—including ours—show cost-effectiveness for managing hypertension and long-term CVD [71-73]. In line with this, an economic evaluation of home-based cardiac telerehabilitation reported a high probability of cost-effectiveness despite nonsignificant differences in clinical outcomes and costs [74]. The BP reductions underlying our analysis are likewise consistent with this evidence base. Telemonitoring in the TASMINH4 trial lowered systolic pressure by 4.7 mm Hg relative to usual care [10], and comparable reductions are reported in an individual-patient-data meta-analysis of self-monitoring [75]. Reductions of this magnitude remain

XSL•FO
RenderX

clinically relevant at the population level, as an approximately 5 mm Hg systolic reduction has been associated with around a 10% lower risk of major cardiovascular events in a large individual-participant-data meta-analysis of BP-lowering treatment [76], corresponding to a meaningful absolute reduction in events for a scalable primary care population. Our findings contribute to ongoing discussions about the cost-effectiveness assessment processes for digital health interventions. In recent years, the focus has shifted from solely clinical outcomes and cost-effectiveness as value indicators to incorporating clinical workflows and health care professionals' perspectives [14,77,78]. As also found in our previous implementation studies of the CVRM-Box [14,15], stakeholders suggest that RPM's impact on health care professional workload is increasingly important, particularly in the context of labor shortages in primary care [14]. Despite this, current practices still prioritize (cost-)effectiveness and BIAs, while considerations related to workload reductions have not yet become mainstream. These indicators are high on the political agenda and are important to decision-makers as factors for the value of RPM in practice. We partly addressed this knowledge gap through our estimation of expected reductions in annual workload for GPs and PNs assuming scale-up in Dutch primary care centers. That said, our workload estimates should be interpreted as exploratory, as they are based on observed consultation frequencies from the prospective CVRM-Box study translated to a Dutch reference practice, and are not embedded within the state-transition model.

Importantly, scaling potential is not determined by economic considerations alone (eg, cost-effectiveness and budget impact). Our previous implementation studies identified additional practical factors influencing large-scale adoption [14,15]. Key barriers included additional clinical and technical tasks for health care professionals and uncertainties regarding reimbursement arrangements, while facilitators included early detection of at-risk patients, the presence of an implementation manager overseeing procedures and implementation metrics, and ambassador roles supporting adoption. Together, these findings reflect that economic evidence should be complemented by attention to practical implementation challenges when considering large-scale deployment of RPM interventions.

In a previous BIA study [79] where upscaling scenarios were calculated from one hospital ward to all Dutch hospitals, it was found that replacing in-hospital care with virtual care did not directly lead to cost savings within a single hospital ward due to labor-intensive virtual care services. The study suggested that minimal involvement of health care professionals, as applied in our intervention, was necessary. Similar to our findings, the previous study noted that scaling regionally (whole hospital) or nationally (all Dutch hospitals) resulted in cost savings relatively quickly. However, they observed cost savings for all patient groups, while we estimated potential cost savings exclusively in the subgroup with uncontrolled hypertension and a history of CVD. This discrepancy is likely due to differences in patient populations.

Strengths and Limitations

Economic evaluations always rely on assumptions, and despite our validation efforts using the TECH-VER checklist [67], several limitations remain. First, only 3 cardiovascular events were considered. Our choice of events, despite excluding other events like heart failure and sudden cardiac arrest, enabled us to simulate patient transitions using the state-of-the-art SCORE2 and SMART2 risk prediction models, which also focus on MI, stroke, and cardiovascular death. Importantly, long-term cardiovascular outcomes in our model were estimated indirectly through the SCORE2 and SMART2 risk prediction equations (rather than observed cardiovascular events), adding uncertainty to the modeled event rates. Second, the prospective CVRM-Box study had an effect on BMI, but we were not able to account for it due to lacking risk prediction models that include BMI as a predictor. This is a minor limitation, however, as reductions in BMI and BP are closely related, and including an independent effect on BMI would have only resulted in lower ICERs. Third, our exploratory analysis of workload reduction was subject to a higher degree of uncertainty than our main model-based analysis, as it did not use the state-transition model due to limited information about (changes in) consultation frequency per disease state. Nonetheless, even our indicative workload estimates are important for decision-makers given the current lack of data and literature on this question. Future studies should prioritize data collection on workload that can be incorporated into state-transition models to obtain more robust results. Relatedly, the estimated workload reductions should be interpreted as potential reductions in routine patient-contact time annually rather than net implementation time savings, as one-off implementation activities (eg, short training for GPs and PNs and ad hoc troubleshooting) were excluded from these calculations. As these implementation-related time investments apply to the practice population as a whole, their contribution to average annual workload per patient is expected to be negligible. Finally, importantly, our model did not account for transitions from uncontrolled to controlled BP status, potentially leading to more conservative estimates of cost-effectiveness. A microsimulation would address these challenges more effectively and allow for unique patient trajectories to be modeled.

A further consideration concerns the evidence on the intervention effect itself. The office-measured systolic reduction did not reach conventional statistical significance and was derived from a matched, controlled pre-post study rather than a randomized trial. Because the main analysis is probabilistic, the uncertainty in this estimate, including its CI, is carried through to the incremental cost and QALY distributions, which is why our cost-effectiveness conclusions are restricted to the higher-risk subgroups. A controlled pre-post design with broad inclusion criteria, such as that of the source prospective study [13], may also reflect the real-world effect more closely than a selective trial, and the proof of concept for home BP monitoring is already established in randomized trials. A placebo or regression-to-the-mean component in the home measurements, which lacked a control group, cannot be fully excluded, although these measurements avoid the well-known white-coat response [80,81] and the economic analysis relies on the office estimates that were matched to a control group.

Despite these limitations, our study has several strengths. A significant strength is our use of primary data from the matched

XSL•FO
RenderX

cohort study of CVRM-Box to inform key model parameters. Other key parameters, including risk factor data for the SCORE2 and SMART2 risk prediction models, came from primary data from the comprehensive ELAN database, which is representative of the current primary care CVD population in a large Dutch region [24]. Our extensive sensitivity and scenario analyses transparently reflect the influence of key assumptions and uncertainties on results, strengthening our overall conclusions.

Implications for Future Research and Practice

This study highlights the importance of incorporating diverse value indicators (ie, cost-effectiveness, budget impact, and workload) into the evaluation of digital health interventions. Payers often rely on payment- and results-based models to align incentives among payers, providers, and patients [77]. By integrating workload for health care professionals into the cost-effectiveness framework, our study offers a more comprehensive perspective to aid decision-making. Workload reductions may substantially influence resource allocation and reimbursement decisions for RPM interventions, particularly in the context of an increasingly constrained primary care workforce. However, real-world implementation decisions should also account for contextual factors not explicitly modeled here, including local staffing capacity, digital infrastructure and support requirements (eg, device logistics, interoperability with electronic health records), and equity considerations. Notably, provider incentive structures may also influence adoption and generalizability across health care systems. In systems with substantial capitation components, including Dutch primary care, the revenue impact of reduced in-person consultations is attenuated relative to predominantly fee-for-service settings, where additional incentive arrangements may be needed to support uptake. Beyond these payment arrangements, several further features of the Dutch setting shape how our findings should be read elsewhere. CVRM here is delivered through protocolized, integrated primary care programs that are largely PN-led, as described above, and is assessed against a relatively explicit national willingness-to-pay threshold for prevention; the intervention itself was financed through the regional shared-savings arrangement outlined in the *Methods*. Where care is instead more physician-led or fee-for-service, where a different cost-effectiveness threshold applies, or where such shared-savings arrangements are absent, the cost, workload, and adoption implications of CVRM-Box may differ appreciably even when its clinical effect is similar. The relative cost-effectiveness ranking across risk subgroups is therefore likely to transfer more readily than the absolute budget-impact and workload estimates, which are the most context-dependent and would need to be reestimated locally. Finally, future research should incorporate a wider range of value indicators focusing on key aspects such as provider workload, and should consider wider factors that may affect implementation.

Conclusion

This model-based evaluation of CVRM-Box found that the intervention is likely to be cost-effective in high-risk groups (uncontrolled hypertension or a history of CVD) and may reduce workload for health care professionals, while results are less favorable in lower-risk patients. In light of these findings, our findings support considering implementation in primary care, particularly for higher-risk subgroups. Regional considerations and subgroup-specific outcomes should be considered alongside other key factors such as local capacity or infrastructure and equity in decisions about the introduction and implementation of similar interventions. Importantly, because digital health interventions interact closely with the local health system, our findings should be interpreted primarily within the Dutch primary care context and may not directly generalize to health care systems with different organization, prices, or incentives.

Abstract

Background: In the management of gestational diabetes mellitus (GDM), the usual medical treatment requires frequent visits for glucose monitoring and insulin dose adjustment, and this imposes significant physical, psychological, and economic burdens on pregnant women. As mobile health platforms become increasingly integrated into diabetes care, telemedicine may help alleviate these burdens; however, evidence evaluating its effectiveness as a replacement for routine in-person GDM care remains limited.

Objective: This study aims to evaluate the impact of telemedicine on the quality of life and costs for patients with GDM requiring insulin therapy.

Methods: This single-center, 2-arm, randomized, open-label, parallel-group study included patients with GDM who started insulin injection therapy. Participants were randomized to either the telemedicine or standard face-to-face care groups for 10 (SD 2) weeks. The telemedicine intervention used a smartphone-linked platform that enabled the automatic transfer of glucose data from connected glucose meters and facilitated real-time video consultations. Primary end points included costs and patient satisfaction. Costs were assessed using claims data, transportation calculations, and wage-based productivity losses, while patient satisfaction was evaluated through changes in the Problem Areas in Diabetes Survey and Diabetes Therapy-Related Quality of Life questionnaire scores. Secondary outcomes included glycemic control and perinatal outcomes.

Results: In total, 38 participants were included, with 18 assigned to the telemedicine group and 20 to the standard care group. Total costs (32,712, 95% CI 15,412 - 50,013 vs 59,202, 95% CI 42,603 - 75,800 Japanese yen; $284, 95% CI 134 - 435 vs $515, 95% CI 370 - 659, purchasing power parity [PPP]–adjusted; *P*=.01), direct non–health care costs (922, 95% CI −240 to 2084 vs 2561, 95% CI 1447 - 3676 yen; $8, 95% CI −2 to 18 vs $22, 95% CI 13 to 32 PPP-adjusted; *P*=.02), and indirect costs (8981, 95% CI −7119 to 25,082 vs 32,832, 95% CI 17,384 - 48,279 yen; $78, 95% CI −62 to 218 vs $285, 95% CI 151 - 420 PPP-adjusted; *P*=.01) reduced significantly in the telemedicine group compared with the standard care group. The improvements in the Problem Areas in Diabetes Survey (−7.6, 95% CI −13.7 to −1.4; *P*=.02) and Diabetes Therapy–Related Quality of Life domain 1 (10.5, 95% CI 0.9-20.1; *P*=.03) scores from the baseline were significantly greater in the telemedicine group than that in the standard care group. Nonetheless, glycemic control and frequency of perinatal complications were comparable between the 2 groups. Consultation time was similar across groups, suggesting no added workload for clinicians.

Conclusions: In this randomized trial, mobile health–enabled telemedicine safely replaced routine in-person visits for patients with GDM requiring insulin therapy. Telemedicine significantly reduced psychological and economic burdens without compromising

XSL•FO
RenderX

glycemic or perinatal outcomes, demonstrating its value as a patient-centered and cost-efficient model of care. These findings support the broader implementation of mobile-based telemedicine approaches in GDM management.

KEYWORDS

gestational diabetes mellitus; telemedicine; mobile health; patient satisfaction; costs

Introduction

Background

The prevalence of gestational diabetes mellitus (GDM) is rising globally due to increasing obesity rates and an aging population of women of childbearing age. GDM affects approximately 6% to 15% of all pregnancies [1] and increases the risk of adverse perinatal outcomes, such as cesarean section, large-for-gestational-age (LGA) infants, macrosomia, shoulder dystocia, and neonatal hypoglycemia [2]. Additionally, GDM raises the long-term complication risks of obesity and impaired glucose metabolism in mothers and infants [3]. Therefore, strict blood glucose management through diet, exercise, and pharmacotherapy is essential. However, conventional treatment requires frequent visits every 2 to 3 weeks for glucose monitoring, thereby imposing significant physical, psychological, and economic burdens on pregnant women. Systematic reviews have revealed that these patients experience a significant decrease in the quality of life (QOL) [4]. Furthermore, evidence from Italy indicates that health care expenditures are 29.2% higher in pregnancies complicated by GDM than in those without GDM [5].

Rationale and Knowledge Gap

Recently, telemedicine, defined as the delivery of health care and the exchange of health care information across distances [6], has become widely prevalent. As a core component of mobile health (mHealth), smartphone-based telemedicine platforms enable real-time data sharing and remote clinical support. The effectiveness and economic efficiency of telemedicine have been demonstrated for many diseases [7-9]. Thus, further research into the safety and effectiveness of this approach for patients with GDM, and its impact on psychological and socioeconomic burdens is required.

Previous studies have shown significant findings. A meta-analysis of 7 randomized controlled trials (RCTs) demonstrated that telemedicine significantly improved Hemoglobin A_{1c} (HbA_{1c}) levels in patients with GDM [10]. A subsequent meta-analysis of 32 RCTs reported a reduced risk of perinatal complications using telemedicine [11]. However, studies on patient satisfaction with telemedicine and its impact on costs among this population remain limited. Mackillop et al [12] conducted an RCT comprising 203 patients with GDM, investigating the effectiveness of a mobile phone–based real-time blood glucose management system and assessing patient satisfaction and direct health care costs as secondary outcomes. The satisfaction score, assessed using the Maternity Diabetes Treatment Satisfaction Questionnaire, was slightly higher in the intervention group. However, the direct health care costs did not differ significantly between the 2 groups, and insulin users, who were considered to have a particularly high level of psychological burden, were excluded. Furthermore, in a nonrandomized controlled trial involving 161 patients with GDM, direct health care costs were evaluated between a conventional therapy group and a group receiving additional support through the online analysis of capillary glucose data. The intervention group showed a 16% reduction in direct health care costs. However, costs other than direct health care costs were not evaluated in this study [13].

Objective of the Study

Thus, based on a review of previous studies, the safety of telemedicine for patients with GDM is becoming clearer. However, no studies in Japan or other countries have examined the effects of telemedicine on psychological burden or costs as primary outcomes for patients with GDM. Furthermore, no reports have revealed how telemedicine use in this population affects not only direct health care costs but also direct non–health care costs, such as transportation expenses or indirect costs, such as production loss due to absenteeism. Therefore, we conducted a prospective randomized controlled trial to investigate the impact of telemedicine on QOL and costs, particularly in patients with GDM who received insulin injections.

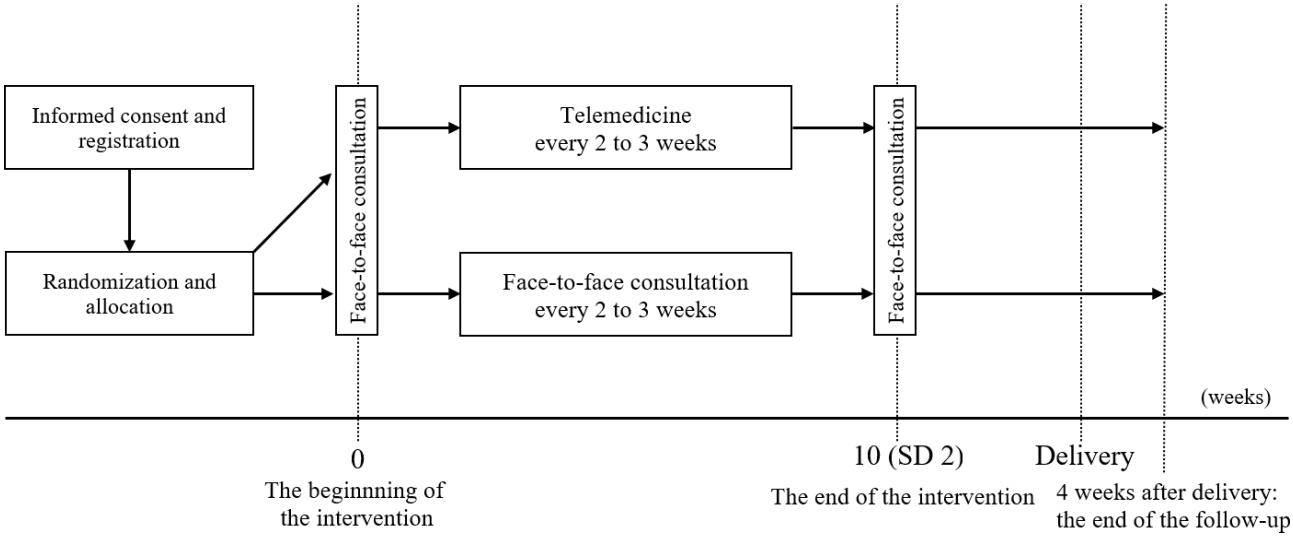
Methods

Study Design and Participants

TELEGLAM (efficacy and safety of a telemedicine system in patients with gestational diabetes mellitus) was a single-center, 2-arm, randomized, open-label, parallel-group study. We included patients attending the Department of Endocrinology, Metabolism and Nephrology, Keio University School of Medicine in Japan. The study was performed between February 7, 2022, and March 3, 2024. Its protocol has been previously described in detail [14]. Participants were eligible for inclusion if they met the following criteria: (1) diagnosed with GDM through an oral glucose tolerance test (OGTT) by 29 weeks and 6 days of gestation, underwent self-monitoring of blood glucose, and received insulin injections; (2) provided written informed consent; and (3) could operate the telemedicine system. In our hospital, the first trimester screening for GDM was performed for high-risk patients as reported previously [15]. If the first trimester screening for GDM was negative or positive but OGTT was negative, pregnant women had to undergo the 50-g glucose challenge test at approximately 24 gestational weeks. If the patients were glucose challenge test–positive, they underwent

XSL•FO
RenderX

OGTT at 24 to 28 gestational weeks [16]. Furthermore, GDM was diagnosed following the International Association of Diabetes and Pregnancy Study Groups Consensus Panel [17]: fasting plasma glucose ≥5.1 mmol/L (92 mg/dL) and/or 1-hour plasma glucose ≥10.0 mmol/L (180 mg/dL), and/or 2-hour plasma glucose ≥8.5 mmol/L (153 mg/dL). The target range of glycemic control was set at a preprandial blood glucose level of 5.6 mmol/L (100 mg/dL) and a 2-hour postprandial blood glucose level of 6.7 mmol/L (120 mg/dL). Insulin therapy was initiated if these targets were not achieved through diet and exercise. Exclusion criteria included (1) a GDM diagnosis after 30 weeks of gestation, (2) overt diabetes in pregnancy, (3) type 2 diabetes, (4) type 1 diabetes, (5) serious uncontrolled complications, (6) pacemakers or other implantable medical devices, (7) unwillingness to participate in the study, (8) being judged inappropriate to participate in the study by the physicians (eg, difficulties in understanding Japanese, refusal to treat GDM, difficulty in making regular visits to the hospital), (9) those without the necessary internet access for telemedicine, and (10) those who did not use smartphones.



Ethical Considerations

The study protocol was approved by the Keio University School of Medicine Ethics Committee on February 7, 2022 (approval number: 20211125) and registered with the University Hospital Medical Information Network Clinical Trials Registry (UMIN000047009) in Japan. The protocols adhered to the principles of the Declaration of Helsinki. Written informed consent was obtained from all participants prior to enrollment. Participants were informed of the study purpose, procedures, potential risks, and their right to withdraw at any time without providing a reason. All collected data were deidentified before analysis. Clinical information and glucose data were stored on secure institutional servers accessible only to authorized study personnel. No personally identifiable information was used in the analytic dataset. Participants did not receive financial or material compensation for their participation in this study.

Intervention and Control

Telemedicine was provided to the patients in the intervention group using the MeDaCa telemedicine system developed by Medical Data Card Inc (Tokyo, Japan). This system connects a medical facility's computer with a patient's smartphone, tablet, or computer via the internet, enabling real-time video consultations similar to face-to-face visits. We did not include lifestyle interventions using smartphone apps, which enabled us to examine the effects of switching from face-to-face consultations to telemedicine. At Keio University, the One Touch Verio Reflect glucose meter (LifeScan Inc) was linked to MeDaCa. This allowed MeDaCa to automatically import blood glucose measurement data. The intervention period began at the first outpatient visit after the initiation of insulin injection and self-monitoring of blood glucose and ended 10 (SD 2) weeks later (Figure 1). In the intervention group, face-to-face consultations were conducted at the beginning and end of the intervention period, and telemedicine was conducted every 2 to 3 weeks in the interim period. In the control group, the patients were examined face-to-face every 2 to 3 weeks as usual. During this study, unscheduled visits were available at any time in both groups. Nurses provided telephone support as needed, and guidance on diet and exercise was similarly provided by doctors, nurses, and registered dietitians in both groups. The prenatal checkup was conducted as usual. Baseline and follow-up clinical information was obtained from outpatient visits and the hospital's electronic medical record system, and glucose data were transmitted through the telemedicine system. No automated or manual reminders were used during the intervention.

Figure 1. Trial design. In the intervention group, face-to-face consultations were conducted at the beginning and end of the intervention period, and telemedicine was conducted every 2 to 3 weeks in the interim period. In the control group, the patients were examined face-to-face every 2 to 3 weeks, as usual.

Outcomes

Primary Outcomes

In this study, we performed a cost-consequence analysis (CCA). CCA is defined as "a form of health economic evaluation study in which all direct and indirect costs and a catalog of different outcomes of all alternatives are listed separately" [18]. Therefore, multiple primary end points were established, focusing on health economic indicators and patient satisfaction. The health economic indicators included (1) direct health care costs, (2) direct non–health care costs, and (3) indirect costs. The actual costs incurred by medical examinations were evaluated as direct health care costs using the claims data, while direct non–health care costs, such as transportation costs, were calculated using Google Maps based on the patient's home or work address. Indirect costs, defined as production losses due to the inability to work because of the disease, were calculated from sick leave hours and the average wage in Japan if the patient was employed. Additionally, indirect costs associated with childcare were also considered, such as leaving a child with a babysitter for a hospital visit or a spouse taking a leave. The costs are presented in Japanese yen (¥), and US $1 was equivalent to 140.56 yen based on the exchange rate between January 2023 and January 2024. Furthermore, to facilitate international cost comparisons, we also converted all cost variables into purchasing power parity (PPP)–adjusted international dollars using a conversion factor of 115 yen per international dollar.

Moreover, we assessed patient satisfaction using the Problem Areas in Diabetes Survey (PAID) [19,20] and the Diabetes Therapy–Related QOL (DTR-QOL) questionnaire [21], both of which were used in their original, unmodified forms. Notably, PAID is a self-administered questionnaire comprising 20 items that measure diabetes-related psychological burdens. Each question was rated on a scale of 1 to 5, and the total score was evaluated. A lower score indicated a lesser psychological burden. The DTR-QOL is a questionnaire that assesses the influence of diabetes treatment on patient QOL, regardless of the treatment method. It comprises 29 questions divided into 4 domains, with each question answered on a scale of 1 to 7. Domain 1 assesses the burden on social and daily activities, domain 2 evaluates anxiety and dissatisfaction with treatment, domain 3 assesses hypoglycemia, and domain 4 evaluates satisfaction with the treatment. A higher score indicates a better QOL. The results were presented as the total scores for each domain, converted to a scale of 100 points. Participants completed the questionnaires at both the start and the end of the intervention, and the change from baseline was evaluated.

Secondary Outcomes

Secondary outcomes included changes in glycemic control indicators and metabolic parameters between the start and end of the intervention and perinatal outcomes. We evaluated fasting and postprandial blood glucose levels from self-monitoring records, total insulin dose, plasma glucose, HbA_{1c}, and glycated albumin as glycemic control indicators. Furthermore, maternal weight, BMI, systolic blood pressure (SBP), diastolic blood pressure (DBP), low-density lipoprotein cholesterol, high-density lipoprotein cholesterol, triglyceride, C peptide, and the urinary albumin-to-creatinine ratio were evaluated as metabolic parameters. BMI was defined as weight in kilograms divided by the square of height in meters. Perinatal outcomes were evaluated based on the following: gestational age; mode of delivery; obstetric complications occurring during the perinatal period, such as premature rupture of the membrane, postpartum hemorrhage, and shoulder dystocia; maternal complications such as gestational hypertension; fetal indices including sex, height, weight, neonatal hypoglycemia, Apgar score (1 min/5 min), umbilical artery pH, macrosomia (>4000 g), low birth weight (<2500 g), LGA (>90th percentile), and small for gestational age (<10th percentile); incidence of congenital diseases; and admission to the neonatal intensive care unit. Additionally, neonatal hypoglycemia was defined as a blood glucose level of <40 mg/dL, and blood glucose was measured using point-of-care testing equipment. We used an intervention criterion of <50 mg/dL.

As an exploratory evaluation item, we measured the time spent in consultation based on the medical records for both groups.

Sample Size

The exploratory nature of the study made it difficult to predict parameter changes because no clinical study had used the PAID or the DTR-QOL for patients with GDM. Of the primary end points, the PAID was assumed to be the least likely to change with intervention. We estimated PAID scores to be similar between the groups before the intervention, with a 10-point difference emerging postintervention based on previous studies using the PAID [22,23]. To achieve a significance level of .05 in a 2-sided test with 80% power, assuming an SD of 10 points, the required sample size was estimated at 32 participants. Accounting for a 20% dropout rate, the target sample size was set at 40 participants.

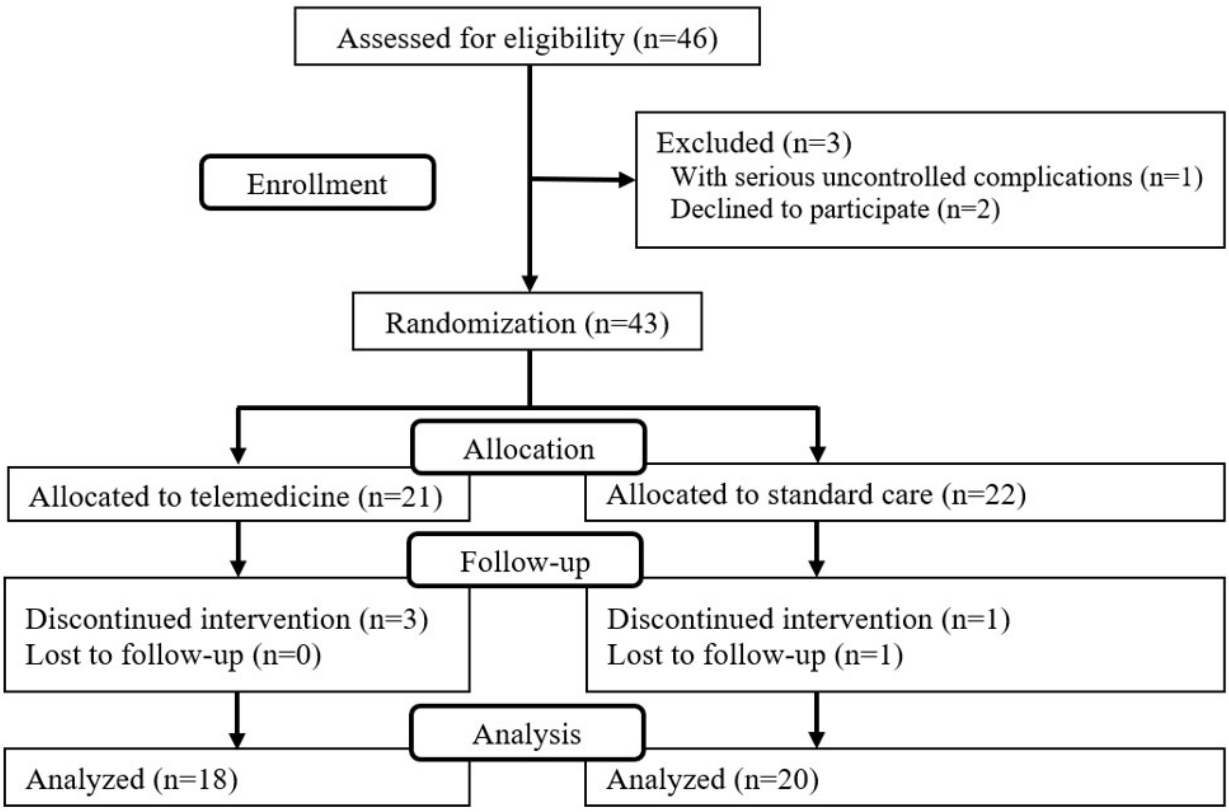
Randomization

We performed randomization in a 1:1 ratio using a modified minimization method with a biased-coin assignment balancing maternal age (≤39 years old vs ≥40 years old), prepregnancy obesity, history of GDM, number of fetuses (singleton vs twins or higher order pregnancy), and ethnicity. The University Hospital Medical Information Network Internet Data and Information System for Clinical and Epidemiological Research (Cloud version) was used for randomization. A physician not involved in the study created the allocation registration form. Participants and physicians were not blinded to the treatment allocation.

Statistical Analysis

Primary and secondary outcomes were analyzed in the full analysis set, which included all patients who completed at least 2 online consultations during the study period and did not violate any of its protocols. Summary statistics comprised frequencies and proportions for categorical variables and means and SDs or medians with IQRs for continuous variables for the baseline characteristics. Categorical variables were compared using chi-square tests, while continuous variables were compared using the 2-tailed *t* test or Wilcoxon rank-sum test. For the primary end points, representative statistics were calculated for each measurement point, and an analysis of covariance was

XSL•FO
RenderX



conducted. The analysis of covariance model included the following covariates: treatment group, maternal age, prepregnancy obesity, history of GDM, and number of fetuses. Secondary end points were analyzed similarly to the primary end points. All comparisons were preplanned, and all *P* values were 2-sided. A *P* value of <.05 was considered statistically significant. Statistical analyses were conducted using IBM SPSS Statistics software for Windows (version 28.0.0.0; IBM Corp).

Results

Patient Flow and Study Population

In total, 46 patients were initially selected for the study between February 7, 2022, and March 3, 2024. Of these, 1 patient was excluded due to serious uncontrolled complications, and 2 patients declined to participate, resulting in the enrollment of 43 patients. We randomly assigned these patients to the telemedicine group (intervention group) or the standard care group (control group). In the telemedicine group, 3 patients delivered before the study concluded, whereas in the standard care group, 1 patient delivered early, and 1 patient was lost to follow-up. Consequently, the full analysis set included 38 patients: 18 in the telemedicine group and 20 in the standard care group (Figure 2).

Figure 2. Flow diagram of patient enrollment.

Baseline Characteristics

Baseline characteristics were comparable between the groups, excluding C peptide, triglyceride, and the proportion of target glucose levels in the previous 7 days (Table 1). The mean age was 37.1 (SD 4.6) years and 35.8 (SD 4.1) years in the intervention and control groups, respectively, with a BMI of 24.7 (SD 4.3) and 24.0 (SD 4.1) kg/m², respectively. All patients, except 1 in the control group, were Japanese. The proportion of working patients was 72% (n=13) and 70% (n=14) in the intervention and control groups, respectively. Additionally, the mean daily insulin dose at the start of the intervention was 10.5 (SD 8.4) U/day and 9.8 (SD 9.1) U/day, respectively. At baseline, there were no significant differences in the PAID and DTR-QOL questionnaire scores between the 2 groups.

Primary Outcomes

The results of the CCA are shown in Tables 2 and 3. Regarding health economic indicators, the direct health care costs were comparable between the 2 groups. However, the telemedicine group had significantly lower direct non–health care costs (922, 95% CI −240 to 2083 vs 2561, 95% CI 1447 - 3676 yen; $8 95% CI −2 to 18 vs $22, 95% CI 13 - 32 PPP-adjusted; *P*=.02), indirect costs (8981, 95% CI −7119 to 25,082 vs 32,832, 95% CI 17,384 - 48,279 yen; $78, 95% CI −62 to 218 vs $285, 95% CI 151 - 420 PPP-adjusted; *P*=.01), and total costs (32,712, 95% CI 15,412 - 50,013 vs 59,202, 95% CI 42,603 - 75,800 yen; $284, 95% CI 134 - 435 vs $515, 95% CI 370 - 659 PPP-adjusted; *P*=.01) than the standard care group. Notably, policies were implemented during the COVID-19 pandemic to promote remote telemedicine to reduce crowding in medical institutions. However, as the number of infections decreased, these policies were discontinued, leading to changes in direct health care costs related to telemedicine during the study period. Therefore, we also analyzed the direct health care costs assuming telemedicine costs were equivalent to face-to-face consultations, and the results were consistent with those obtained using actual costs (Multimedia Appendix 1).

Table . Primary outcomes—cost consequence analysis of health economic indicators.

Variables	Telemedicine group (n=18)		Standard care group (n=20)		Mean difference		*P* value
	Yen (95% CI)	PPP[a]-adjusted dollars (95% CI)	Yen (95% CI)	PPP-adjusted dollars (95% CI)	Yen (95% CI)	PPP-adjusted dollars (95% CI)	
Costs

[a]PAID, Problem Areas in Diabetes Survey.

[b]DTR-QOL, Diabetes Therapy-Related QOL.

Regarding patient satisfaction, improvements in PAID (−7.6, 95% CI −13.7 to −1.4; *P*=.02) and DTR-QOL domain 1 scores (10.5, 95% CI 0.9 - 20.1; *P*=.03) from the baseline were significantly greater in the telemedicine group than in the standard care group. Changes in DTR-QOL domain 2, 3, and 4 scores were comparable between the 2 groups.

Secondary Outcomes

Maternal metabolic parameters and perinatal outcomes are shown in Tables 4 and 5. We observed a trend toward greater maternal weight gain in the telemedicine group; however, the difference was not statistically significant (group difference in change: 1.1 kg, 95% CI −0.6 to 2.7 kg; *P*=.19). Furthermore, the SBP and DBP decreased in the telemedicine group and increased in the control group; however, these differences were not significant (change in SBP between the groups: −8.4 mm Hg, 95% CI −17.7 to 0.9 mm Hg; *P*=.08; DBP difference: −5.5 mm Hg, 95% CI −13.9 to 3.0 mm Hg; *P*=.20). Changes in glucose and lipid parameters were similar between the groups.

[a]Not applicable.

[b]NICU: neonatal intensive care unit.

Gestational age at delivery, mode of delivery, and the frequency of other perinatal complications were similar between the groups. There were no significant differences in neonatal height, weight, frequency of neonatal hypoglycemia, Apgar score, umbilical artery pH, or admission to the neonatal intensive care unit. Additionally, the time required for consultations per person was similar between the groups (543.7, 95% CI 490.2 - 597.3 s vs 518.2 95% CI 466.8 - 569.6 s, *P*=.41).

Discussion

Principal Findings

This study demonstrates that telemedicine use for GDM management improves patient satisfaction and reduces total costs, with comparable glycemic control and perinatal complications between the 2 groups. Thus, mHealth-supported telemedicine in the management of GDM can be a cost-saving technology providing better patient satisfaction. To the best of our knowledge, this is the first study to evaluate the impact of telemedicine on both psychological burden and total costs in patients with GDM.

XSL•FO
RenderX

Comparison With Previous Studies

Several previous studies have examined the effects of interventions through telemedicine or mobile apps for patients with GDM, in addition to regular consultations. These studies reported a reduced incidence of metabolic syndrome [24], decreased weight gain [25], higher rates of achieving target blood glucose levels [26], and a shorter time to reach target blood glucose levels [27]. Our findings share similarities with previous studies reporting a slight improvement in satisfaction scores with a mobile phone–based glucose management system [12] and a reduction in direct medical costs [13]. However, important differences remain because those earlier studies were performed alongside regular in-person consultations and did not evaluate the direct non–health care costs and indirect costs.

Clinical and Economic Implications

The impact of telemedicine on costs for patients with GDM has been previously reported [12,13]; however, these reports focused solely on direct health care costs. In our study, we evaluated the direct non–health care costs and indirect costs, accounting for a significant portion of the actual patient and societal burdens. The evaluation revealed that both costs were significantly lower in the telemedicine group, which may have contributed to the improvement in patient satisfaction. Although findings from a systematic review suggest that telemedicine holds a favorable level of economic efficiency [28], reports on the effectiveness and safety of telemedicine for managing GDM in Japan are lacking. Japan's health care system uses a universal coverage model, and medical services are priced using a unified fee schedule. The typical copayment rate is 30%, with the remainder covered by public health insurance, ensuring universal access to health care. Moreover, the official fees for telemedicine are lower than those for face-to-face consultations in Japan, which is presumed to be a factor hindering its broader adoption. Considering the positive impact on the economic and psychological burdens shown in this study, we believe that these findings could support raising the official fee for telemedicine to the same level as regular consultations for patients with GDM.

Regarding the safety of telemedicine as a replacement for regular clinical visits, an RCT comprising 100 patients with GDM reported that HbA_{1c} levels, the rate of cesarean sections, and the rate of LGA infants were comparable between the groups [29]. Furthermore, a similar report in 2023 indicated that there was no deterioration in glycemic control or increase in perinatal complications and that the telemedicine group had a significantly higher rate of achieving postprandial blood glucose targets [30]. Considering these previous research results, the safety of replacing regular clinical visits with telemedicine has been demonstrated. Most meta-analyses examining the effectiveness of telemedicine in patients with GDM combined studies that used telemedicine in addition to regular clinical visits with those that used telemedicine as a replacement. These analyses also consistently showed favorable results for telemedicine, including improvements in HbA_{1c} levels [10,31] and reductions in the risk of perinatal complications [11]. In our study, the 2 groups exhibited comparable glycemic control and perinatal outcomes, reaffirming the safety as reported in previous studies. The improvements in glycemic control and a reduction in perinatal complications, as observed in other studies, were not seen in this study possibly because of the sample size of this study. Additionally, it was speculated that the interventions of telemedicine or applications, which were conducted in other studies alongside routine care, may have influenced the results.

In this study, the consultation time was measured as an exploratory evaluation item. Considering the preparation required for the telemedicine system, we anticipated that the consultation time would be longer in the intervention group. However, the actual consultation time was comparable between the groups, suggesting that the burden on health care providers was similar in both groups, thereby highlighting the value of the reduced costs and psychological burden observed in the telemedicine group.

Policy Implications

The findings of this study have important implications for health policy and clinical practice. The observed reductions in psychological burden and costs suggest that structured telemedicine pathways may serve as an efficient alternative to conventional in-person GDM management. Incorporating such pathways into routine prenatal diabetes care has the potential to reduce patient time burdens and improve access to care. To achieve broader implementation, it will be essential to establish reimbursement models that appropriately cover telemedicine-based follow-up visits and digital monitoring.

Limitations

This study has some limitations. First, due to its design, blinding was challenging, which may have introduced clinical bias. Second, the study primarily involved Japanese patients residing in urban areas; hence, further research is needed in other settings and among different ethnic groups. Third, the small sample size reduced the power to detect infrequent complications evaluated as secondary outcomes. Fourth, we did not consider internet communication costs or the expenses associated with implementing the telemedicine system in medical institutions. While it is assumed that most participants conducted their consultations in an environment with Wi-Fi, additional costs may have been incurred. Finally, the questionnaire used was originally designed for patients with diabetes mellitus, not GDM. This limitation was communicated to participants on a separate sheet as a precaution.

Conclusions

In conclusion, TELEGLAM is the first study to examine the impact of telemedicine on psychological burdens and total costs in patients with GDM. In this study, we demonstrated that substituting regular consultations with telemedicine for patients with GDM reduced both psychological and economic burdens. Our results underscore the potential of mHealth-enabled telemedicine as a safe and effective substitute for conventional in-person GDM management, and we anticipate that these findings will support its broader implementation in clinical care. To translate these benefits into practice, health systems should integrate telemedicine into routine prenatal diabetes care and adopt policies that reduce financial and psychological burdens for patients.

Abstract

Background: The management of chronic obstructive pulmonary disease (COPD) places a significant burden on health care systems worldwide. Home noninvasive positive pressure ventilation (NPPV) is an established treatment option associated with significant benefits for patients with COPD and hypercapnic chronic respiratory failure. Internet of Things (IoT)–based management may improve communication between patients and physicians and strengthen the integration and comprehensiveness of home NPPV telemonitoring. However, the economic value of such systems remains insufficiently understood.

Objective: This study aimed to assess the cost-effectiveness of IoT-based management versus standard management of home NPPV in patients with COPD and hypercapnic chronic respiratory failure.

Methods: A Markov decision analytic model was developed to simulate real-world COPD progression and predict health outcomes and costs associated with IoT-based and standard management of home NPPV. COPD progression consisted of 4 health states: stable period, nonserious exacerbation period, serious exacerbation period, and death. Efficacy and cost inputs were primarily sourced from a published multicenter, prospective, randomized controlled trial and supplemented by official Chinese databases where necessary. Quality-adjusted life years (QALYs) were used as effect indicators for this model, which were derived from COPD Assessment Test scores. The discounted lifetime cost per QALY gained was calculated from the Chinese health care payer perspective, and sensitivity analyses were conducted to test the robustness of model results across different assumptions.

Results: Compared with standard NPPV, IoT-based NPPV increased costs by ¥3607.26 and improved QALYs by 0.24 per person across the lifetime horizon, resulting in an incremental cost-effectiveness ratio of ¥15,030.25 per QALY, with a 93.6% probability of being cost-effective at the given willingness-to-pay threshold (currency conversion to US dollars was based on the average exchange rate in 2019 [US $1=¥6.9]). Base case results were also robust to multiple one-way sensitivity analyses, with the main drivers being hospitalization costs for the standard and IoT-based NPPV groups during the serious exacerbation period.

Conclusions: IoT-based NPPV was cost-effective compared with standard NPPV for patients with COPD and hypercapnic chronic respiratory failure.

Introduction

Chronic obstructive pulmonary disease (COPD) is a chronic airway disease characterized by airflow obstruction, with a high rate of disability and mortality, and it is also one of the diseases that need to be prevented and controlled by the Healthy China Initiative (2019 - 2030) [1]. COPD is the sixth leading driver of the global burden of disease and imposes a substantial economic burden [2]. From 1990 to 2023, COPD consistently ranked among the top three level 3 causes of age-standardized mortality attributable to noncommunicable diseases in China [3]. The annual per capita direct medical cost for patients with COPD in China accounted for 33.33% to 118.09% of the local average annual income [4], with hospitalization and home oxygen therapy being the main driving factors for direct costs [5]. It is estimated that COPD will cost the world economy Int $4.326 trillion from 2020 to 2050, with China and the United States facing the largest economic burden of COPD [6]. With population aging in China, the burden of COPD is still rising. The prevention and control of COPD remain challenging. Effective management of stable patients with COPD is essential to improve their quality of life and reduce medical costs. Therefore, seeking the most economical and effective treatment and management program for patients with COPD is imperative.

A recent meta-analysis confirmed that home noninvasive positive pressure ventilation (NPPV) in treating patients with hypercapnic COPD was significantly associated with a lower mortality risk, all-cause hospital admission, and intubation [7]. The 2023 report of the Global Initiative for Chronic Obstructive Lung Disease (GOLD) [8], the latest guidelines from the European Respiratory Society [9], and the American Thoracic Society [10] support the use of home NPPV for patients with stable hypercapnic COPD. Therefore, NPPV has become an established treatment for patients with stable hypercapnic COPD. Telemonitoring of home NPPV is an important tool for optimizing follow-up. Using the Internet of Things (IoT)–based medical platform may improve the integration and comprehensiveness of telemonitoring and management of home NPPV [11]. The IoT cloud platform collects information on adherence, ventilator parameters, and physiological indicators and provides daily reports and follow-up summaries to the health care team. Therefore, it could improve the exchange of information between patients and physicians who prescribed NPPV, and between health professionals and the external companies that provide ventilator services, deliver individualized and fully integrated care management, as well as respond quickly to patient needs. These factors are crucial for guaranteeing treatment adherence and effectiveness. Relevant studies also showed that IoT-based home NPPV management is emerging and has produced positive results [12,13].

Hospitalization costs are a major component of the total cost of COPD exacerbations [14]. The use of IoT may save costs by reducing avoidable hospitalizations [15-17]. These potential cost savings need to offset the increased costs associated with IoT services. Therefore, it is vital to investigate the influence of IoT on the overall use of health care resources and to evaluate its cost-effectiveness to determine whether it represents a good value for money. A small number of studies have confirmed that in patients with chronic respiratory failure caused by neuromuscular or thoracic diseases (eg, obstructive sleep apnea, amyotrophic lateral sclerosis, and barrel chest), telemedicine-based continuous NPPV is more cost-effective than traditional follow-up and care [18-22]. However, there are few economic assessments for patients with COPD, and their cost-effectiveness remains uncertain [23-27]. Therefore, more studies from different countries are needed to determine whether IoT-based telemonitoring is more cost-effective. Therefore, we built a Markov model based on a randomized controlled prospective study [28] to simulate and analyze the long-term cost-effectiveness of IoT-based management of home NPPV treatment in patients with COPD and hypercapnic chronic respiratory failure and provide a basis for decision-making regarding the rational selection of COPD treatment strategies.

Methods

Analytical Method

A Markov decision analytical model was built with Microsoft Excel 2016 software to estimate the long-term cost-effectiveness of IoT-based (intervention) versus standard NPPV (control) in patients with COPD and hypercapnic chronic respiratory failure.

Patient Population

This study was based on a multicenter, prospective, randomized controlled trial (RCT; ChiCTR1800019536), which evaluated the effectiveness and safety of IoT-based management of home NPPV for patients with COPD and hypercapnic chronic respiratory failure in China. The trial was conducted over 12 months and involved 148 patients with a mean baseline age of 70.18 years and GOLD grades III-IV [29]. Patients were randomly allocated in a 1:1 ratio to the 2 study groups based on a computer-generated random number sequence implemented by an independent data center [28]. Both groups initiated oxygen therapy and NPPV treatment in the hospital, with an identical ventilator parameter titration protocol during hospitalization, and were discharged after meeting the treatment targets.

In the standard NPPV (control group; n=75), patients were advised to use home oxygen therapy for at least 12 hours per day and home NPPV intermittently for at least 8 hours per day, with continuous NPPV use during sleep, to maintain an oxygen saturation (SpO_2) above the target of 88%.

In the IoT-based NPPV (intervention group; n=73), in addition to the home oxygen therapy for at least 12 hours per day and home NPPV for at least 8 hours per day, with continuous NPPV use during sleep, patients received additional IoT-based management for the full 12 months. The intervention group remotely collected ventilator data via a fourth-generation mobile communication technology (4G) system attached to the back of the ventilator and transmitted the data to the secured platform. The IoT cloud platform (Curative Medical Technology Inc) consists of a data collector, parse server, automatic processing server, data storage center, application interface server, and web server. The platform monitors clinical parameters such as use time, NPPV pressure, mask leaks, breaths per minute, and tidal volume information in real time, and automatically generates daily reports for medical staff. The platform delivers intervention

XSL•FO
RenderX

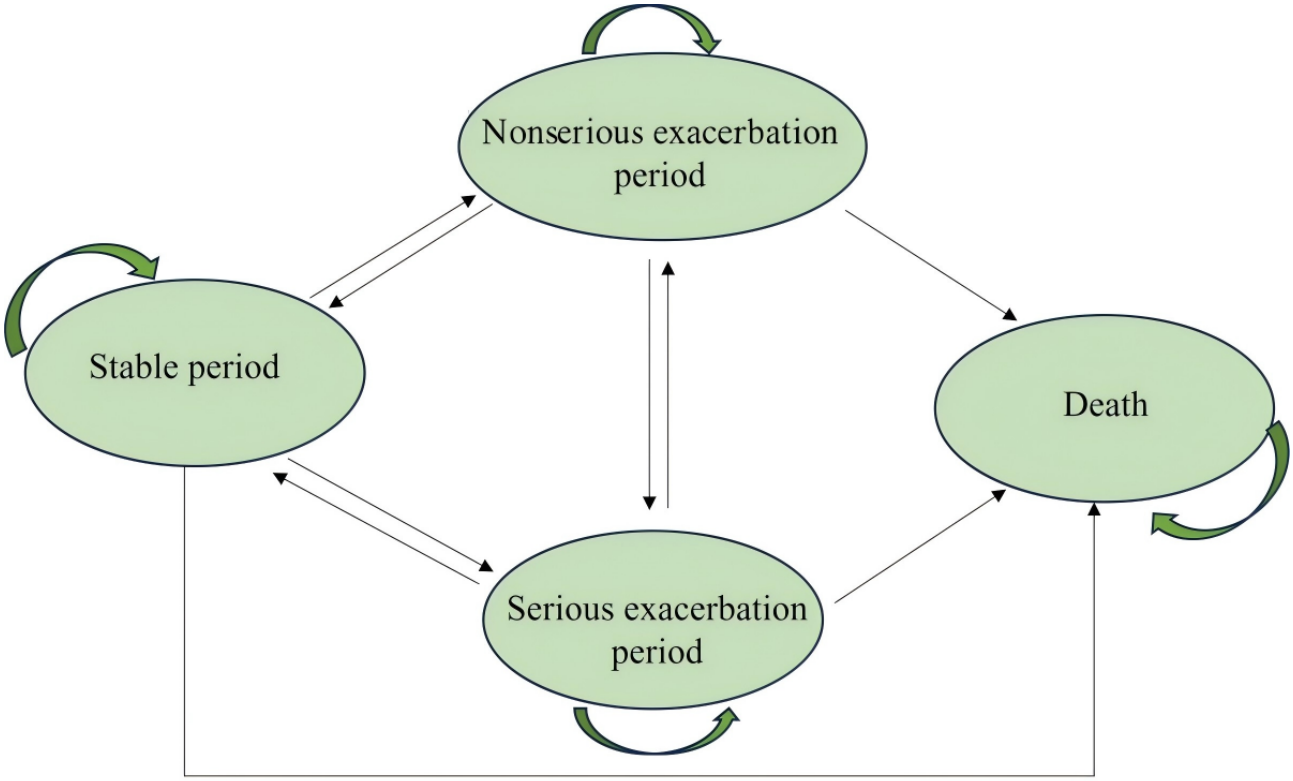
suggestions when adverse reactions, leaks, or poor treatment efficacy occur. The IoT cloud platform triggers automatic alarms when the last 1-week average use is <5 h/night, mask leak is >60 L/min on 3 consecutive nights, or breaths are >25/min on 2 consecutive nights. Health care professionals respond promptly with telephone outreach; if necessary, emergency home visits are arranged, or patients are referred for in-hospital evaluation. Physicians adjust treatment plans based on platform data and patient feedback, with postdischarge management coordinated by family doctors, nurses, and health care providers (Air Liquide Healthcare). Health care professionals conduct in-home follow-ups at 1, 4, and 8 months after treatment, along with monthly telephone follow-ups, to provide health education, monitor the patient's condition, and support long-term treatment adherence.

During the entire study duration, patients in both groups also received standard COPD treatment, including smoking cessation interventions and medication treatment, in accordance with international treatment guidelines.

Patients who were lost to follow-up, were noncompliant, or refused telemedicine, telephone contacts, or home visits were excluded from this analysis. A total of 125 patients (control group, n=67; intervention group, n=58) were included. Full trial details have been published elsewhere [28]. The baseline characteristics of the study population are shown in Table S1 in Multimedia Appendix 1. The groups appeared well balanced with no major differences in baseline characteristics.

Ethical Considerations

The trial was approved by the medical ethics committee of Zhongshan Hospital, Fudan University (Shanghai, China; B2017-176R) and by local research and development committees at participating centers. In this trial, all patients provided written informed consent, and their data were anonymized. After enrollment, patients were provided with 1 year of free device use and transportation subsidies for 4 follow-up visits. Patients or the public were not involved in our research's design, conduct, reporting, or dissemination plans.



Markov Model Structure

The model structure was adapted from Zhou et al [30] based on real-world COPD progression, consisting of 4 health states: stable period, nonserious exacerbation period, serious exacerbation period, and death (Figure 1). The stable period health state represents a period of stable health characterized by the absence of exacerbations. Exacerbation-related health states, namely nonserious exacerbation period or serious exacerbation period, were defined by the severity of an exacerbation and whether additional medical resources were needed. Nonserious exacerbations were events that led to patients needing medications adjusted (increasing the type of medication or dosage or changing medication), whereas serious exacerbations were defined as events that resulted in hospitalization. Patients could transition to the death health state from any other health state. Patients remained in one health state in each cycle and then transferred to another health state in the next cycle. The model adopted a lifetime horizon corresponding to 8 years, calculated based on the difference between China's national average life expectancy in 2019 (77.3 years) and the average age of clinical trial patients included in this analysis (70.04 years). Each year represented a single model cycle, during which the 58 patients in the IoT-based management arm and the 67 patients in the standard management arm could progress throughout the model. The study adheres to Consolidated Health Economic Evaluation Reporting Standards (CHEERS) guidelines.

The RCT followed up with patients at 3, 6, and 12 months, so each patient had 3 periods of follow-up data, including COPD Assessment Test (CAT) scores, medication types, costs, and the number and costs of acute exacerbation hospitalizations. Due to the lack of patients' baseline medication types, we could not identify whether patients had a medication adjustment in the first 3 months. Therefore, we could not identify whether patients were in the stable or nonserious exacerbation period in the first 3 months; we could only identify whether they were in the serious exacerbation period. The calculation of parameters in this study did not include data from this follow-up for patients whose health state could not be determined.

RenderX

Figure 1. Markov model structure.

Cost Parameters

Only direct costs collected as part of the trial, analyzed from the perspective of the Chinese health care payer, were included in this analysis. Cost components were grouped as either treatment costs, IoT costs, or hospitalization costs and were assumed to account for all aspects of care delivered during each health state (excluding death). Annual costs per patient differed for the IoT-based and standard management groups, as shown in Table 1. All costs are reported in Chinese Yuan (¥). Currency conversion to US dollars was based on the average exchange rate in 2019 (US $1=¥6.9).

[a]Stable period represents a period of stable health, characterized by the absence of exacerbations.

[b]IoT: Internet of Things.

[c]Not applicable.

[d]Nonserious exacerbation period represents events that lead to patients needing medications adjusted (increasing in type of medication or dosage or changing in medication).

[e]Serious exacerbation period defined as events that result in hospitalizations.

Treatment costs included device (oxygen concentrator and NPPV device) setup, maintenance, and support costs, considered one-time costs at the beginning of the treatment period based on standardized costs for the previous 12 months. Rental of ventilators and oxygen supply were also included, estimated based on the purchase price using the annuity method [31] over an assumed 3-year lifespan of the devices. Additionally, medication and follow-up examination costs in the stable and nonserious exacerbation period health states were identified based on patients' self-reported case report forms and verified through electronic health records, where possible.

The next cost category, IoT costs, covered all costs associated with implementing IoT-based management and included telemedicine equipment maintenance, telephone contact, and health care professional home visits. The costs of telephone consultations and home visits from research and clinical teams were calculated based on hourly rates for different levels of health professionals.

Finally, hospitalization costs, covering all direct costs resulting from exacerbations, including medical and transportation costs, board and lodging, and nutrition and nursing, were collected again based on patient self-reported case report forms.

XSL•FO
RenderX

Utilities

Quality-adjusted life years (QALYs) were used as effect indicators for this model. Utility values were derived from CAT scores using the following mapping equation (equation 1) [32]. This mapping was developed based on data from patients with COPD in Taiwan, using multiple linear regression with the ordinary least squares method, and was internally validated within the derivation sample, demonstrating good predictive performance.

$$(1)\text{Utility}=1.26848-0.02159\times\text{CAT}-0.00188\times\text{age}$$

In equation 1, *Utility* represents EQ-5D-3L health utility value, where 1 represents full health and 0 represents death, *CAT* represents CAT scores, and *age* represents patient age.

Utility values were calculated for each health state, and values used in this analysis are shown in Table 2, where a utility value of 1 represents perfect health, and a value of zero represents death.

Table . Utility parameters.

Health states	Base value (SE)	Lower limit	Upper limit	α[a]	β[a]
Stable period	0.6195 (0.0121)	0.5956	0.6434	997	612
Nonserious exacerbation period	0.5960 (0.0181)	0.5598	0.6323	437	296
Serious exacerbation period	0.5319 (0.0127)	0.5065	0.5573	820	722
Death	0 (0)	—[b]	—	—	—

[a]The α and β values represent the shape parameters of the beta distribution.

[b]Not applicable.

Transition Probabilities

Transition probabilities were primarily derived from the clinical trial and supplemented by official Chinese databases. The annual natural mortality rate of the population was obtained from the *Chinese and Employment Statistics Yearbook 2021 "National Death Population States by Age and Sex in 2020 (November 1, 2019 to October 31, 2020)"* [33] and converted into the natural mortality rate of participants aged 40 to 80 years of whom 84% were male in the clinical trial. This was used to calculate the transition probabilities of patients from the stable period and nonserious exacerbation period health states to death. Other transition probabilities were calculated based on the patient population in the clinical trial. The conversion from incidence to probability was obtained by using the formula (equation 2) [34]. All model transition probabilities are shown in Table 3.

XSL•FO

$$(2) tpt = 1 - \exp(-r * t)$$

In Equation 2, tp_t represents the probability of event occurrence during t, r means the incidence rate during t, and t represents the study time.

Details of the cost-effectiveness analysis can be found in the Multimedia Appendix 1.

Outcomes

In line with the *Chinese Guidelines for Pharmacoeconomic Evaluation (2020)* [35], future costs and QALYs were discounted at 5% each year. Model outputs included total per-patient costs and QALYs and an incremental cost-effectiveness ratio (ICER), calculated to express the incremental difference in costs and QALYs between IoT-based management and standard management groups. The ICER was judged against a willingness-to-pay (WTP) threshold equal to per capita gross domestic product (GDP). The 2019 per capita GDP was ¥70,100 in China, according to the official data from the National Bureau of Statistics. IoT-based management was considered cost-effective when the ICER value was lower than ¥70,100 per QALY.

Sensitivity Analysis

One-Way Sensitivity Analysis

A one-way sensitivity analysis (OWSA) was used in the study to understand how changes in key parameters influenced results. The transition probabilities were not included in the OWSA because they were correlated with each other. All inputs were adjusted by the 95% CIs of the base value, with the exception of the discount rate, which was varied from 0% to 8%, and the cost of IoT, which was adjusted by −10% to +10% of the base value. Results of the OWSA are presented in a tornado chart.

Probabilistic Sensitivity Analysis

A probabilistic sensitivity analysis (PSA), using Monte Carlo simulations with 1000 iterations, was also performed to incorporate parameter uncertainty into the model analysis. In each iteration, parameter values were randomly drawn from specified distributions and results were presented on a scatter plot. A cost-effectiveness acceptability curve was also used to show the probability of IoT-based management being cost-effective against standard management given different WTP thresholds.

XSL•FO
RenderX

Results

Baseline Results

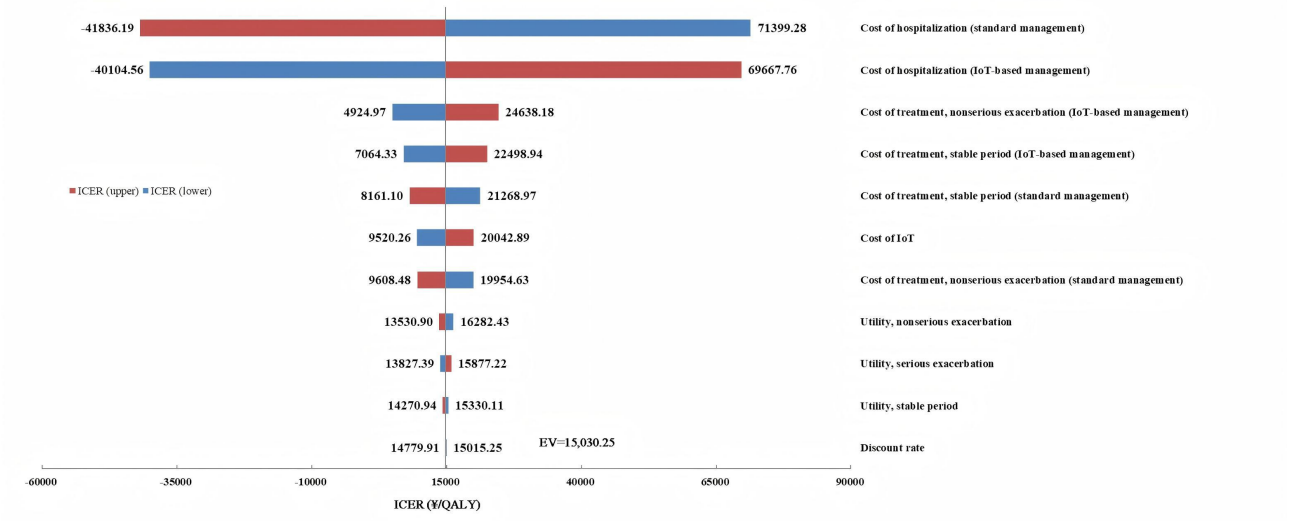
In the base-case analysis, total per-patient costs were ¥94,632.50 for the IoT-based management group and ¥91,025.24 for the standard management group; total QALYs were 3.49 and 3.25, respectively, across the model time horizon. Compared with the standard management group, IoT-based management increased costs by ¥3607.26 but also increased QALYs by 0.24 per patient across the time horizon, resulting in an ICER of ¥15,030.25 per QALY. As the ICER was substantially less than the WTP threshold of ¥70,100 per QALY, IoT-based management was cost-effective compared with standard management. These results are presented in Table 4.

Table . Base case results.

Group	Total costs (¥)	Total effectiveness (QALYs[a])	Incremental cost (¥)	Incremental effectiveness (QALYs)	ICER[b] (¥/QALY)
IoT[c]-based management	94,632.50	3.49	—[d]	—	—
Standard management	91,025.24	3.25	3607.26	0.24	15,030.25

[a]QALY: quality-adjusted life year.

[b]ICER: incremental cost-effectiveness ratio.



[c]IoT: Internet of Things.

[d]Not applicable.

One-Way Sensitivity Analysis

Results of the OWSA, displayed in Figure 2, showed that the parameter that drove the greatest change in ICER results was the hospitalization cost of a serious exacerbation for the standard management group. The second most influential parameter was the hospitalization cost of a serious exacerbation for the IoT-based management group. All other parameter changes had comparatively less influence on model results.

Figure 2. One-way sensitivity analysis tornado chart. EV: expected value; ICER: incremental cost-effectiveness ratio; IoT: Internet of Things; QALY: quality-adjusted life year.

Probabilistic Sensitivity Analysis

Results of the PSA, presented in Figure 3, showed the uncertainty around the model's cost and QALY estimates. A total of 93.6% of iterations fell below the WTP threshold (indicated by the dotted line), indicating that IoT-based management had a 93.6% probability of being cost-effective relative to standard management at the given WTP threshold. This relationship between the probability of being cost-effective as the WTP threshold changes is shown in Figure 4. Additionally, in 80.2% of PSA iterations, IoT-based NPPV was more effective (accumulating more QALYs) and cheaper than standard NPPV.

Discussion

This study demonstrated that, compared with standard NPPV, IoT-based NPPV was cost-effective for patients with COPD and hypercapnic chronic respiratory failure in China. The base case analysis achieved an ICER of ¥15,030.25 per QALY, which was substantially below the ¥70,100 per QALY WTP threshold. PSA results provided robust evidence further supporting the cost-effectiveness of IoT-based NPPV. They confirmed a high probability (93.6%) of IoT-based NPPV being cost-effective,

XSL•FO
RenderX

as well as a high probability (80.2%) of IoT-based NPPV being dominant (ie, cheaper and more effective).

Despite widespread understanding of the significant clinical and economic burdens imposed by COPD, this is, to the best of our knowledge, the first economic evaluation of IoT-based home NPPV treatment for patients with COPD in China. The level of existing economic evidence on the topic is limited, and results differ across countries. Meanwhile, a systematic review [36] highlighted the poor quality of this existing evidence. Five studies included in the systematic review were evaluated as low quality, and only one was evaluated as moderate quality. Further, none of the 6 studies included in the analysis were conducted in China. Consistent with our findings, an Italian study [23] found that a nurse-centered tele-assistance prevented hospitalizations and was a cost-effective intervention for patients with chronic respiratory failure receiving oxygen or home mechanical ventilation. A Spanish study [24] also found that a telehealth program was cost-effective for patients with severe COPD without comorbidities. However, telehealth was not cost-effective compared with usual care in the base case. A Dutch study showed that home initiation of chronic noninvasive ventilation in stable hypercapnic patients with COPD, with the use of telemedicine, is noninferior to in-hospital initiation, is safe, and reduces costs by more than 50% [19]. A study in the United Kingdom also concluded that telemonitoring in patients with COPD was not cost-effective. A possible rationale for the United Kingdom study not being cost-effective is that general practitioner home consultations were more frequent, with higher general practitioner costs in the telemonitoring arm, but differences in QALYs over the trial period were not significant between trial arms [25]. More specifically, existing economic evidence supported the use of telemonitoring in managing COPD [21,37].

The medical IoT is a key part of the digital transformation of health care, as it creates new health care delivery models and enables stakeholders to rebuild the workflows, contributing to increased productivity, enhanced patient experience, and improved effectiveness of home management for chronic diseases [38,39]. Specifically, IoT enables remote patient management and health education through architectures such as real-time monitoring via sensors, cloud-based data processing, and clinical feedback loops, thereby improving patient adherence to home-based therapy. At the same time, it relies on stringent data encryption and privacy protection mechanisms to ensure the long-term safety of patients.

A key outcome from the multicenter, prospective RCT, which formed the basis of this economic evaluation, was that compared with NPPV alone, the addition of an IoT treatment program reduced acute COPD exacerbation-related readmission frequency during the study period. The acute COPD exacerbation-related readmission frequency during the study period was 0.57 (95% CI 0.34 - 0.80) for the IoT-based NPPV group and 0.94 (95% CI 0.68 - 1.21) for the standard NPPV group (P=.05) [28]. The possible reason is that patients with IoT-based management are better able to manage their own condition, signs of exacerbations are identified earlier than without IoT management, and patients' adherence is improved [28]. The reduction in hospitalization costs for the IoT-based NPPV group partially offset the investment in IoT services. Reducing these admissions also reduced organizational burden and potentially lessened pressure on the Chinese health care system.

There exists a disproportionately high burden of global morbidity and mortality caused by chronic respiratory diseases in low- and middle-income countries (LMICs) [40], whereas LMICs typically face the challenge of scarce health care resources, such as inadequate coverage of health care facilities, a shortage of human resources for health, and poor quality of health services. The cost-effectiveness results of this study showed that IoT-based NPPV management could produce greater health and economic outcomes for a given budget. Such interventions are likely to have a greater impact in LMICs, contributing to increased efficiency in allocating limited health resources and increasing the accessibility of health services in LMICs, as well as reducing the pressure on the operation of the health system and the economic burden of COPD-related diseases. Therefore, this intervention should be considered a priority in LMICs. Nevertheless, the scalability of such interventions may depend on local digital infrastructure, workforce readiness, and regulatory frameworks, which vary substantially across LMICs [41]. Therefore, policymakers should consider phased implementation, investment in digital capacity building, and the development of data governance standards to ensure safe and sustainable expansion of IoT-enabled care. Particular attention should also be given to the accessibility of IoT-based management for vulnerable populations, such as those in low-income groups, to avoid exacerbating digital health inequalities.

This study contributes a new perspective to existing international research on the cost-effectiveness of IoT-based home NPPV for patients with COPD, indicating that IoT-based NPPV is cost-effective for patients with COPD and hypercapnic chronic respiratory failure in China. However, this study has several limitations. First, this economic evaluation was based primarily on the results of a single multicenter, prospective RCT, and this restricted clinical trial sample size may differ in some characteristics from the true population of the Chinese health care payer. This approach also means that trial limitations may also impact the inference of model results. Second, given that no studies on utility value measurement for acute exacerbation or stable patients with COPD in mainland China exist, the utility values for patients with COPD adopted in this analysis were derived from a mapping formula based on a study in Taiwan. Given the possible differences in patient characteristics, the formula may have underestimated the utility values of patients with severe disease. Finally, transitions to the nonserious exacerbation health state were determined based on the medication adjustments, as opposed to an objective diagnosis from a doctor, and this may introduce certain bias to the flow of patients throughout the model.

In conclusion, this study demonstrated that from a Chinese health care payer perspective, IoT-based NPPV was cost-effective compared with standard NPPV for patients with COPD and hypercapnic chronic respiratory failure. Further large-sample RCTs, additional real-world data, and more

XSL•FO
RenderX

widespread implementation of IoT-based NPPV throughout China should be sought to validate this.

Correction of: https://mhealth.jmir.org/2025/1/e59884

(JMIR Mhealth Uhealth 2026;14:e88648) doi:10.2196/88648

Following the publication of "Trustworthiness of Web-Based Pharmacy Apps in Pakistan Based on the Mobile App Rating Scale: Content Analysis and Quality Evaluation" [1], concerns were raised regarding potential conflicts of interest between reviewers Huma Ali and Sadia Shakeel and the authors. These concerns included prior copublication with members of the author list and an active professional relationship between a reviewer and an author. These conflicts were not disclosed to the JMIR Publications Editorial Office as per journal policy.

This article has been subsequently reassessed by the editor in chief, who determined that the content of these reviews did not unduly influence the decision to accept the article. The decision to accept the submission was based primarily on the remaining reviewer's comments and the editor in chief's contemporary appraisal of the manuscript.

As such, the JMIR Publications Editorial Office issues this corrigendum to update the Conflicts of Interest statement:

> *Reviewers Huma Ali and Sadia Shakeel were found to have undisclosed conflicts of interest with members of the author list under the terms of JMIR Publications policy. The editor in chief determined that the content of the reviews did not unduly influence the decision to accept the article. The decision to accept the submission was based primarily on the remaining reviewer's comments and the editor in chief's contemporary appraisal of the manuscript.*

We regret that these issues were not identified before publication.

The correction will appear in the online version of the paper on the JMIR Publications website together with the publication of this correction notice. Because this was made after submission to PubMed, PubMed Central, and other full-text repositories, the corrected article has also been resubmitted to those repositories.

Related Article:

Correction of: https://mhealth.jmir.org/2026/1/e72242

(JMIR Mhealth Uhealth 2026;14:e113548) doi:10.2196/113548

In "Efficacy and Safety of a Telemedicine System in Patients With Gestational Diabetes Mellitus (TELEGLAM): Single-Center, 2-Arm, Randomized, Open-Label, Parallel-Group Study" [1], the authors identified errors in the equal contributor designations, the academic degree listed for author YN, and affiliation 4. Due to an error in the metadata submitted by the authors, several authors were incorrectly designated as having contributed equally.

In the originally published version, the author byline appeared as follows:

> *Kazuki Aoyama[1*], MD; Yuya Nakajima[2*], MD, PhD; Shu Meguro[1], MD, PhD; Yasunori Sato[3*], PhD; Rei Goto[4*], MD, PhD; Mariko Hida[5*], MD, PhD; Takeshi Arimitsu[5], MD, PhD; Yoshifumi Kasuga[6], MD, PhD; Mamoru Tanaka[6], MD, PhD; Hiroshi Itoh[2*], MD, PhD; Kaori Hayashi[1], MD, PhD*
>
> **these authors contributed equally*

The corrected author byline appears as follows:

> *Kazuki Aoyama[1], MD; Yuya Nakajima[2], MD; Shu Meguro[1], MD, PhD; Yasunori Sato[3], PhD; Rei Goto[4], MD, PhD; Mariko Hida[5], MD, PhD; Takeshi Arimitsu[5], MD, PhD; Yoshifumi Kasuga[6], MD, PhD; Mamoru Tanaka[6], MD, PhD; Hiroshi Itoh[2], MD, PhD; Kaori Hayashi[1], MD, PhD*

The equal contributor asterisks and the accompanying footnote have been removed. In addition, YN's academic degree has been corrected from "MD, PhD" to "MD." The author list and author order remain unchanged. These corrections do not affect the results or conclusions of the article.

In addition, affiliation 4 was originally published as follows:

> *Graduate School of Business Administration, Keio University,, Kanagawa, Japan*

The affiliation has been corrected to the following:

> *Graduate School of Business Administration, Keio University, Kanagawa, Japan*

The correction will appear in the online version of the paper on the JMIR Publications website together with the publication of this correction notice. Because this was made after submission to PubMed, PubMed Central, and other full-text repositories, the corrected article has also been resubmitted to those repositories.

In "Short-Term Effects of an mHealth Intervention on Healthy Behaviors and Cardiometabolic Health in Sedentary Employees: Quasi-Experimental Study" [1], the authors noted one error in Figure 1.

Figure 1. Flow diagram of participant recruitment and retention. mHealth: mobile health.

In the originally published Figure 1, the box "Assignment of worksites" appeared before "Completed assessment 1."

The figure has been corrected so that "Completed assessment 1 (Baseline; N=101)" appears before "Assignment of worksites." This corrected sequence is consistent with the Methods section,

XSL•FO
RenderX

which states that group assignments were concealed until completion of baseline assessments.

This revision does not affect the sample size, intervention or control conditions, outcome data, statistical analyses, results, interpretation, or conclusions of the article.

The correction will appear in the online version of the paper on the JMIR Publications website, together with the publication of this correction notice. Because this was made after submission to PubMed, PubMed Central, and other full-text repositories, the corrected article has also been resubmitted to those repositories.

(JMIR Mhealth Uhealth 2026;14:e91934) doi:10.2196/91934

In "Evaluating Characteristics and Quality of Mental Health Apps Available in App Stores for Indian Users: Systematic App Search and Review" [1], the authors made two additions.

First, toward the end of the Methods section, the authors added the following:

Phase 5: Supplementary Analyses

> *The interrater reliability of the MARS ratings was assessed using 10% of the apps randomly selected from the 350 previously reviewed. Each app in this subset was independently evaluated by all four reviewers, and the intraclass correlation coefficient (ICC) was calculated using Mangold International GmbH - ICC Calculator. In addition, this phase included a further detailed evaluation of paid apps. While the primary analysis focused on free apps or the free content of paid apps, we conducted an additional review of paid content within a subsample of subscription-based apps. Of the 350 apps initially reviewed, 226 involved in-app purchases, and 5 were fully paid apps. At the time of this supplementary review, 20 out of the 226 apps involving in-app purchases and 3 out of the 5 fully paid apps were no longer available in the app stores. Thus, a pool of 206 that offered in-app purchases and 2 that were fully paid was available for review of their paid content. We randomly selected 25% of these 206 in-app purchase apps (n=53) from each of the app categories such as intervention, assessment, multifunctional, etc, ensuring adequate representation across categories. The paid content of these 53 apps, along with the two fully paid apps, yielded a total of 55 apps reviewed between October 25 and November 20, 2025, by the same team members who conducted the primary review. Of the initially selected 55 apps, 10 could not be reviewed due to unavailability on app stores or persistent technical issues; these were replaced with alternative apps drawn from the corresponding categories. The final sample comprised 41 multifunctional apps, 6 intervention-based apps, 5 monitoring and tracking apps, and one app each in the assessment, journaling, and informative categories. The review process strictly followed the same protocol used in the evaluation of free versions.*

Second, toward the end of the Results section, the following was added:

Results of Supplementary Analyses

> *ICC analysis demonstrated good to excellent interrater reliability among the four reviewers at the*

XSL•FO
RenderX

95% confidence level. Single-measure ICCs ranged from 0.77 (absolute agreement) to 0.80 (consistency), while average-measure ICCs were excellent, ranging from 0.93 to 0.94. These results indicate strong agreement and consistency across raters, particularly when aggregated ratings were used.

A comparison of MARS scores between paid and free versions of the reviewed apps using the Wilcoxon signed rank test indicated no significant difference (z=–1.34; P>.05). The average MARS scores for paid versions ranged from 3.4 to 4.7, while the corresponding free versions ranged from 3.3 to 4.8. These observations suggest that inclusion of paid content in the reviewed apps did not substantially influence the overall MARS ratings. As far as MARS subscales are concerned, the average ratings on functionality and aesthetics were relatively higher (4.3 and 4.6, respectively) compared to ratings on information quality (3.9), mirroring the observations in the primary review.

The correction will appear in the online version of the paper on the JMIR Publications website, together with the publication of this correction notice. Because this was made after submission to PubMed, PubMed Central, and other full-text repositories, the corrected article has also been resubmitted to those repositories.

Abstract

Background: Ubiquitous smartphone access and statistical advances offer opportunities to continuously track affect intensity, which is central to various psychological processes and behaviors. Research demonstrated the potential of personalized predictions of momentary negative affect (NA) and positive affect (PA) using passive sensing. However, studies typically incorporated all available data sources without differentiating their added value, nor did they investigate whether refining location features with self-reported semantic location (eg, workplaces) improved personalized predictions.

Objective: We evaluated three specific aims: (1) how different combinations of data sources improved performance compared to personalized baseline models, (2) whether model predictions differed across passive data aggregation timescales, and (3) whether incorporating self-reported semantic locations improved model predictions.

Methods: Adults (final n=133) completed a 14-day ecological momentary assessment (EMA) protocol reporting emotional experiences 5 times daily alongside smartphone sensing. Testing data (n=532 EMAs) used the last 4 surveys for each individual, with the remaining used for training and validation (n=6805 [NA]/6800 [PA] EMAs). We evaluated whether combinations of personalization, passive sensing, and affect history improved baseline prediction, and how full-information temporal fusion transformers (TFTs) performed across 6 timescales (1, 3, 6, 12, 24, and 48 hours), with or without self-reported semantic location features.

Results: The baseline model, using each individual's mean affect in the training set, demonstrated moderate predictive performance for NA (mean absolute error [MAE]=0.66, 95% CI 0.60 - 0.73; R^2=40.2%) and PA (MAE=0.71, 95% CI 0.65 - 0.78; R^2=36.1%). Full-information TFTs improved NA prediction (MAE=0.62, 95% CI 0.56 - 0.69; R^2=45.2%; ΔMAE=−0.04, 95% CI −0.06 to −0.01; *P* values ≤.004; Cohen *d*=−0.27) but not PA prediction (MAE=0.70, 95% CI 0.64 - 0.78; R^2=32.5%; ΔMAE=−0.01, 95% CI -0.03 to 0.02; *P* values >.10; Cohen *d*=−0.04). No pairwise timescale comparison survived false discovery rate (FDR) correction (NA: P_{FDR}=.05-.98; PA: P_{FDR}=.08-.99). Adding self-reported locations did not improve NA prediction (ΔMAE=0.02, 95% CI −0.01 to 0.04; *P* values >.20; Cohen *d*=0.11) or PA prediction (ΔMAE=0.01, 95% CI −0.01 to 0.03; *P* values>.33; Cohen *d*=0.07). However, incorporating self-reported semantic locations changed the composition and relative ranking of important inputs, with these changes varying across NA and PA and between past and future inputs.

Conclusions: Incorporating smartphone features provided a modest and significant improvement in momentary NA prediction, but not PA prediction. Model performance did not vary across passive data aggregation timescales. While adding self-report semantic locations did not improve prediction accuracy, it changed variable-importance patterns and may provide additional context for interpreting digital behavioral markers. Future personalized predictions should incorporate person-mean affect as an essential benchmark. These findings support passive smartphone sensing as a valuable supplement to, rather than a replacement for, active EMA.

Introduction

Background

Modern technologies already enable us to unobtrusively and accurately track sleep, physical activity, or health essentials such as heart rate and blood pressure, but what about affect intensities? Like the continuous tracking of human behaviors indicative of health status, continuous tracking of affect intensities holds broad research and health implications, given the central role of affect intensity in various outcomes (eg, attention [1], memory scope [2], and decision-making [3]) and its defining role in the diagnostic criteria of many mental disorders [4]. In evaluations for mood and anxiety disorders, for example, diagnostic impression relies on individuals' retrospective reports of their affect intensity patterns compared to their own baseline patterns (eg, intense negative affect [NA] or blunted positive affect [PA]) over an extended period in the past (eg, the past several months or years). However, retrospective reports are affected by recall bias, especially in clinical samples [5,6]. Assessing the intensity of one's subjective feelings from moment to moment reduces bias but requires constant attention that results in burden and missingness (eg, 30% missingness for data collection less than a month [7]). These limitations, bias in recalling experiences in the past, and the burden of subjective momentary assessment could be overcome by personalized models to passively and continuously compute affect intensities. Research suggested the potential of such personalized prediction using data from smartphone sensors [8-10]. However, existing studies combined all data sources in models without differentiating each source's contribution, particularly between an individual's own affective history and passively sensed behaviors. As a result, it remains unclear whether passive sensing meaningfully improves prediction beyond what could already be achieved from a person's own affective history (eg, person-mean affect). The overarching aim of this study was to parse out variances of different data sources from personalized prediction models. In addition, we used linear mixed-effects models and post hoc interpretability measures (ie, attention weights) from machine learning (ML) to generate hypotheses about relations between affect and smartphone-tracked behaviors.

Monitoring and Understanding Momentary Affect Intensity Through Smartphones

Cheap and wide access to smartphones (91% ownership in the United States [11]) provides unprecedented opportunities not only for passive monitoring of momentary affect intensity but also for understanding ubiquitous human-smartphone interactions. Five studies incorporated smartphone sensor data and modeled momentary affect intensities. Three of the studies dichotomized affective intensity as outcomes and achieved modest prediction with data from smartphones, smartwatches, and smartrings [8-10]. Research showed that traditional AI algorithms could make moderate predictions on whether an individual's daily affect intensities [9] or momentary affect intensities [10] were above a certain threshold, and make just-surpassing-chance predictions of the presence of affect in unseen individuals [8]. However, dichotomizing affect intensity loses important granular information, as different levels of intensity of the same type of emotion lead to different behavioral outcomes. For example, strong feelings of anger might lead to physical violence, whereas weak feelings of anger might lead to verbal profanity or no overt behavior. Therefore, affect intensity is, by nature, continuous and, therefore, motivates approaches that preserve variation across a continuous scale.

Research that continuously modeled momentary affect included predictors that require individuals' active engagement [12,13] and only focused on certain NA without modeling PA. One study predicted momentary depressed feelings with smartwatches and self-reported items [13]. Both momentary anxiety and depressed affect were reported at the same time, and anxiety was the most important predictor of momentary depressed affect in the models, above smartwatch predictors, for 11 out of 14 participants. The other study collected heart rate metrics (ie, participants pressed their finger against the rear camera for 30 seconds hourly), along with smartphone sensors, to predict momentary depressed mood [12]. Importantly, these models combined all sources and did not test against simple baselines of a person's mean affect. Thus, it remains unclear how much smartphone sensing specifically adds to personalized prediction. Finally, it is equally important to test personalized PA prediction using smartphone sensing. Theoretical models [14] and clinical trials [15,16] have highlighted the critical role of raising PA in reducing depression, and PA is conceptually independent of NA [17] and influenced by different biopsychosocial predictors from NA [18-20].

Smartphones are both a data-collection tool people carry and an object to interact with regularly, but few studies have examined associations between momentary affect intensity and smartphone-tracked behaviors. People engage in social interactions (eg, making phone calls) and interact with phone screens for multiple purposes, including using social media. Revealing relations between everyday affective experiences and behaviors tracked by smartphones could inform intervention strategies to aid emotion regulation. For example, if total screen use time in the prior hour is an important predictor of feeling worse among other smartphone-tracked behaviors (eg, total distance traveled), individuals could practice limiting their screen usage. One challenge for elucidating affect–smartphone-based behavior associations (and probably for most psychological research) is the large number of smartphone-tracked behaviors and the dependencies between them. For example, when individuals are traveling (as collected through GPS), they may make fewer phone calls and have fewer screen interactions. On the other hand, when individuals remain at home for an extended time, their likelihood of unlocking their screens may be higher. Thus, smartphone-tracked behaviors can be predictors of each other and work together to shape affective experiences.

Temporal fusion transformer (TFT) is well-suited to address the challenge brought by multiple and interacting predictors. As a state-of-the-art algorithm for time-series analysis, TFT may predict momentary affect intensity more accurately than traditional AI models while addressing the challenge brought by multiple and interacting predictors, as shown in its performance for other time-series predictions (eg, electricity,

XSL•FO
RenderX

traffic, retail, and volatility [21]). As a transformer-based model, TFT uses self-attention to capture dependencies across time, while its variable selection networks identify predictors that are most informative for the prediction task [21]. Additionally, TFT accommodates 3 types of inputs based on their temporal availability: static inputs (time-invariant inputs), past inputs (predictors before the time point of making predictions), and future inputs (inputs corresponding to prediction time points processed by the decoder [21]). TFT's capacity to distinguish the 3 input types is important for predicting momentary affect intensity. Because affect intensity is often viewed as an individual difference characteristic [22], adding static inputs may enhance prediction, although there is high intraindividual variability for momentary affect intensity. Additionally, it remained unclear at which lag length momentary affect intensity can be predicted by different smartphone-tracked behaviors. While traditional psychological research testing temporal associations usually adopts one lagging length (eg, lagging one assessment schedule), TFT could integrate sensing features derived across multiple temporal windows, allowing information from both proximal and more distal timescales to contribute to prediction.

Timescales and Semantic Locations

Passive sensing research showed that the timescales to aggregate passive sensing data may influence the interpretation of results on psychological well-being [23]. Research on predicting momentary affect with passive sensors has used different timescales [8-10,12,13], and there is a lack of empirical tests comparing the influence of timescales on model performance and predictor importance. For affect intensity, the same behavioral indicator from smartphone sensors with different timescales could have different clinical implications. Intuitively, staying stationary for most of the time in the past hour might be less influential on momentary affect intensities than staying stationary for most of the time in the past 48 hours. Thus, how TFTs performed differently across timescales of aggregating the smartphone sensor data warrants empirical investigation. The timescales might also change the attention that TFTs put on the mobility markers (as collected by GPS) and social interaction markers (as collected by phone calls). Since social interactions are acute events or stressors [24], proxies of social interactions tracked by smartphones may be important predictors for NA and PA intensities when they are aggregated in smaller timescales. By contrast, physical mobility patterns in shorter timescales may be influenced by random factors (eg, weather), whereas they may indicate behavioral routines when aggregated in larger timescales. Therefore, mobility patterns tracked by smartphones may be more important when aggregated on larger timescales.

Contextual features, such as the semantic meaning of a location to an individual (eg, where they work, or where they entertain, or where they spend time with important others), might improve both model performance and interpretations. Affective experiences are constructed by subjective evaluations of both internal and external cues [25,26]. A model of situation perception [27] proposes three situational cues: (1) persons and interactions (who?); (2) objects, events, and activities (what?); and (3) spatial location (where?). Physical locations recorded through GPS can provide information about "where" but not "what," namely, the activities or the motivations for activities. Semantic meaning of a location may offer such information. For example, one may assume the major activities that individuals engage in are work in their self-reported workplaces, or that the major activities that they engage in are recreational in their self-reported leisure places. In prior studies, usually one semantic location feature (time spent at home) was included [11,28,29]. Collecting self-report locations from individuals at baseline may improve the coding accuracy of semantic locations and help create new location features, thereby potentially improving model performance. Additionally, semantic locations could inform intervention strategies, as they may elicit more awareness of what patients are engaging in than where they are. Overall, the role of semantic locations in predicting momentary affect warrants further investigation.

Study Aims and Hypotheses

This study collected data from a sample of unselected adults who completed an ecological momentary assessment (EMA) protocol measuring self-report emotional experiences alongside continuous smartphone behavioral monitoring. For aim 1, we evaluated the incremental predictive value of contributions of personalization (participant identity and affective history) versus smartphone sensing data in momentary affect prediction, by comparing TFT and other ML models that vary in their usage of these data sources against a person-mean affect baseline. We hypothesized that the full TFT model incorporating all data sources would achieve prediction performance for unseen momentary NA and PA above the person-mean-affect baseline (hypothesis 1). For aim 2, we examined how feature extraction across 6 aggregation timescales (1, 3, 6, 12, 24, and 48 hours preceding the report) affected TFT's performance. We explored the optimal aggregate windows (exploratory aim 1) and identified top behavioral predictors across timescales. We hypothesized that social interaction (eg, call logs) and screen activity would demonstrate greater feature importance at proximal timescales (hypothesis 2a), whereas mobility markers might be more important at longer timescales (hypothesis 2b). For aim 3, we examined the impact of integrating participant-annotated semantic location features (eg, work and home of significant other). We hypothesized that refining semantic location features with participant self-reports would improve model performance (hypothesis 3a) and shift variable importance rankings (hypothesis 3b). Because attention weights reflect predictive relevance rather than causal mechanisms, findings from hypotheses 2a, 2b, and 3b are framed as exploratory and hypothesis-generating.

Methods

Participants

A total of 179 adults from the greater area of St. Louis, Missouri, United States, participated in a study to understand daily emotional experiences [30,31]. Individuals were eligible if they had a smartphone and at least one active social media profile. They were ineligible if they had any contraindications for peripheral physiological assessment (eg, pregnant and with an implanted cardiac device). Participants with less than 40 valid

XSL•FO
RenderX

EMAs (70 possible surveys) on NA or PA (n=46) were excluded from further analysis. As a result, 133 out of 179 (74.3% of original participants) were retained in final analysis. Although there are no recommendations or requirements on the number of time points within each individual, in general, more time points are better. The time points ranged from 90 to 252 in the original TFT paper [21]. Considering the sample size to be retained, we decided on the threshold of 40 EMAs such that the rate of sample size to be retained in this study (74.3%) was comparable to or higher than existing studies that predict momentary affect intensity (71.6% [8]; 35% [9]).

Ethical Considerations

The study was approved by the Washington University Institutional Review Board (number 202209063) and was performed in line with the standards of the 1964 Declaration of Helsinki. Informed consent and assent were collected from all participants. To protect participant privacy, all data were deidentified before analysis and stored on secure, password-protected servers. Participants were compensated US $135 for completing the study. There was a US $15 bonus if participants completed 80% (56/70) surveys or more. Thus, participants can receive up to US $150 depending on their survey completion rates.

Study Design and Procedure

Eligibility was determined via a phone screen. Participants were scheduled for an in-person laboratory session. During the laboratory session, participants completed a semistructured EMA tutorial, including a practice EMA survey, administered by a staff member or an undergraduate research assistant. The tutorial included helping participants download and install the SEMA^3 app (developed and hosted by the Melbourne eResearch Group at the University of Melbourne [32]) for EMA surveys and the AWARE ([33]; University of Oulu) apps for smartphone sensing. EMA surveys occurred during a 15-hour window of the participants' choice. Participants were surveyed 5 times a day for 14 days, starting the day after the laboratory session. At the laboratory session, participants also reported anticipated locations they frequently visited (eg, office and home) and their addresses in the next 14 days. The AWARE framework [33] is an open-source mobile app to unobtrusively record location coordinates, screen interactions (ie, when the screen status changed to on or off and locked or unlocked), call logs for incoming, outgoing, and missed calls, and Bluetooth connections. The AWARE started to collect deidentified data unobtrusively from the smartphone sensors after installation. By default, location coordinates are sampled once per 180 seconds, and Bluetooth is sampled once per 60 seconds. Calls and screen usage are event-based sensor streams. Bluetooth data were not included in analyses due to high missingness. A total of 156 out of 179 (87.2%) participants had no Bluetooth scans recorded in the hour preceding any EMA prompt, and a total of 103 out of 179 (57.5%) participants had no Bluetooth data at all.

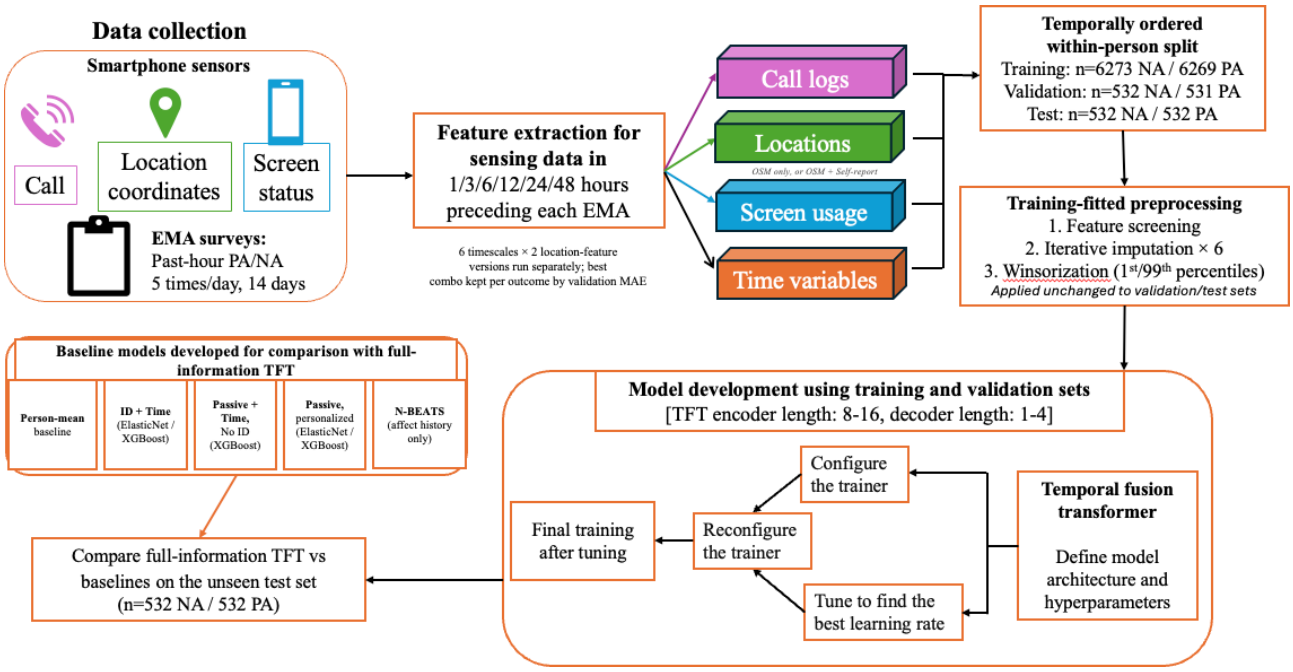
The original sample completed a total of 8690 out of 12,530 (69.4%) EMA surveys. On average, individuals completed 49 out of 70 (70%; SD 15.1) EMA surveys. The completion rate was higher in the final analytic sample, which on average completed 56 out of 70 (80%) EMAs because of the selection criteria (see the "Participants" section). Participants could receive up to US $135 for completing the study and a bonus of US $15 if their EMA completion was more than 80%, resulting in a possible compensation of $150.

Measures

EMA: Momentary Affect Intensity

In each survey, participants were asked to report on how they felt in the hour preceding the EMA survey. They indicated the extent to which they felt 4 PA and 4 NA using a 7-point Likert scale (1=not at all; 7=extremely). Items were chosen to represent a 2-dimensional affective circumplex (ie, valence and arousal). The PA items were "During the last hour, I felt CONTENT/CALM/HAPPY/ENTHUSIASTIC," and the NA items were "During the last hour, I felt SAD/SLUGGISH/WORRIED/FRUSTRATED." In the final analytic sample, both NA and PA showed acceptable within-person reliability (NA: ω_{within}=0.64, PA: ω_{within}=0.69) and great to excellent between-person reliability (NA: $\omega_{between}$=0.88, PA: $\omega_{between}$=0.90).

Measures Derived From Passive Sensors



Overview

Figure 1 illustrates the pipeline of data collection, cleaning, and analysis.

Table 1 presents a list of extracted features. We computed features from 3 smartphone sensors (location coordinates, screen interactions, and call logs) because of their potential to predict depression severity [28,29,34,35] or predict dichotomized momentary affect intensity [10].

Table . Predictors derived from smartphone sensors and their sources[a].

Variable type and sensor source	Variables
Spatial mobility markers	
GPS coordinates [28,34,35]	• Location variance • Log of location variance • Total distance traveled • Average speed • Variance in speed • Percentage of time being stationary (stationary: momentary speed <1 km/h) • Radius of gyration
GPS coordinates clustered by DBSCAN[b] [28,35]	• Number of significant places • Number of significant transitions • Percentage of time spent in rarely visited locations (ie, outliers by DBSCAN) • Location entropy • Normalized location entropy
Clusters labeled by OSM[c] or self-report locations	• Percentage of time spent at home (OSM) • Percentage of time spent at leisure places (OSM) • Percentage of time spent at home (OSM + self-report) • Percentage of time spent at leisure places (OSM + self-report) • Percentage of time spent at workplaces (OSM + self-report) • Percentage of time spent at home of significant others (OSM + self-report)
Proxies of smartphone social interactions	
Call logs [28]	• Number of incoming calls • Number of outgoing calls • Number of missed calls • Number of correspondents called • Duration of incoming calls (average, maximum, minimum, and total duration) • Duration of outgoing calls (average, maximum, minimum, and total duration)
Screen interactions	
Screen status [36]	• Number of unlocked episodes • Average, maximum, minimum, and total screen-on duration
Time variables	
Timestamp	• Relative time in hours since the first self-report EMA[d] survey • Weekend or weekday (1=weekend; 0=weekday) • Time of day (night: midnight to 6 AM; morning: 6 AM to noon; afternoon: noon to 6 PM; evening: 6 PM to midnight) • Prompt (the number of the self-report EMA survey)

[a]Each predictor was computed for each timescale. For example, for the timescale of 3 hours, the location variance of the 3 hours preceding each survey was created.

[b]DBSCAN: Density-Based Spatial Clustering of Application with Noise.

[c]OSM: OpenStreetMap.

[d]EMA: ecological momentary assessment.

Location Feature Sets

Location features are derived from the coordinates of latitude and longitude and the timestamp of each coordinate. We first removed duplicated data points for each individual and then extracted the following location features consistent with research [28] that detected depression and predicted its onset from smartphone data: (1) location variance (sum of the variance in latitude and longitude coordinates), (2) log of location variance, (3) total distance traveled, (4) average speed, (5) variance in speed, (6) the percentage of time being stationary (stationary was defined as momentary speed being less than 1 km/h), and (7) radius of gyration. When calculating distances and speed, only adjacent data points whose time difference was greater than 1 second and less than twice the sampling rate (ie, 180 seconds) were retained.

XSL•FO
RenderX

Then each individual's location coordinates were clustered using Density-Based Spatial Clustering of Applications with Noise (DBSCAN [37]), a clustering algorithm for large spatial databases with noise. Consistent with prior work [28], based on identified clusters, we extracted the (1) number of significant places, (2) the number of location transitions, (3) the percentage of time spent in insignificant or rarely visited locations (ie, outliers identified by DBSCAN), (4) location entropy (higher location entropy occurs when time is spent evenly across significant places), and (5) normalized location entropy across significant places (following previous definitions and operationalizations [35]).

Consistent with prior work [11,28,29], we assumed the place most visited by the participant late at night (between midnight and 6 AM) was their home location. Specifically, the location coordinates of the cluster most frequently used during all nights were assumed to be the participant's home location center. Then, based on the coordinates of longitude and latitude for each individual's core clusters, we labeled their type of location through the OpenStreetMap Nominatim API's geocoding [38]. Locations labeled as "highway," "aeroway," "tourism," "leisure," and "shop" by OpenStreetMap were categorized as leisure and recreation. For each of the location labels (including the labels in the next paragraph), when participants' GPS coordinates were within 100 meters of one location center cluster, their location at that timestamp was given the label of the location center cluster. For example, a participant was assumed to be at home if they were within 100 m of the home location. With these 2 labels, we extracted two location features: (1) the percentage of time spent at home and (2) the percentage of time spent at leisure and recreation.

We tested whether adding more semantic location features could improve model prediction and interpretation through their indication of possible activities. These sets of location features were extracted based on participants' self-reported locations, which included categories of personal home, home of significant others (eg, parents, partner, and so on), workplace, and places for leisure and recreation. Based on their self-report addresses, the locations of the previously coded home and leisure were corrected, resulting in two extracted features: (1) the percentage of time spent at home (self-report) and (2) the percentage of time spent at leisure and recreation (self-report). Additionally, with 2 additional addresses (workplace and home of significant others), we extracted (3) the percentage of time spent at work (self-report) and (4) the percentage of time spent with significant others (self-report).

We created 6 sets of location features based on 6 temporal resolutions (ie, 1, 3, 6, 12, 24, and 48 hours) preceding each momentary affect (ie, NA and PA) report. Take the location variance feature as an example. We created 6 location variance features for a given momentary affect report—the location variance during 1, 3, 6, 12, 24, and 48 hours preceding the report.

Calls Feature Sets

Call features were calculated using the smartphone's call logs. Consistent with prior work [28], we extracted the following six features: (1) the number of all incoming and outgoing calls, (2) the number of missed calls and the number of correspondents overall, and (3) the duration of all incoming and outgoing calls (in terms of their average, maximum, minimum, and total duration). As with the location features, we created 6 sets of call features based on 6 temporal resolutions (ie, 1, 3, 6, 12, 24, and 48 hours preceding each momentary affect report).

Screen Feature Sets

Screen features were calculated using the smartphone's screen status sensor, which recorded screen status (ie, on or off) and its timestamp once the screen switched from one status (eg, on) to the other (eg, off). Consistent with prior work [28], we extracted the following five phone usage features: (1) the number of unlock episodes, (2) the average, (3) sum, (4) maximum, and (5) minimum duration of the screen-on time. Similar to the location features, we created 6 sets of screen features based on 6 temporal resolutions (ie, 1, 3, 6, 12, 24, and 48 hours preceding each momentary affect report).

Time Variables

We included several time variables based on the time of the EMA survey completion as predictors of momentary affect because of emotion's time-varying nature. We computed one continuous time variable, (1) relative time (relative time in hours since the first EMA survey), and 2 categorical variables: (2) weekend or not (1=yes; 0=no [ie, weekday]) and (3) time of day (midnight to 6 AM: night, 6 AM to noon: morning, noon to 6 PM: afternoon, 6 PM to midnight: evening; dummy coded). Finally, one count variable, (4) prompt (the EMA survey number), was used as the time indicator required by the time-series deep learning algorithm.

Data Preprocessing

Before imputation, we screened the passive-sensing predictors for near-constant and redundant features: a predictor was dropped if (1) it was near constant, defined as a single value accounted for at least 99% of its nonmissing observations, (2) it was highly correlated with another one, defined as an absolute Spearman correlation over 0.95. We dropped the one with higher missingness in the highly correlated pair. We then handled missing data and extreme values of the smartphone sensor features for each timescale by performing 6 imputations and then 6 winsorizations. For each of the 6 feature sets, we performed single imputation for the missing values in predictors using an iterative imputer (IterativeImputer) that uses the chained equations (MICE [Multivariate Imputation by Chained Equations]) algorithm from the scikit-learn library [39] in Python. Instead of performing imputations for each smartphone sensor (locations, calls, and screen), we performed imputations across smartphone sensor data simultaneously, in which IterativeImputer could use interactions between different sensor data to impute missing values. Importantly, we excluded outcome variables (ie, NA and PA) from imputations to avoid data leakage and overfitting of the prediction models. Finally, we winsorized extreme values in the predictors using the quantile-based method, where we replaced values above the 99th percentile with the 99th-percentile value and replaced values smaller than the 1st percentile with the 1st-percentile value.

XSL•FO
RenderX

To avoid data leakage, the feature screening, feature selection, imputation, and winsorization were all performed in the training set only. The feature list, imputation model, and clipping bounds from the training set were then applied to the validation and test sets. For the TFT, the same principle applied to the participant-level target normalizer used to construct the NA and PA center and scale, which was fit on the training set and reused, rather than refit, in the validation and test sets. A similar training-only-fitted preprocessing pipeline (including standardization for the ElasticNet [elastic net regression]) was also performed for approaches using the ElasticNet and XGBoost (extreme gradient boosting).

Training and Testing Split

We used a temporally ordered split approach, splitting observations within each individual into three subsets: (1) a test set for final model evaluation, comprising the last 4 consecutive EMA surveys (~1 day); (2) a validation set for hyperparameter tuning, early stopping, and, for model selection between ElasticNet, XGBoost, and N-BEATS (neural basis expansion analysis for interpretable time series forecasting; described below), comprising the 4 consecutive EMA surveys immediately preceding the test window; (3) a training set with all earlier entries (~85% of all EMA surveys). Because the validation and test windows followed the training window, this setup prevents temporal leakage and evaluates short-term within-person generalization. This approach resulted in 6273/6269 EMAs in the training set, 532/531 in the validation set, and 532/532 in the test set for NA and PA, respectively. The training set of 6273 (NA) and 6269 (PA) EMAs allowed 6672 (NA) and 6669 (PA) rolling training sequences (encoder length: 8 - 16, prediction length: 1 - 4; window lengths were allowed to be flexible and can overlap, so they can exceed observation counts), across 133 participants. The small NA and PA differences reflect outcome-specific missingness. Because the sliding window allows the same EMA to be reused as parts of multiple different-length windows (eg, first window being 1 - 11 EMAs predicting 12 - 15 EMAs and second window being 2 - 13 EMAs predicting 14 - 16 EMAs), the number of training sequences to fit the TFT exceeds the number of EMAs in the training set.

For the TFT, we allowed the encoder length to vary between 8 and 16 time points and the prediction length to vary between 1 and 4 time points. As a result, training sequences consist of different combinations of encoder and decoder lengths (eg, 1 - 11 EMAs predicting the next 2 EMAs). The final TFT configuration used an encoder length of 16 observations because this window spans roughly 3 days of recent data, given the study's sampling schedule of approximately 5 EMAs per day. We considered this interval sufficiently long to capture short-term temporal patterns in affect while minimizing data loss that would occur from requiring longer continuous observation histories. A prediction length of 4 was chosen to forecast affect over approximately the subsequent day, directly aligning with the study's objective of predicting near-term affective dynamics which may ultimately be relevant for timely, adaptive interventions. The final TFT configuration used a maximum encoder length of 16 observations and a maximum prediction length of 4 observations.

Statistical Analysis

Model Evaluations

Model performance metrics were mean absolute error (MAE), root-mean-square error (RMSE), and coefficient of determination (R^2). The MAE is the average of all the absolute values of the differences between the predicted values and the actual values. The RMSE is the square root of the mean of the squared differences between predicted values and actual values. R^2 represents the proportion of variance explained by the model. When R^2 equals zero, a model explains no more than the average score. When R^2 equals 1, a model perfectly explains all the outcome variances. Unlike R^2, lower values of MAE and RMSE indicate better performance. Both MAE and RMSE are in the original scale of the outcomes and indicate the extent to which predicted values deviate from the actual values. RMSE is more sensitive to extreme deviations. When MAE or RMSE equals zero, the model perfectly predicts the actual values. When RMSE equals the SD of the outcome variable, the model performs no better than the average score.

Person-Mean Affect: For Baseline

In this baseline model, the predicted value for each held-out validation or test observation was set to each participant's mean NA and PA intensity calculated across the training set. This benchmark required no model fitting or hyperparameter tuning and operated without smartphone sensing or temporal information.

ElasticNet and XGBoost Models: For Nonpersonalized Sensing, Personalized Time, and Personalized Sensing Approaches

ElasticNet regression [40], implemented in scikit-learn, and XGBoost (gradient-boosted trees) [41] were used to fit three model variants: (1) nonpersonalized sensing model, (2) personalized time (incorporating participant ID and time variables, without smartphone-sensing features), and (3) personalized sensing (incorporating participant ID, time, and smartphone sensing features, without affect history). Both ElasticNet and XGBoost used a standardized preprocessing pipeline (z-scoring of continuous predictors) prior to model fitting. For ElasticNet, we evaluated 21 hyperparameter combinations crossing 7 regularization strengths (α=0.001, 0.003, 0.01, 0.03, 0.1, 0.3, 1.0) with 3 L1 mixing parameters (l1_ratio=0.1, 0.5, 0.9), each fit for up to 20,000 iterations. For XGBoost, we searched 6 candidate configurations varying the number of trees (200-500), maximum tree depth (2-3), learning rate (0.02 - 0.05), row and column subsampling (0.8 - 1.0), minimum child weight (1-5), and L1/L2 regularization strength. Within each of the 6 sensor aggregation timescales and 2 semantic-location label versions, the hyperparameter configuration with the lowest validation-set RMSE was selected. Across test sets, the specific timescale and semantic label specifications that yielded the lowest test-set MAE were selected and reported as the top-performing model under each.

RenderX

N-BEATS Model: For Personalized Affective History Approach

To evaluate the personalized affect-history approach, we implemented N-BEATS, a neural network for time-series forecasting composed of stacks of fully connected blocks with backward (backcast) and forward (forecast) residual connections. Unlike the TFT, N-BEATS relied exclusively on each participant's own historical affect sequence as input, incorporating no smartphone-sensor features. We used fixed-length sequence windows of 16 encoder time points and 4 prediction time points to match the TFT's maximum window. Outcomes were normalized within participants using a group normalizer with a softplus transformation, and missing time steps were permitted. We set the N-BEATS stack widths to 32 and 64 and the backcast loss ratio to 0, thereby weighting the training loss entirely toward the forecast; all other architecture parameters retained the PyTorch Forecasting defaults. Training used a learning rate of 0.001, weight decay of 0.01, batch size of 64, and gradient clipping at 0.01. We monitored validation loss and retained the checkpoint with the lowest validation loss. Training stopped after 5 consecutive validation checks without an improvement of at least 0.0001, with a maximum of 30 epochs. Training was deterministic and used a random seed of 42. This fixed-window procedure yielded 3746 (NA) and 3741 (PA) windowed training sequences derived from the same underlying training observations described above.

Temporal Fusion Transformer: For Full-Information and Personalized Sensing Approaches

To test hypothesis 1, we compared TFTs' performance (ie, R^2, MAE, and RMSE) with that reported in existing studies [12,13]. For exploratory aim 1, we examined TFTs' performance across 6 temporal scales (paired n=133). To test hypotheses 2a and 2b, the distal and proximal effects of different types of smartphone-tracked behaviors, we evaluated the top feature importance weights across timescales across encoder and decoder inputs. Because raw TFT variable importance weights reflect nonlinear transformations, we cross-referenced top predictors with statistically significant effects from within-person linear mixed-effects models (detailed below). We used up to 16 consecutive data points (encoder 8 - 16) of smartphone sensor data (past inputs) to predict the following up to 4 time points (decoder 1 - 4; future inputs) of momentary affect. The important predictors in the past inputs represent more distal factors, whereas future inputs represent more proximal factors in predicting momentary affect. In addition, important predictors in larger timescales and past inputs indicate features with more distal effects, whereas those in smaller timescales and future inputs indicate more proximal or immediate features. For hypothesis 3a, which tested whether self-reported semantic-location features changed performance, we used the paired participant-clustered bootstrap and participant-level Wilcoxon procedures described for aim 1. To test hypothesis 3b, we compared the pattern of important past and future inputs before and after incorporating self-report semantic location features.

All TFT models were implemented in the PyTorch Lightning framework through Google Colab Pro (NVIDIA A100-SXM4-40GB, 40 GB RAM). Model configurations were: (1) initialized the learning rate at 0.001 and then determined it via a systematic finder. The learning rate suggested by the systematic finder was scaled down by a factor of 4 in model training; (2) set the hidden size to 64 and hidden continuous size of 32 to deal with complex features; (3) added 4 multihead attention heads to capture multiscale temporal dependencies; (4) applied a dropout rate of 0.1 and gradient norm clipping threshold of 0.1 in the network to avoid overfitting; (5) used the Quantile loss function for probabilistic interval predictions; and (6) set the batch size to 10 to balance memory footprint and gradient estimation stability.

Using the validation set described above, we monitored validation loss after each epoch, retained the checkpoint with the lowest validation loss, and applied early stopping after 5 consecutive epochs without a minimum improvement of 0.0001 (up to 100 epochs). The retained checkpoint was used for all subsequent test-set evaluation. To make personalized predictions, the full-information TFT included 4 static covariates: participant ID, sequence encoder length, NA or PA center (individual's mean affect intensities), and NA or PA scale (individual SD of affect intensities). To isolate variance sources for our aim 1, we specified a separate personalized sensing TFT model by refitting the optimal specification for NA and PA after omitting static affect-history statistics (NA or PA center and NA or PA scale). Test-set performance for this model was compared against the ElasticNet and XGBoost baselines to select the best models under the personalized sensing approach.

CIs and Significance Testing

We computed 95% CIs for R^2, RMSE, and MAE using a participant-level bootstrap. To account for the nonindependence of repeated observations within individuals, resampling was performed at the participant level rather than the observation (EMA) level. Specifically, participants (not individual rows) were resampled with replacement for 2000 resamples, and all test-set rows of each selected participant were pooled. Model performance (R^2, RMSE, and MAE) was computed for each resample, and the 2.5th and 97.5th percentiles of the resulting bootstrap distribution were the CI.

To test aim 1, which was to evaluate whether each approach's held-out predictive performance differed from the baseline (person-mean affect), we conducted 2 complementary paired statistical tests applied to each approach's best-performing specification (see above). First, we performed a primary bootstrapping comparison by calculating the MAE difference ($\Delta MAE = MAE_{Approach} - MAE_{Baseline}$) for each EMA in the test set. Using 2000 resamples at the participant level (with a fixed random seed of 42 for reproducibility), we derived a 95% CI and a 2-sided bootstrap P value (defined as twice the smaller proportion of resampled ΔMAE values falling at or below zero vs at or above zero). Second, as a supplementary test, we conducted a participant-level paired Wilcoxon signed-rank test comparing paired series of mean per-participant $MAE_{Approach}$ and $MAE_{Baseline}$ values, avoiding the assumption of independent repeated observations. To remain conservative, an approach's improvement over the baseline was considered statistically

XSL•FO
RenderX

significant only when both tests met the significance threshold of α=.05. Effect sizes for these paired comparisons were reported as Cohen d_z (mean of participant-level ΔMAE divided by its SD, accompanied by approximate 95% CIs).

For exploratory aim 1 (evaluating whether TFT performance differed across the 6 temporal aggregation windows), we conducted a nonparametric Friedman test on a participant-by-window matrix containing each participant's mean MAE at each timescale (n=133). When the omnibus test indicated significant differences across windows, we conducted a post hoc analysis using all 15 pairwise Wilcoxon signed-rank tests between timescales, adjusting for multiple comparisons using the Benjamini-Hochberg false discovery rate (FDR) procedure. For hypothesis 3a (testing whether incorporating self-reported semantic-location features improved model performance), we applied the same dual-testing procedure as in aim 1, a paired participant-clustered bootstrap alongside a participant-level paired Wilcoxon signed-rank procedure.

Linear Mixed-Effect Models

Since the TFTs extract the importance of a feature but not the direction or the magnitude of associations, we further examined the within-person associations with a series of linear mixed-effects models. Models were estimated using restricted maximum likelihood (REML) via the lmer() function in the *lme4* package in R (R Core Team; accessed via pymer4 in Python). All variables were standardized (z-scored) before analysis to yield standardized coefficients β. All predictors were person-mean centered to only investigate within-individual associations. In each linear mixed-effect model, momentary NA or PA intensities were outcomes and were regressed on one smartphone-tracked predictor (eg, person-mean-centered total distance traveled in the 3 hours preceding the survey). In each model, we included a random intercept to handle between-person baseline differences in affect and included a random slope to allow the relationship between the predictor and outcome to vary across individuals.

Results

Participants Characteristics

The final analytic sample consisted of 133 adults (mean age 36.4, SD 12.0, age range: 19 - 63 years). Participants' gender composition was as follows: 71 out of 133 (53.4%) women, 51 out of 133 (38.3%) men, 3 out of 133 (2.3%) gender diverse, and 8 out of 133 (4.9%) unknown. Their race was 91 out of 133 (68.4%) White, 14 out of 133 (11.8%) Asian, 12 out of 133 (6.9%) Black or African American, 7 out of 133 (5.3%) others, and 9 out of 133 (6.8%) preferred not to say. A total of 9 out of 133 (6.8%) of the analytic sample reported being Latinx or Hispanic.

Aim 1: Model Performance in Predicting Momentary NA and PA

Table 2 presents the best-performing model under different approaches (ie, including different sets of predictors and algorithms). Results showed that models that simply used the mean affect intensity for each person (predictors: ID + training NA or PA) showed moderate performance on unseen test sets (NA: R^2=40.2% [95% CI 31-48.2], RMSE=0.89 [95% CI 0.80-0.97], MAE=0.66 [95% CI 0.60-0.73]); PA: R^2=36.1% [95% CI 20.4-48.3], RMSE=0.93 [95% CI 0.84-1.03], MAE=0.71 [95% CI 0.65-0.78]). Nonpersonalized sensing models performed significantly worse than the baseline for both outcomes (both P values<.001; NA Cohen d=0.56; PA Cohen d=0.37). Among personalized benchmarks, the ID-and-time ElasticNet was significantly worse for NA (ΔMAE=0.020, 95% CI 0.004-0.036; $P_{bootstrap}$=.01; $P_{Wilcoxon}$=.04; Cohen d=0.21), whereas the affect-history N-BEATS model did not differ for NA. N-BEATS produced a statistically significant but very small improvement for PA (ΔMAE=−0.002, 95% CI −0.003 to−0.000; $P_{bootstrap}$=.04; $P_{Wilcoxon}$=.01; Cohen d=−0.18). The personalized sensing TFT without Affect Center and Scale did not differ from the baseline for either outcome. The full-information TFT significantly improved NA prediction (ΔMAE=−0.040, 95% CI −0.065 to−0.015; $P_{bootstrap}$=.001; $P_{Wilcoxon}$=.004; Cohen d=−0.27) but not PA prediction (ΔMAE=−0.006, 95% CI −0.031 to 0.020; $P_{bootstrap}$=.66; $P_{Wilcoxon}$=.13; Cohen d=−0.04). The best full-information models used 6-hour features with self-reported semantic locations for NA and 1-hour features with self-reported semantic locations for PA.

[a]NA: negative affect.

[b]PA: positive affect.

[c]R^2, RMSE, and MAE are computed on the held-out test set; brackets denote the 95% participant-level bootstrap CI (2000 resamples with replacement). ΔMAE vs Baseline=$MAE_{approach}$- $MAE_{Person\text{-}Mean\ Baseline}$, calculated from a paired participant-level bootstrap (positive values indicate worse performance than baseline, negative values indicate improvement). The *P* (bootstrap) value represents the 2-sided bootstrap *P* value for this difference; *P* value (Wilcoxon) is derived from a participant-level paired Wilcoxon signed-rank test on MAE (n=133 participants rather than 532 observations, to avoid pseudoreplication). Cohen *d* indicates the paired-samples effect size (mean difference divided by the SD of the MAE differences). Bold text indicates a statistically significant improvement or decline relative to the person-mean baseline (requiring both bootstrap and Wilcoxon *P*<.05). For approaches incorporating passive sensing feature sets (combinations of time windows and semantic-location label sets), the row displays the best-performing specification based on test-set MAE.

[d]RMSE: root-mean-square error.

[k]N-BEATS: neural basis expansion analysis for interpretable time series forecasting.

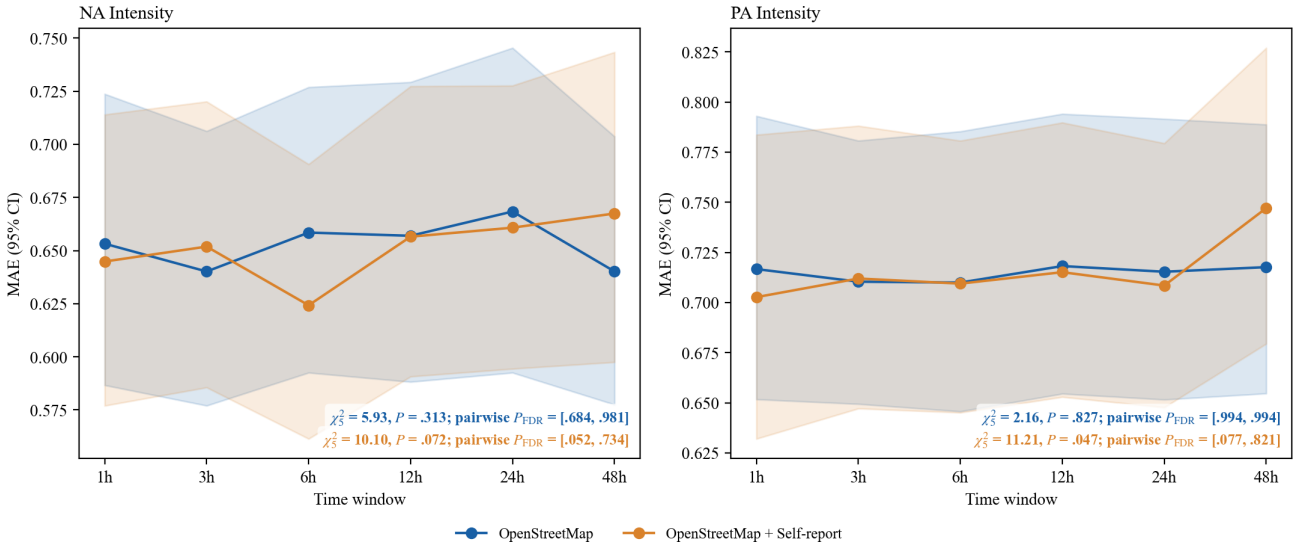
Aim 2: Role of Timescales in Model Performance and Variable Importance

Overview

Figure 2 shows MAE across the 6 aggregation windows. In the figure, shaded bands represent 95% participant-level bootstrap CIs. In-panel statistics report the Friedman omnibus test across all 6 time windows and the range of FDR-corrected pairwise Wilcoxon *P* values across all 15 window-pair comparisons for each semantic-location feature set. For NA, neither the OpenStreetMap-only specification (χ^2_5=5.93, *P*=.31) nor the OpenStreetMap-plus-self-report specification (χ^2_5=10.10, *P*=.07) differed significantly across windows. FDR-corrected pairwise *P* values ranged from .05 to .98. For PA, the OpenStreetMap-only omnibus test was nonsignificant (χ^2_5=2.16, *P*=.83), whereas the OpenStreetMap-plus-self-report omnibus test reached significance (χ^2_5=11.21, *P*=.05), which was driven by the worst performance using the 48-hour OpenStreetMap-plus-self-report specification. However, none of the PA pairwise comparisons survived FDR correction (P_{FDR}=.08-.99). Thus, no specific pair of aggregation windows showed a robust performance difference.

Variable Importance Across Timescales

Figure 2. Temporal fusion transformer (TFT) mean absolute error (MAE) across time windows (1, 3, 6, 12, 24, and 48 hours) in predicting momentary negative affect (NA, left) and positive affect (PA, right) intensity, for semantic-location features derived from OpenStreetMap versus OpenStreetMap supplemented with self-report in the test set (n=133 individuals; total 532 surveys). FDR: false discovery rate.



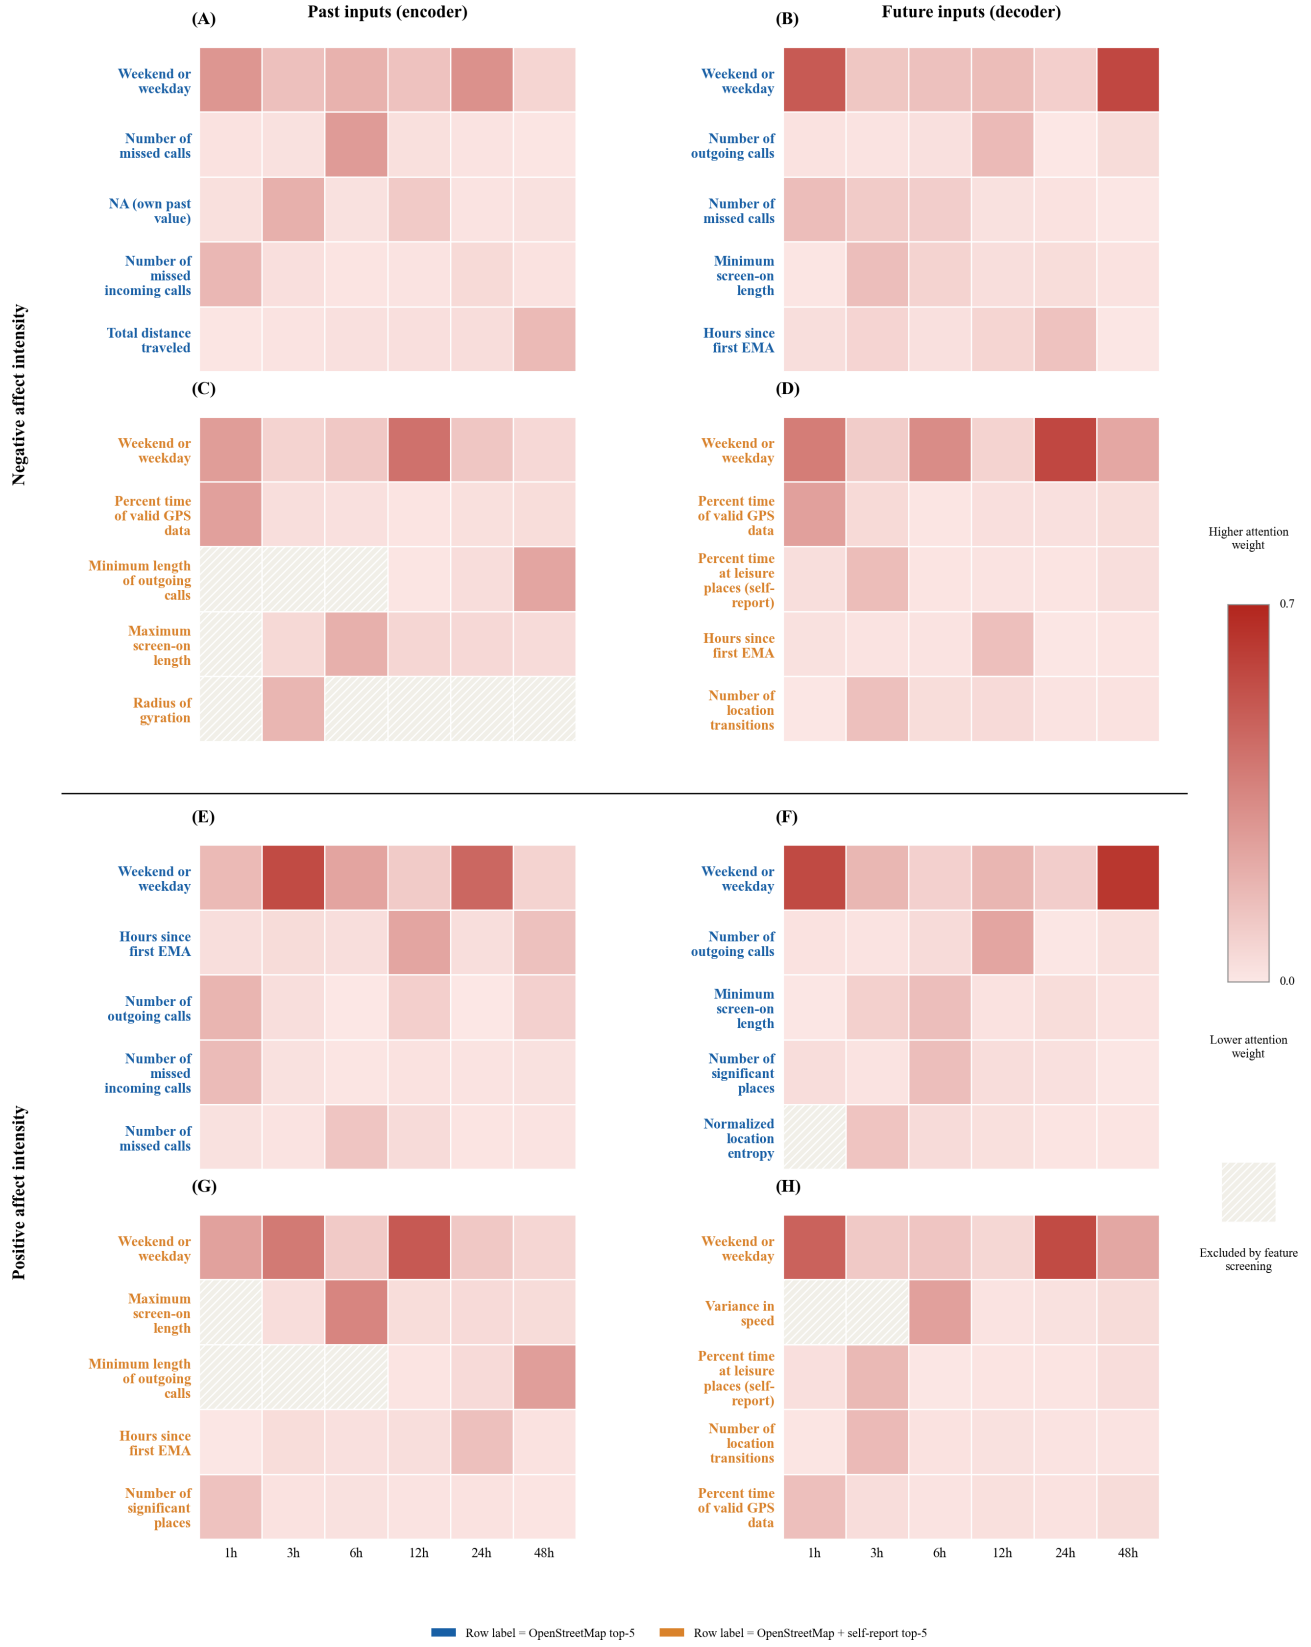


Figure 3 presents a heatmap of important past (left) versus future inputs (right) identified by the TFTs across time windows for predicting NA (upper 2 panels) and PA (lower 2 panels) using location features from OpenStreetMap (blue names) versus from OpenStreetMap supplemented with self-report. We did not find consistent support for hypothesis 2a. Although behavioral indicators of social interactions (ie, calls) and screen interactions appeared among the important future inputs for both NA and PA, this holds only before supplementing OpenStreetMap with self-reported locations to refine location features. After supplementing OpenStreetMap with self-reported locations to refine location features, percent time at leisure places (self-report) was an important future input for both NA and PA, especially in the 3-hour window (NA 0.16, PA 0.17). Partially supporting hypothesis 2b, partial-mobility features contributed as both past and future inputs, with number of location transitions and variance in speed as notable proximal (future) inputs and radius of gyration and number of significant places as distal (past) inputs. Not supporting hypotheses 2a and 2b, there is no clear pattern in variable importance across time windows (eg, consistently darker or lighter from left to right).

XSL•FO
RenderX

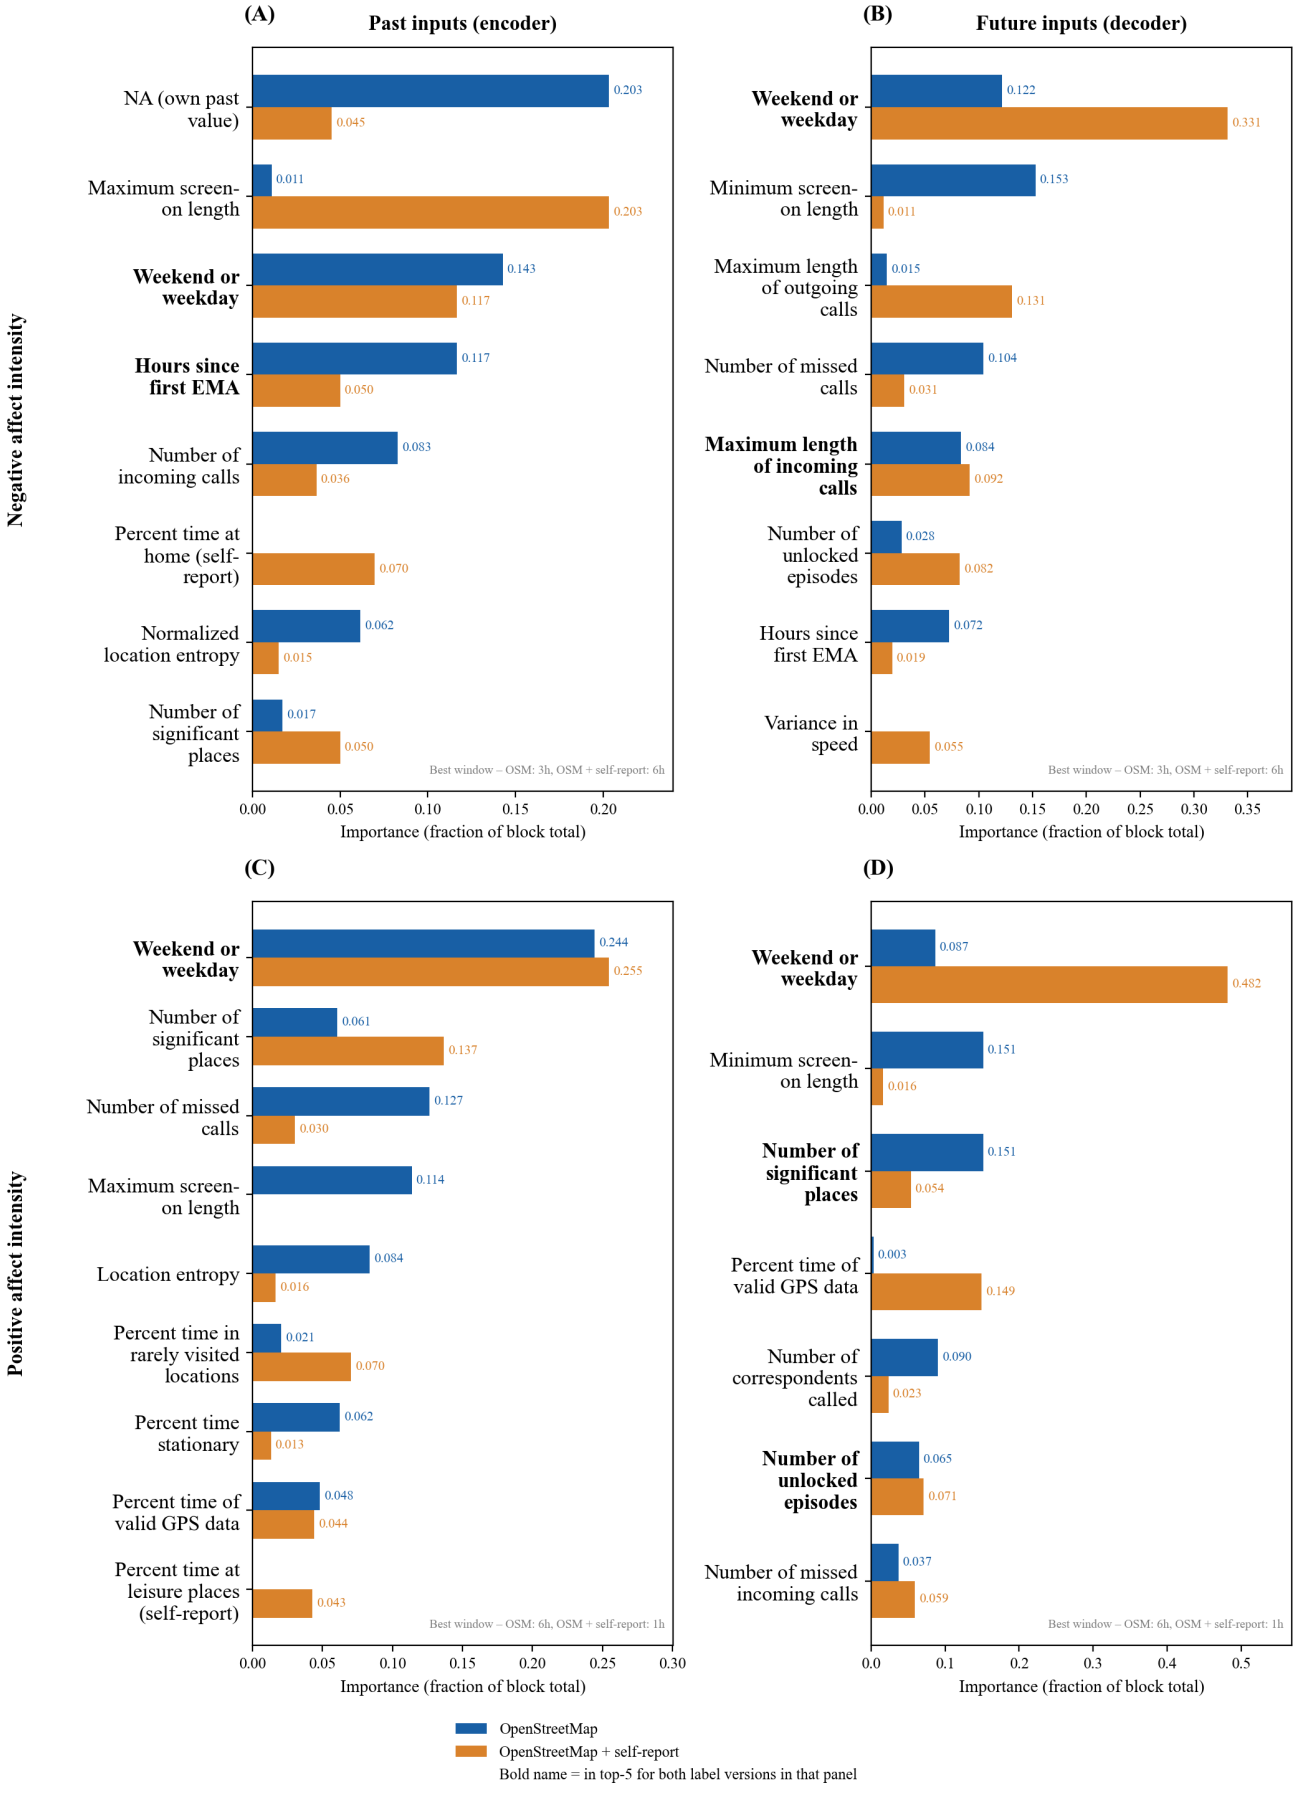
Figure 3. Heatmap of important past (left, panels A, C, E, and G) versus future inputs (right, panels B, D, F, and H) identified by temporal fusion transformer (TFT) across time windows for predicting negative affect (NA; upper panels A-D) and positive affect (PA; lower panels E-H) using location features from OpenStreetMap (blue names) versus from OpenStreetMap supplemented with self-report. EMA: ecological momentary assessment.

Outside of hypotheses, the individual's affect history was an important predictor across time windows for both NA and PA (left panels in Figure 3). Across time windows, a time variable (weekend or weekday) is an important future input and, sometimes, a past input across location feature sets for NA and PA, especially at the longer windows (24-hour as a future input and 12-hour as a past input; Figure 3).

XSL•FO
RenderX

Aim 3: The Role of Self-Report Semantic Locations

Overview



Overall, both bootstrapping and Wilcoxon significance tests suggested that adding self-report semantic-location features did not significantly change prediction accuracy for either NA or PA. Specifically, for predicting NA intensity, the best TFT using semantic-location features derived from OpenStreetMap only, which was based on 3-hour features (MAE=0.64), did not perform significantly differently from the TFT using semantic-location features from OpenStreetMap supplemented with self-report locations, which was based on 6-hour features (MAE=0.62; ΔMAE [95% CI]=0.016 [−0.009 to 0.040]; $P_{bootstrap}$=0.21; $P_{Wilcoxon}$=0.35; Cohen *d* [95% CI]=0.11 [−0.06 to 0.28]). Results were similar for PA, such that the best TFT before incorporating self-report locations, which was based on 6-hour features (MAE=0.71), did not perform significantly differently from the best TFT after incorporating self-report locations, which was based on 1-hour features (MAE=0.70; ΔMAE [95% CI]=0.007 [−0.012 to 0.026]; $P_{bootstrap}$=0.44; $P_{Wilcoxon}$=0.34; Cohen *d* [95% CI]=0.07 [−0.10 to 0.24]).

Variable Importance After Adding Self-Report Semantic Locations

Figure 4 presents the attention weights of past (left) versus future inputs (right) from the best-performing TFT for NA intensity (top) and PA intensity (bottom). Blue bars represent attention weights before adding self-report semantic locations, whereas orange bars represent attention weights after adding self-report semantic locations. Consistent with hypothesis 3b, incorporating self-report semantic locations changed the composition and relative ranking of important inputs, although the pattern of change varied across past and future inputs. The percent time spent at leisure places (self-report) emerged as an important input in the TFT attention weights, particularly at the 3-hour window for both NA and PA (Figure 3; NA: 0.16, PA: 0.17; see detailed attention weights for each variable in Tables S1 and S2 in Multimedia Appendix 1). Several GPS features indicating spatial mobility (variance in speed, number of location transitions, and radius of gyration) were identified among important inputs across models.

XSL•FO
RenderX

Figure 4. Attention weights of top-5 past (left; panels A and C) versus future inputs (right; panels B and D) from the best-performing temporal fusion transformer (TFT) in predicting momentary negative affect (NA, top, panels A and B) and positive affect (PA, bottom, panels C and D) intensity, for semantic-location features derived from OpenStreetMap (blue) versus OpenStreetMap supplemented with self-report (orange) in the test set (n=133 individuals; total 532 surveys). EMA: ecological momentary assessment.

RenderX

Within-Individual Associations in Linear Mixed-Effects Models

Tables S1 and S2 present standardized coefficients in linear mixed-effects models for NA and PA, respectively (see them in Multimedia Appendix 1). Smartphone-tracked behaviors showed weak, if any, bivariate associations with momentary affect intensity (all $|\beta|<0.06$). After FDR correction across 236 tests per outcome, 5 proximal call features were positively associated with NA: the numbers of incoming calls, outgoing calls, and correspondents in the 1-hour window and the numbers of outgoing calls and correspondents in the 3-hour window ($\beta=0.03$-0.06, $P_{FDR}=.003$-$.05$). Thirteen features were associated with PA after correction. PA was positively associated with location diversity across 3- to 24-hour windows (log location variance, location entropy, normalized location entropy, and number of significant places; $\beta=0.04$-0.06) and negatively associated with time at self-reported workplaces in the 1-, 3-, and 6-hour windows and with the number of correspondents in the 1-hour window ($\beta=-0.04$ to -0.05; $P_{FDR}=.002$-$.03$).

Sensitivity Analyses

Three sensitivity analyses supported the robustness of the primary findings. First, lowering the minimum number of valid EMA reports from 40 to 20 retained 167 participants (n=8398 NA EMAs and n=8391 PA EMAs), compared with 133 participants in the primary sample (n=7337 NA EMAs and n=7332 PA EMAs). Predictive performance did not differ significantly for either NA (6-hour, OSM + self-report; ΔMAE=0.04, 95% CI −0.10 to 0.20; $P_{bootstrap}=.624$; $P_{Wilcoxon}=.54$) or PA (1-hour, OSM + self-report; ΔMAE=0.12, 95% CI −0.07 to 0.36; $P_{bootstrap}=.26$; $P_{Wilcoxon}=.32$). Second, replacing MICE with median imputation did not significantly change performance for NA (6-hour, OSM + self-report; ΔMAE=0.010, 95% CI −0.001 to 0.021; $P_{bootstrap}=.07$; $P_{Wilcoxon}=.21$) or PA (1-hour, OSM + self-report; ΔMAE=0.0005, 95% CI −0.0046 to 0.0052; $P_{bootstrap}=.84$; $P_{Wilcoxon}=.70$). Finally, increasing the maximum encoder length from 16 (minimum 8) to 20 (minimum 12), while retaining a maximum decoder length of 4, did not significantly affect performance for NA (6-hour, OSM + self-report; ΔMAE=0.0008, 95% CI −0.0089 to 0.0106; $P_{bootstrap}=.89$, $P_{Wilcoxon}=.86$) or PA (1-hour, OSM + self-report; ΔMAE=0.0035, 95% CI −0.0080 to 0.0137; $P_{bootstrap}=.53$; $P_{Wilcoxon}=.21$).

Discussion

Principal Findings

This study parsed the contributions of EMA and smartphone sensing data to personalized predictions of momentary affect. On held-out EMA observations, smartphone sensing within the full-information TFT added statistically significant and modest predictive value for NA but small, nonsignificant value for PA relative to the person-mean baseline. Person-specific mean affect accounted for a substantial share of predictive performance. Although one PA omnibus test differed across aggregation windows, no pairwise time-window comparison survived FDR correction. Adding self-reported semantic locations did not significantly improve NA or PA prediction. Before these locations were added, mobility markers and smartphone social interactions appeared among important past and future inputs. After they were added, mobility markers appeared more often as past inputs, partially supporting hypothesis 2b, whereas screen and smartphone social interactions showed no consistent proximal or distal pattern, providing no support for hypothesis 2a. Overall, our results suggest modest added value of smartphone sensing over EMA for NA prediction following person-specific calibration.

Aim 1: Model Performance in Predicting Momentary NA and PA

Aim 1 tested how much each data source contributed to personalized prediction and whether the TFT improved on a person-mean baseline. Partially consistent with hypothesis 1, smartphone sensing added significant predictive value for NA (but not PA), empowered by transformer-based models. All prior studies made personalized predictions through incorporating all data sources, including both active and passive inputs [11-13]. Ultimately, the primary promise of digital phenotyping is the possibility of generating accurate predictions of momentary affect intensity using passive inputs alone. This is a goal that has attracted increasing interest given its broad clinical and practical implications. The present findings can be situated within a broader affect-dynamics framework in which momentary affect reflects a combination of relatively stable person-specific tendencies, recent affective trajectories, and immediate contextual inputs. Findings showed that participants' mean affect and affective history accounted for a substantial proportion of predictive performance, whereas smartphone sensing provided only modest incremental information. This pattern indicates that smartphone sensing should not yet be viewed as a standalone replacement for active self-report, but rather as a complementary source of information to EMA. Future personalized prediction research should consistently evaluate the person-mean affect intensity as an essential benchmark and explore richer multimodal passive signals that capture dimensions of emotional experience beyond smartphone-tracked behaviors (eg, physiological measures and linguistic features).

Another motivation of the study was to address the relative neglect of PA in the affective computing literature, particularly given its established importance for psychological well-being and depression treatment. Our findings show that the incremental value of smartphone sensing was significant and modest for NA, but small and nonsignificant for PA. Consequently, high predictive performance for NA (or depressed mood, which is more commonly investigated) should not be assumed to automatically generalize to PA. Current sensing modalities may be differentially informative across valence dimensions. Improving PA prediction may require larger sample sizes or alternative digital markers. Future affective computing research focused on PA is clearly warranted.

Aims 2 and 3: The Role of Timescales and Self-Reported Semantic Locations

Aims 2 and 3 examined aggregation timescales and self-reported semantic locations. Across 6 windows, 3 omnibus tests were

XSL•FO
RenderX

nonsignificant and 1 PA test reached statistical significance, but no pairwise comparison survived FDR correction. Aggregation-window choices may therefore be guided partly by practical considerations, such as computational efficiency, pending replication. Adding self-reported semantic locations did not improve predictive performance, so the value of collecting these data appears to lie more in contextual interpretation than in accuracy.

Three broader patterns emerged from the attention-weight analyses. First, incorporating self-reported semantic locations changed the composition and relative ranking of important inputs despite not improving predictive accuracy, suggesting that contextual information may contribute more to interpretation than to predictive accuracy. These changes did not follow a clear pattern across NA and PA or across past and future inputs. Time at self-reported leisure places appeared as an important input after semantic-location features were added. Second, the TFT prioritized different classes of smartphone-tracked behavior across aggregation windows while maintaining broadly comparable predictions. Third, spatial-mobility features appeared more consistently as past than future inputs, suggesting that they may summarize accumulated behavioral context rather than immediate affective triggers. However, these attention weights indicate model-based predictive relevance, not causal effects, and should be treated more as hypothesis-generating.

Implications for Research and Applications

The affective computing approach to personalized monitoring of affect intensity is still in its infancy, and this study addressed three key methodological questions: (1) how much variance did smartphone sensing add to personalized prediction of momentary affect beyond EMA baselines, (2) does the data aggregation timescale impact predictive performance, and (3) what is the value of integrating self-report semantic locations. First, our framework provides a more rigorous benchmark for evaluating passive sensing for affect monitoring. Future work on personalized predictions should benchmark models against person-specific mean affect, demonstrating incremental predictive value rather than relying solely on absolute accuracy metrics. Second, because predictive performance remained stable across the 6 evaluated timescales, feature engineering decisions regarding aggregation windows can be guided by practical considerations, such as computational efficiency. Third, incorporating contextual self-reports may enhance the interpretability of digital behavioral markers, even when they do not directly improve prediction accuracy. Finally, rather than replacing EMA, passive sensing may reduce the frequency of active assessment while maintaining continuous, individualized monitoring between self-reports.

Limitations and Future Directions

This study has several limitations. First, within-person reliability was modest for NA and PA (ω=0.64 and 0.69), which constrains achievable predictive accuracy. Future studies should balance more reliable measurement of momentary affect against EMA burden. Second, the feature-importance rankings produced by the TFT reflect associational rather than causal relationships. A predictor may receive high attention weight simply because it is correlated with an unobserved driver or acts as a proxy that reduces prediction error. Consequently, these findings should be interpreted as hypotheses regarding potential mechanisms rather than definitive evidence of causal influence. Experimental manipulation or microrandomized intervention studies are necessary to establish causal pathways.

In addition, our models were good at predicting momentary affect intensity at time points immediately following the training period (about 2 weeks) for the same individuals. However, it is unclear whether our models can make good predictions days, weeks, or even months after the training data time points. Future work could examine whether algorithms can stop assessing self-report experiences after a certain period and then allow ubiquitous and continuous monitoring. If so, it would also be important to clarify the maximum length of the no-report period.

The present findings illustrate AI's potential to predict momentary affect in daily life (situational generalizability) by forecasting an individual's future states from their own past data (within-person temporal generalizability). A critical remaining question concerns population generalizability and whether such models can generalize to entirely new individuals. We maintain that, at least for predicting momentary affect intensity, developing personalized models is more feasible than building universal models expected to generalize across individuals. In human-to-human interactions, people can readily recognize distinct emotions in a stranger, but accurately gauging another person's emotional intensity typically requires familiarity. Consistent with this distinction, research evaluating whether passive sensor data could classify discrete momentary affect states (eg, angry or not angry) across new individuals found that traditional ML models performed only slightly above chance [8]. Although population-level prediction of affect intensity without a priori calibration remains challenging, achieving it would carry substantial public health implications.

Third, the present work is limited by the number of modalities in data sources. Additional smartphone sensors collecting other social interaction data (eg, text messages or social media) and audio information (eg, volumes and frequency of meaningful conversations around an individual) could add modalities while maintaining the benefits from the cheap and wide access of smartphones. Future affect computing research could also benefit from a larger dataset with more people and more observations, as other AI fields (eg, large language models) have illustrated that "a 'dumb' algorithm with lots and lots of data beats a 'clever' one with modest amounts of data" [42].

Conclusion

This study highlights the incremental value of smartphone sensing for personalized, short-term prediction of momentary affect beyond simple person-specific affective baselines. Notably, this added predictive value was significant only for NA, while participants' mean baseline affect accounted for a substantial proportion of overall predictive performance across all models. No pairwise performance difference emerged across the 6 passive-data aggregation windows. Furthermore, incorporating self-reported semantic locations did not improve prediction accuracy, though it provided more interpretable contextual features for generating hypotheses about affect-behavior relations. Overall, these findings suggest that

XSL•FO
RenderX

smartphone sensing is currently better positioned to augment rather than replace EMA. Following an initial period of person-specific calibration, passive sensing may estimate short-term affective fluctuations between self-report prompts and support lower-burden or adaptive EMA designs. Replication in larger, more diverse, and clinical samples remains essential before deploying these models in real-world assessment or intervention use.

Acknowledgments

The authors would like to thank Dr Ellen E Fitzsimmons-Craft, Dr Joshua R Oltmanns, Dr Nathaniel S Eckland, and Dr Jocelyn Lai for their review and feedback on the manuscript. The authors thank Anna Leah Davis and Analise Black for their assistance with data collection.

Generative AI tools were used to assist with code development, debugging, and refinement, including code for data preprocessing and implementation of the temporal fusion transformer and comparison models. They were also used to support language editing and improve the clarity and organization of selected portions of the manuscript. The tools used included ChatGPT-4o and GPT-5.6 (OpenAI), Claude 3.5 Sonnet and Fable (Anthropic), Gemini 1.5 Pro (Google), and Microsoft Copilot (Microsoft Corporation). All AI-assisted code and text were critically reviewed and revised by the authors. The authors retained full responsibility for the study design, analytic decisions, accuracy of the code, interpretation of the results, and final manuscript.

Funding

Funding was provided by the Office of the Provost at Washington University in St. Louis (total amount of US $50,000). The funder had no involvement in the study design, data collection, analysis, interpretation, or the manuscript preparation.

Data Availability

The datasets generated or analyzed during this study are not publicly available because they contain sensitive smartphone-sensing and location information, and because public data sharing was not covered by participants' consent. However, they may be available from the corresponding author on reasonable request, subject to institutional approval, and an appropriate data-use agreement. The analysis code is available from the corresponding author on reasonable request.

Abstract

Background: Bipolar disorders (BDs) represent a significant global health challenge, with frequent and severe affective episodes that impair quality of life. Accurate, early prediction of these episodes remains difficult. Recent advances in mobile sensing offer new possibilities to detect prodromal changes via smart digital phenotypes, such as geolocation data.

Objective: This study aimed to examine whether spatial exploratory behavior, assessed via passive GPS data, can predict depressive and manic episodes in individuals with BD. Specifically, we evaluated the predictive value of unique places visited and related mobility metrics using statistical process control (SPC) techniques to identify both early deviations indicative of prodromal states and changes occurring during ongoing affective episodes.

Methods: Using high-resolution GPS data from the BipoSense dataset, we applied Density-Based Spatial Clustering of Applications with Noise to extract behavioral mobility indicators: number of unique places visited, frequency of location changes, and time spent per location. We implemented exponentially weighted moving average (EWMA)–based SPC to identify "out-of-bounds" deviations from individual baselines. We then tested the alignment of these deviations with affective episodes and the prodromal periods. Optimization of SPC parameters (λ and control limit L) was performed to enhance predictive accuracy.

Results: The analysis included 28 participants with BD and a total of 10,213 observation days, covering 26 depressive and 20 (hypo)manic episodes. Examining whether control limits distinguish affective episodes from euthymic days via multilevel models revealed that median time spent at clusters indicated both depressive and (hypo)manic episodes the best, whereas the number of unique clusters showed no significant association with phase transitions. While EWMA-SPC detected behavioral deviations during affective episodes, no single variable consistently met predefined thresholds for both sensitivity and specificity. Optimized SPC settings improved performance, but the number of unique places alone did not robustly predict prodromal or acute episodes. No statistically significant predictive accuracy (eg, sensitivity >70% and specificity >70%) was achieved for any individual indicator (P>.05). However, some SPC charts suggested within-person temporal deviations preceding episodes, indicating limited yet potentially informative patterns.

Conclusions: Although unique places visited alone may not suffice as a predictive marker, the application of EWMA-based SPC to GPS data holds promise for the development of smart digital phenotypes. Although our analysis to predict upcoming episodes did not yield robust predictive accuracy in its current form, it provides a promising conceptual framework for individualized, low-burden behavioral monitoring. Further research is needed to refine existing digital biomarkers, develop new ones, and validate their clinical utility in reducing the frequency and severity of illness phases.

Introduction

Smart Digital Phenotyping in Bipolar Disorder

Bipolar disorders (BDs) affect up to 40 million people worldwide and represent a significant global burden of disease [1], imposing considerable personal and societal challenges [2]. Characterized by recurring episodes of depression and mania, the aim of BD disease management is to reduce the frequency, duration, or intensity of affective episodes, thereby extending the time spent in remission (euthymia) [3]. One promising strategy for maintaining euthymia is the early detection of emerging episodes, which facilitates timely interventions that may prevent the development of full-blown episodes. This can be achieved through intensive longitudinal study designs, such as digital phenotyping [4] and ambulatory assessment [5], as they enable continuous passive monitoring of symptom-related parameters over extended periods, thereby facilitating real-time feedback and automated forecasting.

Despite their potential, digital phenotyping approaches have yet to demonstrate a meaningful impact on disease trajectories in BD [6-10]. To address this, the need for clinically relevant smartphone-derived indices, so-called "smart digital phenotypes," has been emphasized [11]. Unlike conventional smartphone-based measures, such as the number of incoming calls or steps per minute, smart digital phenotyping aims to extract clinically meaningful features that more closely reflect psychopathology. For instance, rather than measuring the number of incoming calls, analyzing speech patterns (eg, number of words spoken per minute [11]) may better capture the *Diagnostic and Statistical Manual of Mental Disorders* (Fifth Edition; *DSM-5*) criteria, such as talkativeness or pressure to keep talking [12]. Similarly, analyzing mobility patterns, such as visits to novel or unusual locations, may provide a more nuanced understanding of behavioral changes, compared to simply calculating daily kilometers traveled.

In particular, enhancing the analysis of location-based passive sensing data holds significant yet underused potential [13]. Given the rich behavioral insights embedded in raw GPS data, sophisticated geospatial analyses could substantially improve passive sensing approaches for BD, offering a novel and promising avenue for research.

Previous Work

A recent systematic review of geospatial analyses in depression has shown multiple correlations across several key mobility metrics, such as entropy or distance. Notably, among 31 studies, 16 explored the relationship between depression and individual location-based data, 12 focused on predicting depression states, and 3 integrated location data with additional sensing modalities to assess depression [14]. The authors of the systematic review state that location data reflect changes in individual mood states and consistently exhibit a strong correlation with depression. Additionally, the reviewed studies demonstrate the predictive power and utility of location data in forecasting depressive symptoms.

However, the applicability of these study designs to BD is far from trivial. First and foremost, studies must not only ensure a sufficient number of participants to guarantee statistical power but also cover a sufficiently long observation period. Shorter study durations may fail to encapsulate critical episodes, thereby undermining the true potential of digital phenotyping [4]. Second, studies should involve individuals with a verified BD diagnosis, ideally reviewed by a clinician to ensure accurate ground truth, which is crucial for precise episode onset identification in analyses. Thus, precise identification of episode onset at the day level is critical. Even a deviation of only 3 days in a retrospective assessment spanning 3 months can blur the distinction between true prediction and the mere confirmation of an imprecisely recorded episode onset, especially when forecasts only anticipate episodes by a few days and lack a high-frequency, valid ground truth measurement [15]. Thus, several studies on digital phenotyping for BD episode prediction have yielded inconclusive results due to these challenges, as well as heterogeneous protocols and variable parameters [7].

Considering this, there are 2 studies worth mentioning that analyze spatial data to detect episodes in BD. Palmius et al [16] analyzed geographic data from 22 participants with BD and 14 healthy controls (HC), detecting depressive symptoms as measured via QIDS-SR16 (Quick Inventory of Depressive Symptomatology–Self-Report, 16 items) with 85% accuracy using location recordings alone. However, location variance was operationalized as "entropy" by clustering stationary locations via k-means, adjusting k until clusters were 400 m apart. This differs from classical spatial entropy in geography [17] and may limit the clinical relevance of smart digital phenotyping. A more clinically meaningful approach should distinguish between unique places visited, frequency of location changes, and time spent at each cluster. Additionally, the study's short 3-month duration, limited symptom variance, and reliance on self-reported symptoms without expert classification pose significant limitations. Another relevant study examined differences in passively collected smartphone-based location data between 48 patients with BD and 31 HC [18], as well as investigating location data across different affective states for up to 9 months. Lower mobility was observed during depressive states compared to euthymic periods in patients with BD. Furthermore, patients with BD demonstrated lower location variance during affective states compared to euthymic periods. Limitations of this study, similar to those reported earlier, primarily concern the conceptualization of entropy, which poses challenges in constructing clinically relevant indices, as well as the study duration, which, although extended to up to 9 months, remains relatively short.

In sum, empirical findings on BD episode prediction from geospatial parameters remain inconclusive. This may be largely due to the methodological limitations mentioned earlier and the suboptimal operationalization of entropy. Most importantly, however, both studies adopt a dimensional approach to BD symptomatology, rather than distinguishing distinct affective episodes. This is evident in their reliance on self-reported symptom fluctuations, rather than focusing on the prediction of actual emerging episodes. However, this distinction is crucial because accurately predicting new affective episodes is essential for mitigating patient suffering and improving clinical care. Addressing these gaps requires well-designed longitudinal

XSL•FO
RenderX

studies that capture a sufficient number of emerging episodes and accurately detect their onset [8].

Spatial Movement Patterns in BD

Investigating the predictive properties of nuanced location-based passive sensing parameters in a sufficiently powered, temporally exact dataset to assess their clinical value in patients with BD holds significant promise. Changes in activity and energy are cardinal symptoms of BD: mania is, among other things, characterized by increased goal-directed activity and psychomotor agitation, whereas depressive episodes show reduced drive, diminished activity, and low energy (*DSM-5* [12]). These symptoms manifest in observable behavioral changes and translate to spatial movement patterns or exploratory behavior.

Empirical evidence supports this link. Animal models reveal altered exploratory behavior in mania-like [19] and depression-like [20] states. Reverse-translational models using an adapted version of the open field test (a standard rodent paradigm that assesses locomotor activity, anxiety-related behavior, and exploration) indicate that patients with BD display increased motor activity, more unpredictable exploration patterns, and more object interactions compared to HCs or patients with schizophrenia [21-23]. Notably, heightened activity and exploratory behavior persist even during euthymic phases [21,24,25]. Furthermore, it is generally assumed that individual movement patterns tend to be highly regular and predictable over time [26], as evidenced, for instance, by rather stable numbers of visited locations [27]. This raises an important question: Do patients with BD exhibit generally altered yet stable movement patterns as a trait, or do these patterns fluctuate according to symptomatology and affective state (eg, depressed, manic, and euthymic)?

To assess their clinical utility to predict and detect affective episodes, temporal dynamics of movement patterns in BD must be examined in detail. Current metrics, such as entropy used in the studies mentioned earlier, show routine but often fail to capture the full complexity of spatial behavior. It is crucial to differentiate between the time spent at a given location and the number of unique locations visited. For instance, very simplified, a regular daily commute might reflect euthymia, while frequent visits to different bars could indicate mania, whereas predominantly staying at home might signal depression. Understanding the timing and nature of these changes is key for early detection of emerging episodes.

These movement patterns can be effectively analyzed in spatial science cluster analysis tailored for longitudinal GPS data, combined with Geographic Information System–based mapping approaches, can visualize movement paths, hotspots, and clusters, and refine statistical parameters for greater accuracy. This simplifies complex data, uncovers hidden geographical patterns, and helps detect outliers, while also accommodating environmental factors such as geography, infrastructure, climate, and social context. Ultimately, advanced geospatial analysis of GPS data could be a valuable tool in developing smart digital phenotypes for BD.

Statistical Process Control

Predicting emerging episodes relies not only on valid smartphone-derived indices but also on a prediction model. The exponentially weighted moving average (EWMA)–based statistical process control (SPC) method may offer a valuable approach in this context. SPC was originally developed to monitor industrial production processes and detect when the quality or performance of a product deviates significantly from expected standards by giving “out-of-bounds” indications [28]. This concept can also be applied to psychopathology, where euthymia is defined as a stable, functioning phase, and affective episodes are seen as processes that are “out of bounds” [29].

For instance, Schreuder et al [30,31] applied EWMA-SPC to repeated emotion assessments in at-risk and remitted adults, showing that deviations beyond control limits could signal persistent mental health problems or predict depressive episode recurrence. While SPC provided useful warning signals, its sensitivity remained limited, and its classification accuracy was moderate, highlighting both the promise and current limitations of the method [31].

EWMA-based SPC methods that use passive sensing and e-diary parameters have recently been used to detect prodromal symptoms of emerging affective episodes in patients with BD by Ludwig et al [15]. They tested whether digital phenotypes derived from passive sensing are marked as “out of bounds” during affective episodes and investigate whether these changes were already visible in the prodromal phases of affective episodes. Their results showed that, despite its potential as a low-burden tool, passive sensing did not reliably detect episodes or prodromal states. Self-reported bipolar mood was more effective than passive sensing in predicting current episodes, while prodromal phase prediction remained challenging. SPC with personalized control limits did not outperform established clinical cutoff scores, and optimizing SPC settings did not improve the balance between emerging episodes and false alarms. Ludwig et al [15] suggest that future research should focus on mobile sensing parameters more aligned with psychopathology to improve validity and sensitivity.

Research Questions

Given the reported findings of altered exploratory behavior of humans and animals in mania-like and depression-like episodes, we investigated spatial movement patterns in patients with BD. To enable a comparison between episodes (euthymic, manic prodromal, manic, depressive prodromal, and depressive), we leveraged GPS data from the BipoSense dataset to analyze characteristics of the unique places visited by patients with BD (number of unique places visited, frequency of location changes, and time spent at each place). Although this study used the same dataset as Ludwig et al [15,32], our analytical approach differed.

The previous studies from this dataset focused on e-diary measures and on standard mobile sensing parameters. As the latter approach was disappointing, we argued that future studies might focus on mobile sensing parameters that more closely align with psychopathology. Developing smarter digital phenotypes, such as specific geolocation measures derived from GPS data, represent a promising direction, as these parameters

XSL•FO
RenderX

can be aligned with empirical evidence, partly informed by animal models, while at the same time offering a low-burden, continuously monitored approach with substantial potential. Although Ludwig et al demonstrated that e-diaries still outperform passive sensing, passive sensing offers considerable advantages, as mentioned earlier. Consequently, our study aimed to identify a passive sensing parameter (or "smart digital phenotype") that is most suitable for predicting emerging episodes, which is of highest priority from a clinical perspective.

To achieve this, we used EWMA-based SPC methods as a prediction model. We hypothesized that during depressive episodes, the EWMA-based number of unique places visited is lower (oversimplified: "fewer unique locations are visited") and that the EWMA-based number of cluster changes in general is lower (oversimplified: "fewer changes between locations are happening"). Additionally, we hypothesized that the EWMA-based time spent at each place is higher (oversimplified: "individuals remain at specific locations longer"). Conversely, we expected the opposite pattern to emerge during manic episodes. Furthermore, we extended our investigation to prodromal phases, examining whether these same spatial behavior patterns precede the onset of depressive or (hypo)manic episodes. In fact, we hypothesized that the same EWMA-based spatial behavior patterns observed during depressive and (hypo)manic episodes will also manifest in prodromal phases, preceding full episodes and potentially allowing early detection. Second, we investigated whether the predictive accuracy can be enhanced by adjusting SPC settings (λ and L) and evaluate the resulting sensitivity and specificity in the context of potential clinical application.

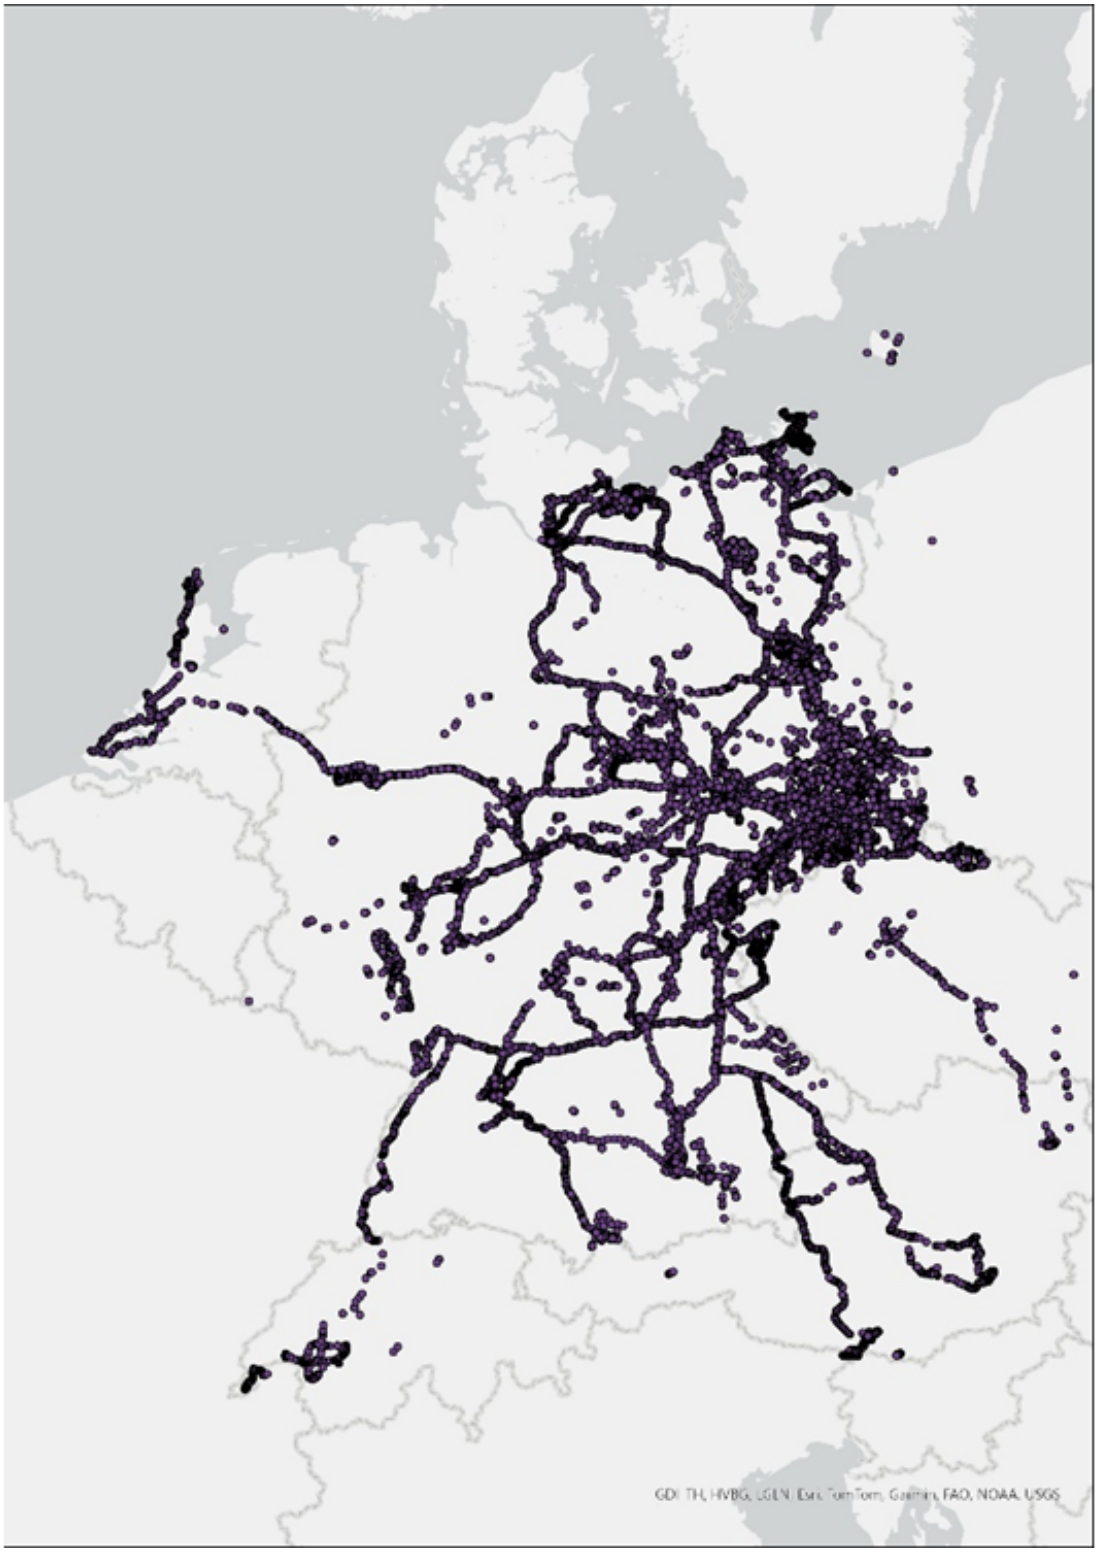
Methods

Sample

To investigate our stated research questions, we used the BipoSense dataset [15,30,31], which offers continuous passive and active sensing over 12 months alongside biweekly expert interviews (26 interviews in total). Patients were recruited from a specialized outpatient clinic at Dresden University Hospital, meeting strict inclusion criteria, including a diagnosis of BD type I or II and a history of at least three affective episodes in the past 5 years [32,33]. A trained clinical psychologist conducted biweekly interviews (alternating between in-person and telephone) to assess categorical data on affective status (eg, being in a depressive episode, (hypo)manic episode, or euthymic) via the SCID-I section A (*DSM-5* criteria [34]) covering the previous 14 days. This served as "ground truth." Moreover, dimensional symptom scores were assessed via standardized questionnaires, including Young Mania Rating Scale [35], the Bech-Rafaelsen Mania Rating Scale [36], and the Montgomery-Asberg Depression Rating Scale [37]. These tools covered symptoms over the preceding 3 days and demonstrated excellent reliability and validity. On the basis of the biweekly SCID interviews, day-level mood status (depressed, euthymic, and (hypo)manic) was labeled for the previous 14 days. Each mood episode contributed to multiple analytical phases: preepisode weeks were categorized as early prodromal (days −14 to −8) and late prodromal (days −7 to −1), following previous research [15,32,38], and stratified by episode polarity. The onset and subsequent course were further classified as first week (days 1 - 7), second week (days 8 - 14), and ongoing (day 15 onward). This structure enabled the identification of temporal dynamics surrounding episode onset.

Of the 112 patients who initially contacted the BipoSense study, 53 (47.3%) agreed to undergo screening for eligibility. Ultimately, 31 (27.7%) patients were enrolled in the study. Reasons for exclusion included not meeting the eligibility criteria (n=15, 13.4%), nonresponse after the initial contact (n=25, 22.3%), living too far from the study site (n=18, 16.1%), and technical concerns (n=4, 3.6%), while others did not provide reasons for refusal [33].

Measures



Digital phenotyping was conducted via the app movisensXS [39] (movisens GmbH, Karlsruhe, Germany). In addition to standard e-diary variables, such as end-of-day entries on sleep (time spent asleep, awake, or sleepless in bed over the previous 24 hours, recorded in 60-min segments) and medication use (both adapted from ChronoRecord, a rigorously validated electronic mood charting system [40,41]), a wide range of passive sensing variables was collected. In this study, we focused on indices of unique places as derived from GPS location data.

Data Preparation

Initially, 31 participants were included. After 3 weeks, 1 (3.2%) participant dropped out, leaving 30 (96.8%) with at least 10 months of data. One participant was excluded due to data extraction issues, and another was excluded because of the absence of 6 euthymic weeks. The final sample comprised 28 participants. For this sample, geospatial data were available at a very high resolution of approximately 5 to 10 seconds, totaling 8,616,671 data points. To optimize computational efficiency, the data were downsampled to 1 entry per minute, resulting in a reduced dataset comprising 1,861,321 data points. Afterward, the Haversine algorithm was used to calculate distances between consecutive entries. To ensure data quality, entries were filtered out if the distance from the previous point implied an exceeded speed of 300 km/h, as such deviations may result from inaccurate GPS signals, often due to battery-saving measures using GSM data instead of GPS satellites. To make a cluster analysis feasible, the points were projected from the global geodetic coordinate system, WGS84 (EPSG 4326) to UTM 32 (EPSG 25832). Owing to energy efficiency, GPS data collected via movisensXS were not recorded continuously, causing temporal gaps. If a participant remains stationary, new GPS coordinates were only captured when a change in location occurs, evidenced by a signal in the acceleration sensor of the smartphone. Accordingly, missing entries were filled with the value of the last nonmissing entry, leading to a dataset containing 14,483,536 points. The spatial distribution of all GPS points of all participants is presented in Figure 1.

XSL•FO
RenderX

Figure 1. Spatial distribution of all GPS points (14,483,536 entries) of all participants (n=28). Owing to the fact that the study took place at University Hospital Dresden, the majority of the points are concentrated in and around Dresden.

DBSCAN Cluster Analysis

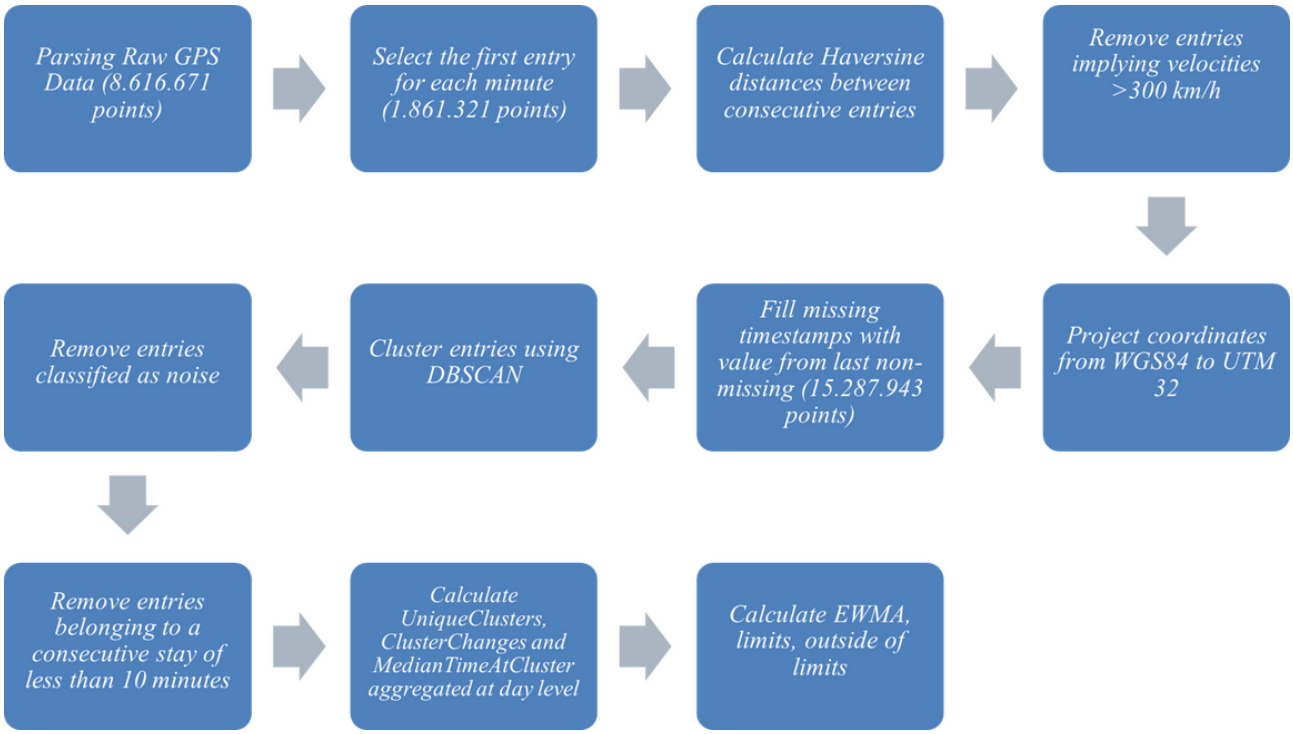
To identify unique places, the density-based spatial clustering algorithm DBSCAN (Density-Based Spatial Clustering of Applications with Noise [42]) was used. Unlike k-means, DBSCAN does not require a predefined number of clusters and classifies observations as core points, border points, or noise points. Its nonparametric density estimation allows for the detection of complex cluster shapes, making it particularly effective for data with varying densities and irregular structures such as spatial data [40]. On the basis of visual tests of BipoSense data, we set epsilon to 100 m and n to 20 minutes per day. In practical terms, core points must fall within a 100 m radius to form a cluster, requiring at least 20 points.

The DBSCAN algorithm considers all points within the predefined radius (epsilon). To prevent frequently traveled

XSL•FO
RenderX

routes where GPS points overlap from being defined as clusters, an additional criterion was applied: a cluster must involve a minimum of 10 consecutive minutes spent at a unique place. Thus, a cluster is defined as "a minimum of 20 GPS measurements or minutes that fall within a 100-m diameter with at least 10 consecutive minutes spent at that location."

On the basis of the spatial data and the conducted DBSCAN, we derived the following variables:



- UniqueClusters: the number of unique locations visited by the participant on that day
- ClusterChanges: the number of location (cluster) changes, grouped by each participant and each day
- MedianTimeAtCluster: the median number of minutes spent across all clusters, grouped by each participant and each day

Statistical Process Control

The central assumption was that (upcoming) depressive or manic episodes are associated with changes in behavior, which in turn are reflected in changes in the means and/or variances of appropriate mobile sensing parameters compared to a 28-day baseline period. To ensure that this baseline period reflected a stable euthymic state, it was only assigned when biweekly clinician ratings indicated the absence of an affective episode. If a participant experienced an episode at study entry, baseline assignment was postponed until a confirmed euthymic phase. Additionally, we compared mean self-rated and clinician-rated mood scores between the baseline and all other phase categories. We attempted to detect these shifts using EWMA-based control charts, which smooth the incoming data using an exponentially weighted moving average of previous values, minimizing the influence of noise. If the EWMA value exceeds or falls below control limits established using the mean and variance of the baseline period, this should be an indicator of an episode.

There are 2 parameters that can be used to tune the sensitivity and specificity of the method: λ and average run length (ARL). The smoothing parameter λ determines how much weight is given to the value of the most recent observation. The closer λ is to 0, the more weight is given to the previous days. Conversely, the closer λ is to 1, the smaller the smoothing effect and the more sensitive the EWMA is to changes. The ARL is the expected number of days before a false-positive alert occurs; that is, the limits are exceeded or undercut although there was no underlying change. λ and ARL were used to calculate another parameter L, which determines the width of the control limits. We set λ to 0.15 and decided on an ARL of 180 days, which resulted in an L of 2.536435. For comparability and methodological consistency, these parameters were applied globally across participants rather than optimized individually. This approach was chosen based on prior SPC research in affective disorders [15,29-31]. We provide a detailed illustration of SPC charts with varying parameters λ and L using synthetic data to demonstrate the principles of EWMA-based SPC (see Figures S1 and S2 in Multimedia Appendices 1 and 2). Additionally, a detailed tutorial on the application of the EWMA procedure for detecting real-time changes in intensive longitudinal psychological data is provided by Smit et al [29]. A complete list of all data processing steps is shown in Figure 2.

Figure 2. Overview of the GPS data processing methodology. The initial raw GPS data are refined through a sequence of procedures encompassing data parsing, coordinate transformation (WGS84 to UTM), Density-Based Spatial Clustering of Applications with Noise (DBSCAN) clustering, and exponentially weighted moving average (EWMA) calculation.

RenderX

Generalized Linear Mixed Models

To account for the nested structure of daily observations within participants, multilevel (mixed effects) models were estimated, incorporating both fixed and random effects. Specifically, multilevel logistic regression models were applied. Each unique place parameter was treated as the independent variable (fixed main effect), while disorder status served as the binary-dependent variable. For the models, unique place parameters were dichotomized to reflect whether daily values were within or outside the control limits. To address the risk of α-error inflation due to multiple comparisons (3 variables tested across 9 disorder status contrasts), a Bonferroni-Holm correction was applied separately for the depressive and manic states, reflecting the differing number of phases. Thus, for depression, the smallest *P* value was multiplied by 15 (3×5), the second smallest by 14, and so forth. For mania, the correction followed the same scheme, starting with a multiplication factor of 12 (3×4). Upon reasonable request, day-level data will be provided.

Sensitivity and Specificity

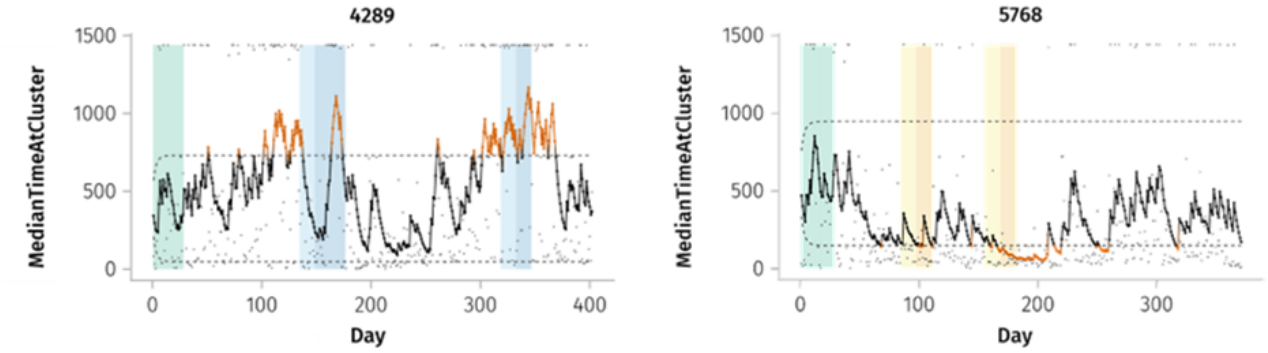
To better assess the potential clinical value of an SPC-based early warning system, we evaluated its sensitivity and specificity. Sensitivity represents the proportion of affective episodes correctly detected out of all episodes, while specificity reflects the proportion of euthymic days accurately classified out of all euthymic days. In clinical practice, balancing sensitivity and specificity is essential. While high sensitivity is necessary to capture most emerging episodes, an excessive number of false positives may reduce the likelihood that patients and clinicians respond to frequent alerts. We used established cutoffs for both sensitivity (50%) and specificity (95%) [15] translating into detecting at least 50% of new emerging episodes while having less than one false alarm per month.

Ethical Considerations

The study adhered to the Declaration of Helsinki and was approved by the ethics committee at the Technical University of Dresden (EK-Nr.: 26012014). All participants provided written informed consent prior to participating in the study. After having signed informed consent, patients received a study smartphone (optional) and reimbursement of €35 (US $40.7) per month [33]. All self-report data were pseudonymized, and personal identifiers were removed prior to analysis. Raw GPS data, which could potentially allow for the reidentification of individual participants, are not publicly shared and were strictly accessible only to the research team, thereby ensuring the protection of participant privacy.

Results

Sample Characteristics



As described previously, 28 participants were included in our analyses, with a mean age of 43.82 (SD 12.09) years, ranging from 25 to 70 years. The cohort consisted of 16 (57.1%) female and 12 (42.9%) male participants, of whom 16 (57.1%) were diagnosed with BD type I and 12 (42.9%) with BD type II. Participant compliance in the BipoSense dataset was notably high. In total, 726 (97%) of 749 biweekly diagnostic visits were completed. Participants completed 9433 (89%) evening e-diary entries, with 1154 (11%) entries missing due to technical issues, low battery, or nonresponse [33]. Over the course of the assessment period, mobile sensing data were recorded for 10,213 (99%) patient days, covering 26 depressive and 20 (hypo)manic episodes. This included 7851 (76.9%) euthymic days, 161 (1.5%) days classified as early prodromal depressive, 164 (1.6%) days classified as late prodromal depressive, 179 (1.8%) days marking the onset of a depressive episode, 168 (1.6%) days within a second depressive episode, and 194 (1.9%) days categorized as part of ongoing depressive phases. In total, 866 days (8.5% of all observation days) were classified as depressive phases across all participants. Regarding (hypo)mania, the dataset comprised 133 (1.3%) early prodromal days, 141 (1.4%) late prodromal days, 147 (1.4%) days marking the onset of a (hypo)manic episode, 146 (1.4%) days within a second (hypo)manic episode, and 98 (1.0%) days of ongoing (hypo)manic states. This resulted in 665 days (6.5% of all observation days) classified as manic episodes. Additionally, 856 (8.4%) days were marked as missing. For statistical analysis, extended (hypo)manic episodes lasting longer than 3 weeks were excluded due to an insufficient number of recorded days.

EWMA-Based SPC Charts

Figure 3 shows 2 example SPC plots for the MedianTimeAtCluster variable in 2 patients, that is, 4289 and 5768. The baseline phase is depicted by the green area, while affective episodes are color-coded (yellow for manic episodes and blue for depressive episodes). Prodromal phases are denoted by lighter shaded areas that precede the affective episodes. The daily EWMA is depicted in black when within the upper and lower control limits and in red when values exceed these thresholds. To verify that the baseline periods represented stable mood states suitable for EWMA phase I initialization, we compared clinician-rated and self-rated symptom scores across all phase categories. Ensuring that the baseline represents a stable state is crucial for the validity of the EWMA procedure. As expected, baseline scores closely resembled those observed during euthymia, with minimal symptom burden (eg, baseline YMRS: mean 1.06, SD 1.95 vs euthymia YMRS: mean 1.06, SD 1.88; baseline self-rating: mean 49.25, SD 12.45 vs euthymia: mean 49.88, SD 10.46). In contrast, both manic and depressive phases were clearly distinguishable from baseline. For example, during depressive phases, participants showed low YMRS scores (first week: mean 0.54, SD 1.24; ongoing: mean 0.61, SD 1.08) alongside reduced self-rated mood (first week: mean 39.71, SD 14.60; ongoing: mean 31.14, SD 16.31), whereas during manic phases, YMRS increased (first week: mean 9.57, SD 5.07; ongoing: mean 9.98, SD 4.42) with correspondingly higher self-rated mood (first week: mean 54.88, SD 9.37; ongoing: mean 51.24, SD 10.40). These differences confirm that baseline periods were indeed “in control” and distinctly separate from symptomatic phases. A complete overview of clinician-rated and self-rated symptom scores across all phase categories is provided in Table S1 in Multimedia Appendix 3.

XSL•FO
RenderX

Figure 3. Exponentially weighted moving average (EWMA) statistical process control chart for participants 4289 and 5768 for the variable MedianTimeAtCluster. The x-axis represents the days of the study, and the y-axis shows the median time participants spent at a cluster. The baseline period used to compute personalized upper and lower control limits is depicted by the green area. Yellow areas indicate (hypo)manic episodes, and blue areas indicate depressive episodes. Shaded regions mark the 2 prodromal weeks (early and late prodromal). Black dots represent daily raw values, and the black line depicts the EWMA. The line turns red when the EWMA exceeds the control limits.

As can be seen, the EWMA-based median time per cluster significantly fluctuates over time and shows low values during manic episodes, whereas values are higher during and after a depressive episode. Nevertheless, we have to strongly emphasize that we selected those particular exemplar figures because they illustrate the proposed concept best. A more comprehensive examination of all variables across all patients revealed a more ambiguous picture. SPC charts for all observed parameters from patients 4289 and 5768 can be found in Figure S3 in Multimedia Appendix 4.

Testing the SPC Assumptions on Unique Places Visited

Overview

Table 1 presents the results of the multilevel models examining whether control limits distinguish affective episodes from euthymic days. In reference to Figure 3, these models assess whether the proportion of "red dots" is higher during affective episodes compared to euthymic periods.

Table . Estimates from multilevel logit models differentiating disorder status[a].

Disorder status and phase	Unique clusters		Cluster changes		Median time at cluster	
	OR[b] (95% CI)	*P* value	OR (95% CI)	*P* value	OR (95% CI)	*P* value
Depressive episodes versus euthymia						
Early prodromal	0.623 (0.34-1.15)	.13	0.920 (0.86-0.98)	.01	1.002 (1.00-1.004)	.01
Late prodromal	0.803 (0.56-1.16)	.24	0.978 (0.96-0.99)	.01	1.001 (0.99-1.01)	.82
1st week depressive episode	0.910 (0.81-1.03)	.12	1.007 (1.00-1.02)	.08	1.002 (1.00-1.01)	.39
2nd week depressive episode	0.826 (0.14-4.73)	.83	1.017 (0.82-1-27)	.88	1.001 (1.00-1.002)	.08
Ongoing depressive weeks	0.803 (0.58-1.12)	.19	0.975 (0.94-1.02)	.17	1.001 (1.00-1.002)	<.001
(Hypo)manic episodes versus euthymia						
Early prodromal	0.997 (0.99-1.01)	.45	1.031 (0.91-1.17)	.63	1.001 (1.00-1.002)	.05
Late prodromal	0.782 (0.60-1.02)	.07	0.985 (0.97-1.01)	.12	1.002 (1.00-1.01)	.56
1st week (hypo)manic episode	0.958 (0.46-2.02)	.91	1.012 (0.96-1.05)	.53	1.001 (1.00-1.002)	<.001
2nd week (hypo)manic episode	1.128 (0.83-1.53)	.44	1.031 (1.01-1.06)	.01	1.000 (1.00-1.001)	.05

[a]Disorder status is categorized into the following phases: "early prodromal" (days 14 to 8 prior to episode onset), "late prodromal" (days 7 to 1 before onset), "first week" (days 1 to 7 of the episode), "second week" (days 8 to 14), and "ongoing weeks" (day 15 onward), with separate classifications for (hypo)mania and depression. "Euthymia" serves as the reference category.

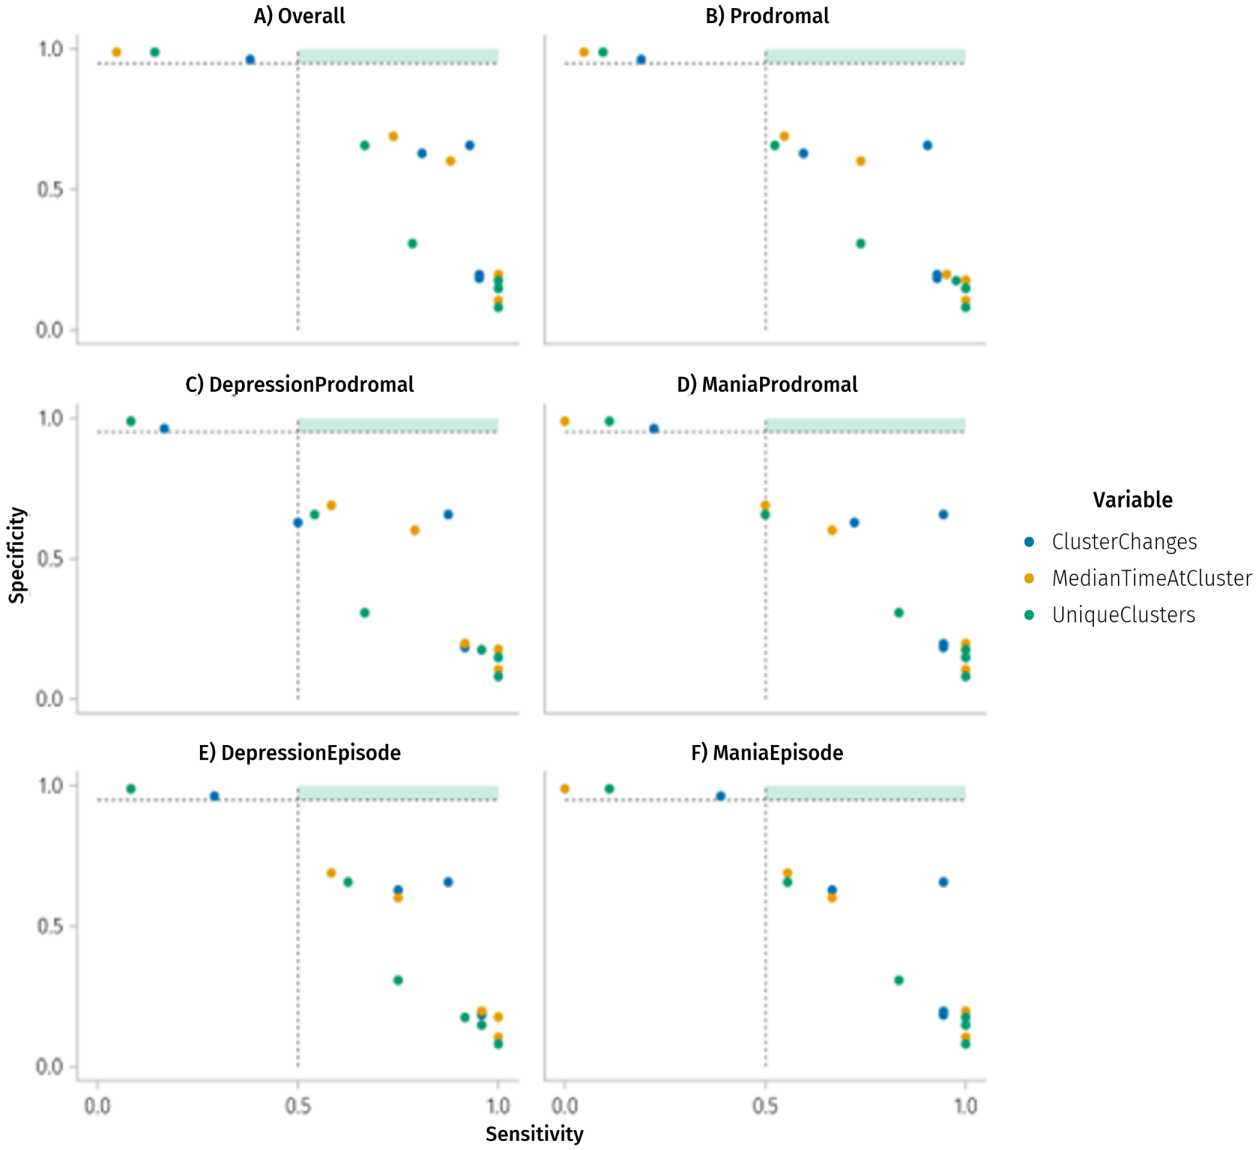
[b]OR: odds ratio.

XSL•FO
RenderX

In the early prodromal phase preceding depressive episodes, a lower number of EWMA-based unique clusters (odds ratio [OR] 0.623, 95% CI 0.34-1.15) was observed, although this is not statistically significant. EWMA-based cluster changes (OR 0.920, 95% CI 0.86-0.98; *P*=.01) show a significant negative association, indicating fewer cluster transitions in this phase. EWMA-based median time spent at each cluster (OR 1.002, 95% CI 1.0-1.004; *P*=.01) is significantly elevated, suggesting that higher median time spent at clusters is linked to an increased likelihood of entering a depressive episode. During the late prodromal phase, EWMA-based unique clusters (OR 0.803, 95% CI 0.56-1.12), EWMA-based cluster changes (OR 0.978, 95% CI 0.96-1.0), and EWMA-based median cluster values (OR 1.001, 95% CI 0.9-1.01) show no statistically significant associations with depressive onset. During the first and second weeks of depressive episodes, no cluster indicators show significant effects. In ongoing depressive episodes, EWMA-based unique clusters (OR 0.803, 95% CI 0.58-1.1) and EWMA-based cluster changes (OR 0.975, 95% CI 0.96-1.05) are not significantly associated with the disorder status. However, EWMA-based median time spent at clusters (OR 1.001, 95% CI 1.000-1.001; *P*<.001) is significantly elevated.

Regarding (hypo)manic episodes, in the early prodromal phase as well as late prodromal phase, EWMA-based unique clusters, EWMA-based cluster changes, and EWMA-based median time spent values show no statistically significant associations. During the first week of a (hypo)manic episode, EWMA-based unique clusters (OR 0.958, 95% CI 0.46-2.02) and EWMA-based cluster changes (OR 1.012, 95% CI 0.97-1.05) are not significantly related to disorder status. However, EWMA-based median time spent at cluster (OR 1.001, 95% CI 1.000-1.002) demonstrated a small but statistically significant association with (hypo)manic symptom onset. In the second week of a (hypo)manic episode, EWMA-based unique clusters and EWMA-based MedianTimeAtCluster show no significant effects. In contrast, EWMA-based cluster changes (OR 1.031, 95% CI 1.01-1.06; *P*=.01) exhibit a significant positive association, indicating increased cluster variability during this phase.

Bonferroni-Holm Correction



To account for random findings caused by multiple testing, we used a Bonferroni-Holm correction, as described in the *Methods* section. From the reported 6 significant findings in Table 1, only 2 remained significant, namely, EWMA-based MedianTimeAtCluster for ongoing depressive weeks (*P*=.01) and EWMA-based MedianTimeAtCluster for the 1st week of (hypo)manic episode (*P*=.004).

Optimizing Sensitivity and Specificity

In the next step, the clinical applicability of an SPC-based early warning system was evaluated through the computation of sensitivity and specificity metrics. Before conducting the analysis, a threshold was defined whereby identifying at least every second impending episode was considered satisfactory (sensitivity >50%), while false-positive alerts were to remain limited to a maximum of one per month (specificity >95%). As detailed in the *Methods* section, the SPC parameters λ and L were systematically optimized and assessed in accordance with 6 distinct optimization criteria. Figure 4 compiles and graphically depicts the sensitivity and specificity evaluations. The green markers in the upper-right segment represent the predetermined cutoff thresholds. Cluster parameters are highlighted using color distinctions.

XSL•FO
RenderX

Figure 4. Results for sensitivity and specificity after optimizing the parameters λ and L are presented, divided according to different periods and clinical phases: (A) Overall represents the entire assessment period, (B) prodromal includes all prodromal days, (C) depression prodromal covers only depressive prodromal days, (D) mania prodromal covers only manic prodromal days, (E) depression includes all depressive days, and (F) mania includes only manic days during optimization. The dotted lines and the green area indicate the suggested threshold of 50% sensitivity and 95% specificity, respectively, which we consider a prerequisite for clinical application.

While some configurations approach the predefined thresholds of sensitivity (>50%) and specificity (>95%), none of the evaluated variables met both criteria at the same time. Specificity is often too low, particularly for detecting depressive and manic episodes (panels E and F), leading to excessive false positives. In contrast, prodromal and depression prodromal phases showed a better balance, suggesting potential clinical utility in these cases. The 3 variables (ClusterChanges, MedianTimeAtCluster, and UniqueClusters) vary in performance, without a clear best predictor. For a complete overview of the results, please refer to Table S2 in Multimedia Appendix 5.

Discussion

Principal Findings

This study investigated the application of EWMA-based SPC methods using spatial movement patterns to detect prodromal symptoms of emerging affective episodes in individuals with BD. Building upon previous work, we examined whether location-based smart digital phenotypes derived from GPS data, namely the number of unique places visited, the frequency of location (cluster) changes, and the median number of minutes spent across all clusters could effectively capture the dynamic changes in behavior associated with different phases of BD.

First, we observed that, at least in BD, individual movement patterns indeed vary over time, in contrast to the findings of González et al [26] and Allessandretti et al [27]. Regarding our

XSL•FO
RenderX

hypotheses, visual descriptive approaches, such as examining SPC charts, demonstrated the potential of this method. During depressive phases, we observed that fewer locations were visited, and individuals tended to spend longer durations at specific locations, which aligns with our hypothesis. Conversely, during manic episodes, the opposite pattern emerged, which was consistent with our expectations. Notably, it is observed that the out-of-bounds processes were flagged even before the onset of the episodes, which may hold potential for prospective phase prediction and eventual clinical application. It can be assumed that during depressive episodes, individuals spend more time in a cluster, reflecting symptoms of apathy, whereas during manic episodes, they spend significantly less time in such clusters, indicating restlessness and increased mobility. This observation is in line with animal models that demonstrate altered exploratory behavior in mania-like [19] and depression-like [20] states.

However, a broader analysis across all patients and variables (Table 1) reveals a more complex and ambiguous picture. Examining whether control limits distinguish affective episodes from euthymic days via multilevel models revealed that overall, the median time spent at clusters emerged as the most consistent indicator across both depressive and (hypo)manic episodes. In contrast, the number of unique clusters was generally not significantly associated with phase transitions, even before Bonferroni-Holm correction. These patterns suggest that the frequency of location changes may serve as a more robust marker of affective episodes than the sheer number of distinct locations visited. Specifically, participants experiencing depressive episodes tend to remain temporally and spatially bound, whereas those in (hypo)manic episodes are highly mobile. In the latter group, individuals tend to move repeatedly between certain locations rather than visiting a large number of distinct places. Moreover, the phase-specific significance indicates that different aspects of movement behavior become relevant at different stages of episode development, highlighting the complexity of predicting mood episodes from passive sensing data.

Although our dataset is of high quality, featuring 1 year of longitudinal data and frequent reliable expert interviews, creating ideal conditions for applying SPC methods, digital phenotypes did not consistently prove reliable in detecting prodromal states and affective episodes through SPC analysis. Thus, the results partially support our initial hypotheses, suggesting that the analysis of visits to unique places may hold promise as a tool for capturing subtle behavioral changes indicative of impending mood shifts. In our descriptive investigation of optimizing predictions through systematic adjustments of SPC settings, we found that the inability to achieve sufficient sensitivity and specificity, even post hoc with the optimal parameter combinations, challenges the approach and/or the variables used. Previous EWMA-SPC studies on intensive emotion data indicated early warning signals for depressive episodes, but with limited sensitivity [31]. Consistent with this, our application to GPS-derived movement patterns showed some phase-specific behavioral changes, yet predictive accuracy remained insufficient, highlighting both the potential and current limitations of SPC for real-time episode detection.

Comparing our findings to previous studies, our results are in line with and expand upon the observations of Palmius et al [16] and Faurholt-Jepsen et al [18], who reported correlations between spatial movement patterns and mood states. While these earlier studies primarily focused on symptom correlations, our approach incorporates clearly defined episode onsets and aims to predict episodes prospectively. The more differentiated variables used here (unique clusters, cluster changes, and median time) allow for a more nuanced characterization of spatial behavior. This provides a more granular understanding of how changes in spatial behavior precede and accompany mood episodes, highlighting both consistencies and divergences with prior work. However, in direct comparison to Ludwig et al [15], self-rated mood appeared to outperform even the more advanced smart digital phenotypes examined in this study, although its ability to predict prodromal phases remains limited as well.

While systematic reviews of geospatial analyses in affective disorders [14] demonstrate remarkable potential for predicting depressive symptoms, their application to BD, as outlined earlier, is far from trivial. Moreover, predicting full episodes remains particularly challenging as demonstrated in our analysis. However, to effectively advance research on BD and integrate digital phenotyping into clinical practice, it is essential not only to adopt a purely dimensional approach to BD symptomatology [16,18] but also to differentiate between distinct illness phases and predict their occurrence. As demonstrated by Palmius et al [16] in the analysis of spatial patterns and Faurholt-Jepsen et al [18] in the analysis of unique places, while clear correlations were identified, the transfer to episode prediction remains challenging.

In summary, while the analysis of visits to unique places offers a low-burden, continuous monitoring approach with high potential, our findings did not confirm the consistent effectiveness of EWMA-based SPC methods for predicting affective episodes using passive sensing data in clinical practice. Furthermore, the use of EWMA-based SPC with individualized control limits did not surpass established threshold values.

Limitations

First, although the study exceeded the duration of previous studies by a significant margin and included patients with a high number of prior episodes, providing the most temporally precise labeling of days per patient, the number of newly emerging episodes remained limited. Future research aimed at predicting new episodes may benefit from longer study durations, such as the 18-month period used in our most recent randomized controlled trial [5]. Second, while it has been suggested that frequent assessments of psychopathological status could prevent the occurrence of new episodes, our dataset provides no empirical evidence to support this claim [33]. Third, our study deviated from the intended chronological sequence in 7 cases due to insufficient initial euthymic days, requiring retrospective upper control limit or lower control limit application and compromising the SPC's prospective nature. While this aimed to capture more affective episodes, it may have introduced confounding effects from postepisode behavioral changes, such as increased activity after depression. Moreover, participants were aware that their GPS data were being collected, which

XSL•FO
RenderX

may have influenced their behavior due to a potential Hawthorne effect. However, as our study covered an extended observation period of 365 days, we do not assume that participants consistently altered their behavior throughout the entire duration. Another limitation concerns the evaluation of model performance, which was based on prespecified operating thresholds (≥95% specificity and ≥50% sensitivity) chosen based on clinical reasoning rather than empirically derived or standardized criteria. While this choice reflects the practical prioritization of minimizing false-positive alerts in real-world clinical settings, it necessarily introduces a degree of subjectivity into the performance assessment. In particular, the strict specificity constraint may limit achievable sensitivity and thereby influence the apparent trade-off between both metrics. Moreover, the absence of established guidelines for optimal threshold selection in SPC-based early warning systems for affective disorders limits the comparability of our results to other approaches and may affect generalizability across different clinical contexts and monitoring frequencies. Finally, prodromal phases were defined exclusively by a temporal criterion, specifically the 2-week period prior to affective episodes, without clinical assessment of actual prodromal symptoms. As a result, we lack a "ground truth" and cannot rule out the possibility that patients may not have exhibited any prodromal symptoms to capture to begin with, whether via passive sensing or self-reported bipolar mood. This observation is consistent with clinical reports in which patients sometimes describe a sudden "switch" from euthymia to an affective episode overnight. Our data may partially support this hypothesis, as, at least for (hypo)mania, late prodromal days were more frequently differentiated from euthymia than early prodromal days.

Future Directions

Although our study makes a significant contribution to the current state-of-the-art research by developing smart digital phenotypes based on GPS data in patients with BD, we have only scratched the surface with regard to location-based passive sensing. First, we acknowledge that no direct comparison with classical entropy-based mobility metrics was conducted in this study. While our DBSCAN-based feature set was designed to capture more granular spatial-temporal structure than aggregated entropy measures, we cannot empirically claim superiority over entropy without a head-to-head evaluation. Importantly, from a theoretical standpoint for longitudinal spatial data, DBSCAN is particularly well suited, as it preserves discrete location states and transitions, which are otherwise compressed in entropy formulations. This property is essential for enabling the derivation and interpretation of the specific variables used in this work (UniqueClusters, ClusterChanges, and MedianTimeAtCluster), which explicitly depend on identifiable spatial clusters rather than aggregate distributional summaries. Future work should explicitly benchmark entropy-based and cluster-based mobility representations within the same predictive framework to quantify their relative clinical utility. Second, there are numerous other potential parameters that could correspond closely to psychopathological features. These include exposure to highly frequented areas, such as city centers and shopping malls, as well as exposure to green spaces or urban environments [43]. Additionally, interactions related to residential locations present a promising avenue for future exploration. Thus, future research should explore how multiple behavioral and physiological indicators can be integrated into a more comprehensive model. Furthermore, incorporating machine learning algorithms to identify complex patterns across multiple variables could improve the sensitivity and specificity of the model. Finally, regarding our SPC methods, previous work suggests that combining changes in variability (eg, SD) with mean-level changes may improve the sensitivity of early warning signals [31,44]. In our study, we focused on mean-based SPC indicators, which may have contributed to the limited sensitivity observed. Future research should therefore explore combined approaches integrating both mean and variability-based indicators.

Conclusions

In conclusion, this study contributes to the growing body of evidence supporting the use of digital phenotyping in BD with a particular focus on location-based passive sensing, specifically visits to unique places by individuals with BD. While SPC charts highlight the potential of this approach, a broader analysis across all patients and variables reveals a more complex and ambiguous picture, with overall effects being limited and of insufficient clinical applicability. Notably, after applying Bonferroni-Holm corrections to our generalized mixed models, only time spent at each cluster remained of some significance for certain phases, underscoring the selective predictive value of this approach. The comparison between SPC charts and the statistical modeling approach showed that further research is needed to refine and validate these findings. Yet, our results underscore the conceptual value of digital phenotyping for improving our understanding and monitoring of BD. By leveraging the power of mobile technology and data analytics, we may move toward a future where personalized interventions could be delivered proactively.

Abstract

Background: Alzheimer disease (AD) is characterized by progressive cognitive decline, with olfactory dysfunction emerging among its earliest symptoms. Conventional olfactory tests rely on subjective self-reports and patient cooperation, limiting their clinical applicability. Noninvasive olfactory bulb (OB) recordings may provide objective physiological measures for early detection of cognitive decline.

Objective: This study investigated the relationship between olfactory dysfunction and cognitive decline across the AD spectrum and evaluated whether noninvasive OB recordings obtained via a wearable electroencephalography-based device could serve as digital biomarkers for early detection and home-based monitoring.

Methods: We recruited 71 participants, including individuals who were cognitively normal (CN; n=18), patients with mild cognitive impairment (MCI) subdivided into early MCI (n=30) and late MCI (n=9), and patients with dementia of the Alzheimer type (n=14). OB activity was recorded noninvasively during odor stimulation using a 6-channel wearable electroencephalography system. Behavioral olfactory function was assessed using a culturally adapted 6-item modified Brief Smell Identification Test and compared with electrophysiological responses. Time-frequency analyses identified disease-related components via nonparametric permutation testing (1000 iterations; $P<.05$). A support vector machine classifier was applied for group discrimination. Structural brain integrity was assessed through diffusion tensor imaging and magnetic resonance imaging, and cognitive performance was evaluated using comprehensive neuropsychological testing. Beta-band power (reflecting top-down cortical feedback) and gamma-band power (representing OB activity) were analyzed to characterize neural communication patterns.

Results: Beta-band power progressively declined from CN to dementia of the Alzheimer type, while gamma-band power decreased and response latency increased beginning in late MCI. Behavioral olfactory testing failed to differentiate CN from early MCI ($P=.77$), whereas electrophysiological recordings revealed significant differences ($P=.02$). The support vector machine classifier achieved 83.1% accuracy in distinguishing all groups based on olfactory spectral features. Reduced beta-band power showed a trend-level association with cingulum-hippocampal tract diffusivity ($R^2=0.28$; $P=.061$), whereas gamma-band power correlated with OB volume in later disease stages ($R^2=0.21$; $P<.001$). Electrophysiological features explained 91.7% of the variance in cognitive scores (Seoul Neuropsychological Screening Battery II; $P<.001$). The brief 5 to 10-minute testing protocol, requiring less than 2 minutes to fit the device, supports its feasibility for repeated, home-based assessments.

Conclusion: Bidirectional interactions between the OB and higher-order brain regions appear altered early in the AD continuum, with beta-band changes emerging first and gamma-band alterations occurring later. Digital OB recordings offer objective, noninvasive biomarkers for detecting cognitive decline before overt structural changes. Their portability and short duration make this approach ideal for longitudinal, home-based cognitive assessments within mobile health frameworks and for evaluating therapeutic efficacy in future interventional studies.

Introduction

Continuous Monitoring for Early Alzheimer Disease Detection

Alzheimer disease (AD) represents a complex clinical challenge characterized by gradual and heterogeneous neurodegenerative progression over years to decades. While AD pathology involves amyloid and tau accumulation, its clinical manifestations span a continuum from individuals who were cognitively normal (CN) with AD pathology to mild cognitive impairment (MCI) and dementia. The subtle and variable trajectory of cognitive decline limits the sensitivity of traditional, episodic clinical assessments such as positron emission tomography (PET) imaging or cerebrospinal fluid analysis [1,2]. Continuous and home-based monitoring technologies offer a transformative approach to early disease detection by enabling real-time tracking of subclinical functional changes in naturalistic settings [3-6]. Quantitative physiological and behavioral biomarkers, such as gait velocity, sleep architecture, and circadian activity, can reveal gradual deterioration over weekly or monthly timescales that are often missed during infrequent clinical evaluations. Integrating these continuous monitoring systems into clinical workflows expands the therapeutic window for both pharmacological and nonpharmacological interventions, including targeted cognitive rehabilitation and personalized lifestyle management [7].

Olfactory dysfunction is one of the earliest symptoms of AD. It is recognized both as an early indicator and a potential clinical marker of the progression and severity of the disorder [8-11]. In addition to cognitive impairment, approximately 90% of patients with dementia of the Alzheimer type (DAT) experience a loss of olfactory abilities, such as difficulties with olfactory recognition and identification [12-16]. These deficits were previously attributed to pathological changes in the olfactory bulb (OB) and associated regions, including the entorhinal cortex, hippocampal cornu ammonis-1 region, and subiculum [17-19]. However, the timing of olfactory dysfunction during the progression of AD and its relationship with cognitive function remain unclear. Sniffing kits, such as the University of Pennsylvania Smell Identification Test (UPSIT), are frequently used to examine olfactory dysfunction in patients suspected of having MCI or DAT [19-22]. Although behavioral olfactory tests such as UPSIT and the Brief Smell Identification Test (B-SIT) have demonstrated feasibility in cognitively impaired populations, they fundamentally depend on participants' subjective reports of odor identification. This subjective nature introduces variability from individual interpretation, decision-making processes, and verbal or written communication abilities that may confound assessment of actual olfactory function [23-25]. Even with full participant cooperation, responses reflect a complex integration of sensory perception, cognitive processing, and motor output rather than isolated olfactory capability. In contrast, electrophysiological recordings from the OB capture objective neural signals during odor processing, providing quantifiable biomarkers in terms of latency, amplitude, and frequency components. Consequently, several studies have proposed using electroencephalography recordings during odor tests to reduce nonolfactory-related performance interference [26-30]. Structural magnetic resonance imaging (MRI) studies have also sought to differentiate MCI from DAT by evaluating volumetric decreases in the OB and primary olfactory cortex [31-34]. Therefore, olfactory evaluation using sniffing kits is likely to be undervalued in clinical assessment of AD despite its potential as an early indicator.

Objectives

To address these challenges, recent studies have proposed noninvasive and temporally precise recordings of the human OB, validated across a range of experiments, as a reliable method for assessing signals from the OB [35,36]. This approach has demonstrated olfactory dysfunction in patients with Parkinson disease (PD) compared with participants who were CN [37]. In this study, we conducted noninvasive digital recordings of olfactory responses among individuals who were CN, patients with MCI, and patients with DAT, using advanced digital signal processing and machine learning algorithms to transform raw electrophysiological data into quantifiable biomarkers. This computational approach allows the extraction of subtle features from neural signals that can objectively differentiate between cognitive states. We compared the results of various clinical examinations, including diffusion tensor imaging (DTI), MRI, and neuropsychological assessments. This study aimed to (1) identify differences in olfactory responses between CN and patient groups to extract olfactory characteristics critical for AD diagnosis, (2) explore the association between olfactory response characteristics and cognitive impairment in clinically diagnosed MCI and DAT using a hospital-based cohort, and (3) establish how the dynamics of olfactory responses across frequency bands relate to structural brain changes observed through medical imaging. Digital recording of odorant-mediated OB responses addresses the subjectivity inherent in behavioral olfactory assessments by providing objective, reproducible neural measurements. Unlike self-reported odor identification, electrophysiological signals directly reflect the functional integrity of olfactory neural circuits and can reveal temporal dynamics of olfactory processing not accessible through behavioral testing alone. The rapid advancement of mobile health (mHealth) and ubiquitous health technologies has created new opportunities for continuous, home-based assessment of neurological function. Our electrophysiological olfactory testing approach embodies these paradigms by using a lightweight, wearable 6-electrode electroencephalography device that can be quickly applied by users or caregivers. The entire testing procedure requires only 5 - 10 minutes, enabling regular self-assessment or caregiver-assisted monitoring in home settings. Unlike conventional clinic-based evaluations, this system allows individuals to track their olfactory and cognitive function through brief, repeatable sessions. Its portability and ease of use facilitate longitudinal monitoring, which is critical for detecting subtle, early changes in olfactory processing associated

XSL•FO
RenderX

with neurodegeneration. We hypothesized that digital recordings of OB responses could provide a more comprehensive understanding of cognitive decline in AD, serving as a potential digital biomarker.

Methods

Study Population

This study used a cohort design across 3 cohorts: CN, MCI, and DAT. The prospective registry study of olfactory response heterogeneity in AD progression enrolled participants from 2 tertiary medical centers in the Republic of Korea (Hanyang University Hospital and Myongji Hospital) between September 2023 and September 2024. The community-dwelling cohort was recruited from 3 geographically diverse provinces: Seoul, Gyeonggi, and North Chungcheong. A total of 129 individuals were initially screened for this study, of whom 71 were included in the final analysis, including 18 CN controls, 39 individuals with MCI, and 14 patients with DAT. All participants with DAT satisfied the diagnostic criteria of the National Institute on Aging and the Alzheimer's Association (NIA-AA) [25]. Comprehensive baseline assessments, including neuroimaging and neuropsychological evaluations, were conducted according to standardized protocols under physician supervision.

Eligibility and Diagnostic Criteria

The study defined eligibility criteria for participant inclusion, restricting the age range for enrollment to 50 - 85 years. Inclusion criteria required participants to have sufficient cognitive capacity to complete both neuropsychological and olfactory assessments. Participants with contraindications to neuroimaging were excluded. The diagnostic status was determined following the updated NIA-AA workgroup criteria [23]. Notably, MCI was diagnosed independently of the Seoul Neuropsychological Screening Battery II (SNSB-II) score using a comprehensive clinical evaluation. Diagnosis was based on documented cognitive decline corroborated by caregivers, objective episodic memory impairment on the delayed recall component of the Seoul Verbal Learning Test (performance below −1.5 SD, adjusted for age and education), a Clinical Dementia Rating score of 0.5, and fulfillment of the NIA-AA core clinical criteria for MCI due to AD. After the diagnosis of MCI was established, participants were further subdivided into early and late stages according to cognitive severity. The SNSB-II provides age-, sex-, and education-adjusted *z* scores across 5 cognitive domains (attention, language, visuospatial function, memory, and frontal and executive function), from which a composite *z* score was calculated by averaging domain scores. This composite score was used solely for severity stratification within the MCI group and was not involved in diagnostic determination. Participants with a composite *z* score ≥−1.0 were classified as early mild cognitive impairment (EMCI), whereas those with scores <−1.0 were classified as late MCI, in line with prior studies linking lower composite scores to broader multidomain impairment and increased risk of progression to dementia [38,39]. Using this criterion, 30 participants were classified as EMCI and 9 as late MCI. The relatively preserved composite scores observed in the EMCI group (mean 0.15, SD 0.58) reflect focal memory impairment that becomes attenuated when averaged across largely preserved cognitive domains, a pattern commonly observed in early-stage MCI. Clinical evaluation consisted of a comprehensive medical history review, neuroimaging analysis, and neuropsychological examination conducted by a qualified physician. Detailed diagnostic criteria are provided in Multimedia Appendix 1.

Neuropsychological Assessments

Neuropsychological assessments were performed using a standardized neuropsychological battery called the SNSB-II [38]. This battery includes examinations of attention, language, calculation ability, visuospatial skills, memory, frontal-executive function, and general cognition, such as the Mini-Mental State Examination (MMSE) [40] and Clinical Dementia Rating. The SNSB-II comprises the digit span test (forward and backward), the Korean version of the Boston Naming Test, Rey-Osterrieth Complex Figure Test, Seoul Verbal Learning Test, Phonemic Controlled Oral Word Association Test, and Korean Color Word Stroop Test. All SNSB-II variables were converted to *z* scores and standardized for age, sex, and years of education.

Amyloid PET and Structural Brain MRI

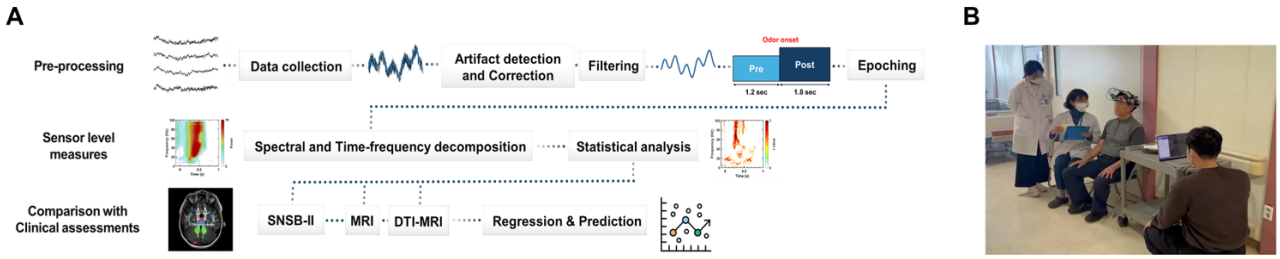
All participants underwent an 18F-florbetaben amyloid PET and structural MRI scan. Brain DTI was performed using a 3.0-T Achieva MRI system (Philips Medical Systems). DTI images were acquired in the transverse orientation using a pulse sequence with a single-shot spin-echo diffusion-sensitized echo-planar imaging sequence (15 gradient directions plus a B0 image with b value=800 s/mm², repetition time/echo time=13898/55 ms, field of view=224×224, matrix=112×112, number of averages=2, slice thickness=2.0 mm, and flip angle=90°). Amyloid positron emission tomography–computed tomography imaging was conducted following intravenous injection of 8 mCi of the amyloid radiotracer F-18 Florbetaben (Neuraceq; Piramal). Following a 90-minute uptake period, imaging was conducted for approximately 20 minutes using a dedicated PET/computed tomography (CT) scanner (Biograph 6; Siemens Medical Systems). The PET scans were reviewed by 2 expert PET readers and 1 neurologist based on predefined regional cortical tracer uptake and brain amyloid plaque load scoring systems. Four regions of interest, including the frontal, temporal, and parietal cortices along with the posterior cingulate and precuneus, were assessed in the visual analysis of the 18F-florbetaben PET scans. The regional cortical tracer uptake scores were condensed into a single 3-grade scoring system for each PET scan (brain amyloid plaque load score) as follows: 1 for no Amyloid-beta (Aβ) load, 2 for minor Aβ load, and 3 for significant Aβ load. Tract-based spatial statistics (TBSS) analysis was conducted to examine differences in DTI between patients with AD and healthy controls using the Functional Magnetic Resonance Imaging of the Brain Software Library (University of Oxford). The preprocessing pipeline included correction for head motion and eddy current distortions, followed by the computation of diffusion tensor metrics, specifically fractional anisotropy (FA), axial diffusivity, and radial diffusivity, to characterize the white matter fiber architecture. Subsequently, FA images were spatially normalized to a standardized brain template using the Functional Magnetic Resonance Imaging of the Brain nonlinear imaging registration

XSL•FO
RenderX

tool. A mean FA skeleton was generated using projection techniques to represent the central white matter pathways common to all participants, with an applied threshold criterion of 0.2. Individual FA maps were then projected onto this skeleton for group-level analyses. Regional white matter tract identification was facilitated using the Johns Hopkins University ICBM-DTI-81 white matter atlas [41]. Statistical analyses used permutation-based nonparametric inference (5000 permutations) to assess between-group differences [42]. The statistical threshold was established at $P<.05$, with correction for multiple comparisons implemented using threshold-free cluster enhancement. Volumetric quantification of the OB was performed by manual delineation of sequential T1-weighted images using ImageJ (version 1.53h; National Institutes of Health). Bilateral OB annotations were independently conducted by 2 experienced raters using FreeView (Massachusetts General Hospital), a FreeSurfer visualization tool, and ambiguous cases were resolved by consultation with a qualified neurosurgeon [43]. To minimize bias, the raters were blinded to participant group assignment, age, and sex. Individual OB volumes were calculated by summing the product of the surface area measurements and slice thickness, with the total OB volume derived from the mean of the bilateral measurements.

Behavioral Olfactory Testing

Olfactory function was assessed using a modified 6-item version adapted from the B-SIT, which itself is a 12-item subset of the 40-item UPSIT [44]. Participants were presented with a 4-category multiple-choice questionnaire and asked to identify which smells corresponded to the scent strip. As familiarity and responsiveness to certain odors may vary among ethnic groups, we selected 6 types of odors (cinnamon, smoke, chocolate, gasoline, soap, and onion) with a correct answer rate of 70% or more among healthy individuals from the 12 smells in B-SIT for this experiment. This culturally adapted version showed comparable diagnostic performance to the full B-SIT while avoiding misclassification due to odor unfamiliarity rather than true olfactory dysfunction.



Digitalizing Olfactory Testing

The olfactory assessment protocol integrated the 6-item modified B-SIT, a validated and standardized instrument for evaluating olfactory function, with concurrent electrophysiological measurements to characterize the temporal dynamics of olfactory processing. Olfactory responses were recorded using a 6-channel active electrode electroencephalography system (Cyton; OpenBCI), and data were collected and digitized at a sampling rate of 250 Hz. In this study, the configuration of the OpenBCI electroencephalography cap was modified to optimize the detection of signals from the OB, following the approach proposed by Iravani et al [35]. Six electrodes were symmetrically placed on a mount along the centerline of the forehead, with each electrode spaced 5 cm apart to optimize the detection of OB signals. The helmet mount was designed to be adjustable, allowing the examiner to loosen it for easier electrode placement and subsequently tighten it to maintain firm and consistent contact with the participant's skin. This configuration ensured reliable signal detection from the OB, as illustrated in Figures 1A and 1B. The electroencephalography signals were recorded continuously throughout the test session.

During olfactory testing, a respiratory sensor monitored participants' breathing patterns to trigger olfactory stimulation. Recordings were segmented into epochs ranging from 1200 ms prestimulus to 1800 ms post stimulus, time locked to respiratory triggers, and rereferenced to the average of the left and right earlobe electrodes. Recorded signals were notch filtered at 60 Hz to eliminate power line noise. Additionally, muscle artifacts were detected by applying a bandpass filter (Butterworth filter, order 8) to the raw data, followed by a Hilbert transformation to extract the amplitude values. These values were standardized using z scores, with trials exceeding a z score of 6 assumed to be contaminated by muscle artifacts and excluded from further analysis. Considering the impact of eye movements and blinking on olfactory response signals, a lower z score threshold of 4 was used to improve the detection sensitivity, leading to the exclusion of trials with z scores exceeding this threshold. To further reduce blinking-related artifacts, participants were instructed to keep their eyes closed throughout the test. For signal processing, preprocessed and artifact-corrected olfactory signals were decomposed into time-frequency maps using a multitaper sliding window approach. This method was applied across a frequency range of 0.1 - 100 Hz, with a step size of 0.1 Hz, and across a time range of –1 to 1 second, with a step size of 5 ms. Power in each time-frequency bin was estimated using 2 tapers derived from discrete prolate spheroidal sequences. To capture at least 2 cycles of each frequency bin, the taper length was selected to ensure accurate power estimation across the spectrum. Wavelet transformation for each time bin was conducted using 2 sets of wavelet functions derived from discrete prolate spheroidal sequence tapers. This transformation involved convolving the wavelet functions with the olfactory response signal in the frequency domain by multiplying the fast Fourier coefficients of the signal by those of the wavelets. The frequency-smoothing parameter was set to 80% of the value in each frequency bin. To account for motor responses to sniffing, baseline-corrected odor trials were compared with baseline-corrected sniff trials to analyze phase-locked responses, which were subsequently converted into decibels. For regression and classification, features were extracted by identifying time-frequency regions with maximal group differences via permutation testing and calculating each participant's mean power within these regions. This process yielded 5 electrophysiological features in the beta and gamma bands for subsequent analyses. All preprocessing and time-frequency decompositions were performed using the open-source Fieldtrip toolbox in MATLAB (version R2023b; The MathWorks, Inc).

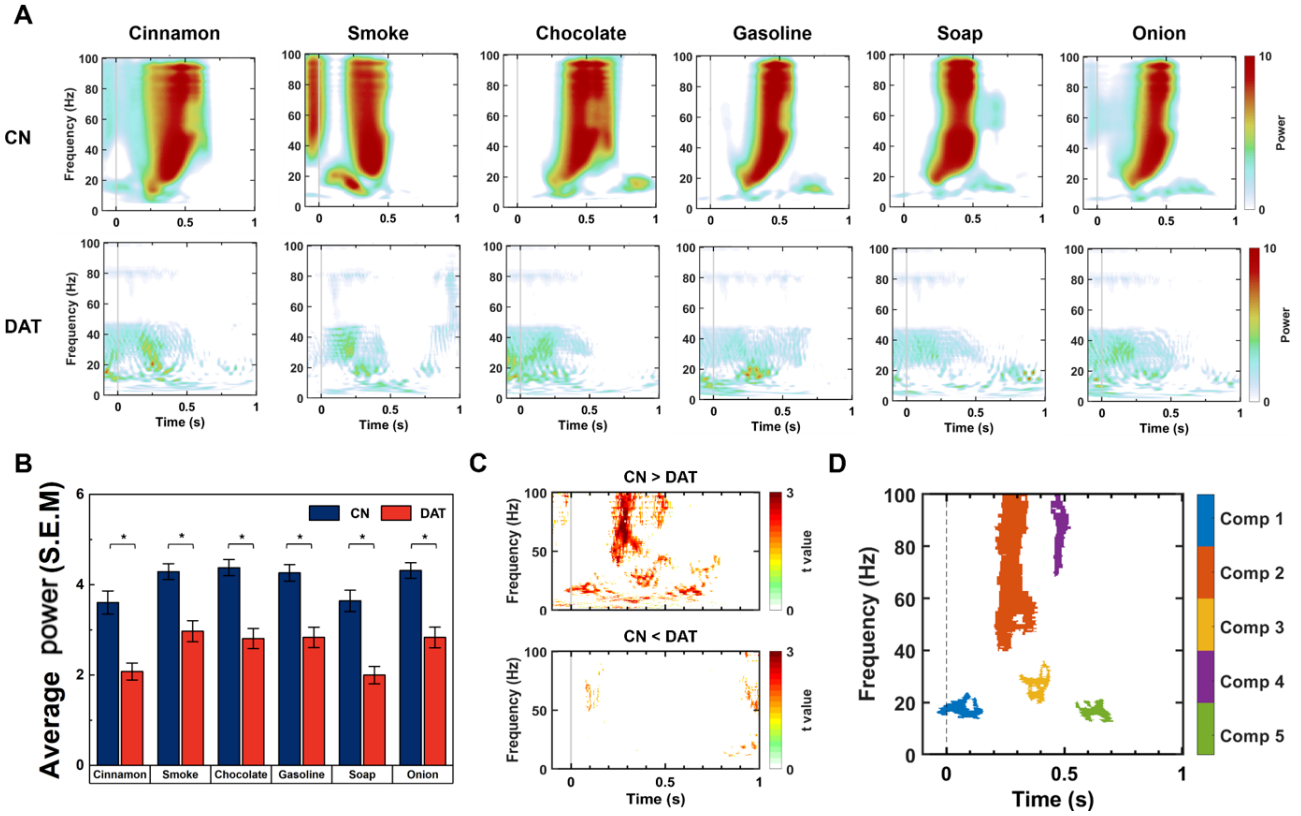
Figure 1. Experimental workflow for olfactory bulb signal analysis and clinical implementation. (A) Flow diagram illustrating the complete data processing pipeline: preprocessing of raw signals followed by data collection, artifact detection and correction, filtering, and epoching (with observation and rest periods of 3 seconds each). Secondary processing includes sensor-level measures with spectral and time-frequency decomposition, statistical analysis, and clinical comparisons using Seoul Neuropsychological Screening Battery II (SNSB-II), magnetic resonance imaging (MRI), and diffusion tensor imaging (DTI) with regression and prediction modeling. (B) Representative image of the experimental setup in a clinical environment, showing researchers administering the olfactory testing protocol to seated participants wearing the noninvasive olfactory bulb recording device.



Statistical Analysis

All statistical analyses were conducted using MATLAB (version R2023b) with the Signal Processing and Fieldtrip toolboxes [45]. Spectral densities of the 6 electrodes were averaged across the channels. Initially, the average power comparison was used to assess the intensity of gamma synchronization (30 - 100 Hz) in the olfactory response one second after olfactory stimulation. Time-frequency maps of the olfactory responses between the 2 comparable groups were assessed using a nonparametric Monte Carlo permutation test. A total of 1000 permutation tests were conducted to identify significant clusters that differed between the 2 groups within the time-frequency maps, with significance defined as $P<.05$ and a cluster size exceeding 300 bins. This cluster-based permutation approach inherently controls for multiple comparisons across all time-frequency bins by evaluating cluster-level statistics, thereby maintaining the family-wise error rate without requiring additional correction methods. The identified clusters were labeled according to their latencies (for example, components 1 and 2; Figure 2). Machine learning classification was performed using a support vector machine with a radial basis function kernel. Model development involved leave-one-out cross-validation to maximize sample usage given the limited dataset. The 5 electrophysiological components were used as input features. Classification performance was evaluated using accuracy, precision, recall, and F_1-score metrics. Regression and classification analyses used only the 5 electrophysiological components extracted from the time-frequency analysis as input features, without inclusion of demographic covariates. All *t* tests were 2-tailed. Statistical significance was indicated by asterisks, with * representing $P<.05$, ** denoting $P<.01$, and *** signifying $P<.001$.

Figure 2. Odorant-mediated olfactory responses differentiate patients with dementia of the Alzheimer type (DAT) from cognitively normal (CN) controls. (A) Odor-mediated olfactory responses in CN controls and patients with DAT. Gamma synchronization was observed in CN controls following odor onset (indicated by the vertical gray line at time 0). In contrast, no synchronization was detected in the DAT group during the same period. (B) Averaged power change for odorant across the 0-1 second interval, presented with SE of the mean (SEM) for responses to the 6 selected odorants. Statistical significance is indicated by * for $P<.05$. (C) T-map derived from 1000 Monte Carlo permutation tests, illustrating significant differences in the beta (13 - 30 Hz) and gamma (30-100 Hz) bands between the CN and DAT groups. Threshold t-maps indicate areas with higher power in CN controls compared to DAT at $P<.05$. (D) Threshold t-maps indicate significant clusters ($P<.05$; cluster size >300) that differentiate olfactory response components between the CN and DAT groups. Five distinct components were identified in the gamma and beta bands during early and late time points, with each component represented in a specific color. Color labels can be found in the color bar on the right side of the panel.

Ethical Considerations

This study was approved by the Institutional Review Board of Hanyang University Medical Center (2023-06-019) and conducted in accordance with the Declaration of Helsinki. All participants or their legally authorized representatives provided written informed consent and were informed of their right to withdraw at any time without penalty. All participant data were deidentified and assigned unique study codes, with the linking key stored separately in a password-protected file accessible only to the principal investigator. Neuroimaging data were anonymized using defacing algorithms to remove identifiable facial features. No financial compensation was provided to participants. However, participants received their complete diagnostic test results and medical consultations free of charge, which were disclosed as benefits of participation during the informed consent process.

Results

Overview

Digital olfactory testing was conducted alongside several traditional methods for AD diagnosis, including brain imaging techniques such as MRI and DTI, as well as neurobehavioral assessments such as the SNSB-II and MMSE. To evaluate olfactory ability, we conducted a 6-item modified B-SIT while simultaneously recording the electrical activity of the OB across the CN, MCI, andDAT groups. Demographic characteristics, cognitive status, and medication profiles of the participants are summarized in Table 1. Six electrodes were attached to positions capable of measuring OB responses for digital olfactory testing (Figure 3). The obtained signals were subjected to preprocessing and spectral analysis, resulting in a spectrogram. The spectral density of the signal was time-locked to stimulus onset and averaged across the 6 electrodes and trials to optimize the signal-to-noise ratio. The time-frequency map for the odor trials was determined within the specified time and frequency bands. To exclude contamination from sniffing and other motor-related artifacts, we compared the air and odor conditions. Odor event-related synchronization was observed in the beta (13 - 30 Hz) and gamma (30 - 100 Hz) bands at approximately 200 - 550 ms post stimulus. Subsequently, specific areas showing significant differences between the CN and DAT groups were identified using nonparametric tests with 1000 permutations, resulting in the isolation of 5 distinct components. The 5 extracted components were analyzed for correlations with existing medical imaging results, such as MRI and DTI findings, as well as neurobehavioral test outcomes (MMSE and SNSB-II), to validate their effectiveness. This process was investigated to determine whether these olfactory characteristics could serve

XSL•FO
RenderX

as early diagnostic markers of AD. An illustration of this process is shown in Figure 1.

Table . Demographic and clinical characteristics according to diagnostic group. Values are presented as mean (SD) or n (%). *P* values are from post hoc pairwise comparisons with the cognitively normal (CN) group using Bonferroni correction. Overall group differences (one-way ANOVA or chi-square test) were as follows: age ($F_{3,67}$=3.21; *P*=.03), sex (χ^2_3=3.84; *P*=.28), Brief Smell Identification Test ($F_{3,67}$=8.45; *P*<.001), 6-item modified Brief Smell Identification Test ($F_{3,67}$=9.72; *P*<.001), education ($F_{3,67}$=2.89; *P*=.04), Mini-Mental State Examination ($F_{3,67}$=15.32; *P*<.001), Seoul Neuropsychological Screening Battery II ($F_{3,67}$=12.84; *P*<.001), Clinical Dementia Rating (Kruskal-Wallis H test statistic [H_3]=21.45; *P*<.001), Clinical Dementia Rating–Sum of Boxes (H_3=28.93; *P*<.001), brain amyloid plaque load ($F_{3,67}$=6.78; *P*<.001), and APOE ε4 (χ^2_3=7.92; *P*=.05).

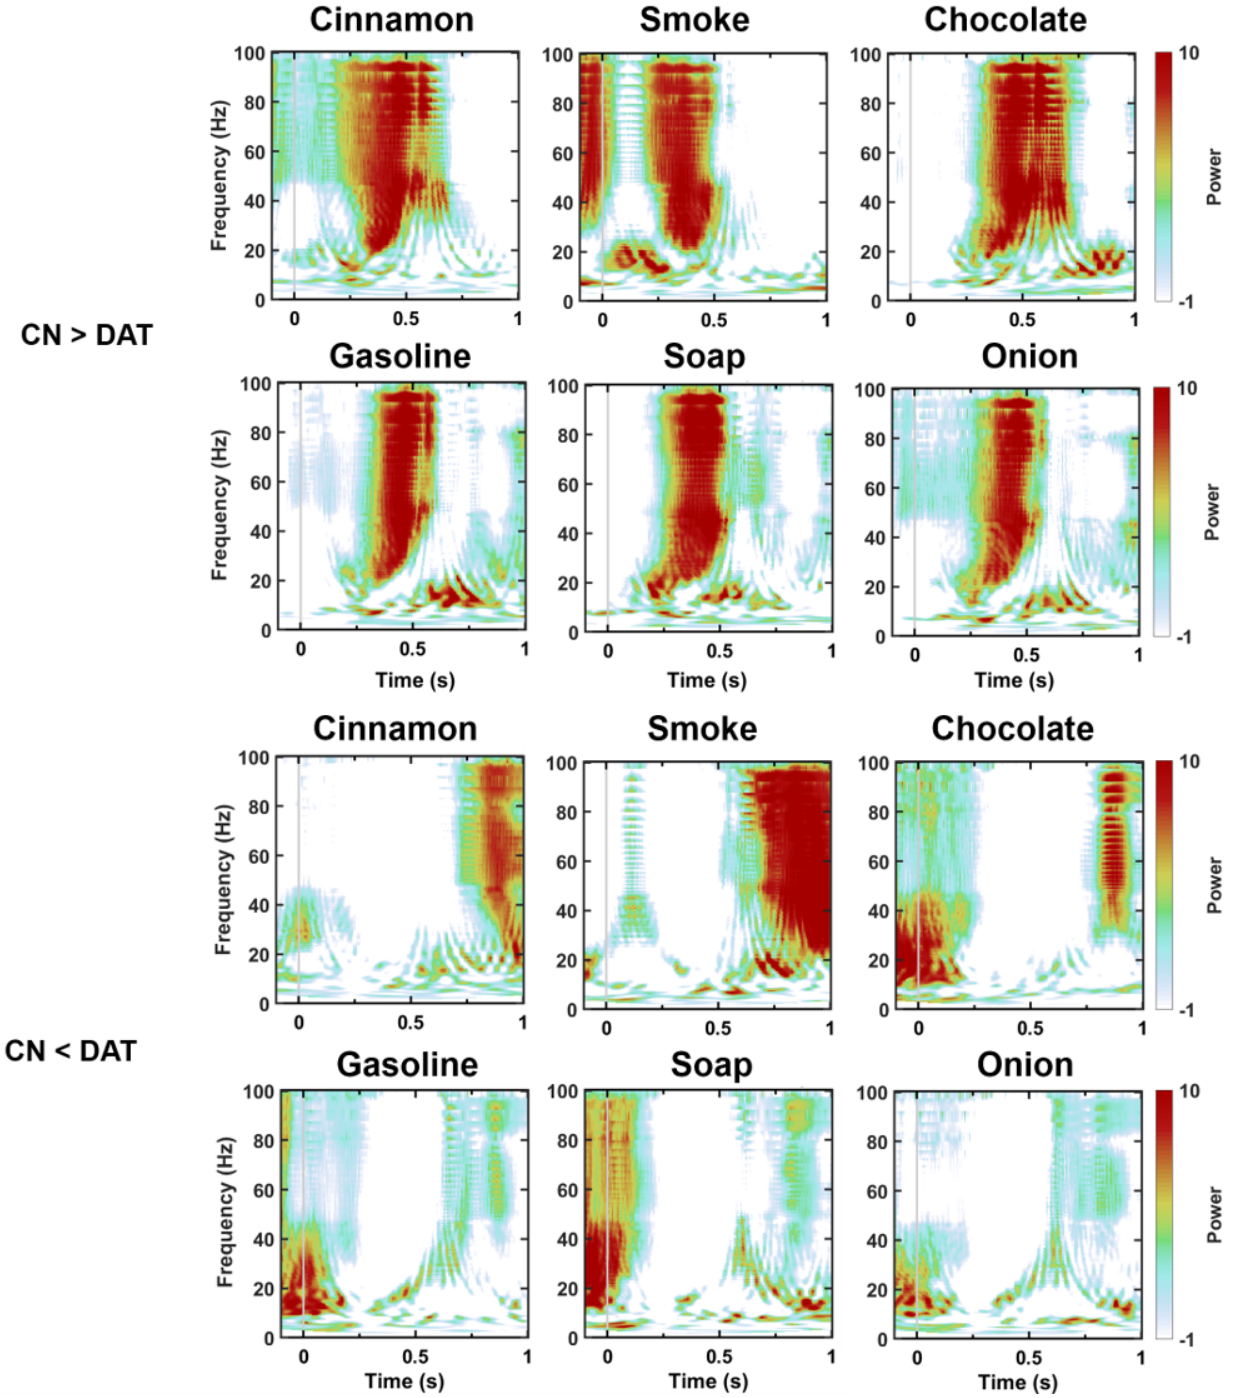
Component Identification Through CN-AD Contrast Analysis

Patients with DAT reported olfactory impairment when assessed using the B-SIT [20,22,25], which included 12 odors selected from the UPSIT [44]. As familiarity and responsiveness to certain odors may vary among ethnic groups, we first selected 6 types of odors (cinnamon, smoke, chocolate, gasoline, soap, and onion) with a correct answer rate of 70% or more among healthy individuals from the 12 smells in the B-SIT (Figure 4). Behavioral olfactory testing failed to distinguish between the CN and MCI groups. Discrimination rates were comparable across all 6 odors tested, with both groups showing relatively preserved identification performance (mean correct: CN 81.5%, SD 16.5% vs MCI 74.2%, SD 25.1%; *P*=.14). Only the clinical dementia group showed significant impairment (mean 45.3%, SD 31.8%; *P*<.001 vs both CN and MCI). Figure 2A shows the spectrum of olfactory responses to the 6 selected odors in healthy individuals and patients with DAT. In the CN group, odor-responsive signals were observed within 0.6 seconds after odor exposure, specifically in the beta and gamma frequency bands across 6 electrodes. Conversely, patients with DAT showed no detectable gamma synchronization at these temporal and frequency intervals, thereby confirming the ability of the control group to identify robust olfactory signals. As shown in Figure 2B, the average power recorded in the response of patients with DAT to the selected odors was significantly lower than that in the CN group for cinnamon (*P*=.02), smoke (*P*=.04), chocolate (*P*=.01), gasoline (*P*=.03), soap (*P*=.01), and onions (*P*=.02). This uniform impairment across chemically diverse odorants indicates a central olfactory processing deficit rather than peripheral receptor-specific dysfunction. Figure 2C shows the statistically significant differences in odor responses observed between the CN and DAT groups. To identify specific regions between the 2 groups, we performed nonparametric tests with 1000 permutations. The results are indicated by threshold t-maps, highlighting areas with *P*<.05. The upper panel demonstrates that the CN group showed enhanced power in the beta and gamma bands in response to the selected odors compared to the DAT group (CN > DAT). Notably, no significant difference in power was observed in patients with DAT when compared to the CN group (CN < DAT). This analysis revealed significant increases in the beta and gamma band power in the CN group compared to the DAT group at approximately 250 ms postodor onset (t_{30}=2.1192; *P*=.02). Conversely, a decline in gamma frequency power was observed at approximately 950 ms and 980 ms in the CN group compared with the DAT group (t_{30}=−1.8412; *P*=.04). Significant clusters (*P*<.05; cluster size > 300) were identified and sequentially labeled based on their temporal order as component 1,

XSL•FO
RenderX

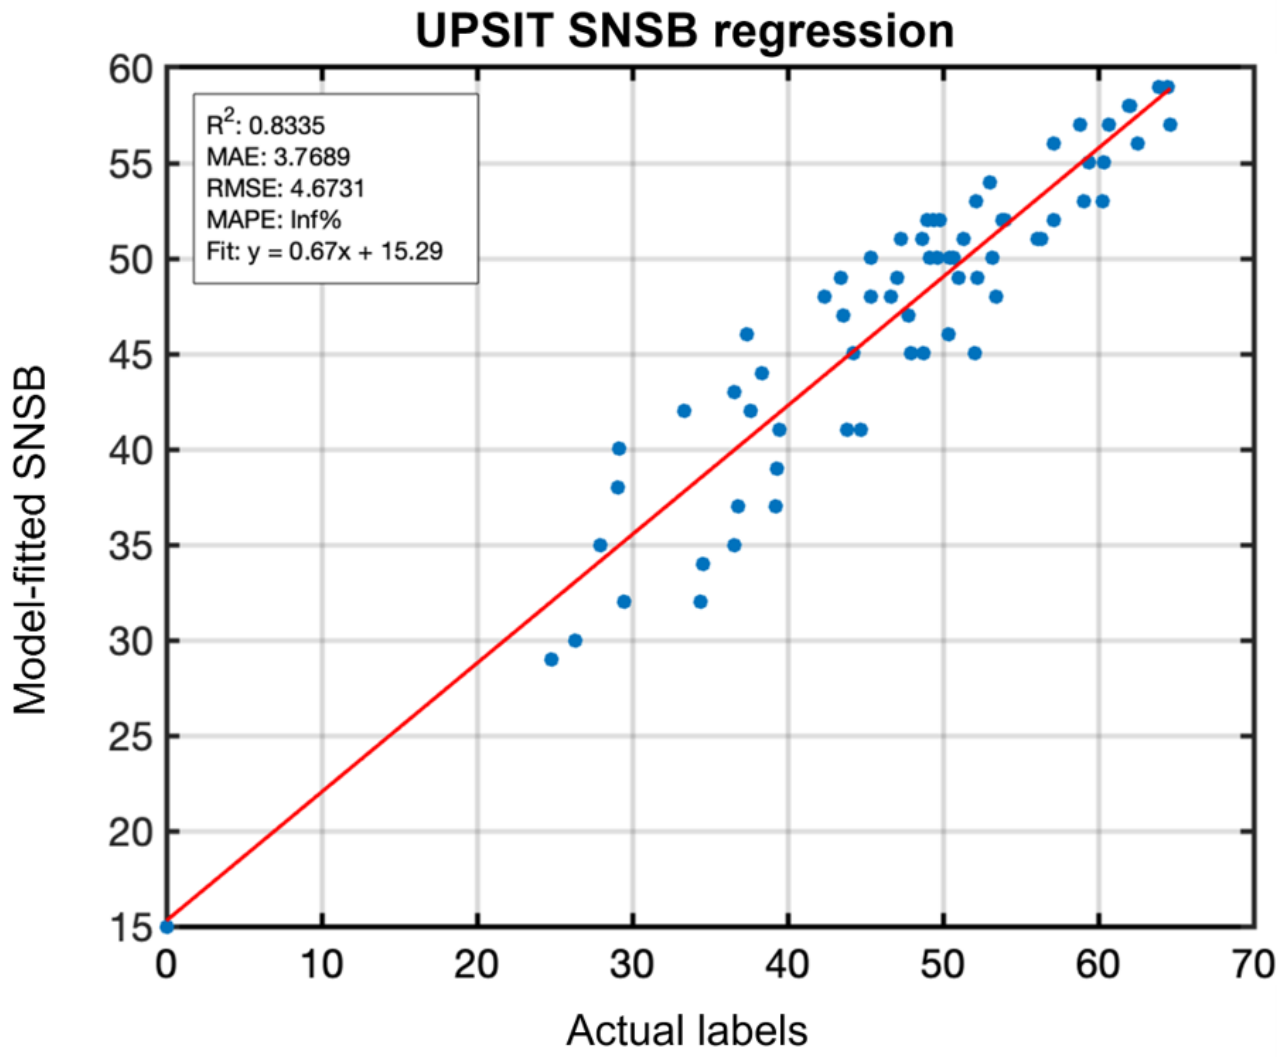


component 2, and so on. As shown in Figure 2D, 5 distinct components were identified, each of which was visually represented by a different color. The statistical parameters for each component were as follows: component 1 (t_{30}=1.9934; P=.03), component 2 (t_{30}=2.1823; P=.03), component 3 (t_{30}=1.9938; P=.03), component 4 (t_{30}=1.9182; P=.04), and component 5 (t_{30}=2.1393; P=.02). Additionally, Figure 5 provides the differences in the time-frequency maps between the CN and DAT groups in response to each of the 6 odorants.

Figure 4. Rates of correct answers for each Brief Smell Identification Test odor identification question, categorized into 3 patient groups. The shading of each bin indicates the rates of correct answers, with darker colors representing higher accuracy and lighter colors indicating higher error rates. Odors that achieved over 70% correct answers in the cognitively normal group are highlighted with a red border and marked in bold in the labels below. CN: cognitively normal; DAT: dementia of the Alzheimer type; MCI: mild cognitive impairment.

XSL•FO
RenderX

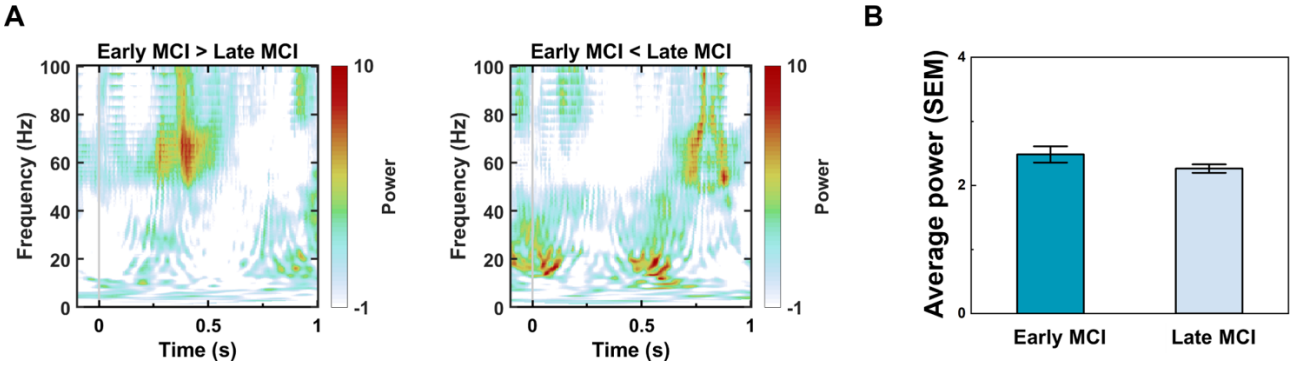
Figure 5. Time-frequency representation of odor-mediated olfactory responses for each selected odorant, shown as a 3 × 2 grid of the six odorants (cinnamon, smoke, and chocolate in the top row; gasoline, soap, and onion in the bottom row). The upper block (CN > DAT) indicates higher power for the cognitively normal (CN) group relative to the dementia of Alzheimer type (DAT) group, and the lower block (CN < DAT) indicates lower power for the CN group relative to the DAT group. Gamma synchronization is observed in the normal controls after odor onset, as indicated by the vertical gray line at time 0.



Stage-Dependent Spectral Alterations and Clinical Associations

For the loss of smell to be used as an early diagnostic method for AD, the detection of early signs is essential during the MCI stage, which precedes dementia. However, existing approaches do not clearly differentiate between individuals who were CN and those with MCI. Therefore, we conducted an experiment to determine whether digitalized measurements of olfactory function could effectively classify MCI severity. To examine the progression of olfactory dysfunction across the cognitive spectrum, the MCI group was stratified according to cognitive severity. Using the SNSB-II composite *z* score with a cutoff of –1.0 (adjusted for age and education), 30 participants were identified as EMCI (mean *z* score 0.15, SD 0.58) and 9 as late MCI (mean *z* score –1.65, SD 0.42) [38,39]. This score reflects multiple cognitive domains, including language, attention, visuospatial skills, memory, and frontal and executive function. Neuropsychological evaluations and relationships between the groups are summarized in Table 1 and Figure 6. First, we generated a differential time-frequency spectrum comparing EMCI to late MCI (EMCI > late MCI) and vice versa (EMCI

XSL•FO
RenderX



< late LMCI). No significant differences in the odor-induced gamma band power were observed among the groups. Notably, the EMCI group exhibited faster responses within 490 ms of odor onset across the 6 electrodes. In contrast, the late MCI group showed delayed gamma synchronization at approximately 850 ms post stimulus after controlling for sniffing and evoked responses (Figure 7A). However, no difference in the average gamma-band power was found between the groups (Figure 7B). Furthermore, we analyzed significant increases in the average power spectrum across the CN, EMCI, late MCI, and DAT groups. As shown in Figure 8A, the gamma band power spectrum showed a significant reduction and delayed response time starting from the late MCI stage compared with individuals who were CN. Additionally, the beta band power spectrum progressively decreased as the condition advanced from CN to EMCI, LMCI, and DAT stages. These results were consistent for each of the 6 selected odors, as shown in Figures 9A and 9B. In this regard, the structural similarity index matrix (SSIM) analysis of the olfactory response spectrograms revealed high similarity between the control and EMCI groups (SSIM=0.43) and between the late MCI and DAT groups (SSIM=0.61), as provided in Figure 10. Olfactory characteristics were derived by computing the mean values across the temporal stages for each component. Components 1, 3, and 5 were associated with the beta band, whereas components 2 and 4 were associated with the gamma band (Figure 2D). The spectral analysis in Figure 8B revealed significant decreases in the beta band power from EMCI (P<.001) to late mild cognitive impairment (LMCI; P=.03), culminating in DAT (P=.009). The gamma band power demonstrated a distinct temporal progression, with significant reductions emerging at LMCI (P=.01) and progressing through DAT (P=.001), while showing marginal alterations at EMCI (P=.08).

Figure 6. Plot of model-fitted Seoul Neuropsychological Screening Battery II (SNSB-II) scores with University of Pennsylvania Smell Identification Test (UPSIT) vs actual SNSB-II scores using the multiple linear regression model, with the selected 6 UPSIT scores as the independent variables and the SNSB-II score as the dependent variable. The mean absolute error (MAE), root mean square error (RMSE), and model fit are expressed as the adjusted R^2 of the model.

XSL•FO
RenderX

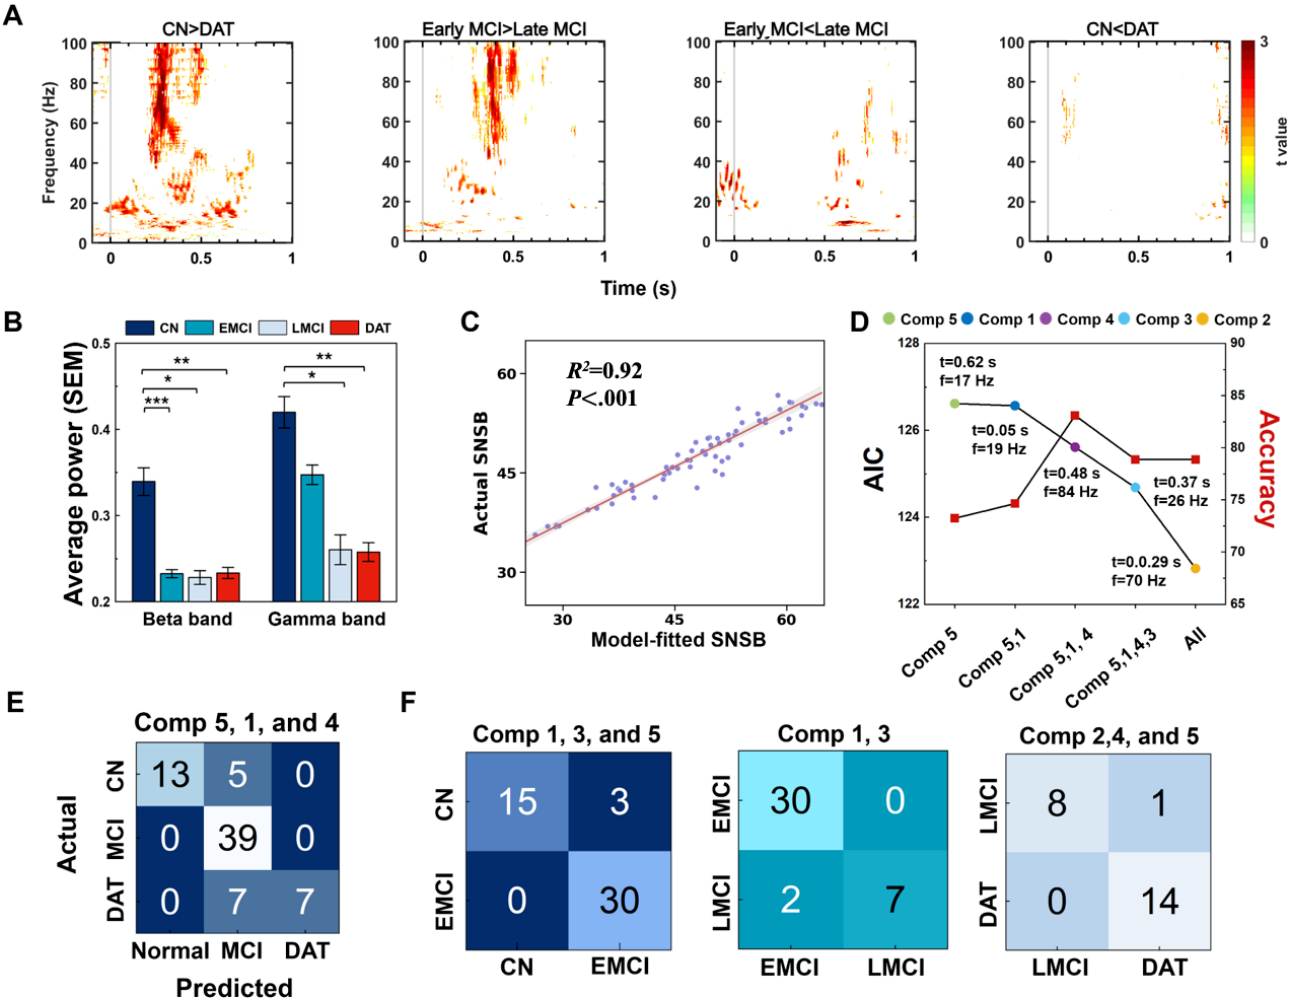


Figure 7. Averaged time-frequency map of 6 odorant-mediated olfactory responses, demonstrating higher power in the early mild cognitive impairment (MCI) group compared to the late MCI group, and averaged odorant-mediated olfactory responses showing reduced power in the late MCI group compared to the early MCI group. Warmer colors in the time-frequency response represent higher power values, as shown in panel A. Averaged power change for odorants across the 0-1 second interval, presented with SE of the mean (SEM) for responses to the 6 selected odorants, as shown in panel B. Statistical significance is indicated by * for *P*<.05.

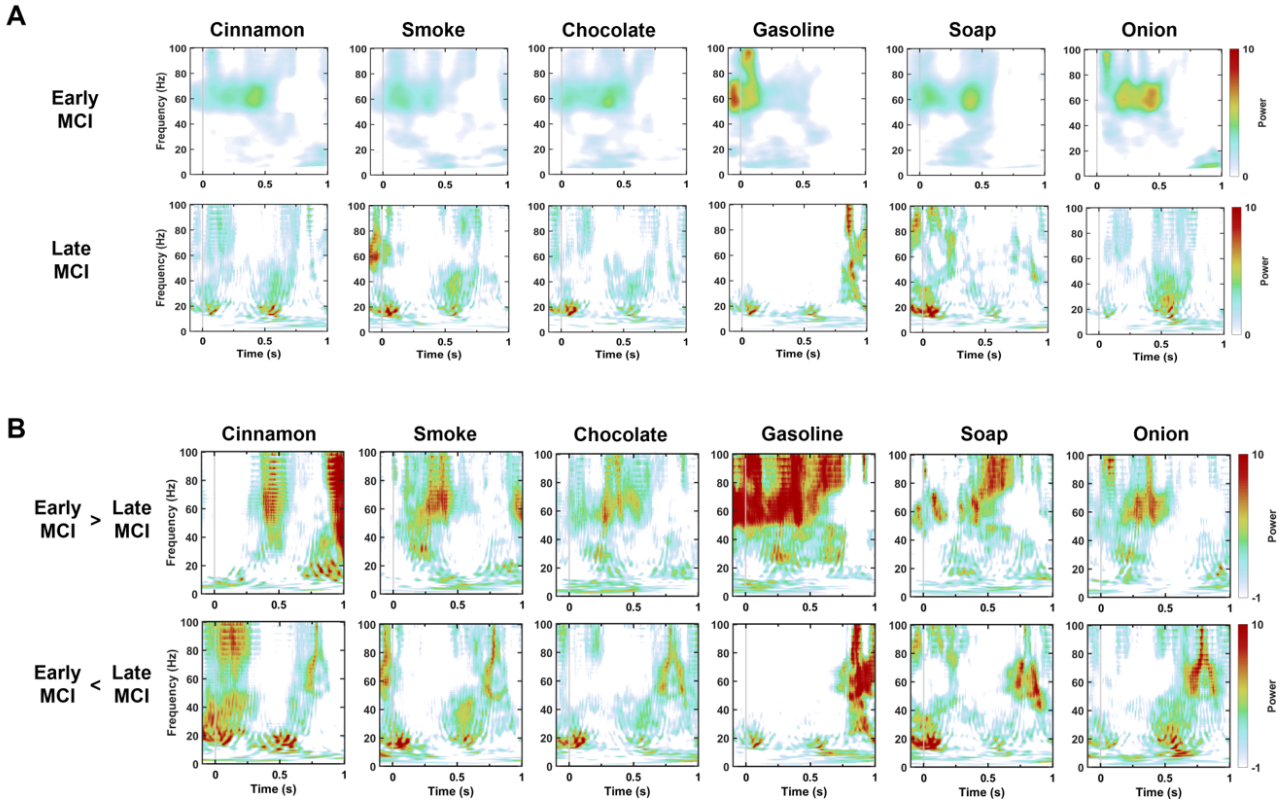
To evaluate clinical applicability, the extracted spectral characteristics, categorized into beta and gamma frequency bands, were used to examine their association with cognitive performance. As shown in Figure 8C, multiple linear regression analysis demonstrated that electrophysiological features explained 91.69% of the variance in SNSB-II *z* scores (*P*<.001). This remarkably strong association between olfactory biomarkers and cognitive function was consistent across the entire cognitive spectrum from CN to DAT. The extremely low *P* value indicates that this relationship is highly unlikely to have occurred by chance. Additionally, MMSE scores showed similarly strong associations with olfactory responses (R^2=0.94; Figure 10). These results demonstrate that the magnitude of electrophysiological responses in beta and gamma bands closely tracks with the severity of cognitive impairment, supporting the potential of these biomarkers for objective cognitive assessment.



XSL•FO
RenderX

Figure 8. Olfactory response components as a digitalized diagnosis tool. (A) Threshold t-maps derived from 1000 Monte Carlo permutation tests at $P<.05$, indicating a gradual decrease in gamma synchronization and delayed reaction time from individuals who were cognitively normal (CN) to patients with dementia of the Alzheimer type (DAT), significant in the beta and gamma bands. (B) Averaged power change for odorants from each olfactory component, presented with SE of the mean (SEM) for responses to the 6 selected odorants (components 1, 3, and 5 exhibited the beta band, whereas components 2 and 4 belonged to the gamma band). Statistical significance was indicated using asterisks, with * representing $P<.05$, ** denoting $P<.01$, and *** signifying $P<.001$. (C) Plot of the predicted Seoul Neuropsychological Screening Battery II (SNSB-II) scores vs actual SNSB-II scores using the multiple linear regression model, regressing the extracted key features from the olfactory response components as dependent variables. The model fit is expressed as the adjusted R^2 of the model and the Pearson correlation between the 2 variables, indicating the proportion of variance in SNSB-II scores explained by the model parameters. (D) Akaike information criteria (AIC) for each olfactory response component. Accuracy of models with stepwise adding of components shows maximum accuracy for the model, including components 5, 1, and 4. (E) Confusion matrix of the support vector machine classifier model: out of 18 individuals in the CN group, 13 were classified correctly as CN, whereas 5 were misclassified as mild cognitive impairment (MCI). The classification was accurate for the MCI groups. Among 14 individuals in the DAT group, 7 were misclassified as MCI. (F) Cross-tables distinguishing adjacent cognitive stages (cognitively normal vs early mild cognitive impairment, early vs late mild cognitive impairment, and late mild cognitive impairment vs dementia of the Alzheimer type) show true-positive, false-positive, true-negative, and false-negative values. Comp: component; EMCI: early mild cognitive impairment; LMCI: late mild cognitive impairment.

XSL•FO
RenderX

Figure 9. Time-frequency representation of odor-mediated olfactory responses in early and late mild cognitive impairment (MCI) for each of the 6 selected odorants (cinnamon, smoke, chocolate, gasoline, soap, and onion), arranged in columns. (A) Absolute time-frequency responses for the early MCI group (top row) and the late MCI group (bottom row). Early gamma synchronization was observed in the early MCI group shortly after odor onset (indicated by the vertical gray line at time 0), whereas synchronization was delayed in the late MCI group. (B) Between-group contrasts: the top row (early MCI > late MCI) indicates higher power in the early MCI group, and the bottom row (early MCI < late MCI) indicates higher power in the late MCI group. Comparably high gamma synchronization was observed in both MCI groups after odor onset, in contrast to the markedly reduced responses previously shown for the dementia of the Alzheimer type group.

Model selection was conducted using the Akaike information criterion to assess the accuracy of fit for each olfactory component based on the in-sample prediction error. In classifying the CN, MCI, and DAT groups, component 2 showed the optimal performance, with the lowest Akaike information criterion value of 122.82, followed by component 3 (124.69), component 4 (125.61), component 1 (126.57), and component 5 (126.62). Subsequently, we used a stepwise component addition approach within the regression framework to optimize the prediction accuracy. The analysis revealed a peak performance with a 3-component model that included components 5, 1, and 4, as shown in Figure 8D. We implemented a support vector machine regressor that integrates component-specific olfactory characteristics to assess the diagnostic utility of digitalized olfactory response recordings. Model performance was evaluated using leave-one-out cross-validation, where each participant was held out as a test sample. The resulting classification model demonstrated exceptional discriminative capability across the 3 groups, achieving 83.09% accuracy, 88.64% precision, perfect recall (100%), and an F_1-score of 93.98% (Figure 8E). These metrics underscore the robust diagnostic potential of the proposed multicomponent approach. Therefore, the strong predictive relationship between odorant-mediated olfactory responses and cognitive performance underscores the potential clinical utility of this method for early diagnosis of AD. Further analyses were performed to evaluate the component-specific contributions in distinguishing between adjacent cognitive stages (CN-EMCI, EMCI-LMCI, and LMCI-DAT) to identify the key components for the early detection of AD. The discrimination between CN and EMCI states was achieved with remarkable precision using components 1, 3, and 5, all representing beta band activity, resulting in 93.75% accuracy, 90.91% precision, and 100% recall (Figure 8F). Notably, the predominant use of beta band components rather than gamma band components in the pre-DAT stage classification aligned with the findings presented in Figure 8B. The gamma band components were critical in differentiating patients with DAT from the LMCI group, marking a distinct transition point in disease progression. Table 2 summarizes the classification performance across different diagnostic comparisons.

XSL•FO
RenderX

Figure 10. Structural similarity index matrix (SSIM) of olfactory response spectrograms across the cognitively normal (CN), early mild cognitive impairment (MCI), late MCI, and dementia of the Alzheimer type (DAT) groups. Higher values indicate greater similarity between spectrograms; high similarity was observed between the CN and early MCI groups (SSIM=0.43) and between the late MCI and DAT groups (SSIM=0.61), as shown in panel A. Plot of predicted vs actual Mini-Mental State Examination (MMSE) scores using the multiple linear regression model, with the extracted key features from the olfactory responses as the independent variables and the MMSE score as the dependent variable, as shown in panel B. The model fit is expressed as the adjusted R^2 and the Pearson correlation between the 2 variables, indicating the proportion of variance in MMSE scores explained by the model parameters. The shaded band denotes the 95% CI of the regression line.

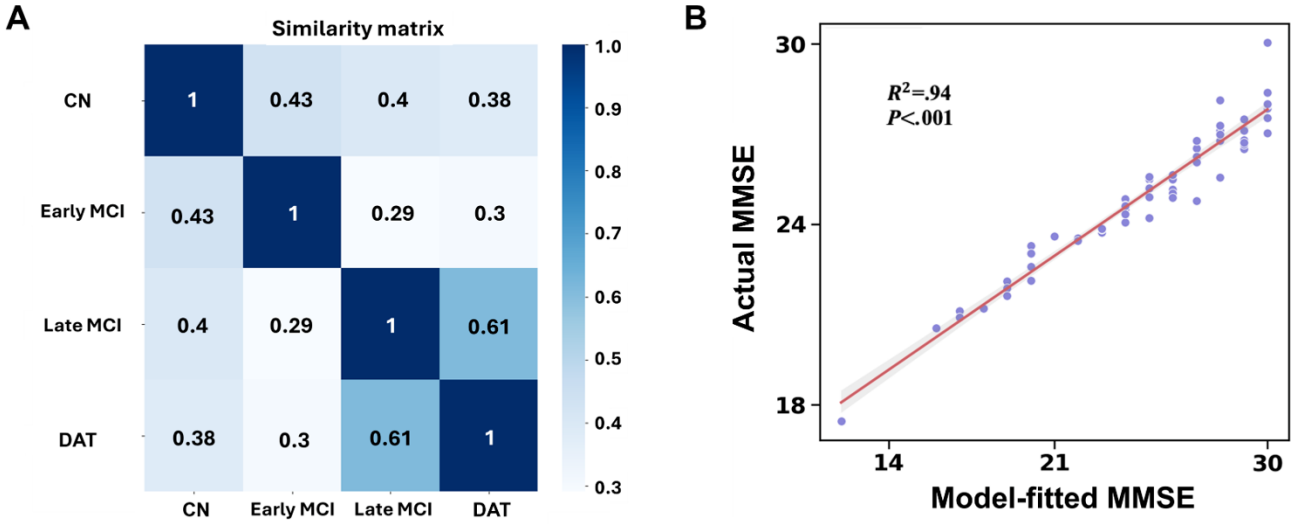


Table . Classification performance of support vector machine models using olfactory electrophysiological features. Performance metrics for support vector machine classification across different diagnostic group comparisons. Models were trained using electrophysiological components extracted from time-frequency analysis of olfactory responses. Leave-one-out cross-validation was performed for the 3-way classification. Binary classifications between adjacent cognitive stages reveal differential importance of frequency bands: beta-band components (1, 3, and 5) were most effective for distinguishing cognitively normal from early MCI, whereas gamma-band components (2 and 4) became crucial for late-stage discrimination.

Classification task	Accuracy (%)	Precision (%)	Recall (%)	F_1-score (%)	Features
3-way classification (CN[a], MCI[b], and DAT[c])	83.09	88.64	100	93.98	5,1,4

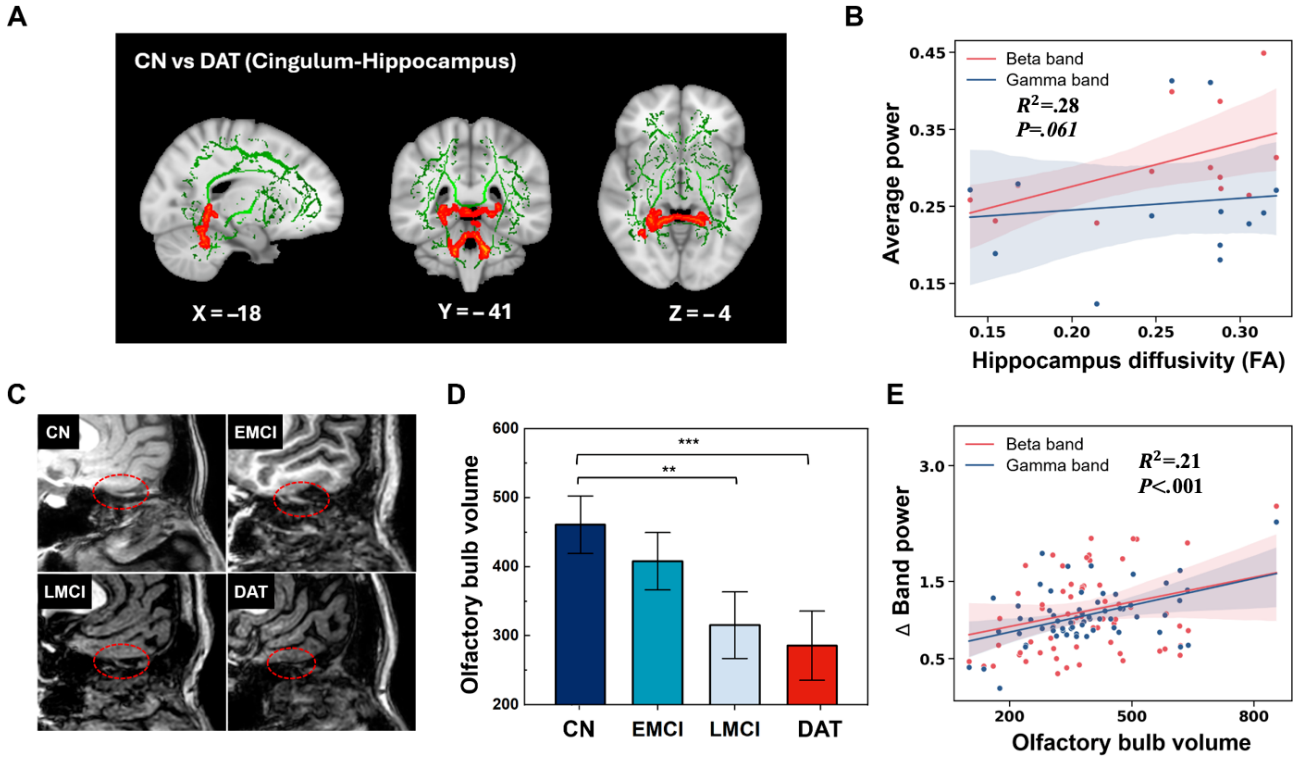
[e]LMCI: late mild cognitive impairment.

Structural Correlations of Bidirectional Spectral Components



To elucidate the brain areas associated with the beta and gamma components within the olfactory system, we used a dual analytical approach that combined TBSS and volumetric MRI quantification. TBSS analysis revealed significantly reduced FA in the hippocampus cingulum of the DAT group compared with that in the CN group (P<.05), as shown in Figure 11A. The inverse correlation between FA values and cognitive impairment suggests that reduced white matter integrity in the hippocampal cingulum region is associated with more severe cognitive deficits [46-48]. Further analysis revealed a positive correlation approaching statistical significance between the beta-band components (mean of components 1, 3, and 5) in olfactory responses and FA values within the hippocampal-cingulum tracts in patients with DAT (R^2=0.28; P=.06), consistent with beta-band oscillations representing top-down cortical feedback signals. In contrast, gamma-band components showed minimal correlation with the integrity of the hippocampal-cingulum tracts (R^2=0.013; P=.53; Figure 11B).

In T1-weighted MR images, volumetric analysis of the OB revealed progressive atrophy across the disease spectrum, with a notable reduction in volume as cognitive status declined from CN to EMCI, LMCI, and DAT stages. Figure 11C provides representative T1-weighted MR images from each stage, with the OB regions delineated by red dashed circles, illustrating sequential volume reduction corresponding to cognitive decline. Quantitative analysis revealed significantly reduced OB volumes

XSL•FO
RenderX

in patients with LMCI compared with those in the CN group (P=.005), whereas patients with DAT exhibiting a pronounced volume reduction (P<.001), as shown in Figure 11D. In contrast, the EMCI group did not show a statistically significant volume reduction relative to the control group (P=.20), indicating that substantial OB atrophy may become more evident during later stages of cognitive decline [32,49]. This temporal pattern aligns with the delayed reduction in gamma-band olfactory components (components 2 and 4), suggesting parallel trajectories between structural and functional changes during later stages of the disease. Demographic analyses confirmed minimal influence on our primary outcomes. For OB volume, weak correlations with age (r=–0.23; P=.05) and education (r=0.17; P=.15) cannot explain the stage-specific volume reductions observed between groups (P<.01). Further analysis of OB volume and frequency-band power revealed a positive correlation between average frequency-band power and OB volume (Figure 11E). Specifically, for gamma bands, the coefficient of determination was 0.2108, with P<.001, indicating a strong and statistically significant relationship. In contrast, the correlation observed for the beta bands showed minimal optimization in linear fitting, yielding an R^2 value of 0.0613 (P=.05), suggesting a weaker association compared with the gamma bands, although still statistically significant.

Figure 11. Comparison of olfactory responses with clinically relevant structural evidence. (A) White matter structures showing a significant fractional anisotropy (FA) decrease in the hippocampal cingulum in the dementia of the Alzheimer type (DAT) group (P<.05). Statistical images were overlaid onto the mean skeleton (green) and the MNI152 template (gray scale) for visualization (B) FA values of the hippocampal cingulum positively correlated with the beta-band olfactory component (mean of components 1, 3, and 5), whereas gamma-band components (components 2 and 4) exhibited minimal correlation with hippocampal white matter integrity. (C) Representative T1-weighted magnetic resonance imaging of each cohort (cognitively normal [CN], early mild cognitive impairment, late mild cognitive impairment, and DAT, from left to right) with OB regions delineated by red dashed circles. (D) Olfactory bulb volume change across CN to DAT, presented with SE of the mean (SEM). Statistical significance was indicated using asterisks, with * representing P<.05, ** denoting P<.01, and *** signifying P<.001. (E) The olfactory bulb volume positively correlated with the gamma-band olfactory component (mean of components 2 and 4), whereas beta-band components (components 1, 3, and 5) exhibited minimal optimization in linear fitting. EMCI: early mild cognitive impairment; LMCI: late mild cognitive impairment.

Discussion

Objective Biomarkers for Early AD Detection

Objective measurement of odorant-mediated olfactory responses has the potential to enable the early diagnosis of AD by accurately predicting clinical neurobehavioral examination scores. In this study, we aimed to determine whether the olfactory response can serve as an early biomarker for AD, enabling us to distinguish between CN, EMCI, LMCI, and DAT groups. Consequently, a significant difference in the average power was observed between individuals who were CN and patients with DAT, which is consistent with the results of the 6-item modified B-SIT. These findings highlight a potential advantage of electrophysiological over behavioral olfactory assessments. While behavioral testing revealed no significant differences between CN and MCI groups, OB recordings showed distinct neural signatures that may reflect subtle disease-related changes. However, given the modest sample size and partial overlap in performance, these results should be considered preliminary. Larger validation studies are warranted to confirm whether OB electrophysiological responses can reliably detect early olfactory dysfunction not captured by behavioral tests. When measuring the electrical signals from the OB across all 4 groups, we observed a decrease in the beta- and gamma-band power and a delay in responses to odor exposure, which correlated with the progression of cognitive dysfunction.

XSL•FO
RenderX

In addition, signals obtained through digitalized olfactory measurements enabled the identification of olfactory response components distributed across various frequencies and time intervals, which allowed for discrimination between the DAT and CN groups at the individual level. The model exhibited outstanding performance in distinguishing among groups: CN (72.22% accuracy), MCI (100% accuracy), and DAT (50% accuracy, 100% precision). These results correlated strongly with the SNSB-II cognitive dysfunction levels and structural characteristics of the brain. Post hoc analyses demonstrated that potential demographic confounders had minimal influence on our findings, with negligible correlations observed between age and cognitive scores (r=–0.16; *P*>.20) and between education and cognitive scores (*r*=0.24; *P*>.05). These findings were further confirmed by formal demographic adjustment, in which the primary electrophysiological predictor retained independent significance for both SNSB-II (*P*=.04) and MMSE (*P*=.009) after controlling for age, sex, and education. While age and education shared some explanatory variance with secondary spectral components, this overlap is expected given the known influence of these factors on cognitive performance and the fact that SNSB-II scores are already standardized for age, sex, and education. Importantly, classification performance did not improve when demographic covariates were included, supporting the independent contribution of electrophysiological features. Future studies with larger, demographically balanced cohorts will be essential to further refine the generalizability and demographic robustness of these electrophysiological biomarkers.

Furthermore, we recorded signals from 6 electrodes using a slightly modified version of a previously reported electrobulbogram to measure the electrical response of the OB. This method has proven to reliably assess OB function in healthy participants, demonstrating high test-retest reliability in previous studies [35]. Notably, patients with PD show a high prevalence of olfactory dysfunction, with approximately 90% of patients experiencing some degree of smell impairment [50]. The high rate of olfactory dysfunction, which is often evident years before the onset of motor symptoms, highlights its potential role as an early indicator of disease. Recently, a noteworthy study presented the electrobulbogram method as an effective tool for detecting PD by distinguishing patients diagnosed with the condition from control participants [37].

Bidirectional Neurophysiological Insights and mHealth Applications

Olfactory dysfunction is one of the earliest clinical symptoms of AD. It is recognized as both an early indicator and a potential clinical marker of the progression and severity of the disorder [8-10]. In addition to cognitive impairment, approximately 90% of patients with DAT experience loss of olfactory abilities, such as difficulties with olfactory recognition and identification [12]. Sniffing kits, such as UPSIT, are frequently used to examine olfactory dysfunction in patients suspected of having MCI or AD [20-22]. In this study, although the sniffing kit clearly distinguished between healthy individuals and patients with DAT, the differences between healthy and MCI participants were not significant. When electrical signals from the OB were compared across all 4 groups, a decrease in beta- and gamma-band power and delayed responses to odor exposure were observed. Given that the gamma band is primarily associated with processes within the OB [51-55], these observed differences indicated impaired OB processing in DAT due to neuronal loss [10]. Moreover, activity in the beta band is likely generated by top-down projections, which is further supported by the increased latencies and high correlation with cingulum hippocampus diffusivity observed in our data [54,56]. These findings suggest an impairment in the bidirectional interaction between the OB and higher olfactory cortex regions, such as the amygdala and orbitofrontal cortex, which are involved in the processing of various aspects of odor perception. Although a significant reduction in total power was noted between the CN and DAT participants, no significant decrease in total power was found between the CN and MCI groups (early and late) or between the early and late MCI groups. These results suggest a gradual delay in gamma-band synchronization, ultimately leading to a complete loss of olfactory response. This observation is consistent with prior research, indicating that the recognition ability in patients with DAT declines early, whereas the detection threshold is preserved for a relatively longer period [22]. The combined use of TBSS and volumetric analyses offers complementary insights; TBSS enables a detailed investigation of white matter tracts, whereas volumetric quantification assesses regional brain volume changes. This comprehensive structural analysis framework helps map the relationships between functional olfactory components and their underlying neuroanatomical correlations. The observed differential patterns of association suggest distinct neuroanatomical substrates for the beta- and gamma-frequency components of olfactory processing. Our cross-sectional findings show that functional olfactory changes can be present even when volumetric measures remain relatively intact. However, the cross-sectional nature of our study precludes any conclusions about temporal relationships or causality. While we observed functional changes in the presence of preserved structure in some groups, we cannot determine whether electrophysiological changes truly precede volumetric alterations during disease progression. Longitudinal studies are essential to establish these temporal relationships and to confirm whether OB dysfunction represents an early biomarker that emerges before structural brain changes.

In summary, we attempted to digitize the measurement of OB function to differentiate individuals who were CN from patients with EMCI, LMCI, or DAT in a noninvasive manner. Accordingly, we isolated specific olfactory characteristics that significantly differentiate CN and DAT groups, which were successfully regressed against clinical AD diagnostic examinations, demonstrating high levels of sensitivity, specificity, and accuracy. Notably, these olfactory responses are specifically associated with disease characteristics and affected brain regions according to their frequency bands. This finding suggests that the OB, which is responsible for olfactory responses, is pathologically damaged in patients with DAT, resulting in olfactory dysfunction caused not only by the affected brain regions but also by direct biological damage to the OB. Therefore, our results support the potential of this methodology for further development as a tool to facilitate the early diagnosis of AD and provide a robust and objective biomarker for the disease.

RenderX

Conclusion

Our study demonstrates that noninvasive digital recordings of OB function can serve as a novel biomarker for continuous and home-based monitoring of cognitive states across the continuum from normal aging to Alzheimer dementia, supporting early detection and timely intervention within an mHealth framework. The electrophysiological biomarkers we identified—particularly the progressive decline in beta-band power and later-stage reduction in gamma-band power—correlate strongly with established clinical and neuroimaging markers of AD progression. These electrophysiological changes may precede structural brain alterations, highlighting their potential value for early detection and longitudinal tracking. As a digital health tool, this technology has potential applications beyond diagnosis, including monitoring disease progression and potentially assessing therapeutic efficacy in clinical trials. Beyond objective signal capture, our wearable olfactory recording system offers distinct practical advantages for mHealth deployment. The device can be fitted in less than 2 minutes, and the entire assessment takes approximately 5‐10 minutes, allowing frequent, home-based measurements with minimal burden on users or caregivers. This approach embodies the mHealth paradigm, where continuous, real-world monitoring of physiological biomarkers enables early detection of cognitive decline and supports timely, personalized interventions. These findings support the development of accessible mHealth technologies for early AD detection and ongoing disease surveillance, addressing the growing need for noninvasive, cost-effective screening tools that can be deployed more widely than expensive neuroimaging techniques or invasive procedures.

Acknowledgments

We would like to express our sincere gratitude to all participants who took part in this study. Their commitment and cooperation made this research possible. No generative artificial intelligence tools were used in any portion of the paper writing process.

Funding

This work was supported by the National Research Foundation of Korea (NRF) grant funded by the Ministry of Science and ICT (MSIT) of the Korean government (RS-2023-00302751); the Bio&Medical Technology Development Program of the NRF funded by MSIT (RS-2023-00226494); the Commercialization Promotion Agency for R&D Outcomes (COMPA) funded by MSIT (RS-2025-02311678); and the Regional Innovation System & Education (RISE) program through the Seoul RISE Center, funded by the Ministry of Education (MOE) and the Seoul Metropolitan Government (2026-RISE-01-027-01).

Data Availability

The olfactory response data and MATLAB (The MathWorks, Inc) code supporting the findings of this study are available from the corresponding author upon reasonable request for noncommercial use, subject to a materials transfer agreement with Allfacto Lab. Raw medical data, including magnetic resonance imaging and diffusion tensor imaging, are not publicly available owing to privacy restrictions and ethical considerations but may be available from the corresponding author upon reasonable request and subject to appropriate ethical approvals.

Authors' Contributions

JH, HJK, and YJ conceptualized the study. JH, JB, and YL curated the data. JH and JB conducted the formal analysis. HJK and YJ acquired the funding. JH, YSK, and YL conducted the investigation. JH, HJK, and YJ developed the methodology. HJK, JCK, and YJ administered the project. HJK and YJ supervised the study. JH visualized the data. JH and YJ wrote the original draft. HJK and YJ contributed equally as corresponding authors.

Conflicts of Interest

None declared.

Multimedia Appendix 1

Flowchart of participant recruitment, screening, exclusion, and diagnostic classification. Eligible participants were assigned to the cognitively normal, early mild cognitive impairment, late mild cognitive impairment, or dementia of the Alzheimer type groups based on standardized clinical, neuropsychological, and neuroimaging criteria.

Abstract

Background: When trying to intervene early to prevent manic episodes, clinicians are hindered by patients underreporting their symptoms as they are becoming hypomanic or manic (ie, emerging symptoms). Continuous passive monitoring using wearable technology offers a potential solution to address this problem by capturing behavioral signals that do not depend on self-awareness. However, its clinical usefulness requires validation before implementation.

Objective: This study aimed to evaluate whether passively collected wearable data can detect hypomanic symptoms using an explainable machine learning framework.

Methods: We applied explainable machine learning to densely sampled multimodal data from a 2-year observational study of digital monitoring in 178 patients with a diagnosis of bipolar disorder (mean follow-up 540 days; range 120-706 days). Data on activity and sleep were collected continuously using wearable technology. Self-reported data were collected daily on their mood, energy, and anxiety, and weekly using the Altman Self-Rating Mania Scale (ASRM). To identify robust digital markers of hypomanic symptoms, we analyzed 252 time- and frequency-domain features from 43 participants who experienced at least 1 ASRM-defined symptomatic interval.

Results: Passively collected data achieved high accuracy, comparable with daily self-reported data in detecting symptomatic intervals (area under the receiver operating characteristic curve 0.91 vs 0.93, respectively). Combined daily passive wearable data features achieved higher sensitivity (92.0% vs 85.4%), balanced accuracy (0.90 vs 0.89), and stronger rule-out usefulness (negative predictive value 97.8% vs 96.1%) than self-report data, with daily sleep features alone driving most of this signal (area under the receiver operating characteristic curve 0.91, sensitivity 91.8%). The high classification performance using wearable data was explained by reductions in spectral entropy and flux across domains, reflecting a decreased complexity and variability in mood, activity, and sleep patterns, consistent with a shift toward pathologically stable states.

Conclusions: Passive monitoring using wearable technology can detect hypomanic symptoms with high accuracy, supporting its potential as a clinically meaningful tool for continuous, objective monitoring in patients who underreport hypomanic symptoms. These findings are associative and concurrent in nature; they do not establish predictive validity. Prospective studies are needed to evaluate predictive validity for early detection of ASRM-defined symptomatic intervals.

Introduction

Clinical assessment typically relies on retrospective self-reports during clinical visits, which are prone to recall bias. A key limitation of symptom self-report in bipolar disorder (BD) is that insight into illness is frequently impaired, particularly during hypomanic or manic episodes: fewer than a quarter of patients recognized having ever experienced a hypomanic or manic episode, compared with over 80% who recognized past depressive episodes [1]. Because diagnosis and ongoing monitoring rely heavily on patients reporting their own symptoms [2,3], this lack of insight contributes directly to the underdetection and undertreatment of hypomanic or manic episodes [4].

Passive monitoring using wearable technology offers a way around this problem: physiological (eg, sleep architecture) and behavioral (eg, activity levels) signals are captured continuously in the patient's natural environment, moving beyond retrospective clinical assessments toward continuous, objective monitoring [5,6]. This approach, often termed digital phenotyping, can capture subtle yet significant changes in patterns that precede the onset of a mood episode and has shown promise in mental health [7]. In BD specifically, disruptions in activity and circadian rhythms have shown their potential for episode prediction [8-13]. Furthermore, a major insight in digital phenotyping is that day-to-day variability in behavioral and physiological metrics may be more informative than static measures for detecting episode onset. We have demonstrated that variability in activity levels precedes mood changes by approximately 7 days in depressive episodes [14]. Similarly, we identified variability in sleep stages and activity levels as the earliest indicators of hypomanic episode onset, achieving high sensitivity (0.94) and specificity (0.80) [8]. While these findings underscore variability as a fundamental concept for the early detection of episodes, spectral or frequency-domain features that reveal rhythmic dynamics remain underexplored in the context of BD.

Additionally, the optimal integration of objective, passively collected wearable data with subjective reports of a participant's state (eg, electronic visual analog scales [e-VASs] and self-rating scales) remains underexplored [15]. In this context, while machine learning (ML) is essential for detecting subtle patterns in high-dimensional data, its clinical translation is often hindered by limited interpretability and the need for personalized approaches that account for heterogeneity [16-18]. Hence, robust, multimodal digital markers that combine passive and active data, validated through repeated within- and across-participant testing, are needed to develop personalized, clinically actionable early-warning systems.

Beyond methodological considerations, several clinical and technical challenges further complicate the development of digital markers for hypomanic or manic episodes. Clinically, hypomanic or manic episodes occur less frequently and are shorter in duration than depressive episodes [19]. This imbalance results in fewer training examples for predictive models and reduced statistical power to detect changes. From a technical perspective, many digital phenotyping studies in BD are characterized by short follow-up durations, limiting the capture of hypomanic or manic symptoms and hindering the development of robust, generalizable predictive models for detecting these types of episodes.

To address all these gaps, this manuscript describes a longitudinal observational study designed to identify and validate robust digital markers of hypomanic or manic symptoms. Our approach integrates 2 key data sources: objective (ie, continuous, passively collected activity and sleep data from a consumer-grade wearable), and subjective (ie, daily self-reports of mood, energy, and anxiety collected via e-VAS, and weekly self-reports of symptom severity collected via Altman Self-Rating Mania Scale [ASRM], a validated self-report measure [20] used to operationalize mood state classification). By applying explainable ML techniques to a diverse set of time- and frequency-domain features extracted from a longitudinal multimodal dataset, we aimed to (1) identify the most robust and accurate digital markers of hypomanic symptoms and (2) compare the discriminative accuracy of passively collected wearable data against self-reported measures.

Methods

Participants and Data Collection

The study was approved by the Research Ethics Board (REB) at the Centre for Addiction and Mental Health (CAMH), Toronto, Ontario, Canada, and at the Queen Elizabeth II Health Sciences Centre (QEII Health Care Center), Halifax, Nova Scotia, Canada, in accordance with the Declaration of Helsinki, REB number 059 - 2019. All participants signed an informed consent form approved by the local REB before any research procedure was initiated.

We have previously described the overall methods of this ongoing longitudinal study [21]. In summary, between December 12, 2020, and January 1, 2025, we recruited and followed 178 adults diagnosed with BD type I or II in the outpatient clinics of 2 academic psychiatric hospitals in Canada: the CAMH and the QEII.

Primary diagnoses of BD I or II were confirmed with the SCID-5 (Structured Clinical Interview for the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*) [22] based on the diagnostic criteria of the DSM-5 (*Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*) [23]. Baseline assessments included sociodemographic and clinical data. Clinical polarity at study entry was defined using Young Mania Rating Scale (YMRS) [24] and Montgomery-Asberg Depression Rating Scale [25] thresholds.

We instructed each participant to wear an Oura Ring (Oura Health Oy; Generation 2) continuously throughout the study course. The ring collected multiple activity and sleep data variables, of which we selected a comprehensive subset [26] relevant to the goals of this study (Figure 1A). Additionally, participants received a daily email with a link to an e-VAS to self-rate their mood, energy, and anxiety levels over the previous 24 hours. Reminders were sent to participants when e-VASs were not completed for 3 consecutive days. Participants also received a weekly email with a link to an electronic version of

the ASRM [20] to rate their symptoms for the previous week. Weekly symptom self-reports were stored in a REDCap (Research Electronic Data Capture) [27] secure database.

We evaluated participant adherence to device-wear protocols by quantifying nonwear time and modality-specific missing data ratios. We obtained nonwear time directly from the Oura Ring activity dataset and calculated missing data ratios separately for each modality (activity, sleep, and e-VAS) [28,29].

Data Generation and Processing

Data Generation

Figure 1 presents an overview of the clinical course and data generation time scales. Using the longitudinal ASRM scores of each participant, we applied a 1-week rolling window with 50% overlap to identify ASRM-defined symptomatic intervals, defined as at least 1 weekly rating with an ASRM score of ≥10. The ASRM is a self-rating scale comprising 5 items designed to evaluate the existence and severity of 5 hypomanic or manic symptoms: elation, overconfidence, decreased need for sleep, talkativeness, and increased energy levels, with good validity and reliability [30] when compared with the clinician-administered YMRS [20]. Each item is rated on a scale from 0 to 4, with 0 representing the absence of symptoms and 4 indicating sustained and pronounced symptoms.

Symptomatic Interval Labeling

Because the ASRM has shown high sensitivity and low specificity [31], our operationalized definition of a score of ≥10 typically indicates the presence of 3 or more symptoms nearly every day. By requiring a score of ≥10 for a week, we also captured the DSM-5 four days duration requirement for hypomania and the 1-week duration requirement for mania. The standard ASRM threshold of ≥6 has been recommended by the scale developers for screening purposes [31]. However, we used a more conservative threshold of ≥10 for the following reasons: (1) the ASRM has been shown to have high sensitivity but low specificity [31], and a higher threshold reduces false positives, which is critical when weekly ratings are used to define interval-level labels for ML classification; (2) a score of ≥10 typically requires that a participant endorse at least 3 of 5 symptoms at a moderate-to-severe level (ie, ≥2 on at least 3 items), providing higher clinical specificity for a symptomatic interval; and (3) by requiring this threshold to be sustained over a rolling 1-week window, we further reduce noise from transient elevations (“symptomatic blips”). Moreover, we defined a symptomatic interval as 1 or more consecutive weeks in which the ASRM overall score was ≥10 based on previous studies defining “symptomatic remission” as an ASRM score of <10 [32,33].

To assess the robustness of our findings to this threshold choice, we conducted a sensitivity analysis repeating the full analytical pipeline (feature extraction, classification, and feature importance) using the standard ASRM threshold of ≥6. Some participants presented with an ASRM score of ≥10 on 1 occasion. Because our dataset uses weekly symptom ratings, we could not determine whether these elevated ASRM scores lasted 4 to 6 days (ie, the minimum duration for a hypomanic episode according to DSM-5). Thus, these elevations in ASRM scores that did not span at least 2 weekly ratings were not considered symptomatic intervals in the primary analysis.

Because elevations in symptoms were not independently confirmed by a clinician or a clinician-rated scale, we refer to them as “symptomatic intervals,” rather than “episodes.” Weeks for which the ASRM was not completed were not assigned a label and were excluded from the definition of symptomatic intervals and the euthymic comparator. Depressive and mixed symptomatic intervals were identified using a Patient Health Questionnaire (9-item; PHQ-9) threshold of ≥10; such intervals were excluded from the binary classification analysis (see euthymic comparator definition).

Euthymic Comparator Labeling

Euthymic segments were defined as data segments during which the participants’ weekly ASRM score was <10 and their weekly PHQ-9 score was <10. The use of both ASRM and PHQ-9 thresholds ensured that euthymic segments fell below the standard screening threshold for hypomanic or manic symptoms (ASRM score of <10) and depressive symptoms (PHQ-9 <10), although we cannot ensure that subsyndromal presentations were present. Segments that did not meet criteria for either ASRM-defined symptomatic intervals or euthymia (eg, intervals with elevated PHQ-9 but not ASRM, or transitional periods) were excluded from the binary classification analysis.

Data Variables

Among the 39 data variables generated by the wearable, we selected a smaller set of 12 objective variables (1 of 16 related to activity and 11 of 23 related to sleep). We derived the activity variables included in the analysis from (1) the 5-minute-sampled metabolic equivalent of task (MET), produced by the wearable; and (2) its aggregated variants over 1-hour periods, as well as daytime, evening, and nighttime. Similarly, we derived the sleep variables from (1) the 5-minute hypnograms produced by the wearable and (2) a set of 10 daily data variables provided by the wearable’s proprietary algorithms (eg, wake-up count). Moreover, 3 daily e-VAS variables were collected to describe self-reported mood, energy, and anxiety dynamics (Figure 1A and Table S1 in Multimedia Appendix 1). Overall, based on objective and subjective data across the various time periods, we created a set of 21 variables.

Sleep stages in the 5-minute hypnogram were encoded categorically into 4 stages: awake, light sleep (N1/N2), deep sleep (N3/slow-wave sleep), and rapid eye movement (REM) sleep using the Oura Ring’s proprietary stage labels. This encoding preserves the physiological ordering of sleep stages and allows the same time series feature extraction pipeline to be applied to both activity and sleep-stage data. Irregular sampling within 5-minute windows (eg, brief gaps from device removal) was handled by forward-filling missing epochs from the immediately preceding nonmissing epoch, capped at a maximum of 2 consecutive missing epochs (10 minutes); isolated stage flickers that are typical of automated staging outputs were filtered via moving-window mode smoothing (categorical “majority vote”); days with more than 60 consecutive minutes of missing epochs were classified as nonwear and excluded from analysis.

XSL•FO
RenderX

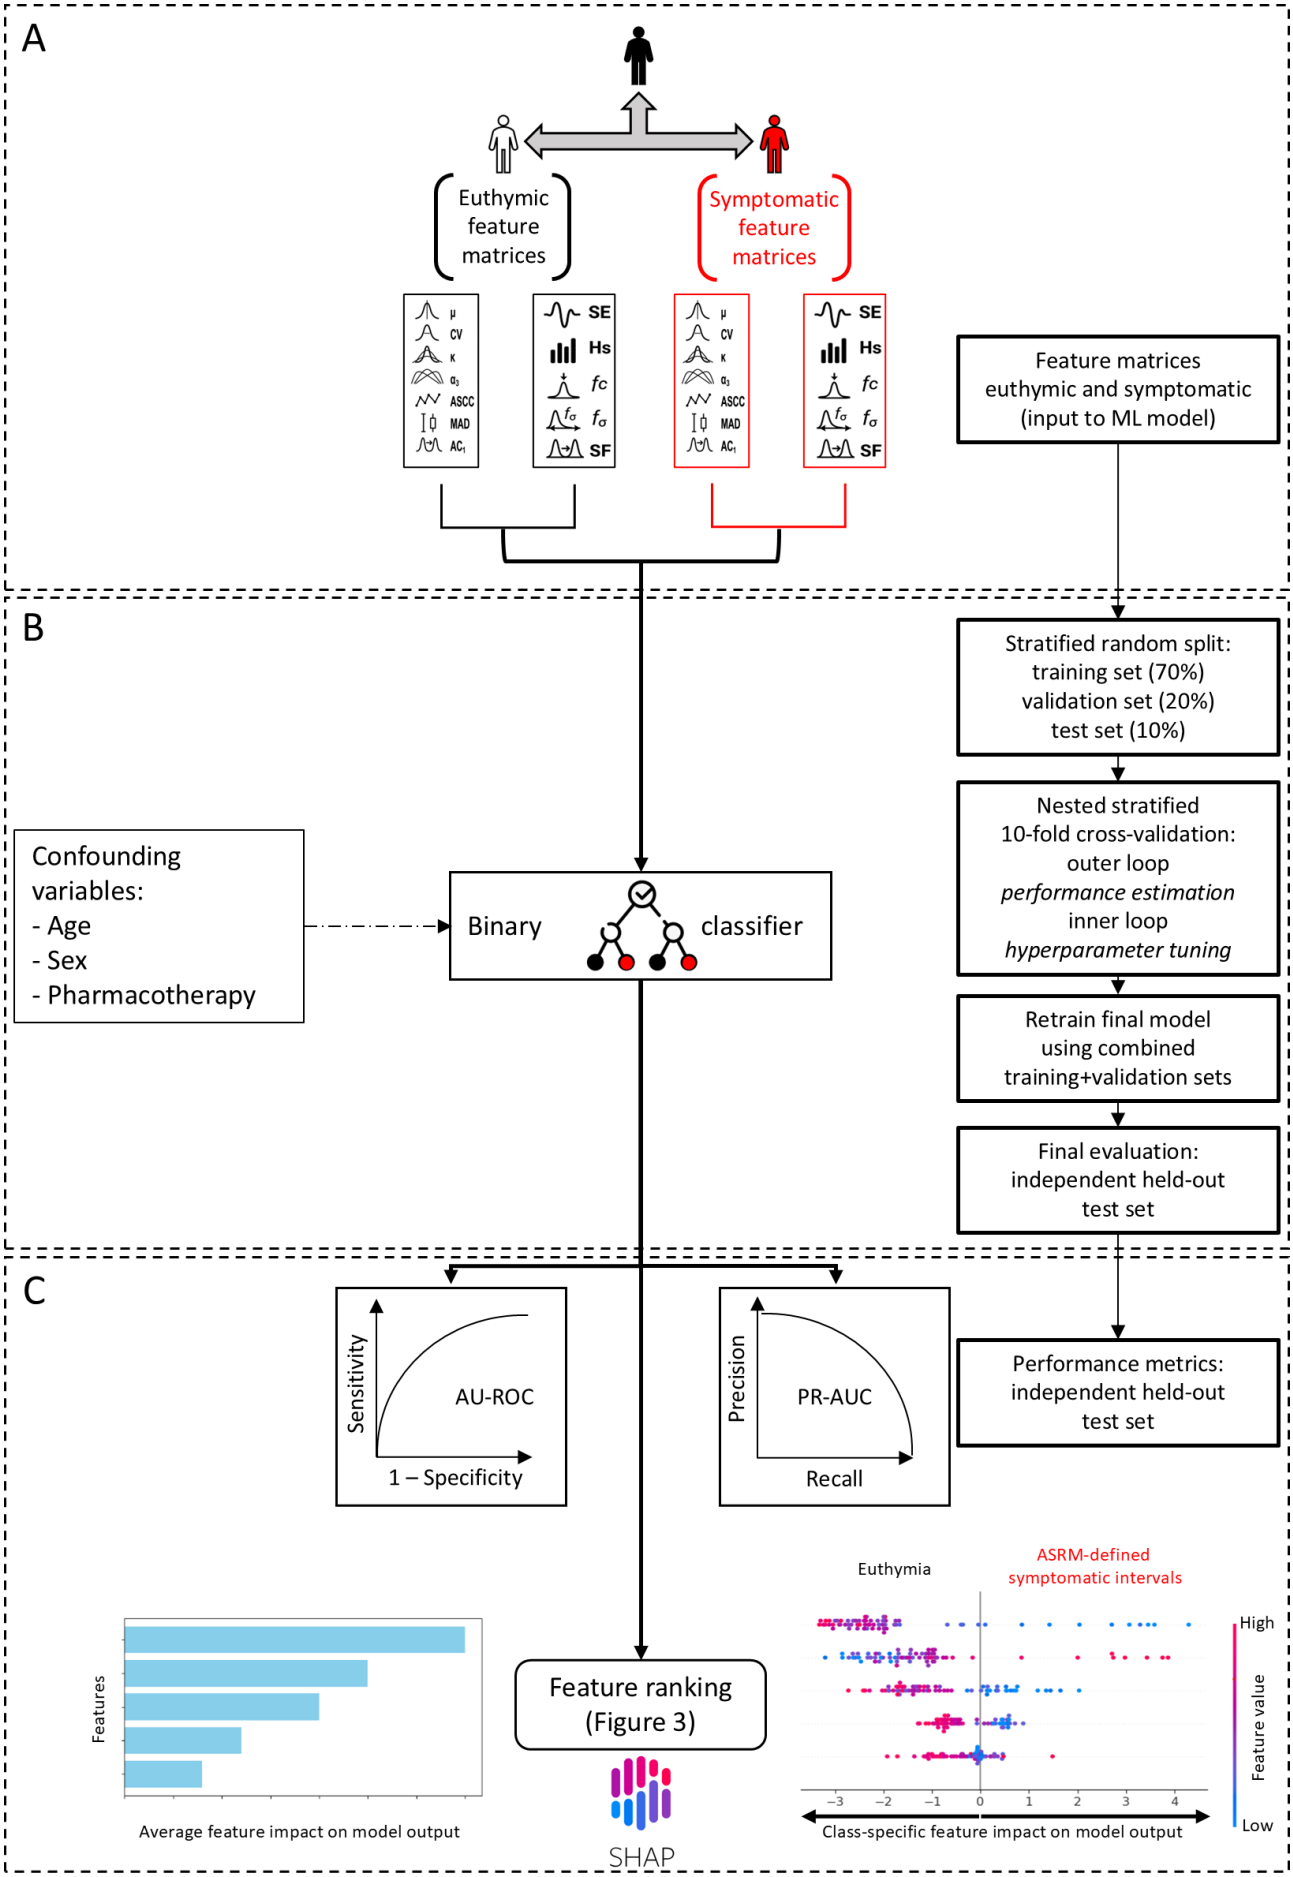
Data Inclusion Criteria

Data inclusion criteria required at least 80% completeness per data segment; segments failing this threshold were excluded from analysis. For the 5-minute MET activity data, nonwear periods were identified using the Oura Ring's proprietary wear detection algorithm and confirmed by sustained zero-MET readings of ≥60 minutes. The 5-minute hypnograms were filtered to remove artefactual sleep-stage transitions (ie, rapid cycling between stages within <5 minutes inconsistent with physiological sleep architecture). Daily sleep variables provided by the wearable's proprietary algorithms (eg, wake-up count and sleep efficiency) were used as is without additional filtering, as these are already validated outputs of the device's sleep pipeline.

Data Completeness

Given our previous findings showing that data in our sample were missing not at random [29], we imputed the daily sleep variables and the 5-minute hypnograms using completeness-based adaptive segmentation (Figure 1B). The k-nearest neighbors (KNNs) method [34] was performed with k=5 neighbors using Euclidean distance, with the imputation model fit within each participant's data and within each cross-validation training fold to prevent information leakage. The adaptive segmentation approach identified contiguous data segments of >7 days with ≥80% completeness; segments shorter than 8 days or with >20% missingness were excluded. To systematically characterize missingness, we report the proportion of missing data for each modality (activity, sleep, e-VAS, and ASRM) both overall and stratified by clinical state (euthymic, ASRM-defined symptomatic interval). We assessed whether data were missing completely at random (MCAR) using Little MCAR test, reporting the test statistic and associated *P* value [35]. Based on our previous work [29], we hypothesized that Little MCAR test would be rejected; we therefore report sensitivity analyses comparing classifier performance, selected features, and importance rankings with and without imputation.

Data Features



For each participant and each of the 21 variables' data segments, we calculated 12 features in the time and frequency domains. Seven time-domain features (ie, using the raw data) were calculated to characterize the statistical properties of the data segments over the entire duration of participation while euthymic and during ASRM-defined symptomatic intervals (where applicable): the mean (μ), coefficient of variation, kurtosis (κ), skewness (α_3), absolute sum of consecutive changes, mean absolute differences, and autocorrelation at lag 1 (Figure 1C; Table S2 in Multimedia Appendix 1). Moreover, we transformed the segmented time-domain variables to the frequency domain (ie, fluctuation rate) using the Fast Fourier Transform [36] and then calculated 5 frequency-domain features: spectral energy (SE), spectral entropy (H_s), spectral centroid (f_c), spectral spread (f_σ), and spectral flux (SF) (Figure 2A). These frequency-domain (ie, spectral) features were calculated to assess the overall and instantaneous fluctuation rate's central tendency, variability, and complexity. All features were normalized using minimum-maximum scaling to the range (0, 1), with scaling parameters fit only on the training data within each cross-validation fold. Outliers were clipped to the 1st and 99th percentiles of the training distribution within each fold. Feature extraction and preprocessing were implemented in Python (version 3.11; Python Software Foundation) using NumPy (version 1.24; NumPy Developers), SciPy (version 1.10; SciPy Developers), and scikit-learn (version 1.3; scikit-learn Developers).

See Table S1 in Multimedia Appendix 1 for the full list of data, variables, and features, and Table S2 in Multimedia Appendix 1 for the mathematical description and interpretation of the features.

Classification Model Development and Performance Evaluation

ML Model Development and Training

The present analysis was designed to assess the association between specific features and concurrently assessed clinical polarities: ML models were used to distinguish ASRM-defined symptomatic intervals from euthymic states (rather than to forecast future episodes) (Figure 2B-C). We constructed binary feature matrices labeled by clinical polarity (euthymic vs ASRM-defined symptomatic interval) and trained an ensemble of tree-based classifiers, specifically Random Forest, Extra Trees, and XGBoost (Extreme Gradient Boosting), to discriminate states within concurrent data segments. Features were computed from the same 7-day window used to assign the ASRM-based clinical state label; accordingly, this is a retrospective state classification analysis and not a predictive or forecasting model. Data were split into training (70%), validation (20%), and test (10%) sets with stratified sampling. Nested cross-validation with 10 outer folds and 10 inner folds was used for unbiased performance estimation, hyperparameter tuning, and feature selection. To prevent information leakage from nonindependent observations, all cross-validation folds were grouped at the participant level (group k-fold), so that every data segment from a given participant was assigned entirely to either the training or the testing partition within each fold.

To evaluate the independent contribution of passive wearable data relative to active self-reports, we trained and evaluated 5 model variants on the following feature subsets: (1) passive wearable features (daily activity+covariates), (2) passive wearable features only (daily sleep features+covariates), (3) passive wearable features only (activity+sleep features combined+covariates), (4) active self-report features only (daily e-VAS mood, anxiety, and energy features +covariates), and (5) the full combined model (passive wearable+active self-report+covariates). All variants used the same nested cross-validation procedure, class-weighted training, and out-of-fold (OOF) evaluation applied to the primary analysis.

Hyperparameter tuning was performed via randomized search within the inner cross-validation folds. The search spaces were as follows: Random Forest (n_estimators: {100, 200, 500, 1000}, max_depth: {3, 5, 8, 12, None}, min_samples_split: {2, 5, 10}, min_samples_leaf: {1, 2, 4}, max_features: {"sqrt", "log2", None}); Extra Trees (n_estimators: {100, 200, 500, 1000}, max_depth: {3, 5, 8, 12, None}, min_samples_split: {2, 5, 10}); and XGBoost (n_estimators: {100, 200, 500}, max_depth: {3, 5, 7, 9}, learning_rate: {0.01, 0.05, 0.1, 0.3}, subsample: {0.7, 0.8, 1.0}, colsample_bytree: {0.7, 0.8, 1.0}, reg_alpha: {0, 0.1, 1.0}, reg_lambda: {0.5, 1.0, 5.0}) (Table S3 in Multimedia Appendix 1). The best-performing model and hyperparameter configuration were selected based on inner-fold area under the receiver operating characteristic curve (AUROC) and refit on the full outer training fold.

Class Imbalance Handling and ML Model Performance

Given the unequal number of euthymic and ASRM-defined symptomatic interval segments, we addressed class imbalance through 2 complementary approaches. First, we applied class weighting (ie, assigning weights inversely proportional to class frequency) during model training so that the minority class (symptomatic intervals) received proportionally greater influence during learning. We did not use oversampling (eg, Synthetic Minority Over-sampling Technique) or undersampling techniques, as class weighting preserves the full data distribution while adjusting for imbalance. In addition to AUROC and AUPRC (area under the precision-recall curve), we report sensitivity, specificity, positive predictive value, and negative predictive value computed at the threshold that maximizes the F_1-score across outer-fold held-out test sets, aggregated across 100 bootstrap iterations. Class prevalence (proportion of ASRM-defined symptomatic interval segments) is reported alongside AU-PRC to facilitate interpretation relative to the no-information baseline. Calibration was assessed using the Brier score and a reliability diagram (calibration curve) constructed on OOF predicted probabilities; the no-information Brier score equals the product of class prevalence and (1 − class prevalence). All bootstrapped confidence intervals were computed by resampling at the participant level (ie, all observations from a given participant were sampled as a block in each bootstrap replicate) to account for the nonindependence of repeated observations within participants. Held-out test performance is referred to as internal validation throughout, as the held-out fold was drawn from the same cohort.

Model Explainability: Permutation Feature Importance and Robustness

To interpret the contribution of individual features to the classification model, we computed SHAP (Shapley Additive Explanations) [37] values on the held-out test sets, providing model-agnostic, local explanations of feature effects (Figure 2C). We aggregated SHAP values across all outer cross-validation folds to derive an overall feature importance ranking, thereby characterizing how each feature influenced the model's outputs. SHAP values were computed using TreeSHAP applied to held-out (OOF) test observations only, ensuring that feature importance reflects model behavior on unseen data and is not inflated by in-sample fitting. SHAP values quantify each feature's marginal contribution to the model's predictions and should be interpreted as characterizing how the fitted model used the features to discriminate ASRM-defined symptomatic intervals from euthymia; they do not establish that these features causally influence mood state or constitute validated biomarkers.

To further evaluate feature robustness and importance stability, we performed permutation importance (PI) analyses on the held-out test sets, derived 3 stability metrics for each feature, and aggregated feature importance and ranking statistics across bootstraps and outer folds to quantify robustness, thereby identifying features that consistently contributed to model performance across resampling procedures. The details of our variable selection and processing, feature extraction, and ML model's robust explainability pipeline are described thoroughly in our previous manuscript [26]. Model explainability was conducted using TreeSHAP (for tree ensembles) via the SHAP library (version 0.43; SHAP Developers) using Random Forest

XSL•FO
RenderX

classifiers. All models were implemented in Python (version 3.11).

Statistical Analysis

We performed label permutation testing (n=100) to generate a null distribution of group differences between euthymia and ASRM-defined symptomatic intervals and applied bootstrapping (n=1000) to estimate variability of the test statistics, thereby addressing limitations imposed by the relatively small sample size. Group differences were assessed using the Mann-Whitney *U* test across the resampled distributions. To ensure reliable inference, we included only clinical polarities with at least 5 observations per group, a threshold chosen to maintain adequate statistical power in each bootstrap iteration. Multiple comparisons across top 5 features in Table 1 were controlled using the Benjamini-Hochberg false discovery rate correction method; statistical significance was assumed for false discovery rate–corrected *P* value <.05. We also computed Cohen *d* effect sizes to quantify differences between the euthymic and symptomatic intervals. All models were adjusted for clinical and demographic covariates (age, sex, and pharmacotherapy) at study entry (Table 2), which we included as additional input features in the classification models. Additionally, we conducted a series of sensitivity analyses by repeating the full analytical pipeline with and without imputation of missing data. We compared classifier performance, selected features, and permutation-based importance rankings across the 2 datasets to assess whether imputation significantly influenced the results.

All statistical tests are reported with the test name, test statistic, and exact *P* value (reported as *P*<.001 when the computed value is below this threshold). Effect sizes are reported as Cohen *d* with 95% CIs derived from bootstrap resampling (n=1000). Sample sizes (n) for each comparison are reported. Nonwear time was also expressed as a percentage of each participant's total follow-up duration to enable comparison across participants with varying enrollment lengths: % nonwear = (nonwear days/total follow-up days)×100.

[a]Values represent pooled out-of-fold point estimates along with 95% CIs derived from 100 iterations of participant-level block bootstrapping to account for repeated within-subject observations. Models were evaluated using nested, participant-grouped cross-validation (*StratifiedGroupKFold*) to ensure internal validation on participants unseen during training and feature preprocessing. All models included baseline demographic and clinical covariates (age, sex, and pharmacotherapy at study entry). Decision thresholds were determined per bootstrap iteration by identifying the cutoff that maximized the F_1-score on held-out test predictions. Sensitivity, specificity, positive predictive value, and negative predictive value are presented as percentages. Calibration was evaluated using the Brier score, where lower scores indicate superior probabilistic accuracy.

Sensitivity Analysis for ASRM Threshold

To evaluate whether the choice of ASRM threshold (≥10 vs the standard ≥6) substantially influenced the results, we repeated the complete classification pipeline, including feature extraction, model training with nested cross-validation, SHAP-based explainability, and PI, using ASRM score of ≥6 as the alternative threshold for defining symptomatic intervals. We report the number of participants and intervals identified under each threshold, the AUROC and AUPRC for each modality, and the correlation of the performance metrics between the 2 thresholds (Spearman ρ).

Segments with ASRM score of ≥10 satisfy both the ≥6 and ≥10 threshold criteria and therefore represent matched observations that are classified as symptomatic under both thresholds. On the other hand, segments with ASRM scores of 6 to 9 satisfy only the ≥6 threshold and constitute the additional unmatched observations unique to the sensitivity analysis and are therefore not classified as symptomatic under the primary ≥10 criterion.

Identification of Top Descriptors of ASRM-Defined Symptomatic Intervals

We used a supervised ML approach within a 10-fold nested cross-validation framework to classify clinical polarity (euthymia vs ASRM-defined symptomatic intervals) using activity, sleep, and e-VAS–derived features. We evaluated model performance on held-out test sets and quantified feature contributions using SHAP impact scores, complemented by a feature robustness analysis based on PI (top-k selection frequency) across 100 bootstraps with 100 permutation repeats (Figure 2).

As shown in Figures 1C and 2B, we directly compared features across multiple temporal scales within a unified analytical framework, including corresponding classification performance metrics and SHAP analyses for each time scale.

Ethical Considerations

The study was approved by the REB at the CAMH, Toronto, Ontario, Canada, and at the QEII Health Care Center, Halifax, Nova Scotia, Canada, in accordance with the Declaration of Helsinki REB number 059 - 2019. All participants consented in writing to participate in the study. All participants signed an informed consent form approved by the local REB before any research procedure was initiated. As an incentive, participants received CAD $180 (CAD $1=US $0.72 as of May 28, 2026) upon completing their first year. For the second year, they could choose between an additional $180 payment or ownership of the Oura Ring.

Results

Participant Characteristics

Of the 178 participants enrolled in the study, 43 (24.2%) experienced at least 1 ASRM-defined symptomatic interval during the study period, totaling 133 intervals. Participants were followed for a mean of 540.1 (SD 170.9; range 120 - 706) days; of these 43 participants, 21 (48.8%) entered the study euthymic, 20 (46.5%) in a depressive episode, and only 2 (4.7%) in a hypomanic episode. Using the operationalized euthymia definition (ASRM score of <10 and PHQ-9<10 on 2 consecutive ratings separated by at least 7 days), 4774 euthymic segments were identified across participants; 1216 met the duration (>7 days) and wearable completeness (≥80%) criteria for inclusion as comparator euthymic segments. The 43 participants who experienced at least 1 symptomatic interval experienced a mean of 3.1 (SD 2.6; range 1 - 10) ASRM-defined symptomatic intervals, lasting a mean of 10.7 (SD 11.1) days. Table 2 summarizes the sociodemographic and clinical characteristics of these 43 participants. The distribution of ASRM-defined symptomatic intervals (ASRM score of ≥10) per participant is presented in Figure S1 in Multimedia Appendix 1.

Using objective and subjective data, we extracted 252 features characterizing variability in objective (ie, wearable-derived) and subjective (eg, mood) variables during euthymic periods versus symptomatic intervals (see Methods section and Table S1 in Multimedia Appendix 1).

Adherence and Data Completeness

Across all participants, nonwear accounted for a median of 19.9% (IQR 6.5 - 42.0) of the follow-up duration, corresponding to a median wearable adherence of 80.1% (IQR 58.0 - 93.5). Median daily self-reported e-VAS adherence was 82.6% (IQR 60.2 - 94.1), and median weekly self-reported ASRM adherence was 81.2% (IQR 58.1 - 91.9) (Table S4 in Multimedia Appendix 1).

Across pooled follow-up observations, missingness was 15.0% for daily activity, 23.8% for sleep, 23.9% for daily mood ratings, and 26.2% for weekly ASRM assessments. At the participant level, median missingness was 8.1% (IQR 1.1% - 28.0%) for daily activity, 20.4% (IQR 6.8% - 42.8%) for sleep, 17.4% (IQR 5.9% - 39.8%) for daily mood ratings, and 18.8% (IQR 8.1% - 41.9%) for weekly ASRM assessments (Table S5 in Multimedia Appendix 1). When stratified by clinical state, missingness was lower during ASRM-defined symptomatic intervals compared with euthymic periods (activity: 11.4% vs 15.1%, sleep: 19.4% vs 23.9%, and e-VAS: 7.8% vs 24.2%). Missingness in activity and e-VAS differed significantly between clinical states at the participant level (Wilcoxon signed-rank test: activity, P=.016; e-VAS, P<.001), whereas

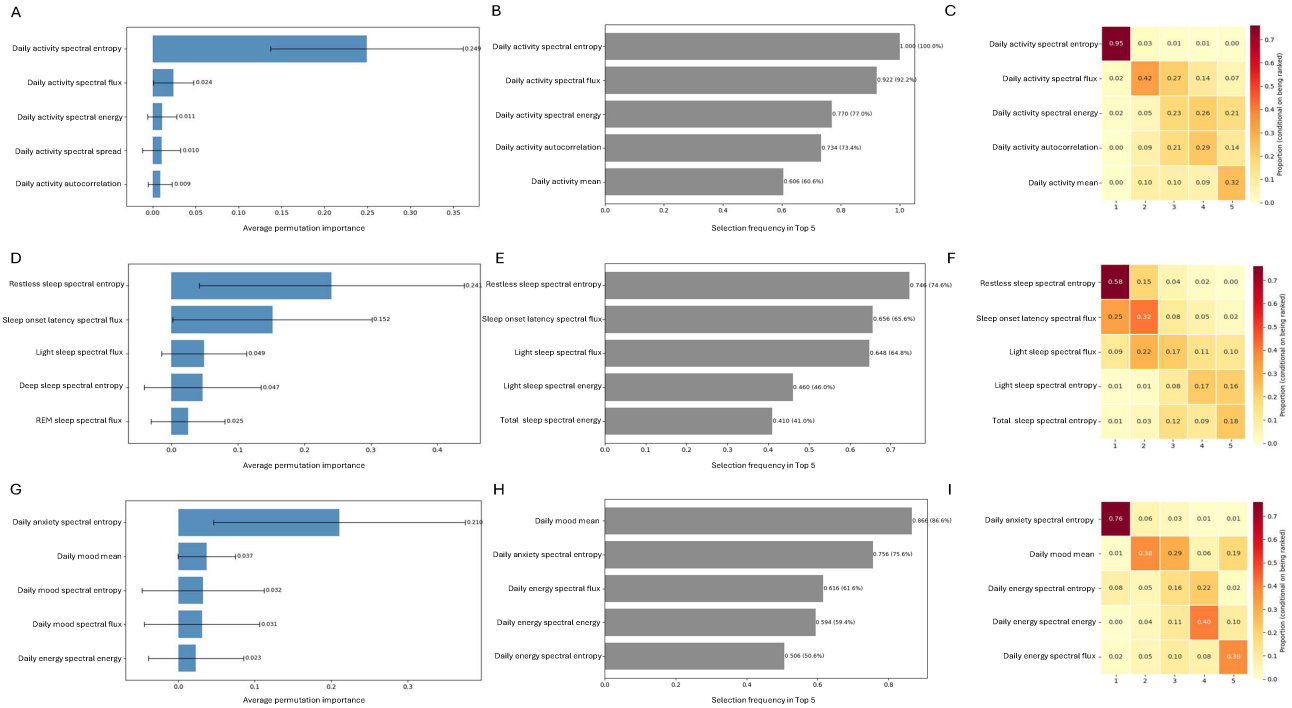
XSL•FO
RenderX

the difference in sleep missingness was not significant (P=.472) (Table S6 in Multimedia Appendix 1). Little MCAR test rejected the null hypothesis of MCAR for both the daily passive/active stream matrix (χ^2_{1031}=20696.27, P<.001) and the weekly assessment matrix (χ^2_{15}=29.70, P=.013), confirming that the data are not MCAR and that missingness is associated with clinical state (Table S7 in Multimedia Appendix 1).

Identification of Top Descriptors of ASRM-Defined Symptomatic Intervals

Daily features consistently outperformed features derived at other temporal scales. Accordingly, we present results for daily features in the main text and report results for other time scales (Figures S2 and S3 in Multimedia Appendix 1).

The daily activity feature (Figure 3A-C) that best described an ASRM-defined symptomatic interval was lower activity spectral entropy (ie, consistently more predictable daily activity patterns: PI=0.25; P<.001; Cohen d=1.92, 95% CI 1.56-2.36) (Table 1). Moreover, symptomatic intervals showed significantly lower daily activity SF (ie, lower day-to-day change in behavioral rhythms: PI=0.02; P<.001; Cohen d=1.46, 95% CI 1.24-1.67) and significantly lower activity SE (ie, weaker rest-activity cycle rhythmicity: PI=0.01; P<.001; Cohen d=1.01, 95% CI 0.89-1.15).



The daily sleep features (Figure 3D-F) that best described an ASRM-defined symptomatic interval were lower restless sleep spectral entropy (ie, consistently higher restlessness during sleep; PI=0.24; P<.001; Cohen d=2.24, 95% CI 1.79-2.74) and lower deep sleep spectral entropy (ie, reduced complexity and variability of deep sleep duration; PI=0.05; P<.001; Cohen d=2.19, 95% CI 1.73-2.76) (Table 1). In addition, ASRM-defined symptomatic intervals were characterized by significantly lower sleep onset latency SF (ie, reduced night-to-night variability in sleep onset; PI=0.15; P<.001; Cohen d=1.33, 95% CI 1.17-1.49), light sleep SF (ie, consistently longer and more predictable light sleep durations; PI=0.05; P<.001; Cohen d=1.43, 95% CI 1.22-1.65), and REM sleep SF (ie, consistently shorter and more predictable REM sleep durations; PI=0.03; P<.001; Cohen d=1.29, 95% CI 1.10-1.47), indicating consistently lower variability across sleep stages.

The daily e-VAS features (Figure 3G-I) that best described ASRM-defined symptomatic intervals were anxiety spectral entropy (PI=0.21; P<.001; Cohen d=1.92, 95% CI 1.53-2.38) and mood spectral entropy (PI=0.03; P<.001; Cohen d=1.89, 95% CI 1.48-2.36), both significantly lower during symptomatic intervals, associated with reduced day-to-day complexity in self-reported anxiety and mood (Table 1). Symptomatic intervals were also characterized by significantly lower mood SF (ie, lower day-to-day change in mood rhythms; PI=0.03; P<.001; Cohen d=1.38, 95% CI 1.13-1.60), alongside significantly higher mean mood levels (PI=0.04; P<.001; Cohen d=−0.76, 95% CI −1.16 to −0.35). Similarly, energy spectral entropy was significantly lower during symptomatic intervals (PI=0.02; P<.001; Cohen d=1.92, 95% CI 1.50-2.40), indicating consistently higher and less complex energy levels during symptomatic intervals.

The results of the statistical comparison of the top 5 daily features of activity, sleep, and e-VAS, during euthymia or an ASRM-derived symptomatic interval, and their average PI are presented in Table S7 in Multimedia Appendix 1. The absolute and clinical state-specific permutation feature importance of the aggregated passive data features (ie, sleep and activity) is presented in Figure S5 in Multimedia Appendix 1, and those of the combined active self-report and passive data features are presented in Figure S6 in Multimedia Appendix 1. The ASRM threshold sensitivity analysis (ASRM score of ≥6 vs ASRM score of ≥10) revealed moderate overlap in the most robust descriptors of ASRM-defined symptomatic intervals, namely, in light sleep features (Figure S7 in Multimedia Appendix 1), which is expected upon relaxing the ASRM symptom severity cutoff and including less symptomatic intervals in the analysis (Figure S8 in Multimedia Appendix 1).

Figure 3. Feature importance results for daily activity, sleep, and electronic visual analog scale features in a longitudinal cohort of 43 outpatients with bipolar disorder who experienced ≥1 Altman Self-Rating Mania Scale–defined symptomatic interval (N=133 intervals). Panels (A, D, and G): feature importance plot showing average permutation importance values with error bars representing 95% CI of bootstrapped samples. Panels (B, E, and H): feature selection frequency bar plot showing the percentage of times each feature was selected among the top predictors across models. Panels (C, F, and I): feature rank distribution heat maps showing feature ranking probabilities, with darker colors indicating higher likelihood of being selected in the top rank positions. (A-C): activity features, (D-F): sleep features, and (G-I): electronic visual analog scale features. Results are from nested cross-validation with group k-fold at the participant level.

Classification Performance

Primary Classification: ASRM Score of ≥10

Classification performance increased significantly when aggregating sensor data to daily 24-hour summaries compared with fine-grained sub–daily intervals (within-day activity: AUROC 0.74, 95% CI 0.64 - 0.81 and Brier score of 0.14, 95% CI 0.12 - 0.16; within-night sleep: AUROC 0.74, 95% CI 0.66 - 0.81 and Brier score of 0.14, 95% CI 0.11 - 0.16). The prevalence of ASRM-defined symptomatic intervals in the daily analytic sample was 20.4%, yielding a no-information AUPRC of 0.20. Among daily data modalities, active daily self-report data (e-VAS mood, energy, and anxiety) yielded the highest point estimates for overall discrimination (AUROC 0.93, 95% CI 0.88 - 0.96; AUPRC 0.75, 95% CI 0.62 - 0.87; specificity 91.9%, 95% CI 0.88 - 0.97; positive predictive value 72.9%, 95% CI 0.61 - 0.89; Brier score of 0.08, 95% CI 0.06 - 0.11). However, passive wearable data models achieved broadly comparable discrimination with substantially overlapping confidence intervals, while demonstrating distinct advantages for continuous detection. Specifically, combined daily passive wearable data features (activity and sleep) achieved higher point-estimate sensitivity (92.0%, 95% CI 0.80 - 1.00 vs 85.4%, 95% CI 0.72 - 0.95), higher balanced accuracy (0.90, 95% CI 0.85 - 0.94 vs 0.89, 95% CI 0.83 - 0.93), stronger rule-out usefulness (negative predictive value 97.8%, 95% CI 0.95 - 1.00 vs 96.1%, 95% CI 0.93 - 0.99), and similar risk prediction error (Brier score of 0.09, 95% CI 0.061 - 0.108) to active self-report data, with daily sleep features alone driving most of this passive signal (AUROC 0.91, 95% CI 0.86 - 0.95; sensitivity 91.8%, 95% CI 0.83 - 0.99; Brier score of 0.09, 95% CI 0.06 - 0.11). Integrating active self-reports and passive sensor metrics into a full multimodal model (AUROC 0.92, 95% CI 0.87 - 0.96; AUPRC 0.75, 95% CI 0.63 - 0.85; Brier score of 0.08, 95% CI 0.06 - 0.10) yielded no meaningful incremental gain over either modality alone (Table 1; Figure S9 and Table S10 in Multimedia Appendix 1).

Class weighting (models were trained with weights inversely proportional to class frequency) modestly improved minority-class performance: across nested coefficient of variation, the AUPRC increased by a median of 0.07, balanced accuracy by 0.06 with weighting, while AUROC increased the least by a median of 0.01, indicating weighting boosted sensitivity/precision for ASRM-defined symptomatic intervals without substantially altering overall discrimination.

For all top-performing daily models, AUROC values were significantly higher than those obtained under random label assignment, as demonstrated by permutation testing (all P<.01). In contrast, models based on within-day features alone achieved lower performance than daily features while consistently outperforming random-chance models (within-night sleep: AUROC, mean 0.72, SD 0.12, P<.05; within-day activity: mean 0.64, SD 0.11, P<.05). Statistical comparison of the top 5 daily features of activity, sleep, and e-VAS during euthymia and during symptomatic intervals are reported in Table S8 in Multimedia Appendix 1, and permutation-based performance comparisons are shown in Figure S4 in Multimedia Appendix 1.

RenderX

Sensitivity Analysis: ASRM Score of ≥6

Using the threshold of ASRM score of ≥6, 93 participants (vs 43 when using a threshold of ASRM score of ≥10) experienced at least 1 symptomatic interval, totaling 392 intervals (vs 133 with ASRM score of ≥10). Segments with ASRM score of ≥10 (n=133) represent matched observations classified as symptomatic under both thresholds; the remaining 259 segments with ASRM scores of 6 to 9 are classified as symptomatic exclusively under the ≥6 threshold. In the sleep-only (selected data modality) ASRM-threshold sensitivity analysis using primary KNN imputation, model discrimination was comparable with the ASRM score of ≥10 and ASRM score of ≥6 thresholds (pooled OOF AUROC 0.91 vs 0.89; AUPRC 0.66 vs 0.81), with a paired difference (ASRM score of ≥6 minus ASRM score of ≥10) of 0.01 for AUROC (95% CI −0.05 to 0.08) and 0.18 for AUPRC (95% CI 0.01-0.35). However, the OOF-predicted probabilities from the 2 threshold-specific models showed expected negligible correlation at the individual-observation level (Spearman ρ=0.016; *P*=.81; 211 matched observations), indicating that although both thresholds yielded similarly separable classifications, the specific observations identified as high-risk differed substantially between thresholds. This suggests that the ASRM score of ≥10 and ASRM score of ≥6 thresholds capture a different set of symptomatic segments rather than a shared signal at differing sensitivity levels. This interpretation is based on the OOF-predicted probability correlation (ρ=0.016), a prevalence-independent measure of model agreement at the individual-observation level, rather than on the AUPRC threshold comparison (0.66 vs 0.81), which is susceptible to between-threshold differences in positive class prevalence and no-information AUPRC baseline.

Sensitivity Analysis: Missing Data Imputation

Using daily sleep features as sample representative inputs to a Random Forest classifier, OOF-predicted probabilities were highly correlated between KNN and mean imputation (Spearman ρ=0.984; *P*<.001; 211 matched observations) and remained strongly correlated between KNN imputation and complete-case analysis (ρ=0.91; *P*<.001; 186 matched observations), supporting the robustness of model performance to the missing data strategy. Using KNN imputation (k=5), the model achieved mean AUROC 0.91 (SD 0.07) across folds and pooled AUROC 0.90 (95% CI 0.84 - 0.95); pooled AUPRC was 0.66 (95% CI 0.52 - 0.82) versus a no-information AUPRC of 0.20. Mean imputation produced similar discrimination (AUROC mean 0.92, SD 0.05; pooled AUROC 0.91, 95% CI 0.86 - 0.95; pooled AUPRC 0.64, 95% CI 0.51 - 0.81). Complete-case analysis gave comparable AUROC (mean 0.90, SD 0.12; pooled 0.90, 95% CI 0.83 - 0.96) but a wider AUPRC CI and lower pooled AUPRC point estimate (0.59, 95% CI 0.42 - 0.81) (Table S9 in Multimedia Appendix 1). Moreover, no changes were observed across the top 5 sleep features best characterizing ASRM-defined symptomatic intervals from euthymia, further proving the robustness of the extracted digital markers to imputation strategies.

Discussion

Principal Findings

The primary aim of this study was to identify the most accurate and robust digital markers for detecting ASRM-defined symptomatic intervals. We systematically analyzed multivariate, densely sampled data that combined continuously collected objective data (ie, from a wearable) and subjective data (ie, daily and weekly self-reported measures). We analyzed more than 250 features extracted from 43 participants who experienced at least 1 ASRM-defined symptomatic interval during the study period, totaling 133 intervals.

Our analysis revealed a distinctive pattern: ASRM-defined symptomatic intervals are characterized by reduced variability across all measured domains (ie, activity, sleep, and e-VAS), rather than simply elevated activity levels. In other words, not only were mood and energy levels elevated during ASRM-defined symptomatic intervals but their day-to-day patterns also became more stationary (ie, less variable). Moreover, our analysis revealed that complexity measures derived from frequency-domain analysis outperform traditional time-domain statistics, and spectral entropy emerged as the most robust discriminator across mood, energy, anxiety, sleep, and activity domains.

Our findings showed that the complexity of sleep patterns is disrupted during symptomatic intervals, in accordance with a recent systematic review discriminating unipolar from bipolar depression [38]. Our work extends these findings by demonstrating that frequency-domain features capturing temporal dynamics are more informative than simple duration measures (eg, total sleep time).

In parallel, reduced complexity in self-reported mood and anxiety emerged as highly discriminative features. Mean mood levels were elevated during symptomatic intervals, but with significantly reduced variability compared with euthymia, illustrating the phenomenon of elevated mood with reduced variability (ie, participants were consistently happier than usual). This finding aligns with recent studies demonstrating that entropy-based measures can effectively classify mood states [39-41]. On the other hand, reduced variability in anxiety during ASRM-defined symptomatic intervals is in keeping with clinical observations and consistent with theoretical models proposing hypomanic or manic episodes as a persistent drive to seek rewards, with reduced flexibility to disengage from these behaviors [42].

Similarly, ASRM-defined symptomatic intervals are characterized by more predictable and less complex daily activity patterns. This finding aligns with prior research showing dysregulation of 24-hour motor activity patterns in BD [43]. Furthermore, our findings suggest that activity becomes less adaptive during symptomatic intervals (ie, consistently higher and more predictable). SF and SE of activity were also significantly reduced during symptomatic intervals, further supporting that activity patterns become more rigid [15].

Finally, temporal scale analysis revealed that daily feature aggregation consistently outperformed finer temporal resolutions

XSL•FO
RenderX

(ie, within-day features [AUROC 0.76]), suggesting that day-to-day variability captures the most discriminatory and clinically relevant patterns of polarity changes. These findings are consistent with prior research showing that appropriate temporal aggregation improves predictive performance [44,45].

Overall, the consistent pattern of reduced complexity across domains (ie, activity, sleep, and e-VAS) is associated with a pattern consistent with "pathological stability" in underlying regulatory systems during ASRM-defined symptomatic intervals, which may reflect a shared underlying process affecting emotional regulation broadly [46]. These findings are consistent with, but do not establish, a mechanistic explanation.

Strengths and Limitations

This study represents a rigorous study of digital markers for ASRM-defined symptomatic intervals in BD, jointly extracting signature patterns in activity, sleep, mood, energy, and anxiety from more than 100 symptomatic intervals. Several limitations in our study require consideration. First, our participants had relatively high educational levels and limited racial diversity, which constrains generalizability. Future studies should validate these findings in more diverse samples. Second, the current analysis is associative rather than predictive (ie, features are concurrent with ASRM-defined symptomatic intervals). Third, symptomatic intervals were defined by ASRM self-ratings rather than clinical adjudication, which are subject to recall bias, insight limitations during elevated mood states, and variable item endorsement across participants and time points. Clinician interviews or clinician-administered ratings (eg, YMRS) were not routinely performed within each interval; accordingly, the outcome should be interpreted as an "ASRM-defined symptomatic interval" rather than a confirmed hypomanic or manic episode, and findings may not directly generalize to clinician-confirmed diagnoses. Fourth, the euthymic comparator was operationalized using ASRM score of <10 and PHQ-9 <10 thresholds, which reduce but do not eliminate the possibility of residual subsyndromal symptoms. Fifth, sleep staging by the Oura Ring is produced by a proprietary algorithm trained primarily on nonclinical populations; device-derived sleep stages may deviate from polysomnographic standards, particularly during mood episodes when sleep architecture is disrupted. The 5-minute hypnogram should therefore be treated as an approximation rather than a validated measure of sleep staging in BD. However, a major strength of this analysis is the length of follow-up and the value that longitudinal studies offer to the field (ie, after 2 years of follow-up, 25% of the sample had at least 1 ASRM-defined symptomatic interval). Another major strength is the use of explainable ML with systematic feature selection and validation coupled with a rigorous statistical analysis. The additional analysis of all the studied features using traditional statistics identified the features that statistically differentiated ASRM-defined symptomatic intervals from periods of euthymia. However, some features did not contribute as much to the explainable ML retrospective state classifications because they were redundant in their contribution to the models' outputs (ie, even after managing multicollinearity, their SHAP importance was distributed among correlated features; eg, activity spectral spread).

The choice of ASRM threshold warrants discussion. We used a threshold ≥10 rather than the standard ≥6 to enhance specificity, given the ASRM's known high sensitivity and low specificity. This choice may limit direct comparability with studies using ≥6, as we may have excluded milder or subsyndromal presentations. However, our sensitivity analysis using ≥6 showed comparable clinical state classification results, suggesting that the identified digital markers are robust to threshold choice and identifiable at comparable accuracy and precision, yet detected across different sets of symptomatic intervals. Future studies should systematically evaluate the optimal threshold for digital phenotyping applications (eg, the degree to which the ≥6 and ≥10 thresholds capture distinct symptom presentations), potentially using receiver operating characteristic analysis to derive data-driven thresholds.

In addition, we introduced and validated a novel set of frequency-domain features and demonstrated their robustness. The use of nested cross-validation, PI analysis, and bootstrapped feature ranking, complemented by data-quality sensitivity analyses, further provided confidence in the robustness of the identified markers. This within-participant analytical framework allowed each individual to serve as their own control, reducing between-participant heterogeneity.

Conclusions

This systematic analysis identified a small set of robust digital markers across activity, sleep, and e-VAS domains to detect ASRM-defined symptomatic intervals using objective and subjective data. Our main finding is that passive monitoring using wearable technology matched self-reported data in detecting ASRM-defined symptomatic intervals. This finding is particularly important during hypomanic or manic episodes, as symptoms tend to be underreported. Furthermore, the finding that symptomatic intervals are characterized by decreased variability is consistent with nonlinear dynamics of mood regulation and warrants further prospective investigation. Our study also highlights the importance of study designs with longer follow-ups to capture symptoms that would otherwise go undetected with the conventional weeks-long observation windows in digital phenotyping studies. Together, our findings point to a future in which passively collected digital markers, embedded within a strong clinical foundation, enable us to improve the detection of mood episodes.

Abstract

Background: Consumers are increasingly moving away from the traditional 3-meal-a-day eating routine to a pattern where they are snacking throughout the day to fulfill dietary needs, a trend known as "snackification." Snacking depends on a variety of product-, context-, and consumer-specific determinants, but consumers' long-term snacking behaviors in light of these determinants have remained little studied.

Objective: This study aims to enhance understanding of consumers' snacking behaviors by capturing longitudinal real-world situational snacking behaviors. As snackification is highly prominent in the Netherlands, and especially among millennials (born between 1980 and 2000), Dutch millennials were used as a case study.

Methods: FOODLOOP studied situational snacking behaviors of a cohort of 264 Dutch millennials over the course of a year through a time-series structure. Data were collected on 12 nonconsecutive days, divided over the 4 seasons, using the mobile app Traqq (Department of Human Nutrition and Health of Wageningen University) and following the principles of ecological momentary assessment.

Results: On average, 4.52 snacks were consumed per day, of which 64% were more healthful snacks, including coffee, tea, fruit, and bread products. Snacking was mostly driven by the food choice motives liking and appetite, as well as hunger and thirst, convenience, and pleasure. Most snacking occurred at home, with others, in the afternoon, and in spring. Dutch millennials with children consumed more snacks than Dutch millennials without children, and Dutch millennials born between 1980 and 1990 consumed more snacks than Dutch millennials born between 1990 and 2000.

Conclusions: Our study shows that situational snacking determinants are essential for understanding consumers' real-world snacking behaviors, as Dutch millennials' snacking behaviors differ given product-, context-, and consumer-specific determinants, and are not restricted to specific motives, locations, social settings, or times, congruent with the ongoing snackification trend. We also demonstrate that a mobile app following the principles of ecological momentary assessment is a highly valuable methodological tool to gather longitudinal data on consumers' situational snacking behaviors.

situational snacking; contextual eating; food choice motives; mobile app; ecological momentary assessment

Introduction

Consumers' eating patterns have fundamentally changed in the past few years due to their increasingly busy lives. Many consumers are moving away from the traditional 3-meal-a-day pattern, consisting of breakfast, lunch, and dinner at predetermined times. Instead, consumers are moving toward a more flexible eating pattern, where snacking is becoming a new way of eating; consumers are increasingly having unplanned eating moments outside of meals, replacing meals with mini-meals and snacks, and snacking throughout the day to fulfill dietary needs [1-3]. This new eating pattern, where anything can be a snack, consumed anywhere, with anyone, and anytime, is known as "snackification" and is considered to stay [4,5].

An increase in snacking has often been linked to a poorer diet quality, body weight gain, and subsequent deterioration of health (cardiovascular diseases, obesity, etc), as snacks have traditionally been considered to consist of highly palatable "junk food" products (eg, cookies, confectionery, and chips), which contain high levels of calories, salt, sugar, and (saturated) fat [2,6]. In the new snackification frame, this view might be obsolete. Many consumers no longer merely snack on conventional highly palatable food products but on any type of food or beverage, including fruits, vegetables, and dairy products [3], which are tailored to different specific situations and support

XSL•FO
RenderX

consumers' health goals [7,8]. Therefore, snacking nowadays could also fit within a healthy dietary pattern and potentially benefit health by contributing to the daily intake of fibers, vitamins, minerals, and protein [3,7,9-13].

Snackification is a worldwide phenomenon, but the increase in snacking is especially pronounced in the Netherlands; the Dutch engage in, on average, 4-5 snacking occasions daily, which make up half of all daily consumption and 30% of the Dutch daily energy intake [14,15]. Snackification in the Netherlands, as well as in other countries, is mainly prominent among millennials [16,17], a generation born between 1980 and 2000 and characterized by the use and adaptation of technology [18]. Millennials have different life stages, undergoing significant lifestyle changes, such as leaving home, graduating, getting a job, and starting a family. Due to their increasingly busy lives and lifestyle changes, millennials often engage in snacking more than other generations [16] and seek snacks that support different situations and their health goals, in line with snackification [16,19,20]. In addition, millennials also influence the behaviors of other generations by spotting, adopting, and spreading consumer trends such as snackification [18]. Therefore, it is interesting to focus on millennials when studying snacking, since there is little knowledge to date about millennials' snacking behaviors.

Multiple studies have been devoted to snacking. However, snacking and snacking-related concepts are often defined in different ways, using varying classifications (based on the time of day, type of food consumed, location of consumption, portion sizes, caloric values, nutrient quality, healthfulness, etc), therewith including or excluding certain products (eg, beverages, fruits, and vegetables) and consumption occasions (eg, meal replacements). This definition variability contributes to conflicting and incomparable findings around snacking behaviors and adds an additional uncertainty to the translation of scientific messages on snacking behaviors into effective snacking interventions, such as guidelines or recommendations [21-23]. To enable the formulation of successful snacking interventions, consumers' snacking behaviors in different consumption situations need to be more fully understood [22,24].

Snacking, like any other dietary behavior, is situational; whether, what, where, when, with whom, how long, how, and how much to eat and/or drink can differ greatly in every snacking situation [14,25,26]. Snacking depends on a variety of determinants, including product-specific (eg, product type and portion size), context-specific (physical, social, and temporal contexts), and consumer-specific determinants. Consumer-specific determinants, including sociodemographic (eg, gender, age, socioeconomic status, education, and family composition) and lifestyle characteristics (health interest, activity level, diet, etc), also comprise mental processes, such as the motives for consumption [3,14,27-29]. These motives, known as food choice motives (FCM), are essential for understanding snacking behaviors and include physiological (eg, hunger or thirst), psychological (eg, affect regulation and pleasure), sociocultural (eg, traditional eating and sociability), practical (eg, convenience and choice limitation), and economic (eg, price) drivers, which shape everyday snacking consumption decisions [26,30].

Given the situational nature of snacking, there is a need for real-time, context-sensitive insights into consumers' snacking behaviors. However, most snacking-related research focused on how snacking affects energy balance and weight status [3] or studied consumers' snacking behaviors in isolation, in short time frames, and with a limited consideration of situational determinants [31]. To address this gap, we aim to provide a broader and more integrated understanding of consumers' snacking behaviors by longitudinally exploring Dutch millennial consumers' situational snacking behaviors given product-, context-, and consumer-specific determinants. We, therewith, extend prior work on snacking behaviors by capturing real-world snacking situations while accounting for variances given situational determinants.

Studying situational behaviors longitudinally poses a challenge in using suitable and effective methods for correct measurement and understanding [31]. Given recent advancements in mobile technologies and the proven benefits of apps for mobile health (mHealth) purposes (eg, facilitating dietary monitoring and supporting health education and policies), mobile apps are increasingly used among behavioral and nutrition researchers for answering key food and health-related research questions and therewith achieving greater understanding of dietary behaviors [26,31-34]. Mobile apps allow researchers to capture context-rich real-world insights into dietary behaviors, increase compliance, reduce missing data, improve data quality and accuracy, and reduce costs, participant burden, and recall bias [26,31,35,36]. Mobile apps could, thereby, generate large amounts of rich data that offer a detailed description of situational dietary behaviors [26,31] over longer time periods with relative ease [34]. Ecological momentary assessment (EMA) methods leverage the capabilities of mobile apps while enabling the assessment of dietary behaviors in real-world settings [37].

Notwithstanding these promising aspects, few studies to date have used mobile apps to explore dietary behaviors considering situational variances over a longer period of time [36]. Given the objectives of this study and the promising aspects of mobile apps and EMA for exploring real-world dietary behaviors, a mobile app was used to repeatedly and comprehensively sample situational snacking behaviors. This study, called FOODLOOP, used the mobile app Traqq (Traqq Pty Ltd) with EMA to support the detailed exploration of longitudinal situational snacking behaviors of a cohort of Dutch millennials. Specifically, FOODLOOP captured how real-world snacking behaviors vary within and across snacking situations given a comprehensive combination of product-, context-, and consumer-specific determinants. Even though the FOODLOOP study is descriptive in nature, it was guided by the expectations that (1) Dutch millennials would snack frequently; (2) snacking would show substantial variability both across and within a wide range of contexts, including locations, social settings, the time of day, days of the week, and the 4 seasons in a year; and (3) snacking would differ based on key consumer-specific characteristics.

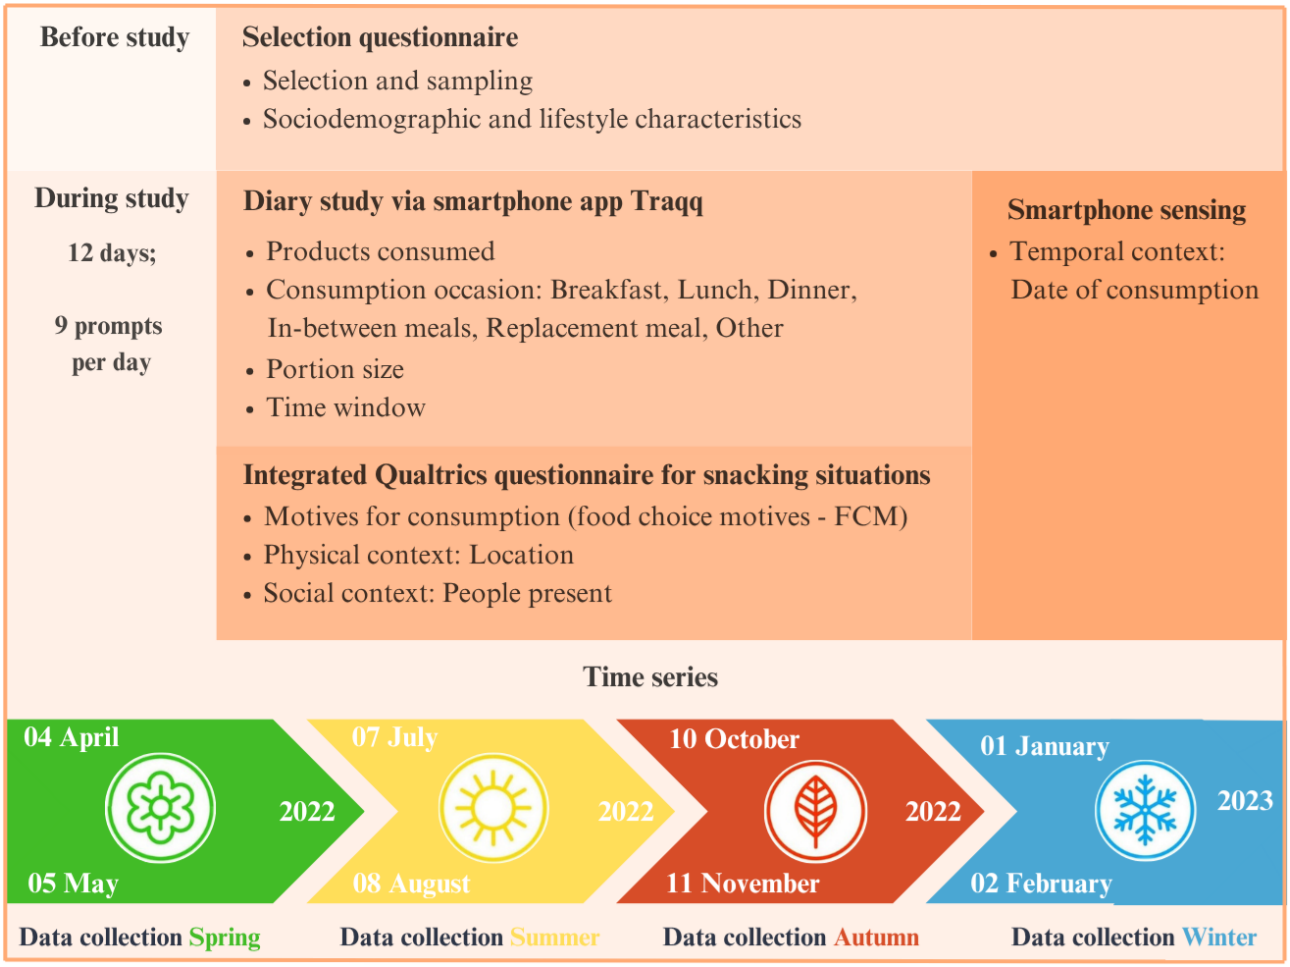
RenderX

Methods

Operationalization of Concepts



Given the different ways of defining snacking-related concepts in literature and the challenges this brings in unambiguously interpreting and comparing findings concerning snacking, the main snacking-related concepts as studied in FOODLOOP are operationalized as follows:

- Snack*:* a food or beverage product consumed outside the 3 traditional main meals (breakfast, lunch, and dinner)
- Snacking*:* the consumption of foods and/or beverages outside the 3 traditional main meals
- Snacking situation: the combination of a snack; FCMs for consuming a snack; and a physical, social, and temporal snacking context
- Snacking behavior: the totality of snacking situations of all participants

Study Design

The FOODLOOP study was carried out on a sample of 264 millennials (born between 1980 and 2000) residing in the Netherlands. Digital dietary diaries in a mobile app, following the principles of signal-contingent active EMA [33,37,38] and a time series structure [39], were used to collect data on participants' self-reported snacking situations and situational variations. A selection questionnaire was used to gather potential participants, as well as data on participants' sociodemographic and lifestyle characteristics (see Figure 1 for an overview of the study design).

Figure 1. FOODLOOP data collection overview and time series structure.

Potential participants filled in the selection questionnaire. Once admitted to the study, participants participated in the diary study for 12 days, equally distributed over 4 data collection periods within 1 year (start: April 2022, end: February 2023). Following a time series structure (Figure 1), the 4 data collection periods took place over the course of 2 months every season. The data collection periods were separated by 1 month in which no data collection took place. In each data collection period, participants registered their data on 3 days to capture behavioral cycles [40]. The data collection days were randomly assigned to participants by an automatic sampling scheme per data collection period, for which a set of rules was written. These rules entailed that data collection days (1) were nonconsecutive; (2) consisted of 2 weekdays and 1 weekend day; and (3) took place within the 2 months deemed most representative for a particular season (Figure 1), which were chosen based on meteorological variations in different seasons in the Netherlands [41]. Participants had to successfully complete 3 data collection days within each data collection period, thus 12 data collection days in total. Participants were not informed about the dates of their data collection days beforehand. The whole FOODLOOP study,

XSL•FO
RenderX

including the diary study and selection questionnaire, was conducted online.

Ethical Considerations

The Social Sciences Ethical Committee of Wageningen University (WUR) approved consent procedures and study protocols of the FOODLOOP study (2022 - 32-Vaal). The study was performed in accordance with ethical standards as laid down in Dutch privacy legislation and a data confidentiality declaration governed by Dutch law. To ensure participant privacy and confidentiality, all personal identifying information (such as names and contact information) was removed from the dataset before analysis, and participants were given a neutral identifier based on their study identifier. The research team only had access to the pseudoanonymized data. All participants provided informed consent to have their pseudoanonymized data published in journals. The compensation for participation in FOODLOOP consisted of a fixed monetary compensation, a lottery, and a donation possibility to heighten compliance [42-44]. Only participants who successfully completed all 12 data collection days received compensation. The fixed compensation consisted of €50 (US $59). Participants who successfully completed the study also automatically participated in a lottery where 10 prizes of €500 (US $585) were raffled. Participants received their compensation and prize after completion of the last data collection period (April 2023). Participants were given the option to keep the fixed compensation and prize themselves or have the research team donate the compensation and/or (part of) the prize on their behalf to the charitable organization Voedselbanken Nederland (Food Bank Netherlands), which provides basic food products to people who live below the poverty line. In total, €1800 (US $2106) was donated to Voedselbanken Nederland on behalf of the FOODLOOP cohort.

Participant Selection and Compliance

Potential FOODLOOP participants were recruited via online platforms (social media and forums) and the snowball sampling technique [45]. Potential participants (n=798) filled in the selection questionnaire to screen them for their eligibility for participation in the follow-up diary study whilst collecting relevant data on sociodemographic and lifestyle characteristics (age, sex, education, urbanity, living situation, activity level, etc). Results were screened based on selection criteria, being that participants were (1) born between 1980 and 2000; (2) living in the Netherlands and Dutch-speaking; (3) eating and drinking outside of what they defined as main meals (ie, snacking); (4) not following a diet for medical reasons or under supervision of a health professional; and (5) not having eating disorders (eg, anorexia or bulimia). Based on the screening, 534 participants were eligible for participation in FOODLOOP and were invited for the diary study. In total, 398 participants consented to participation and started the diary study.

Diary Study

Traqq

The FOODLOOP diary study was executed using the mobile app Traqq. Traqq (available for Android and iOS) was developed for dietary research purposes by Wageningen University [46] and allows for descriptive data collection, has no commercial focus, ensures privacy and safe storage of users' data, and enables customizations in line with this study's objectives. In Traqq, participants registered their daily food and beverage intake by choosing what they consumed from the Traqq food database, which includes products from the NEVO (Nederlands Voedingsstoffenbestand) 2016/2019 Dutch Food Composition Database [47,48] and Dutch food stores' assortments. Additional variables measured for consumed snacks were captured through questionnaires in Qualtrics XM (2022 - 2023). These questionnaires were programmed such that they appeared integrated within Traqq itself to participants. At the start of the study, participants received log-in credentials for Traqq, which remained valid throughout the entire study period. Once logged in, participants stayed continuously logged in, enabling them to receive prompts for all data collection days. Access to Traqq was deactivated upon study completion. All additions to and changes in features in the existing Traqq app to align it with FOODLOOP study objectives can be found in Table S1 in Multimedia Appendix 1.

Data Reporting Protocols

Signal-Contingent Active EMA

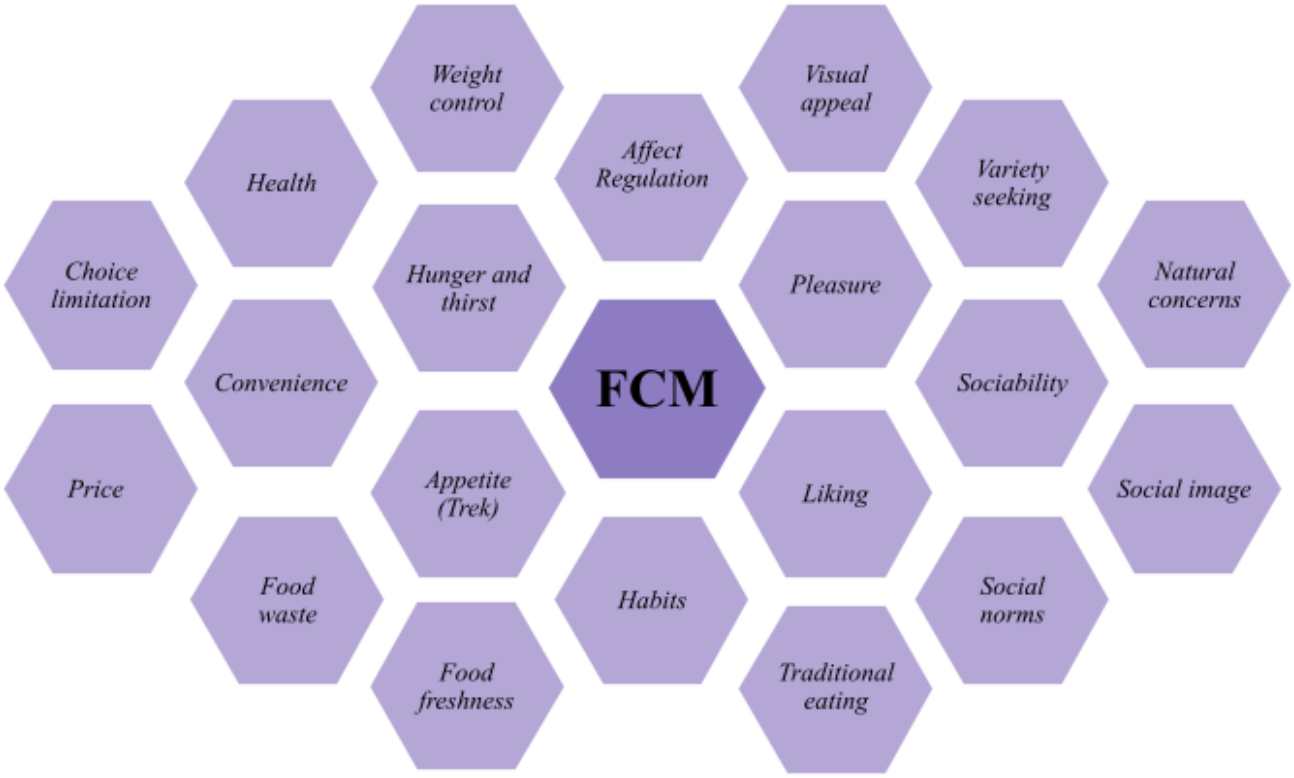
Given the nature of the study, the possibilities of the app, and the interference of the app with daily activities and social life when collecting data in real-time [49], it was decided to use signal-contingent active EMA for data collection. EMA allows for repeated data collection on participants' situational dietary behaviors in their typical real-world context via mobile devices [37,38]. In the case of FOODLOOP, data were repeatedly collected on participants' self-reported near real-time situational snacking behaviors in the physical, social, and temporal context in which they prevailed, via participants' own mobile phones to reduce recall and social desirability bias.

Data collection days lasted 24 hours (06:00 AM-06:00 AM) and consisted of 9 prompts delivered via Traqq following a fixed schedule (Table S2 in Multimedia Appendix 1). Each prompt concerned one of the time windows and appeared as a push notification on the participant's phone, which stayed salient for 2 hours until responded to. Participants indicated whether they had consumed anything during each time window. Nonresponses were registered as missing, and data collection days with too many missing prompts were considered invalid. Participants with invalid days were automatically rescheduled to repeat the session 2 days later within the designated data collection period until 3 valid days were achieved per data collection period.

Data Recording

During each of the 9 daily prompts, participants entered all food and beverage products consumed within the corresponding time window. They selected products from the Traqq database via the search bar and indicated the self-perceived portion size (Figure S1 in Multimedia Appendix 1). If a product was not listed, participants chose the most similar option available. Participants were instructed to record all consumed products except for plain water, fats and oils (eg, butter, margarine, and

XSL•FO
RenderX



baking oil), and herbs and spices (Table S3 in Multimedia Appendix 1).

After entering the consumed product, participants had to label the product according to their perception of the associated consumption occasion as either one of the meal occasions (breakfast, lunch, and dinner) or one of the snacking occasions (replacement of meals, in-between-meals, or other), without giving instances of what foods and beverages constituted these occasions. This approach, adopted from Biel et al [36], allowed participants to self-define consumption occasions. Products of all consumption occasions, including meals, were recorded. Participants were not informed that FOODLOOP's focus was on snacking behavior until after study completion to prevent bias among participants toward snacking entries.

Additional Questions for Snacks

After entering a product and labeling the associated consumption occasion, participants received additional questions only when the product was marked as one of the snacking occasions. First, participants reported their FCM using the Dutch 1-scale-per-item Eating Motivation Survey (TEMS). This version contained 20 items (Figure 2), each assessing a unique FCM on a 3-point Likert scale ranging from 1 ("not applicable") to 3 ("applicable"). The survey was based on the 1-scale-per-item TEMS used in the study of Wahl et al [26] and TEMS as used in multiple studies [27,30,50].

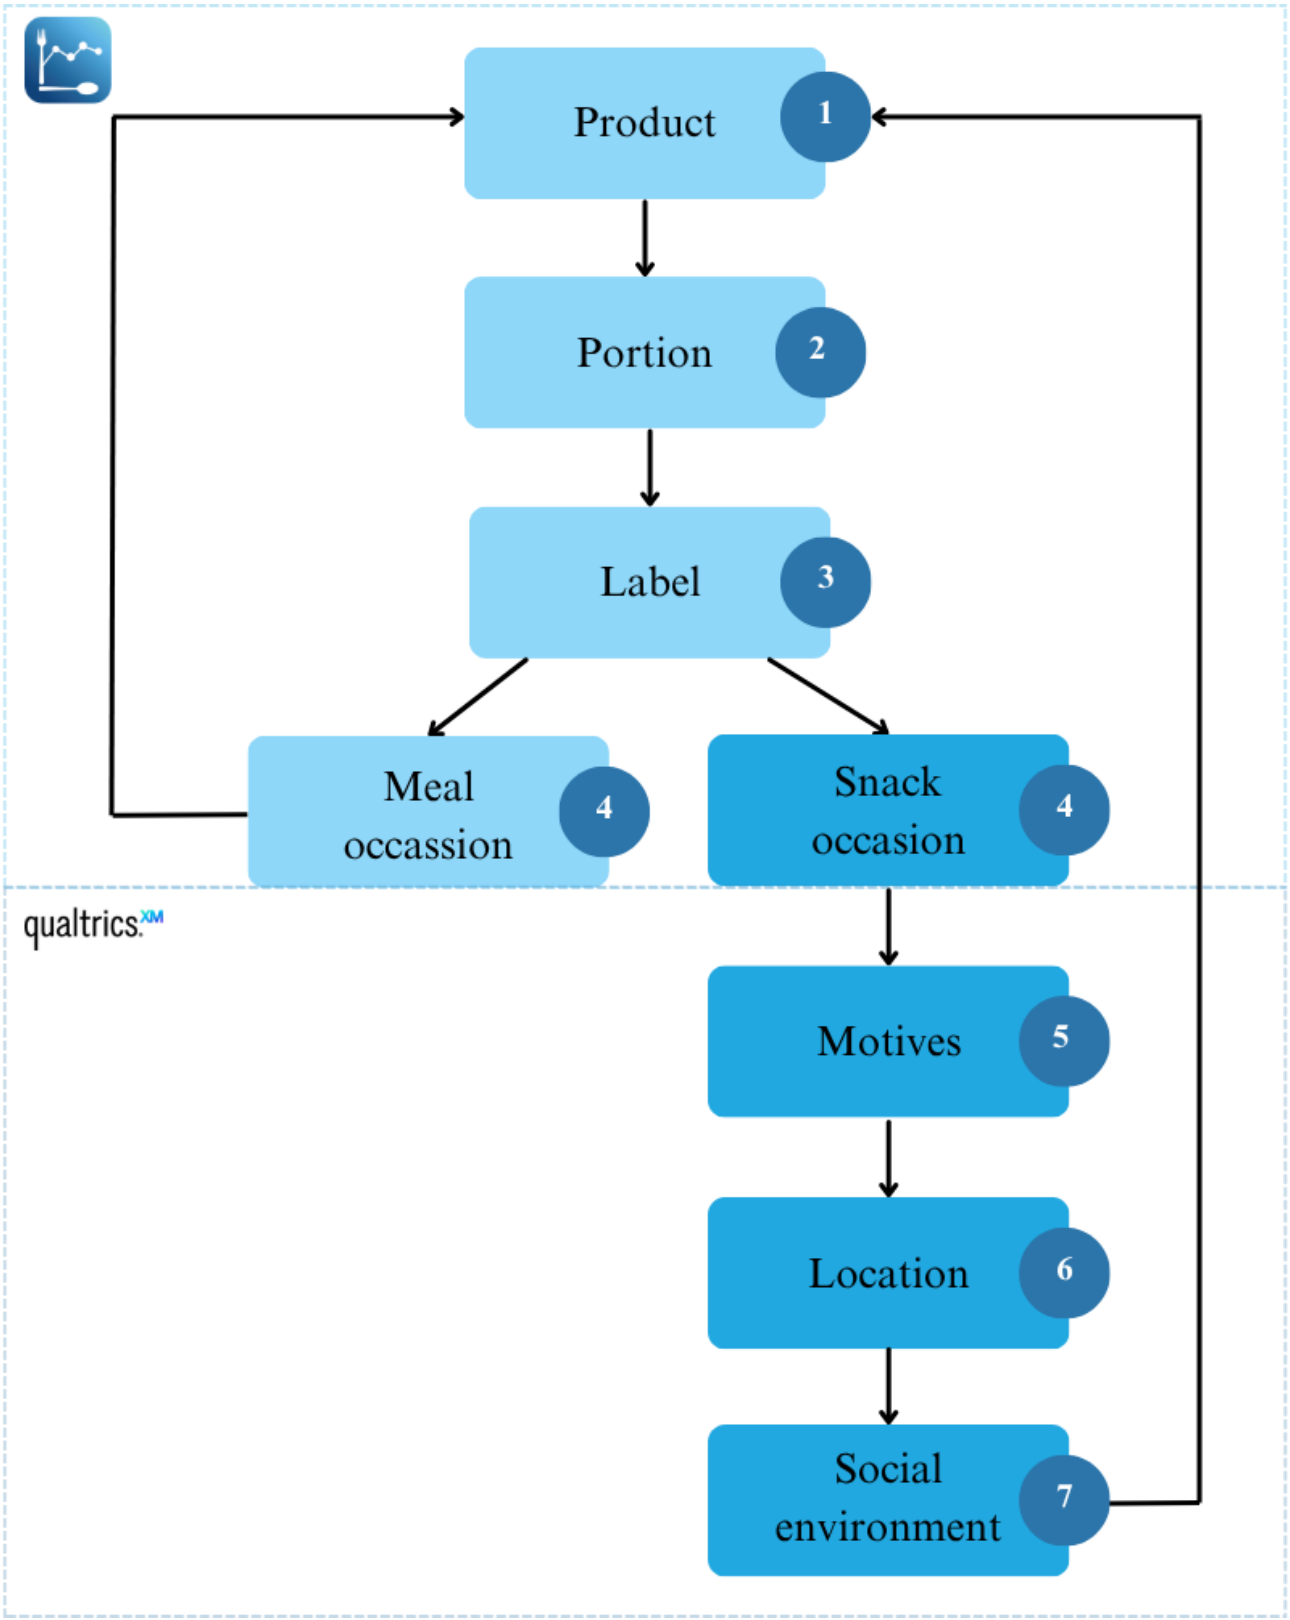


Figure 2. Food choice motive (FCM) of Dutch 1-scale-per-item Eating Motivation Survey (TEMS). FCM: food choice motive.

Thereafter, participants indicated the physical (location) and social (people present) context of each consumed snack from predefined categories. The temporal context (eg, time window, type of day, and season) was derived after the study from the app's recorded date and time data of each entry. When a product was labeled as a meal occasion or after completing a snacking entry, the app automatically returned to the Traqq home screen, where participants could log additional products or finalize the time window (Figure 3).

XSL•FO
RenderX

Figure 3. Protocol Traqq for entry of products.

All consumed products were entered separately, with associated questions answered for each product individually (eg, if coffee and a cookie were consumed together, first the coffee was entered and questions about the coffee were answered, then the cookie was entered and questions about the cookie were answered). When participants entered all the products consumed within a time window and filled in the associated questions, or when participants indicated that they had not consumed anything, they completed the time window by submitting their answers. The time window was then recorded as successful. Data collection days with the required number of valid time windows were deemed successful, and participants remained promptable for subsequent data collection days. The app was refined through several pilot iterations to balance user burden

XSL•FO
RenderX

and compliance. One data collection day took approximately 30 minutes to complete.

Data Analysis

Data Preprocessing

Given the objectives of this study, only data concerning products labeled as snacking occasions were included in the analyses. Data related to meals, incomplete collection days, and dropout participants were excluded. Therefore, there were no participants with missing data for any of the variables of interest (Table 1). After data collection, all snack products were classified into categories (Table 1; Table S4 in Multimedia Appendix 1), based on the Dutch Food Composition Database (versions 2016 and 2019; NEVO [47,48]), Dutch National Food Consumption Survey [51,52], and the Netherlands Nutrition Center (Voedingscentrum [53]). These snack product category variables were subsequently used in the analyses. In addition, the variables concerning physical context were merged into 2 categories, “At home“ and “Out of home,” and the social context variables into the categories “Alone” and “With others.” Table 1 shows the snacking determinants, corresponding variables, and response categories for analyses.

XSL•FO
RenderX

Table . Snacking determinants, corresponding variables, and response categories for analyses.

Snacking determinants and variables	Response categories
Product	
Snack categories beverages (3)	Nonalcoholic beverages; alcoholic beverages; dairy (substitutes)
Snack categories foods (7)	Breads and cereals; fruits; vegetables and legumes; dairy (substitutes); meat (substitutes); cookies, bars, and pastries; confectionery and ice cream; savory snacks
Context	
Physical context (2)	At home; out of home
Social context (2)	Alone; with others
Temporal context	
Daypart (3)	Morning (06:00 AM-12:00 PM); afternoon (12:00 PM-06:00 PM); evening and night (06:00 PM-06:00 AM)
Type of day (2)	Weekday (Monday-Friday); Weekend day (Saturday and Sunday)
Season (4)	Spring, summer, autumn, and winter
Consumer	
Motives (FCM[a]; 20)	Liking; appetite; hunger and thirst; convenience; pleasure; health; visual appeal; habit; food freshness; sociability; variety seeking; weight concerns; choice limitations; price; food waste; traditional eating; social image; social norms; and natural concerns
Sociodemographic and lifestyles	
Age (2)	Younger millennials (1990 - 2000); older millennials (1980 - 1990)
Sex (2)	Men; women
Education (2)	Lower educated; higher educated
Net income per month (4)	Below modal (<€2000; <US $2340); modal (€2000–€3000; US $2340-US $3510); above modal (>€3000; >US $3510) not disclosed
Daily occupation (4)	None; study; paid job; study and paid job
Urbanity (5)	Rural; low urbanity; moderate urbanity; high urbanity; very high urbanity [54]
Living situation (2)	Living alone; living with others
Parental status (2)	No child or children; child or children
Grocery shopping autonomy (3)	No or little autonomy; shared autonomy; most or all autonomy
Diet (2)	No diet; diet
BMI group (4)	Underweight (<18.5); healthy weight (18.5 - 25); overweight (25-30); obese (>30)
Activity level (3)	Nonactive; semiactive; norm-active [55]
Fit level (3)	Nonfit; semifit; norm-fit [55]
Health interest (1-7)	Very low health interest – … - very high health interests

[a]FCM: food choice motive.

XSL•FO
RenderX

All analyses were performed with standardized snacking frequencies for each response category of all considered variables (Table 1) to correct for unequal participant weights, as some participants recorded more snacks than others. Each snack originally represented one case in the dataset. To ensure that all participants contributed equally to the analyses, absolute snacking frequencies for each response category were divided by the number of data collection days (12), resulting in the daily average frequency (DAF) of snacks consumed. The DAFs provided a uniform measure of comparison, with each row in the dataset representing one participant rather than one snack. To account for the differing number of data collection days across contexts, the DAFs were adjusted for the number of days per week (for "Type of day") and per season (for "Season"). DAFs were calculated for all response categories of all variables (Table 1) separately for (1) beverages as snacks, (2) foods as snacks, and (3) all snacks combined (for the detailed calculation of DAFs and all DAFs for each of the response categories, consult the Data Preprocessing and Descriptive Data sections and Tables S5-S8 in Multimedia Appendix 1).

Data Analyses

Data analyses were performed with Jamovi (Version 2.5; The jamovi Project), using R statistical packages (Version 4.1; R Core Team). Descriptive statistics and statistical tests were used to examine relationships between variables. In all analyses, a consumed snack represented a case (n) and the total number of participants was treated as the population (N). Descriptive statistics for snack category variables (Table S5 in Multimedia Appendix 1) demonstrated skewness toward nonalcoholic beverages (n=4204), indicating an imbalance between snack food and beverage categories. Given this imbalance and sufficient sample sizes for both beverages as snacks (n=5164) and foods as snacks (n=9148), analyses were conducted separately for these 2 groups.

Statistical tests were performed using DAFs of each response category (Table 1) to examine differences in snacking frequencies across determinants. Each variable was analyzed individually, aligning with the study's aim to explore snacking determinants one-dimensionally, as these determinants were not mutually exclusive (eg, the same snack could be categorized as "At home," "Alone," and "In the morning"). For each variable, differences in DAFs were tested both between and within response categories for (1) beverages as snacks, (2) foods as snacks, and (3) all snacks combined (eg, comparing DAFs of "Alone" vs "With others" and subsequently beverages vs foods within each category).

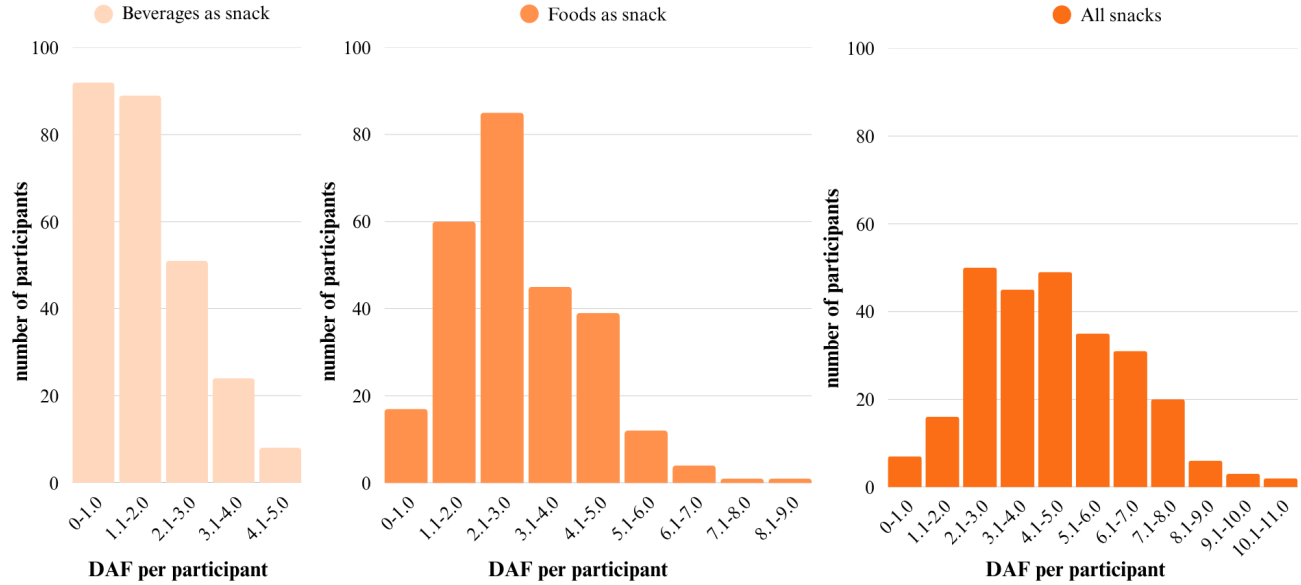
Nonparametric tests were used given nonnormality (Shapiro-Wilk; $P<.05$). No sensitivity analyses or multivariable confounder-adjusted models were used, given the descriptive nature of the study. Differences in DAFs for product-, context-, and motivation-related variables were analyzed using Friedman ANOVA with Durbin-Conover pairwise comparisons. For motivation variables, McDonald ω was calculated to assess reliability [56,57], showing high internal consistency across all 20 FCM scales (beverages: ω=0.81; foods: ω=0.82; all snacks: ω=0.84). Subgroup analyses were conducted to explore differences in DAFs across sociodemographic and lifestyle variables and were analyzed using 2-tailed independent samples *t* tests, Mann-Whitney *U*, and Kruskal-Wallis tests. Depending on Levene test results, either Student *t* ($P>.05$) or Mann-Whitney *U* ($P\leq.05$) was used for 2-category variables, while Kruskal-Wallis tests (Shapiro-Wilk, $P\leq.05$) with Dwass-Steel-Critchlow-Fligner pairwise comparisons were applied for variables with more than 2 categories. Test values (except *P* values) were reported with 2 decimals, due to which minor rounding deviations may occur. For all statistical tests, a *P* value of ≤.05 was considered significant.

Results

Sample Compliance and Characteristics

Of the 398 participants who started the study, 264 (66.3%) fulfilled the entire year of data collection. These 264 Dutch millennials constitute the cohort of this study, the FOODLOOP cohort. More details about compliance rates throughout the longitudinal study period can be found in Table S9 and Figure S2 in Multimedia Appendix 1. Most of the FOODLOOP cohort consisted of women (232/264, 87.8%), who were highly educated (224/264, 84.8%), had a paid job (216/264, 81.8%), and a relatively high income (>€3000; US $3510) net income per month; 136/264, 51.5%). The ages of the participants ranged from 22 to 42 years (mean 30.14, SD 5.63) at the start of the study, with 72.3% (191/264) of participants belonging to the younger millennial age group (born between 1990 and 2000). As for the living situation of the participants, most were living in more urbanized areas of the Netherlands (198/264, 75%), with others (216/264, 81.2%), especially with a partner (108/264, 40.9%), and did not have children (212/264, 80.3%). Most participants could make grocery shopping decisions autonomously (158/264, 59.8%) or share this decision with other members in the household (100/264, 37.8%).

Seventy-two percent of participants (n=190) had a healthy weight (BMI: mean 23.28, SD 3.92) and 59.8% (158/264) did not follow a particular diet. Also, 21.2% (56/264) of participants skipped at least 1 meal a day or replaced meals with smaller consumptions. Most participants engaged in moderate and/or intense exercise at least once a week (moderate: 260/264, 98.5%; intense: 209/264, 79.1%), of which 39.3% (104/264) engaged in moderate exercise more than 5 times a week, and 26.5% (70/264) engaged in intense exercise more than 3 times a week. Weighted health interest of participants ranged from 2.75 to 6.88, with a mean of 5.02 (SD 0.78), indicating higher interest in health amongst participants in the FOODLOOP cohort.



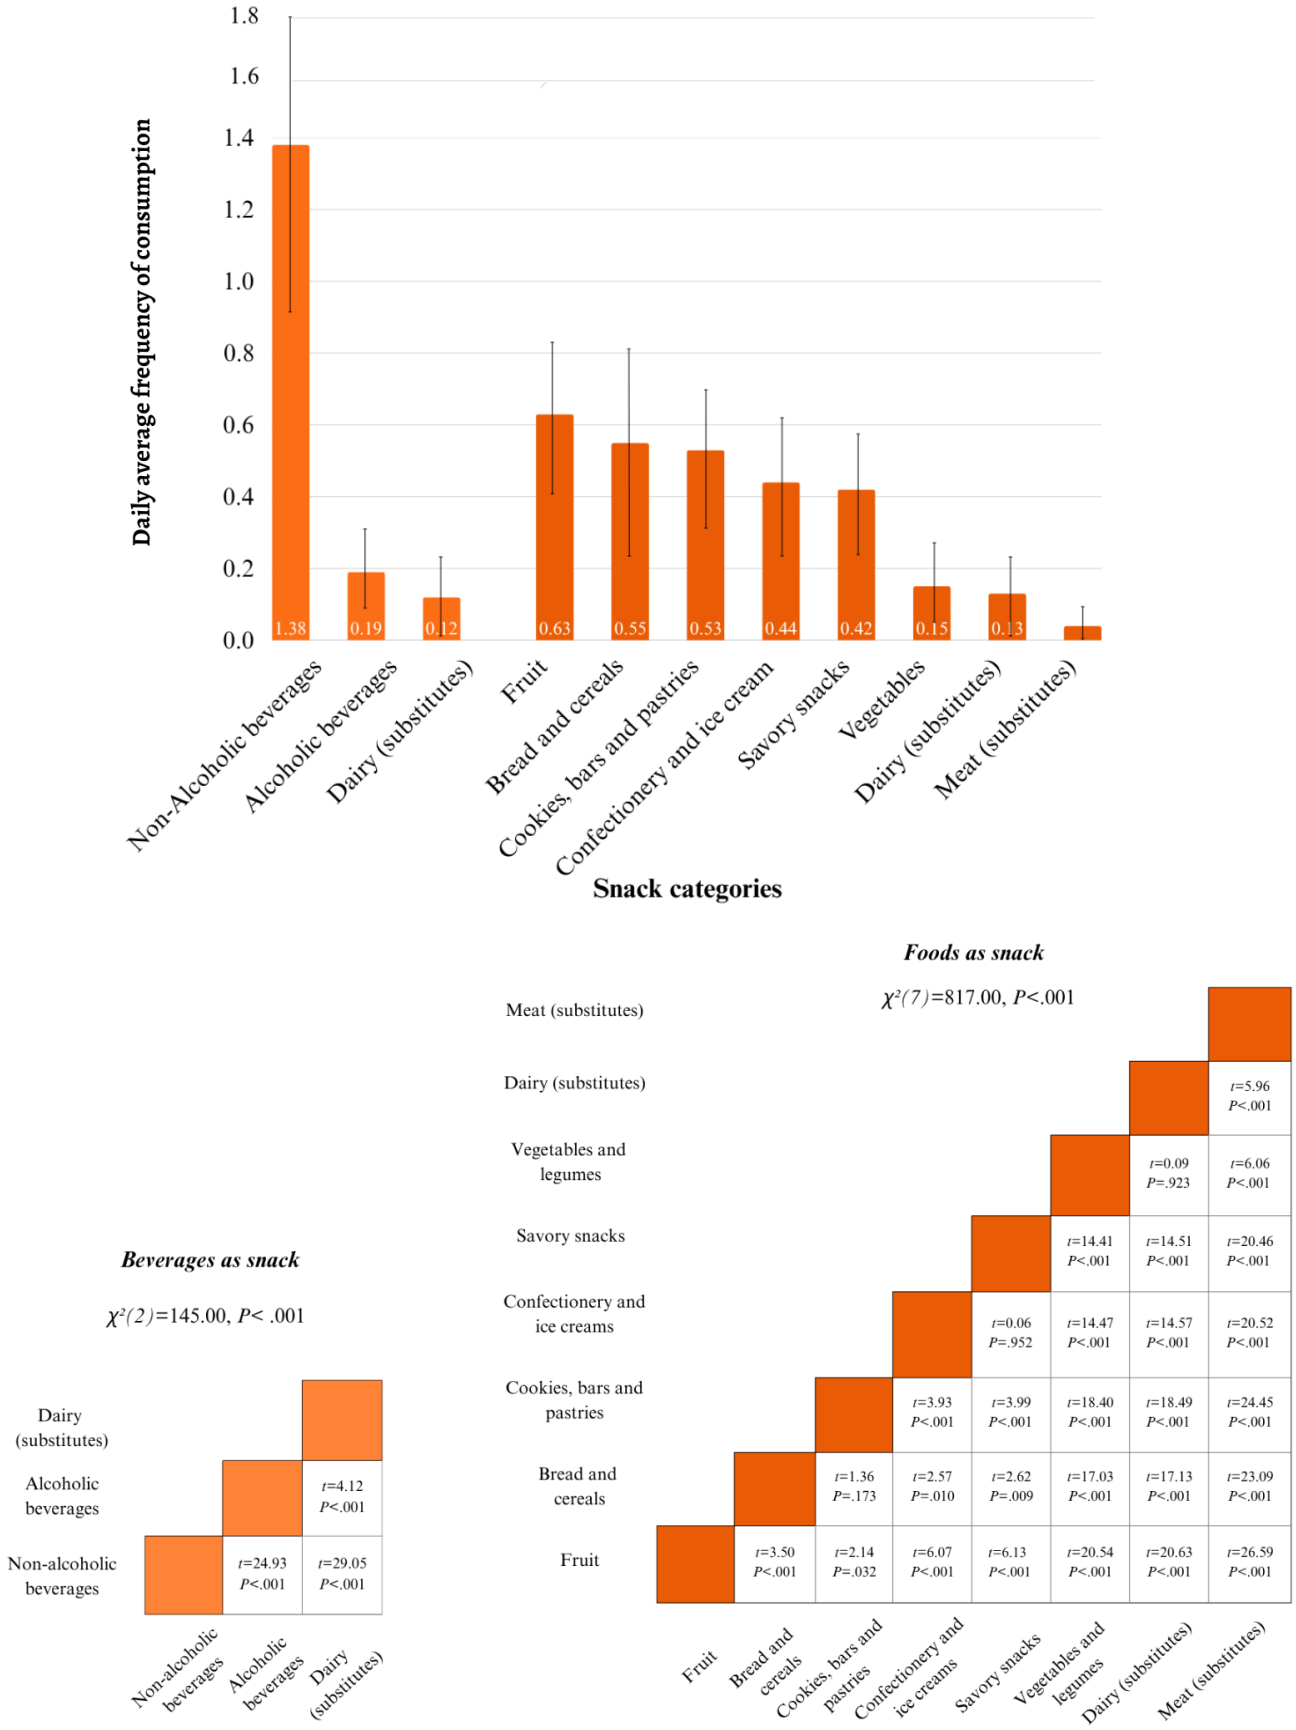
Product-Specific Determinants

Over the longitudinal study period, 14,312 snacks, of which 5164 beverages as snacks (36.1%) and 9148 snack foods (63.9%), were consumed by the 264 participants in the FOODLOOP cohort over the course of 2987 unique days, across 4 different seasons. The DAFs of snacking range from 0 to 5 for beverages, 0 to 9 for foods, and 0 to 11 for all snacks. Most participants consumed 1 - 2 beverages, 1 - 4 foods, and 1 - 5 snacks in total per day (Figure 4). On average, 1.63 beverages, 2.89 foods, and 4.52 snacks in total were consumed per participant per day. In all snacking situations, DAFs of foods

XSL•FO
RenderX

were significantly higher than those of beverages (Table S10, Multimedia Appendix 1).

Figure 4. Distribution daily average frequencies (DAFs) of all participants for beverages as snacks, foods as snacks, and all snacks.



Snacking Categories

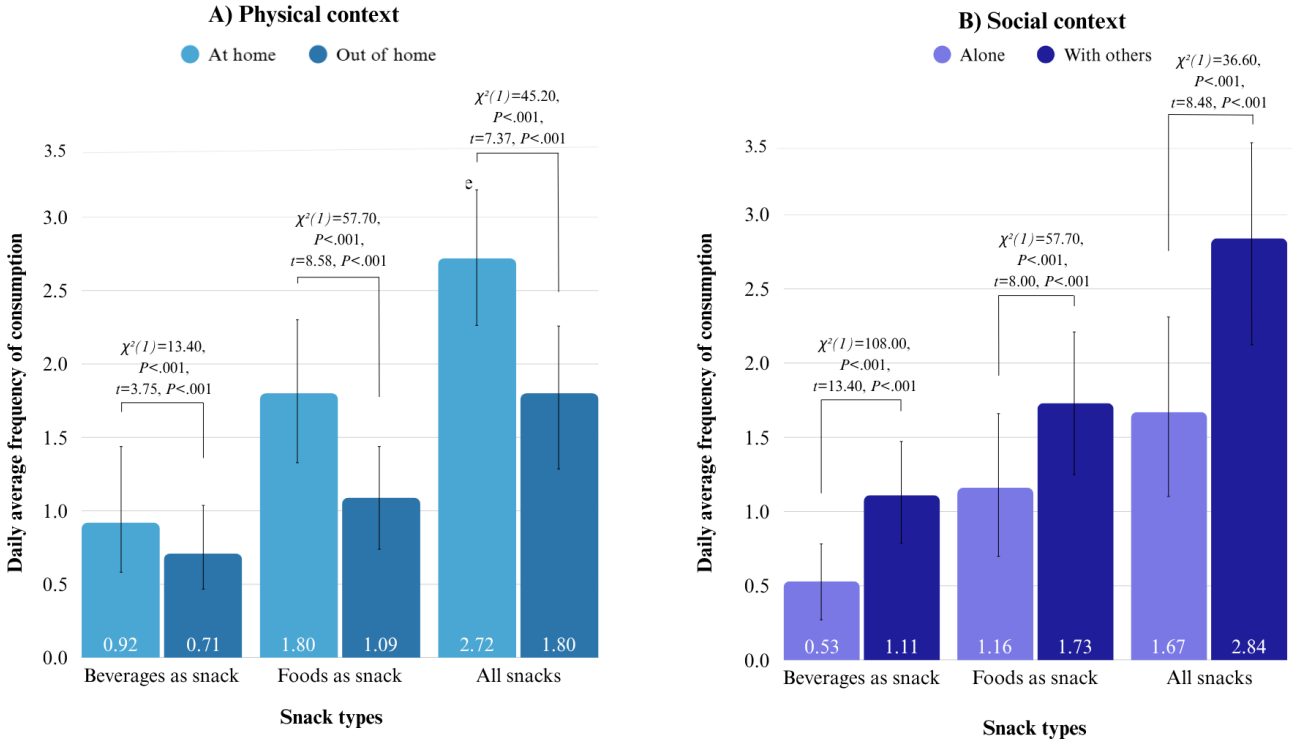
Nonalcoholic beverages (consisting of mainly coffee and tea) were mostly consumed as snacks. For beverage categories, this was followed by alcoholic beverages. Dairy beverages and substitutes were least consumed. All differences between DAFs of the beverage categories were statistically significant (Figure 5).

XSL•FO
RenderX

Figure 5. Daily average frequencies (DAFs) for snack categories and pairwise comparisons of differences between snack categories. Higher *t* values imply larger differences between DAFs of 2 snack categories.

Of all foods, fruit was mostly consumed as snacks, followed by bread and cereals; cookies, bars, and pastries; confectionery and ice cream; and savory snacks. Meat, poultry, fish, eggs, and substitutes were the least consumed foods as snacks. Most differences between DAFs for foods as snack categories were statistically significant (Figure 5). Most consumed snacks were

XSL•FO
RenderX



perceived as an in-between meal consumption occasion. For replacement meal occasions, the DAF of foods was higher than that of beverages, whereas the DAF of foods was lower than that of beverages for snacking occasions other than in-between or replacement meals. All differences were statistically significant (Tables S10 and S11 in Multimedia Appendix 1).

Context-Specific Snacking Determinants

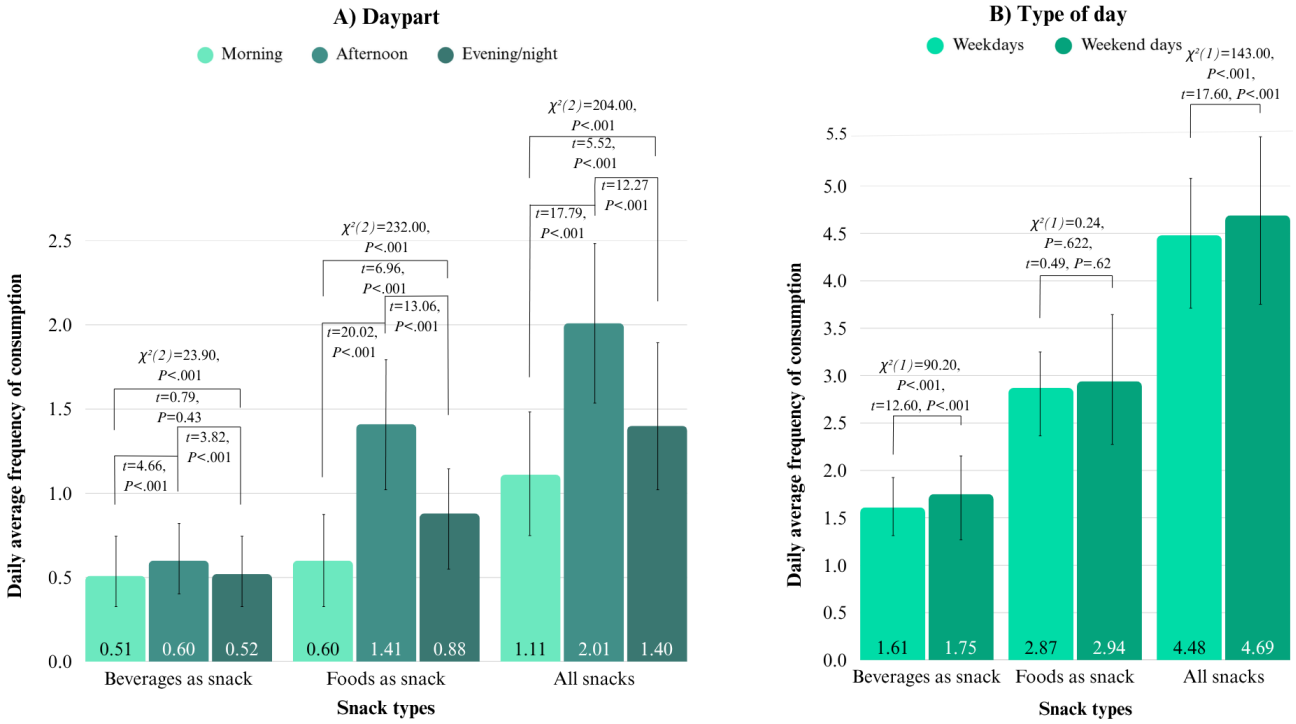
Physical Context of Snacking

Most snacks were consumed at home rather than out of home. This was the case for both foods and beverages (Figure 6A). In both contexts, the DAFs of foods were higher than those of beverages, but at home, the difference was larger. This indicates that foods were relatively more frequently consumed than beverages at home compared to out of the home. All differences were statistically significant (Figure 6A; Table S10 in Multimedia Appendix 1).

Figure 6. Bar charts of daily average frequencies (DAFs) of consumption and pairwise comparisons showing differences between DAFs in the (A) physical context at home versus out of home and (B) social context alone versus with others. Higher chi-square values imply larger differences between DAFs of 2 context categories.

Social Context of Snacking

Most foods and beverages as snacks were consumed with others, rather than alone (Figure 6B). In both contexts, the DAFs of foods were higher than those of beverages. However, this difference was larger when alone. This indicates that foods were relatively more frequently consumed than beverages alone, as compared to others. All differences were statistically significant (Figure 6B; Table S10 in Multimedia Appendix 1).



Temporal Context of Snacking

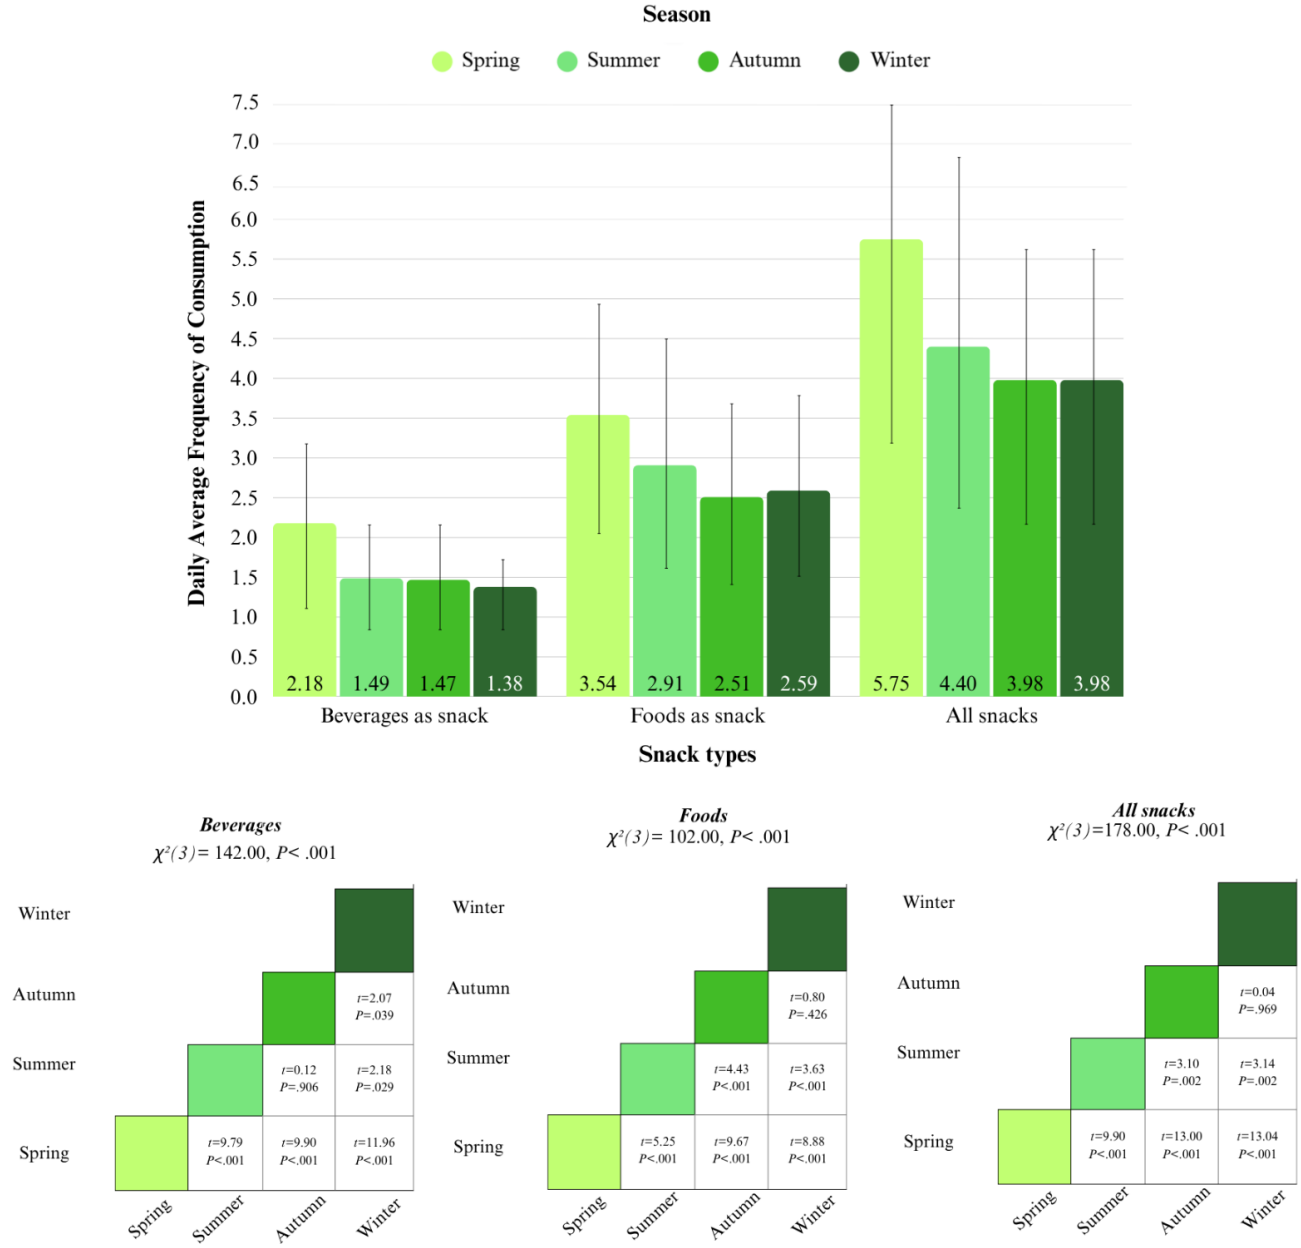
Snacking During the Day

Data demonstrate that snacks were consumed throughout the day, but most snacks were consumed in the afternoon, followed by the evening and night, and least snacks were consumed in the morning. This was the case for both foods and beverages but especially pronounced for foods. For foods, the DAF was lowest in the morning, whereas the DAFs of beverages did not differ significantly between the morning and the evening and night (Figure 7A). In all dayparts, DAFs of foods were significantly higher than those of beverages, but this difference was largest in the afternoon and smallest in the morning. This indicates that foods were relatively more frequently consumed than beverages in the afternoon as compared to other dayparts (Figure 7A; Table S10 in Multimedia Appendix 1).

XSL•FO
RenderX

Figure 7. Bar charts of daily average frequencies (DAFs) of consumption and pairwise comparisons showing differences between DAFs in the temporal contexts. (A) Daypart, morning versus afternoon versus evening and night, and (B) day types, weekdays versus weekend days. Higher chi-square values imply larger differences between DAFs of 2 context categories.

Snacking During the Week



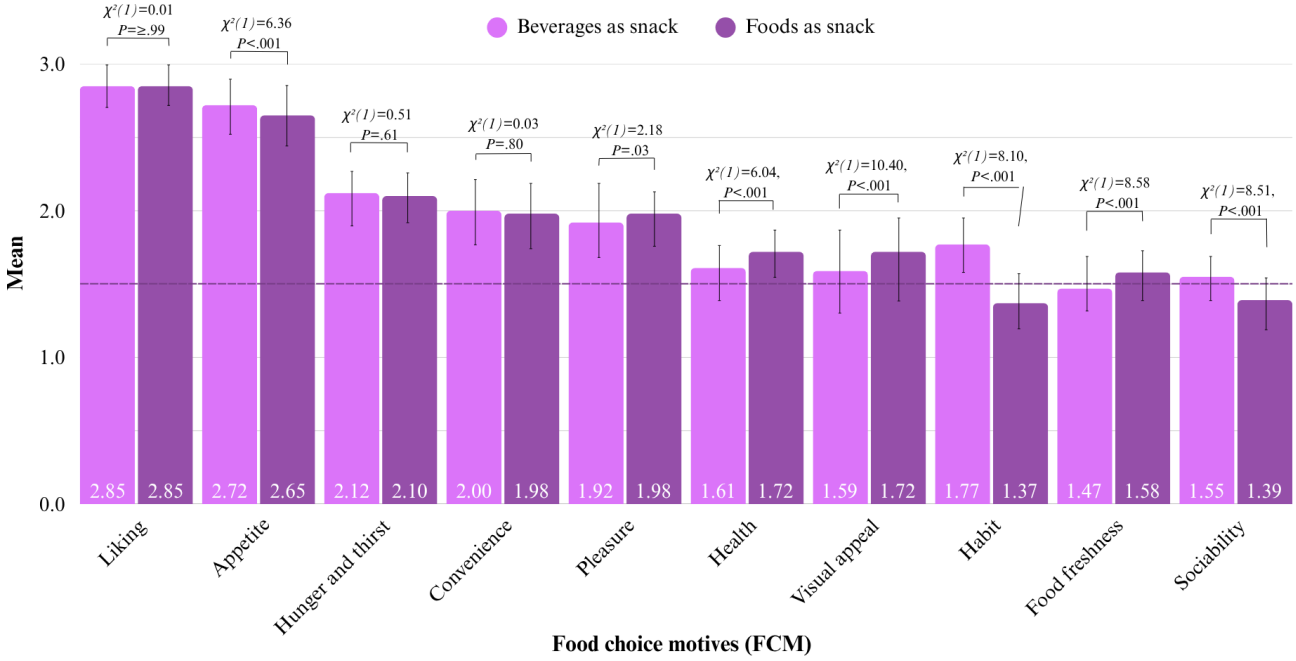
Data show that snack consumption on weekdays and weekend days was comparable. There were only minor differences in snack consumption between weekdays and weekend days. The weighted DAFs (accounting for the number of weekdays and weekend days) show that relatively more beverages were consumed on weekend days than on weekdays. Even though the difference was minimal, it was statistically significant. The weighted DAFs of foods did not differ significantly between weekdays and weekend days (Figure 7B). In both day types, the DAFs of foods were significantly higher than those of beverages, but this difference was larger on weekend days. This indicates that foods were relatively more frequently consumed than beverages on weekend days as compared to weekdays (Figure 7B; Table S10 in Multimedia Appendix 1).

Snacking During the Year

Most snacks were consumed in spring, followed by summer. DAFs of snacking were lowest in autumn and winter. Most differences in DAFs between seasons were significant. Only the DAFs of beverages did not differ significantly between summer and autumn, and the DAFs of foods did not differ significantly between autumn and winter (Figure 8). Within all seasons, the DAFs of foods were significantly higher than those of beverages. This difference was most pronounced in summer, indicating that foods were relatively more frequently consumed than beverages as compared to other seasons (Figure 8; Table S10, Multimedia Appendix 1).

XSL•FO
RenderX

Figure 8. Bar charts for daily average frequencies (DAFs) of temporal context and pairwise comparisons. Seasonality of differences in DAFs between spring versus summer versus autumn versus winter. Higher chi-square values and *t* values imply larger differences between DAFs of seasons.



Consumer-Specific Snacking Determinants

Snacking FCMs

Data demonstrate that 10 out of the 20 FCMs played a prominent role in snacking (mean ≥1.5; Table S7 in Multimedia Appendix 1). Snacking was mainly motivated by liking and appetite (mean >2.5), followed by hunger and thirst, and convenience. Pleasure, visual appeal, health, habit, and food freshness were also found to belong to the core snacking drivers. The other 10 FCMs, including variety seeking, weight concerns, and affect regulation, did not often motivate participants to snack (mean <1.5). The role of most of the prominent FCM (mean ≥1.5) differed significantly between beverages and foods (Figure 9). These differences were largest for the FCM visual appeal, habit, and sociability. For beverages, the FCM habit, sociability, and appetite were more prominent, whereas visual appeal, health, pleasure, and food freshness were more prominent for foods. The other FCMs, liking, hunger and thirst, and convenience, were shown to be more universal snacking drivers, as they played a similar role in the consumption of both beverages and foods (Figure 9).

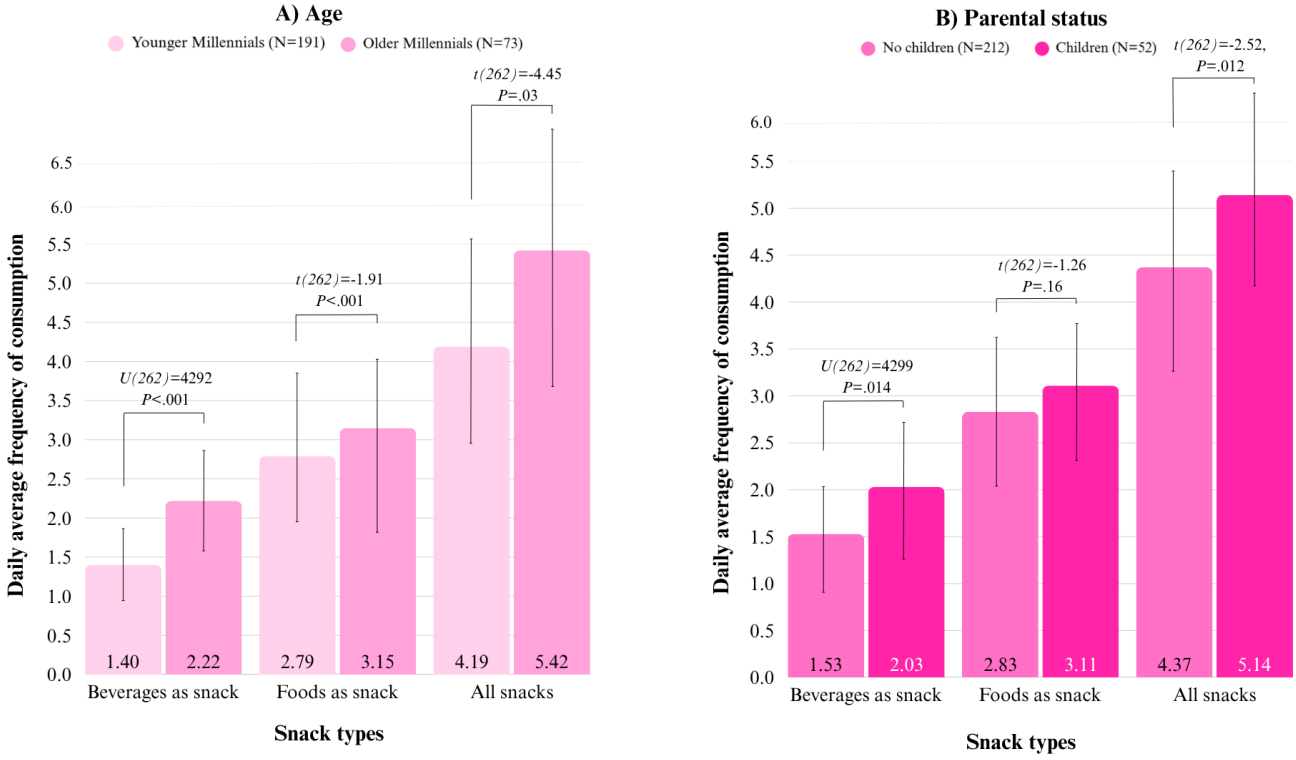

Figure 9. Average scores on food choice motives (FCM): pairwise comparisons results of FCM with means ≥1.5 (measured on 3-point Likert scales).

Sociodemographic, Lifestyle Factors, and Snacking

Regarding sociodemographic and lifestyle groups, the data demonstrate that there were statistically significant differences in DAFs for beverages and foods, given participants' age and parental status. Participants belonging to the older millennials (born between 1980 and 1990) consumed more beverages and foods than participants belonging to the younger millennials (1990-2000) (Figure 10A). Participants with children consumed significantly more beverages than participants without children (Figure 10B). There were no statistically significant differences in DAFs for beverages and foods, given other sociodemographic and lifestyle factors of the participants, such as sex, education, urbanity of living area, and the activity and fit levels.

Figure 10. Bar chart showing daily average frequencies (DAFs) of consumption and pairwise comparisons showing differences between DAFs according to the sociodemographic characteristics of age and parental status. (A) Younger versus older millennials and (B) participants with children versus without children. Higher *U* values and *t* values imply larger differences between DAFs of demographic groups.

Discussion

Overview

This study used Dutch millennials as a case to explore consumers' longitudinal situational snacking behaviors by investigating the role of product-, context-, and consumer-specific determinants in snacking situations, as well as how foods and beverages for snacking differ within and across these determinants, using a mobile app following the principles of signal-contingent active EMA.

Principal Findings

Product-Specific Determinants

Examining the aggregated EMA data across all participants and snacking situations, this study found a daily average snacking frequency of 4.5. This is higher than reported in other studies, which range between 1.5 and 3.5 [58-62]. The higher frequency in our study might be explained by the composition of our cohort (1) millennials, who tend to snack more than other age groups, especially given the ongoing snackification trend [16], and (2) Dutch consumers, who likely adhere to the Dutch diet. As found by Geurts et al [14], Dutch adults (aged 19 - 69 years) report more than 7 eating occasions per day, including 4 between-meal (ie, snacking) occasions, which aligns with our findings. Together, these findings suggest that snacking forms a substantial part of the daily diet of the Dutch, classifying them as heavy snackers (>3 snacks per day [21]).

Across all contexts, participants consumed relatively more foods than beverages as snacks. This contrasts with van Rossum et al [15], who found that the Dutch diet in general consists of more beverages than foods. However, our findings support existing snacking literature, showing that beverages are less prominent than foods in snack frequency, as beverages are less likely to be perceived as snacks by consumers [63,64].

Notwithstanding this smaller role of beverages in snacking, our findings do show that nonalcoholic beverages (mainly coffee and tea) were frequently consumed as snacks. This aligns with the Dutch diet in general being characterized by high consumption of nonalcoholic beverages [14,15] and the trend that an increasing proportion of beverages is consumed as snacks [21].

Concerning food categories, fruit, bread and cereals, cookies, bars and pastries, confectionery and ice creams, and savory snacks were among the top snacks for Dutch millennials. Vegetables, meat, and dairy (substitutes) were the least frequently consumed snacks. Most of these findings are consistent with previous studies [15,62,65,66]. Different from other studies is that our results show relatively high consumption of bread and cereal products as snacks. This may be explained by findings from other Dutch studies [14,15], showing that bread and cereal products are staple foods and important energy sources in the Dutch diet, especially for meal occasions. Our results suggest that these foods also play an important role in Dutch millennials' snacking occasions.

Context-Specific Determinants

Confirming our expectations, findings show that context plays a central role in shaping snacking behaviors. Findings regarding the physical context show that most snacks were consumed at home, aligning with previous studies [29,67-69] and national dietary data showing that over 85% of foods and beverages in the Netherlands are consumed at home [14,15]. This could be explained by the convenience of the accessibility to snacks at home and the cost-effectiveness of home snacking [70]. The timing of data collection, shortly after the COVID-19 pandemic (2022 - 2023), may also have influenced these results. Postpandemic patterns show that consumers not only snack more frequently in general [71-73], but especially at home, a habit established during lockdowns [74-76]. Furthermore, the COVID-19 pandemic remnant of remote and hybrid working [77] may have increased participants' time spent at home, thereby facilitating more home snacking.

Concerning the social context, our study shows that most snacks were consumed with others, rather than alone. Since information regarding social snacking consumption patterns of the Dutch is scarce [14], our findings offer new insights into the role of the social environment in Dutch millennials' snacking. Our findings, however, contrast with social snacking consumption patterns in other Western countries, where snacking is considered a personal eating event and mostly done alone [3,50,78,79]. A possible explanation for the higher consumption of snacks with others in our study might be the interaction between the physical and social environment; most snacks were consumed at home, and since most of our cohort lived with partners, children, and/or family members, snacking at home may have naturally occurred in the presence of other inhabitants.

Concerning the temporal context, our study shows that snacking occurred throughout the day. This suggests that snacking is not necessarily confined to intervals between the regular Dutch mealtimes, but that any consumption at any time not perceived as (part of) a meal can be a snack. This is in line with findings of other studies [3,80,81] and the snackification trend [82]. Throughout the day, snacking was most prevalent in the afternoon, followed by the evening and morning, consistent with prior studies [60,69,83]. To the best of our knowledge, our study is one of the first to explore seasonal variations in consumers' snacking behaviors. We show that snack consumption was the highest in spring and the lowest in autumn and winter. These seasonal variations in snacking frequency might be explained by the seasonal climate of the Netherlands, where variations in meteorological factors such as temperature, precipitation, sunshine hours, and humidity are more noticeable throughout the seasons. In such climates, seasonal variations are also more pronounced in food consumption [84]. Even though literature on the effect of seasonality on food behaviors is scarce, our findings support those of Girju and Ratchford [85], who also observed less snacking in winter and more snacking in spring and summer.

Consumer-Specific Determinants

Concerning sociodemographic and lifestyle factors, we found some differences in snacking frequencies given age and parental status. Interestingly, older millennials snacked more frequently

XSL•FO
RenderX

in general than younger millennials, and millennials with children consumed more beverages as snacks than those without. These 2 findings might be connected, as most of the participants with children were older millennials. Our findings concerning age align with those of Geurts et al [14], who reported that overall food consumption among the Dutch increases with age until middle age. The lack of expected differences in snacking frequencies for other sociodemographic and lifestyle factors, including sex, education, and activity levels, may reflect a possible type II error around the estimates, given minor subgroups of participants for factor levels [86].

Concerning FCMs, our study extends prior work by capturing within-person variations in snacking motives across different snacking contexts, thereby providing a deeper understanding of why consumers choose specific snacks in specific situations. We found that liking was the primary driver for snacking in all consumption situations, congruent with other studies [50,62]. Other core motivators for snacking in our study, including hunger and thirst, convenience, weight control, health, pleasure, and visual appeal, are also aligned with findings from other studies. Different from other studies is that we found other core FCM for snacking to entail sociability, food freshness, and habit [50,62]. The role of these FCMs in our study might be explained by the interaction of multiple snacking determinants, as the motives driving consumers' snacking behaviors depend largely on the consumption context [29,50,87].

The role of FCM Sociability in our study could be explained by the finding that most snacks were consumed in the presence of others. The statement measuring this FCM included the Dutch word "gezellig." The meaning of "gezellig" is not straightforward [88] but can be explained as the experience of togetherness in doing everyday activities together, often at specific times of the day and in one's own home, implying collective enjoyment [88,89]. The "gezelligheid" of consuming snacks with others has played a noteworthy role in our study, possibly due to the social enjoyment and collectiveness of snacking. Even though "gezelligheid" is culturally embedded within the Dutch snacking context, the TEMS has demonstrated high cross-country and cultural group validity [26,30]. Therefore, our findings concerning FCM sociability might be translatable to other cultural contexts given sociability-related concepts similar to "gezelligheid," but future studies are warranted.

The role of food freshness might be explained by our finding that mostly fruits, bread, and cereals were consumed as snacks. Food freshness includes the recency of production or harvest and the overall product quality [90-93]. It is a key determinant of consumers' food choices, especially for fruits and baked products, which are highly susceptible to deterioration over time and perceived as having higher quality closer to the moment of harvest, production, or purchase [91,92]. This interaction of snack product categories and FCM might have played a role in our study.

The prominence of the motive habit in snacking has been established in other studies, but mainly for unhealthy snacking behaviors [94] and fruit intake in general [95]. The high consumption of fruit as a snack, alongside the cumulative consumption of cookies, bars, and pastries; savory snacks; and confectionery and ice creams in our study, might explain the prominent role of the FCM habit.

The prominence of the FCMs health and hunger and thirst in our study demonstrates that our cohort often selected snacks based on perceived healthfulness and satiating properties. Health- and hunger-driven snacking tends to be associated with the consumption of more healthful products [9,96]. This is observed in our study, as 64% of all consumed snacks consisted of coffee and tea, fruits, bread and cereal products, dairy products, and vegetables. This challenges the traditional view of snacking as a merely unhealthy dietary behavior characterized by underconsumption of nutrient- and fiber-rich products (such as fruits and grains) and excessive consumption of highly palatable traditional snack foods high in salt, saturated fat, trans fat, and sugar [97,98]. Our findings thus contrast with the traditional representation of snacking as merely unhealthy and harmful and support the growing scientific evidence that argues that snacking is not necessarily detrimental to but could also potentially benefit health [7,12,13,99]. We endorse the notion of Barnes et al [60] that snacking, like any other dietary behavior, can be practiced in a healthful or nonhealthful manner, depending on the product chosen, variety within the diet, and the underlying motives for consumption.

Strengths

One of the main strengths of the FOODLOOP study is the use of a mobile app following a signal-contingent active EMA method, which enabled the collection of data on situational snacking behaviors in participants' natural environments, using the routinized handling of mobile phones. Large amounts of detailed data concerning participants' near real-time snacking behaviors, together with the comprehensive combination of product-, context-, and consumer-specific determinants present at specific moments in unique snacking situations, were documented, which allows for a better understanding of real-world snacking behaviors. As beverages consumed as snacks were distinctly captured, the data also enabled the analyses of differences in snacking behaviors between foods and beverages, accounting for variances in situational determinants. Given the use of a mobile app following an EMA method, practical applications of the findings from FOODLOOP are expected to be more relevant to real-world snacking situations [100] while minimizing missing data, memory loss, recall bias, and social desirability bias and maximizing ecological validity [26,31,35,36,38,46].

Another strength is the longitudinal nature of our study. FOODLOOP is one of the first to use a time-series structure for longitudinal data collection on consumers' snacking behaviors, enabling the exploration of temporal relationships among variables, especially the little-studied seasonal variations in snacking. As data were collected from the same group of 264 participants in all data collection periods, both inter- and intraindividual variability in snacking behaviors could be analyzed. The completion rate of 66.3% (264 of 398 participants) is comparable to those of previous EMA studies [101,102], and the FOODLOOP study managed to keep compliance of the participants throughout several data collection

XSL•FO
RenderX

periods throughout the year, notwithstanding months in which no data collection took place. Participants' compliance was supported by the FOODLOOP study design in 3 ways:

- Limiting participant burden through the data collection structure
  - Data were collected on 3 days each season, as 3-day surveys are shown to capture data with similar sufficiency to surveys with more data collection days [40].
  - Prompts were sent as push notifications on participants' phones to heighten engagement and minimize data loss [103].
  - No prompts were sent between 11:00 PM and 08:00 AM to ensure that participants were not bothered at inappropriate times.
  - The number of questions per prompt was minimized while capturing all necessary data (eg, through using the extensively piloted 1-scale-per-item TEMS).
  - Notifications were sent once per prompt to prevent notification excessiveness, a known barrier in mobile app-based dietary intake [33,103,104].
- Communication with participants
  - Participants received concise and detailed user manuals (documents and videos) to heighten compliance [103-106] via email and the study's web page before data collection, which remained continuously accessible during the study.
  - Participants received personalized reminder emails after each data collection day about the progress of participation.
  - The research team remained available 24/7 to enhance participants' motivation [83,105,107-110] via email and Instagram (Meta) for participants' remarks and questions during the full length of the study, including the no-data-collection months.
  - Emails and direct messages from participants were responded to within a day.
- The incentive scheme
  - The combination of multiple types of incentives (fixed monetary incentive, lottery, and donation possibilities) is the most effective strategy for increasing compliance rates [42-44] in studies using dietary mobile apps [105,111].

Limitations

Notwithstanding the insights we provide into Dutch millennial consumers' situational snacking behaviors through longitudinal EMA time-series assessment, several limitations should be acknowledged.

First, the sample was skewed toward women and higher-educated millennials, and most participants were living in urbanized areas, with a healthy weight and more active lifestyles. This likely resulted from recruiting participants through health- and nutrition-related channels (eg, Netherlands Nutrition Center and nutrition blogs) using a snowball sampling technique, rather than targeted sampling. This selection bias could have caused the inclusion of participants with a stronger interest in health and nutrition than the average Dutch millennial, which might have influenced the findings. Other possible forms of selection bias in this study could be self-selection, as participants who partook were likely more interested or experienced in tracking dietary intake throughout the day. Finally, there may be nonresponse and dropout bias, as participants failing to complete the study were often less motivated or unable to adhere to the sampling scheme due to being in settings (eg, working in the hospital) where using a phone every 2 hours was infeasible. Even though the profile of the FOODLOOP participants is skewed toward higher-educated, urban, health-conscious, active women, therewith limiting the generalizability of our findings to the broader Dutch or millennial population, the profile of our participants aligns with the group most engaged in the snackification trend [112]. Future studies are needed to explore whether the findings can be replicated in more balanced samples by including more men, lower-educated people, people living in more rural areas, and those with lower health interests and activity levels.

Second, sociodemographic and lifestyle variables were measured once at the beginning of the study and were therefore treated as static features in our analyses. However, some of these variables are susceptible to change over time (change in weight, meal patterns and diets, household composition, daily occupation, etc). Such changes were not accounted for during the data collection and might have influenced outcomes concerning the relation between snacking frequencies and sociodemographic and lifestyle variables. Furthermore, residual confounding by unmeasured sociodemographic and lifestyle variables cannot be excluded. Future longitudinal studies exploring the relation of sociodemographic and lifestyle variables with snacking should measure these variables at multiple moments during the data collection to account for possible changes over time and to enable analyses of how changes in these variables affect snacking behaviors.

Third, our findings should also be interpreted in light of the broader postpandemic context in which they took place (2022 - 2023). Even though data collection did not prevail during the COVID-19 pandemic, several behavioral changes that may have emerged during the pandemic (eg, remote and hybrid working, different daily routines, more time spent at home than before) could have persisted into FOODLOOP data collection periods. This might have altered participants' snacking situations and partly explain some of our findings, such as more snacking in general, as well as more home-based and healthful snacking [71-77,113,114]. Future research could examine whether these snacking behaviors are short-term postpandemic adaptations or reflect more stable long-term snacking behavioral changes.

Finally, this study explored a selection of determinants in snacking situations, due to which the generalizability of our findings to other determinants is limited, similar to the study of Verain et al [29]. Capturing snacking situations in their entirety is challenging, given the number of determinants playing a role in real-world snacking situations and the complexity of the interrelatedness of these determinants. However, many of the main determinants in snacking situations [29,115,116] were included in our analyses. The determinants that were not

XSL•FO
RenderX

measured (eg, satisfaction with snack choice, activities executed during snacking, and participant's mood) might constitute interesting topics of exploration for future snacking-related studies.

Implications and Conclusion

Despite the limitations, the FOODLOOP study offers empirical insights into Dutch millennial consumers' real-world snacking behaviors and how multiple situational determinants relate to these behaviors over a longer time period. FOODLOOP shows that snacking is a multifaceted situational behavior, where a comprehensive combination of product-, context-, and consumer-specific determinants plays a role. Confirming the expectations guiding our work, snacking occurs frequently and varies both across and within contexts, including the 4 seasons. This suggests that snacking is not restricted to specific products, motives, locations, social settings, or times, including anything can be a snack, consumed for any reason, anywhere, with anyone, and at any time, congruent with the snackification trend.

The contributions of our findings to research are 2-fold. First, the substantive insights into situational variances in Dutch millennials' real-world snacking behaviors extend prior work on snacking and highlight the importance of its multidimensional nature. Our findings encourage future work to explore situational snacking behaviors across other age groups and cultural contexts and to further investigate interactions between situational determinants, including FCMs, seasonality, and meteorological factors. Future studies may also build on our findings to explore consumers' perceptions and definitions of snacking, factors influencing interindividual variations in definitions of snacking, and the role of beverages as standalone snacks. Second, the methodological experiences could inspire future research on consumers' snacking and other dietary behaviors. FOODLOOP demonstrates the value of using a mobile app based on EMA to study longitudinal, real-world dietary behaviors. The data collection structure, app programming, measure design, and participant communication provide a methodological framework that can be adopted and further refined in future studies on situational snacking and other dietary behaviors.

Beyond research, our findings also have practical relevance. The real-world situational snacking insights gained in FOODLOOP through EMA could support health professionals, nutrition experts, and policymakers in designing more effective and realistic, tailored interventions (eg, campaigns, guidelines, and public health strategies) aimed at encouraging healthier snacking patterns by targeting specific snacking occasions (locations, social settings, moments, and motives) to intervene in the critical moments of situations that are associated with more snacking. Furthermore, our results could inform the development of mobile app–based dietary tools in more effectively guiding healthier snacking choices. For instance, our insights could be used to create context-sensitive features, such as timed prompts and personalized nudges providing healthier snacking options that are suitable for a given context (eg, home alone in the afternoon) and that match users' snacking motives in such situations (eg, convenience, hunger and thirst, and liking).

Overall, the FOODLOOP study underscores the importance of considering snacking as multidimensional and situational behavior within the growing snackification trend. Our insights provide guidance for research and practice in developing more targeted, context-sensitive approaches and interventions that deepen the understanding of snacking and support healthier snacking behaviors.

Acknowledgments

We would like to thank Desiree Lucassen, Edith Feskens, Hanne de Jong, and Arvind Datadien (Wageningen University & Research [WUR]) for providing the Traqq app for usage in the FOODLOOP study. Furthermore, we thank Wouter Rosekrans and Paul Peeters (Voedingscentrum) for their aid in sampling and consultation. We would also like to thank Laura König (University of Bayreuth) and Daniel Gatica-Perez (EPFL, Idiap) for advice concerning the study set-up, Stefan Wahlen (Giessen University) for help with the validation of the translation of the Dutch 1-scale-per-item Eating Motivation Survey, Noanne Pinkert (WUR) for help with the data collection, Luc Scheepens (TU/e) and Zihao Wang (EPFL) for help with data pre-processing, and Jarl Kampen (WUR) for consultation concerning the data analysis. Finally, we thank the FOODLOOP participants for their dedication and participation throughout the year of data collection.

Abstract

Background: Work-related stress has been widely associated with an increased risk of various mental disorders and poor mental well-being. The fast-growing mobile health services industry has provided new opportunities for workplace mental health.

Objective: This randomized controlled trial examined the effectiveness of *Neurum* (Neurum Limited), a smartphone-based intervention tool featuring ecological momentary assessments and interventions that aims to reduce workplace stress in real-time and real-world settings.

Methods: A total of 201 working adults were recruited for a 4-week smartphone-based intervention that incorporated cognitive behavioral therapy, mindfulness exercises, and self-regulation exercises delivered on *Neurum*. A simple randomization procedure was used. Participants in the intervention group were encouraged to log mood journals, complete mental health exercises, and provide user feedback whenever applicable. The key outcome was measured by the Depression, Anxiety, and Stress Scale-21 items (DASS-21; Cronbach α=0.87).

Results: The intervention group consisted of 102 participants, while the control group consisted of 99 participants. More participants dropped out from the intervention group (n=21) than from the control group (n=2; χ^2_1=18.259; *P*<.001). The final sample consisted of 178 participants (male: 85/178, 47.8%; female: 93/178, 52.2%; mean age of 34.65, SD 7.67 y). Analyses revealed that after the 4-week intervention, the DASS-21 scores decreased in the intervention group (mean difference [MD]$_{\text{post-pre intervention}}$=−14.518) but increased in the control group (MD$_{\text{post-pre intervention}}$=3.319; $F_{1,176}$=59.358, *P*<.001; η^2=0.252). This effect was largely led by stress reduction ($F_{1,176}$=64.679, *P*<.001; for the intervention group, MD$_{\text{post-pre intervention}}$=−6.692, while for the control group, MD$_{\text{post-pre intervention}}$=2.000). On average, participants completed 6.27 (SD 9.4) exercises and provided 9.74 (SD 18.2) mood journal logs, with a daily engagement of 4.95 (SD 6.89) minutes. However, the associations between the changes in DASS-21 scores and the numbers of exercises or mood journal logs did not reach statistical significance.

Conclusions: This study primarily established the effectiveness of *Neurum* in alleviating depression, anxiety, and stress symptoms in noninstitutionalized working adults, with a satisfactory user retention rate. Despite potential health-related culture differences, *Neurum* contributed to evidence-based digital health in nonclinical settings for timely needs and general accessibility as an alternative to traditional, face-to-face, and high-cost mental health services. Future directions involving a personalized approach in online mental health services were discussed.

Introduction

Background

While the working population is the driving force of the global economy, common mental disorders (ie, depression and anxiety) alone have cost US $1 trillion each year due to the loss of productivity [1,2]. Pharmacotherapies, psychotherapies, or a combination of both are the primary approaches in managing the symptoms of common mental disorders [3-5]. However, suboptimal service use exists to hinder the influence of the mental health care system [6,7]. The poor mental health service use suggested an immense service gap that might not sufficiently or appropriately support the needs of individuals with mental health difficulties. Against this backdrop, it has become essential to further explore accessible, affordable, and effective alternatives to existing mental health care services for the working population.

Longitudinal studies have demonstrated that work-related stress—such as excessive workload, effort-reward imbalance, and low work social support—is associated with increased risks of depression and anxiety disorders and poor mental well-being [8-11]. Despite a large investment in mental health services and their significant effectiveness, the cost of maintaining these face-to-face interventions is high and often challenging, steering the research direction towards identifying low-cost, evidence-based strategies to optimize intervention cost-efficiency [12-18]. Worse yet, the COVID-19 pandemic has further threatened the mental health landscape of working adults by impacting individuals' job security, chronic isolation, and uncertainty about the future, as well as adding constraints to traditional face-to-face intervention options [19]. Most of the existing interventions are limited in reaching out to those in need during a pandemic situation, increasing the risk and prevalence of mental ill health [19-22]. This limitation also applies to long-existing underuse issues of mental health services, especially in Asian countries [23,24]. For illustration, previous research in China revealed that only 24% of the participants who were diagnosed with moderate or severe mental health problems sought help from mental health professionals [25]. Reasons included issues such as health service accessibility and costs, as well as associated mental health stigmas. Therefore, mobile health (mHealth) seems a practical approach to improve the low rate of health-seeking behaviors given its advantages of being low cost, easily accessible, and stigma-free. Therefore, attention has increasingly shifted toward digital approaches as a feasible and scalable alternative.

A recent randomized controlled trial (RCT) showed that web-based mindfulness and cognitive behavioral training were efficacious in alleviating psychological distress among college students and young working adults [26]. Several meta-analyses suggested that web-, application-, and/or computer-based interventions were effective in alleviating depression, anxiety, and stress, though with undeniably concerning attrition rates ranging widely from 43% to 99% [27-31]. Taken together, these findings pointed out the effectiveness of internet-based psychological interventions while urging further refinement of their user retention especially for long-term benefits. In addition to internet-based interventions, mHealth platforms that adopt mobile and wireless devices to improve health care also appear promising [32]. Not only has mHealth long been used in physical health care, such as for diabetes management, infectious disease management, and immunization management, increasing application of mHealth to mental health also has emerged, ranging from alcohol and substance use assessment to low-intensity interventions for mental disorders [33-38]. Despite the enlightening trend, less than 5% of the mHealth platforms underwent peer-reviewed research, while the majority of these were conducted in western countries [39,40]. Peer-reviewed, demographically diverse research awaits attention.

Advancements, availability, and affordability of mobile technology have given rise to ecological momentary assessment (EMA), which allows individuals to report experiences and behaviors in everyday lives and in naturalistic settings [41,42]. The rationale for using EMA rests upon 3 major advantages including reducing retrospective recall, improving generalizability and ecological validity, and enabling the exploration of temporal relationships among variables. Similarly, ecological momentary intervention (EMI) refers to the delivery of intervention while individuals are naturally engaged in their everyday lives [43,44]. Emerging evidence suggested the effectiveness of EMI in alleviating anxiety and stress and treating a variety of health behaviors and psychological symptoms [44,45]. However, RCTs of EMA and EMI in mental health promotion remained scarce [45]—and their application in workplace mental health services is even more limited. This is noteworthy given that both approaches could offer unique benefits to working adults, as they deliver mental health care services free from temporal and spatial constraints. Therefore, this gap underscores the need for rigorous investigation of EMA- and EMI-based mHealth tools, particularly in workplace populations and non-Western contexts.

Objectives

To address this gap, this preregistered RCT was designed to evaluate the effectiveness of a smartphone-based intervention (ie, the *Neurum* app; Neurum Limited) that leverages both EMA and EMI in reducing workplace stress [46]. Study hypotheses and corresponding analytical schemes were preregistered in September 2020 (registration reference: osf.io/z829u) before the data collection was finished. No statistical analysis was done before the preregistration or the completion of data collection. Specifically, it was hypothesized that participants who received intervention through the *Neurum* app would display better workplace stress management and mental health improvement as reflected by the reduction in depression, anxiety, and/or stress symptoms. The design, conduct, and reporting of this study followed the CONSORT-EHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and Online Telehealth) guidelines (Checklist 1).

Methods

Participants

This study was a 2 (between: intervention vs waitlist control groups) × 2 (within: premeasures vs postmeasures) mixed factorial design. A priori power analysis using *F* test family

XSL•FO
RenderX

(repeated measures, between factors) in *G*Power* was conducted [47]. Assuming a small effect size (ie, f=0.25) and a high correlation between premeasures and postmeasures of the outcome variable (ie, r=.85), with an α level of .05, a total number of 196 participants was needed to achieve a power of 0.80. Assuming an attrition rate of 25%, a sample of 262 participants was determined prior to data collection.

Participant recruitment started in September 2019, Hong Kong SAR. Advertisements were posted on the company websites and populated through themed webinars and offline workshops to reach local working adults. However, due to local social unrest and the COVID-19 pandemic, few signed up within the planned 1-month recruitment period. Therefore, under all authors' and the funding agency's approval, the recruitment process was prolonged until the deemed sample size would be achieved. The recruitment process lasted for over a year and was finally terminated by the end of October 2020, when nearly no more participants signed up within 30 days. To maximize the sample size, those who signed up and passed the screening immediately underwent the intervention process. However, no data analysis was conducted before the end of the study. In total, 201 working adults were recruited from a selected list of local companies, who were first directed to an online survey with screening questions, in which they reported their demographic and mental health information. A research assistant who remained unaware of the study design was in charge of the eligibility screening. Specifically, participants were eligible if they (1) were aged 18 years or older at sample recruitment, (2) had access to the internet and a smartphone, and (3) were not diagnosed with major mental disorders. Exclusion criteria included (1) mental illness diagnosis history, (2) current reception of professional mental health services, or (3) current use of psychotropic medication.

Ethical Considerations

Ethical approval was obtained from the Subcommittee on Research Ethics and Safety of the Research Committee of Lingnan University (reference: EC047/2021). All procedures contributing to this work complied with the ethical standards of the relevant national and institutional committees on human study. Informed consent was obtained via electronic signatures indicating the awareness of the study procedure, potential risks and benefits, data confidentiality, and the right to quit the study at any time. Data were encrypted and stored in a financial-sector security level server and deidentified before statistical analysis. No incentives or compensations were provided.

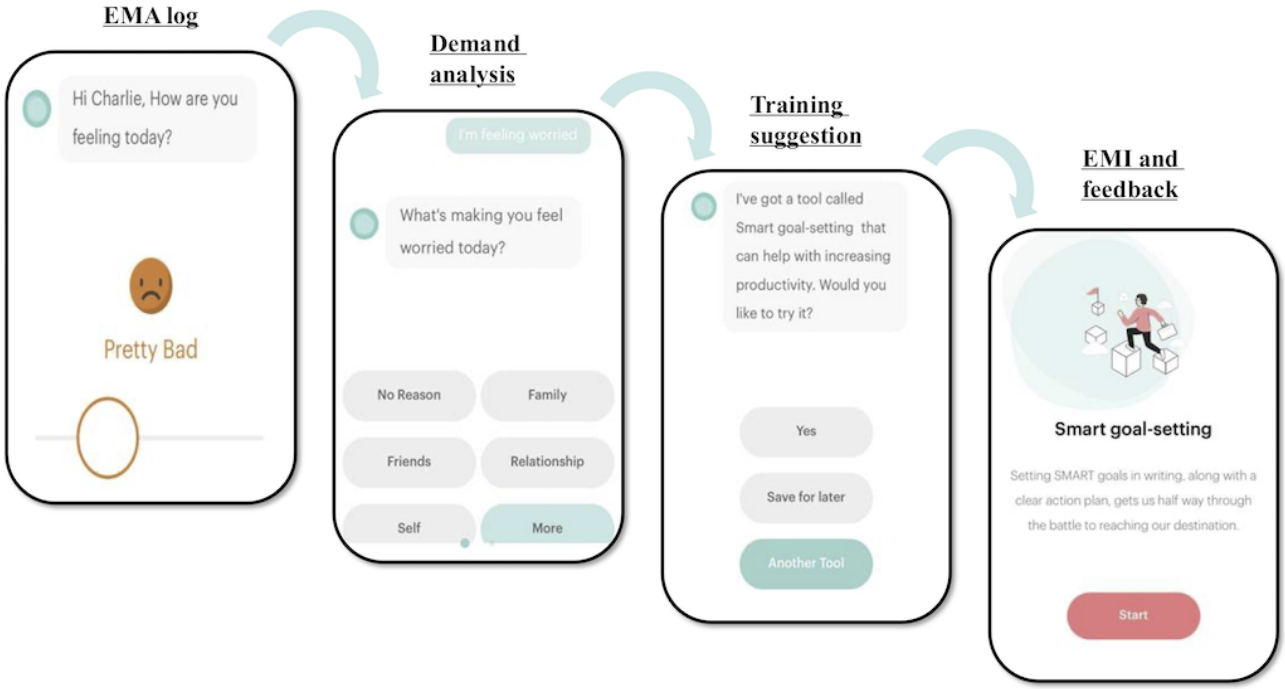
Procedure

All procedures were delivered via *Neurum*. Included participants first completed the preintervention assessment, and then they were randomly allocated at a 1:1 ratio to the two groups via a computer algorithm of simple randomization. Specifically, a numerical value between 0 and 1 was assigned to each participant. Those who received a value smaller than 0.5 were assigned to the control group; otherwise, participants were assigned to the intervention group. Double blindness was achieved such that a research assistant who remained unaware of the study design was in charge of the participant assignment, while participants received a unique study ID in a singular format that revealed no group information, and therefore, remained unaware of the grouping. Then, participants in the intervention group received EMA and EMI via *Neurum* for 4 weeks, while those in the waitlist control group were offered the intervention after the RCT was completed. Finally, all participants completed a postintervention assessment with debrief at the end of the trial (ie, after the designated 4-week intervention [or control] duration).

Intervention

Neurum is a smartphone app that comprises self-managed mental health modules designed in various combinations of (1) featured techniques, namely cognitive behavioral therapy, mindfulness exercises, and self-regulation skills with (2) various session formats including informational (ie, psychoeducation), evaluative (ie, assessment), and applicable (ie, exercise), aiming at (3) tangible goals in alignment with the biopsychosocial model, namely the improvement and maintenance of biological, psychological, and social health. See Table 1 for a summary of the different components and the rationale.

Table . *Neurum* intervention framework and module examples.



Example module	Featured technique	Format		
		Psychoeducation	Assessment	Exercise
Biological				✓
Acupressure	Self-regulation			✓
Sleep quality	Mindfulness	✓		✓
Psychological				
Focus timer	Self-regulation			✓
Managing stress	Cognitive-behavioral therapy	✓	✓	✓
Sustaining happiness	Mindfulness	✓		✓
Social				
Workplace boundaries	Self-regulation	✓	✓	✓

XSL•FO
RenderX

Neurum is designed with an instant messenger–like user interface where users interact with the virtual app assistant in a conversation format. The palatability of the dialogues was ensured by using layman and local terms in either English or Chinese. The app content was developed with standard app development iterations that involved digitizing of modules based on previously validated mental health education and behavioral changing paradigms, and then user testing with an A/B test method to compare the performance of 2 versions of content. This study describes the foundation of the app, which matches users to an EMI based on information from their EMA via a combination of supervised learning models, but future iterations of *Neurum* involved personalization of EMI modules based on nuances from EMA, session feedback, and other baseline user data via a more complex deep learning algorithm. As part of the safeguarding protocol, a referral mechanism is established, such that users who score past a certain threshold in their levels of psychological distress are automatically referred to crisis management protocol, which involves the algorithm providing the user with immediate support via distress reduction modules, crisis hotlines, and face-to-face care delivered by a licensed, on-board clinical psychologist. No adverse events were reported during the study.

EMA is delivered such that users are invited to complete a mood journal on *Neurum* to log their instant emotions, thoughts, and behaviors relevant to workplace stress as well as other psychological distress whenever they feel in need. Users evaluate their general feelings along a negative-to-positive continuum, specify a specific experience they would like to work on, and then identify one or more associated stressors. EMI is delivered such that, upon EMA logs, *Neurum* would make a recommendation to relevant, evidence-based intervention modules based on an immediate matching of the current demand and available training tools using a self-developed, built-in supervised machine learning algorithm. User feedback is further collected after each training session, which also informs the algorithm. A daily summary of the reported mood experiences and taken exercises was provided for self-monitoring of workplace stress and management performance. See Figure 1 for the overview of *Neurum*'s EMA or EMI workflow.

Figure 1. Illustration of ecological momentary assessment (EMA) and ecological momentary intervention (EMI) workflow on the Neurum (Neurum Limited) app.

Measures

Depression, Anxiety, and Stress

Key outcomes, namely the intervention effectiveness, were evaluated by comparing the prescores and postscores of the Depression, Anxiety, and Stress Scale-21 items (DASS-21) [48]. Participants rated the extent to which they experienced depression, anxiety, and stress symptoms (7 items for each dimension; eg, "I was worried about situations in which I might panic") on a 4-point scale (0="Did not apply to me at all" to 3="Applied to me very much or most of the time"). Sum scores were computed for the 3 subdimensions as well as the total scores such that higher scores reflected more severe symptoms. The adopted Chinese version of the DASS-21 exhibited satisfactory psychometric properties (Cronbach $\alpha \geq 0.80$) [49]. Cronbach α in this study was 0.87.

Mood Journal

Participants in the intervention group were invited to report, every time they logged in, on (1) how they were feeling in general; (2) whether they were feeling any specific emotion, such as happy or disappointed; and if yes, (3) the source of emotion such as family, work, or friends.

User Activity

User activity was measured by the number of mood journals completed and exercise sessions taken, as well as daily user engagement (in min).

XSL•FO
RenderX

Other Measures

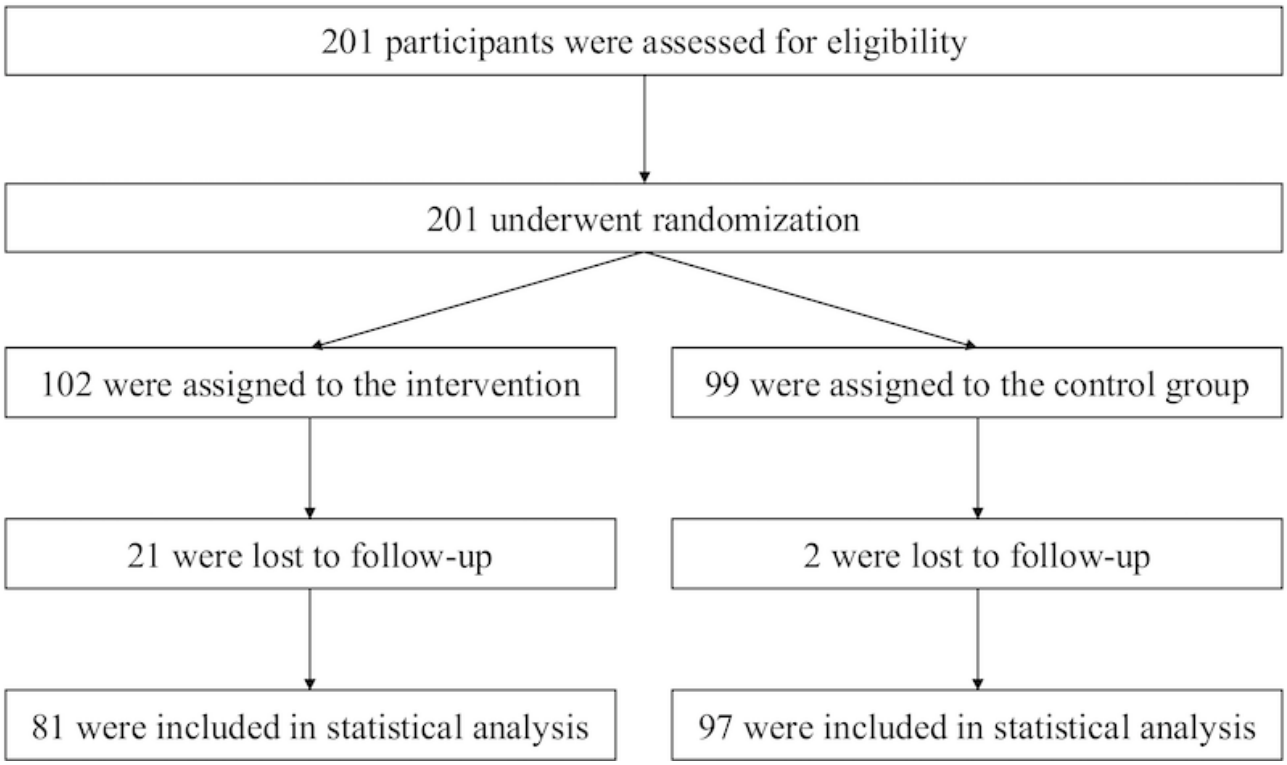
At baseline, participants provided demographic information including sex, age, and marital status.

Analytical Scheme

To examine the intervention effect, pre– and post–DASS-21 scores of the intervention and control groups were submitted to a 2 (between: intervention vs control groups) × 2 (within: premeasures vs postmeasures) mixed ANOVA. Additional analyses included categorical demographic characteristics (namely sex, education, and marital status; Table 2) as control variables. A supplementary set of mixed ANOVA was conducted to compare intensity level changes for each symptom. Finally, 2 multiple linear regressions with a number of mood journals and exercise sessions completed were conducted to explore any dose-response effect.

Table . Demographic characteristics and baseline Depression, Anxiety, and Stress Scale-21 items (DASS-21) scores for each group.

Characteristics	Control group (n=97)	Intervention group (n=81)
Age (y), mean (SD)	34.65 (7.67)	36.43 (12.84)
Sex, n (%)		
Female	51 (53)	42 (52)
Male	46 (47)	39 (48)
Education, n (%)		
High school	5 (5)	8 (10)
Bachelor’s degree	64 (66)	48 (59)
Master’s degree	0 (0)	18 (22)
PhD or above	6 (6)	3 (4)
Prefer not to tell	22 (23)	4 (5)
Marital status, n (%)		
Single	54 (56)	40 (49)
Married	33 (34)	38 (47)
Divorced	7 (7)	2 (2)
Separated	3 (3)	0 (0)
Prefer not to tell	0 (0)	1 (1)



Results

Sample Characteristics

Figure 2 shows the participant flow diagram. Demographic characteristics are summarized in Table 2. The majority of study participants were females, had bachelor’s degrees, and were single in terms of marital status. Though the overall attrition rate was low (23/201, 11.4%), there were significantly more participants dropped from the intervention group (n=21) than from the control group (n=2; χ^2_1=18.259; P<.001), resulting in 81 participants in the intervention group and 97 in the control group. Considering the intensive EMA or EMI procedures, the differential attrition rates between the 2 groups were not surprising. More importantly, the final sample consisted of 178 working adults and was still sufficient in statistical power.

XSL•FO
RenderX

Figure 2. Participant flow diagram.

User Activity

On average, participants in the intervention group provided 9.74 (SD 18.2; maximum=130) mood journals and completed 6.27 (SD 9.4; maximum=51) exercises, while neither was correlated to preintervention DASS-21 scores ($|r|$s ≤.156; Ps≥.16), and neither was predicted by sex (t_{79}s≤0.744; Ps≥.46), education level ($F_{3,\ 73}$s≤1.947; Ps≥.13), or marital status ($F_{2,\ 77}$s≤2.002, Ps≥.14). Daily user engagement on average was 4.95 (SD 6.89; maximum=30) minutes, which was positively correlated with preintervention stress scores (r=0.233; P=.002) and total DASS-21 scores (r=0.175; P=.02), but was not predicted by sex (t_{78}=0.791; P=.22), educational level ($F_{3,\ 73}$=1.595; P=.20), or marital status ($F_{2,\ 76}$=0.100; P=.91).

Intervention Effects

Preintervention and postintervention DASS-21 scores, as well as the mean differences, are presented in Table 3. Mixed ANOVAs were applied to compare the pre– and post–DASS-21 total and subscale scores between groups (Table 4). For the total score, equal variance between groups was satisfied (Levene statistics ≤2.127; P≥.15). Results revealed that there was no significant difference between the intervention (mean difference [MD]=21.990) and the control (MD=21.852) groups; but as expected, there was a significant postintervention decrease ($MD_{preintervention}$=24.721 and $MD_{postintervention}$=19.121). More importantly, the above effects were quantified by a significant, large-effect size interaction between time and group (Figure 3A) such that the DASS-21 total scores decreased for the intervention group ($MD_{preintervention}$=29.111 and $MD_{postintervention}$=14.593) but increased for the control group ($MD_{preintervention}$=20.330 and $MD_{postintervention}$=23.649). Similar patterns (Figure 3B-D) were found for the three symptoms such that average scores notably decreased for the intervention group but slightly increased for the control group ($F_{1,\ 176}$s≥22.689, Ps<.001), with the strongest effect observed in the stress symptom.

Table . Preintervention and postintervention scores and mean differences between groups ($n_{control}$=97 and $n_{intervention}$=81).

Variable	Preintervention, mean (SD)		Postintervention, mean (SD)		Mean difference[a]	
	Control	Intervention	Control	Intervention	Control	Intervention
Depression	6.866 (6.843)	8.938 (7.417)	7.588 (7.071)	4.691 (7.015)	0.722	−4.247
Anxiety	5.361 (6.289)	7.185 (5.812)	5.959 (5.752)	3.605 (4.398)	0.598	−3.580
Stress	8.103 (7.248)	12.988 (7.76)	10.103 (7.796)	6.296 (6.520)	2.000	−6.692
Total	20.33 (16.283)	29.111 (17.975)	23.649 (16.857)	14.593 (15.174)	3.319	−14.518

[a]Mean differences are computed as postintervention minus preintervention scores.

Figure 3. Preintervention and postintervention Depression, Anxiety, and Stress Scale-21 items (DASS-21) results including (A) total score and (B) depression, (C) anxiety, and (D) stress subdimensional scores between intervention and control groups. Error bars represent 95% CIs.

Supplementary Analyses

A set of supplementary models found similar patterns controlling for sex, education, and marital status (for condition effects, $F_{1, 146}$s≤1.601, *P*s≥.21, η^2≤0.011; for time effects, $F_{1, 146}$s≥2.933, *P*s≤.09, η^2≥0.020; for interaction effects $F_{1, 146}$s≥19.286, *P*s≤.001, η^2≥0.117), suggesting that the above intervention effects held after controlling for these demographic covariates.

Another set of supplementary models (Table 5) found similar patterns using DASS-21 symptom intensity levels as the outcome variables. Change(s) of these intensity levels suggested that the control group ascended while the intervention group descended in symptom severity (χ^2_2s≥ 8.605; *P*s≤.02). Finally, and surprisingly, a final set of supplementary models (Table 6) using multiple linear regressions revealed that none of the exercise session number, mood journal number, or average daily engagement predicted the postintervention DASS-21 scores.

Table . Intensity level changes between groups ($n_{control}$=97 and $n_{intervention}$=81)[a].

	Intensity level change			Chi-square (*df*)	*P* value
	Worsen, n (%)	No change, n (%)	Improved, n (%)		
Depression					
Control	17 (18)	64 (66)	16 (16)	8.605 (2)	.02
Intervention	9 (11)	44 (54)	28 (35)		
Anxiety					
Control	21 (22)	67 (69)	9 (9)	27.581 (2)	<.001
Intervention	5 (6)	43 (53)	33 (41)		
Stress					
Control	19 (20)	72 (74)	6 (6)	23.404 (2)	<.001
Intervention	4 (5)	52 (64)	25 (31)

[a]For model 1, adjusted R^2=0.068, $F_{1,78}$=5.731, P=.02; and for model 2, adjusted R^2=0.097, $F_{1,72}$=0.777, P=.51.

[b]For model 1, adjusted R^2=0.080, $F_{1,78}$=7.855, P=.006; and for model 2, adjusted R^2=0.049, $F_{1,72}$=0.162, P=.92.

[c]For model 1, adjusted R^2=0.091, $F_{1,78}$=8.866, P=.004; and for model 2, adjusted R^2=0.076, $F_{1,72}$=0.601, P=.62.

[d]For model 1, adjusted R^2=0.045, $F_{1,78}$=4.762, P=.03; and for model 2, adjusted R^2=0.067, $F_{1,72}$=1.593, P=.20.

Discussion

Overview

This RCT examined the effectiveness of a smartphone-based EMA or EMI mental health care services delivered by the *Neurum* app in mitigating workplace stress and improving mental health for working adults in Hong Kong SAR, China. Consistent with the hypotheses, results demonstrated that the approach was effective in reducing psychological distress after 4 weeks of intervention, suggesting that the EMA or EMI approach via the *Neurum* app could support working adults' stress management in real time and in naturalistic settings.

Principal Findings

This study demonstrated the effectiveness of integrating EMA or EMI techniques with supervised machine learning algorithms in digital mental health care for a nonclinical population. The findings were broadly compatible with previous studies supporting the effectiveness of mHealth tools in reducing general anxiety, various stress, and depression symptoms [45,50]. Importantly, the effectiveness of *Neurum* was supported not only by the continuous reduction of psychological symptoms but also by the shifts in symptom intensity levels, suggesting potential use that extends from non–clinical contexts into early-stage clinical applications. One well-known advantage of the ecological momentary approach is its ability to minimize retrospective bias and enhance event trigger monitoring. Previous research has highlighted the promise of such digital phenotyping for routine clinical assessment, particularly for early onset or relapse [51]. Our observed changes in categorical symptom intensity levels further supported this clinical relevance, indicating that symptom improvement was substantial enough to cross the established cutoff thresholds. Because categorical severity shifts could provide a more interpretable indicator of treatment effectiveness than numerical score changes alone, these findings underscore the potential of EMA or EMI-based mHealth tools for early identification, timely intervention, and preventative health care in mental health. Additionally, previous meta-analyses research revealed that multicomponent intervention was tentatively more effective than single-component ones (eg, with cognitive behavioral therapy alone), and that patient preferences for specific intervention components played a pivotal role in treatment outcomes [52,53]. In response to these challenges, the intervention delivered in *Neurum* integrated multiple modules in various delivery formats for actionable outcomes, enabling participants to decide whether and which exercises to engage in upon each log-in. This inclusive design undoubtedly promoted user retention and engagement and maximized the alignment between individual needs and intervention content, a pattern supported by our user activity data. Taken together, these novel findings highlighted the importance of developing scalable, personalized mHealth tools as accessible, affordable, and flexible alternatives to face-to-face mental health care services.

There were several important issues in the interpretation of results. First of all, more participants dropped out of the intervention group than from the control group. It is noteworthy that the overall dropout did not exceed the predetermined attrition rate for power analysis. It is also noteworthy that the current attrition rate (ie, 11.4%) was smaller than those reported in previous studies (eg, about 26% for cognitive behavioral therapy and about 19% for mindfulness-based traditional interventions, or widely ranging from 43% to 99% for general digital health interventions [27-31,54-56]). Despite this, authors speculated the presence of some exposure effects particularly for the intervention group. Specifically, EMA or EMI required participants to review their mood swings on a daily basis, to exert efforts in managing especially those negative daily experiences, and to review their own performances on the taken exercises. Compared to those assigned to the control groups, these tasks might make the mental health issues more evident than they used to be (namely, before participating in this study) for the intervention group, possibly resulting in a withdrawal from treatment effect frequently observed in traditional psychotherapies [57]. Regrettably, the current design did not include relevant measures to test this speculation. However, to improve its future retention, the intervention could benefit from including methods to cope with the aforementioned exposure effect in the onboarding stage. Meanwhile, a personalized approach that maps personal needs with module recommendations can also improve user retention and performance. In fact, future iterations of *Neurum* have involved personalization of EMI modules based on nuances from EMA, session feedback, and other baseline user data via a more complex deep learning algorithm. Second, the results somewhat failed to support the association between the number of completed exercises or mood journals with DASS-21 score changes. In other words, the underlying dose-response effect remained unclear. One possible reason was that participants were only *encouraged* but not forced to report their daily mood journals or to take exercises. Granted that it strategically maximized participants' acceptance and adherence [58], it undeniably resulted in the limitation of a relatively low daily response rate, and subsequently, the lack of statistical power to reveal the targeted dose-response effect, if any. Therefore, future studies might consider assigning a compulsory number of daily responses to unveil potential underlying mechanisms. Despite this, the current intervention effects could be a result of the improved awareness of one's own mental health status and consequently improved proactive mental health management effort, or an effect generalized from in-app exercises to realistic life scenarios.

This study also contributes to the relatively nascent field of mHealth research, typically the application of EMA or EMI, in Asian countries [40]. Though with a rapid growth and a wide application, empirical supports of EMA or EMI for mental health were mostly from the United States and European countries (eg, Germany and the Netherlands), with the only exception being a study involving Chinese participants with mild-moderate depression [59-61]. However, western-based mHealth apps were not necessarily applicable to eastern ones [62]. The common mHealth apps in Asian contexts have remained in psychoeducation, counseling services, and self-assessment tools [40,63], while this study expanded them by leveraging the more intense EMA or EMI approach. Furthermore, *Neurum* takes health equity and cultural adaptivity into consideration by offering multiple language versions (viz, both traditional and simplified Chinese, English, Filipino, and Hindi) to serve local people with different cultural backgrounds. Though ethnicity was not collected in this investigation, the recruitment process was indeed carried out in international enterprises in Hong Kong, SAR. Finally, this study expanded the use of EMA or EMI beyond clinical settings to community populations, which broadened the spectrum of the recipients of such digital health care services. While some digital health tools can be used by patient populations to clinically reduce their depression and/or anxiety, this must be differentiated from digital health tools that are meant to reduce these symptoms in a non–clinical population. The demonstrated effectiveness of *Neurum* is similar to other well-being and mindfulness apps,

XSL•FO
RenderX

such as *Calm* and *Headspace* [64-66]. Furthermore, the function of these digital health platforms and the reduction in mental health symptoms are similar to those of other non–clinical interventions like yoga [67]. The wellness technology industry has been growing exponentially with app-based options that are not designed to replace clinical treatment altogether, but to offer complementary early intervention tools, or as alternative options for those that struggle to access in-person care. Relatedly, *Neurum* essentially represents a shift from disease-centered to health-centered, proactive mental health approach. EMA or EMI, combined with diverse delivery formats (namely, informational, evaluative, and practical), comprehensively supports a proactive mental health management system by addressing foundational mental health literacy, enabling timely monitoring, fostering essential skills, and promoting sustained actions. Such a shift of medical models for mental health corroborates the notion of prevention over treatment, as globally advocated by many governmental and regional health policies [68-71].

Limitations

This study has several limitations. First, despite the authors' effort to recruit participants and maintain their engagement during the local social unrest and the COVID-19 pandemic, the final sample size was still slightly smaller than expected. However, the effect size of mixed ANOVA was large, supporting the effectiveness of the intervention. Second, even though *Neurum* was designed with multiple languages, ethnicity information was not collected, which precluded the possibility of examining cultural differences, if any. Factors such as mental health beliefs, perceptions, and literacy should merit future research attention to improve the generalizability of *Neurum* in other cultures [72,73]. Third, while the attrition rate of the current study was low, local RCTs on web-based and application-based mental health programs suggested that personalized feedback might mitigate the high attrition rates typically in internet-based programs [26,74]. Indeed, several lines of evidence demonstrated the benefits of personalized intervention including better intervention outcomes, stronger subject adherence, and more persuasive feedback, in both physical and mental health domains [62,75-78]. As such, *Neurum* could be further advanced by incorporating the personalized intervention approach based on computational algorithms of the EMA or EMI data. Finally, the results of this study did not reveal a dose-response relationship between the reductions in psychological symptoms and the number of EMI sessions completed. A requirement of minimum sessions in the future can help examine the potential dose-response effect and better understand the intervention's effectiveness.

Conclusions

In sum, this RCT supported that *Neurum*, a new mHealth intervention that coupled the ecological momentary approach with supervised machine learning algorithms, could effectively reduce workplace stress and psychological distress in working adults. Beyond establishing its efficacy, the findings also highlight the potential of day-to-day, context-sensitive data to deepen the understanding of how EMA or EMI functions within digital psychological interventions. By introducing inclusive design and diverse user groups, this work further underscores the importance of equity and cultural relevance in the next generation of digital mental health care. Together, these insights highlight the promise of adaptive, data-driven mHealth tools in expanding the access to effective psychological support across different populations and in real-time and real-world settings.

Acknowledgments

The authors would like to express their sincere appreciation for the participants' devotion. No generative artificial intelligence was used in any portion of the manuscript writing.

Funding

This study was funded by the Research Grants Council of Hong Kong, SAR, to MC (reference: 17601421).

Data Availability

Anonymized data would be available upon appropriate requests towards the corresponding author.

Editorial Notice

This randomized study was only retrospectively registered. The editor granted an exception from ICMJE rules mandating prospective registration of randomized trials, because the risk of bias appears low with a record of the protocol available publicly prior to the end of enrolment. However, readers are advised to carefully assess the validity of any potential explicit or implicit claims related to primary outcomes or effectiveness, as retrospective registration does not prevent authors from changing their outcome measures retrospectively.

Abstract

Background: Traditional clinical assessments in psychiatric research or clinical practice rely on global retrospective self-report depression measures, which do not adequately capture intra- and interindividual variability in depressive symptoms over time and across contexts.

Objective: This study aimed to (1) assess the sensitivity of mobile ecological momentary assessment (EMA) for monitoring depressive symptoms compared with traditional depression scales, (2) investigate changes in depressive symptoms and recall consistency observed between the first week (FW) and the second week (SW), and (3) identify subgroups at higher risk for depression and suicidal ideation, and characterize their sociodemographic, psychological, and psychiatric profiles.

Methods: Participants' self-reports were collected once daily for 14 consecutive days via a mobile app–based EMA to monitor the presence of 20 depressive symptoms based on a 24-hour recall period, thereby capturing naturalistic severity and variability. Baseline questionnaires measured sociodemographic characteristics, digital sensitivity, and personality traits. On day 14, postquestionnaires were administered to assess their clinical symptoms. In addition, modified depression scales were administered on day 7 for 1-week recall, and day 14 for both 1-week and 2-week recalls. For cluster analysis, 3 active EMA-derived features were included: mean symptom severity, within-person symptom variability, and frequency of suicidal ideation.

Results: Generalized Linear Mixed Model analysis (model 1) revealed that traditional 2-week recall explained only 35.5% of the variance in daily symptom presence (odds ratio 0.666, 95% CI 0.659 - 0.674; $P<.001$). Additional Generalized Linear Mixed Model analysis (model 2) identified a robust interaction, indicating that the consistency between weekly retrospective recall and daily EMA differed significantly between FW and SW ($F_{1,\ 81876}=124.550$; $P<.001$). While overall symptom severity scores significantly decreased from FW to SW across both assessment methods (Cohen $d=0.10$ - 0.34; $P<.001$), the estimated mean of the probability of symptom reporting showed a contrasting upward trend from 0.853 to 0.908. In cluster analysis, 695 participants (244 males and 451 females; aged 19 - 73 years, mean 36.14, SD 10.71 years) who completed at least 7 EMA sessions over a 2-week period were classified into three distinct clusters: (1) no or low risk (n=445, 64.0%), (2) moderate risk (n=223, 32.1%), and (3) high risk (n=27, 3.9%). While depressive symptom severity, frequency of suicidal ideation, and psychiatric profiles progressively increased across clusters (cluster 1<2<3), the highest symptom variability was observed in cluster 2 (cluster 1<3<2).

Conclusions: This study demonstrated that mobile EMA effectively reduced recall bias in assessing depressive symptoms and revealed symptom dynamics. Using a minimal set of active EMA-derived features, we differentiated 3 distinct risk clusters; within-person symptom variability emerged as a clinically significant indicator not captured by traditional 2-week recall–based assessments. Despite the brief 2-week assessment period, these findings suggest that mobile EMA may serve as a robust real-world data collection tool.

Introduction

Background

As one of the key symptoms of major depressive disorder (MDD), suicidal ideation is common among patients with MDD. The overall prevalence of suicidal ideation is estimated at 37.7% among patients with MDD [1]. While sustained depressed mood is not associated with lifetime suicidal ideation and suicide attempts, MDD can increase suicide risk regardless of the presence of sustained depressed mood [2]. Therefore, it is crucial to track the changes across all 9 symptoms of major depressive episode (MDE) meeting the *DSM-5* (*Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition) diagnostic criteria for MDD [3] rather than focusing solely on those in mood. Furthermore, depressive symptoms are the only risk factor that can differentiate the high-risk group with suicidal ideation and suicide attempt history from the nonsuicidal group [4]. The trajectory of depression symptoms with the highest mean scores and variability over time can be identified as a predictor of suicide attempts, particularly in young adults [5]. Since suicide is conceptualized as a process or a continuum of suicidal ideation or behaviors developing from mild to severe levels of suicidality among patients with MDD [6], monitoring and treating the day-to-day variations in depression symptoms and self-harm or suicidal ideation may lower the risk of suicidal behaviors. Among patients with MDD, the decline in suicidal ideation is preceded by the alleviation of depressive symptoms [7]. As suicidal ideation in remitted patients with MDD predicts the recurrence of depression, consistently measuring suicidal ideation among individuals with MDD, as well as among those with minimal suicidal ideation at any presentation, can also prevent the worsening of suicidal symptoms and recurrence of depression [8]. In this respect, the severity and variability of depressive symptoms should be measured alongside suicidal thoughts in daily life.

Unlike many previous studies that considered affective dynamics (ie, variability, inertia, and instability) as risk factors for depression [9-12], this study focuses more on the feasibility of identifying digital phenotypes that distinguish homogeneous and distinct subgroups at risk for major depression and suicidal ideation, as well as on developing an evidence-based measurement tool to minimize recall bias and facilitate enhanced recall of current MDE symptoms in everyday life [13,14]. According to the self-schema model of depression based on the concept of organizational breakdown and subsequent restoration to effective processing of schema-compatible information [15,16], nondepressives and clinical depressives with well-organized, efficient cognitive schemas showed higher self-referent yes recall for nondepressed content and depressed content, respectively, when compared with mild depressives in a state of uncertainty and disorganization concerning one's self-schema. In line with this model, it can be postulated that mild depressives appear to contain both positive and negative personal information in their self-schema because they begin to view themselves with depressed (or negative) content although positive information has not yet been completely displaced. In this context, individuals with mild to moderate depression may show greater fluctuations in symptoms due to mixed self-schema representations, making variability a potential marker for identifying subgroups and their profiles. To explore different profiles in the dynamics of depressive symptoms, there is a need to address the limitations of standard depression scales, which rely on summated total scores based not only on classical test theory [17] but also on retrospective recall of symptom frequency over the preceding 2 weeks.

From the findings of previous studies, the issue of recall bias has been highlighted in ratings from traditional depression scales. More individuals reported severe depressive symptoms and higher suicidal ideation via ecological momentary assessment (EMA) than via retrospective self-report measures [18-20]. Moreover, more than half of the participants who reported suicidal ideation via EMA denied even past-week ideation on the scale for suicidal ideation, and the participants reporting suicidal ideation via EMA but not on the scale were just as likely to have a history of suicidal behavior as those reporting suicidal ideation in both formats [21]. In other words, EMA can capture instances of suicidal thoughts that go undetected via retrospective reports, thereby helping to identify at-risk subgroups that would otherwise be missed. Previous studies primarily demonstrated recall bias by comparing the total scores of depressive symptoms calculated from EMA data and those calculated from retrospective methods such as well-established interviewer- or self-administered measures. However, relatively little is known about how the frequency of depressive symptoms collected via EMA differs from that reported through traditional retrospective measures. To tackle these issues, we conducted a preliminary study, developing a self-administered 24-hour recall–based EMA tool to prospectively assess daily MDE symptoms over a 2-week period [13,14]. Specifically, this app uses the mobile version of the standardized Korean Version of the Center for Epidemiologic Studies Depression Scale–Revised (K-CESD-R), in which respondents are asked to report the presence of depressive symptoms within the past 24 hours by answering "yes" or "no" once daily at a self-selected notification time over a 2-week period. Taken together, using smartphone–based EMA technique (hereinafter, mobile EMA or active EMA) may allow for more accurate measurements of within- and between-participants variations in daily depressive symptoms, including self-harm and suicidal ideation, by reducing the recall period for symptom assessment.

Mobile EMA apps can enhance measurement precision and motivate repeated self-observation, thus increasing emotional reactivity and facilitating behavioral change, potentially reducing depressive symptoms [22,23]. Such symptom improvements may occur even without a formal intervention due to assessment reactivity, defined as symptom changes induced by repeated EMA assessments [24]. However, concerns remain that frequent self-monitoring might exacerbate negative affect and depressive symptoms [25,26]. Despite these concerns, previous evidence indicates that digital self-monitoring typically leads to enhanced emotional awareness, symptom reduction, and increased empowerment without triggering negative reactivity [27-29]. Although many studies have demonstrated the feasibility of using mobile EMA to capture moment-to-moment affective dynamics related to depression, relatively few studies have

XSL•FO
RenderX

prospectively monitored MDEs using EMA [11,18]. Moreover, limited research exists on whether repeated self-monitoring itself directly contributes to measurable improvements in depressive symptoms.

Objectives

The objectives of this study are (1) to assess the sensitivity of mobile EMA for monitoring depressive symptoms in daily life compared with traditional depression scales, (2) to investigate changes in depressive symptoms and recall consistency observed between the first week (FW) and the second week (SW), and (3) to identify homogeneous groups of community-dwelling adults at higher risk for depression and suicidal ideation and characterize their sociodemographic, psychological, and psychiatric profiles.

Methods

Study Design

In this study, we used a 2-week observational study design using mobile EMA and traditional retrospective scales. To address objectives 1 and 2, we administered a 24-hour recall–based mobile EMA once daily for 14 days and a modified version of the K-CESD-R in a 1-week recall format on day 7 and day 14, as well as in a 2-week recall format on day 14, reflecting the K-CESD-R reporting frame (“in the past week or so,” including an option reflecting “nearly every day for 2 weeks”). To further address objective 3, we restricted our cluster analysis to active EMA data-driven features (symptom severity, symptom variability, and frequency of suicidal ideation) that could be extracted even if participants did not respond every day during the 2-week study period, given that greater depressive symptom severity might be associated with lower adherence to digital intervention for depression [30].

Participant Recruitment

As a fully decentralized clinical trial, this study was conducted in collaboration with dataSpring Korea, Inc., over an approximately 1-month period from August 16, 2023, to September 18, 2023. A total of 1049 community-dwelling adults were recruited through PanelNow, a proprietary online research panel service operated by dataSpring Korea.

Eligibility and Dropout Criteria

In accordance with the institutional review board (IRB)–approved protocol, potential participants were assessed based on the following inclusion and exclusion criteria. This study required participants to meet all the following inclusion criteria: a person (1) who checks “Agree” on the e-consent form presented at the beginning of the online survey, (2) who is aged 19 years and older, (3) who owns a smartphone registered in their name and is able to install the mobile app used in this study, and (4) whose smartphone operating system meets the minimum requirements to install the app. However, even if all the inclusion criteria are met, people for whom (1) the mobile app is not properly installed and does not work on their smartphones or (2) the app does not run due to unknown errors that occur after completing its installation are not enrolled according to the exclusion criteria.

Participants were considered to have dropped out or were discontinued from the study if they met any of the following criteria: (1) failure to complete all mandatory prequestionnaires within the designated period; (2) never completing a single session after registering for the mobile EMA app; (3) inadequate adherence to the research protocol, defined as completing fewer than 7 out of the 14 scheduled EMA sessions or failing to complete all 3 traditional assessments; (4) providing responses judged to be insincere or unreliable; or (5) expressing a voluntary withdrawal of consent to participate in the study at any point. For participants who withdrew their consent or failed to meet the adherence criteria, all response data were immediately deleted from the server and not used for any analyses, with only basic app account logs and study participation logs retained for the legally mandated period.

Ethical Considerations

To conduct this study, the study protocol was approved by the IRB of Yongin Severance Hospital, Yonsei University College of Medicine (IRB number 9-2023-0122). All participants provided electronic informed consent (e-consent) prior to their involvement in the study. The study information and consent form were presented online via the PanelNow platform and mobile app. Potential participants were required to sign in to their registered accounts to access the study link, where they read a comprehensive description detailing the research purpose, procedures, potential benefits and risks, and compensation. Consent was obtained voluntarily when participants checked an “Agree” radio button, which allowed them to proceed to the screening and baseline questionnaires. This e-consent explicitly covered the collection and processing of personal and sensitive data, including sociodemographic characteristics, clinical symptoms, and digital phenotypes. Participants were clearly informed of their right to withdraw from the study at any time for any reason without any disadvantage or penalty. They were also provided with instructions on how to request the permanent deletion of their previously collected data by contacting the PanelNow customer center should they choose to opt out. To protect participant privacy and confidentiality, all datasets were deidentified by the online panel service provider (dataSpring Korea) before being transferred to the research team; directly identifiable information (birth date and mobile phone number) was removed, providing only the minimum necessary variables (sex and age) for statistical analysis. The deidentified data are stored on a secure, password-protected computer and server whose access is restricted to authorized individuals directly involved in the study. To ensure multilayered security, separate passwords were set for reading and writing files, and these passwords were communicated through independent channels and updated periodically. Furthermore, the mobile EMA app used a secure protocol where user identities were converted into nonidentifiable IDs; it was technically impossible to decode these IDs back into identifiable personal information. Compensation was provided via “PanelNow” points (1 point=1 KRW [1 KRW=US $0.00075 as of September 19, 2023]), a redeemable reward unit used within the service platform. Eligible participants who completed all tasks received 6000 points; those with 100% adherence to the mobile EMAs received

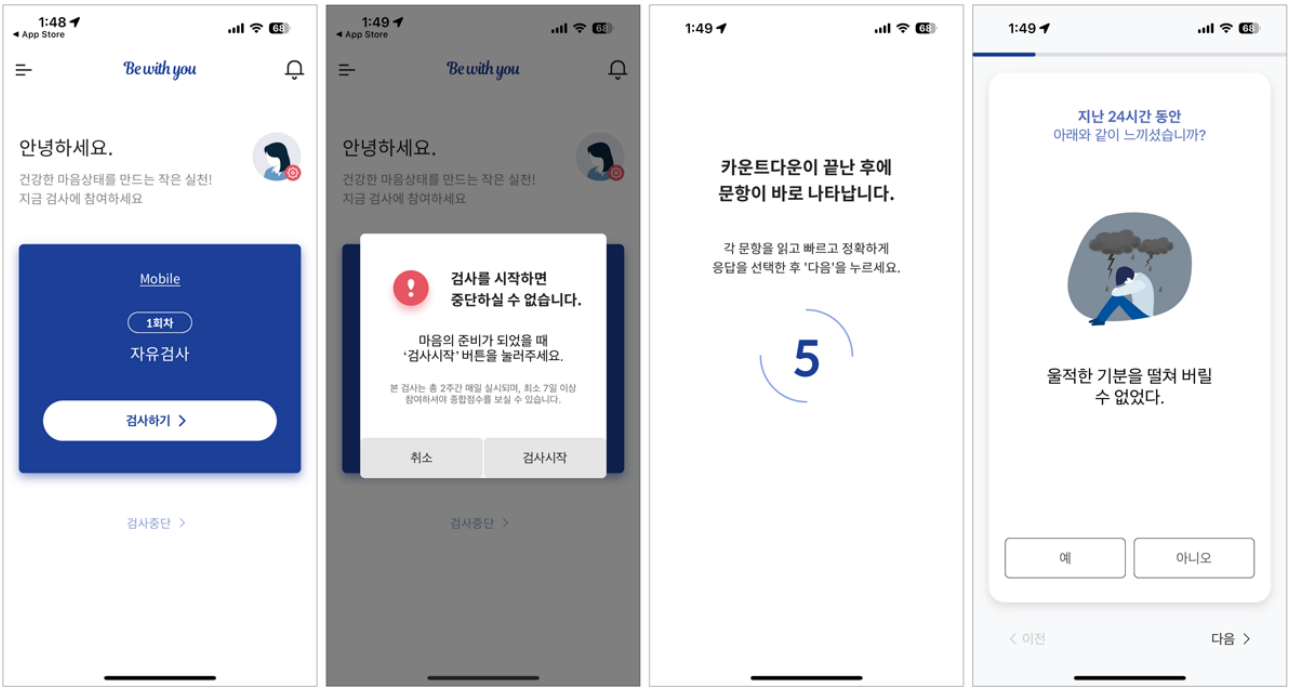
XSL•FO
RenderX

an additional 1000 points. The total possible compensation of 7000 points was equivalent to 7000 KRW (US $5.27).

Traditional Retrospective Measure

Modified K-CESD-R

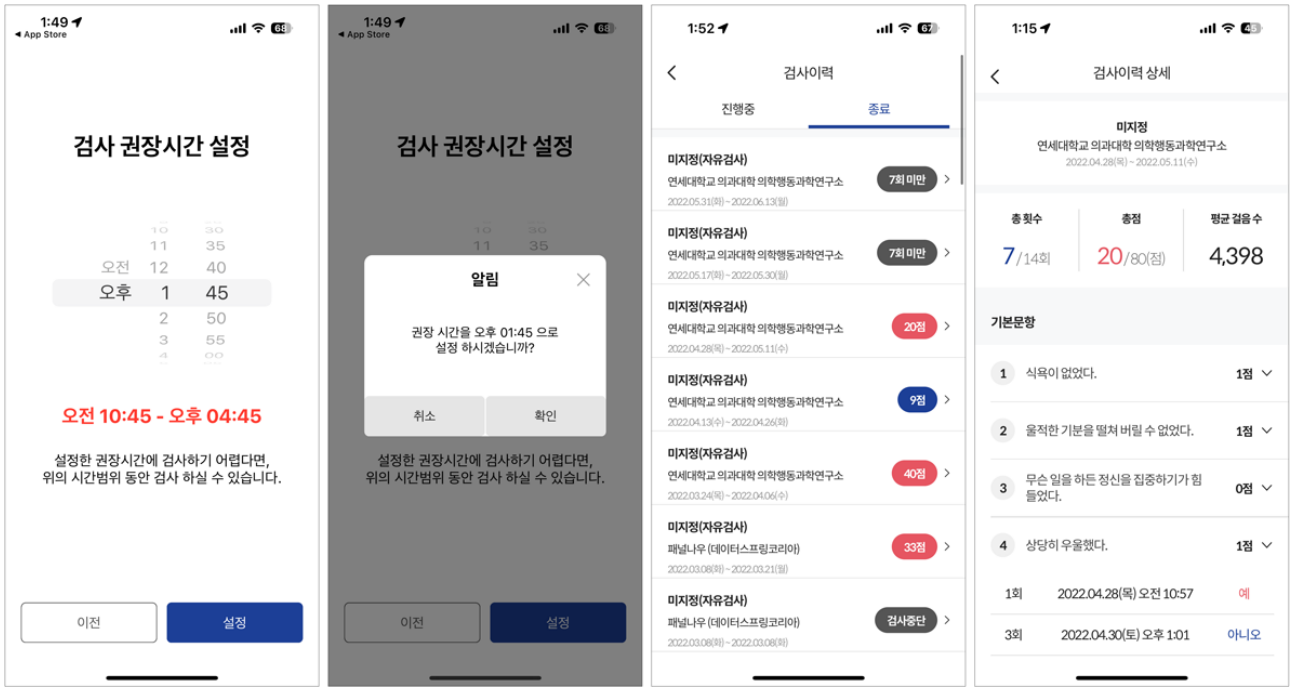
To determine whether recall bias affects the retrospective report of depressive symptoms on the standardized CESD-R assessment [31], we modified the K-CESD-R scale [32] to additionally require participants to specify the number of days they experienced the symptoms and to input numerical values for their responses into the modified format. Specifically, a 2-week recall was conducted on day 14 to evaluate the sensitivity of mobile EMA compared with traditional retrospective recall. To investigate changes in depression symptoms and recall consistency, a 1-week recall was also administered on day 7 (for first week, FW) and day 14 (for second week, SW). Furthermore, the modified scale was designed to prevent insincere random responses. If inconsistencies were detected between the responses on the original scale and the directly entered values, the survey system displayed a warning pop-up to reduce careless entries.



The K-CESD-R is a 20-item self-report measure of depressive symptoms in 9 different domains: sadness/dysphoria (questions 2, 4, and 6), loss of interest/anhedonia (questions 8 and 10), appetite (questions 1 and 18), sleep (questions 5, 11, and 19), thinking/concentration (questions 3 and 20), guilt/worthlessness (questions 9 and 17), tiredness/fatigue (questions 7 and 16), movement/agitation (questions 12 and 13), and suicidal ideation (questions 14 and 15). Participants are asked to rate each item on a 5-point scale to indicate how they felt or behaved during the last week or so: 0=not at all or less than 1 day in the last week, 1=1 - 2 days in the last week, 2=3 - 4 days in the last week, 3=5 - 7 days in the last week, and 4=nearly every day for 2 weeks. All responses are summed for a total score ranging from 0 to 80, with scores of 13 or higher indicating the need for individuals to seek further clinical diagnostic interview. In this study, the total scores from the modified K-CESD-R, administered separately on day 7 and day 14 to assess the preceding 1-week recall periods, ranged from 0 to 60 rather than the original 0 to 80.

EMA-Based Retrospective Measure

Mobile App–Based Depression Assessment



The "BeWithYou" app, an upgraded version of the K-CESD-R mobile app developed in our previous study [13], is designed as a 24-hour recall–based prospective depression assessment tool. A single test set consists of 14 sessions over a 2-week period and can be repeatedly administered to monitor the improvement and deterioration of depressive symptoms in individuals with or with no previous diagnosis of major depression. In the test set, 20 items are presented in a randomized order in each session, and participants respond either "yes (1=presence)" or "no (0=absence)" to each item (eg, "In the past 24 hours, I felt depressed") (Figure 1). At the start of the first session, the app allows participants to set a daily assessment reminder, ensuring that they can report their symptoms regularly during this study period (Figure 2). Regarding the clinically validated scoring algorithm embedded in the app [13], the total score is automatically calculated only if participants complete at least 7 sessions. If they complete fewer than 7 sessions, only the total number of tests taken over the 2 weeks and the number of days each symptom is reported can be viewed in the main menu of the assessment history (Figure 2).

Psychological and Psychiatric Measures

Digital Sensitivity

The Yongin Severance Digital Sensitivity Scale, developed by Park et al [33], is a self-report instrument designed to measure individual differences in digital sensitivity. The scale comprises 6 subfactors across 2 domains: digital literacy (14 items) and digital efficacy (6 items). The digital literacy domain includes 4 subfactors: digital application (4 items), digital communication (3 items), critical thinking (4 items), and digital ethics (3 items). The digital efficacy domain consists of digital confidence (3 items) and digital anxiety (3 items). All items are rated on a 7-point Likert scale ranging from 1 (strongly disagree) to 7 (strongly agree), yielding a total score ranging from 20 to 140. Items in the digital anxiety subscale are reverse-scored before computing the total score. Higher total scores indicate higher levels of digital sensitivity.

Personality Traits

To quickly and easily measure the Big Five personality traits, we used a Korean version of the brief Big Five Inventory-15 [34], which was adapted and shortened to 15 items from the 44-item Big Five Inventory [35]. The Korean version of the brief Big Five Inventory-15 comprises 15 items across 5-factor personality domains: (1) neuroticism (3 items), (2) extraversion (3 items), (3) openness (3 items), (4) conscientiousness (3 items), and (5) agreeableness (3 items). Each item is rated on a 5-point scale (1=strongly disagree to 5=strongly agree). The responses to the 3 items within each domain were averaged for the data analysis.

Depression

As a well-validated multipurpose instrument for screening and diagnosing major depression, the Patient Health Questionnaire–9 (PHQ-9 [36]) is adopted to measure the presence and severity of 9 MDE symptoms over the past 2 weeks. On the last day of the 2-week study period, we administered the Korean version of PHQ-9 scale [37] to collect these data, aligning them with the data measured through the modified K-CESD-R scale and the BeWithYou app. As each of the 9 items can be scored from 0 (not at all) to 3 (nearly every day), the total score of the PHQ-9 ranges from 0 to 27 (≤4: no depression, 5 - 9: mild depression, 10 - 19: moderate depression, and ≥20: severe depression), with scores of 10 or greater indicating clinically significant depression.

State-Trait Anxiety

As a measure of the severity of anxiety, the Spielberger State-Trait Anxiety Inventory (STAI-form X [38]) was adopted to separately measure 2 types of anxiety: state anxiety (ie, how you feel right now, ie, at this moment) and trait anxiety (ie, how you generally feel). In this study, we administered a revised version of the STAI [39], a 40-item self-report questionnaire with 2 subscales: the STAI-X-1 (state anxiety) and the STAI-X-2 (trait anxiety). Both subscales consist of 20 items each, rated on a 4-point scale with different anchors for the STAI-X-1 (1=not at all, 2=somewhat, 3=moderately so, and 4=very much so) and the STAI-X-2 (1=almost never, 2=sometimes, 3=often, and 4=almost always). All responses to positively stated items are reverse-coded to calculate each of the total scores for the STAI-X-1 (items 1, 2, 5, 8, 10, 11, 15, 16, 19, and 20) and the STAI-X-2 (items 1, 6, 7, 10, 13, 16, and 19); after that, the total scores of the STAI-X-1 and the STAI-X-2 are calculated by summing the responses to the 20 items for each subscale. The total scores range from 20 to 80, with higher scores indicating greater levels of anxiety.

Insomnia

As a brief self-report instrument measuring subjective insomnia complaints in the last 2 weeks, the Insomnia Severity Index (ISI [40]) consists of 7 items: (1) the severity of sleep-onset (1a: initial), sleep maintenance (1b: middle), and early morning

XSL•FO
RenderX

awakening (1c: terminal) difficulties; (2) the dissatisfaction with current sleep pattern (dissatisfaction); (3) the interference with daily functioning (interference); (4) the noticeability of impairment in the life quality attributed to the sleep problem (noticeability); and (5) the degree of concerns or distress caused by the current sleep problem (distress). Each of the ISI items is rated on a 5-point scale with different anchors from 0 to 4, and scores are summed to yield a total score ranging from 0 to 28, with high scores indicating greater insomnia severity. The total scores are interpreted as follows: no clinically significant insomnia (0‐7), subthreshold insomnia (8-14), clinical insomnia (moderate, 15‐21), and clinical insomnia (severe, 22‐28). In this study, we administered the Korean version of the Insomnia Severity Index (ISI-K), standardized and validated by Cho et al [41]. A cutoff score of 15 on the ISI-K is used as the threshold for clinically significant insomnia.

Somatic Symptoms

In this study, somatic symptoms were assessed using the Korean version of the Patient Health Questionnaire–15 [42]. This instrument consists of 15 items that ask how often respondents have been bothered by various physical symptoms over the past 4 weeks, rated on a 3-point Likert scale ranging from 0 (not at all) to 2 (bothered a lot). Total scores range from 0 to 30, with higher scores indicating more severe somatic symptom burden. A cutoff score of 8 or above was used to indicate clinically relevant somatization.

Sociodemographic Measures

Sociodemographic measures included sex, date of birth, educational attainment, marital status, number of other household members, and subjective socioeconomic status (SES), all of which were collected by self-report. Sex was assessed as a dichotomous variable (male or female). Using the date of informed consent as the reference date, age was automatically calculated from the participant's self-reported date of birth. Educational attainment was measured as the highest level of education completed, with response options of no formal education, elementary school, middle school, high school, 2‐ to 3-year college, 4-year university or higher, master's degree, doctoral degree, or other. Marital status was measured using 6 categories: single, cohabiting or common-law marriage, married, separated, divorced, or widowed. A current living arrangement variable was derived from the reported number of other household members and categorized into none (1-person household) through 5 or more people (6-or-more-person household). For analysis, this variable was recategorized as living alone (1-person household) or living with others (≥2-person household). SES was assessed with a single item asking participants to rate their overall socioeconomic position considering occupation, educational level, income, and assets on a 5-point scale ranging from very low to very high.

Procedure

In this study, potential participants were recruited via PanelNow, a mobile panel platform directly operated by dataSpring Korea. Access to the study was restricted to registered app users, who received an in-app notification with an embedded link redirecting them to the e-consent form and online prequestionnaires. These prequestionnaires consisted of screening items to determine eligibility, followed by baseline questions regarding sociodemographic information, digital sensitivity, and personality traits. After providing e-consent, individuals who met all eligibility criteria and successfully completed the BeWithYou app installation and registration process were enrolled.

During the 2-week study period, enrolled participants followed a protocol consisting of four assessment components: (1) a first traditional assessment (1-week recall), (2) a second traditional assessment (both 1-week recall and 2-week recall), (3) a mobile app–based active EMA, and (4) final postquestionnaires. To ensure a rigorous evaluation of each component, specific protocols were established as follows. For traditional retrospective assessments, modified versions of K-CESD-R were administered on day 7 and day 14. Concurrently, the mobile EMA was conducted daily for 14 sessions. To be eligible for the final data analysis, participants were required to meet minimum adherence criteria, defined as completing at least 7 mobile EMA sessions and all 3 traditional assessments. On day 14, only those who fulfilled these requirements were provided with the link to the final postquestionnaires, which assessed clinical symptoms such as anxiety, depression, insomnia, and somatization. Except for the daily mobile EMA using the BeWithYou app, all questionnaires were administered online via URL links sent to the contact channels (including app push, email, or SMS text messaging) for which participants had maintained opt-in status for research participation notification.

Statistical Analysis

All statistical analyses were performed using IBM SPSS Statistics (version 29.0.2.0 for Mac; IBM Corp), with 2-tailed *P* value of .05 considered statistically significant. Missing EMA sessions were retained as missing values so that all available repeated observations could be included in the analyses. To address objectives 1 and 2, we fitted 2 Generalized Linear Mixed Models (GLMMs), with a binomial distribution and logit link to predict the outcomes of daily EMA ("Symptom Presence"; 0=no and 1=yes). Retrospective K-CESD-R responses were first aggregated into 9 MDE symptom domains using the maximum number of days reported within each domain (eg, if "Sadness" items [3 items] were reported as 2, 0, and 5 days, the value "5" was used for that domain). In both models, "participant ID" was included as a random intercept to account for the nonindependence of repeated observations and control for stable between-person differences in reporting tendencies. Model 1 examined the association between daily EMA symptom presence (EMA sensitivity) and 2-week retrospective recall (systematic recall bias), with fixed effects of "Symptom Days_T2W" (0‐14) as a continuous covariate and "Day" (1-14) and "Domain" (1-9) as categorical factors. Model 2 further examined week-to-week differences in recall consistency using 1-week retrospective recall. Fixed effects included "Symptom Days_1W" (0‐7) as a continuous covariate and "Week" (FW vs SW), "Day" (1‐7, nested within week), and "Domain" as categorical factors. The "Week" × "Symptom Days_1W" interaction was also included to test whether recall consistency differed between weeks. Model fit was evaluated using the Akaike Information Criterion Corrected (AICC) and Bayesian

XSL•FO
RenderX

Information Criterion (BIC). Variance explained was estimated using marginal (fixed effects only) and conditional (fixed and random effects) pseudo R^2 values. The magnitude of between-person variability was assessed using the intraclass correlation coefficient (ICC). Finally, we conducted the paired samples *t* test to compare modified K-CESD-R total scores obtained on day 7 and day 14, representing the first and second 1-week recall periods, respectively. This comparison was intended to assess whether repeated EMA–based self-assessments in daily life were associated with positive changes in depression severity.

To address objective 3, K-means clustering was conducted using 3 *z*-standardized EMA-derived features: (1) mean number of daily depressive symptoms over the 2-week period (symptom severity: 0‐20 symptoms), (2) within-person SD of daily depressive symptom counts (symptom variability), and (3) mean number of days with suicidal ideation (items 14 and 15, frequency of suicidal ideation: 0‐14 days) (Table 1). We compared 3-, 4-, and 5-cluster solutions and selected the 3-cluster model based on silhouette coefficients and clinical interpretability. To validate the extracted clusters, 1-way ANOVA tests were performed using the cluster assignment as the independent variable and the means of the 3 EMA features as the dependent variables. Cluster differences in sociodemographic, psychological, and psychiatric profiles were evaluated using 1-way ANOVA, chi-square tests, and Bonferroni-adjusted post hoc comparisons ($P<.05$). Cramér *V* was used as the effect size for chi-square tests, with values of 0.10, 0.30, and 0.50 typically interpreted as indicating small, medium, and large effects, respectively [43].

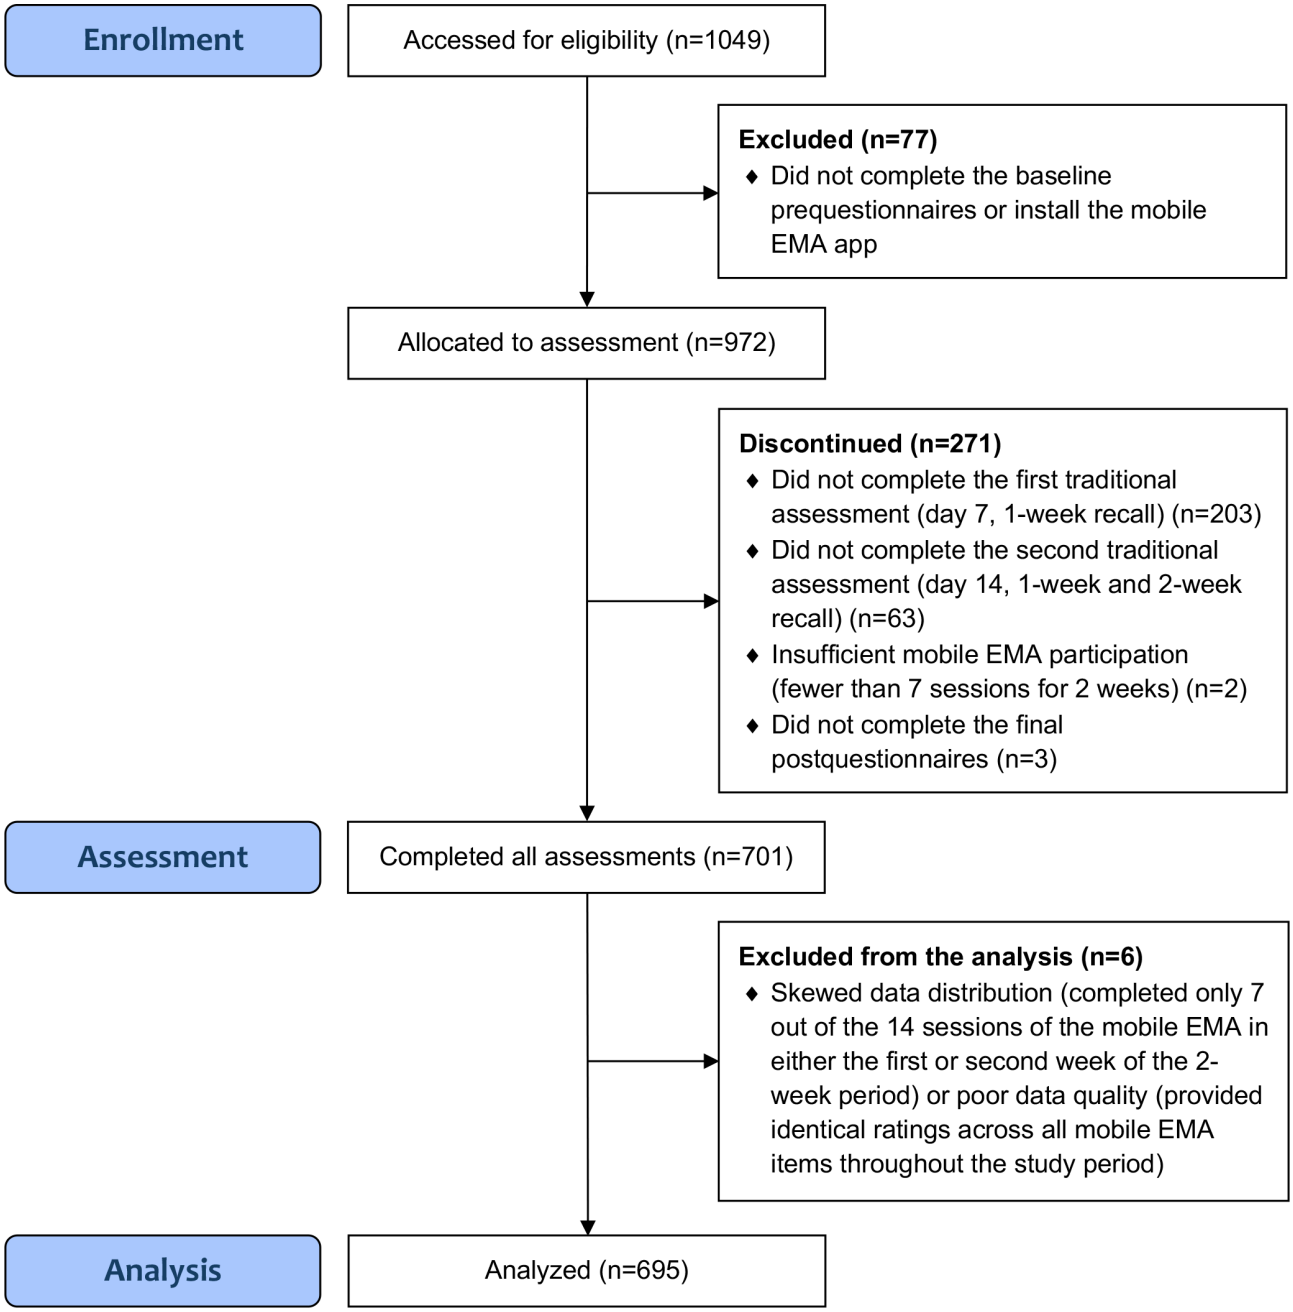
[a]EMA: ecological momentary assessment.

[b]K-CESD-R: Korean Version of the Center for Epidemiologic Studies Depression Scale–Revised.

[c]N/A: not applicable.

Results



Participant Flow and Sociodemographic Characteristics

The participant flow from initial recruitment to the final analysis is illustrated in Figure 3. Out of 1049 participants who were initially screened, 701 met all eligibility and adherence criteria and were included in the data analysis, while 348 were excluded based on predefined dropout criteria. Even if they met the minimum requirement of 7 sessions, we further excluded 6 participants who exhibited highly skewed or nonrepresentative response patterns that could undermine the clinical and statistical validity of the study.

Specifically, these exclusions included (1) participants whose responses were concentrated exclusively within a single week (either the FW or the SW), which not only precluded the assessment of the temporal continuity of depressive symptoms over the required 2-week period—a critical clinical criterion—but also rendered them ineligible for the planned comparison between the FW and the SW; and (2) participants who exhibited straight-lining EMA response patterns with zero variance, suggesting insincere participation. After these final exclusions, the sociodemographic and psychological characteristics of the final analytic sample (N=695) are summarized in Table 2.

[a]Previously married was defined as having been legally married at some point, including those currently separated, divorced, or widowed.

Final Analytic Sample and Mobile EMA Outcome Events

Of the total 87,570 potential sessions, 81,900 (93.5%) valid EMA observations from 695 participants were included in the final analysis. This high inclusion rate, achieved by using all available data points through a GLMM, effectively mitigated potential selection bias and preserved statistical power despite occasional missing daily entries.

Assessing Recall Bias in Traditional vs Mobile EMA–Based Depression Measures

The primary objective of model 1 was to quantify the systematic discrepancy and information loss inherent in traditional retrospective reports (2-week recall) compared with daily EMA records (24-hour recall). The final GLMM demonstrated robust statistical fit (AICC=473,906.603 and BIC=473,915.916). The overall classification accuracy for model 1 was 88.3%. Omnibus tests for fixed effects revealed that traditional retrospective reports ("Symptom Days_T2W") were a statistically significant predictor of daily symptom presence ("Symptom Presence"; $F_{1, 81877}$=4,826.322; P<.001). Significant main effects were also observed for "Domain" ($F_{8, 81877}$=284.483; P<.001) and "Day" ($F_{13, 81877}$=118.344; P<.001). Parameter estimates for "Symptom Days_T2W" yielded a significant negative slope (B=−0.406, SE 0.006; P<.001), with an odds ratio of 0.666 (95% CI 0.659 - 0.674). The marginal pseudo R^2 value was 0.355, indicating that the traditional retrospective recall method explains only 35.5% of the variance in actual daily symptom presence. When accounting for random intercepts, the conditional pseudo R^2 value increased to 0.504, with an adjusted ICC of 0.232. These results show that while interindividual heterogeneity accounts for 23.2% of the total variance, nearly 76.8% of the symptomatic variability is driven by intraindividual fluctuations, approximately half of which (49.6%) remains entirely unexplained by the 2-week recall method.

Investigating Temporal Dynamics and Interaction Effects of Recall Periods

The second objective of model 2 was to investigate whether the consistency of recall remained stable or exhibited temporal fluctuations across the assessment period by comparing the FW and the SW. The final GLMM also demonstrated a robust statistical fit (AICC=469,917.005 and BIC=469,926.318) and achieved an overall classification accuracy of 88.5%. Omnibus tests for fixed effects revealed significant main effects for all predictors, including "Domain" ($F_{8, 81876}$=276.180; P<.001), "Day" ($F_{12, 81876}$=56.555; P<.001), and "Symptom Days_1W" ($F_{1, 81876}$=7146.780; P<.001). Notably, a significant main effect of "Week" was also observed ($F_{1, 81876}$=50.317; P<.001), with the estimated mean of "Symptom Presence" increasing from 0.853 (FW) to 0.908 (SW). Similar to model 1, parameter estimates for "Symptom Days_1W" yielded a significant negative slope (B=−0.749, SE 0.011, P<.001; odds ratio 0.473, 95% CI 0.463 - 0.483). The marginal pseudo R^2 value of 0.335 indicates that the fixed effects, including the temporal interaction, explain only about one-third of the variance in daily symptom reporting. When accounting for random intercepts, the conditional pseudo R^2 value increases to 0.475, indicating that more than 52% of the total variance in daily symptom presence remains entirely unexplained even when considering individual differences. The adjusted ICC of 0.211 further revealed that while interindividual heterogeneity accounts for 21.1% of the total variance, the vast majority of symptomatic variability, specifically nearly 79%, is attributable to within-person fluctuations. Most importantly, a robust interaction was found between "Week" and "Symptom Days_1W" ($F_{1, 81876}$=124.550; P<.001). This significant interaction revealed that the consistency between weekly retrospective recall and daily EMA significantly differed between FW and SW.

Evaluating Week-to-Week Changes in Depression Severity Across Recall Methods

To further elucidate the symptomatic trajectory observed in model 2, a supplementary analysis was conducted to compare the change in depression severity scores between FW and SW across 2 different assessment methods: a 1-week recall–based version (original) and a 24-hour recall–based version (mobile). Paired samples t tests revealed that the original scores significantly decreased from 12.46 (SD 13.54) in the FW to 11.17 (SD 13.76) in the SW (t_{694}=5.41, Cohen d=0.10; P<.001). Additionally, a comparable reduction was observed in the mobile scores, which decreased from 14.29 (SD 13.71) to 11.11 (SD 14.03) (t_{694}=13.04, Cohen d=0.34; P<.001). Notably, this overall reduction in symptomatic severity across both assessment methods stands in direct contrast to the upward trend in symptom reporting probability observed in model 2.

Identifying and Profiling High-Risk Subgroups Using Active EMA Features

A K-means cluster analysis (k=3) was performed using active EMA features—symptom severity, symptom variability, and frequency of suicidal ideation—which were standardized using a z-score transformation. In the analysis, a total of 695 participants were identified as 3 distinct risk groups, and based on their symptom profiles, each cluster was subsequently labeled as no- or low-risk (cluster 1), moderate-risk (cluster 2), and high-risk (cluster 3) groups. Cluster 1 (n=445) was characterized by low symptom severity (z=−0.57; raw mean 1.07, SD 1.15), low symptom variability (z=−0.56; raw mean 0.95, SD 0.65), and minimal suicidal ideation (z=−0.30; raw mean 0.02, SD 0.12). Cluster 2 (n=223) had moderate symptom severity (z=0.79; raw mean 6.42, SD 3.20), the highest symptom variability (z=1.04; raw mean 3.07, SD 1.16), and occasional suicidal ideation (z=0.07; raw mean 0.62, SD 0.98). Cluster 3 (n=27) showed the highest symptom severity (z=2.80; raw mean 14.34, SD 2.13), moderate symptom variability (z=0.36; raw mean 2.17, SD 1.55), and frequent suicidal ideation (z=4.23; raw mean 7.37, SD 2.82). While both the severity of depressive symptoms and frequency of suicidal ideation, as well as all psychiatric characteristics, increased with the level of risk in

XSL•FO
RenderX

the clusters (cluster 1<2<3), the highest variability of depressive symptoms was observed in cluster 2 (cluster 1<3<2).

To assess the robustness of the clustering outcomes, 1-way ANOVAs were conducted using the cluster assignments as the independent variable. Results confirmed significant between-group differences across all 3 EMA indices: $F_{2, 692}$=892.24, partial η^2=0.72, P<.001, for symptom severity; $F_{2, 692}$=423.18, partial η^2=0.55, P<.001, for symptom variability; and $F_{2, 692}$=1117.36, partial η^2=0.76, P<.001, for frequency of suicidal ideation. These findings support the internal validity of the 3-cluster classification.

Sociodemographic and Psychological Characteristics Across Clusters

As presented in Table 3, the sociodemographic and psychological characteristics are summarized for each of the 3 clusters identified in the cluster analysis: (1) cluster 1 (no or low risk: 445/695, 64.0%), (2) cluster 2 (moderate risk: 223/695, 32.1%), and (3) cluster 3 (high risk: 27/695, 3.9%).

XSL•FO

[b]Not available.

[c]Scores with the same superscript are not significantly different from each other but are significantly different from those with different superscripts.

[d]Scores with the same superscript are not significantly different from each other but are significantly different from those with different superscripts.

[e]Scores with the same superscript are not significantly different from each other but are significantly different from those with different superscripts.

According to the chi-square analyses for categorical variables, there were no significant differences among the 3 clusters in sex (χ^2_2=3.27, Cramér *V*=0.07; *P*=.20), age group (χ^2_8=8.42, Cramér *V*=0.08; *P*=.39), educational attainment (χ^2_8=7.21, Cramér *V*=0.07; *P*=.51), marital status (χ^2_6=10.29, Cramér *V*=0.09; *P*=.11), current living arrangement (χ^2_2=2.42, Cramér *V*=0.06; *P*=.30), and smartphone operating system (χ^2_2=2.34, Cramér *V*=0.06; *P*=.31). For continuous variables, separate 1-way ANOVAs revealed no significant group differences across the clusters in age ($F_{2, 692}$=2.46, partial η^2=0.007; *P*=.09) and digital sensitivity ($F_{2, 692}$=0.86, partial η^2=0.002; *P*=.42).

Among all variables examined, only SES and personality traits showed significant differences across the 3 clusters. For subjective SES, a significant group difference was observed (χ^2_8=17.41, Cramér *V*=0.11; *P*=.03). To compare column proportions, pairwise *z*-tests were conducted, and *P* values were adjusted using the Bonferroni method (*P*<.05). These comparisons revealed that the proportion of participants reporting a low SES level was significantly higher in cluster 3 (12/695, 44.4%) than in cluster 1 (98/695, 22.0%). In terms of personality traits, a 1-way MANOVA revealed a significant multivariate effect of group on the combined dependent variables (Pillai trace=0.26, $F_{10, 1378}$=18.85, partial η^2=0.13; *P*<.001). Among the Big Five personality dimensions, 1-way ANOVAs revealed significant group differences in conscientiousness ($F_{2, 692}$=17.09, partial η^2=0.05; *P*<.001), neuroticism ($F_{2, 692}$=105.37, partial η^2=0.23; *P*<.001), extraversion ($F_{2, 692}$=5.61, partial η^2=0.02; *P*=.004), and agreeableness ($F_{2, 692}$=3.37, partial η^2=0.01; *P*=.04), whereas no significant difference was found in openness to experience only ($F_{2, 692}$=1.63, partial η^2=0.005; *P*=.20).

As shown in Table 3, post hoc comparisons with Bonferroni correction indicated that both conscientiousness and neuroticism significantly differed across all 3 clusters (*P*<.001). Specifically, individuals in higher-risk clusters demonstrated lower levels of conscientiousness and higher levels of neuroticism than those in lower-risk clusters. Extraversion was significantly lower in cluster 3 than in both cluster 1 (*P*<.001) and cluster 2 (*P*=.04). For agreeableness, individuals in cluster 1 exhibited significantly higher scores than those in cluster 3 (*P*=.04), whereas no significant differences were found between cluster 2 and either of the other clusters.

Psychiatric Characteristics Across Clusters

To investigate differences in psychiatric characteristics across the 3 clusters, 1-way ANOVAs were conducted for each variable. As shown in Table 4, all psychiatric variables demonstrated significant group differences. Significant effects of cluster membership were found for the severity of depression ($F_{2, 692}$=463.22, partial η^2=0.57; *P*<.001), state anxiety ($F_{2, 692}$=232.61, partial η^2=0.40; *P*<.001), trait anxiety ($F_{2, 692}$=273.99, partial η^2=0.44; *P*<.001), insomnia ($F_{2, 692}$=137.15, partial η^2=0.28; *P*<.001), and somatization ($F_{2, 692}$=197.63, partial η^2=0.36; *P*<.001). Effect size interpretation based on partial η^2 indicated large effects for all variables (≥0.14). Post hoc analyses with Bonferroni correction indicated that all pairwise comparisons were statistically significant (*P*<.001) for depression, state and trait anxiety, and somatization. For insomnia, the difference was significant between cluster 1 and cluster 2 (*P*<.001) and between cluster 1 and cluster 3 (*P*<.001) but not between cluster 2 and cluster 3 (*P*=.07), indicating a similar level of insomnia severity between the moderate- and high-risk groups.

Discussion

Principal Findings

The main findings of this study are as follows. First, we confirmed the superior sensitivity of mobile EMA for monitoring daily depressive symptoms compared with traditional retrospective scales. Second, our analysis revealed distinct temporal changes in depressive symptoms and patterns of recall consistency between the FW and SW of observation. Third, we identified specific subgroups at heightened risk for depression and suicidal ideation and characterized their unique sociodemographic, psychological, and psychiatric profiles. These results provide a multidimensional understanding of symptom dynamics and underscore the clinical usefulness of high-frequency digital monitoring for effective risk stratification among community-dwelling Korean adults.

This study provides empirical evidence that traditional retrospective reports systematically underestimate symptomatic experiences compared with daily EMA, which captures the simple daily recording of symptom presence. We found that a substantial portion of daily-level symptomatic variance is lost as participants are required to mentally reconstruct their experiences and estimate the total number of symptomatic days over successive recall periods. This process of heuristic estimation introduces a “smoothing effect” that obscures the true density and temporal complexity of depressive symptoms, resulting in significant information loss. Consequently, our findings suggest that retrospective frequency estimates insufficiently capture the full burden of depression, as the nuanced symptomatic fluctuations captured by prospective monitoring are flattened during memory-based aggregation.

What is more, we identified a paradoxical divergence in symptomatic patterns from the FW to the SW of assessment. While retrospective assessments indicated a significant decrease in depression severity scores, the prospective probability of actual symptom reporting concurrently increased. If this decrease in scores were due to regression to the mean, symptom reporting should have also decreased. Instead, the observed increase supports a psychological shift in symptom sensitization rather than a mere statistical artifact. This discrepancy is closely linked to intraindividual dynamics, which account for the vast majority of symptomatic variability and remain largely unexplained by traditional retrospective recall methods. Ultimately, the interaction between assessment week and recall consistency provides robust evidence that recall bias is not a fixed or static error; rather, it is a dynamic process associated with changes in a participant’s internal standards and cognitive framework for symptom recall during sustained daily monitoring.

Last but not least, this study highlights the value of digital phenotyping by identifying 3 distinct clinical clusters with diverging symptomatic patterns. While both mean symptom severity and suicidal ideation frequency increased linearly across the 3 risk groups, within-person symptom variability (SD) exhibited a nonlinear pattern, particularly peaking in the moderate-risk group. This peak in symptom variability may reflect the underlying complexity of ambivalent self-schemas in moderate-risk individuals. Furthermore, these clusters were validated by psychiatric and personality profiles, with the high-risk group distinguished by the highest neuroticism, the lowest conscientiousness, and a higher prevalence of low subjective SES. Collectively, these findings underscore within-person symptom dynamics as a critical feature in characterizing heterogeneous depression phenotypes and their associated suicide risk, both of which are often masked by the traditional retrospective assessments.

Comparison With Prior Work

In line with previous findings that EMA has greater sensitivity in detecting depressive symptoms and suicidal ideation than retrospective self-report scales [18-20], this study suggests that traditional retrospective reports are not merely imprecise but systematically distorted. Indeed, the substantial information loss inherent in traditional 2-week recall was evidenced by its limited explanatory power, accounting for only 35.5% of the variance in actual daily symptom presence (model 1). The significant negative slope observed (B=−0.406; P<.001) further indicates a fundamental misalignment between memory-based reports and actual daily occurrences. Whereas the traditional K-CESD-R scores were significantly higher for the FW than for the SW, the actual probability of daily symptom presence was found to be significantly higher in the SW than in the FW (0.908 vs 0.853; model 2). This discrepancy is likely rooted in cognitive heuristics; specifically, this inverse relationship suggests that retrospective recall is not a simple summary of experiences but is heavily distorted by specific intense episodes from the past, reflecting the “peak bias” of the peak-end rule [44]. In this case, participants appeared to rely on intense MDEs from the more distant past (FW) to calibrate their overall 2-week symptom reports, thereby overriding the actual increase in symptom frequency observed in the more recent period (SW). Given that nearly 79% of symptomatic variability is linked to intraindividual fluctuations, mobile EMA serves as a cognitively robust alternative that captures these dynamic patterns which are otherwise lost to recall bias.

Beyond identifying these recall biases, the observed paradoxical divergence between the decrease in retrospective scores and the increase in the daily probability of symptom reporting highlights shifting patterns in how participants perceive and evaluate their affective states over the course of the study. Engagement with EMA is associated with a refinement of internal standards for symptom appraisal, which may be related to heightened emotional awareness and behavioral reflection [22,23]. These results align with the concept of assessment reactivity [24], indicating that the act of frequent monitoring can be reflected in reporting patterns by sensitizing participants to their subtle symptomatic fluctuations. Therefore, mobile EMA provides a more ecologically valid reflection of symptomatic trajectories than traditional static measures, capturing the daily engagement with their own symptoms. While such heightened awareness may facilitate self-regulated recognition, it remains critical to acknowledge that increased self-focus or reinforced negative symptom monitoring may exacerbate psychological distress in certain individuals [25,26]. Overall, these findings support the potential usefulness of mobile EMA as a fine-grained tool for capturing the complexity of symptom trajectories.

To address inconsistent findings on daily negative affect dynamics across levels of depression severity [9,12,45], we classified community-dwelling participants into 3 distinct subgroups with depressive symptom dynamics: (1) cluster 1 (no or low risk; 445/695, 64.0%): low symptom severity, low symptom variability, and minimal suicidal ideation; (2) cluster 2 (moderate risk; 223/695, 32.1%): moderate symptom severity, the highest symptom variability, and occasional suicidal ideation; and (3) cluster 3 (high risk; 27/695, 3.9%): the highest symptom severity, moderate symptom variability, and frequent suicidal ideation. As hypothesized, within-person symptom variability, among the 3 active EMA features, played a key role in distinguishing not only between cluster 2 and cluster 3 but also between cluster 1 and clusters 2 and 3, as validated by the significant differences in the PHQ-9 scores across the 3 clusters. In line with the self-schema model for depression [15,16], these findings suggest that the highest symptom variability observed in cluster 2 may be attributed to the underlying instability of ambivalent self-schema representations, characterized by the coexistence of both positive and negative self-referent information. Importantly, the finding that higher variability was not always associated with greater symptom severity further suggests the presence of heterogeneous depression profiles.

Although cluster 3 (27/695, 3.9%) represented a relatively small proportion of the total sample, this distribution aligns with the expected epidemiological prevalence of high-risk individuals with suicidal ideation in the South Korean general population. Recent national surveys report that the proportion of adults who experienced suicidal thoughts within the past year ranges from 2.1% (2023 National Survey on Suicide [46]) to 4.6% (2023 Korea National Health and Nutrition Examination Survey [47]). The high degree of consistency between our findings (27/695, 3.9%) and these national representative data strongly supports the ecological validity of this cluster analysis, suggesting that cluster 3 is not a statistical outlier but a clinically valid subgroup of the at-risk population in a real-world context. Moreover, while national statistics often estimate suicide risk based on a 1-year history of suicidal ideation without considering depression severity, this study evaluated the co-occurrence of both active suicidal thoughts and depressive symptoms within a brief 2-week window. Furthermore, consistent with the previous study [21], mobile EMA may reduce the concealment of suicidal thoughts typically encountered in retrospective assessments and identify highly specific, high-risk phenotypes, providing a more sensitive clinical snapshot of acute suicidal risk associated with depression.

As well as the PHQ-9 scores, the STAI-X-1, STAI-X-2, and Patient Health Questionnaire–15 scores significantly differed across the clusters, showing a consistent increase with higher-risk levels (cluster 1<2<3). Consistent with the previous findings that individuals with depressive symptoms are more vulnerable to insomnia than those with no depressive symptoms in a general population–based sample from the Republic of Korea [48], this study also observed an increase in the ISI-K scores in accordance with the cluster risk level. Furthermore, the lack of a significant difference in the ISI-K scores between clusters 2 and 3 aligns with prior evidence suggesting that the severity of depressive symptoms is not significantly influenced by the presence or severity of insomnia symptoms among those with depressive symptoms [48]. In this regard, the risk levels assigned to each cluster closely corresponded to their psychiatric characteristics, providing theoretical support for the association between symptom variability and the instability of depressive self-schema.

In addition to psychiatric profiles, the cluster classification was also associated with sociodemographic factors and personality traits known as risk factors for both depressive symptoms and

XSL•FO
RenderX

suicidality. Consistent with the previous findings that low subjective SES predicted higher levels of depressive symptoms and suicidal ideation [49,50], cluster 3 (12/27, 44.4%) accounted for a significantly higher proportion of individuals with low subjective SES than cluster 1 (98/445, 22.0%), showing that their proportion increased with the cluster risk level. Interestingly, even in cluster 3 (the high-risk group), only a small proportion of participants reported the lowest level of subjective SES, while those with low (but not the lowest) SES were overrepresented. This pattern supports prior findings that relative deprivation, rather than absolute poverty, is more closely associated with depression and suicidal risk [51,52]. These findings also align with the social rank theory of depression [53], which posits that lower perceived social status increases vulnerability to depression and suicidality.

Among the Big Five personality traits, neuroticism, conscientiousness, extraversion, and agreeableness significantly differed across the 3 clusters. Individuals in the high-risk cluster exhibited the highest neuroticism and the lowest levels of conscientiousness, extraversion, and agreeableness. Consistent with prior evidence [54-56], neuroticism and conscientiousness were the personality traits that most clearly distinguished the 3 clusters. Particularly, cluster 3 exhibited the highest levels of neuroticism and the lowest levels of conscientiousness. These findings suggest that those in cluster 3 are more prone to emotional instability including heightened sensitivity to stress and frequent negative emotions, such as anxiety and anger, and experience greater difficulties with self-regulation in impulse control, organization, and goal-directed behavior. Although extraversion and agreeableness also differed across some of the clusters, both traits were not as clearly discriminative of depression risk as neuroticism and conscientiousness [57,58]. Extraversion was significantly lower in cluster 3 than in clusters 1 and 2, whereas agreeableness was significantly lower than in cluster 1 but did not differ from cluster 2. The observed reductions in extraversion and agreeableness among individuals in cluster 3 may reflect increased social withdrawal and interpersonal difficulties, which are commonly associated with depressive symptomatology [3]. Taken together, the current findings highlight the importance of neuroticism and conscientiousness in differentiating depression risk profiles, while emphasizing the added value of interpersonal traits such as extraversion and agreeableness in identifying individuals at high risk for social and emotional dysfunctions associated with increased vulnerability to depression and suicidality.

Limitations and Future Directions

This study provides quantitative evidence of systematic recall bias and the clinical usefulness of digital phenotyping. Despite its strengths, the following limitations should be considered when interpreting the results of this study. Most of all, specific methodological limitations regarding the temporal scope of the study, including the frequency of daily assessments and the overall duration of observation, warrant consideration. First, although mobile EMA offers high ecological validity, a 24-hour recall format used in this study may still be subject to reporting biases (eg, underreporting or momentary inattention) and have missed more granular, in-the-moment fluctuations that occur throughout the day. Particularly, the present EMA framework may still have been insufficient to capture the diurnal variability and transient surges of suicidal thoughts, which are often short-lived yet clinically significant. Second, it is true that the identification of the relatively small, high-risk group (27/695, 3.9%) underscores the superior sensitivity of mobile EMA in capturing the dynamic nature of suicidal risk that might otherwise be underreported in conventional retrospective assessments. However, the brief 2-week observation window represents only a snapshot of the dynamic nature of suicidal ideation in depressed individuals. Since suicidal ideation can be reactive to transient environmental stressors or life events, the long-term stability of this high-risk phenotype remains to be established, suggesting that cluster assignments might vary over a more extended longitudinal period.

Beyond these temporal considerations, additional limitations involving our analytical procedures, study design, and potential measurement effects also require careful interpretation. Third, the exclusion of 203 participants, who failed to complete the midpoint K-CESD-R survey (day 7), may have introduced selection bias. Although this criterion was applied to maintain the continuity of depressive symptoms, which is a key diagnostic criterion for MDD, the primary reason for this exclusion was adherence to the IRB-approved study protocol, which mandated the disposal of data from participants who withdrew or were lost to follow-up. Accordingly, we were not able to perform sensitivity analyses to compare the excluded and retained groups, which remains a limitation in confirming the robustness of our results against potential attrition bias. Fourth, although we observed significant decreases in week-to-week symptom severity scores across 2 different assessment methods, the observational design precludes causal inferences regarding the effects of EMA-based self-monitoring on symptom improvement. Finally, the repeated use of the same depression scale (K-CESD-R) in both online and mobile formats may have had a carryover effect, potentially improving participants' symptom recall over time and reducing recall bias in the traditional online version.

Several research directions are suggested to overcome these methodological limitations. To improve the limited temporal resolution of a 24-hour recall format, follow-up protocols could incorporate higher sampling frequencies, such as multiple assessments per day, to more precisely capture transient surges of suicidal ideation. Expanding the observation window through longitudinal study designs that span more than 2 weeks will also be essential to establish the long-term stability of the identified phenotypes. Furthermore, implementing more flexible data retention policies in coordination with IRB would allow for the inclusion of partial data in sensitivity analyses, which in turn would minimize selection bias. The integration of real-time passive sensing (eg, step count, sleep time, GPS, screen time, call or app logs, etc) with active EMA could further enhance predictive precision while alleviating participant burden. To establish the causal efficacy of EMA-based self-monitoring, future studies should also use randomized controlled trials comparing EMA with appropriate control conditions. Finally, future research should replicate this methodological approach using other validated depression scales to determine whether similar patterns of recall-related

XSL•FO
RenderX

underreporting are observed, thereby addressing potential carryover effects from repeated measurements. Such efforts to establish convergent evidence would significantly improve the reliability and generalizability of findings regarding recall bias.

Conclusions

This study demonstrates that mobile EMA provides more sensitive and ecologically valid monitoring of depressive symptoms than traditional retrospective measures. Conventional assessments are subject to both systematic underreporting (recall bias) and limited sensitivity to daily symptom variability. Further week-to-week analysis revealed a significant reactivity effect, with daily symptom reporting increasing over the 2-week period. This finding suggests that EMA acts as a mechanism to enhance self-awareness. Finally, active EMA features, including symptom severity, symptom variability, and frequency of suicidal ideation, effectively identified integrated depression and suicide risk subgroups and their distinct sociodemographic, psychological, and psychiatric profiles, highlighting the usefulness of digital phenotyping. Among these markers, symptom variability emerged as a key indicator for differentiating moderate-risk individuals, providing more detailed information than traditional measures. These findings pave the way for more personalized and timely mental health assessments and interventions in clinical practice.

Abstract

Background: Psychological stress poses a risk to mental and physical health and has become a major public health challenge. As physical behaviors (ie, physical activity, sedentary behavior (SB), and sleep) play a key role in mental well-being, their targeted modification could be an approach to coping with stress in everyday life. Previous studies have primarily either analyzed the associations between isolated physical behaviors and stress-related outcomes or employed cross-sectional designs. Accordingly, there is a need for deeper insights into the within- and between-person associations between physical behavior over a 24-hour cycle and psychological stress in naturalistic settings.

Objective: This study aimed to investigate how 24-hour physical behavior compositions are associated with daily self-perceived stress and stress-related coping self-efficacy and how replacing time in one behavior with another is linked to changes in both stress-related indicators.

Methods: A total of 198 healthy university employees (mean age 35.87 y, SD 10.76; 109, 54.8% female) participated in a 15-day ambulatory assessment study. Participants reported their momentary stress and coping self-efficacy perceptions up to 6 times a day in electronic diaries. 24–hour physical behavior was measured using a thigh-worn Move 4 accelerometer. The movement data were then classified on a daily basis into the 4 behavior categories of sleep, SB, light physical activity (LPA), and moderate-to-vigorous physical activity (MVPA). In order to obtain physical behavior compositions, an isometric log-ratio transformation was applied, resulting in 4 different sets. The associations between physical behavior compositions, self-perceived stress, and coping self-efficacy were analyzed using 2-level mixed multilevel models. Exploratory reallocation models were conducted to simulate the effects of time shifts from one behavior to another on both stress-related outcomes.

Results: The geometric average day comprised 33.9% (8.1/24 h) sleep, 45.2% (10.8/24 h) SB, 15.8% (3.8/24 h) LPA, and 5.1% (1.2/24 h) in MVPA. More time spent sleeping compared to being sedentary was associated with lower self-perceived stress (standardized β=–.03; t_{1988}=–2.045; P=.04) but not with coping self-efficacy (t_{1988}=–1.333; P=.18) in the 24-hour cycle. The ratio of SB to the other physical behaviors and time spent in LPA or MVPA relative to SB showed no association with either stress-related outcome. Significant random effects indicate high individual variability in the analyzed associations. The exploratory substitution of SB by LPA, MVPA, or sleep showed no significant changes in self-perceived stress or coping self-efficacy within a 60-minute period.

Conclusions: Adapting 24-hour physical behavior seems to be a promising approach to reduce stress in everyday life, for example, by extending sleep duration instead of being awake in SB. Further research should be conducted on contextual and personal influencing factors in order to develop tailored stress management interventions for the 24-hour cycle.

Introduction

The feeling of stress is a familiar human experience in everyday life. In particular, high, recurrent, and long-lasting psychological stress is thought to be associated with various physical and mental illnesses, such as coronary artery disease or depression [1-4]. Furthermore, a link is suggested between higher stress levels and an increased risk of mortality [5,6]. Across several studies, reviews indicate that the prevalence of self-reported stress during the COVID-19 pandemic ranged from 32% to 56%, with a focus on both the general population and specific subgroups, such as patients, health care workers, pregnant women, and students [7-9]. Among higher education employees from 16 different countries, 73% reported experiencing moderate to high levels of stress [10]. Psychological stress has become a public health issue with far-reaching implications for society [11], such as an increased risk of substance misuse or addiction [12-14], poorer relationship quality [15-17], or the financial burden resulting from stress-related productivity losses and absenteeism [11,18].

Studies indicate that coping self-efficacy, which refers to the belief that one is capable of effectively managing one's own stress [19-21], might contribute to effective coping [22] and reduced perceived stress in different target groups [23-25]. Numerous studies have explored associations between individual physical behaviors, including physical activity (PA), sedentary behavior (SB), or sleep, with psychological stress and coping strategies. PA was found to exhibit a medium beneficial effect on stress in adults [26], although the association is characterized by a high degree of individual variability [27,28]. More inconclusive results are reported in studies on the association between indicators of SB and stress [29-33]. Thus, further studies are required that take different time frames, contexts, and domains into consideration [27,30,33]. An insufficient sleep duration appears to be another indicator of experiencing more stress [34-36], while sleep quality was positively associated with higher coping self-efficacy in adolescents [23]. Since physical behaviors do not occur in isolation, their interrelationships must be taken into account. This is addressed by the growing paradigm in sport and health science, which conceptualizes physical behaviors as compositional elements within a 24-hour cycle [37,38]. Reflecting this perspective, recent practice-oriented activity guidelines—such as those promoted under the motto "Make Your Whole Day Matter"—increasingly emphasize the need for balanced time allocation across PA, SB, and sleep, including the recommendation to limit screen time [39,40].

A growing body of literature addresses physical behavior over a 24-hour period and its associations with mental health. Current systematic reviews highlight the positive effects of replacing time in SB with PA for mental health in adults and children [41-43]. For example, among adults, spending 15 minutes more in light physical activity (LPA) instead of being sedentary was associated with lower anxiety, depression, and stress scores [44]. Additionally, reallocating 30 minutes in SB to moderate PA in women or to walking in men aged 21 to 35 years both resulted in a decline in self-reported stress levels [45]. Other cross-sectional studies indicate that replacing time spent in SB with sleep in adults is also associated with lower perceived stress and improved mood [46,47]. However, we are not aware of any study that has examined the association between 24-hour physical behavior and stress-related coping. Overall, much of the evidence linking physical behavior to perceived stress is derived from cross-sectional designs [41,45,47] that analyze between-person differences at a single time point and are therefore inherently limited in their ability to elucidate temporal within-person dynamics, including day-to-day variability in 24-hour physical behavior and stress [48,49].

To overcome these limitations, intensive longitudinal studies (also known as ambulatory assessment or ecological momentary assessment) are currently the state - of - the - art methodology for examining within - person associations [50,51]. These study designs have several advantages, namely, the assessment in everyday life, in real - time, with device - based methods, and repeated measurements with a high sampling frequency, which enables researchers to track dynamic relationships [48,52]. Therefore, they bypass laboratory distortions and minimize recall biases associated with traditional approaches [53]. Accordingly, the implementation of ambulatory assessments is promising for capturing fluctuations in stress-related processes and their associations with physical behavior throughout the day [54]. To the best of our knowledge, no previous study has focused on this within-person interplay. We aimed to investigate the association of device-based 24-hour physical behavior, self-perceived stress, and coping self-efficacy in everyday life. Based on previous empirical findings and theoretical models [42,46], we expected that the composition of 24-hour physical behavior is associated with both daily perceived stress (hypotheses 1 - 4) and coping self-efficacy (hypotheses 5 - 8) in healthy adults.

We hypothesized that the ratio of SB to sleep, LPA, and moderate-to-vigorous physical activity (MVPA) would be positively associated with self-perceived daily stress (H1), whereas more time spent in (1) MVPA relative to SB (H2), (2) LPA relative to SB (H3), and (3) sleep relative to SB (H4) would be associated with less self-perceived stress. Furthermore, we expected the proportion of SB relative to the other physical behaviors to be negatively associated with coping self-efficacy (H5), while a higher ratio of (1) MVPA to SB (H6), (2) LPA to SB (H7), and (3) sleep to SB (H8) is associated with a stronger belief in being able to cope with tasks at hand. Additional exploratory analyses were conducted to examine the effects of reallocating time from one physical behavior to another on perceived stress and coping self-efficacy. Furthermore, subjective sleep quality and exercise behavior were exploratively fitted into the existing models in order to obtain indications of the robustness of results.

Methods

Ethical Considerations

This study was approved by the Ethics Committee of the Karlsruhe Institute of Technology (A2020-001). Prior to the start of the study, participants received comprehensive information about the aim and procedure of the investigation and provided informed consent. Participants had the option of

XSL•FO
RenderX

withdrawing from the study at any time. In order to protect participants' privacy and confidentiality, we deidentified the data after collection. The successful completion of the study was rewarded with a fitness tracker worth €100 (US $114.24).

Participants

Potential participants were recruited via flyers, mailings, word of mouth, and an internal newsletter from the Karlsruhe Institute of Technology. The study leaders consulted with interested parties via email or telephone to ensure that all predefined inclusion criteria for the study were met. Eligibility criteria included predominantly sedentary work and the absence of current physical injuries or psychological disorders. In total, 222 university employees participated in the study between October 2022 and December 2023 in Karlsruhe, Germany.

Study Design

This study represents an intensive longitudinal method [55] and is a secondary analysis of a within-person encouragement design investigation, the details of which can be found in Giurgiu et al [56]. However, no overlapping analyses were conducted.

The study started with an in-person session during which participants received detailed information about the study procedures, completed a questionnaire assessing demographics, and were equipped with a study smartphone (Nokia G50 or 6; Nokia Corporation), a Fitbit wearable (Fitbit Inspire 2; Google), and a Move 4 accelerometer (Movisens GmbH). The ambulatory assessment period began the following day and lasted 15 working days. To maintain motivation and ensure compliance, weekend days were not included [57]. During the study period, participants were asked to wear the Fitbit wearable on their wrist and the Move 4 sensor on their thigh as continuously as possible. Moreover, the smartphone prompted participants up to 8 times per day to answer short e-diary questionnaires, with e-diaries occurring based on a wearable-triggered sedentary algorithm, except for the additional morning and evening queries.

Measures

24-Hour Physical Behavior

Triaxial accelerometer data assessed by a Move 4 sensor (Movisens GmbH) with a sampling frequency of 64 Hz and a range of ±16 gravitational acceleration were used to measure 24-hour physical behavior. The raw accelerometer data were preprocessed after the study period with the software ActiPASS (version 2024.05; ActiPASS) [58]. ActiPASS implements algorithms for nonwear, sleep detection, posture, and activity intensity derived from cadence measures that have demonstrated high accuracy for wake-time movement behaviors and sleep in validity studies [59-61]. Based on the preprocessed data, we aggregated the most commonly examined physical behavior categories—sleep, SB (sitting or lying episodes outside of sleep intervals), LPA (walking with a cadence <100 steps/min and standing), and MVPA (walking with a cadence ≥100 steps/min)—as average minutes per day [38]. In line with previous wearing protocols [62], participants and days were only included when (1) participants had at least 3 valid wear-time days (≥20 h of wear time per day), (2) at least 1 period of walking was detected that day, and (3) days comprised more than zero minutes of sleep.

Momentary Self-Perceived Stress and Coping Self-Efficacy

Participants received all e-diaries on the study smartphone (Nokia G50 or 6). A morning and an evening survey were conducted between fixed time periods (morning: 7 AM-8:30 AM, evening: 9:45 PM-11 PM), during which participants were permitted to respond at their chosen time. The e-diary assessments during the day occurred up to 6 times per day between 8:40 AM and 9:40 PM. They were based on a sedentary-triggered design [63], appearing after 30 consecutive minutes in a sitting or lying body position. While half of the triggers exclusively prompted questions on momentary constructs such as affective states or perceived stress, the other half included a prompt to interrupt SB for 3 minutes before answering the identical e-diary questions. To reduce participants' burden, prompts could be delayed up to 15 minutes and did not occur within at least 30 minutes after a completed e-diary rating.

Momentary perceived stress and coping self-efficacy were each captured by one item in the e-diary assessments completed during the day and then aggregated at the daily level. Previous studies showed single-item measures to be valid and reliable for stress measurement [64]. Both items were based on the Perceived Stress Scale-10 [65]. Following Jones et al [31], participants were asked to rate their subjectively perceived stress level on a visual Likert scale from 1 to 5 ("Do you feel nervous or stressed at the moment?," 1="not at all" to 5="extremely"). Based on the question "Do you currently feel that you can cope with all your upcoming tasks?," we assessed participants' current coping self-efficacy on a Likert scale ranging from 1="not at all" to 5="extremely."

Covariates

In the initial in-person session, age in years as well as sex (female vs male) were assessed through self-reports, and anthropometric data were objectively measured in order to calculate the BMI. One adapted item from the Pittsburgh Sleep Quality Index [66] was implemented in the morning survey to assess the perceived sleep quality of the previous night on a scale from zero to 100 ("How would you rate your sleep quality last night?"). In the evening survey, participants used a dichotomous response format to indicate whether they had exercised that day (yes vs no). A definition of the term "sports exercise" was not provided.

Statistical Analysis

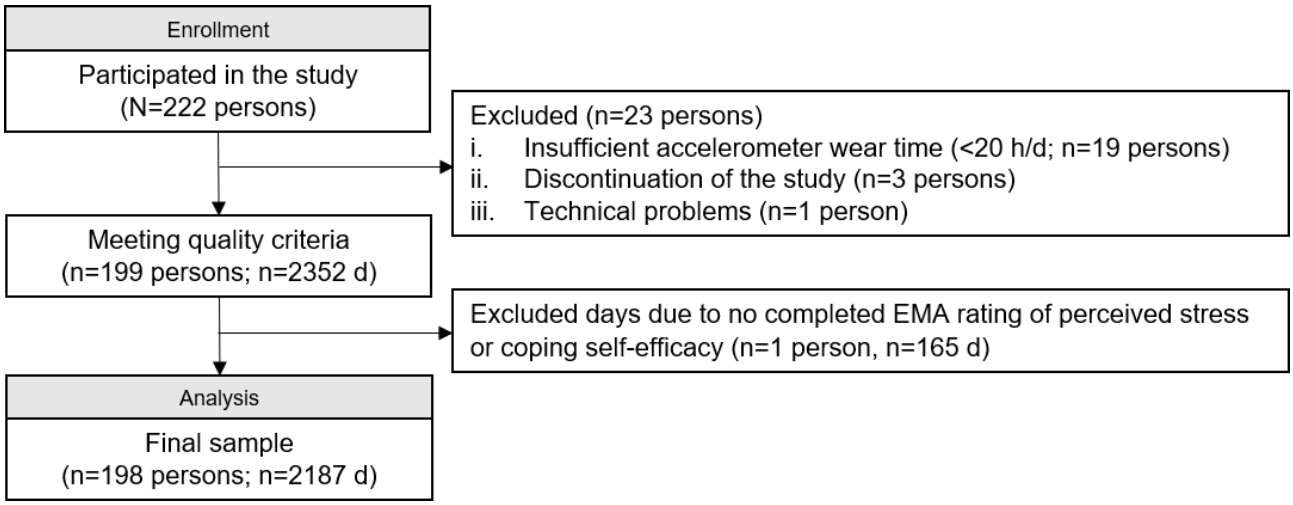
Prior to compositional data analysis procedures, we used an isometric log-ratio (ilr) transformation to account for the multicollinearity of direct composition measures [67]. The compositions of sleep, SB, LPA, and MVPA were expressed as ilr coordinates, containing information about one activity in relation to the remaining physical behaviors in the 24-hour cycle. In accordance with existing literature, 3 zero values were replaced before the transformation using the log-ratio expectation maximization algorithm [68].

XSL•FO
RenderX

As is the state of the art when analyzing hierarchically structured intensive longitudinal data, we used a multilevel approach [69]. Prior to fitting the multilevel models, we determined intraclass correlations (ICCs) using unconditional models with daily averaged self-perceived stress (hypotheses 1 - 4) and coping self-efficacy (hypotheses 5 - 8) as outcomes. Afterwards, multilevel models with repeated measurements (level 1) nested within participants (level 2) were estimated using restricted maximum likelihood and an unstructured covariance matrix for the random effects. In the interest of model parsimony, nonsignificant random effects were excluded. Model assumptions, including multicollinearity, homoscedasticity, and normal distribution of residuals, were checked [69,70]. The covariates *age* (years), *sex* (female vs male), *BMI* (kg/m^2), and *coping self-efficacy* (only in hypotheses 1-4) were selected a priori and added as predictors based on data availability as well as known associations [71-79]. The respective compositions represented by ilr1, ilr2, and ilr3 were centered within clusters in advance and integrated as predictors. The following equation model refers to hypothesis 1 (further models are presented in Supplementary File A in Multimedia Appendix 1).

- H1: Y (stress perception)$_{ij} = \gamma_{00} + \gamma_{01} \times sex_j + \gamma_{02} \times age_j + \gamma_{03} \times BMI_j + \gamma_{10} \times$ *coping self-efficacy*$_{ij} + \gamma_{20} \times$ ilr1 (SB/LPA×MVPA×Sleep)$_{ij} + \gamma_{30} \times$ ilr2 (LPA/MVPA×Sleep)$_{ij} + \gamma_{40} \times$ ilr3 (MVPA/Sleep)$_{ij} + u_{0j} + u_{1j} \times$ ilr3 (MVPA/Sleep)$_{ij} + r_{ij}$
- ilr1 = $\sqrt{(3/4)}$ ln (SB / (LPA×MVPA×Sleep))
- ilr2 = $\sqrt{(2/3)}$ ln (LPA/$\sqrt{}$(MVPA×Sleep))
- ilr3 = $\sqrt{(1/2)}$ ln (MVPA/Sleep)

Exploratively, we used substitution analyses to examine the expected change in the outcome when time was reallocated between physical behaviors in a 60-minute window. Pairwise reallocations were calculated in 20-minute increments, with estimates based on the average composition of the included participants [80].



All analyses were performed in R (version 4.4.0; The R Project for Statistical Computing), using the packages *compositions* [81], *zCompositions* [82], and *lme4* [83], with a predetermined α level of .05. To facilitate the comparison of results, standardized β coefficients were calculated based on established procedures [70].

Results

Descriptive Statistics

Due to insufficient accelerometer wear time (<20 h/d, n=19), discontinuation of the study (n=3), and technical problems (n=1), 23 participants were excluded from the analysis (Figure 1). In total, 199 participants answered momentary assessment prompts on 2352 days, representing an average compliance rate of 69.9% at the personal level. On average, 4.4 surveys were completed per day. Days without any stress or coping self-efficacy rating (n=165 d) were excluded from the analysis, which led to the exclusion of one further participant due to the lack of valid days (n=1). A total of 198 participants were included in the final sample, of whom 109 (54.8%) were female participants, and the average age was 35.87 (SD 10.76) years (Table 1).

Table . Descriptive characteristics of study participants (N=198, female 54.8%, 109/199).

Variable	Mean (SD)	Minimum	Maximum
Age (y)[a]	35.87 (10.76)	20.18	64.74
BMI (kg/m²)[a]	23.99 (3.28)	17.87	35.25
Valid days[b]	11.84 (3.86)	3	22
Sleep (h/d)[c]	7.95 (1.12)	4.27	12.70
SB[d] (h/d)[c]	10.51 (1.11)	6.68	14.14
LPA[e] (h/d)[c]	3.94 (1.00)	1.91	7.33
MVPA[f] (h/d)[c]	1.35 (0.42)	0.51	2.89
Self-perceived stress[c]	2.34 (0.65)	1.00	4.30
Coping self-efficacy[c]	3.64 (0.65)	1.00	5.00

[a]Aggregated within participants.

[b]Accelerometer wear time ≥20 h/d, aggregated within participants.

[c]Accelerometer wear time ≥20 h/d, aggregated within days and participants.

[d]SB: sedentary behavior.

[e]LPA: light physical activity.

[f]MVPA: moderate-to-vigorous physical activity.

Over the course of all days, participants wore the accelerometer for an average of 23.79 (SD 0.65) hours per day. The 24-hour geometric mean composition of physical behavior for all analyzed days consisted of 33.9% sleep (8.1/24 h), 45.2% SB (10.8/24 h), 15.8% LPA (3.8/24 h), and 5.1% MVPA (1.2/24 h). Further information on participants' physical behavior, self-perceived stress, and coping self-efficacy is provided in Table 1.

Across all days, the average daily perceived stress score was 2.36 (SD 0.87, mean of per-person minimum=1.49, mean of per-person maximum=3.28), with lower values indicating lower stress perception than higher values (scale: 1 - 5). ICC calculations (ρI=0.483) revealed that 51.7% of the variance of the stress perception was based on the within-person fluctuations. The average coping self-efficacy score (scale: 1 - 5) was 3.62 (SD 0.85, mean of per-person minimum=2.83, mean of per-person maximum=4.33), where 40.8% of the variance can be explained by within-person variances (ρI=0.592).

Association Between 24-Hour Physical Behavior and Self-Perceived Stress

Daily self-perceived stress was not significantly associated with time spent in (1) SB relative to the other behaviors (H1), (2) MVPA relative to SB (H2), or (3) LPA relative to SB (H3) (Table 2). In line with hypothesis 4, results indicate a significant negative association between ilr3 (sleep/SB) and self-perceived stress (standardized β=–.03; t_{1988}=–2.045; *P*=.04). Coping self-efficacy and age of the participants were both significantly negatively related to perceived stress in all models (Table 2). The presence of significant random effects in models 1, 2, and 3 indicates that the effects of the ratio of MVPA to sleep, sleep to MVPA and SB, as well as sleep to MVPA, LPA, and SB, vary between individuals (Supplementary File B in Multimedia Appendix 2).

Association Between 24-Hour Physical Behavior and Coping Self-Efficacy

Contrary to our hypotheses, the composition of SB to LPA, MVPA, and sleep was not significantly associated with the daily averaged coping self-efficacy score (H5). Furthermore, none of the other expected associations between the compositions of physical behavior and coping self-efficacy (H6, H7, H8) were observed (Table 3). A positive association between coping self-efficacy and age became evident in all 4 models (H5-H8). Additionally, random effects were found for the ratio of LPA to SB, as well as LPA to all other remaining activities (Table 3).

Exploratory Analyses

We exploratively calculated reallocation analyses within a 60-minute frame, simulating the effects of replacing the same amount of time (20-min increments) in one physical behavior with another on self-perceived stress and coping self-efficacy. The starting point represents the empirically observed mean-centered composition of 490 minutes sleep, 649 minutes SB, 227 minutes LPA, and 74 minutes MVPA. The replacement of SB by LPA, MVPA, or sleep was analyzed, with no significant changes of self-perceived stress or coping self-efficacy within a 60-minute period (Figure 2).

Figure 2. Estimated changes in predicted daily averaged self-perceived stress and coping self-efficacy associated with pairwise reallocations[a]. [a]95% CIs were derived by bootstrapping with 1000 replicates. CSE: coping-self-efficacy; LPA: light physical activity; MVPA: moderate-to-vigorous physical activity; SB: sedentary behavior.

As part of our exploratory analyses, self-reported exercise behavior was added as an additional fixed predictor in all models including PA (models 1 - 3 and 5 - 7; Supplementary File C in Multimedia Appendix 3, Tables 1 and 2). We found no statistically significant association between exercise behavior and perceived stress or coping self-efficacy. However, adding exercise behavior revealed a significant positive association of time in SB relative to the remaining physical behaviors on perceived stress (standardized β=.04; t_{1379}=2.039; P=.04). Furthermore, adding subjective sleep quality as a fixed predictor in both models investigating the association of the ratio of sleep to SB revealed sleep quality to be associated with coping self-efficacy (model 8: standardized β=.08; t_{1769}=5.279; P<.001) but not with perceived stress (model 4: standardized β=–.01; t_{1769}=–0.724; P=.47) (Supplementary File C in Multimedia Appendix 3 and Table 3). The addition of sleep quality did not alter the effect of the ratio of sleep duration to SB on self-perceived stress (standardized β=–.03; t_{1776}=–2.364; P=.02).

Discussion

Principal Findings

The relationship between individual physical behaviors and stress has been studied extensively in recent years. Our 15-day ambulatory assessment study with 198 participants expands existing evidence with real-time assessments in a naturalistic setting, providing within- and between-subject insights into participants' everyday lives. We aimed to investigate the associations between device-based 24-hour physical behavior compositions with perceived stress and stress-related coping self-efficacy in an intensive longitudinal data design. Our results indicate that time spent sleeping relative to being sedentary over the 24-hour cycle is negatively associated with perceived daily stress level (H4) but not with coping self-efficacy (H8). The ratios of SB to the remaining behaviors (H1/H5), MVPA to SB (H2/H6), and LPA to SB (H3/H7) were not significantly related to either self-perceived stress or coping self-efficacy. In the exploratory analyses, replacing time spent in SB by LPA, MVPA, or sleep within a 60-minute period did not result in any significant changes in perceived stress or coping self-efficacy.

One possible explanation for why the assumed associations between the composition of SB and the other physical behaviors with perceived stress or coping self-efficacy were not evident could be that the level of mental workload during SB was not taken into account. Research has shown that mentally passive SB, for example, watching television, can increase the risk of depression, while mentally active SB, such as reading, is considered a protective factor [84,85]. As the relationship between SB and stress-related parameters is particularly important for developing targeted health-promoting measures in working environments with high levels of sedentariness, it may be advisable to consider the aggregation of data not on a daily basis but rather within the context of working and nonworking hours [74]. When adding exercise behavior as an additional fixed predictor to our main models (H1/H5), more time in SB compared to the remaining behaviors was associated with higher stress levels. Accordingly, the association between

XSL•FO
RenderX

more time in SB compared to the remaining behaviors and stress levels might not be independent of other constructs and influencing factors such as mental load or time of the day. Therefore, future research endeavors might be interested in analyzing the associations between the composition of physical behaviors and momentary stress levels at different aggregation levels (eg, 1 or 2 h) [86].

We found a negative association between the time spent sleeping relative to SB and self-perceived stress, which is in line with previous compositional analysis studies suggesting that replacing sedentary time with sleep is associated with lower psychological stress in young individuals [46] and in working adults [47]. As Bassett et al [87] identified sleep quality, but not sleep duration, to influence cortisol responses to acute psychosocial stress, we exploratively included sleep quality as a further fixed predictor in our model. Sleep quality did not emerge as an additional influencing factor in our model, whereas the association between the ratio of sleep to SB and perceived stress remained significant, underscoring its robustness. Contrary to our hypotheses, a higher ratio of sleep to SB was not related to coping self-efficacy, even after adding sleep quality as a further exploratory fixed effect. The exploratively expanded model revealed a positive association between sleep quality and coping self-efficacy, which is consistent with the findings of Ten Brink et al [23]. This study investigated the importance of coping self-efficacy in breaking the bidirectional cycle between sleep and stress in adolescents. The findings showed that sleep quality not only leads to a higher coping self-efficacy but also a lower level of reported stress the following day [23]. Based on our results, we can only vaguely expect an indirect effect of sleep quality on stress perception, as coping self-efficacy appears to be significantly negatively associated with self-perceived stress in all models (H1-H4). However, these findings emphasize the potential of promoting one's belief in being able to cope with stress for interventions to reduce stress in everyday life, especially as some areas of work as well as personal obligations do not allow for an increase in sleep duration.

The compositions of LPA to SB and MVPA to SB in the 24-hour cycle were not significantly associated with either perceived stress or coping self-efficacy. In the limited existing literature, Rong et al [45], for example, found that replacing self-reported SB with walking or moderate PA had a positive effect on perceived stress. One reason for the differing results might be that subjective measures, possibly related to common method variance [88], tend to be more predictive of affect-related outcomes than objective measures [89]. Additionally, our study design (ie, half of the assessments were captured after a sedentary bout of ≥30 min) could have resulted in lower daily stress ratings. Our analyses revealed various significant random effects, for example, for the ratio of LPA to SB and LPA to remaining behaviors on coping self-efficacy, thus underlining the variability across participants regarding the association of 24-hour physical behavior and both stress-related outcomes. The occurrence of these within-subject associations should be taken into account in future investigations. Momentary assessments could provide further insights into the temporal sequencing within a day and help assess potential contextual influences, such as the environment of PA, since it has been found that outdoor PA is associated with lower negative affect than indoor PA [90].

Overall, based on our results, we suggest examining the relationship between compositional predictors, psychological stress, and further moderating and mediating factors in more detail. Studies and replications should be conducted with diverse and stress-prone samples, such as students [91], to gain application-oriented insights into the interplay of the 24-hour physical behavior and mental health outcomes. A more comprehensive understanding of the complex association between the mechanisms underlying SB, PA, and sleep and the biological, psychosocial, and behavioral facets of stress could advance a greater focus of the 24-hour approach not only in stress management but also in public health [92,93] and health promotion recommendations [34].

Limitations

This study has a number of strengths, but a few limitations must be taken into account. The fact that the sample included only university employees with predominantly sedentary working conditions limits the generalizability of the results. Additionally, the observational study design does not allow the elucidation of causalities. Due to its multidimensionality, the assessment of the stress is challenging [94]. In line with previous studies [31,64], we measured both stress-related outcomes with subjective, self-report-based single-item measures that capture only the stress that participants are aware of [95,96]. However, using an ambulatory assessment design promoted the reduction of retrospective biases [50]. Half of our assessments occurred after a sedentary bout, which may have resulted in reduced variance, so that further random sampling studies are required. However, ICC calculations show that both stress-related outcomes can be adequately explained by within-person variance. As we aggregated device-based activity data within days from 12 AM to 11:59 PM, the actual sleep time per day might be distorted, because the time in bed before midnight is not represented as sleep time on the following day. Finally, the implemented sleep algorithm used may incorrectly classify daytime sleep as being sedentary (ie, if not a primary time-in-bed period was detected) [59]. However, this appears to play a subordinate role in the analyses, as daytime sleep was only reported in the evening e-diaries on 5.6% (122/2187) of all analyzed days.

Conclusions

This study investigated the associations between device-based 24-hour physical behavior, self-perceived stress, and coping self-efficacy in daily life. Our findings suggest that spending more time asleep relative to being sedentary in the 24-hour period is associated with lower levels of perceived stress on the same day. However, the ratio of sleep to SB was not associated with the perceived ability to cope with daily demands. The composition of SB to the other physical behaviors and time in LPA or MVPA relative to SB showed no association with either stress-related outcome. Nonetheless, within-subject associations and descriptive trends of behavioral reallocation hint at the potential relevance of daily activity patterns for handling stressful situations. These findings underscore the need for future ecologically valid studies that incorporate contextual and

XSL•FO
RenderX

individual variables, as well as momentary assessments, in order to better understand the role of physical behavior in stress regulation. Such insights are necessary in order to provide target group–appropriate health-promoting recommendations for coping with stress in everyday life.

Acknowledgments

The authors would like to sincerely thank the participants who contributed to the study. They further thank Selina Schneider, Til Becker, Ellen Rulf, Rebecca Nissen, Jonas Behlke, and Lennart Buday for their research support.

The authors declare the use of generative artificial intelligence in the research and writing process. According to the GAIDeT taxonomy (2025), the following tasks were delegated to generative artificial intelligence tools under full human supervision: code optimization. ChatGPT (GPT-4) by OpenAI (free version) was used to support code optimization, which was further reviewed and revised by the study group.

Abstract

Background: Young adults report high levels of anxiety, yet their access to timely treatment remains limited. Mobile-based digital therapeutics, particularly ecological momentary assessment and intervention (EMA/EMI), offer a promising approach to deliver context-responsive care. The integration of wearable-derived digital phenotypes with digital therapeutics may enhance the personalization of feedback in such interventions, but empirical evidence from real-world settings remains scarce.

Objective: This study examined the real-world applicability and effectiveness of an EMA/EMI-based digital therapeutic, ANZEILAX-Green (HAII Corp), for use in anxiety reduction in young adults and investigated how personalized feedback generated by combining EMA/EMI data with wearable-based digital phenotypes ameliorates symptoms and promotes self-management and user engagement.

Methods: An 8-week exploratory experimental study was conducted with young adults aged 19-39 years. Participants used a smartphone app in which EMA/EMI modules had been integrated with a smartwatch that continuously collected digital phenotyping data, including heart rate, sleep, and activity. Psychological outcomes were assessed using the Generalized Anxiety Disorder 7-item scale (GAD-7) and Patient Health Questionnaire-9 (PHQ-9) at baseline and weeks 2, 4, 6, and 8, and the Rosenberg Self-Esteem Scale (RSES) at baseline and week 8. Quantitative changes were analyzed using paired-samples *t* tests and repeated-measures ANOVA, and qualitative interviews were thematically analyzed to identify user experience mechanisms and design implications.

Results: In all, 29 participants were included in the final analysis. Significant improvements were observed in their GAD-7 (mean difference –4.79, 95% CI –6.56 to –3.02; Cohen d=1.03; *P*<.001), PHQ-9 (mean difference –3.86, 95% CI –5.79 to –1.93; Cohen d=0.76; *P*<.001), and RSES scores (mean difference +5.21, 95% CI 3.47 to 6.95; Cohen d=1.14; *P*<.001). Consistent improvements in GAD-7 scores were observed across the assessment points, with statistically significant reductions from week 4 onward. Participants demonstrated high adherence, completing 80% of the EMA/EMI prompts. The digital phenotype showed trends of increased deep sleep and reduced mobility, and sleep indicators were significantly correlated with depressive symptoms. Analysis of the interview findings revealed 5 mechanisms: enhanced self-awareness, data-driven reflection, behavioral change, intrinsic motivation, and extension of treatment into daily life.

Conclusions: EMA/EMI-based digital therapeutics integrated with wearable-derived digital phenotypes are feasible and acceptable for use by young adults and were associated with within-group reductions in anxiety, suggesting acceptable efficacy, though this warrants confirmation in a controlled trial. The combination of real-time self-reported assessments of emotional states

XSL•FO
RenderX

and passive physiological monitoring enables personalized feedback suited to users' emotional and physiological states. These findings offer empirical and design insights for automated, personalized mental health intervention systems.

KEYWORDS

mobile health; anxiety disorder; digital phenotypes; ecological momentary assessment; ecological momentary intervention; acceptance and commitment therapy; wearable data

Introduction

Anxiety disorders are a major global mental health concern that affect an estimated 301.39 million people worldwide, accounting for 28.68 million disability-adjusted life years in 2019. Their burden has increased substantially since the COVID-19 pandemic [1,2]. The burden of anxiety disorders is especially pronounced in young adulthood, with the highest prevalence and disability burden observed among individuals aged 20-24 years [3-5]. This age group is especially vulnerable to anxiety due to the pressure of such developmental tasks as academic pursuits, career planning, identity formation, financial independence, and complex social relationships. Thus, timely and accessible early intervention is crucial to reduce delays in care and mitigate the risk of persistent symptoms and long-term functional impairment [6-8], yet treatment use remains remarkably low due to a variety of barriers, including mental health stigma, limited mental health literacy, negative attitudes toward treatment, accessibility constraints, and financial burden [9-11].

Traditional assessments and treatments for anxiety primarily rely upon retrospective self-reports, which fail to capture the dynamic fluctuations of anxiety, which may change rapidly depending on the situation and are vulnerable to recall bias [12-14]. This may cause the aggravation of momentary symptoms and contextual triggers to be overlooked, undermining the accuracy of assessment and the design of personalized intervention.

As a result, digital therapeutics (DTx) have emerged as a promising adjunctive approach to deliver accessible and scalable mental health interventions [15-17]. DTx provide evidence-based therapy at any time and place, decrease financial burdens, and facilitate self-management in daily life [16,18,19]. Given the high engagement with digital technologies among the young, mobile-based DTx may usefully complement traditional mental health care by offering accessible, on-demand therapeutic content, facilitating symptom monitoring, and providing tailored feedback in daily-life contexts [4,20,21]. Numerous studies have reported that mobile-based interventions exerted a positive effect on anxiety by alleviating symptoms [22-24], and DTx hold the potential to resolve issues of cost and accessibility while enhancing users' self-management abilities [25-27].

Of the variety of DTx approaches currently available, ecological momentary assessment (EMA) is particularly promising, as it repetitively samples users' responses in their natural daily environments, thereby precisely capturing the momentary fluctuations and context-specific triggers of anxiety [12,14,28]. The implementation of EMA on mobile-based platforms can facilitate the real-time capture of self-reported psychological states in everyday contexts, support time-stamped data collection, and achieve generally good participant compliance [14,29]. Ecological momentary intervention (EMI) uses data derived through EMA to deliver interventions in real time within the context of daily life [30-32], thereby providing therapy right when symptoms occur or when individuals are most receptive to the therapy content [30-33]. By delivering support in daily-life contexts, EMI may help individuals practice and apply therapeutic skills outside clinical settings, which may support the generalization and maintenance of treatment gains [32,34,35]. Together, EMA and EMI represent a promising approach for overcoming the limitations of traditional anxiety treatments [36,37].

Digital phenotype refers to the continuous traces that individuals generate in their everyday interactions with digital technologies, which may reflect health- and illness-related characteristics in real-world contexts [38,39]. EMA/EMI systems may be further enhanced through their integration with wearable-based digital phenotyping by enabling continuous, passive, and context-sensitive monitoring for more personalized and timely interventions [39-42]. Comprising behavioral, physiological, and environmental data collected via smartphones or wearable devices, a digital phenotype represents a person's real-time digital traces and enables the quantitative characterization of moment-to-moment changes in an individual's state [39,42-45]. It can thus capture natural variations in physiological states through indicators such as heart rate, sleep patterns, and activity levels that may signal fluctuations in mental health and stress-related states, although the capacity of wearables to reliably infer such states in real-world settings remains limited [43,46-48].

Wearable-derived digital phenotypes complement conventional EMA by allowing an individual's emotional and physiological states to be captured separately from repeated self-reports. For example, changes in heart rate variability (HRV), activity levels, or sleep patterns may indicate anxiety-related states in daily life [49,50], and when these physiological patterns are examined together with emotional or situational information reported through EMA, they can provide a more comprehensive understanding of an individual's state [45,50-53].

Additionally, subjective emotional reports and wearable-derived physiological signals may provide complementary rather than redundant information about anxiety-related states [50,54], supporting a more contextualized understanding of individuals' moment-to-moment experiences and enhancing self-reflection in daily life [52,53,55]. Feedback integrating these subjective and physiological data not only provides information but also

XSL•FO
RenderX

serves as a therapeutic tool to boost self-efficacy and treatment adherence [56].

Integrating digital phenotyping into EMA/EMI systems enables more refined mental health assessments by considering subjective experiences and objective physiological indicators together. Such an integrated approach provides a robust foundation for timely personalized interventions grounded in an individual's physiological and behavioral context, ultimately supporting a more accurate understanding of complex mental health states that cannot be captured with data from a single source.

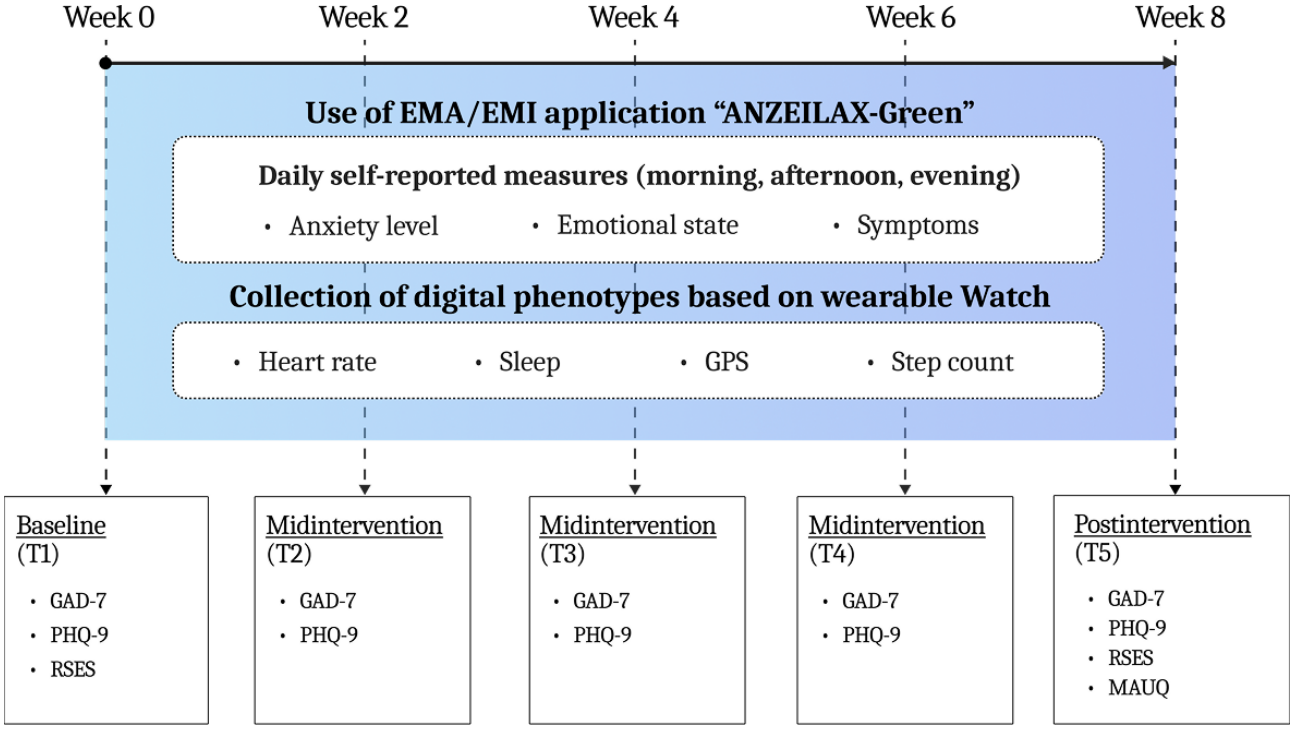
Despite the promise offered by combining subjective self-reports and objective physiological data in this way, research integrating these approaches remains limited, particularly that comprehensively examining the relationships between EMA/EMI data and physiological signals [57]. Accordingly, further investigation is needed regarding the potential contributions of combined digital-phenotype and EMA/EMI systems to the design of automated intervention systems.

Accordingly, we conducted a study using "ANZEILAX" (HAII Corp; a blend of "anxiety" and "relax," reflecting the app's aim of relieving anxiety), a digital therapeutic whose efficacy in treating anxiety disorders has been empirically validated [58]. A randomized controlled trial demonstrated that ANZEILAX significantly alleviated symptoms in patients with generalized anxiety disorder when delivered in combination with usual care, including pharmacotherapy [58]. This study integrated EMA and EMI functions into this proven therapeutic system to assess its real-world applicability and potential for the design of automated intervention systems.

This study explored the real-world applicability of EMA/EMI digital interventions for anxiety reduction among young adults and evaluated their effectiveness. Specifically, it investigated the impact of personalized feedback generated by an EMA/EMI system integrated with a wearable-based digital phenotypic data system on anxiety reduction and self-management capabilities. In addition, this study qualitatively examined the associations of users' experiences with EMA/EMI systems and integrated digital phenotypic feedback with anxiety-related physiological indicators to identify key design features for automated interventions.

Ultimately, this study sought to provide empirical evidence to support the effective implementation of context-responsive digital interventions, and to help advance personalized intervention strategies to improve mental health in young adults.

Methods



Study Design

This study was a follow-up to a randomized controlled trial of ANZEILAX, a digital therapeutic designed to alleviate anxiety symptoms in young adults. This 8-week exploratory single-group study examined the real-world applicability of interventions that integrate EMA/EMI-based digital therapeutics with wearable-derived digital phenotypic data and evaluated the operation of intervention routines, user acceptance, and potential changes in clinical outcome measures before a controlled clinical evaluation of the EMA/EMI-based DTx.

This study used the ANZEILAX-Green smartphone app (HAII Corp) with integrated EMA/EMI functions in conjunction with a smartwatch-based tool that collects health data to comprehensively explore real-time emotion assessment, momentary intervention delivery, and changes in behavioral and physiological responses in everyday contexts. The study was conducted from September to November 2025. An overview of the study design and procedures is presented in Figure 1.

Ethical Considerations

This study was reviewed and approved by the Institutional Review Board of Yonsei University (IRB number 7001988-202509-HR-2892-03). All participants provided written informed consent after receiving a full explanation of the study purpose and procedures from the research team. Participant confidentiality was maintained throughout the study, with each individual being assigned a numerical code by their order of participation. All collected data were anonymized to ensure participant privacy. Participants who completed the 8-week study were compensated with KRW 130,000 (approximately US $88) for their time and effort, and those who completed the postintervention interview received an additional KRW 20,000 (approximately US $14) as supplementary compensation.

Participants

The participants were Korean young adults aged between 19 and 39 years, with a Beck Anxiety Inventory (BAI) score of 8 to 25 (indicative of mild-to-moderate anxiety), who could communicate in Korean and use smartphones, and included individuals who had not been prescribed psychiatric medication by a psychiatric department within 30 days before the start of the study or those without changes in medication if they had been taking any. Individuals with current or past psychiatric disorders (including schizophrenia, psychosis, bipolar disorder, and epilepsy), brain injury, cognitive impairment, neurological disorders, intellectual disability, or substance or alcohol use disorders, as well as those who had exhibited suicidal intent, suicidal impulses, or self-harming behavior within the past 6 months, were excluded. High-risk individuals with BAI scores of 26 or higher were also excluded.

Procedures

Purposive sampling was used to ensure sufficient representation across age groups and anxiety severity levels (mild and moderate). Participants were approached by a member of the research team who had not been involved in quantitative data collection so as to minimize response bias. A total of 30 participants were enrolled after the research team confirmed their eligibility through online recruitment. After providing informed consent, the participants completed baseline assessments covering their sociodemographic characteristics, anxiety, and depression and then downloaded the ANZEILAX-Green app (HAII Corp). They used the app for 8 weeks in combination with a Galaxy Watch 7 to be worn throughout the study period. On the enrollment day, all participants received hands-on onboarding instructing them in the use of the app and the wearable device and were instructed to contact the research team at any time if they encountered technical difficulties.

Participants completed survey evaluations at weeks 2, 4, and 6, followed by a postintervention assessment at week 8, and those who had volunteered were invited to take part in in-depth interviews following the intervention; all 29 participants who had completed the 8-week intervention voluntarily agreed to participate in the interviews. A research team experienced in qualitative interviews conducted semistructured interviews to explore their experiences with the intervention and elicit suggestions for improvement. The key topics included participants' overall experience with the app, their perceptions of its effectiveness and satisfaction, and any facilitating and hindering factors they had noted. In particular, an interview guide was developed a priori based on the study objectives and reviewed by the research team for content validity, and the

XSL•FO
RenderX

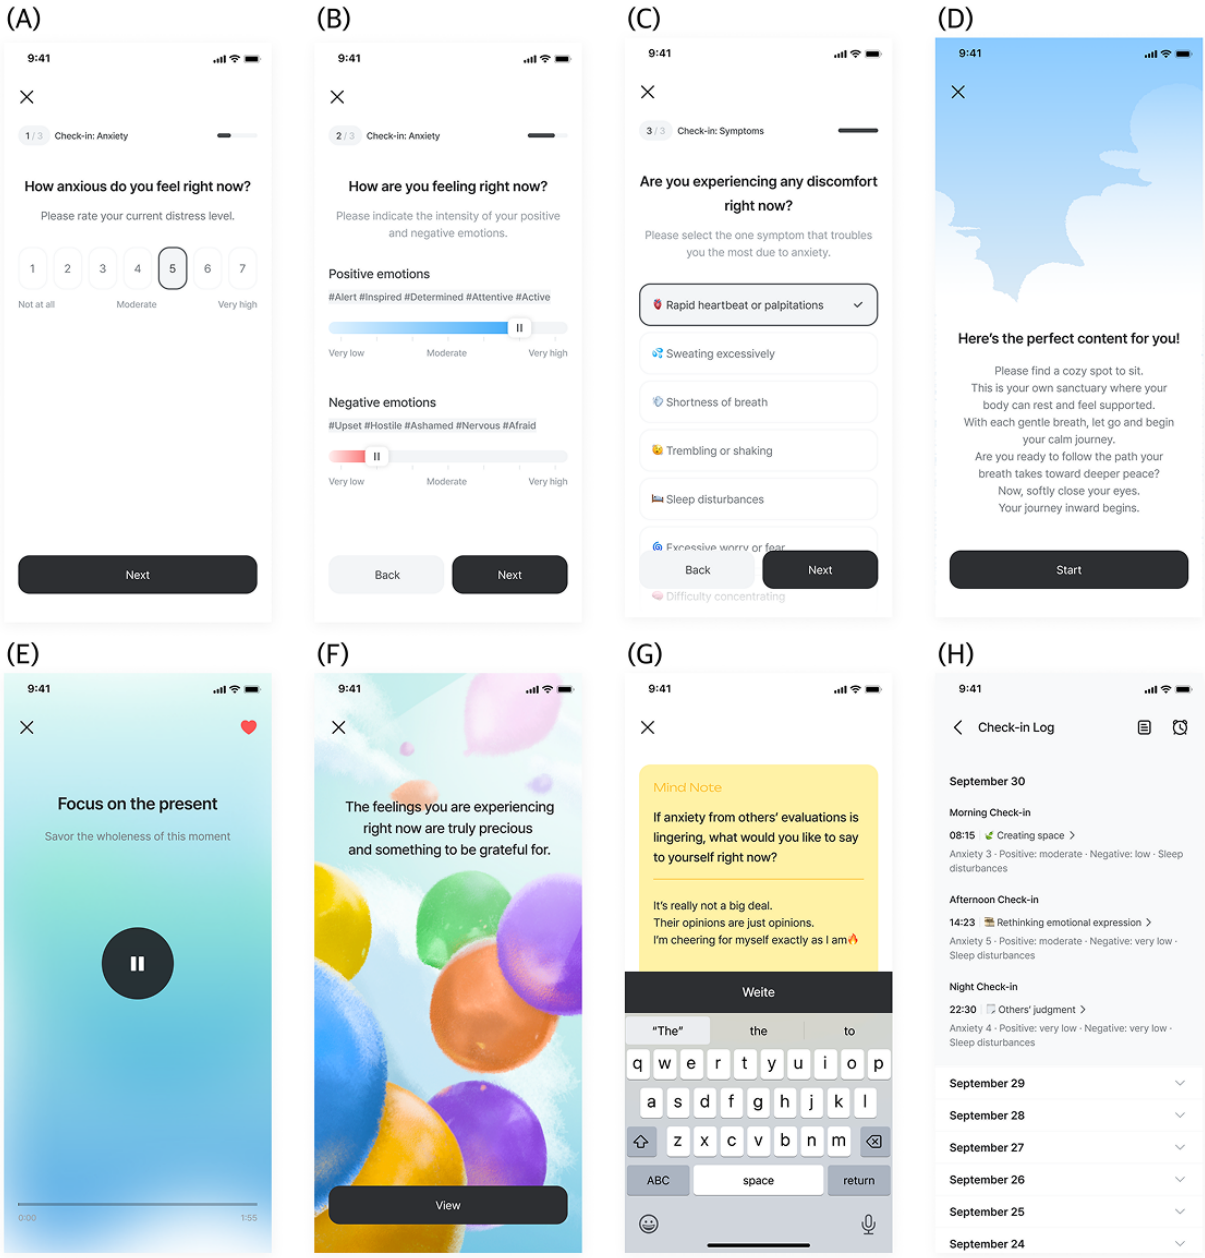
following topics were set in advance: (1) overall experience with the ANZEILAX-Green app and wearable device, (2) perceived effectiveness and satisfaction with the intervention, (3) factors facilitating and hindering engagement, (4) perceptions of the personalized weekly feedback reports, and (5) suggestions for improvement.

All interviews were conducted individually via video call after the intervention period had ended and were audio-recorded with participants' prior written consent. Interviews lasted approximately 30-60 minutes. The interviewer maintained a reflexive stance throughout, bracketing their assumptions about the intervention and remaining open to participants' perspectives. The audio recordings were transcribed verbatim by a research assistant and reviewed for accuracy before analysis. Transcripts were not returned to participants to be checked at this stage. However, participant quotations representative of each theme were verified against the original transcripts to ensure accuracy.

Intervention

Personalized Emotion Regulation App Based on EMA/EMI Systems

The intervention is based on the mobile app ANZEILAX, which received approval from the Korea Food and Drug Safety Administration in April 2025. ANZEILAX incorporates a variety of therapeutic modules, including a self-talk program based on acceptance and commitment therapy (ACT), to support users' psychological flexibility. EMA- and EMI-based functions were integrated into ANZEILAX to evaluate users' emotional states in real time and automatically provide tailored interventions, enabling more dynamic and personalized intervention delivery than the original version. This integrated version, named ANZEILAX-Green, was developed for the Android platform and launched in 2025 by HAII Corp.



In this study, participants were primarily instructed to use the EMA/EMI functions, while the other therapeutic modules in ANZEILAX were available for optional use. The participants completed EMA questionnaires regarding their anxiety and emotional states through the smartphone app multiple times per day at self-scheduled notification times in the morning, afternoon, and evening. They were required to respond to at least 3 assessment prompts per day over the 8-week period. The questionnaire consisted of items assessing anxiety (1-7 points), positive and negative emotions (each 1-7 points), and symptoms (10 items covering physical, cognitive, and behavioral domains). Positive and negative emotions were assessed using an adapted version of the International Positive and Negative Affect Schedule Short Form (I-PANAS-SF) [59].

The app analyzes users' EMA responses (anxiety, positive and negative emotions, and symptom scores) in real time and supports the automated delivery of EMI content based on ACT principles that induce immediate emotional relief through adaptive delivery based on real-time conditions. The EMA/EMI workflow is as follows: (1) upon EMA input of a user's condition, the system calculates priorities, and (2) automatically selects the intervention type (audio meditation, image, or text) appropriate to the condition and immediately provides EMI content.

The app was designed to strike a balance between automation and personalization. It functions as a state-responsive digital treatment model in which interventions are determined based on a user's actual emotional state, instead of unilateral push interventions. Users thereby learn to recognize their emotional changes in real time and immediately experience the results of interventions, thereby cultivating their emotional self-regulation skills. Detailed screenshots of the app interface are presented in Figure 2.

Digital Phenotype Collection App

Digital phenotypes, including heart rate, sleep patterns, and activity levels, were automatically collected in the background through Samsung Health integrated into the Android platform. Physiological data were captured via synchronization between the smartwatch and smartphone. Researchers have examined the validity of consumer smartwatch sensors for heart rate and sleep-stage estimation [60,61]. Nonetheless, such devices remain less accurate than polysomnography for sleep-stage classification, which was taken into consideration in data interpretation.

The digital phenotype indicators collected in this study reflect physiological and behavioral responses known to be associated with anxiety. Heart rate–related indicators are representative physiological markers of autonomic nervous system activity reported to reflect heightened arousal and autonomic imbalance associated with increased anxiety levels. Location (GPS) data and mobility patterns have been shown to capture social avoidance behaviors related to anxiety objectively [62]. Sleep-related indicators are also closely linked to anxiety, as individuals reporting higher anxiety levels tend to exhibit poorer sleep quality [63]. Finally, activity-related indicators, including step count and movement patterns, have been used as behavioral markers reflecting avoidance behaviors and irregular daily activity associated with anxiety [56]. However, because heart rate is also elevated by physical activity, the heart rate indicators were not interpreted as anxiety-specific markers, and the absence

XSL•FO
RenderX

of activity adjustment constitutes a limitation of this approach [64].

The collected data thus included physiological and behavioral indicators strongly associated with anxiety and related mental health conditions and were analyzed alongside quantitative assessment measures over time. Before the analysis, preprocessing procedures, including the removal of missing values and sensor-specific corrections such as segment adjustments, were performed. A detailed list of the collected digital phenotype items is presented in Textbox 1.

Textbox 1. Description of digital phenotypes.

Heart

- Heart rate (HR): average HR collected at 1- to 3-second intervals.

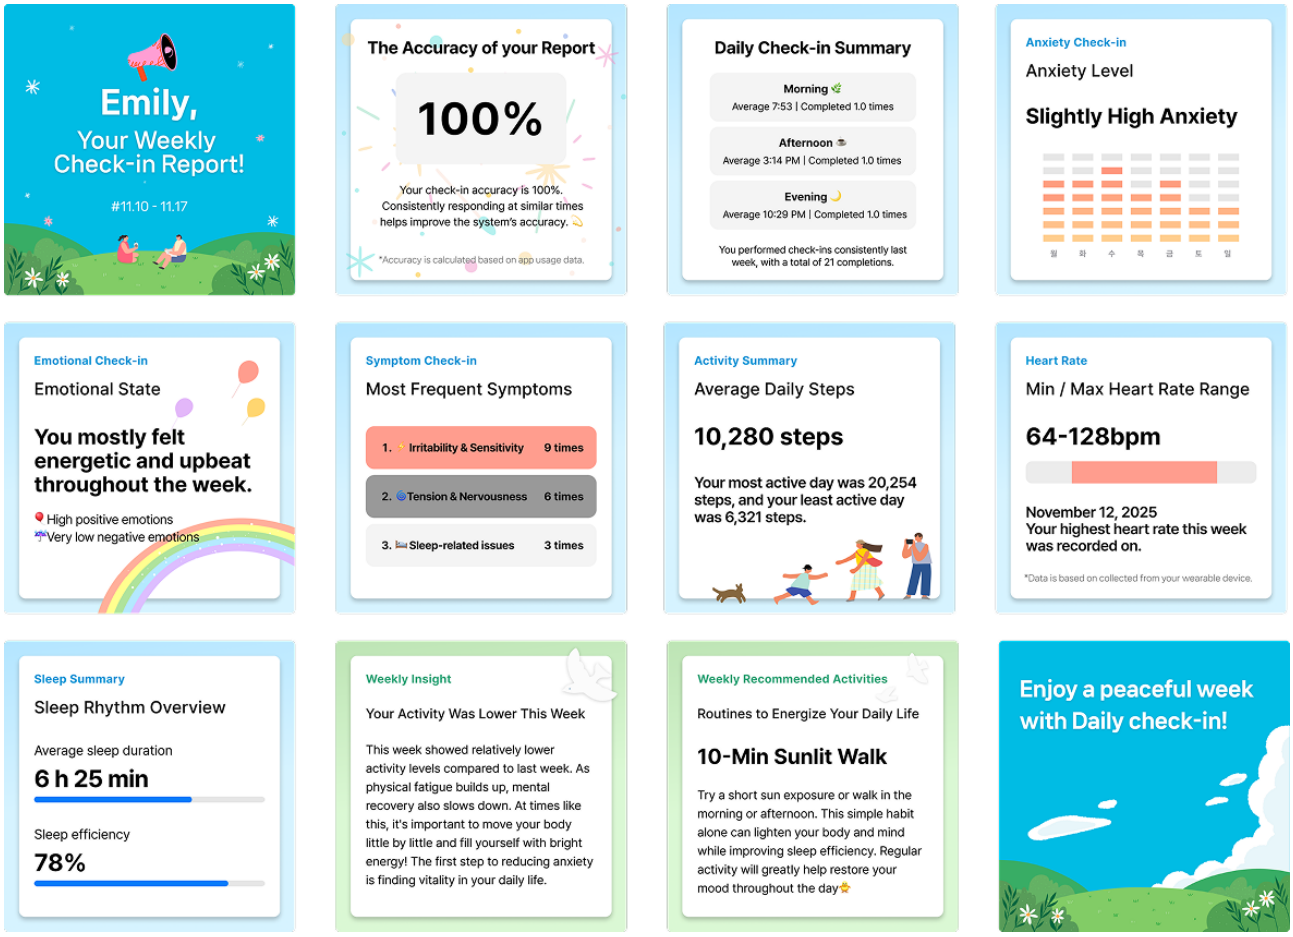
GPS

- Latitude: latitude value collected every 5 minutes.
- Longitude: longitude value collected every 5 minutes.

Sleep

- Light sleep duration: duration of light sleep per sleep event.
- Total sleep duration: total sleep duration per sleep event.
- Rapid eye movement duration: duration of rapid eye movement sleep per sleep event.
- Deep sleep duration: duration of deep sleep per sleep event.

Steps



- Step count: number of steps taken across a 5-minute interval.

Personalized Weekly Feedback Report

While the participants engaged with the ANZEILAX-Green, physiological data such as heart rate, sleep, and activity levels were simultaneously collected via the wearable device as digital phenotype data and reported weekly as objective biometrics. The weekly report summarized app usage, key usage patterns, daily anxiety scores, reported emotions and symptoms, activity levels, heart rate, and sleep metrics and provided a personalized summary with recommended activities. These biometrics facilitated the translation of abstract sensations into concrete, interpretable indicators, thus fostering a clear recognition of one's state. The long-term patterns could help users identify personal triggers and protective factors, while regular data reviews could promote sustained attention and reminder effects, which can prompt behavioral change. Feedback based on objective numbers can be an effective therapeutic tool to enhance self-efficacy and treatment adherence (Figure 3).

XSL•FO
RenderX

Figure 3. ANZEILAX-Green weekly report for participants.

Measures

This study used the following measures. The Generalized Anxiety Disorder 7-item scale (GAD-7) was administered to assess anxiety symptom relief [65] and the Patient Health Questionnaire-9 (PHQ-9) to evaluate depressive symptoms, which frequently co-occur with and are closely associated with anxiety [66]. Self-esteem, a psychological construct associated with anxiety levels, was assessed using the Rosenberg Self-Esteem Scale (RSES) [67]. Finally, app usability was evaluated using the mHealth App Usability Questionnaire (MAUQ) [68].

Statistical Analysis

Analyses were conducted using SPSS version 29.0 statistical software (IBM Corp). Outcome measures were analyzed using repeated-measures ANOVA to examine changes over time. When the assumption of sphericity was violated, the Greenhouse-Geisser correction was applied, and pairwise differences across time were examined using post hoc comparisons with Bonferroni adjustment. Associations between digital phenotype indicators and clinical outcome measures were examined using ordinary least squares (OLS) regression implemented in Python (version 3.12; Python Software Foundation).

Qualitative Data Analysis

The qualitative data from the semistructured interviews were analyzed independently by 2 researchers using reflexive thematic analysis following the 6-phase framework of Braun and Clarke [69]. This approach was selected for its flexibility and suitability for exploratory research aimed at identifying experiential patterns across participants. The analysis proceeded inductively without a predetermined coding framework, allowing themes to emerge from the data.

The six phases were as follows: (1) familiarization, in which both researchers read and reread the transcripts and recorded initial impressions; (2) systematic coding, in which meaningful units of data were assigned descriptive codes; (3) searching for themes, in which codes were collated into candidate themes; (4) reviewing themes, in which the coherence and distinctiveness of the themes were evaluated in relation to the full dataset; (5) defining and naming themes, in which each theme was clearly delineated and given a descriptive name; and (6) writing up, in which themes were reported with supporting participant quotations.

To enhance the rigor and dependability of the analysis, each researcher coded the transcripts independently, and discrepancies were resolved through iterative discussion until consensus was reached. Initial coding was compared to ensure consistency. Credibility was supported through the use of verbatim participant quotations illustrating each theme and by grounding interpretations in the data. Transferability was addressed through a thick description of the study context, setting, and participant characteristics. Confirmability was maintained by documenting analytic decisions throughout the process. Reflexivity was

XSL•FO
RenderX

practiced throughout the analysis, with both researchers reflecting on how their professional backgrounds and prior knowledge of the intervention might have shaped their interpretation of the data. All qualitative data were managed and organized using a structured coding matrix in Microsoft Excel.

Results

Demographic Information

A total of 61 individuals were screened for eligibility in this study. Of these, 31 were excluded because their BAI scores fell outside the range of 8-25. The other 30 participants met all the inclusion criteria and were enrolled.

Table 1 provides an overview of the demographics and baseline clinical characteristics. The mean age was 29.83 (SD 5.81) years, with participants evenly distributed between the 19-29 (15, 50%) and 30-39 years age groups (15, 50%). The majority of the participants were women (21/30, 70%), and the remaining 9/30 (30%) were men. Most participants had completed an undergraduate degree or higher, and about half were employed. The reported duration of anxiety symptoms varied, most commonly falling in the range of 1-3 years. The mean BAI score, which was used for screening, was 15.03 (SD 4.12), with 17/30 (57%) participants classified as having mild anxiety and 13/30 (43%) moderate anxiety.

Baseline outcome scores indicated moderate levels of anxiety and depressive symptoms, with mean scores of 10.70 (SD 2.85) on the GAD-7 and 10.50 (SD 4.47) on the PHQ-9. The mean baseline score on the RSES was 29.13 (SD 7.22). Based on the baseline GAD-7 scores, 10/30 (33%) participants were classified as having mild, 17/30 (57%) moderate, and 3/30 (10%) severe anxiety. Based on their PHQ-9 scores, 3/30 (10%) had none-to-minimal, 11/30 (37%) mild, 9/30 (30%) moderate, and 7/30 (23%) moderately severe depressive symptoms, with none classified as severe (Table 1).

Intervention Effects on Psychological Outcomes

A total of 29 participants were included in the final analysis. One participant was excluded because they did not respond to contact after the baseline assessment.

The main findings are as follows. Compared with the baseline, the GAD-7 and PHQ-9 scores showed significant within-group reductions in anxiety (GAD-7) and depression (PHQ-9), and a significant increase was found in self-esteem (RSES) scores. Please note that the following are within-group changes from a single-arm design without a control group. The mean GAD-7 score decreased from 10.66 (SD 2.89) at baseline to 5.86 (SD 4.34) at the completion of the intervention, with an average change of –4.79 points (95% CI –6.56 to –3.02; Cohen *d*=1.03; *P*<.001). The mean PHQ-9 score decreased from 10.31 (SD 4.43) to 6.45 (SD 4.99) over the same period, with an average change of –3.86 points (95% CI –5.79 to –1.93; Cohen *d*=0.76; *P*<.001), while the mean RSES score increased from 29.34 (SD 7.25) to 34.55 (SD 7.31) over this period, with an average change of 5.21 points (95% CI 3.47 to 6.95; Cohen *d*=1.14; *P*<.001), indicating a significant improvement in self-esteem over the course of the intervention (Table 2).

Table 2. Impact of changes in outcomes from baseline to postintervention (N=29).

Outcomes	Baseline (week 0), mean (SD)	Postintervention (week 8), mean (SD)	Δ Mean (95% CI)	Effect size (Cohen *d*)	*P* value
GAD-7[a]	10.66 (2.89)	5.86 (4.34)	–4.79 (–6.56 to –3.02)	1.03	<.001
PHQ-9[b]	10.31 (4.43)	6.45 (4.99)	–3.86 (–5.79 to –1.93)	0.76	<.001
RSES[c]	29.34 (7.25)	34.55 (7.31)	5.21 (3.47 to 6.95)	1.14	<.001

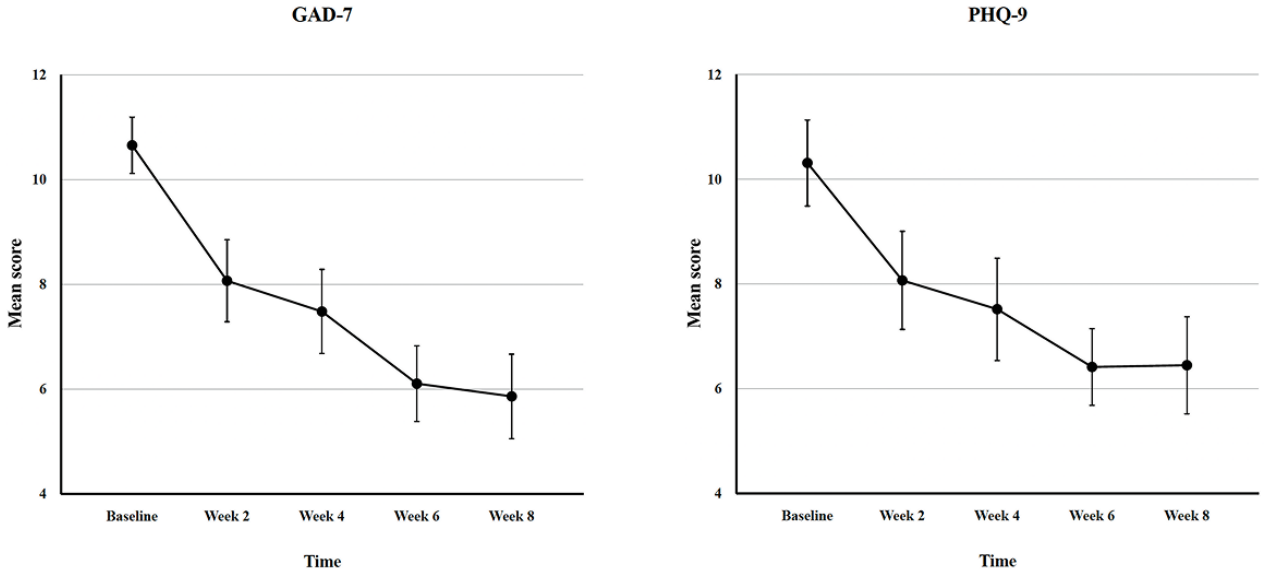
[a]GAD-7: Generalized Anxiety Disorder 7-item scale.

[b]PHQ-9: Patient Health Questionnaire-9.

[c]RSES: Rosenberg Self-Esteem Scale.

The changes over time also exhibited consistent improvement, as reflected by ongoing reductions in the symptom severity scores. Gradual improvements from the midpoint assessment were noted for anxiety and depression, with a significant reduction observed at week 4 during the early phase of the intervention. The downward trend continued steadily through weeks 6 and 8, with the most pronounced improvement observed postintervention. Anxiety symptoms, measured by GAD-7, showed a steady and sustained decrease from week 4 onward, while depressive symptoms, measured by PHQ-9, followed a similar overall trajectory. Although the PHQ-9 scores in week 8 were numerically slightly higher than in week 6 (not formally tested), they remained significantly lower than baseline at postintervention (Table 3; Figure 4).

Table 3. Changes in GAD-7a and PHQ-9b scores over the intervention period (N=29).



Outcomes	Mean (SD)	Δ Mean (95% CI)	*P* value versus baseline
GAD-7			
Midintervention (week 2)	8.07 (4.22)	−2.59 (−5.20 to 0.03)	.05
Midintervention (week 4)	7.48 (4.32)	−3.17 (−5.74 to −0.60)	.008
Midintervention (week 6)	6.10 (3.90)	−4.55 (−6.83 to −2.27)	<.001
Postintervention (week 8)	5.86 (4.34)	−4.79 (−7.43 to −2.16)	<.001
PHQ-9			
Midintervention (week 2)	8.07 (5.05)	−2.24 (−4.95 to 0.46)	.18
Midintervention (week 4)	7.52 (5.27)	−2.79 (−5.45 to −0.14)	.03
Midintervention (week 6)	6.41 (3.94)	−3.90 (−6.23 to −1.56)	<.001
Postintervention (week 8)	6.45 (4.99)	−3.86 (−6.73 to −0.99)	.003

[a]GAD-7: Generalized Anxiety Disorder 7-item scale.

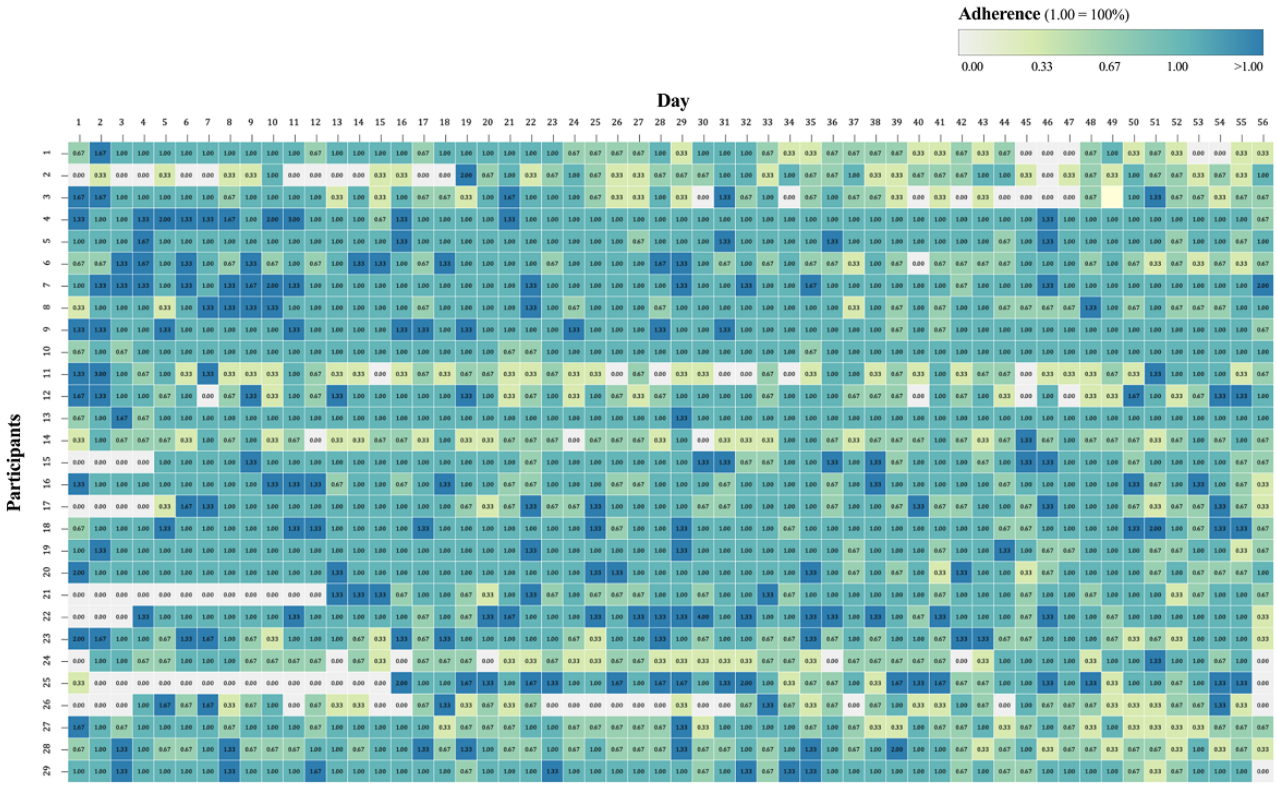
XSL•FO
RenderX

Figure 4. Mean GAD-7 (Generalized Anxiety Disorder 7-item scale) and PHQ-9 (Patient Health Questionnaire-9) scores at baseline and weeks 2, 4, 6, and 8 during the 8-week intervention.

These patterns of change suggest consistent improvements in symptoms throughout the intervention, with early changes significantly contributing to the overall effect. The effect sizes and temporal change patterns observed in this study are consistent with those reported in previous ANZEILAX clinical studies [58]. In particular, rapid responses and sustained effects on anxiety symptoms may be of clinical interest, although this requires confirmation by research using controlled designs.



Adherence and Usability

Adherence was calculated based on the protocol requirement of 3 daily EMA/EMI completions over the 8-week intervention period. The participants maintained an average compliance frequency of 80%, thus adhering to the EMA/EMI protocols at a consistently high level.

The heatmap presented in Figure 5 displays the adherence patterns of the 29 participants along the vertical axis over 56 days. Colors closer to green indicate higher adherence, with 1.0 representing full compliance, whereas those closer to gray indicate lower adherence. Blue indicates additional EMA/EMI completions beyond the prescribed 3 daily completions.

XSL•FO
RenderX

Figure 5. Daily ecological momentary assessment and ecological momentary intervention completion patterns among participants during the 8-week intervention.

As the heatmap illustrates, most participants consistently completed 2 to 3 EMA/EMI reports per day throughout the study, thus maintaining stable use patterns. The average adherence to EMA/EMI remained stable throughout the study period, with no sharp declines at any specific time points or weeks, despite variations in completion frequency among participants.

After the 8-week intervention period, participants completed the MAUQ to assess the usability of the app. The MAUQ results showed an average score of 5.03 (SD 1.32) on a 7-point Likert scale. Among the subscales, ease of use and satisfaction scored the highest at 5.28 (SD 1.28), followed by information organization at 4.98 (SD 1.31) and usefulness at 4.84 (SD 1.36). These results indicate that participants rated the overall usability of the app as favorable, while also making suggestions to further optimize the user experience.

Digital Phenotypes

In this study, several digital phenotypes, including heart rate, GPS-derived mobility indicators, sleep patterns, and activity levels measured by step count, were collected and analyzed to comprehensively detect changes in participants' mental health status. The procedures for preprocessing and analysis were applied based on the characteristics of each type of data.

Heart rate data were categorized into 3 ranges: high, ≥100 bpm; medium, 60 bpm to <100 bpm; and low, <60 bpm. The total distance and movement radius were calculated from the GPS latitude and longitude information and normalized from 0 to 1 for comparison between individuals.

To analyze behavioral patterns by time of day, the total distance was classified into daytime and nighttime intervals, with 8 PM as the cutoff. Sleep data were analyzed using Samsung Health's 4-stage classification, including awake, light, REM, and deep, based on sleep records from 6 PM of the preceding day to noon of the following day. Step count data were also normalized from 0 to 1, as with the GPS-derived indicators.

Weekly averages were calculated for data analysis, and trends over the 8-week period were examined using the ordinary least squares method. Statistically significant changes were observed in several physiological and behavioral indicators. The proportion of measurements within the low heart rate range significantly increased over time (β=0.008, *P*=.02), while GPS-based movement data exhibited a significant decrease in distance over the 8-week period (β=–0.3029, *P*=.03). Among sleep-related indicators, deep sleep duration showed a significant increase (β=0.2624, *P*=.02), whereas light sleep duration showed a decreasing trend. Although changes in step count did not reach statistical significance, an upward trend was observed (β=0.1475, *P*=.11). These wearable-derived indicators were not adjusted for physical activity. In addition, heart rate ranges were defined using fixed rather than individualized thresholds, and consumer-wearable sleep-stage estimates are less accurate than polysomnography. These exploratory findings should thus be interpreted with caution.

Analyses of the correlations between digital phenotyping indicators and clinical measures revealed several significant associations. A significant correlation was identified between PHQ-9 scores and deep sleep duration (*r*=0.655, *P*=.04), indicating an association between depressive symptom severity and deep sleep characteristics. In addition, low heart-rate

XSL•FO
RenderX

indicators showed significant positive correlations with both anxiety and depressive symptom severity, as measured by GAD-7 (r=0.578) and PHQ-9 (r=0.836).

Exploratory analyses found that several digital phenotyping indicators showed concurrent changes during the intervention period. Given the small sample and wide CIs, these associations should be interpreted cautiously (Table 4; Figure 6).

Table 4. Correlation analysis between digital phenotypes and GAD-7[a] and PHQ-9[b] scores.

User Interviews

Overview

Poststudy interviews were conducted to explore participants' experiences with the ANZEILAX-Green app, its integration with wearable devices, and the weekly feedback reports. The interview findings revealed 5 major themes, indicating that the design features of the system enhanced participants' self-awareness, facilitated data-driven reflection, supported behavioral change, strengthened their intrinsic motivation, and enabled them to apply therapeutic strategies in daily life. At the same time, participants described several challenges, including difficulty in calibrating subjective emotional intensity, the burden of frequent self-monitoring during busy or distressing periods, and heightened awareness of anxiety from repeated self-rating.

Theme 1: Enhanced Self-Awareness

Participants reported that the frequent EMA prompts enabled them to notice emotional and physiological changes that had typically gone unnoticed in daily life. Regular check-ins helped structure their self-reflection across different times of day, encouraging a habit of monitoring their internal state.

> *Being asked several times a day made me pay attention to emotions I would normally ignore... I realized my mood swings were actually more intense than I thought.* [P13]

> *Dividing the day into morning, afternoon, and night helped me reflect on each period individually.* [P17]

Participants also noted increased awareness of the links between physical states and psychological experiences.

> *Seeing my sleep pattern made me realize why I became irritable and sensitive.* [P11]

Several participants initially had difficulty in determining the appropriate intensity of their emotions, reflecting the subjective nature of emotional self-assessment. These findings highlight the importance of clear guidance for subjective emotional self-assessment during repeated EMA monitoring.

Theme 2: Promoting Data-Driven Reflection

Weekly reports presenting their EMA patterns and digital phenotype data allowed participants to reflect more deeply on their emotional states and interpret their emotional experiences in a clearer, more structured way. Rather than merely displaying data, the reports provided objective cues for reviewing daily patterns and emotional fluctuations that helped the participants identify underlying factors linking their emotions and behaviors and offered useful insights for more intentional self-management.

> *Seeing everything in one place helped me understand whether the week was good or stressful, and what triggered the fluctuations.* [P28]

Objective indicators also challenged participants' inaccurate assumptions about their well-being.

XSL•FO
RenderX

> *I thought I lacked sleep, but the report showed that fitness was the bigger issue.* [P23]

These insights helped participants develop more targeted self-management strategies. Several participants reported that the repeated daily check-ins and reflective responses initially felt burdensome, particularly when they were busy or emotionally distressed. These findings suggest that EMA systems should balance repeated self-monitoring with users' perceived burden [70].

Theme 3: Supporting Behavioral Change

Participants stated that personalized EMI content, such as breathing exercises, guided prompts, and reflective messages, motivated immediate action and supported symptom reduction. These interventions were perceived as actionable strategies rather than passive information.

> *The suggestions in the report made me walk more or adjust my sleep patterns the following week.* [P13]

Self-monitoring also encouraged intentional shifts in thinking.

> *When I marked negative emotions (in the app), I tried to reframe the situation more positively.* [P03]

Brief, affirming messages from EMI provided immediate emotional relief.

> *Messages like 'You deserve this happiness' stayed with me all day and helped me feel calmer.* [P05]

Theme 4: Maintaining Intrinsic Motivation

Participants stated that the routine of checking their status was internalized as a daily habit, helping them sustain their engagement beyond external prompts. Use of the app also reinforced self-efficacy and positive self-regard.

> *Checking in became a habit. When I didn't record, something felt missing.* [P13]

> *Managing myself boosted my self-esteem and helped me understand myself better.* [P25]

Personalized and empathetic messages were described as supportive, helping maintain engagement even during periods of distress or positive emotional states.

> *The messages comforted me when I was anxious and recognized my good moments too.* [P21]

Theme 5: Expansion of Active Treatment

Participants described exploring additional therapeutic modules independently, such as self-talk exercises, meditation, and emotional journaling, through which the treatment effects were extended beyond EMA/EMI. Furthermore, skills acquired through the system transferred into real-life contexts.

> *I practiced breathing techniques and self-talk almost every day, and it really supported my mental growth.* [P23]

> *When I felt anxious offline, I recalled solutions I had learned through the app and applied them naturally.* [P29]

These findings suggest that an autonomous, flexible environment enhances user agency and broadens the therapeutic impact of the intervention.

Discussion

Principal Findings

This study examined the real-world applicability and effectiveness of an EMA/EMI-based digital therapeutic, ANZEILAX-Green, in anxiety reduction among young adults and investigated how the personalized feedback generated by the combined EMA/EMI data and wearable-based digital phenotypes supported symptom improvement, self-management, and user engagement. The results of this 8-week exploratory study indicate that personalized feedback integrating the EMA/EMI system with wearable-based digital phenotype data was associated with improvements in both clinical outcomes and participants' capacity for autonomous symptom management, although causality cannot be inferred due to the single-arm design of this study.

The intervention was associated with significant improvements in psychological outcomes. GAD-7 scores showed a marked reduction with a large effect size (Cohen d=1.03) and PHQ-9 scores a medium-to-large effect size (Cohen d=0.76), while RSES scores showed a significant increase with a large effect size (Cohen *d*=1.14). The intervention was thus associated with reductions in anxiety symptoms and concurrent improvements in depressive symptoms and self-esteem, suggesting a broader positive impact on overall mental health. GAD-7 scores began to decline from week 2, showed statistically significant reductions from week 4 onward, and continued to improve through postintervention. These effect sizes and temporal change patterns are generally comparable to those reported elsewhere [58].

The magnitude of the observed effects suggests a meaningful therapeutic signal in real-world use. The relatively large effect sizes may in part reflect the single-arm study design, but they also appear to be related to participants' repeated engagement with the EMA/EMI system in their daily lives. Repeated use of the app likely supported continuous self-monitoring and the timely application of therapeutic strategies. In addition, the study sample primarily consisted of young adults with mild-to-moderate anxiety symptoms and relatively short symptom histories, who might have been more responsive to structured self-management support.

This pattern of early improvement and sustained reduction in symptoms suggests that EMA/EMI-based interventions can help attenuate symptom exacerbation in everyday contexts and support ongoing self-management through the timely delivery of therapeutic content. The EMA/EMI system was designed for frequent use while imposing a low perceived burden through personalized, context-appropriate intervention tasks. This balance might have supported sustained engagement and enabled repeated exposure to therapeutic strategies feasible for use in daily life, which might have contributed to gradual symptom regulation and the reinforcement of adaptive coping processes.

XSL•FO
RenderX

Participants maintained a high compliance rate of 80% over the 8 weeks, consistently adhering to the EMA/EMI protocol. Most participants completed 2 to 3 EMA/EMI per day throughout the study, demonstrating stable usage patterns without sharp declines at any time point. This suggests that EMA/EMI use was naturally integrated into the participants' daily routines. The provision of weekly personalized feedback reports might have further supported sustained engagement by reinforcing a sense of individualized care and ongoing monitoring. Given that user attrition has been identified as a major challenge in digital mental health intervention research, the stable engagement patterns observed in this study demonstrate that the EMA/EMI approach can be an acceptable and sustainable intervention modality for young adults. These improvements are broadly consistent with those obtained from digital therapeutics and app-based interventions that reported reductions in anxiety and depressive symptoms [71,72].

At the same time, although the frequent EMA prompts and repeated self-reporting were generally well tolerated, they were perceived as cognitively or emotionally demanding in certain situations. In particular, during periods of heightened stress, users' receptivity to intensive assessment may vary, highlighting the importance of flexibly balancing assessment frequency with user burden in the design of EMA/EMI systems. The streamlined nature of the EMA/EMI tasks might have contributed to the high levels of engagement observed in this study. However, the therapeutic effects demonstrated in this population with mild-to-moderate anxiety symptoms may not readily generalize to individuals with chronic anxiety or more severe psychiatric conditions, for whom more intensive or clinically supervised interventions may be necessary.

Significant changes in several physiological and behavioral indicators were also observed in the digital phenotype analysis. Deep sleep duration increased significantly while light sleep decreased, and GPS-based movement distance decreased significantly. In addition, the proportion of measurements falling within the low-heart-rate range increased significantly over time, which is to some extent consistent with lower physiological arousal. However, heart rate alone is a weak index of relaxation. HRV, which reflects parasympathetic modulation, would be a more informative physiological marker. Furthermore, these analyses were not adjusted for physical activity. A significant correlation was identified between PHQ-9 and deep sleep duration, indicating a possible association between depressive symptoms and deep sleep. This interpretation assumes reliable wearable sleep-stage detection and, given the small sample, requires cautious reading.

The concurrent increase in deep sleep and reduction in light sleep may indicate an overall improvement in sleep quality, which has been associated with reduced physiological arousal and greater emotional stability. Similarly, the increasing proportion of low heart rate measurements may reflect a more stable pattern of autonomic regulation, consistent with reduced sustained stress or anxiety-related arousal in daily life. Naturalistic studies combining wearable sensing with EMA have similarly examined the physiological correlates of affect and stress in everyday settings, albeit with varying predictive accuracy [42,54,73]. Although the decrease in movement distance may appear negative at first glance, when considered alongside the increasing trend in step count, it suggests that regular activity patterns within primary living areas were established rather than more extensive movement.

The interview analysis yielded 5 major themes in participants' experiences with the intervention: enhanced self-awareness, promotion of data-driven reflection, support for behavioral change, maintenance of intrinsic motivation, and expansion of active treatment. These themes suggest that the integration of EMA/EMI systems with digital phenotype data contributed to meaningful changes in clinical outcomes, behavioral patterns, and participants' capacity for self-management.

The combination of real-time self-reported data and objective physiological indicators helped participants develop a more coherent understanding of their emotional and physical states and appears to have been particularly beneficial for individuals with elevated anxiety, who often experience discrepancies between their physical symptoms and subjective perceptions. By providing objective reference points alongside subjective assessments, the system helped participants recognize patterns that might otherwise have remained unnoticed and supported the development of more targeted self-management strategies. Furthermore, the finding that participants independently explored additional therapeutic modules beyond the core app functions suggests that the intervention successfully fostered user autonomy. The therapeutic benefits were thus not confined to moments of active app use but extended into participants' daily lives through the self-initiated exploration and application of learned strategies.

Design Implications

Overview

The EMA/EMI-based intervention in this study was associated with young adults' engagement- and intervention-related outcomes in real-world contexts. Because the design did not allow the comparison of the conditions with and without wearable data, the added value of the wearable component cannot be isolated and has thus been discussed only in terms of user experience. Three major design implications were identified to inform the development and integration of automated EMA/EMI-based interventions for mental health care.

Temporal Calibration for Personalized Intervention Delivery

An initial adjustment and calibration phase is needed to account for individual differences in emotional expression and the interpretation of EMA response scales. Participants reported that the repeated EMA responses facilitated a clearer recognition of their emotional and behavioral patterns by encouraging reflection on internal states that they might otherwise not have noticed.

During early use, participants experienced uncertainty in translating subjective emotional intensity into numerical scores. Rather than relying on predefined standards, users gradually developed personalized reference points through repeated interaction with the EMA system. Over time, EMA scoring became aligned with individual emotional experiences,

XSL•FO
RenderX

indicating that score interpretation is shaped through use rather than established at baseline.

These findings underscore the importance of incorporating an explicit calibration phase during early system use. By jointly analyzing EMA response patterns and wearable-derived digital phenotype data during this phase, individualized emotional baselines can be established that enable the system to identify deviations from users' typical daily emotional rhythms, allowing personalized interventions to be delivered at moments when support is most needed.

Modality Flexibility in Intervention Design

Participants expressed preferences for a variety of intervention formats depending on their situational context and highlighted the importance of flexibility in intervention delivery. The feedback reports supported their reflection on emotional patterns and symptom fluctuations, while the ability to select from among several intervention formats enabled users to engage with the system in ways that aligned with their daily routines.

Participants also emphasized that the feasibility of intervention formats varied across contexts, with some approaches being perceived as difficult to engage with during ongoing activities. This indicates that the effectiveness of the intervention is closely linked not only to its content but also to users' ability to choose formats that fit their immediate circumstances.

These findings suggest that flexible intervention options enhance users' sense of choice and self-directed engagement, which may contribute to sustained use and therapeutic effectiveness. Accordingly, EMA/EMI systems should support multiple intervention modalities to accommodate situational constraints, as modality flexibility directly affects users' ability to engage with interventions at the moment they are delivered.

Digital Phenotype–Driven Predictive Emotional Support

The participants in this study reported that reviewing their wearable-derived digital phenotype indicators supported self-reflection on emotional fluctuations and facilitated adjustments in their daily behavior. Notably, the impact of digital phenotype data was enhanced when numerical indicators were accompanied by empathic messages based on their current states.

These findings highlight the importance of an integrated design approach in which predictive interventions informed by digital phenotype data are combined with empathic emotional support delivered through EMA/EMI systems. Rather than relying solely upon reactive interventions provided after explicit user input, this approach emphasizes proactive interventions that synthesize actively self-reported data and passively collected digital phenotypes to anticipate and respond to changes in users' emotional states. This proactive, context-sensitive direction aligns with the Just-in-Time Adaptive Intervention (JITAI) framework, which we consider a goal for future development rather than a feature of the present system [32].

In this context, digital phenotype data not only function as stand-alone signals for predictive intervention but become meaningful when coupled with empathic emotional support, which reinforces users' perceptions of being understood and supported by the system.

The participants' qualitative accounts suggest tentative design considerations to support automated interventions that integrate EMA/EMI systems with wearable-derived digital phenotypes, including adaptive calibration, flexible intervention delivery, and the use of digital phenotype data for predictive intervention combined with empathic emotional support, to facilitate context-responsive mental health care.

By leveraging multidimensional data to detect meaningful changes in users' emotional states and deliver personalized interventions, EMA/EMI-based approaches can closely align with users' lived experiences. At the same time, the design of such systems should prioritize the secure handling of sensitive biometric data and the protection of user privacy as fundamental principles to ensure user-centered and sustained implementation.

Limitations

This study has several limitations that should be borne in mind. First, the exploratory single-arm design limits causal inference regarding the observed changes. Without a control group, natural course, regression to the mean, recruitment bias, and expectancy effects cannot be excluded. In addition, because participants could optionally use other therapeutic modules within ANZEILAX-Green, the observed changes cannot be attributed specifically to the EMA/EMI or wearable components.

Second, the wearable-derived indicators were treated as contextual physiological and behavioral signals rather than validated objective measures of anxiety. Therefore, these findings should be interpreted cautiously. Repeated self-monitoring may also have affected participants differently, as a small number of participants reported heightened awareness of anxiety during periods of elevated distress. Future EMA-based interventions should therefore consider individual differences in response to repeated self-assessment and balance monitoring intensity with user burden [74].

Third, although the sample size was sufficient for this exploratory assessment of feasibility and acceptability, it limited the analysis of individual differences and the generalizability of the findings. In addition, because no follow-up assessment was conducted, it remains unknown whether the observed improvements were sustained beyond the intervention period. Future studies should use larger and more diverse samples and include longer follow-up periods to examine the durability of the observed effects.

Conclusions

In conclusion, this study provides preliminary evidence for the feasibility, acceptability, and potential clinical benefits of ANZEILAX-Green, an EMA/EMI-based mobile intervention, in reducing anxiety symptoms among young adults. The integration of EMA/EMI systems with wearable-derived digital phenotype data enables a comprehensive assessment of subjective symptom changes and objective indicators, including physiological and behavioral data, demonstrating how personalized feedback can operate within everyday contexts. This integrative approach extends the clinical applicability of

XSL•FO
RenderX

mobile mental health interventions by allowing the multidimensional emotional changes associated with anxiety symptoms in daily life to be captured. A randomized controlled trial is thus needed to confirm its effectiveness.

Beyond symptom reduction, the findings suggest that EMA/EMI-based interventions integrated with digital phenotyping can support ongoing self-management by mitigating symptom exacerbation in everyday contexts and facilitating the application of therapeutic strategies outside moments of active app use. In addition, the observed clinical effects appear to be supported by an integrated feedback structure that leverages digital phenotype data to enhance the acceptability and enactment of the intervention in daily life.

Furthermore, the findings provide empirical support for the design and advancement of automated digital mental health interventions that reflect individuals' ongoing states and contextual conditions in the feedback they provide. By showing that the integration of EMA/EMI systems with digital phenotyping extends and supports self-awareness, reflection, and self-management, this study highlights a scalable and clinically meaningful direction for future context-responsive digital mental health interventions.

Acknowledgments

The authors gratefully acknowledge all the study participants for their time and dedication to this study. We would like to disclose that generative AI was used for grammatical corrections to enhance the clarity and readability of the manuscript. However, all intellectual contributions, including the study design, analysis, interpretation of results, and overall writing, were entirely conducted by the authors.

Abstract

Background: Ecological momentary assessment (EMA) methods can provide assessment of alcohol-related beliefs and behaviors when people are in their natural environments. An increasingly common EMA approach involves the use of passive sensors (eg, continuous sharing of Bluetooth and GPS cell phone data) to collect rich data and trigger alcohol assessment in specific contexts. While collecting real-time assessments allows researchers to explore contextual factors impacting alcohol use, there is a lack of research examining compliance rates to alcohol-related EMAs that use daily questions for study periods over 2 weeks. EMAs over longer periods allow researchers to assess meaningful changes over time and sample low-base-rate events. Further, there is limited research exploring how EMA compliance is influenced by individual-level factors (eg, privacy concerns and alcohol use). Identifying factors associated with compliance can help inform EMA protocol design.

Objective: This study had 2 primary goals. First, we add to the literature by examining the feasibility and acceptability of a 60-day college student alcohol-EMA that uses phone-based, passive sensors. Second, we examined whether compliance was associated with event-level alcohol use, privacy concerns, and types of questions asked (ie, questions triggered by time or GPS location).

Methods: College students (N=68) who reported regular alcohol use completed the 60-day EMA study. At baseline, participants completed an online survey that included an assessment of privacy concerns. During the study period, participants completed up to 15 questions a day, including evening and morning self-reports of alcohol use. Feasibility was assessed based on enrollment, retention, and compliance rates. Acceptability was examined at the end of the study period using open- and close-answered questions on perceptions of the EMA experience.

Results: The findings supported the feasibility of the 60-day EMA with enrollment exceeding benchmarks and high compliance across the study period (average compliance=90%). Overall, students found the protocol acceptable with 88% (58/66) indicating that they would be willing to complete another EMA study. Participants' compliance was not associated with alcohol use at the event-level (odds ratio [OR] 0.94, 95% CI 0.80-1.10) or at the trait level (OR 0.92, 95% CI 0.73-1.17). Participants' compliance was greater for time-trigger assessment than GPS-triggered questions (P<.001). Privacy concerns were not associated with reduced responding.

Conclusions: This study has implications for those designing alcohol EMAs for college populations that involve the use of passive sensors, including recommendations for balancing predictable timing of questions and variability in question content.

Introduction

Background

Heavy alcohol use is an issue of concern among college students, with 21.9% of students reporting binge drinking [1]. Alcohol use is associated with a range of negative consequences both for students who drink (eg, unintentional injuries, problems with friends, and interference with schoolwork) and the broader community (eg, damage to property and interrupted sleep) [2,3]. Ecological momentary assessments (EMAs) offer one approach to understand proximal predictors of high-risk drinking behaviors, test theoretical models of alcohol use, and inform the development of just-in-time interventions targeting heavy alcohol use.

EMAs involve real-time assessment of beliefs and behaviors as participants go through their daily lives (ie, in their natural environment) [4]. EMAs are a broad category of approaches that vary in format (eg, text messaging–based vs app-based). In comparison to traditional survey methods assessing retrospective reports of behaviors and beliefs at a single time point, EMAs have a number of advantages. For instance, EMAs increase ecological validity and allow researchers to study dynamic processes that influence drinking, the influence of context on alcohol beliefs and behaviors, and temporal associations between constructs of interest [4,5]. EMAs are well suited to study alcohol use among college students because drinking often happens during discrete events [5]. Indeed, there is a growing body of alcohol-focused research using EMAs to study craving [6], drinking motives and decisions [7-9], negative affect or anxiety [10,11], impact of exposure to alcohol marketing [12], and social context [13,14] in college populations.

In order for EMAs to produce valid and useful data, participant compliance is essential. Work on alcohol-related EMAs among college students has produced compliance rates between 63.8% [6] and 96.8% [8]. There is a growing body of work, including meta-analyses, examining factors that might explain variation in EMA protocol compliance across different research topics, protocols, and samples [15-18]. One factor that might impact compliance is the length of the protocol. In the context of noncollege populations, alcohol-related EMAs over short periods (2 to 4 weeks) have generally been found to be acceptable and feasible, with participants describing EMAs as easy to complete and nondisruptive [19-21]. In contrast, there are mixed findings on the feasibility of alcohol-related EMAs over longer periods. Sokolovsky et al [22] found a steady increase in missed questions across a 56-day EMA divided into 2 bursts. Similarly, a 14-week EMA study found compliance rates significantly dropped over time (93% to 39%) [23]. While another college-based study found less pronounced reductions (90% to 70%) [24]. These inconsistencies in the college alcohol literature suggest that additional research exploring protocols greater than 14 days would be beneficial. Furthermore, Wrzus and Neubauer's [16] recent review of EMAs did not identify a single study that used more than 10 prompts per day over a period of greater than 14 days, highlighting the need for more studies of this type.

In addition to length of data collection, other aspects of an alcohol-related EMA protocol may impact compliance. For instance, Hultgren et al [25] examined compliance to both daily questions administered at set times and event-contingent momentary assessments initiated by participants on drinking occasions. They demonstrated that compliance was greater for regular daily questions than more irregular, self-initiated EMA questions. Differences in compliance might reflect the ease of remembering to respond to questions at set times or challenges to completing questions once alcohol use is initiated. Indeed, event-contingent momentary assessments were less likely to be completed when students were drinking more than usual for them. Similarly, Suffoletto et al [23] note that intoxication negatively impacts completion of reaction time–based EMA tasks. However, the relationship between alcohol use and EMA compliance remains unclear. For instance, other research suggests that neither same-day or past year alcohol use are associated with EMA compliance [24,26].

Other individual-level predictors may be important for understanding protocol compliance in EMA studies, but this type of research to date has been limited [26]. In a college-based alcohol-related EMA, Howard and Lamb [24] explored demographic, personality, and well-being variables and found no associations between these variables and compliance. In non-EMA survey studies, one factor that may be related to missing data is participants' privacy concerns [27]. These concerns might be particularly relevant to understanding compliance in the context of EMA studies examining sensitive topics, such as substance use, or for EMA approaches perceived as more invasive. For example, GPS and Bluetooth data can be integrated into EMAs in order to address novel questions about the environmental and social context of drinking and help identify risk factors for alcohol use beyond individual-level factors (eg, mood). In addition, integrating sensor data allows questions to be triggered based on, for example, someone's geographic location. While incorporating mobile sensors into EMAs is not common, representing about 5% of EMA studies [15], this approach is likely to become increasingly popular given the opportunities that it provides for studying contextual factors. That said, it is possible that both GPS tracking and triggering questions based on a participant's geographic location may raise privacy concerns [28,29]. Therefore, research is needed to determine if privacy concerns impact compliance in these types of EMA studies.

While research has examined the acceptability of traditional EMA techniques, there is less known about participants' perceptions of EMAs that include passive sensing methods that

XSL•FO
RenderX

occur automatically and continuously [30] and how individual-level factors impact compliance for this approach. Further, based on a recent review of EMA including geographic technology [31], no studies to date have specifically explored the use of EMAs that incorporate GPS-based sensors when examining college student alcohol use. Therefore, this study extends past research by examining the feasibility and acceptability of a 60-day, alcohol-related EMA that required participants to share Bluetooth, motion and fitness sensor, and GPS cell phone data.

Current Study

This study has 2 primary goals. First, we aim to assess the feasibility (eg, based on enrollment, retention, and overall compliance to daily questions) and acceptability (eg, participants satisfaction with the protocol) of a 60-day EMA alcohol-related protocol. While EMAs have the potential to advance our understanding of the proximal predictors of alcohol-related outcomes, they will only do so if participants are willing to enroll in and complete EMA protocols. This study adds to the limited research using daily surveys over periods greater than 14 days. Testing the practicality of these types of longer EMA designs is important for a number of reasons. For example, longer EMAs are important both for understanding alcohol-related risk factors that unfold and meaningfully change over weeks rather than days (eg, shifts in mood trajectories, coping patterns, and intervention response). As such, longer assessment windows are critical to observe within-person change instead of short-term variability. Moreover, longer assessment periods increase the chance of sampling low-base-rate events (eg, rare stressors and high-intensity drinking episodes) that are essential for testing risk models and just-in-time intervention assumptions. In the context of college drinking, this study's focus on a 60-day time frame allowed us to test feasibility and collect rich data across different phases of the semester including multiple weekends, midterms, and Spring break.

The second aim of the paper is to explore whether individual-level and EMA-design elements impacted compliance. Identifying factors that could impact compliance is important for understanding potential data biases and for improving EMA protocol design. This study adds to the literature by examining whether compliance rates were related to (1) students' alcohol use, (2) students' privacy concerns, and (3) EMA question type (ie, daily time-based question vs geolocation-triggered question). Based on past research [25], we expected compliance to be greater for time-based vs geolocation-based questions. Given the lack of data on compliance and privacy concerns, and the mixed findings on the relationship between alcohol use and compliance, these analyses were exploratory.

Methods

Procedures

A random sample of students from a university in the Northeastern United States (N=399) were invited to participate via email that provided a link to an online screening survey. In addition, participants were given the option to invite friends to participate in the study either by providing the researcher with their friend's email address or by the student sharing a link to the study. This approach was used to increase the likelihood of phones being collocated in order to maximize the amount of Bluetooth data collected. Eligibility was determined based on cell phone ownership, being 18 years of age or older, not planning to study abroad during the study period (n=1 excluded), and drinking at least twice a week (n=137 excluded). Of the 107 eligible participants, 84 expressed interest in participating, completed an online baseline survey, and provided contact information. Participants were enrolled in the study until our recruitment goal (n=75) was reached and remaining students were placed on a waitlist (n=9). Participants were scheduled to attend a brief meeting (in-person or on Zoom [Zoom Communications, Inc]) to receive more information about the study and the EMA app (called ODIN; Grouptheory Inc). Participants were guided through installing the ODIN app on their personal phones and received information about use of passive sensors and how to adjust their phone settings to allow or suspend access. Participants were then shown what to expect while using the app, including example questions, how to track their own participation, and how to contact the research team through the app.

The final study sample (N=68, 91% of those initially enrolled; 68/75) includes participants who attended a training meeting and installed the ODIN app (41/68, 60% recruited directly; 25/68, 37% through friend referral). Participants completed daily questions via the ODIN platform over a continuous, 60-day period between February and April. At the end of the 60 days, participants were sent an email to complete a follow-up survey.

Ethical Considerations

All procedures were approved by the Lehigh University Institutional review board (protocol #1940662-5). All participants provided informed consent. EMA and survey data were anonymized and linked via a random number. Participants received US $20 for completing both the baseline and follow-up survey. In addition, participants could earn up to US $3 a day based on the percentage of questions they answered (eg, a participant who received 10 question prompts and responded to 5 would receive US $1.50).

Participants

The majority of the participants were women (45/68, 66%; 22/68, 32% men; 1/68, 1.5% nonbinary) and were aged between 18 and 23 (mean 20.4, SD 1.2) years. In terms of race, 78% (53/68) identified as White, with 9% (6/68) multiracial, 6% (4/68) Black or African American, 6% (4/68) Asian, and 2% (1/68) Native Hawaiian or Pacific Islander. Further, 9% (6/68) of the sample identified as Latine. At baseline, on average, students reported drinking 17 (SD 11.7) drinks per week. Most participants had smartphones that ran on iOS (65/68, 96% Apple Inc; 3/68, 4% Android users, Google LLC) and at baseline reported using their phone approximately 263.5 minutes a day. Prior to the EMA period, 67 of the 68 (99%) participants reported using their cell phone when out at a party or bar, with the most frequent usages being texting and/or instant messaging and taking pictures and/or video.

XSL•FO
RenderX

Event-Level Procedures

Overview

Questions varied by day of the week, with participants receiving up to 15 questions per day. This included a combination of questions triggered by time (eg, drinking plans reported at noon Thursday to Saturday) or GPS location (see below for more details). Participants received between 2 and 4 time-based surveys a day (plus additional surveys triggered by GPS location). Each survey consisted between 1 and 6 questions. In order for participants to receive questions, the ODIN app had to be running on their phone. If participants closed the app, they would receive a notification asking them to reopen it. If a participants' app was closed for ~3 days, they received up to 4 emails inviting them to continue their participation.

Passive Sensors

The ODIN app uses Bluetooth Low Energy (BLE) protocols on iOS and Android to ensure that each participant's app continuously broadcasts their assigned participant identification number, albeit encrypted by the study-wide secret key. This allowed us to detect when participants were close to other phones that were running the ODIN app. We continuously collected geolocation data (~every 5 m). In order to optimize battery life, motion sensor data was monitored, but not recorded. More specifically, when motion sensor information determined that a participant had not moved from the previous recorded GPS location, GPS data was not recorded.

Morning Retrospective Report

Every morning (9 AM) participants were asked about the previous night including if they attended a social gathering where drinking occurred, how many alcoholic drinks they and others consumed, and what harm reduction strategies they used. The morning self-reported drinking item was used to predict compliance to questions presented the prior evening. Participants also indicate if and when they became too intoxicated to respond to ODIN questions (response option: "No [were never too intoxicated]," "Yes, by 8PM," "Yes, by 10PM," "Yes, by midnight," and "Yes, after midnight").

Time Triggered Questions

In order to assess compliance during common drinking times, participants received a question at 10 PM (Thursday-Saturday) that varied in content (eg, a word unscramble task or being asked to locate someone close by who had a specific characteristic). At 10:30 PM (Thursday-Saturday) participants also received alcohol-related questions, "Are you currently with other students?" "Are you or people around you drinking alcohol?" "What is the MAXIMUM number of drinks it would be acceptable for a typical student to drink at the place you are at?" and "How many standard alcoholic drinks have you had today?" In addition to alcohol questions, participants received nonalcohol related questions related to sense of belonging at college (Sunday-Wednesday at 4 PM). For example, participants were asked to indicate the extent to which "I feel at home in this space."

Geolocation-Triggered Questions

On Thursdays through Saturdays, ODIN delivered geolocation-triggered questions when a participant's phone remained within a prespecified circular geofence surrounding a target drinking venue for at least 10 minutes. The research team identified seven bars and clubs that served alcohol and were located within approximately 0.5 miles (0.8 km) of campus. Target venues were identified using local knowledge and verified using Google Maps (Alphabet Inc), Google Maps venue listings, and the latitude and longitude associated with each venue's Google Maps place pin were used as the center of the geofence. The 0.5-mile distance was used as a practical criterion for selecting target venues; it was not the spatial buffer used to trigger questions. Prompt delivery was instead based on a fixed circular buffer with a radius of 100 feet (30.5 m) around each venue coordinate. For each venue, prespecified triggering hours were determined based on when each establishment was open. Before study launch, research staff visited each target location and confirmed that a prompt was generated after the 10-minute dwell criterion was met. Prior research using ODIN documented high completeness of GPS acquisition over a 30-day period [32]. The geolocation-triggered survey asked participants whether they had been or were currently at a location where alcohol was served.

Survey Measures

Baseline Survey

Prior to EMA data collection, participants completed 3 baseline measures of privacy concerns: location privacy, general privacy risk awareness (adapted from [33]), and concern for information privacy (CFIP; [34]). For all privacy measures, participants indicated their level of agreement on a 7-point scale (1=strongly disagree, 7=strongly agree). Location privacy consisted of 4 questions that began with the stem, "I am fine with sharing my location with…," followed by different types of apps (ie, map, weather, camera, and shopping apps) as well as one question regarding location sharing in general (ie, "In general, I am comfortable sharing my location information on my smartphone, Cronbach α=–0.87). General privacy risk awareness consisted of three questions (ie, "I am aware of potential privacy threats and their consequences from using my smartphone," "I am aware of possible privacy breaches from using my smartphone," and "I understand the privacy risks from using a smartphone," Cronbach α=0.91). The CFIP consisted of 15 questions (Cronbach α=–0.91) assessing participants' concerns that corporations were misusing their data and other private information, with higher scores indicating more concern.

Follow-Up Survey

At the end of the 60-day EMA, participants completed measures of acceptability (based on [35]), including general perceptions of study protocol [36,37] and emotional responses to using the EMA (eg, interest, enjoyment, and annoyance [37]). For example, participants were asked questions related to ease of use: "How did using the ODIN app fit into your routine?" and "How easy was it to answer the daily questions?" (1=very easily to 5=very difficult). Overall satisfaction was assessed with items such as, "Overall, how satisfied are you with the app you used

XSL•FO
RenderX

over the last 60 days?" (1=very satisfied to 5=very dissatisfied) and "Would you be willing to take part in another ODIN study that involves daily surveys?" (1=no, definitely not, to 4=yes, definitely). After individual items, open-ended prompts ("please explain," "why or why not?") were used to clarify responses. Participants were also asked to describe any problems (What problems or challenges did you encounter using the ODIN app throughout the study?) or benefits experienced while using the app (Did you experience any benefits from using the ODIN app?). Finally, participants were provided with a list of potential difficulties in maintaining answering the daily questions and asked to indicate which applied to their experiences. The list included privacy concerns (ie, type or quantity of data collected and worries about data safety), social reasons (ie, busy schedule, interfering with schoolwork), question-related issues (ie, too many questions, too often, or at inconvenient times), and technical issues technical issues (ie, app did not work, app crashed).

At follow-up, participants were also asked to describe their alcohol use over the 60-day EMA period both in terms of the average number of drinks they had on each occasion and how many drinks they had on their maximum drinking occasion [38].

Analysis Plan

Feasibility and Acceptability

Feasibility and acceptability were evaluated using proportions. Benchmarks for feasibility included ≥50% enrollment, ≥70% of participants retained (ie, still engaged with the app at the end of the 60 days, and ≥70% response rate to daily questions [39-41]. Our target benchmark for acceptability was ≥80% endorsement of statements supporting satisfaction with participants' experience with study protocol. In addition, we examined whether participants' emotional responses to using the app (interest, fun, and annoyance) significantly differed from the neutral midpoint of the response scale (4). Open-ended responses were reviewed by 2 authors and summative content analysis was used to identify common categories of responses.

Associations With Compliance

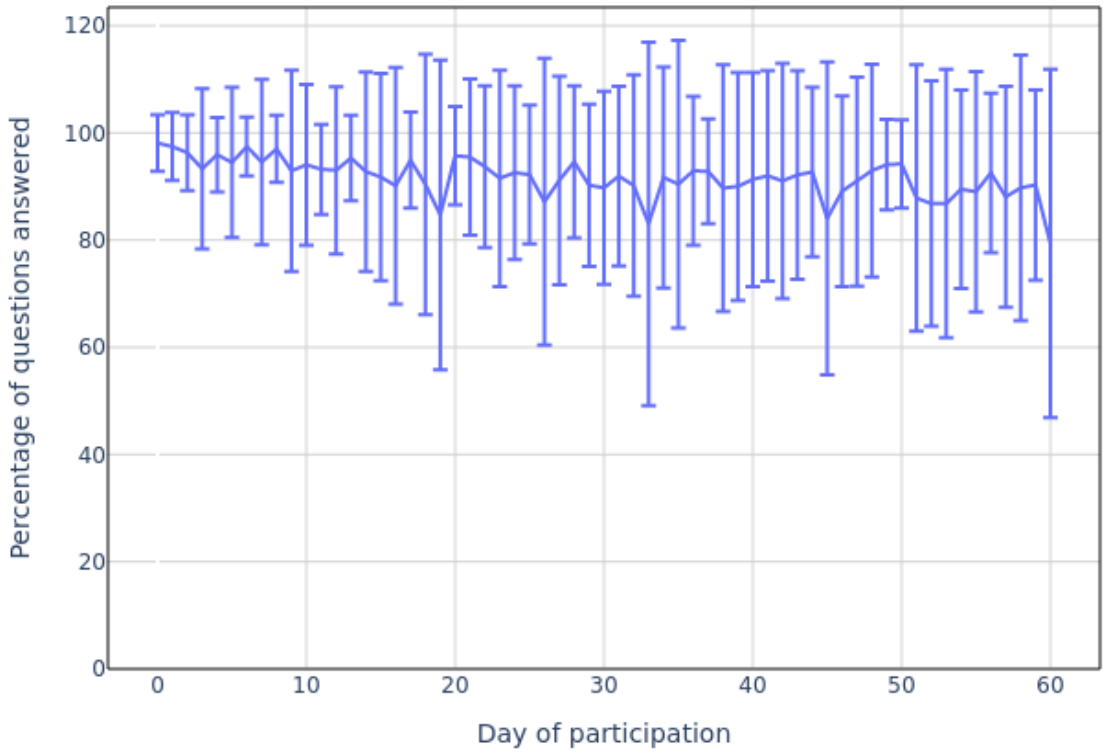
Overall compliance rates were calculated separately for each person by adding the number of surveys completed, dividing this number by the number of surveys received, and multiplying by 100. We examined whether the overall measure of compliance was correlated with privacy concerns assessed baseline. To address whether compliance differed based on sensor type used to trigger questions, we conducted a paired 2-tailed *t* test comparing mean compliance rates for 2 alcohol questions that were triggered by GPS location (bars during opening hours) and time of day (10:30 PM) on Thursday, Friday, and Saturday nights.

To examine the association between compliance rates and alcohol use we examined model fit for generalized linear mixed-effects models using a range of distributions and link functions. Given rates of compliance were generally high and there was little variability (318/362, 88% of the time participants were 100% compliant), based on residual diagnostics and model fit information, we determined that dichotomizing the data (0=not compliant [less than 100%], 1=100% compliant) was the most appropriate analysis strategy. We examined the relationship between morning reports of total alcohol consumed the night before with compliance rates from the night before (for all time-based and GPS trigger questions answered between 10 PM and 2 AM) fitted with a logistic mixed model estimated using maximum likelihood using the glmer function from the *lme4* package in R (version 4.3.1; R Core Team). Fixed effect coefficients were exponentiated to obtain odds ratios (ORs) and associated 95% CIs. Responses on occasions where participants did not drink were not included in these analyses. We examined both whether state- (alcohol use on a given night [person-centered]) and trait-level drinking (average alcohol use on occasions when they drank [grand mean-centered]) predicted compliance while accounting for random variability between participants.

Data Quality

As per Checklist for Reporting Ecological Momentary Assessment Studies (CREMAS) guidelines [42] for reporting EMAs, we describe information about data quality. This includes information on participants' response latencies to question prompts and the minimum number of prompts planned and delivered. In addition, we explore preliminary support for the concurrent validity of participants' responses by examining the correlations among alcohol use reported in the EMA to retrospective reports based on the post-EMA online survey.

Results



Feasibility

Overview

We exceeded our benchmark for enrollment with 70% (75/107) of eligible participants signing up and an additional 8% (9/107) expressing interest but being placed on a waitlist due to study spaces being filled. Of the 75 students who signed up, 68 attended a meeting to install the ODIN app (68/107, 64% of eligible students). Of the 68 study participants, 64 completed the follow-up survey (94%). To further assess feasibility, average participant compliance (Figure 1) was examined. At all timepoints, average compliance was above the benchmark threshold, with an overall average adherence rate of 90% (median 93%, SD 0.13%, maximum 100%, minimum 0%). Overall, people were asked an average of 339.9 questions (SD 126.92) during the study, and answered an average of 315.9 (SD 122.61) questions. Overall, 65 of the 68 (96%) participants met our benchmark of completing at least 80% of questions asked. One participant received four questions and then did not respond to further questions or attempts to contact them, and they were excluded from subsequent analyses.

Figure 1. Study compliance overtime. Maximum number of drinks refers to the maximum number of drinks on a single occasion. Survey responses reflect post EMA self reports of drinking during the past 60 days.

Compliance Based on Sensor Type (Time vs GPS)

The analysis comparing compliance based on sensor type used to trigger questions revealed that participants' compliance rates differed as a function of question type, with higher compliance for time-based (mean 87%, SD 16%) compared to location-based questions (mean 76%, SD 27%; t_{59}=3.65; *P*<.001).

Association Between Compliance and Participants' Alcohol Consumption

There were high rates of compliance for both morning (85%) and evening (87%) alcohol assessments, and there were 362 person-level drinking days observed. Participants' average consumption on a given night varied from 1.7 to 11.5 (mean 5.16, SD 2.07) drinks. The logistic mixed model (adjusted intraclass correlation coefficient [ICC]=0.28) explained a moderate amount of variance in compliance (conditional R^2=0.29); however, only a small amount was explained by fixed effects alone (marginal R^2=0.01). The number of drinks a participant reported consuming on a given night (assessed the following morning) was not related to compliance for that night (OR 0.94, 95% CIs 0.80-1.10). Further, participants' average number of drinks consumed was not associated with their typical compliance (OR 0.92, 95% CIs 0.73-1.17).

If a participant indicated that they had drank alcohol the previous evening, they were asked if at any point they felt too drunk to respond to ODIN questions. Overall, 79.1% of the time (568/718 morning reports) participants indicated that they were never too drunk to respond to EMA questions. When participants indicated that they did become too drunk to respond, this most commonly occurred between 10 PM and midnight (59/718, 8%) and after midnight (56/718, 8%).

Compliance and Privacy Concerns

Location privacy concern was not associated with participants' overall compliance rates, r_{65}= 0.07, *P*=.57. Both greater general privacy risk awareness (r_{65}=0.24; *P*=.0497) and privacy concerns (r_{65}=0.25; *P*=.04) were associated with higher compliance rates.

Data Quality

Prompt Latency

We examined the amount of time between a question prompt and participants answering the question. Looking at all types of questions prompts, on average participants took 7.1 minutes to respond. We then explored response times specifically to questions that were the first in a chain of prompts, for these questions response times were slower (mean 23.8, SD 9.8 minutes).

Prompt Delivery

In addition to examining compliance (i.e., participants' response rate to questions they received), we also examined data quality and missingness in terms of failure to receive anticipated question prompts. We were not able to calculate the exact total

XSL•FO
RenderX

number of questions each participant should have received for a number of reasons. This included geolocation questions not being predictable and participants' responses to prompts determining if and how many additional questions they received in a chain. Therefore, we estimated the total number of first questions in time-based chains that each person should have received during the study (20 per week or 172 across the 60 days) and compared this to the number of time-based first in chain questions received. On average, participants received less than the minimum number of prompts (median 143, IQR 110.5-161.0), receiving on average 83% of the time-based question chains. In most cases, it was not possible to determine why the prompts were not received, though it may have reflected phones being turned off or phones losing network connection. In addition, we did experience a technical issue related to daylight savings that impacted prompts being delivered for a number of days after the time change. In total, 19 participants had to relaunch or reinstall the app and this impacted data collection for a period of 1 to 10 days (mean 5.5, SD 3.6 days). One participant received a new phone during the study period and went 2 days without receiving questions before rejoining the study. A second student reported that their phone broke during the study period and that they had not taken the time to have the app set up on their new phone.

Concurrent Validity

As a preliminary exploration of the quality of drinking self-report data, we examined the correlation between self-reports of alcohol use post-EMA with EMA drinking data (Table 1). Participants' retrospective estimates of their average alcohol consumption on a single occasion during the 60-day EMA period were positively correlated with their average drinks per occasion reported in the EMAs (r_{62}=0.71; P<.001). Similarly, participants' retrospective estimates of how much they consumed on their maximum drinking occasion during the study period were positively associated with the maximum number of drinks observed in the EMA data (r_{62}=0.71; P<.001). These positive associations lend some support to the validity of the EMA alcohol data.

Table 1. Correlations between ecological momentary assessment alcohol reports and post-EMA self-report.

	Values, mean (SD)	EMA[a] average drinks per occasion	EMA maximum number of drinks[b]	Survey average drinks per occasion[c]	Survey maximum number of drinks[c]
EMA average drinks per occasion	5.1 (2.0)	—[d]			
EMA maximum number of drinks	8.4 (3.8)	.83[e]	—[d]		
Survey average drinks per occasion	4.5 (2.2)	.71[e]	.39[f]	—[d]	
Survey maximum number of drinks	9.5 (4.7)	.77[e]	.71[e]	.58[e]	—[d]

Acceptability

Survey Data

Across measures we consistently approached or met benchmarks for acceptability (≥80% endorsement). For example, the vast majority of participants stated that answering questions daily was easy to extremely easy (55/66, 84%) and that using the ODIN app fit somewhat easily to very easily into their routine (51/66, 78%). Overall, 72% (47/66) stated they were moderately to very satisfied with the ODIN app, 88% (58/66) stated they were willing to complete another ODIN EMA study, and 88% (58/66) said that they would recommend being part of an ODIN study to their friends. In terms of emotional responses to using the app, ratings of annoyance (mean 3.84, SD 1.14) did not significantly differ from the neutral midpoint (4; t_{63}=–1.10; P=.28, Cohen d=–0.14). Ratings of interest in the app (mean 4.55, SD 1.26) and enjoyability of using the app (mean 4.58, SD 1.23) were significantly higher than the neutral midpoint (both P<.001, Cohen d=0.44 and 0.48 respectively), indicating that participants tended to have slightly positive responses to the app.

When asked specifically what difficulties interfered with answering the daily questions, very few participants (6/66, 9%) noted concerns about privacy and data safety. More common difficulties included issues with questions (ie, too many questions or questions at inconvenient times; 27/66, 41%), social reasons (ie, busy schedule, interfering with school work; 33/66, 46%), or technical reasons (eg, app bug related to daylight savings, battery drain; 37/66, 56%).

Open-Ended Data

Open-ended responses suggested there were several reasons students found the experience positive. In addition to receiving incentives, participants (21/66, 32%) described that the EMA made them more conscious of their drinking habits. For example, one student stated that, "I was more aware of how many drinks I was consuming on a nightly basis" and another reported, "I thought more about what an appropriate amount of drinks to have was." Some students also suggested that participating in the EMA changed their drinking behavior in beneficial ways. One student stated that the prompts "would remind me [of] tactics to use before going out and drinking alcohol at night"

XSL•FO
RenderX

and another student reported that, “It helped with drinking habits. I was able to control my alcohol better and reflect on how I drank the night before.”

Some students reported that they found answering the questions enjoyable or fun to answer (15%; 10 / 66). These comments often referred specifically to the 10pm evening questions that varied nightly in terms of content. For example, one student stated that “the questions that came sporadically and focused on a variety of topics about student experience… were engaging.” and another said, “Unscrambling the words was random but enjoyable.” At the same time, they appreciated consistency in the timing of questions (11/66, 17%). For example, one student stated, “It was good that the times were predictable” and another said that they were satisfied with their experience because questions were “Routine and easy to predict.”

Discussion

Principal Findings

This study adds to the literature by examining the feasibility and acceptability of a 60-day alcohol-related EMA that integrated the use of passive sensors (GPS, Bluetooth, and motion) and triggered questions based on GPS location data. Further, the study examined the role of both individual-level predictors (alcohol use and privacy concerns) and question type in relation to compliance. The study provides support for both the feasibility and acceptability of this approach among college students who drink regularly. The results suggest that college students do not have significant concerns about sharing passive data. Indeed, acceptability ratings suggested that participants generally had a positive experience using the ODIN app and would be willing to take part in a similar study in the future. Further, compliance rates remained high across the 60-day study period, suggesting that it is feasible to conduct this type of EMA for more than a month and maintain engagement.

Predictors of Compliance

In addition to examining overall feasibility and acceptability, this study examined predictors of compliance rates. Past research has suggested that alcohol use may interfere with students’ responses to EMA questions [23,25]. Our findings are consistent with research suggesting that alcohol use at both a trait [24] and state-level [22,26] are not associated with EMA compliance. Participants’ subjective self-report data suggested that the majority of the time participants did not perceive their alcohol use to interfere with their responses. These findings are somewhat surprising given that alcohol use can impact people’s cognitive capacity in ways that reduce the ability to perform intentional behaviors or engage in deliberative information processing [43]. The lack of impact of alcohol on compliance could be explained by alcohol myopia theory [44], which suggests that once alcohol is consumed people will become more focused on the salient aspects of their immediate environment. Given that the vast majority of the sample reported typically using their cell phones at bars and parties to engage in a number of activities (eg, texting, instant messaging, and taking pictures and/or video), it is possible that cues or prompts to complete EMA surveys are salient and influential for intoxicated people who are already engaging with their phones. The questions participants were asked to complete in this study did not require complex information processing or decision making. Based on the dual-process model [43], it is possible that the impact of alcohol use on compliance may become more pronounced in EMA studies that require participants to complete more novel and effortful tasks.

To our knowledge, this study is the first to examine the relationship between privacy concerns and EMA participation. Given that the study included passive sharing of sensor data, including GPS data, it is notable that location privacy was not related to overall compliance. Furthermore, privacy concerns and awareness were unexpectedly associated with higher compliance rates. Research among community samples of people who use drugs suggests that privacy concerns may be perceived as a barrier to compliance for EMA studies using GPS data [28]. The current findings suggest that the impact of privacy concerns may be less significant for college students reporting on their alcohol use. In this study, participants met with the researchers in order to review consent forms and be trained on the app. While this approach is more labor intensive than participants reviewing consent forms independently, it may be beneficial for ensuring participants feel comfortable responding and that they understand the steps taken to ensure their confidentiality. It is also possible that privacy concerns were not associated with decreased compliance because these concerns are more relevant to the decision to take part in a research study and are not as relevant to responding once in a study [30]. As collecting data on privacy concerns of those who chose not to participate may be challenging, further research using hypothetical EMA designs [45] could help determine if privacy concerns differentially affect willingness to enroll in EMAs that involve passive sensing compared to those that do not.

While participants in this study had higher compliance rates for questions triggered by time rather than location, compliance rates for GPS-triggered questions were still above our benchmark. The difference in response rate by question trigger is consistent with past research that indicates that when questions are more unpredictable, response rates are generally lower [25]. In this study, participants were not specifically told what locations would trigger questions. To improve compliance, it may be beneficial to have participants list out bars or clubs that they attend and create a plan or an implementation intention [46] to check their phone for questions when they are in that specific location. Using participant generated locations could also increase the predictability of where location-based questions are triggered. While consistency may be useful for compliance, the current findings also suggest that it may be beneficial to consider ways to balance asking questions at predictable times with variety in question content to promote participant interest and engagement in EMAs over longer periods. We note that while the less predictable timing of geolocation-triggered questions may have contributed to their lower response rate, the absence of independent geofence validation means that we cannot distinguish this explanation completely from effects related to geofence performance or location misclassification.

XSL•FO
RenderX

Limitations

This study has a number of limitations. First, it is possible that the sample is not representative of college students who drink frequently due to a self-selection bias of those more comfortable with an EMA involving passive sensors. While this concern is somewhat diminished by the variability in baseline privacy concerns and the high rates of interest among eligible students, it is possible that the sample underrepresented students who are cautious sharing their data. Furthermore, privacy concerns were only measured at baseline and not as part of the EMA protocol. It is possible that participants' privacy concerns fluctuate or are more salient in some contexts compared to others. While repeatedly asking students about their privacy concerns could itself potentially influence these concerns, longitudinal assessment of context-specific privacy concerns could help better understand EMA responding.

While the current findings suggest that alcohol use did not impact compliance, we did not explore whether the accuracy or quality of participants' responses decreased as their alcohol consumption increased. The preliminary data supporting the validity of the EMA drinking reports based on comparisons with follow-up survey recall of alcohol use does somewhat address this concern; however, additional research examining how alcohol use impacts the reliability of responses is warranted.

This study focused on human factors that impacted compliance, rather than the impact of technical issues on responding. That said, the generally high compliance and acceptability rates should be interpreted in the context of the study protocol and technical challenges experienced during the study. For example, despite issues related to daylight savings that caused data collection disruptions, participants remained generally satisfied with the EMA experience. It is possible that because most participants did not receive the minimum expected number of time-based prompts, participant fatigue was reduced and this enhanced overall compliance. Finally, past research suggests that financial incentives impact compliance rates [16,31] and therefore the high rates of compliance observed in this study may not extend to research that does not employ similar incentive structures.

We did not conduct an independent ground-truth validation of point-level GPS accuracy or geofence classification. Consequently, some prompts may have been generated while a participant was near, rather than inside, a target venue, and some actual visits may not have generated a prompt. The location-triggered compliance estimate should therefore be interpreted as responsiveness to prompts generated by the geofencing protocol, rather than as confirmation that every response was completed inside a bar or club.

Conclusions

The integration of passive sensors into college-alcohol EMAs provides an opportunity to study the influence of context on alcohol beliefs and behaviors. The current results indicate that students were generally willing to respond to alcohol-related prompts and questions generated by geofences surrounding bars and clubs. Compliance was not associated with trait-level or in-the-moment alcohol use and was positively associated with some forms of privacy concerns. Response rates were higher for more consistent time-based questions compared to more variable location-based questions. Overall, the current study provides data suggesting that alcohol-related EMAs among college students that incorporate the use of passive sensors can be both acceptable and feasible.

Abstract

Background: Temporomandibular disorders (TMDs) are common chronic conditions involving orofacial pain and functional limitations. Digital therapeutics (DTx) have demonstrated efficacy in TMD management; yet, the behavioral and clinical mechanisms underlying treatment response remain poorly characterized, particularly whether behavioral modification or DTx engagement intensity drives therapeutic benefit.

Objective: This study aimed to investigate the behavioral mechanisms, responder profiles, and moderators of clinical response to a DTx intervention for TMD through a post hoc analysis integrating self-reported, server-derived, and clinician-rated outcome measures.

Methods: We performed a post hoc secondary analysis of a multicenter, double-blind, sham-controlled randomized superiority trial conducted at 2 tertiary care centers in South Korea. The per-protocol cohort comprised 93 participants (DTx: n=44; sham: n=49). Five complementary analyses were applied: responder logistic regression at ≥30%, ≥50%, and ≥70% Visual Analog Scale (VAS) pain-reduction thresholds; subgroup comparison by Oral Behaviors Checklist (OBC) modifier status; causal mediation analysis using the potential outcomes framework with bootstrap CIs; week-4 sensitivity analysis; and moderator analysis testing the treatment×Patient Health Questionnaire-4 (PHQ-4) interaction on VAS change.

Results: DTx assignment was consistently associated with clinically meaningful pain reduction across all 3 responder thresholds (adjusted odds ratios [ORs] 5.39, 95% CI 1.72 - 16.94 at ≥30%; 3.21, 95% CI 1.14 - 8.99 at ≥50%; and 3.45, 95% CI 1.12 - 10.63 at ≥70%; all P<.05). Mediation analysis suggested that approximately 29.1% of the total VAS treatment effect may be transmitted via OBC-defined behavioral modification (natural indirect effect −6.91 mm; 95% CI −13.23 to −0.58; P=.03), with the mediated proportion rising from 19.6% to 30.2% as responder thresholds became more stringent. Participants with OBC modifiers achieved substantially greater pain reduction than nonmodifiers (−45.71 vs −22.61 mm; difference −23.11; 95% CI −36.97 to −9.24; P<.01) despite no significant differences in any objective DTx engagement metric. Treatment ORs were 33% - 42% higher at week 4 than at the 6-week end point (week-4 ORs 7.15, 95% CI 2.39 - 21.32 at ≥30%; 4.48, 95% CI 1.68 - 11.94 at ≥50%; and 4.91, 95% CI 1.74 - 13.87 at ≥70%), suggesting that week 4 may be a candidate time point for future adaptive protocols. Baseline psychological distress (PHQ-4 ≥3) appeared to moderate the treatment response (interaction β=−19.63; 95% CI −37.86 to −1.39; P=.04).

Conclusions: Sham-controlled randomized trials in TMD that empirically differentiate behavioral realization from digital engagement volume remain scarce. Behavioral modification, rather than engagement volume, appears to be an important pathway associated with DTx efficacy and may mediate approximately 29% of the pain-reduction effect under exploratory causal assumptions. This advances mechanism-based evaluation of DTx beyond engagement-based surrogates. Week 4 may represent

XSL•FO
RenderX

a promising candidate for future adaptive protocols, and baseline psychological distress may warrant investigation for precision patient selection. These preliminary findings should be corroborated by future prospective studies and further mechanistic investigations.

KEYWORDS

temporomandibular joint disorders; behavior therapy; digital therapeutics; mediation analysis; randomized controlled trial

Introduction

Temporomandibular disorders (TMDs) are common, heterogeneous conditions involving the temporomandibular joint, masticatory muscles, and related structures, typically presenting with orofacial pain and functional limitation [1]. Current models emphasize a biopsychosocial framework where symptom persistence reflects interactions among peripheral factors, central pain modulation, psychological distress, and maladaptive oral behaviors [2-4]. In the diagnostic criteria (DC) for TMDs, Axis II instruments operationalize key psychosocial and behavioral domains; parafunctional habits are clinically relevant because they sustain mechanical loading and pain-guarding cycles [2,5]. Although conservative, reversible, and often multidisciplinary approaches in Axis II are recommended as first-line care [6,7], their effectiveness is often limited by variable adherence to daily behavioral changes outside the clinic [8,9].

Digital therapeutics (DTx) are software-driven, evidence-based therapeutic interventions that have been proposed as a scalable means to deliver standardized behavioral and self-management support and reinforce adherence between clinic visits [10,11]. Over the past decade, DTx have expanded rapidly across medical specialties; an analysis of registered trials documented a more than 5-fold increase since 2011, driven predominantly by mental health and neurological applications [12]. Despite this growth, their development remains unevenly distributed across disciplines and is constrained by a lack of standardized evaluation frameworks, and applications in dentistry and orofacial pain remain scarce [13]. Given the chronic, behaviorally mediated nature of TMD, it is a clinically suitable target for DTx; yet, rigorous evidence in this field has emerged only recently [14,15]. Our group previously reported a multicenter, double-blind, randomized, sham-controlled trial evaluating a TMD DTx intervention, demonstrating clinically meaningful improvements in pain, jaw function, and oral behavior over a 6-week treatment phase [14]. The primary analysis appropriately focused on average between-group effects [14].

However, establishing DTx efficacy is the first step. For clinical implementation and product optimization, it is equally important to understand how benefits are distributed within the treated group and through which modifiable domains contribute to improvement. Digital interventions introduce a persistent black box problem; clinical benefit is plausibly contingent on engagement, but actual exposure varies widely and is not captured by treatment assignment alone [16,17]. Unlike pharmacologic dose, digital dose" is behaviorally expressed and often declines over time, raising questions regarding response heterogeneity and effective behavioral pathways [18]. Schmidt et al [19] have recently proposed a conceptual framework distinguishing "consumed dose" (patient-DTx interaction) from "realized dose" (actual cognitive-affective and behavioral change), arguing that clinical outcomes are driven by dose realization rather than dose intake alone. In this context, an exploratory review of usage data from our randomized controlled trial suggested that greater app use alone was not consistently associated with greater clinical improvement, motivating a more granular, process-level analysis [17]. A better understanding of which behavioral changes accompany the treatment effect may help distinguish therapeutic benefit from engagement volume alone and could inform how these interventions are optimized and applied. Such mechanistic insight may support the progression of TMD DTx from demonstrated efficacy toward more precision-oriented use [19,20].

Accordingly, we conducted a post hoc analysis linking objective DTx use data with repeated clinical and Axis II measures. Such mechanistic analyses remain scarce in TMD DTx research, yet they are essential for moving beyond efficacy demonstrations toward a precision-oriented intervention design. We aimed to (1) identify the clinical and behavioral predictors of response across progressively stringent pain-reduction thresholds, (2) evaluate whether Oral Behaviors Checklist (OBC)–defined behavioral changes mediated the treatment effect, and (3) examine the temporal response dynamics and moderating role of baseline psychological distress. As behavioral change and Axis II domains were not randomized exposures, all analyses were interpreted as associative and hypothesis-generating.

Methods

Trial Design

This study is a post hoc analysis of a previously published multicenter, double-blind, randomized, sham-controlled superiority trial (KCT0009493), in which an active TMD DTx app was compared with a visually identical sham app over 6 weeks in a 1:1 allocation at 2 tertiary care oral and maxillofacial surgery clinics in South Korea (Hallym University Sacred Heart Hospital and Hallym University Dongtan Sacred Heart Hospital), with assessments at baseline and weeks 2, 4, and 6 [14]. Detailed eligibility criteria, randomization procedures, intervention content, blinding, ethical approvals, and primary efficacy analyses are reported in the original publication [14]. The present analysis focused on response heterogeneity within the trial by examining predictors of clinically meaningful

XSL•FO
RenderX

response, behavioral mediators, and moderators of treatment effect. Patients and members of the public were not involved in the design, conduct, or reporting of the parent trial or the present secondary analysis.

Sample Size, Randomization, and Blinding

No separate sample size calculation was performed for this post hoc analysis; the analytic sample was determined by the parent trial, which enrolled 102 participants based on a target of 38 participants per group (2-tailed α=.05, 90% power) with an allowance for 25% dropout. In the parent trial, participants were randomly assigned (1:1) by site using stratified block randomization with an independently generated allocation list, and both participants and investigators were blinded to group assignment. The sham application was visually and functionally identical to the active DTx but lacking therapeutic content. Full procedures are reported in the parent trial [14].

Interventions

Both groups received treatment as usual and were provided with a smartphone app for 6 weeks. The active DTx (Clickless DTx TMD-01) delivered TMD-related education, guided jaw exercises, behavioral habit tracking, guided meditation, and medication guidance with reminder alarms. The sham application was visually and functionally identical in interface and navigation but lacked all therapeutic content, permitting only weekly input of passive user data. Components common to both groups included a jaw health diary for symptom self-monitoring, visual feedback via weekly reports, and supportive check-in calls during weeks 1, 3, and 5, so that the 2 applications differed only in therapeutic content while self-monitoring, feedback, and human contact were held constant. Both applications were locked before trial initiation, and participants accessed them on personal smartphones, with daily use recommended throughout the 6-week period. Full details of intervention development and content are reported in the parent trial and Multimedia Appendix 1 [14].

Ethical Considerations

This manuscript reports a post hoc secondary analysis of a multicenter, sham-controlled randomized clinical trial. The present secondary analysis was reported in accordance with the CONSORT (Consolidated Standards of Reporting Trials) 2025 guidelines and the CONSORT-EHEALTH (V1.6.1; CONSORT of Electronic and Mobile Health Applications and Online Telehealth, Checklist 1) extension for web-based and mobile health interventions [21,22]. The parent trial was approved by the Institutional Review Boards of Hallym University Sacred Heart Hospital (HALLYM IRB 2024-04-001-006) and Hallym University Dongtan Sacred Heart Hospital (HDT IRB 2024-04-001-004) and was conducted under the supervision of the Korean Ministry of Food and Drug Safety (MFDS) in accordance with the Declaration of Helsinki and the International Council for Harmonization Good Clinical Practice (ICH-GCP) guidelines. The parent trial was prospectively registered on the Clinical Research Information Service (KCT0009493; registration date, May 31, 2024), before enrollment of the first participant on June 20, 2024 [14]. All participants provided written informed consent face-to-face prior to enrollment in the parent trial. The institutional review boards granted an exemption from review for the present secondary analysis of deidentified data, which did not require additional informed consent. Participant data were pseudonymized and stored in a secure, password-protected system accessible only to authorized investigators, with no personally identifiable information included in the analysis. Participants received compensation of approximately KRW 500,000 (Korean won; approximately US $350; KRW 1=US $0.00072 as of June 20, 2024) upon trial completion. All data were managed and locked by an independent contract research organization before the analysis to ensure data integrity and analytical independence. No images in this manuscript or its supplementary materials allow for the identification of individual participants.

Data Sources

This analysis integrated trial-derived datasets comprising DTx usage logs, module-completion records, and clinical outcome files. Data were cleaned, standardized by participant identifiers and visit labels, and merged using pseudonymized patient IDs. Engagement variables were derived from server logs over the 6-week intervention period and linked to repeated clinical measurements at each scheduled visit.

Outcomes

App engagement was quantified using objective usage and compliance logs. The variables included total app logins, exercise completion counts, meditation module use, jaw health diary entries, behavioral therapy module interactions, educational video views, article reads, notification checks, and pain record entries, all aggregated over the 42-day intervention period.

Clinical outcomes were assessed at 4 scheduled time points: baseline (V1), week 2 (V2), week 4 (V3), and week 6 (V4; end point). Pain intensity was measured using a Visual Analog Scale (VAS; 0 - 100 mm). The jaw function was assessed by a blinded examiner using the maximum mouth opening (MMO; mm) and the Jaw Functional Limitation Scale-20 (JFLS-20). Behavioral and psychological domains were assessed using the OBC and Patient Health Questionnaire-4 (PHQ-4) and scored according to standard procedures for the DC/TMD [23,24].

Statistical Analysis

Statistical analyses were performed on the per-protocol population (N=93; DTx: n=44; sham: n=49). Because the per-protocol population was defined a priori to exclude participants with missing primary outcome data and no item-level missing data were observed among completers, all analyses were conducted on complete cases without imputation, consistent with the parent trial protocol [14]. Normality was evaluated using the Shapiro-Wilk test. Between-group comparisons were performed using independent-samples *t* tests or Wilcoxon rank-sum tests as appropriate. A 2-sided significance threshold of α=.05 was used. No adjustments for multiple comparisons were made, which was consistent with the exploratory framework, and effect sizes with 95% CIs were reported. Analyses were conducted using Stata (version 17;

XSL•FO
RenderX

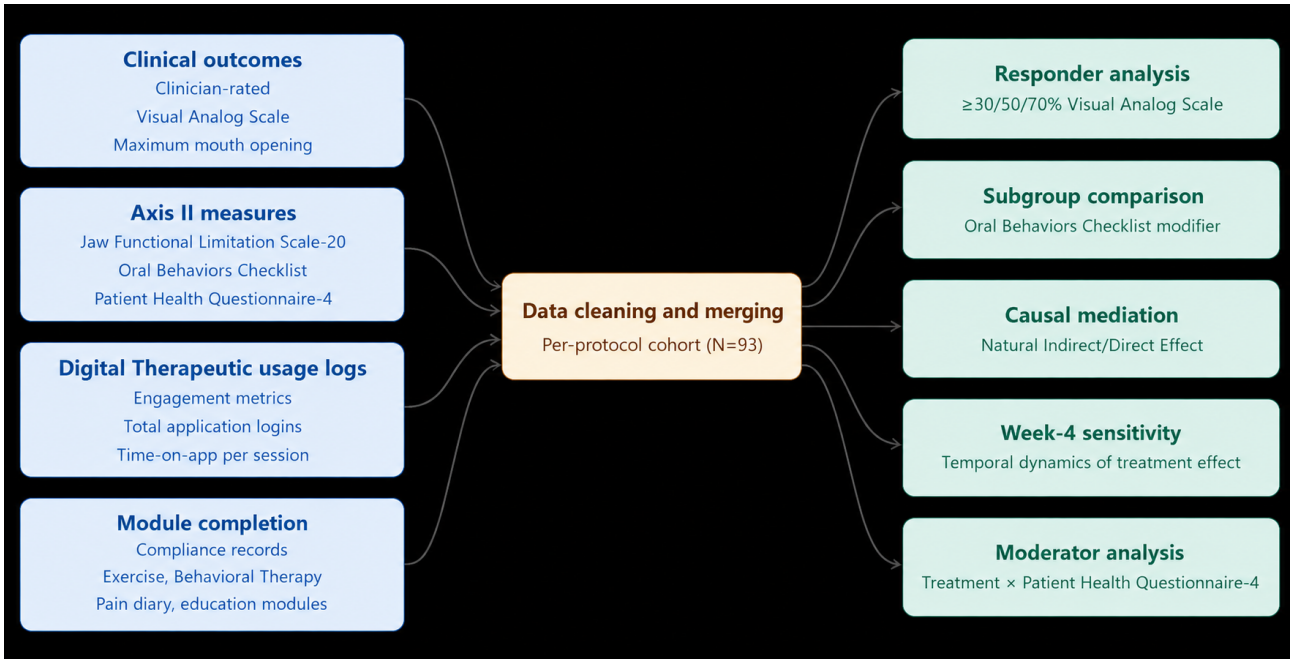
StataCorp LLC) and Python (version 3.14; Python Software Foundation) with the *pandas*, *SciPy*, and *Statsmodels* packages.

Responder Definition and Logistic Regression

Responder status was defined by ≥30%, ≥50%, and ≥70% reduction in pain VAS score from baseline to week 6. Logistic regression models were used to estimate the odds of response for each threshold, with treatment assignment (DTx=1 and sham=0), age, and change in MMO, OBC, and PHQ-4 scores as independent variables. The results were reported as odds ratios (ORs) with 95% CIs.

OBC Behavioral Modifier Classification

Within the DTx arm (n=44), participants were classified as OBC modifiers (n=21) or nonmodifiers (n=23) based on the median OBC change score from baseline to week 6 (median Δ=−8). Participants with OBC changes below the median (ie, greater behavioral improvement) were designated as modifiers. Independent-samples *t* tests were used to compare clinical outcomes and DTx usage metrics between the subgroups.



Mediation Analysis

Causal mediation analysis used the potential outcomes framework as implemented in the Mediate command in Stata (StataCorp LLC) [25,26]. The treatment variable was DTx assignment (vs sham), the mediator was OBC modifier status (binary), and the outcomes were (1) continuous VAS change from baseline to week 6 and (2) binary responder status at each threshold. The natural indirect effect (NIE), natural direct effect (NDE), and total effect were estimated using bootstrap-based 95% CIs (1000 iterations). This framework relies on several identifying assumptions, including no unmeasured treatment-mediator, mediator-outcome, or treatment-outcome confounding, no mediator-outcome confounder affected by treatment, and correct model specification. Because treatment was randomized, confounding of the treatment-mediator and treatment-outcome paths was minimized by design, leaving mediator-outcome confounding as the principal residual concern. Given the nonrandomized nature of the mediator, results were interpreted as exploratory and associative rather than confirmatory causal inference.

Sensitivity and Supplementary Analyses

Logistic regression models were reestimated using week 4 change scores to characterize early treatment effects and their temporal dynamics. Probit regression models were used for robustness checks. A linear regression moderator analysis examined the treatment×PHQ-4 High (≥3) interaction on VAS change. The multidomain responder analysis (triple responder: VAS +OBC improvement+MMO improvement) is shown in Multimedia Appendix 2. Figure 1 summarizes the analytical workflow, linking trial-derived data sources to the per-protocol cohort (N=93) and the 5 complementary analyses described below.

Figure 1. Analytical workflow of the post hoc study. The workflow shows the integration of clinical outcomes, Axis II measures, DTx usage logs, and module-completion records, followed by 5 complementary analyses: responder analysis, OBC modifier subgroup comparison, causal mediation analysis, week-4 sensitivity analysis, and moderator analysis. DC/TMD: Diagnostic Criteria for Temporomandibular Disorders; DTx: digital therapeutic; JFLS-20: Jaw Functional Limitation Scale-20; MMO: maximum mouth opening; OBC: Oral Behaviors Checklist; PHQ-4: Patient Health Questionnaire-4; TMD: temporomandibular disorders; VAS: Visual Analog Scale.

Results

Study Population and Primary Trial Outcomes

Of the 102 randomized participants, 93 met the per-protocol criteria (DTx: n=44; sham: n=49) and were included in the analysis. As previously reported, the DTx group demonstrated significantly greater improvements at week 6 in VAS pain (between-group difference, −23.78 mm; *P*<.001), MMO (+4.93 mm; *P*<.001), JFLS-20 (−19.68; *P*=.001), and OBC (−5.84; *P*=.008), with no significant difference in PHQ-4 (−0.36; *P*=.40). Baseline characteristics and week-6 outcomes are provided in

XSL•FO
RenderX

Multimedia Appendices 3 and 4. Harms were systematically monitored in the parent trial, in which no serious harms or adverse events were reported in either group. The present secondary analysis did not include an additional assessment of harms.

Factors Associated With Clinically Meaningful Pain Reduction

Across all 3 response thresholds, DTx assignment was a strong predictor of responder status (Table 1). The adjusted OR for DTx was 5.39 (95% CI 1.72 - 16.94; *P*<.01) at the ≥30% threshold, 3.21 (95% CI 1.14 - 8.99; *P*=.03) at ≥50%, and 3.45 (95% CI 1.12 - 10.63; *P*=.03) at ≥70%. MMO improvement was independently associated with higher odds of response at all thresholds (ORs 1.13 - 1.15; all *P*<.05). Changes in PHQ-4 scores and age were not significant predictors at any threshold.

Table . Logistic regression: factors associated with responder status at ≥30%, ≥50%, and ≥70% VAS[a] reduction thresholds (N=93).

[i]PHQ-4: Patient Health Questionnaire-4.

[j]Not applicable.

OBC change exhibited a threshold-dependent gradient: each unit reduction in OBC score was associated with increased odds of response (OR 0.94 at ≥30% and ≥50%; *P*=.03; OR 0.91 at ≥70%; 95% CI 0.85 - 0.98; *P*=.01). The association strengthened as the response criterion became more stringent, with improved model fit (Pseudo R^2=0.32 at ≥70% vs 0.25-0.27 at lower thresholds). Estimates were robust to model specification, with probit regression yielding directionally consistent treatment effects across all thresholds (Multimedia Appendix 5).

Under a stricter multidomain responder definition requiring simultaneous VAS, OBC, and MMO improvement, DTx participants showed 8.55-12.32-fold higher odds of triple response than sham across thresholds (all *P*<.01; Multimedia Appendix 2).

OBC Behavioral Modifier Subgroup: Clinical Outcomes and DTx Usage

Within the DTx arm, OBC modifiers (n=21) showed greater pain reduction than nonmodifiers (n=23; VAS change: mean −45.71, SD 17.34 vs mean −22.61, SD 26.75 mm; difference: −23.11 mm; 95% CI −36.97 to −9.24; *P*<0.01) and greater improvement in jaw function (JFLS-20: mean −42.52, SD 26.28 vs mean −22.22, SD 28.72; difference −20.31; 95% CI −37.11 to −3.50; *P*=.02). PHQ-4 improvement did not differ significantly between the subgroups (difference −1.07, 95% CI −2.16 to 0.01; *P*=.05). MMO change also showed no significant difference (difference −0.64, 95% CI −3.88 to 2.61; *P*=.69).

Despite these clinical differences, no significant between-group differences were observed across any objective DTx usage metric, including total logins, exercise completions, meditation sessions, jaw diary entries, educational video views, or behavioral therapy module uses (all *P*>.05), with a nonsignificant trend toward fewer behavioral therapy entries among the modifiers (*P*=.10; Table 2). The waterfall plot illustrates that the OBC modifier cases were concentrated among participants with the greatest VAS reduction (Figure 2).

Figure 2. Individual Visual Analog Scale (VAS) changes from baseline ranked by magnitude across treatment subgroups. Each vertical bar represents one participant's VAS pain change from baseline to week 6, ranked from greatest reduction (left) to smallest reduction or increase (right). Participants are color-coded by treatment allocation and Oral Behaviors Checklist (OBC) modifier status within the digital therapeutic (DTx) arm: DTx-OBC modifier (green; n=21), DTx-nonmodifier (blue; n=23), and sham controls (peach; n=49). Negative values indicate pain reduction. DTx: digital therapeutic; OBC: Oral Behaviors Checklist; TMD: temporomandibular disorders; VAS: Visual Analog Scale.

Mediation Analysis: OBC Behavioral Modification as a Mediator of Treatment Effect

For continuous VAS change, the NIE through OBC modifier status was −6.91 mm (95% CI −13.23 to −0.58; *P*=.03), indicating that approximately 29.1% of the total treatment effect (−23.78 mm) was mediated through behavioral modification. The NDE remained significant (−16.87 mm; 95% CI −27.30 to −6.45; *P*<.01).

A threshold-dependent pattern emerged for the binary outcomes. The NIE was 0.09 (95% CI −0.01 to 0.18; *P*=.07) at ≥30%, 0.11 (95% CI −0.00 to 0.22; *P*=.05) at ≥50%, and 0.13 (95% CI 0.01 - 0.25; *P*=.03) at ≥70%, with the mediated proportion increasing from 19.6% to 25.6% to 30.2%. The NDE remained significant across all models (all *P*<.01; Table 3 and Figure 3).

Sensitivity Analysis: Early Response at Week 4

When logistic regression models were reestimated using week 4 change scores, treatment ORs were consistently higher than at the 6-week end point across all thresholds: 7.15 (95% CI 2.39 - 21.32; *P*<.01) vs 5.39 at ≥30%, 4.48 (95% CI 1.68 - 11.94; *P*<.01) vs 3.21 at ≥50%, and 4.91 (95% CI 1.74 - 13.87; *P*<.01) vs 3.45 at ≥70%, representing increases of 33%, 40%, and 42%, respectively (Table 4, Figures 4A and 4B).

OBC change at Week 4 was significant for the ≥70% threshold (OR 0.92, 95% CI 0.87 - 0.99; *P*=.02) but not at lower thresholds, indicating the behavioral effect matures between weeks 2 and 4. MMO change remained significant across all thresholds at week 4 (ORs 1.10 - 1.11; all *P*<.05). The change in PHQ-4 score was not significant in any model. Week-4 estimates were similarly robust under probit regression, with significant treatment effects retained across all thresholds (Multimedia Appendix 6).

Exploratory Moderator Analysis: Baseline Psychological Distress

To explore whether baseline psychological distress moderated the treatment effect, a linear regression model with an interaction term (Treatment×PHQ-4 High [≥3]) was used with VAS change as the dependent variable (Table 5). A PHQ-4 score of ≥3 was applied as the binary threshold, consistent with established cutoff criteria indicating clinically meaningful anxiety and/or depressive symptoms [27,28]. Of the 93 participants, 65 had PHQ-4 ≥3 and 28 had PHQ-4 <3 at baseline.

In the adjusted model controlling for baseline VAS, age, and sex, the interaction term was significant (β=−19.63; *P*=.04), indicating the DTx effect on VAS change differed by baseline distress level. Among participants with PHQ-4 ≥3, the estimated DTx effect on VAS change was −28.09 mm (sum of treatment coefficient and interaction term: −8.46 + [−19.63]), representing greater pain reduction compared with those with PHQ-4 <3, in whom no significant treatment effect was observed (β=−8.46 mm; *P*=.25). The main effect of PHQ-4 High was significant (β=14.91; *P*=.01), indicating that higher baseline psychological distress was independently associated with greater VAS reduction regardless of treatment assignment. The adjusted model explained 49% of the variance in VAS score change (R^2=0.49), compared with 24% in the unadjusted model (R^2=0.24). As a sensitivity analysis, the interaction was not significant when PHQ-4 was modeled as a continuous variable (β=−4.02 per point; *P*=.06). The CONSORT flow diagram for the overall clinical trial is presented in Figure 5.

Figure 5. CONSORT (Consolidated Standards of Reporting Trials) flow diagram of the randomized controlled trial. DTx: digital therapeutic.

Discussion

Principal Findings

This post hoc analysis of a multicenter, sham-controlled randomized trial of a TMD DTx extends the parent trial's demonstration of aggregate efficacy to the mechanisms and heterogeneity of treatment response. Building on the confirmed clinical benefit of the DTx, we examined which clinical and behavioral factors were associated with pain response, whether oral behavior change might mediate the treatment effect, and how the treatment effect evolved over time and varied with baseline psychological distress. Across all response thresholds, DTx assignment remained a strong and consistent predictor of clinically meaningful pain relief relative to sham. Three exploratory patterns emerged, including oral behavior modification appeared as a possible mediating pathway, the treatment effect appeared to be accelerated and amplified, with responders reaching clinically meaningful pain relief earlier and to a greater degree, and baseline psychological distress may play a modest moderating role. As all analyses were performed post hoc, these patterns were interpreted as associative and hypothesis-generating and are elaborated below.

In the present analysis, OBC change was the most consistent independent factor associated with response, with the association strengthening at progressively more stringent response thresholds. This gradient may indicate that behavioral modification becomes increasingly important as pain relief increases. Mediation analysis was consistent with this pattern. The proportion of the VAS treatment effect potentially transmitted via behavioral modification rose monotonically across increasingly stringent response thresholds, reaching approximately 29% on the continuous VAS scale. This positive dose-response relationship, in which greater behavioral change accompanied greater pain reduction, is consistent with OBC behavioral modification potentially acting as a partial mediating pathway rather than solely as a correlate.

XSL•FO
RenderX

A particularly informative pattern was the dissociation between OBC-defined behavioral change and objective app usage metrics. OBC modifiers achieved significantly greater pain reduction than nonmodifiers, yet no significant differences were observed across any engagement metrics, including logins, exercises, meditation sessions, or diary entries. The nonsignificant but directionally consistent pattern of fewer behavioral therapy violation entries among modifiers provides a triangulation across 3 independent measurement modalities, including self-report OBC, digital behavioral logs, and clinical pain VAS outcomes. Of note, the behavioral therapy module log records patient-reported breaches of behavioral recommendations; therefore, fewer entries indicate better behavioral adherence rather than reduced app use. This directionality aligns the digital log with the lower OBC scores and the greater pain reduction observed in modifiers, with all 3 modalities converging on the same pattern. This suggests that meaningful behavioral change, rather than passive app engagement, may be the more relevant driver of clinical improvement in this cohort [19]. This dissociation should nonetheless be interpreted cautiously, as the present sample may be underpowered to detect modest differences in engagement metrics.

Treatment ORs were consistently higher at week 4 than at the 6-week end point across all responder thresholds, which may suggest that DTx had its strongest discriminatory effect at this intermediate time point. The temporal onset of OBC as an associated marker of response, which was absent at week 2 but emerged for the ≥70% threshold by week 4, may suggest that meaningful behavioral modification requires approximately 4 weeks to consolidate and manifest clinically [29]. Taken together, these temporal patterns may suggest that DTx responders achieve an accelerated and amplified clinical improvement than nonresponders, reaching clinically meaningful pain relief earlier and to a greater degree, with behavioral modification as a plausible temporal correlate of this response.

Baseline psychological distress (PHQ-4 ≥3) appeared to modestly amplify the treatment effect, with a larger estimated DTx effect in the elevated-distress subgroup than in the subgroup without distress. However, the interaction was not significant when PHQ-4 was modeled continuously, and the ≥3 threshold was a predefined clinical cutoff rather than a data-derived optimum; these findings are exploratory and require prospective validation [27].

Behavioral Mechanism and the Realized-Dose Framework

The central role of OBC behavioral change aligns with and extends the biopsychosocial understanding of TMD pathophysiology [30]. Parafunctional oral behaviors, including clenching, bruxism, and habitual jaw tension, are recognized perpetuating factors that sustain mechanical loading on the temporomandibular joint and maintain pain-guarding cycles [30,31]. Longitudinal evidence from the Orofacial Pain: Prospective Evaluation and Risk Assessment (OPPERA) study associated high awake parafunction with both TMD onset and chronification [24,32]. Building on this prevalence-level evidence, our findings suggest that targeted modification of these parafunctional behaviors may yield measurable clinical improvement, moving the inference beyond a statistical between-group comparison toward a data-based mechanistic account of how parafunction-directed intervention may translate into pain reduction.

This dissociation is conceptually consistent with the framework proposed by Schmidt et al [19], who distinguish between "consumed dose," the patient's interaction with a DTx, and "realized dose," the degree to which cognitive-affective and behavioral change is actually internalized by the patient, and who argue that the therapeutic effect is not a direct function of consumed dose but rather of realized dose. This convergence is consistent with the view that therapeutic benefit may depend more on behavioral adaptation, the realized dose, than on engagement volume [19]. It thus raises questions about the assumption that a greater consumed dose should predict clinical outcomes [18]. Our results provide a data-based, exploratory quantification of this distinction within a sham-controlled randomized clinical trial, suggesting that OBC-defined behavioral modification may account for approximately 29% of the total VAS treatment effect independently of any consumed dose metric. For DTx product development, optimization might prioritize facilitating real-world behavioral internalization through adaptive content delivery and habit-change reinforcement rather than maximizing session frequency or time-on-app [33-35]. These findings further caution against the use of engagement metrics such as login frequency or session duration, as surrogate indicators of adherence or therapeutic dose, given that meaningful behavioral change may occur independently of, or even inversely to, raw usage volume [19].

Temporal Dynamics of Response and Moderation by Psychological Distress

Because week-4 behavioral change precedes the week-6 end point, it can be interpreted as an early-treatment predictor with temporal precedence, in contrast to the concurrent change variables measured at the end point, which are more appropriately regarded as factors associated with response. The week-4 amplification has clear precedent in the broader habit-formation literature, where behavioral consolidation typically requires approximately 4 weeks to stabilize [29]. These findings may carry 2 practical implications. First, week 4 may represent a promising candidate time point at which patients who have not demonstrated a behavioral or clinical response by this time point can be identified early to receive augmented or alternative strategies before completing the full 6-week course. However, because these observations are post hoc, prospective adaptive-design or decision-analytic studies would be needed before a week-4 rule could inform clinical practice [36]. These adaptive treatment approaches are increasingly advocated within digital health interventions [36]. Second, the amplified ORs raise the prospective hypothesis that a condensed 4-week protocol might achieve equivalent or near-equivalent gains with reduced patient burden, a question that warrants dedicated evaluation in future trials [37].

The PHQ-4 moderator pattern is clinically plausible: patients with psychological comorbidity may benefit more from the self-management, mindfulness, and behavioral awareness

XSL•FO
RenderX

components in the DTx intervention [38-40]. Despite evidence that 60% - 77% of patients with TMD experience psychological distress [3], routine screening remains underused in dental practice [41]. Brief instruments such as the PHQ-4 could help identify patients most likely to benefit from behavioral digital interventions [42,43].

Limitations

This study has several limitations. All findings are from a post hoc secondary analysis and are associative and hypothesis-generating, not causal. Because the proposed mediator, OBC-defined behavioral change, is a postrandomization variable rather than a randomized exposure, causal mediation inference is precluded despite the use of the potential outcomes framework, and residual unmeasured confounding of the mediator-outcome relationship cannot be excluded [44]. In particular, reverse causation cannot be ruled out: patients whose pain improves may subsequently report fewer parafunctional behaviors because they feel better, are less vigilant, or perceive less need to guard the jaw [3]. Under this scenario, OBC improvement could function as both a consequence and a correlate of pain reduction rather than solely as an antecedent mediator, and the assumed direction from behavioral change to pain relief, while biologically plausible, cannot be confirmed in the present design. Baseline OBC and PHQ-4 scores were higher in the DTx group, which may have influenced the mediation and moderator analyses through regression to the mean. The OBC modifier classification relies on a data-driven median split, introducing cut-point sensitivity, and creating subgroups that may not be stable across samples. Furthermore, multiple responder, subgroup, mediation, sensitivity, and moderator analyses were conducted without formal correction for multiple comparisons; borderline findings, particularly those with *P* values close to .05, should therefore be regarded as exploratory signals rather than confirmatory results. Finally, the mediation estimates were sensitive to distributional assumptions and sample sizes, necessitating replication in larger independent cohorts [44].

The analysis was conducted in the per-protocol population (N=93) rather than the intention-to-treat sample, as the mechanistic question of how DTx exerts its therapeutic effect inherently concerns participants who completed the intervention as intended; intention-to-treat estimates would have diluted the engagement-outcome dissociation with noncompleters and were therefore not appropriate for this specific analytic aim [45]. This principled selection nonetheless restricts inference to completers and should be considered when generalizing the mechanistic findings to broader trial populations. The per-protocol sample size also restricted the statistical power of the subgroup and interaction analyses, particularly for the PHQ-4 moderator, and limited the ability to detect modest between-group differences in engagement metrics. In addition, only a single behavioral mediator (OBC) was examined; other plausible pathways, such as cognitive reappraisal, pain-related self-efficacy, or improved sleep, were not assessed and may also contribute to treatment response [46-48]. The 6-week follow-up precluded the assessment of long-term durability, and a longitudinal follow-up study is currently underway. The trial was conducted at 2 tertiary care centers in South Korea, limiting its generalizability to other health care settings and populations.

Conclusion

These findings may refine the understanding of therapeutic dose in digital interventions. While app engagement may be a necessary vehicle, it may be the patient's internalization of that engagement into sustained behavioral change that is more closely linked to clinical benefit. In TMD, this realized behavioral adaptation, shaped by underlying psychological context and consolidated within a defined temporal window, may represent a key behavioral pathway underlying treatment response. Practically, these observations suggest that DTx development and evaluation might prioritize measures of behavioral realization over engagement volume and that mechanism-driven, precision-oriented trial designs may help clarify for whom and through which pathways these interventions work. These directions remain hypotheses to be confirmed in future prospective studies.

Acknowledgments

The authors thank the clinical research staff at Hallym University Sacred Heart Hospital and Hallym University Dongtan Sacred Heart Hospital for their contributions to the parent trial, and So Young Jung for trial coordination. The authors gratefully acknowledge Soo-Yeon Chung and Woo-Suk Kang of the contracted research organization for their rigorous data management and statistical oversight. All clinical data were managed and locked by an independent contract research organization under the supervision of the Korean Ministry of Food and Drug Safety prior to analysis. The present secondary mediation analysis received no separate funding. The authors also thank Professors Young-Kyun Kim and Jong-Ho Lee for valuable scientific input and mentorship.
