First, a project group consisting of representatives from the professional associations of midwives and gynecologists, as well as a delegate from the umbrella organizations representing drugstores, was assembled. Next, a needs assessment was conducted among the target population using 2 tailored online questionnaires, one for women who were pregnant or gave birth within the past year and one for health care professionals working with this group. These were the only inclusion criteria for participating in the needs assessment. Questions focused on information-seeking behavior, content preferences, and distribution strategies. Given their brief and exploratory nature, the questionnaires primarily assessed opinions and prior behaviors and were therefore not pilot-tested nor formally validated. A translated version of one of the distributed questionnaires is provided as supplemental material. Participants were recruited using convenience and snowball sampling approaches, primarily through the Dutch Pregnancy Drug Registry (as part of the Dutch TIS), social media, an umbrella organization of drugstores, and the TIS's professional network. Together, these recruitment strategies aimed to provide a comprehensive representation of the target population, thereby reducing the risk of sampling bias. The target sample size of 100 completed questionnaires was determined based on feasibility considerations and the exploratory aims of the study. The completed questionnaires were analyzed descriptively and extensively discussed within the project group, and the outcomes were used as a basis for the development phase.

Phase 2. Development Phase

During the development phase, an initial draft of the app was devised together with a marketing agency and information technology partner. When developing the app prototype, insights from the needs assessment were used, and discussions with the project group addressed which barriers health care professionals needed to overcome before recommending the app. Key decisions included the navigation structure, type of information, required warnings, interface design, app name, and integration with the existing TIS knowledge bank on the website for extended content. A comprehensive list of OTC medicines, such as analgesics, antacids, vitamins, and herbal supplements, was based on the most commonly used OTC medicines during pregnancy in the Dutch Pregnancy Drug Registry and further extended with OTC medicines identified during field visits to pharmacies, drugstores, and supermarkets. Medicine safety information included in the app was drafted by teratology experts from the Dutch TIS, based on the latest scientific available evidence. Content drafting was supervised by a medical doctor and a pharmacist. All displayed content was fully managed in-house, allowing for continuous updates and modifications as needed. Finally, in consultation with legal experts, privacy terms and disclaimers were carefully drafted. By the end of this phase, a fully functional app prototype was completed.

Phase 3. Preimplementation Phase

Before the launch, a prototype of the app was extensively tested among the target population using a mixed method approach by collecting both qualitative data (focus groups) and quantitative data (questionnaires). First, focus groups were conducted consisting of target users and teratology experts. Participants were recruited through convenience and snowball-based approaches, primarily via midwifery practices, pregnancy fitness classes, and professional networks. Each focus group was scheduled for a maximum of one hour. Participants first completed exercises designed to facilitate navigation through the app, after which the facilitator led a group discussion following a predesigned script, eliciting feedback aimed at improving the app. Sessions were audio-recorded with consent, and all feedback points were documented and descriptively analyzed without the use of an analytical framework. We aimed to conduct 5 focus groups with a minimum of 5 participants each, a target determined pragmatically in light of feasibility and the short data collection timeframe. Subsequently, an online questionnaire, mirroring the focus group tasks, was distributed among health care providers and women who were pregnant or gave birth within the past year. These were the only inclusion criteria for administering the questionnaire. The aim was to collect 10 completed questionnaire responses. All feedback from the focus groups and questionnaires was evaluated, and final adjustments to the app were made accordingly.

Phase 4. Implementation Phase

The launch of the app was supported by both broad and targeted communication campaigns. Dissemination relied on an informing strategy, engaging stakeholders to promote the app through online and offline channels. Health care professionals were positioned as key figures by recommending the app during consultations, as part of a motivational approach. Booster campaigns were periodically initiated to reach the continuously changing target population. All feedback received from app users was carefully reviewed, and whenever possible, immediate additions or changes were made to the content.

Phase 5. Evaluation Phase

Evaluation metrics included the number of app downloads, App Store ratings, user feedback, number of daily active users, most searched medications, and total number of page views. Tracking of anonymous in-app user behavior commenced 5 months postlaunch, following an app release. A cautious initial target of 15,000 downloads was set for the first year, based on the approximate annual birth rate of 170,000 in the Netherlands, with the understanding that awareness and adoption would take time to build [42].

Ethical Considerations

This study did not require approval from a medical ethics review committee, as it did not qualify as medical research involving human subjects under the Dutch Medical Research Involving Human Subjects Act. All collected data were anonymized before analysis to protect participant privacy and confidentiality. Participation was voluntary, and informed consent was obtained from all participants prior to participation. Only focus group participants received a gift voucher of their choice as a token of appreciation for their time and contribution.

Results

Phase 1. Preparation Phase

A total of 217 individuals completed the needs assessment questionnaire; 184 (84.8%) were women who were pregnant or had given birth within the past year, and 33 (15.2%) were health care professionals (Table 1). Among the women, 160 out of 184 (87.0%) were pregnant at the moment of administering the questionnaire (mainly in the second trimester), and 10 out of the 24 women who recently gave birth (41.7%) were still breastfeeding. The majority of women (134/184, 72.8%) reported actively seeking safety information before using any medication. The need for information on OTC medicines (142/184, 77.2%) and health products (eg, supplements, herbs, and vitamins; 122/184, 66.3%) was higher than the need for information on prescribed medicines (70/184, 38.0%). Preferred sources of information were official (government) websites (151/184, 82.1%), product information (125/184, 67.9%), and health care providers (115/184, 62.5%). The primary motivation for seeking safety information was (1) to determine whether a medicine can be used during pregnancy and breastfeeding or not (2), which medicine is the preferred treatment option for specific (pregnancy) complaints, and (3) what the possible adverse drug reactions are. Open-ended responses underscored challenges in finding trustworthy and accessible information, and frustration with inconsistent recommendations across sources.

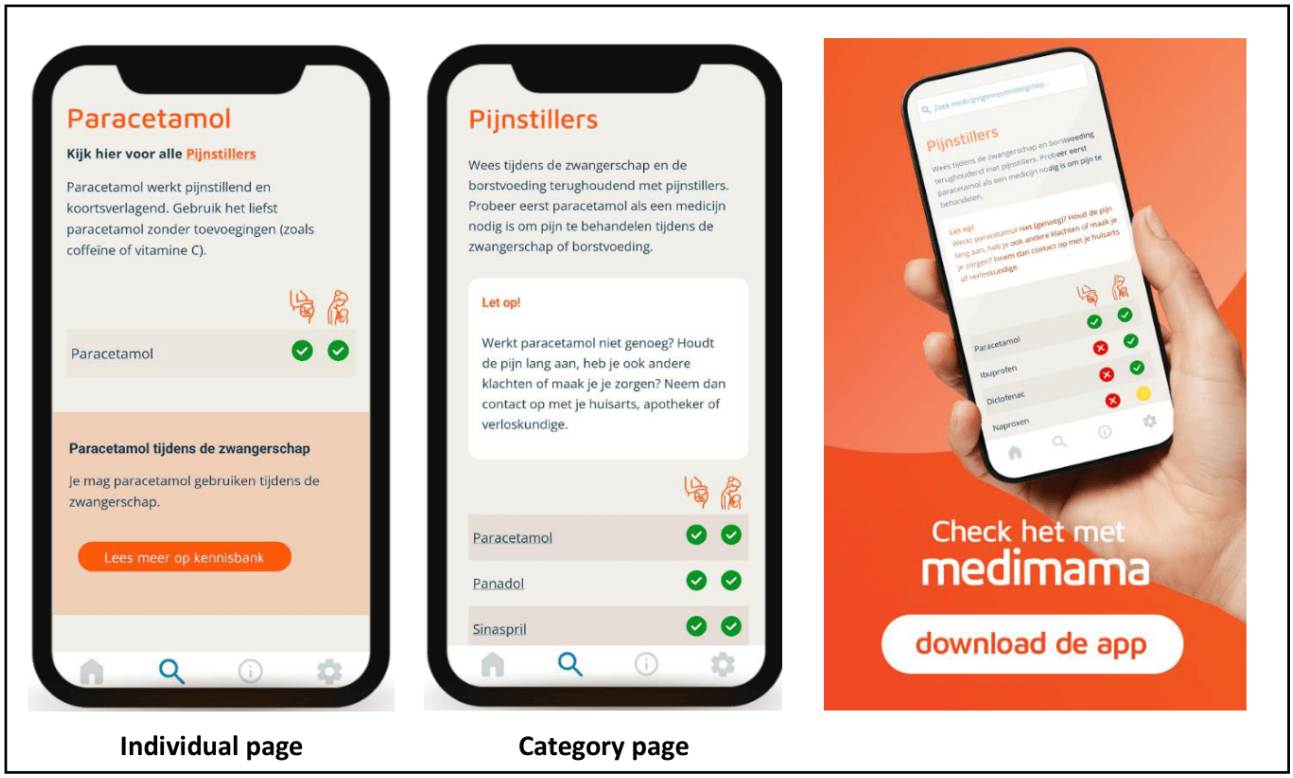
[a]Multiple answers possible.

[b]OTC medicines: over-the-counter medicines.

[c]The exact answer option was "Information about health products other than OTC medicines (eg, supplements, vitamins, and herbal remedies)".

[d]On a scale of 1 (very unlikely) to 10 (very likely).



[e]On a scale of 1 (Totally disagree) to 10 (totally agree).

Health care professionals (n=33) reported using the knowledge bank of TIS on the website frequently and appreciated the clear distinction between pregnancy and breastfeeding guidance. The main reasons for seeking safety information were (1) to determine whether or not a medicine can be used during pregnancy and breastfeeding (2), what the possible adverse drug reactions are, and (3) which medicine is the preferred treatment option for specific (pregnancy) complaints. While some believed the app could reduce their workload, others expected women would still seek personal advice. Finally, health care professionals were moderately likely to use the app themselves (mean 6.0, SD 3.5) but more likely to recommend it to patients (mean 7.3, SD 2.4 out of a scale from 1 to 10).

Phase 2. Development Phase

The primary focus in the user experience testing was to make sure that the required information was found as quickly as possible and was comprehensive and easy to understand. For this purpose, all medicines in the app are classified within 3 risk categories using the traffic light colors, including green (can be used), yellow (be careful and read more information), and red (not to be used). Safety information in the app is distributed through 2 kinds of information pages (Figure 2):

Figure 2. Overview of the different pages and the look and feel of the MediMama app.

1. An individual page contains short and easily understandable product-specific safety and usage information. The app contains 260 individual pages, including medicines, products, vitamins, and herbals. On all individual pages, a referral button to the specific information on the TIS website is placed for more detailed information.

XSL•FO
RenderX

2. The category page provides an overview of a group of medicines or products where all risk categories from all relevant medicines are displayed in a table. The app contains 28 category pages, for instance, analgesics, antacids, or hay fever tablets. Additionally, this page provides lifestyle recommendations to relieve the (pregnancy) complaint before the initiation of medication.

Users can search by active ingredient, brand name, or health complaints. The app name, MediMama (Netherlands Pharmacovigilance Centre Lareb), was selected in collaboration with followers of a large Dutch pregnancy platform. The look and feel of the MediMama app are displayed in Figure 2. Based on user preferences, the app was developed as a native app as well as a web-based version.

Phase 3. Preimplementation Phase

The prototype was tested in 5 focus groups (n=23 participants) and via an online questionnaire (n=14; Table 2). During the focus groups, thematic saturation was observed. Participants in the focus groups reported that the app was easy to use, had an appealing look and feel, and the displayed safety information with the 3 colors was a big plus. Minor technical issues were noted on certain devices. Key suggestions included shortening texts, improving ease of reading, removing account registration, improving the disclaimer text, and considering adding more information about medication usage, such as duration and dosage. The online questionnaire was completed by 6 out of 14 (42.9%) women who were pregnant during the administration of the questionnaire or gave birth within one year of completing the questionnaire and 8 out of 14 (57.1%) health care providers with different backgrounds (Table 2). All questionnaire respondents rated the app's ease of use ≥8/10. Most women reported that they would probably (3/14, 21.4%) or definitely (11/14, 78.6%) use or recommend the app. Suggestions were made to improve specific texts (eg, the disclaimer) and to add references to other sources of information for more detailed information on, for example, medication usage or the health condition. All health care providers agreed with the statement that the information in the app is appropriate and suitable for women who are pregnant or breastfeeding.

Table . Results of the mixed methods prototype testing of the MediMama app conducted in the preimplementation phase.

Category	Findings
Focus groups (n=23 participants)	
Focus group sessions	
Online (team session)	Teratology experts (n=9)
Local gym	Pregnant women or women who gave birth <1 year (n=4)
Online	Pregnant women or women who gave birth <1 year (n=3)
Online	Women who gave birth <1 year (n=2)
Midwifery practice	Pregnant women (n=4) and midwife (n=1)
Examples of technical issues	Disclaimer page crashed on some devices; formatting inconsistencies across devices; design differences between dark and light phone settings
Examples of positive aspects	Appealing layout and app name; easy to search for information; positive feedback on referrals to other platforms for more detailed information
Examples of suggestions to improve	Texts could be shorter and include less jargon; remove the option of creating a personal profile; include the category page in search results when searching for an individual medicine; onboarding information can be overwhelming
Online questionnaires (n=14 participants)	
Target population	
Pregnant	Second trimester (n=1); third trimester (n=2)
Gave birth <1 year	Breastfeeding (n=2); not breastfeeding anymore (n=1)
General practitioner	3
Midwife	2
Other HCP[a]	3
MediMama app easy to use[b]	
Mean	8.6
Score ≥8	14 (100)
Examples of positive aspects	Clear, short, and understandable information; simple design with clear symbols and colors; clear distinction between pregnancy and breastfeeding; useful referrals to other platforms for more detailed information
Examples of suggestions to improve	Improve information in the disclaimer and onboarding; explicitly refer users to the prescribing doctor for information on prescribed medication; consider including preconception recommendations; be cautious when categorizing all vitamins as “green” (safe to use)
Would you use or recommend the MediMama app?	
Definitely not or maybe	0 (0)
Probably	3 (21.4)
Definitely	11 (78.6)

[a]HCP: health care professional.

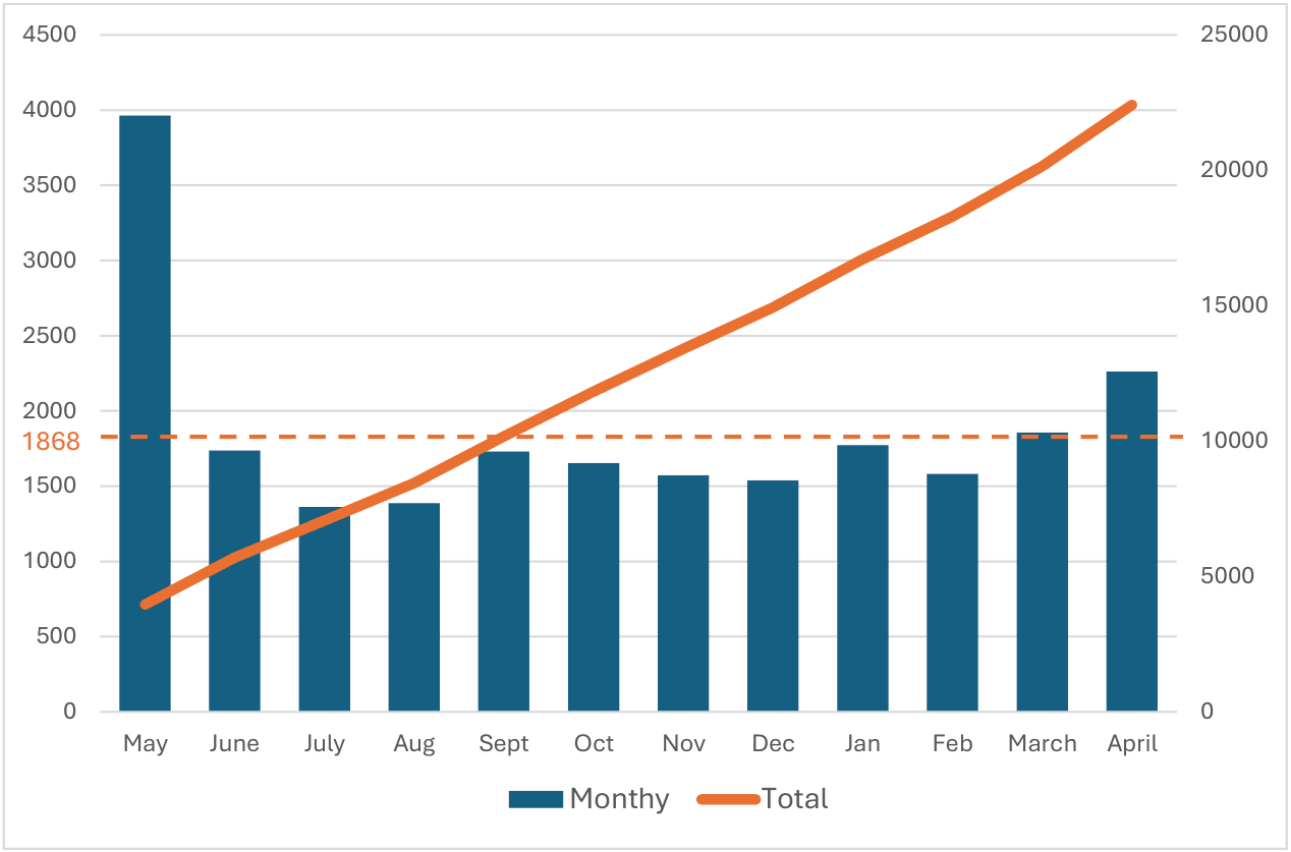
[b]On a scale from 1 (difficult to use) to 10 (very easy to use).

Phase 4. Implementation Phase

The MediMama app was launched on Mother’s Day (May 12th), 2024, and has been freely available in the app stores since then [43,44]. During the first year, the MediMama app was promoted through various channels, with the 4 main promotional strategies being the following:

1. Drug store campaign: in over 800 drug stores, MediMama “shelf cards” were displayed. This generated significant visibility and raised awareness among store employees and visitors.
2. Online social media campaign: targeted campaigns via Instagram (Meta Platforms), Facebook (Meta Platforms), and Google Play (Google Inc) were conducted. Campaigns were updated every few weeks to optimize reach. These platforms use advanced algorithms and machine learning to optimize advertorial performance.

XSL•FO
RenderX



3. Dutch pregnancy convention: over 30,000 (pregnant) visitors attended a 4-day Dutch pregnancy convention. At which the MediMama app was promoted through a booth, daily master classes, and giveaways.
4. To reach health care providers from various disciplines, the development and launch of the app were promoted through channels as presentations at national medical conferences, posters and flyers in waiting rooms, local health care provider meetings, publications in professional journals, and news items from several professional associations.

User feedback led to several app improvements. In response to frequent requests, the most searched prescription medicines were also added. The prescribed medicines in the app all receive the "yellow risk category" (be careful and read more information) and directly refer to the medicine-specific information on the TIS website for more detailed information and the advice to discuss this medication use with their physician.

Phase 5. Evaluation Phase

In its first year, the app was downloaded 22,415 times, averaging 1868 downloads per month (Figure 3). Peak activity occurred in the launch month (n=3963). After the initial peak of reaching the early adopters, the average daily number of downloads gradually increased from 44 per day up to 75 per day. The social media campaign proved to be one of the most effective strategies to reach the target population. On average, app users viewed 3 pages per session; in total, on average, 24,352 pages were viewed each month (Figure 4). The number of daily app users increased from 207 per day to 370 daily app users over the course of 6 months. However, the growth in the number of downloads and app users did not follow a consistent upward trend each month over the course of the first year, resulting in some fluctuation in usage (eg, the short month of February or seasonal changes). To date, the MediMama app has received 11 reviews across both app stores, all of which have awarded it the maximum rating of 5 stars. Most of the feedback received via email and social media concerned the need for the app to be available in multiple languages and to include information on prescribed medications. Paracetamol (acetaminophen) and nasal sprays turned out to be the most frequently searched and viewed medicines in the app (Table 3). While category pages received more overall views, individual pages were more frequently accessed via search. This indicates a distinction in user behavior; searches were primarily aimed at specific medicines, whereas the higher number of views on category pages suggests that users actively navigated through the app to gain a more comprehensive understanding of an entire group of medicines. Finally, seasonal trends in search terms are visible corresponding with the seasonal health complaints (Figure 5). For example, in the flu season (December-February), information-seeking behaviors leaned toward medicines like nasal sprays or cough syrups, while a peak in hay fever medicine (eg, cetirizine tablets) was noticeable from March onward.

Figure 3. Overview of the MediMama downloads within the first year**.** The left Y-axis scale represents the number of monthly downloads (blue); the right Y-axis scale represents the total number of downloads (orange); the orange dotted line represents the average number of monthly downloads; the numbers within the blue bars represent the average number of daily downloads.

Figure 5. Examples of seasonal trends in search terms for 3 medicines in the MediMama app. Numbers correspond with the monthly number of times xylometazoline nasal spray, cetirizine (hay fever medicine), and acetylcysteine (cough syrup) were searched.

Discussion

Key Findings

This study details the development and dissemination process of MediMama, a Dutch mobile app providing evidence-based information on the safety of OTC medicines and products during pregnancy and breastfeeding. Preimplementation research suggested that the preferred route for receiving safety information on medicine was online and emphasized the need for a new mobile app. Involving the target population throughout development ensured alignment with user needs. One year postlaunch, the MediMama app is considered a promising eHealth tool, addressing the demand for accessible, reliable OTC medicine safety information in maternity care.

Comparison to the Literature

Previous eHealth apps in maternity care have demonstrated a successful tool in improving safe medication use and overall maternal health outcomes during pregnancy and lactation [15]. Educational apps and clinical decision support tools have been shown to improve medication adherence, increase antenatal care attendance, and support behavioral changes for topics such as healthy diet, smoking cessation, and vaccination uptake [16,45-47]. Usability and acceptability of mobile health apps during pregnancy are generally high, with pregnant women and health care providers reporting satisfaction and willingness to recommend these tools [16,45,48,49]. Some previously developed apps on the safety of medication use during pregnancy or breastfeeding have been developed, for instance, LactSafe (NIH LactMed - MotherToBaby (OTIS)) [34], MommyMeds (InfantRisk Center) [35], and Meds4Mums2B (Innovative Health Initiative (IHI) ConcePTION, in collaboration with the Medicines and Healthcare products Regulatory Agency (MHRA)) [36]. The MediMama app differs from existing tools by being freely accessible worldwide, providing comprehensive safety information for both pregnancy and breastfeeding based on scientific literature. In addition, the MediMama app has been scientifically evaluated, and data on usability and user satisfaction are available. Because of limited available evidence, the effectiveness of mobile health apps in improving maternal knowledge, behavior, and perinatal outcomes remains inconclusive [45,50].

Despite their potential, eHealth tools during pregnancy also carry certain risks with regard to self-treatment [19]. Self-medication during pregnancy is prevalent and can lead to inappropriate drug selection, misdiagnosis, dosing errors, delayed medical help–seeking, and inefficient treatment which may result in adverse maternal and fetal outcomes [51,52]. The MediMama app aims to mitigate these risks by using intuitive, color-coded guidance that is immediately interpretable at a glance and by advising on how to treat a complaint through lifestyle changes instead of medicines (ie, for heartburn). With regard to the quality of eHealth apps, previous reviews elaborated on the growing concern over the quality of several (commercial) pregnancy apps with regard to poor or unclear evidence base of content, lack of expert involvement, and poor

XSL•FO
RenderX

validation [19,53-56]. Emerging artificial intelligence–based health tools further complicate this landscape, with risks of misinformation due to limited contextualization and transparency [57,58]. To navigate these waters of conflicting health information, health care providers can play a central role in advocating for evidence-based trustworthy health information provided by noncommercial public institutions.

Pregnancy and breastfeeding represent periods of heightened health awareness, yet implementation of interventions is challenging due to the dynamic and transient target population [59,60]. The relatively short duration of pregnancy and the subsequent breastfeeding period means that the target group is constantly changing, with individuals entering and exiting the eligible target population in a matter of months. During the implementation phase of the MediMama app, we also experienced the considerable effort it required to reach this constantly changing target population. We have experienced that focusing on online marketing and involving health care providers in disseminating the app could be a promising and sustainable approach to reaching this constantly changing target population.

Strengths and Limitations

This is the first study to systematically describe the development and dissemination process of a mobile app focused on medicine safety in pregnancy and breastfeeding, using mixed methods to capture user and provider perspectives. The diverse set of offline and online strategies used to distribute the MediMama app enabled us to reach this constantly changing target population. Due to this multifaceted promotional approach, the target aim of 15,000 downloads within the first year was reached within the first 7 months. The MediMama app has been well received; the number of daily users keeps increasing, and reviewers praise its simplicity, trustworthiness of the information, and their privacy protection since the app is used anonymously.

However, anonymity limits evaluation of user demographics, hindering assessment of whether the app reaches intended subgroups (eg, pregnant women vs health care providers) and its impact on clinical workload. Consequently, it is difficult to assess whether the app conveys the appropriate tone of voice in presenting safety information. Further user research is therefore needed. Another limitation of our study is that the preimplementation recruitment via the pregnancy registry may have introduced selection bias and the use of unvalidated and not pilot-tested questionnaires to assess user needs. This may have affected the quality and reliability of the collected data. However, the questionnaires were developed in close alignment with the study objectives, supporting their face validity despite the lack of formal validation. Finally, most suggested feedback after the launch of MediMama was making the information in the app available in multiple languages. By limiting the language options to Dutch only, we were likely unable to reach some of the most vulnerable populations, including individuals with limited digital literacy or access, who might benefit most from health guidance. However, vulnerable pregnant women may require additional and fundamentally different forms of health education because a “one-size-fits-all” approach is unlikely to reach a heterogeneous pregnant population with varying levels of health literacy [60].

Future Research

Prior to the large-scale implementation of mobile health apps during pregnancy, more research is needed on their effectiveness. As previous studies suggested, there is still much to learn on the impact of mobile health apps during pregnancy with respect to cost-effectiveness, potential to reduce health care costs and system burden, and their potential positive effect on maternal and neonatal outcomes [19,45]. Since the MediMama app is freely accessible and operates without a profit-generating model, the lack of secured funding poses a significant risk to its ongoing maintenance and sustainability, potentially jeopardizing its continued availability. Further research is needed to identify sustainable approaches to integrate these interventions within maternity care to ensure their continued maintenance, updating, and optimization. In addition, to reach the entire Dutch population of pregnant and breastfeeding women, establishing and maintaining long-term collaboration with health care professionals, such as midwives and gynecologists, is critical. While the target user group changes over time, health care professionals represent a stable and trusted gateway to this population. Further evaluation of effective strategies to continuously reach the different target populations is warranted. Finally, since the multiplicity of mobile apps in pregnancy can be overwhelming and choosing the best one is proven to be difficult for pregnant women, future efforts should explore unified, multilingual platforms that balance usability with comprehensive, evidence-based content [61].

Conclusion

This study describes the development and dissemination process of the MediMama app, designed to provide easily accessible and evidence-based safety information on OTC medicines during pregnancy and breastfeeding. One year postlaunch, MediMama has been a well-received and frequently used eHealth resource in the Netherlands, effectively meeting the information needs of its target population. While initial feedback and usage patterns of MediMama are promising, the behavioral impact of the app remains untested, and its usability has yet to be formally assessed, warranting further evaluation. Further research is required to evaluate the effectiveness of the implementation strategy, as well as the app’s impact on maternal medication use behaviors and health outcomes. Mobile health is emerging as a pivotal tool in maternity care; increased emphasis is required on the continued development of these tools to improve the health of future generations.

Acknowledgments

We would like to thank all the volunteers who provided feedback in the different steps of the process. We gratefully acknowledge the contributions of our project group, including representatives from KNOV, NVOG, and CBD, as well as our IT and design partners, for their dedicated efforts in developing the MediMama app into the product it is today.

Funding

This research and the development of the MediMama app was funded by The Netherlands Organisation for Health Research and Development (ZonMw). Grant number: 10140162210007. The funder had no involvement in the study design, data collection, analysis, interpretation, or the writing of the manuscript.

Data Availability

The datasets generated or analyzed during this study are available from the corresponding author on reasonable request.

Abstract

Background: Cannabis use (CU) among young adults continues to be an important public health issue. Interventions to support lower-risk CU during young adulthood can improve health outcomes. Mobile applications constitute a promising mode of service delivery. However, there is a lack of evidence-based apps specifically developed for young adult cannabis users.

Objective: This study aimed to evaluate the acceptability of a novel mobile app intervention (Joint Effort) and to assess the feasibility and outcome responsiveness of the study procedures used.

Methods: A pilot study with a parallel-group randomized trial design was conducted with Canadian-based university students aged 18 - 30 years reporting using cannabis ≥1 day in the past month. Participants were randomly assigned on a 1:1 ratio to either an experimental group (EG) involving the use of the Joint Effort mobile app or to a control group (CG) involving a web-based brief normative feedback message. The Joint Effort mobile app was designed to support CU self-management. This theory-informed behavior change intervention aims to reinforce the use of protective behavioral strategies by targeting intention, attitude, social norms, and self-efficacy. The app's acceptability was assessed via uptake, engagement, and appreciation. The feasibility of study procedures was assessed via recruitment time, recruitment rate, and attrition rate. Outcome responsiveness was informed by participant-reported outcomes: CU frequency, intention to take action on CU, protective behavioral strategies use, severity of

XSL•FO
RenderX

dependence, and psychological distress. All data were collected using a web-based survey at baseline, one-month (T1), and 2-month (T2) postbaseline. Descriptive analyses were carried out on all outcomes.

Results: The recruitment period lasted 124 days, and the recruitment rate was 56% (99/178). The final dataset analyzed included 80 participants (39 in EG and 41 in CG). Mean age was 23.4 (SD 2.6) years, and 66% (53/80) self-identified as women. Study attrition was 18% (14/80). User uptake of the Joint Effort app (ie, proportion of participants in the EG who downloaded the app) was estimated at 59% (23/39), and the average time spent on it per participant was 8.2 minutes (SD 7.3; median 7.5, IQR 5.7). The app obtained a mean total score on the User Engagement Scale-Short Form of 3.8/5 (SD 0.5) and a mean app quality total score of 4.2/5 (SD 0.5) on the end user version of the Mobile App Rating Scale. The proportion of participants who reported daily CU in the past month decreased from 13% (5/39) at baseline to 4% (1/24) at T2 in the EG and from 7% (3/41) to 6% (2/36) in the CG.

Conclusions: Joint Effort appears to be a promising, acceptable, and scalable mobile app to help young adult cannabis users who wish to better manage their CU. Findings should inform future randomized controlled trials to assess the efficacy of this mobile-based intervention for cannabis users.

Introduction

Background

Cannabis is one of the most commonly used substances for nonmedical purposes throughout the world. The prevalence of past-year cannabis use (CU) in the global community 15‐64 years of age in 2018 was estimated at 3.8%, which represented nearly 200 million people [1]. Attitudes toward CU have evolved substantially over the past 25 years [2]. The legalization of medical and recreational CU has expanded in Canada and the United States, and the legal status of CU has been shifting in other countries as well [3]. In the last decade, the consumption of cannabis products has increased considerably, particularly among young adults, typically 18‐25 years old [4-6]. In this population group, the prevalence of past-year CU was found to be 25% or higher in high-use regions such as North America, Oceania, and West Africa [1]. Moreover, and important for how it might impact potential life-course outcomes, the median age of onset of regular CU is 18‐19 years [7], and CU level and frequency begin to increase in very early adulthood and peak in middle age [8,9].

CU is associated with a wide range of health harms, including risk for CU disorder [10,11], short-term acute risks (eg, cannabis-impaired driving and related injuries/death, acute intoxication, impaired cognitive functioning), and other negative social consequences (eg, poor schooling or work performance, social isolation, family violence, stigmatization, poor living conditions) [12-14]. Importantly, CU has been linked to long-term adverse health outcomes such as cardiovascular problems, brain development issues, lung tissue injury, and mental health problems [15-18]. In the context of increased availability of high-THC products, country- or state-level legalization reforms allowing recreational CU, and public opinion to the effect that cannabis is a low-risk substance [6,19,20], there is a need for interventions to promote lower-risk CU and to prevent escalation of CU-related consequences among young adults.

Across the intervention continuum, CU interventions range from public awareness campaigns and prevention practices to treatment programs for CU disorder. Among these, lower-risk CU interventions [10] constitute a wide range of public health prevention or intervention tools inspired by harm reduction, a framework that places substance use on a spectrum from total abstinence to continued heavy use [21]. Generally, lower-risk CU interventions are based on health behavior change theories [22-24] and existing harm-reduction prevention approaches (eg, low-risk drinking guidelines, guidance for safe drug use practices) [25,26].

In recent years, particularly, there has been growing interest in the development of digital interventions for the promotion of lower-risk CU [27-30]. Digital modalities not only render interventions more accessible and cost-effective, but they also offer innovative opportunities for delivering personalized and real-time adaptive interventions that meet the needs and preferences of young adults [31-33]. An important body of literature documents the development, adaptation, and evaluation of digital interventions for lower-risk CU among young adults designed to be accessed online (ie, web- or internet-based) or via a mobile device (eg, cell phone, tablet, smartwatch) [28,29,34-40]. Altogether, the scientific evidence on the effects of digital interventions for lower-risk CU on health outcomes has been mixed. Specifically, while several studies have shown that digital interventions can reduce CU among young adults [36-42], other studies have found no effects on use [35] and cannabis-related consequences [34]. Furthermore, a scoping review by Sedrati et al [39] and a recent systematic review by Côté et al [34] both concluded that, despite considerable advances in digital interventions for lower-risk CU among young adults, most of the interventions developed and tested to date are web-based programs. These asynchronous digital tools typically use websites or online platforms, accessed mainly via computers, and consist primarily of didactic, static information (eg, facts, psychoeducational material) [40]. This means that content is neither individualized to the needs and characteristics of intended end users nor tailored in real time. Therefore, more

XSL•FO
RenderX

research is needed to develop and test the acceptability and effectiveness of digital interventions using next-generation mobile health (mHealth) tools (eg, mobile apps, social media) that, undoubtedly, would be more consistent with the technological habits of today's young adults.

Related to these concerns, digital CU interventions for young adults also pose unique challenges in terms of implementation and utilization. For one, adequate engagement is crucial for digital interventions to be successful [43,44]. However, research has shown that engagement tends to be low and that attrition is common [33,35]. This concern is particularly salient with respect to the subpopulation of young adults who do not perceive their CU as problematic and, consequently, have lower readiness to change. In addition, existing digital CU interventions were developed primarily for individuals with a CU disorder (5.1% of people aged 12 years or older in the United States) [45] or mental health needs [31,38,46]. This excludes a larger proportion of young adults who do not experience severe problems from their CU [37]. For example, recent studies have demonstrated the benefits of digital interventions aimed at supporting young adults after substance-use treatment programs [47-49]. However, these interventions are not tailored to individuals with lower severity substance-use who are not necessarily seeking to change their behavior or to prevent relapse [33]. Finally, many digital tools developed specifically for young adult cannabis users include therapist support [50-56]. From a public health perspective, this reduces scalability and may be unnecessary for people with lower CU severity.

In 2018, recognizing the need for a publicly available evidence-based app to promote lower-risk CU tailored to the needs of young adults [57], we developed a mobile app named Joint Effort. The detailed rationale for developing this new intervention is described elsewhere [58]. This mobile app aims to support CU self-management and reinforce protective behavioral strategies (PBS) use among young adult cannabis users. The intervention applies behavior change principles [59,60] that have previously demonstrated their efficacy in trials of interventions targeting risky behaviors [21,61,62]. Consistent with the current best practice in developing mHealth apps [63,64], our team's prior work used an iterative intervention mapping and co-design approach [65-67] in a series of formative studies [58,68,69] to develop, inform, and refine Joint Effort. Additional formative work was required to determine the app's acceptability and feasibility before its efficacy and effectiveness in improving health outcomes among young adult cannabis users could be tested. Against this backdrop, we conducted a pilot parallel-arm randomized controlled trial (RCT) to assess the acceptability of the Joint Effort app in terms of user uptake, engagement, and appreciation in a sample of young adult university students. We also assessed the feasibility of our study procedures and the responsiveness of outcome measures.

Aim and Objectives

The objectives of this study were threefold:

1. To assess the acceptability of the Joint Effort app in terms of user uptake, engagement, and appreciation.
2. To assess the feasibility of study procedures and document the research process throughout the study period.
3. To assess outcome responsiveness in participant-reported outcomes, including CU, intention to take action on CU, PBS use, severity of dependence, and psychological distress.

Methods

Study Design

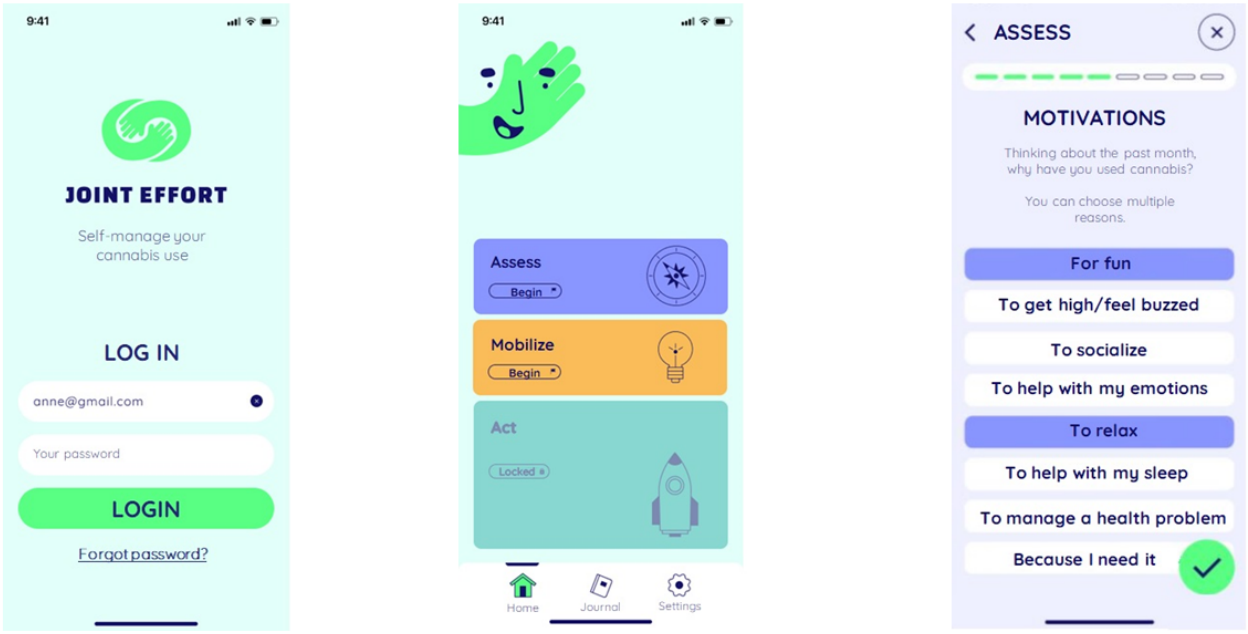
The study design was a pilot RCT [70] where a sample of young adult university students who reported CU in the past month was split into two parallel arms: (1) an experimental group (EG) that was given access to the Joint Effort mobile app; and (2) a control group (CG) that received one brief normative web-based feedback message regarding their CU and had access to publicly available information on lower-risk CU guidelines.

The study was registered in the ClinicalTrials.gov Protocol Registration and Results System (NCT05099016). The study reporting followed the CONSORT extension for Pilot and Feasibility Trials [71] checklist (Checklist 1) in reporting the trial.

Setting and Sample

The target population for this study consisted of young adults studying at the Université de Montréal, a world-class, predominantly French-language university with approximately 67,000 students, located in a metropolitan region of Eastern Canada. We used a recruitment strategy centered on social media ads and posters on university campuses to obtain a broad and diverse sample of university student cannabis users. Individuals were eligible for this study if they met four criteria: (1) 18 to 30 years of age; (2) enrolled in an undergraduate or graduate program at the Université de Montréal; (3) self-reported at least one episode of past-month CU; and (4) had an iPhone to download the app to (Joint Effort was available only as an iOS app at the time of study).

Teare et al [72] recommend that at least 70 participants (35 per group) are needed in a pilot RCT to ensure a statistically precise measurement of each variable. To compensate for potential attrition at follow-up (ie, we expected up to 35% attrition at the 2-month postbaseline assessment) [34,35], we sought to recruit a total of 110 participants in order to end up with a final sample size of at least 70 completers.



Intervention Characteristics: A Mobile App for Lower-Risk CU

The Joint Effort mobile app was designed to promote CU self-management and reinforce PBS use among young adult cannabis users. Developed based on Ajzen's Theory of Planned Behavior [59], Joint Effort focuses on 4 core determinants, namely, intention, attitude, social norms, and self-efficacy. To address these, various evidence-based, theory-driven intervention strategies and methods are used, including personalized feedback, persuasive communication, positive reinforcement, self-observation, and activation of intention. A detailed account of how the principles of the Theory of Planned Behavior were integrated in the app is presented elsewhere [58]. The intervention content is organized into five sections: (1) "Assess" to allow users to gain a higher awareness of their CU, (2) "Mobilize" to support their decision-making process, (3)

XSL•FO
RenderX

"Act" to guide them in establishing an action plan, (4) "Strengthen" to consolidate their change in behavior, and (5) "Observe" to monitor their CU. It addresses various topics such as CU prevalence, potential consequences, PBS, benefits of change, and possible difficult situations. The information is provided through general information messages, questionnaires (checkbox answers, reflection questions), and personalized feedback. The app also includes an optional consumption diary where users can enter information regarding their CU and customize certain features of their logbook for personalized monitoring (eg, frequency of daily entries, format, and concentration of cannabis used, personal notes). The intervention was designed as a self-managed exercise in prevention, given that it proposes simple strategies easy to apply and adopt without the help of outside resources. Joint Effort was available only in French and as an iOS mobile app (ie, for iPhones running on iOS version 13 or 14) at the time of the study. A detailed description of the mobile app intervention and its content, in accordance with the Template for Intervention Description and Replication (TIDieR) [73] Checklist, is available in Checklist 2 and in a publication elsewhere [58]. Figure 1 presents screenshots from the Joint Effort mobile app showing its general look and feel, as well as how features are organized within the app.

Figure 1. Screenshots from the Joint Effort mobile app.

Study Groups

Participants randomly assigned to the EG were invited to download and use the Joint Effort mobile app on their iPhones. Following randomization, members of the research team created a user account for each of them based on their chosen username/email collected during study registration. Participants received an automatically personalized email containing an App Store link to download the mobile app. Access to Joint Effort was unlimited in terms of frequency and duration of use over 8 weeks once their profile had been created by the research team. To optimize engagement with the intervention, optional pop-up notifications were embedded within the mobile app. Two types of notifications were sent: (1) to encourage users to continue with their action plan (scheduled 3, 5, and 7 days after completion of the "Act" section) and (2) to remind users about the app (triggered 9 days after their last login).

Participants randomly assigned to the CG received one brief normative web-based feedback message regarding their CU based on their past-month frequency of use reported during the baseline assessment. They were also sent links to access standardized information about lower-risk CU guidelines on reliable French public websites tailored for the Quebec context (eg, public health agencies, Quebec ministries of health). A single reminder inviting them to visit (or revisit) the recommended websites was sent via email 7 days after baseline.

Randomization and Blinding

As recommended in the CONSORT guidelines [71,74], participants were randomized only after having provided consent and completed a web-based survey at baseline. Participants had an equal chance of being allocated to the EG or the CG (1:1 ratio). The allocation sequence was generated through a permuted block randomization list to ensure that the 2 groups were as even as possible during data collection. The allocation process (concealment and implementation) was entirely computerized. The sequence was programmed within the study website, and participants were automatically informed of the intervention they were assigned to by email. The study was partially single-blinded in that participants in the 2 study groups knew the intervention they were working with, but were unaware whether it was the experimental condition or not. The research

XSL•FO
RenderX

coordinators were not blinded to assignments since they had to create unique profiles for each participant and to monitor follow-up.

Measures

Acceptability was defined as the "suitability of the intervention from the perspective of the population of interest" [75], that is, young adult cannabis users. Acceptability of the Joint Effort mobile app was assessed via 3 distinct yet interrelated constructs, namely, uptake, engagement, and appreciation, only among participants from the EG.

Uptake was defined as the act of downloading the Joint Effort mobile app via the Apple iOS App Store [76]. Uptake rate was measured as a percentage calculated by comparing the number of EG participants who downloaded Joint Effort against the total number of participants randomized to the EG.

Engagement was defined as a quality of the user experience [77] characterized by a substantial exposure to the intervention content among uptakers [78]. Engagement was assessed among participants randomized to the EG using a hybrid approach [79] that included both objective and subjective measures: (1) quantity of exposure, that is, frequency and duration of use of Joint Effort, was collected automatically when users logged in to the mobile app (data extracted by the research team at the end of the 2-month intervention period); and (2) self-report measure of user engagement using the User Engagement Scale-Short Form (UES-SF) [80] after one month of using the app to minimize memory bias. Used in various digital domains, the UES-SF is a self-completed questionnaire that has demonstrated adequate construct validity and good internal consistency [80-82]. It consists of 12 items meant to measure 4 dimensions of engagement across 4 subscales labeled Aesthetic appeal, Focused attention, Perceived usability, and Reward factor (possible total score range: 12 - 60). In this study, a French adaptation of the original English version of the UES-SF was used [83]. This French translation has shown satisfying preliminary psychometric properties in a sample of 57 Canadian-based university students (McDonalds' omega [ω] coefficients of the French UES-SF subscales range from 0.8 to 0.9) [83].

Participant appreciation of Joint Effort was assessed with the end user version of the Mobile App Rating Scale (uMARS) [84]. Considering the detailed nature of the uMARS items, this questionnaire was completed 2 weeks after randomization to minimize memory bias. The uMARS is a reliable method to assess the quality of mobile-app tools that has demonstrated excellent internal consistency with a Cronbach α of 0.90 for the full scale, high internal consistency for the subscales, and good levels of interclass correlation coefficients at follow-up [84]. The uMARS comprises 20 items across 4 objective quality subscales—Engagement, Functionality, Aesthetic, and Information—and a subjective quality subscale, all rated on a 5-point Likert scale (possible total score range: 20 - 100). Stoyanov et al [84] suggested determining the app quality mean score by computing the mean score for each objective quality subscale and averaging the four. The uMARS was translated into French by our research team following a rigorous translation process, similar to the one described in Côté et al [68,69].

Feasibility was defined as success in executing the study design and research procedures as planned [75]. In this study, it was assessed based on 3 parameters: recruitment feasibility, study attrition, and research procedures.

Recruitment feasibility was assessed by measuring recruitment time and recruitment rate. The recruitment time was calculated as the number of days from the time the study was advertised to the time our target sample size of 110 randomized participants was reached. The recruitment rate was measured as a percentage calculated by comparing the number of participants randomized to the study groups against the total number of individuals deemed eligible to participate [85].

The study attrition rate was measured as a percentage calculated by comparing the number of participants enrolled in the study who completed only the baseline assessment (ie, noncompleters) against the number of those enrolled in the study who completed the baseline assessment and at least one follow-up survey (ie, completers).

We also sought to determine the feasibility of the research procedures of a study conducted entirely via the web. To this end, we documented any issue that arose during recruitment or data collection (eg, data security and privacy, filtering fraudulent applications and information), as well as app-level problems (eg, technical issues with the operating system, challenges with software updates, and screen functionality).

The outcome responsiveness was assessed based on the following patient-reported outcomes: CU, intention to take action on CU, PBS use, severity of cannabis dependence, and psychological distress.

CU was measured by frequency of use via the following question adapted from the French version of the Canadian Community Health Survey [86]: "How often did you use cannabis in the past month?." The extent to which participants experienced days of CU in the past month was assessed on the following 6-category rating scale: never; one day in the past month; 2-3 days in the past month; 1-2 days per week in the past month; 3-4 days per week in the past month; 5-6 days per week in the past month; and every day.

Intention to take action on CU referred to "readiness to engage in a behavior" [87] and was assessed via a 3-item French-language questionnaire developed for the purpose of this study, based on Ajzen's guidelines for measuring Theory of Planned Behavior variables [88]. The questionnaire consisted of the following three items: (1) "I intend to take action on my CU in the coming month"; (2) "In the coming month, the chances that I will take action on my CU are…"; and (3) "In the coming month, I will take action on my cannabis use." These were rated on a 7-point Likert scale ranging, respectively, from "strongly disagree" to "strongly agree," "very low" to "very high," and "very unlikely" to "very likely." The final measure of intention to change was arrived at by summing the numbers from 1 to 7 corresponding to answers on the 3 items (possible score range: 3 to 21). The lower the total score, the weaker the intention to take action on CU in the coming month. In a previous study among young cannabis users, this scale showed good internal consistency with a Cronbach α of 0.87 [89].

XSL•FO
RenderX

PBS use was assessed via the short form of the 17-item Protective Behavioral Strategies for Marijuana (PBSM-17) Scale [60], a reliable instrument to identify and measure lower-risk CU strategies used by individuals before, during, and after CU. Methodological work was previously undertaken by our research team to culturally adapt and translate the PBSM-17 into French and evaluate its psychometric properties, as well as those of the original English version, in a sample of 211 bilingual, Canadian-based young adult university students who reported past-month CU [68,69]. Both the French and English versions demonstrated satisfactory psychometric properties, with good internal consistency (Cronbach α=0.88 and 0.91, for the French and English versions, respectively). Each item of the PBSM-17 concerns a particular PBS. Respondents are invited to rate the frequency of use for each strategy on a 6-point Likert scale ranging from never (value of 1) to always (value of 6). The PBSM-17 is scored by summing the values of the responses (possible score range: 17 to 102). The lower the total score, the lesser the use of PBSs.

Severity of cannabis dependence was assessed via the Severity of Dependence Scale (SDS) [90], a self-report instrument designed to measure the degree of dependence experienced by users of different types of drugs, including cannabis. A French language version of the SDS was used in this study [91]. The instrument consists of 5 items covering different psychological aspects of dependence: feeling of impaired control, anxiety, preoccupations, wish to stop, and compulsive use. The response choices for items 1 to 4 are scored as follows: 0=never/almost never, 1=sometimes, 2=often, and 3=always/nearly always. Those for item 5 are scored as follows: 0=not difficult, 1=quite difficult, 2=very difficult, and 3=impossible. The possible score ranges from 0 to 15. The cannabis version of the SDS has demonstrated satisfactory psychometric properties in samples of adults and adolescents from the general population as well as in clinical samples (eg, patients with a schizophrenia spectrum disorder) [92-96] and, more recently, it proved to have good internal consistency (Cronbach α=0.70) in a sample of 577 young adult (18 - 30 y old) frequent and heavy cannabis users [97]. Previous studies have set empirically derived optimal cut-off scores for cannabis dependence at 2 to 4 or greater [92,96,98]. In this study, the cut-off score was set at 4 or greater.

Psychological distress was assessed via the Kessler Psychological Distress Scale–6 items (K6) [99], a psychometrically robust measure of psychological distress in adult populations used in epidemiological surveys globally, including the World Health Organization World Mental Health Survey [100]. The internal consistency of the K6 has been found to be adequate in general population samples (Cronbach α=0.8 to 0.9) [101-104], and one study [105] found the K6 to be valid and reliable in an epidemiological sample of Canadian youth (2010 respondents 15 to 19 years old), demonstrating a high internal consistency (Cronbach α=0.9). The K6 is a nonspecific measure of psychological distress consisting of 6 questions regarding whether the respondent had felt nervous, hopeless, restless, or fidgety in the past month, had felt so depressed that nothing could cheer them up, had felt that everything was an effort, and had felt worthless. Each item is rated on a 5-point Likert scale ranging from “none of the time” (value of 0) to “all of the time” (value of 4) (possible score range: 0 - 24). A total score of 0 to 12 indicates that severe mental illness is unlikely; a total score of 13 or greater indicates that severe mental illness is likely [106]. The French translation of the scale was used [107].

Study Procedures

The study was conducted entirely via web over a 6-month period (November 19, 2021, to May 20, 2022). It was hosted on a secure website developed for the purposes of this study. Recruitment was carried out via social media ads (ie, public and private Université de Montréal student Facebook groups) and posters on university campuses. Interested participants were directed to the study website to find out what the study was about. Once there, they were then asked to complete a web-based screening assessment (ie, 4 questions to confirm eligibility) and a consent form. Eligible participants were invited to register by choosing a username and providing contact information (ie, email address). To complete the registration process, participants had to click on a verification link sent by email, which allowed them to activate their profile and, subsequently, receive a unique link generated automatically to be directed to the web-based baseline survey to be completed.

The web-based baseline survey included a brief sociodemographic questionnaire specifically developed for the purposes of this study. It covered various individual-level parameters, including gender, age, ethnicity, educational level, and use of cannabis, alcohol, or other drugs (eg, cocaine, amphetamines, hallucinogens). The survey also included a question about CU frequency in the past month and instruments to assess outcome responsiveness (ie, intention to take action on CU, PBSM-17, SDS, and K6).

The same web-based survey without the sociodemographic questionnaire was administered to all participants at 2 other time points: 1 month (T1) and 2 months (T2) postbaseline. EG participants, who were invited to download the Joint Effort app and use it for 2 months, were also asked to complete questionnaires regarding acceptability variables, including the uMARS at 2 weeks postbaseline and the UES-SF scales at T1. A question asking participants to confirm their date of birth was included in the survey at each time point for verification purposes. Analytics data on participant use of Joint Effort, including quantity of exposure and usage patterns, were collected automatically by a web-based platform developed specifically for this study, hosted on a secure server. A research assistant could be contacted during the study period by email to answer questions and help participants with issues regarding the app and web-based surveys.

All data collected during the study period were stored digitally at the study website until downloaded onto a secure virtual server at the research center for analysis. Given that fraudulent (or inconsistent) data are a well-known problem in web-based survey studies [108,109], an in-depth examination of the data collected was carried out to assess their reliability and accuracy, and to double-check the identity of the participants before performing any statistical analysis. This involved verifying that the dates of birth provided by participants were consistent across time points and confirming that the email addresses provided

XSL•FO
RenderX

by participants were valid. Participants with inconsistent data or contact information were considered "fraudulent participants" [110] and, therefore, not included in the final dataset analyzed.

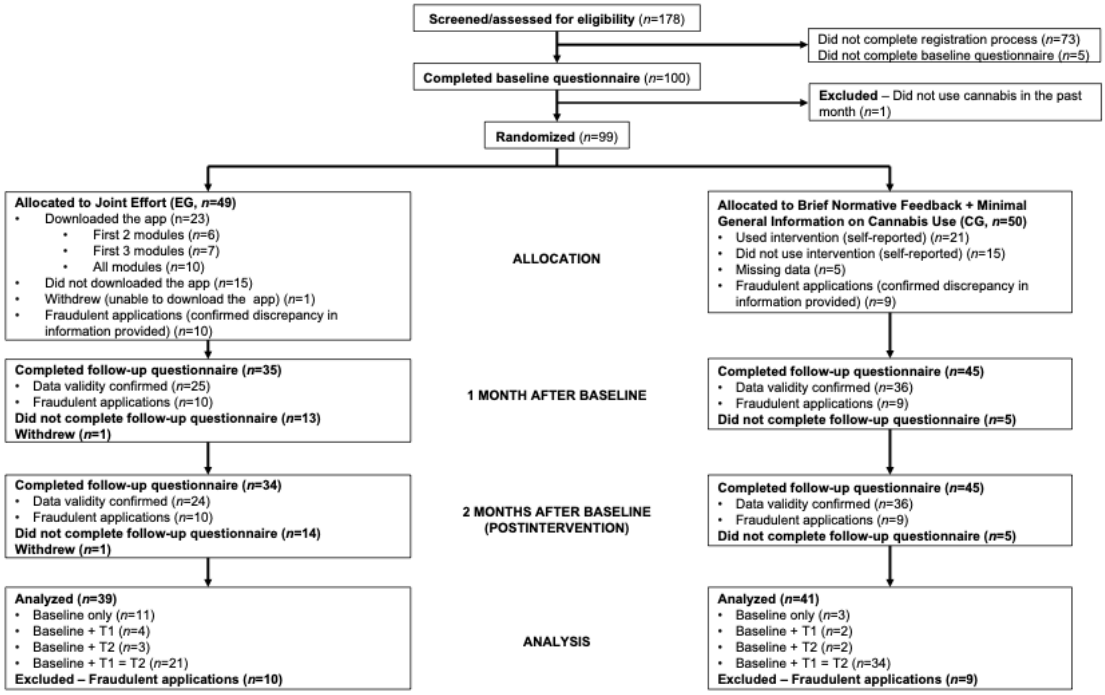
Data Analysis

All statistical analyses were conducted in R (version 4.2.3; R Foundation for Statistical Computing). Analyses were carried out by an independent, experienced biostatistician not blinded to participant group assignment. As per protocol, the biostatistician cleaned the dataset to enhance data consistency and quality. No interim analysis was performed, and, as recommended for pilot study designs [111], no hypothesis testing (ie, inferential analysis) was carried out. Descriptive analyses of sample characteristics included computing means and SDs for continuous variables and the frequency of distribution for categorical variables. Descriptive analyses were carried out on the acceptability and feasibility variables as well. Finally, descriptive statistics were calculated to explore outcome responsiveness, and the same analytical approach was used for all outcomes.

Descriptive analyses, including means and SDs for continuous variables and frequency of distribution for categorical variables, were conducted for sample characteristics, acceptability/feasibility variables, and outcome responsiveness.

Ethical Considerations

Ethical approval was obtained from the Research Ethics Committee of the Centre Hospitalier de l'Université de Montréal (CHUM; #21.196) and from the Comité d'éthique de la recherche en sciences et en santé of the Université de Montréal (CERSES; #2021 - 1223). Informed consent was obtained from all participants prior to study activities. Participants received financial compensation for their time and effort in the form of C $15 and C $25 (US $11 and US $18) Amazon.ca gift certificates at T1 and T2, respectively. All collected data have been deidentified, and results are reported at the sample level.



Results

Feasibility of Study Procedures

Recruitment Feasibility

As a result of our recruitment strategies, 178 people were deemed eligible after completing the screening survey (Figure 2 shows the study flow diagram). Of these, 73 were excluded for not completing the registration process, and 5 others for not completing the baseline survey. A total of 100 participants completed the baseline survey, and one participant was excluded afterward (ie, this participant was eligible according to the screening survey, but reported no CU in the baseline survey). The remaining 99 were randomized to the EG and CG, yielding a 56% (99/178) recruitment rate. Of these, 19 were considered fraudulent participants and eliminated for providing discrepant dates of birth or contact information on the registration form and the baseline or follow-up survey (10/49 participants in the EG and 9/50 participants in the CG). Consequently, there were 80 participants (39 EG and 41 CG) in the final dataset analyzed.

Figure 2. Study flow diagram with a pilot randomized controlled trial design based on Eldridge et al [70]. CG: control group; EG: experimental group.

As for recruitment time, it took 124 days total from the day the study began to be advertised on social media and on campus to the day our target sample size of 110 randomized participants was reached (from November 19, 2021, to March 22, 2022).

Study Attrition

Of the 80 participants, 61 (76%) completed the assessment at one month postbaseline (T1) and 60 (75%) completed the assessment at 2 months postbaseline (T2). In all, 66 participants were considered completers for having completed the

XSL•FO
RenderX

assessments at T0 and T1, T0 and T2, or all 3 assessments (ie, T0, T1, and T2). In the CG, 38 of 41 participants (93%) were considered completers, compared with 28 of 39 (72%) in the EG. The overall attrition rate was 18%, as 14 of the 80 participants (CG: 3/41; EG: 11/39) were considered noncompleters.

Sample Characteristics

The characteristics of participants at baseline are presented in Table 1. Age ranged from 19 to 29 years (mean 23.4, SD 2.6). Two-thirds identified as women (53/80, 66%), nearly 3-quarters were born in Canada (58/80, 73%), and 3-quarters were undergraduate students (60/80, 75%). Just under half were classified as occasional cannabis users (34/80, 43% CU 1-3 d/mo) and one out of ten as daily cannabis users (8/80, 10%). More than half of the participants reported using alcohol regularly (44/80, 55% alcohol use 1-4 d/wk), and the vast majority did not use other drugs (67/80, 84%).

[a]EG: experimental group.

[b]CG: control group.

[c]More than one recruitment strategy possible.

[d]Other included: receiving a personalized email message or a friend referral.

[e]Frequency of use was determined by the number of days on which cannabis, alcohol, or other drugs were used in the past month.

[f]Occasional: 1 - 3 days per month.

[g]Regular: 1 - 6 days per week.

[h]Included but was not limited to cocaine, amphetamines, and hallucinogens.

Joint Effort Acceptability

Uptake

Of the 39 participants randomized to the EG, 23 downloaded the Joint Effort mobile app to their iPhone for an uptake rate of 59%.

Engagement

Of the confirmed uptakers, 43% (10/23) viewed all the sections of the mobile app, while 26% (6/23) viewed only the first two (ie, “Assess” and “Mobilize”), and 30% (7/23) viewed only the first three (ie, “Assess,” “Mobilize,” and “Act”). In terms of quantity of exposure, the mean number of screens viewed per participant was 32.4 (Min-Max=15-89; SD 18.0). Regarding duration of exposure, participants spent an average of 8.2 minutes (Min-Max=53 s-33.5 min; SD 7.3 min) and a median of 7.5 minutes (IQR 5.7) using the app. The total period of use ranged from 1 to 59 days (mean 19.5; SD 21.9) with a 5-day median (IQR 36).

Regarding subjective engagement, the mean total score on the UES-SF was 3.8 (SD 0.46) at T1. Descriptive statistics for the UES-SF subscales and items are given in Table 2. Among the 4 UES-SF subscales, Aesthetic Appeal obtained the highest score (mean 4.3; SD 0.7), followed by Perceived usability (mean 4.2; SD 0.9), while Focused attention obtained the lowest score (mean 2.8; SD 0.9).

Table . Participant subjective engagement scores on the User Engagement Scale-Short Form (UES-SF), one-month postbaseline (T1) (n=18).

Subscale and item	Mean (SD)[a]
Focused attention	2.8 (0.9)
I lost myself in this experience.	2.2 (1.1)
The time I spent using Joint Effort just slipped away.	3.2 (0.9)
I was absorbed in this experience.	2.9 (0.9)
Perceived usability	4.2 (0.9)[b]
I felt frustrated while using this Joint Effort mobile app.	4.0 (1.1)[b]
I found this Joint Effort mobile app confusing to use.	4.1 (0.9)[b]
Using this Joint Effort mobile app was taxing.	4.4 (0.8)[b]
Aesthetic Appeal	4.3 (0.7)
This Joint Effort mobile app was attractive.	4.1 (0.9)
This Joint Effort mobile app was esthetically appealing.	4.4 (0.6)
This Joint Effort mobile app appealed to my senses.	4.3 (0.8)
Reward factor	4.0 (0.7)
Using Joint Effort mobile app was worthwhile.	4.1 (0.8)
My experience was rewarding.	3.6 (0.8)
I felt interested in this experience.	4.3 (0.6)
Overall score	3.8 (0.5)

[a]Possible score range of 1 to 5 (1=strongly disagree; 5=strongly agree); the higher the score, the higher the subjective engagement.

[b]Reverse scored. (1=strongly agree; 5=strongly disagree); the higher the score, the higher the level of perceived usability.

Appreciation of Joint Effort

Sixteen participants in the EG provided data regarding their appreciation of Joint Effort 2 weeks after randomization. The app obtained a mean app quality total score of 4.2 out of 5 (SD 0.5). Among the 5 uMARS subscales, Aesthetics (mean 4.4, SD 0.6), Information (mean 4.3, SD 0.5), and Functionality (mean 4.3, SD 0.5) scored high, while Engagement (mean 3.8, SD 0.6) and App subjective quality (mean 3.3, SD 0.6) scored lower (Multimedia Appendix 1). The Quantity of information item (”Is the information within the app comprehensive but concise?”) included in the Information subscale was the item that scored highest (mean 4.6, SD 0.6) on the 5-point Likert scale, while the Willingness to pay item (“Would you pay for this app?”) part of the App subjective quality scale scored lowest (mean 1.9, SD 0.8).

Outcome Responsiveness

Results for CU frequency, intention to take action on CU, PBS use, severity of cannabis dependence, and psychological distress among participants in the EG and the CG at the 3 measurement time points are presented in Table 3.

Table . Participant outcomes at baseline (T0) and follow-up assessments (T1, T2), by study group (n=80).

Variable	Baseline (T0)		1 month (T1)		2 months (T2)	
	CG[a] (n=41)	EG[b] (n=39)	CG (n=36)	EG (n=25)	CG (n=36)	EG (n=24)
Cannabis use (past month), n (%)						
Never	0 (0)	0 (0)	4 (11)	3 (12)	6 (17)	4 (17)
Occasional (1 - 3 days/month)	17 (41)	17 (44)	11 (31)	7 (28)	16 (44)	8 (33)
Regular (1 - 6 days/week)	21 (51)	17 (44)	19 (53)	13 (52)	12 (33)	11 (46)
Everyday	3 (7)	5 (13)	2 (6)	2 (8)	2 (6)	1 (4)
Intention to take action[c], mean (SD)	12.5 (4.3)	12.4 (5.2)	13.6 (5.4)	14.3 (4.6)	13.4 (6.0)	14.3 (5.3)
PBS-17[d], mean (SD)	72.9 (12.5)	73.7 (15.1)	76.4 (12)	78.8 (15.8)	80.2 (12.3)	80.0 (13.0)
SDS[e,f], n (%)

Dependence[h]	14 (35)	18 (46)	N/A[g]	N/A[g]	10 (29)	7 (32)
Psychological distress[i,j], n (%)						
Low/moderate[k]	28 (68)	28 (76)	N/A[g]	N/A[g]	24 (69)	20 (83)
Severe[l]	13 (32)	9 (24)	N/A[g]	N/A[g]	11 (31)	4 (17)

[a]CG: control group.

[b]EG: experimental group.

[c]Intention to take action on cannabis use; possible score range 3 - 21.

[d]PBSM-17: 17-item Protective Behavioral Strategies for Marijuana Scale; possible score range 17 - 102 (summed score).

[e]SDS: Severity of Dependence Scale (for cannabis); possible score range 0 - 15.

[f]1 missing data at T0, 4 missing data at T2.

[g]Outcome not assessed at T1.

[h]Cannabis dependence=score≥4.

[i]Kessler Screening Scale for Psychological Distress (K6); possible scores range 0 - 24.

[j]2 missing data at T0, 1 missing data at T2.

[k]Low/moderate psychological distress=scores between 0 and 13.

[l]Severe psychological distress=scores between 14 and 24.

Most participants in both the EG and the CG self-assessed their past-month CU frequency as between occasional and regular at baseline, and these proportions remained mostly similar at T1 and T2. The proportion of participants who reported daily CU in the past month decreased from 13% (5/39) at baseline to 4% (1/24) at T2 in the EG and from 7% (3/41) to 6% (2/36) in the CG.

Participants in both the EG and the CG expressed a moderate level of intention to take action on their CU at baseline, and this score tended to increase at T1 and T2 for participants in the EG. Similarly, participants in the EG and CG showed a moderate level of PBS use at baseline, and this result was found to increase in both groups at follow-up time points. Regarding psychological distress, the proportion of participants in the EG

XSL•FO
RenderX

who scored a severe level of psychological distress decreased from 24% (9/39) at baseline to 17% at T2 (4/24), while in the CG, the proportion remained quite similar from baseline (13/41, 32%) to T2 (11/36, 31%). Finally, 46% (18/39) and 35% (14/41) of the participants in the EG and the CG, respectively, scored from 4 to 15 on the SDS at baseline, which indicated cannabis dependence. At T2, the proportions decreased to 32% (7/24) and 29% (10/36), respectively.

Discussion

Principal Findings

This pilot RCT sought to evaluate the acceptability of the Joint Effort mobile app in a sample of Canadian-based university students who used cannabis in the past month, examine the feasibility of the research procedures, and provide data regarding outcome responsiveness.

Acceptability of the Joint Effort Mobile App

Engaging adequately with a mobile app presupposes first downloading it and then using it to an extent corresponding to the optimal exposure threshold. This usage will be largely—but not solely—influenced by the user's appreciation of the app. Therefore, we set out to assess user acceptability of the Joint Effort app via 3 distinct but interrelated parameters, namely, uptake, engagement, and appreciation.

Almost 60% of the participants in the EG downloaded the app (23/39). Thus, many participants who decided to participate in this study failed to use the proposed mobile app. One explanation could be related to potential technical issues with accessing the app and user account setup. Some users contacted the research team for assistance reinitializing their password to access the app. We can hypothesize that others faced the same problem but did not bother to contact us. Various factors can influence uptake, such as basic technological skills, app awareness, app availability and accessibility, social influences, curiosity, and user guidance [76]. In the context of this study, lack of user guidance might have had a negative/deteriorative impact on uptake. Further exploration of barriers and facilitators to uptake and strategies to optimize app download is needed.

Results suggest that Joint Effort was well received, deemed easy to use, and favorably rated by young adult cannabis users who used the proposed mobile app. For instance, the app obtained a good overall score on the uMARS (4.20/5, SD 0.5). Aesthetics was the dimension that obtained the highest score, followed by information, functionality, engagement, and subjective quality. These results are consistent with those obtained by Santesteban-Echarri et al [49], who reported a good uMARS overall score (mean 3.8, SD 0.5) in their pilot test of a mobile-based app to monitor CU among youth at high clinical risk for psychosis.

Engaging with a mobile app requires an autonomous process that depends on one's commitment to the behavior to be changed and one's self-management capabilities. In a systematic review of influences on uptake of and engagement with health and well-being smartphone apps across various fields (41 studies), Szinay et al [76] found that rapid disengagement was common and that uptake and engagement appeared to be influenced by a wide range of individual-level factors related to capability, opportunity, and motivation. In this study, in terms of quantity of exposure, 43% (10/23) of the downloaders viewed all sections, while 57% (13/23) completed the first 2 or 3 only. Regarding duration of exposure, our results showed a wide variation across participants in terms of frequency and time of use. This last finding might reflect the different purposes for which Joint Effort was being used.

Relatedly, in a systematic review of the concept of adherence to electronic health technology (34 studies), Sieverink et al [112] found that most of the time participants did not use technologies as suggested, whether in terms of features used, frequency of use, time of use, or place of use. These findings raise an important question, namely, whether all users need to experience all elements of a technology to achieve effects, especially considering that the intended engagement with an app may vary based on the utility objectives of the app and desired outcomes, as well as the user's personal goals and substance use behaviors. Successful engagement may not be a function solely of the amount of exposure (ie, the more use, the better). This emphasizes the importance of measuring engagement in different but complementary ways.

In this study, in addition to objective engagement (ie, frequency and duration of app usage data metrics collected automatically), we also measured subjective engagement using a self-reported questionnaire. The results showed that Aesthetic Appeal was the UES-SF subscale that obtained the highest score, followed by the Reward factor. Currently, there is no standardized approach in the existing body of literature to assessing engagement in mHealth interventions, as engagement depends on the targeted behaviors and how they are conceptualized, operationalized, and measured [113-115]. For instance, a scoping review of mHealth intervention apps [113] found that 20% of the studies included did not measure user engagement and, of those that did quantifiably (37/54), only 8% (3/37) used an established scale to evaluate engagement outcomes. Consequently, it is difficult to compare our results regarding user engagement with the Joint Effort app against those of other mobile app interventions for CU. Enhancing participant engagement with mHealth apps is undoubtedly a priority for wellness and health care. It remains a significant challenge for many app developers, researchers, and clinical teams [78,113].

Feasibility of Study Procedures

Recruitment primarily via social media ads resulted in the recruitment of our target sample over the span of 18 weeks. This underscores the feasibility of such methods but also highlights that recruitment costs and duration are key factors that must be considered from the outset to ensure successful recruitment. Although representativeness in a small pilot study cannot be determined, larger studies support the utility of web-based recruitment approaches [116,117]. In this pilot study, the recruitment rate was comparable to results from prior formative research on digital interventions targeting young adult cannabis users [33,118,119].

The overall study attrition rate was 18% (14/80), though there were more noncompleters in the EG than in the CG at the 2-month postbaseline assessment. In a similar pilot study

XSL•FO
RenderX

intended to examine the feasibility and acceptability of a smartphone app intervention for adult cannabis users seeking to reduce or cease use [119], attrition rates of 16% and 32% were reported at postintervention (after 4 weeks of using the app) and at one-month follow-up, respectively. Similarly, in a scoping review (54 studies) of the components of mHealth intervention apps that encourage or hinder engagement, participant retention ranged from 14% to 100%, the average was 68% (SD 25%), and the median 79% [113]. Notably, only one-third of the studies included in this review (18/54) reported retention rates of 80% or higher. Against these numbers, the attrition rate (14/80, 18%) or retention rate (66/80, 83%) observed in this study can be considered acceptable.

Participant recruitment and retention are recognized as two of the most important challenges when conducting clinical trials [120]. These challenges are all the greater when research is conducted online. For example, a systematic review and meta-analysis (17 studies) by Meyerowitz-Katz et al [121] found that the "pooled estimate for dropout rates in trials of app-based interventions for chronic diseases was 43% over a variety of timelines". In another review (62 studies), Amagai et al [122] reported that mHealth apps were hampered by substantial participant dropout or attrition and suggested that factors related to particular app elements (eg, feedback, reminders, in-app support from coaches and peers) and research strategies (eg, compensation and niche samples) should be considered to promote retention. Of note, participant engagement in mHealth apps and study retention (or attrition) are distinct constructs that should not be used interchangeably. Engagement in a given intervention can affect a study's retention/attrition rate. Given the interconnected nature of these constructs, an integrated approach to analyzing recruitment, retention/attrition, and engagement outcomes should be used in evaluations of mHealth apps to broaden the evidence base but, more importantly, to determine how different strategies impact these three (ie, participant recruitment, retention, and engagement).

A second feasibility objective of this pilot trial was to document the research process throughout the study period in order to pinpoint and learn from the challenges and other aspects of the procedures applied before moving on to conduct a large-scale web-based RCT of the Joint Effort app. A major challenge faced during this study was the detection and management of fraudulent applications and the identification of information provided by potentially eligible or eligible participants. After reviewing completed surveys for indicators of fraudulent or suspicious data, 19% (19/99) of enrolled participants were found to have provided inconsistent information and, subsequently, were excluded from analysis. Similarly, other web-based trials or survey studies that monitored misrepresentation and fraud have consistently reported fraud rates of 20% to 35% [123-126]. Unfortunately, fraudulent behavior is a fairly widespread phenomenon in online research [127-129], which can have a significant impact on data integrity and quality, sample size and composition, and statistical precision [108,130,131].

Some researchers have outlined processes or methods, indicators, and logistic frameworks to address potential fraud [129,132,133]. In this pilot study, several strategies were rigorously incorporated to prevent, detect, and respond to fraudulent behavior by applicants/participants. These included automated procedures to prevent the same individual from registering more than once with the same email or username, as well as human monitoring (eg, checking for multiple registrations occurring almost simultaneously, identifying suspicious/fake email addresses, and unrealistic survey completion times). We also included combinations of survey questions repeated at each measurement time point (baseline, T1, and T2) designed to identify inconsistent responses in a participant's identity information (eg, date of birth). This method has been identified as an effective strategy for accurately detecting inconsistencies and preventing data quality threats, including fraudulent entries from automated bots and duplicate submissions [108,134,135]. Finally, financial compensation was given only upon completion of the follow-up assessments, as it has been shown that financial incentives can motivate applicants to register more than once [133] and relatively immediate payments have been found to yield greater rates of fraudulent behavior by participants [127].

Although all the strategies implemented in this pilot study certainly contributed to preventing, detecting, and handling fraud, the fact remains that it may be impossible to completely eliminate it. In an online cross-sectional study (414 survey entries), Ballard and colleagues [123] found that, consistent with our observations, even when protocols were put in place to improve fraud detection, 28.7% of submitted web-based surveys were "fraudulent" and an additional 10.1% were cases of "potential fraud." These authors also suggested that researchers should have a fraud detection algorithm in place prior to data collection and use a combination of indicators and methods to systematically review all online applications and verify participant identity and eligibility [123]. Based on the results of this study and our experience designing and implementing pilot RCTs using social media recruitment and web-based data collection, we encourage researchers conducting studies of mHealth apps to be vigilant about the potential for fraud, to keep detailed records of the verification process, and to report their study findings accordingly. Ultimately, there is a need for further reflection regarding the advantages and disadvantages associated with fraud prevention and detection methods, given that ethical tensions can emerge between preserving the integrity of research versus protecting the privacy and confidentiality of study participants.

End User Profile and Outcome Responsiveness

In terms of participant characteristics, a higher proportion of women was reached compared with men. This adds to the growing body of literature indicating that CU treatment-related differences exist between men and women [10,136-138]. Although help-seeking behaviors to address CU problems are rare among both young adult men and young adult women [139,140], women are more likely to seek out anonymous substance use resources, such as web-based or mobile app interventions [33,141]. Women may also more readily recognize the need to change their CU in an attempt to better manage problems related to their CU. Lending support to this hypothesis, research has shown that women often endorse external reasons for change, such as experiencing cannabis-related negative consequences and social acceptability, whereas men seem to

XSL•FO
RenderX

be motivated more by internal reasons, such as self-control and self-efficacy [142-145]. This means that women may be more willing to make behavioral changes and access strategies and motivational support to prevent or reduce the consequences/risks associated with CU. Given that cannabis-related negative consequences are disproportionally more common among young adult males [10,146], it would be worthwhile for future studies to ask young men directly about what they consider motivational or attractive to initiate change. In sum, our findings highlight the challenges of reaching target populations and developing mobile app CU interventions that take into account gender differences across a range of other clinical correlates (eg, readiness to change, sources of motivation to behavior change) that can affect young adults in their decision to take steps towards better CU management.

Regarding change in outcomes over time, our results showed that participants in both the EG and the CG indicated a moderate level of intention to take action on CU at baseline, and that the scores in this regard tended to increase at the follow-up assessments for participants in the EG. Similarly, participants in the EG and the CG indicated a moderate level of PBS use at baseline, and this level was found to increase in both groups over time. Regarding CU frequency, most participants in both groups self-assessed it as occasional to regular at baseline, with similar proportions at T1 and T2. Moreover, from baseline to postintervention, the proportion of participants in the EG who reported daily CU in the past month decreased by 9%, and those who reached the cut-off for cannabis dependence decreased by 12%. Overall, our results indicate that participants responded positively to Joint Effort and demonstrated some potential for behavior change as a result.

Limitations

This study, focusing on user acceptability, study feasibility, and outcome responsiveness, presents some limitations.

One of the major limitations related to our Internet-based recruitment strategy—which is an inherent challenge in online intervention trials—is the discovery of fraudulent identities after participants were enrolled in the study. This is a critical issue as it directly altered the randomization process and, to some extent, may have impacted the integrity of the research. Although several precautions were taken throughout the study to prevent and detect fraudulent applications using both automated detection procedures and human monitoring, our fraud detection methods were not infallible. This limitation is partially due to the lack of in-person interactions between research team members and participants, which increases the risk that applicants are not who they claim to be. The participation incentives offered in the study are another factor that may have contributed to increased fraud. A multi-layered approach to fraud prevention and detection may be warranted in future studies of mHealth apps to help reduce the inclusion of fraudulent applications [127,129,134]. Despite the numerous risks associated with web-based recruitment, this method nevertheless has significant advantages over other traditional recruitment strategies. This pilot study thus affords valuable lessons for subsequent testing of Joint Effort and highlights the need for careful implementation of processes to help address potential fraud in future online trials and in web-based survey research in general.

We focused our means of recruitment mainly on social media and posters on campus in an attempt to reach a diverse population of university students. This strategy allowed us to recruit young adult cannabis users from a large university student population and achieve our sample size goal over a relatively short period of time. However, this recruitment method may have introduced a self-selection bias. We certainly recruited people interested in engaging with the mobile app and motivated to better manage their CU, which may not be representative of the target population. Also, the fact that the app was available on iOS only might have led to a different sociodemographic sample. The decision to develop the mobile application on iOS was based on financial limitations (ie, the cost associated with the development on both smartphone operating systems exceeded the budget). Also, based on a previous study conducted among a similar sample [68,69], more respondents used an iPhone to complete the survey compared with an Android (respectively 41% vs 19%) (data not published). This target population likely had a higher level of digital literacy than the broader population, a factor that potentially limits the transferability of our findings.

Another limitation is related to samples of young adult cannabis users that were relatively small at each time point, with the EG experiencing greater attrition than the CG. Consequently, and despite the generally positive findings supporting the potential of the Joint Effort app, further study is required with a larger sample to determine not only the efficacy of Joint Effort on CU, but also the mediators to use (eg, intention to use, PBS) and the consequences of CU (eg, cannabis dependence). These findings justify further testing of Joint Effort in a fully powered trial.

Conclusions

Most existing interventions for young adult cannabis users wishing to better manage their use are limited by low uptake due to accessibility and stigma concerns. Advancements in technology have brought new ways in which a wide range of digital interventions can be developed and delivered. Joint Effort offers the advantage of convenient delivery via a smartphone app, which considerably minimizes these accessibility and stigma concerns. This pilot study provides support for Joint Effort's acceptability within the target population as an mHealth intervention for lower-risk CU and suggests that the study design used is feasible. This warrants future testing in a fully powered trial (ClinicalTrials.gov NCT05620433).

Acknowledgments

We thank Emma Février for her support with data collection and Michael Yu for his contribution to data analysis. We also thank our corporate partners, iTECH GO, Akufen, and Osedea, and, last but not least, the students who participated in the research.

Abstract

Background: End user co-design in the personal digital health technology space is underdeveloped. Clinical uptake of personal digital health technologies has been poor, highlighting a need to cocreate solutions with end users.

Objective: The study aimed to describe an “end user” co-design framework in the development of 5 prototype personal health apps for patients with different rare or complex diseases.

Methods: A patient-led, user-centered, collaborative personal health app plus wearable plug-in co-design methodology was developed. Five prototype apps were developed for end users with long COVID-19, pancreatitis, primary ciliary dyskinesia, sarcoidosis, and valosin-containing protein disease by a multidisciplinary partnership including patients, app design and development experts, user experience experts, clinicians, and patient-driven organizations. Phase 1 involved a 6-month co-design process with 5 modules involving patient-driven organizations that included the codevelopment of specifications through group workshops and independent exercises that defined the goals, content, features, and user experience of each app. Phase 2 involved app build-out, internal alpha testing, and beta study preparations. Phase 3 involved a usability beta testing study in which end users used the app and associated wearable/smart devices (Oura ring, Lumia ear device, Empatica EmbracePlus, and MIR Spirobank Spirometer)

XSL•FO
RenderX

for up to 5 months. Participant feedback was documented continuously and systematically, centering on the following themes: functionality, usability, harms, benefits, self-explorations, and beta testing study details related to retention and adherence.

Results: While unique app goals were codeveloped by each disease group, a central goal across groups was to develop a personal health app enabling users to track subjective, self-reported symptoms, objective measures of health, and unique modifiers of symptoms. A total of 239 end user participants participated in the beta testing pilot study. Enrollment and retention rates were high, ranging from 94% to 100% and 92.2% to 100%, respectively. All active participants gave some form of feedback: there were 257 unique participant suggestions of how to specifically modify or improve the study app experience. Participant feedback themes commonly centered around customization to reduce daily burden and improve personal tailoring of the app. Participants' desires surrounding symptom displays were heterogeneous.

Conclusions: Personal health app co-design is rooted in a complex digital landscape that requires a significant amount of up-front effort and time. However, the up-front investment of time can result in rich and diverse end user feedback that could save time in the app development trajectory to implementation. This paper provides a co-design framework and the building blocks of 5 prototype personal health apps with publicly available open-source code on GitHub. These prototypes could be leveraged for improving understanding of, communicating symptoms of, and providing n-of-1 suggestions for rare or complex diseases, providing benefit to patient communities and individual patients.

Introduction

Rare and novel conditions can present unique challenges for researchers, clinicians, and patients due to their low prevalence, phenotypic heterogeneity, and lack of natural history data. For rare and novel conditions, there is limited understanding of factors that trigger or modify symptom and disease progression. There is a need for patients to be better equipped with tools to follow their symptoms, along with insights about what improves and worsens their symptoms; for clinicians to be equipped with more accurate knowledge to help guide their patients; and for patient communities to better understand natural histories of their disease to guide research and clinical activities.

Personal digital health technologies (P-DHTs [1]) such as smartphone apps and wearable devices harness the potential for real-world, high-resolution, and longitudinal health monitoring at the individual context [2]. Consumer-grade wearable and smart devices are capable of tracking semicontinuous biometric measures (eg, heart rate, heart rate variability, body temperature, blood pressure, oxygen saturation, and respiratory function), behavior (eg, activity, relative location, and sleep duration and quality), and social activity (eg, social media and phone use) [2]. Smartphone active data can capture high-frequency, in-the-moment subjective assessments of symptom experiences, and the individual-level context of a unique patient's environment. Smartphone passive information, such as phone calls, text, and app usage, daily activities, and movement data, could reflect proxies of an individual's daily habits, levels of fatigue, and cognitive disturbance in addition to facets of disease burden and quality of life [3]. Collectively, P-DHTs could detect objective measures of key symptoms that are unique and common across different rare or complex diseases. This rich information can be returned to the user in near real time, and if returned in the correct way, could empower patients to glean new insights into their condition and its modifiers—a "compass" view.

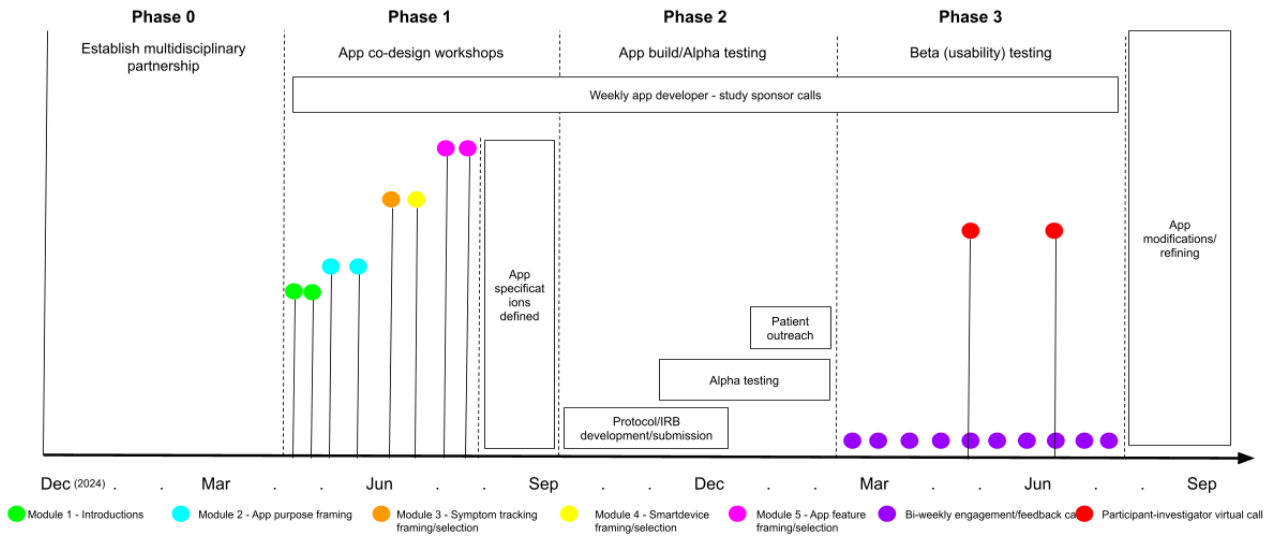
The challenge in the collection of such multimodal objective and subjective information is how to effectively return this back to the user, or draw associations that are insightful [4]. Several consumer brand wearable devices enable users to follow specific measures of health via an associated app [5]. However, there is a lack of user-driven personalization and limited options to combine information from multiple P-DHTs among existing apps, limiting a true multimodal approach to better understanding health. Furthermore, existing apps are largely proprietary-based, come with a paywall, hide algorithms behind provided data and insights, and are not open source. These realities hinder progress to modify and tailor to the individual or population and limit the patient community's ability to benefit from collective insights [2]. An additional challenge is to inspire a user to engage with the app in the long term, so that health-related insights can be made. Most consumer apps target the achievement of fitness goals that are not appropriate for those with chronic illnesses [6-9]. Further, existing health-related apps show strikingly poor engagement [10-13]. Evidence suggests that this low engagement is in part the result of a lack of personalization and, in turn, low perceived value of the tool [1].

Co-design has become a nebulous concept with numerous definitions and applications. While widely used, its applications are underdeveloped, particularly in the P-DHT space [14]. Co-design, sometimes referred to as participatory design, is often described as a method of including end users in a design process to ensure their needs and voices are present to improve the impact of the intended outcomes. However, the level of participation and timing in the design process varies across definitions and applications. Collaborative design considers all participants as experts in their respective domains. User-centered design is an approach that centers on the needs and preferences of the end user through an iterative process in real-world situations during the entire design timeline to better understand when and where a particular health care tool or intervention

XSL•FO
RenderX

will work or fail [15]. Patient-centered design aims to empower patients as agents of their own health and emphasizes patient acceptability and usability [16,17], while patient-led design assigns patients the role of partners, as opposed to end users, or collaborators in the design process—another approach aimed at increasing agency in health. The latter two approaches have unique relevance in the context of P-DHTs that could empower patients to take greater control over their health, potentially without the guiding role of the clinician, shifting the power balance between doctor and patients [4]. There are several other approaches used that describe variants of the approaches listed above (eg, human-centered [18,19], collaborative, and person-based [20]).

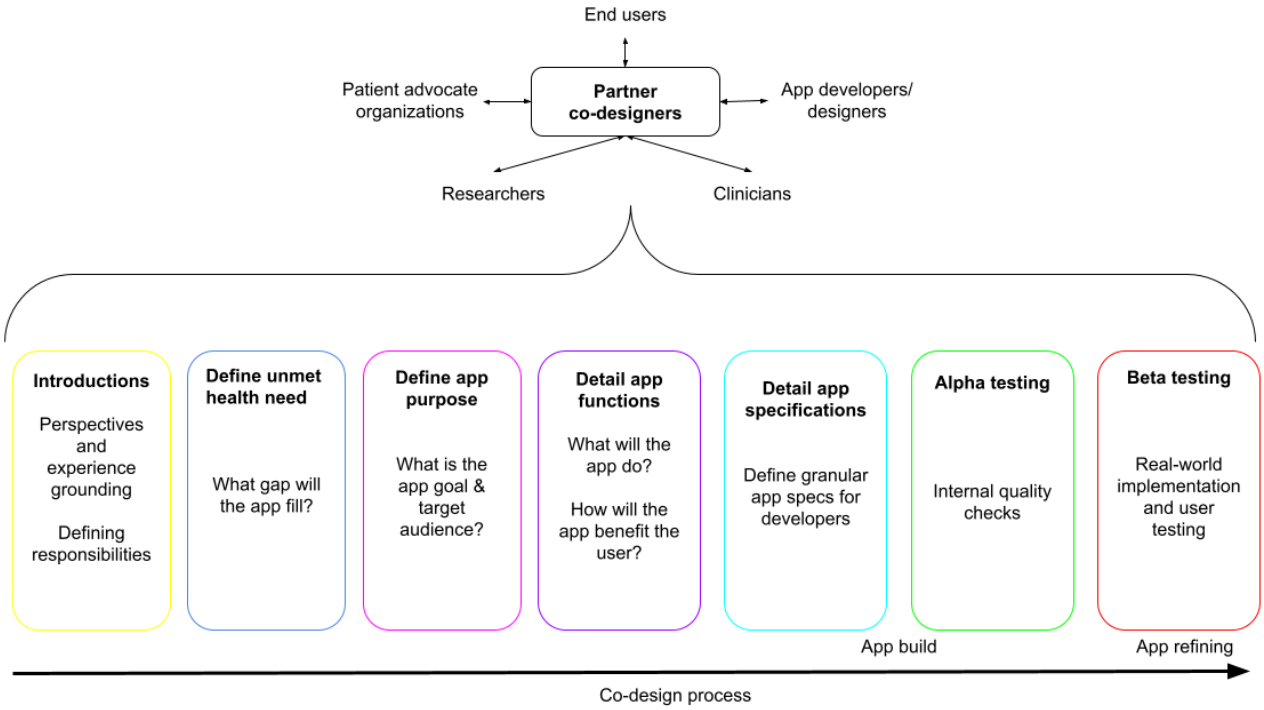
In the past 5 years, a number of digital health co-design frameworks have surfaced that show promise in the cocreation of P-DHTs for a number of applications, including co-designing a smartphone app to improve access to mental health care [21], interventions for obesity [22], and support for people with dementia [23]. While these modern applications include powerful inclusion of end users from the inception of digital design, challenges remain. The complexity in both the development and use of a P-DHT requires a certain level of digital literacy that can result in roadblocks in empowering end users to co-design [23]. Further, there is still an under-involvement of end users in the final usability stages. The needs and realities of how an end user will want to engage with a personal health app can only be realized through the long-term use of a tool through different health states. Usability testing in current co-design applications is limited, and the definition of what is usable is currently vague.



The objective of this paper is to describe an approach to a user-centered, collaborative co-design process in the development of 5 prototype apps for different end user populations, including individuals with long COVID-19, pancreatitis, sarcoidosis, valosin-containing protein (VCP) disease, and primary ciliary dyskinesia (PCD). These apps were codeveloped as part of the Biohub's Rare As One Project, which aimed to support co-design prototype symptom tracking and transmitting apps for rare or complex conditions. In this paper, we discuss lessons learned and provide a health app co-design framework for others hoping to develop a personal health app, including app development novices.

Methods

App Co-Design Synopsis



This project involved a multidisciplinary partnership between the sponsor, 4YouandMe [24] (a nonprofit digital health organization that includes expertise in app design, user experience [UX] and remote digital health app–based research), AgileOps (a software development company), and 5 different disease areas including a patient-driven organization (PDG) lead (patient advocacy groups), an individual with lived experience of the condition (herein referred to as end user), a clinician with condition-specific experience (selected by the PDG), device partners (Empatica, Lumia Health, MIR, and Oura), and Biohub (the study funder). All partners were involved in an extensive 6-month co-design phase (phase 1) that was conducted entirely remotely through frequent virtual meetings and workshops. This was followed by a study preparatory phase to build out the first versions of the prototype apps, prepare institutional review board (IRB) materials, and start patient outreach to identify end user testers (phase 2). Phase 3 involved a 5-month beta testing pilot longitudinal study of approximately 50 participants for each prototype app (Figure 1). The co-design methodology adopted and extended principles from many co-design concepts (user-centered, collaborative, and patient-led), where end users were placed at the center of the design process alongside other equal multidisciplinary partners(Figure 2). We adopted a "by each other for each other" approach where disease experts (end users, clinicians, and PDGs) were not expected to design themselves, but were empowered and provided with the tools to co-design alongside app development experts (app developers, UX experts, and digital health researchers). This approach resulted in significant investment of time from all partners involved. The PDGs received small grants to compensate for their invested time.

Figure 1. Co-design project methodology timeline.

XSL•FO
RenderX

Figure 2. Patient-led, user-centered, and collaborative personal digital health technology co-design.

Development of Multidisciplinary Team (Phase 0)

The first project phase involved the curation of the project team. 4YouandMe worked with Biohub to select 5 different PDGs. These groups were selected based on the following criteria: PDGs having motivation and capacity to participate in the patient-led design process, the ability to identify a clinician representative to participate in the co-design, and the ability to recruit 50 participants for the pilot study. The groups were additionally curated to include diverse disease areas, but with some overlap in symptoms, so that insights could be made from each group. The final selected groups included the following: Patient-led Research Collaborative (long COVID-19), Mission Cure (pancreatitis), Foundation for Sarcoidosis Research, Cure VCP Disease, Inc, and the Primary Ciliary Dyskinesia Foundation.

App Co-Design (Phase 1)

A 6-month app co-design phase was conducted involving the codevelopment of specifications through group workshops and independent exercises developed by the study sponsor that defined the goal, content, features, and UX of each app. This initial phase involved 5 modules (Table 1). The workshops provided an avenue to ground the app development experts in the experience and needs of patients with the disease, and the disease experts in aspects of the app development process. Each workshop included grounding virtual presentations by specific partners depending on the intended outcome, and all included an informal discussion period (Table 1). The co-design process was iterative and bidirectional, where partners were grounded on key concepts in the app development process and were asked to complete independent exercises (Multimedia Appendix 1) that were then reviewed in subsequent workshops to find common ground and build key stepping stones of the app development roadmap. The app development experts synchronously drafted app specification documents in collaboration with the disease experts, which were then used to communicate the final app specifications to the app builders. An example of an app specification document can be found in Multimedia Appendix 2. At each co-design step, PDGs added substantive considerations for end user needs that shaped the app specifications.

This app co-design was guided by core principles, including the following: (1) personal health apps must give back to the end user—what is the app's gift or benefit to the end user; (2) personal health apps must minimize the risk of instigating negative health outcomes; (3) personal health apps aimed at providing insights on specific diseases must be reflective of the unique needs of the patients in those communities; and (4) a personal health app's success cannot be fully measured without a significant amount of usability testing.

XSL•FO
RenderX

Table 1. App co-design module descriptions.

Module, purpose, and workshops (presenter)	Outcome
Module 1. Introductions	
Introduction between partners, description of partner goals, roles, and responsibilities	
Introduce approach, and app development process (sponsor) • What is the current state of the health app market? • What are health apps possibilities and limitations? • Co-design approach (“by each other for each other”)	• Educate disease experts about the app development process, realities
Introduce disease (PDGs[a]) • What is the disease epidemiology, burden? • What are the patient and clinician unmet needs, gaps in care • What is the PDGs past work/experience in digital health research app development?	• Educate app development experts about each disease, patient, and clinician perspectives. • Gauge all partners’ experience in app co-design
Module 2. App purpose/function framing	
Co-design primary app goals and key functionalities	
Defining the app purpose • Sponsor synthesis and discussion of PDG’s suggested patient and clinician needs • App guiding principles • Description of app possible attributes • Independent exercise 1-Preference of potential app purpose/attributes	• App goal and purpose framed and understood by all partners
Module 3. Symptom selection	
Co-design a list of core symptoms to be tracked and transmitted	
Describing subjective and objective symptom tracking through P-DHT[b] possibilities and realities (sponsor) • What symptoms are apps/wearables able to track well, not well? • Challenges in symptom tracking (confounding, uniqueness of individuals, linking objective measures to subjective symptoms) • Important of individual context • Introducing app-based visual tools for following symptoms, gaining health insights • Independent exercise 2-define specific app attributes	• Disease experts grounded on app/wearable realities in following specific symptoms and states of health
Review and discuss independent exercises 1 and 2 (all partners)	• Define app attributes and key symptoms to be tracked and transmitted
Module 4. Digital tool selection/dashboard	
Consider which on the market wearable or smart device could enable the objective tracking of the identified key symptoms, and introduce digital dashboards.	
Introduction to potential digital tool options (sponsor) • Grounding on current on the market wearable/smart devices realities and limitations • Sponsor digital tool suggestions based on PDGs disease/symptoms • Introduction to digital dashboard (ways to follow/share symptoms, experiences) • Introduction to triggers/modifiers (context labels) and how they can be captured through dashboards • Independent exercise 3-dashboard preferences	• Wearable/smart device selected • Disease experts grounded on digital dashboard purpose, realities, limits
Module 5. App feature/UX[c] introduction/app attribute refining	
Determine specific surveys/active tasks, or develop new tasks to enable the subjective tracking of the identified key symptoms, and introduce and refine app features and functionality, and UX.	
Introduction to potential app features and UX/app specification review (sponsor) • Introduce possible app features (beyond surveys/tasks) to capture symptoms and context • Brief introduction to app UX • Provide and review app specification documentation • Independent exercise 4-full app specification review	• App content (surveys/tasks) fully defined in the form of an app specification document
1 on 1 UX session to finalize app feel, and feature function	

XSL•FO
RenderX

Module, purpose, and workshops (presenter)	Outcome
1 on 1 with UX expert (UX expert) • Introduction to app UX • Sponsor synthesis and discussion of PDG's suggested features • Independent exercise 5-UX preferences	• App UX defined

[a]PDG: patient-driven organization.

[b]P-DHT: personal digital health technology.

[c]UX: user experience.

Study Preparatory Phase (Phase 2)

A 5-month study preparatory phase was conducted to prepare for phase 3 of the co-design (a pilot beta testing study with up to 50 end user participants for each prototype app). During this phase, the technology partner built the first version of each app, while in parallel, IRB materials (protocols, consent forms, and participant-facing materials) were codeveloped with all partners and submitted for approval, wearable/smart device companies were engaged, and agreements were completed. During the second half of this preparatory phase, internal alpha testing was conducted by the study partners, and patient outreach began to identify end user participants for each prototype app. Monthly one-on-one virtual meetings were conducted to give disease experts updates on app development and to co-design IRB documents. This period also included an alpha testing phase, where all partners performed an initial usability testing of the app to identify initial bugs before opening up the app to participants.

App Optimization—Beta Testing Pilot Study (Phase 3)

Overview

A 5-month pilot study was conducted with US-based end user participants to perform initial usability testing of the app. Study advertisements were co-designed with each PDG. Participants were recruited through each PDG organization using social media and newsletter advertisements (see Multimedia Appendix 3 for an example) with a cover letter from each PDG introducing the pilot study. Participants were instructed to contact a 4YouandMe study representative and complete an initial screening phone call where they were explained the study, their eligibility was confirmed, and they were given instructions on how to download the app. Briefly, participants were eligible if they were 18 years or older (except for the PCD beta testers that included a minor version of the app, inviting 14-17 year olds), had a suspected or clinician-confirmed diagnosis of each disease, and owned a personal iPhone/Android smartphone (see Multimedia Appendix 4 for full inclusion criteria). The app included an e-consent where participants officially agreed to participate, including a parental authorization mechanism for participating minors (PCD app). Post enrollment, participants were mailed their cohort-specific wearable/smart devices. Participants completed participation in an entirely remote setting.

Beta Pilot Study Procedures

Enrolled participants were instructed to download the prototype app, provisioned with specific wearable and/or smart devices (Multimedia Appendix 5), and instructed to use these devices continuously during their participation. Participants were asked to complete biweekly phone check-in calls with a dedicated engagement specialist. These calls aimed to support participants, work through technological issues, and collect their feedback as beta testers. Engagement specialists entered participant feedback into structured and unstructured fields in Research Electronic Data Capture—a secure data management database. Participant feedback was documented continuously and systematically by engagement specialists, centering on the following themes: functionality, usability, harms, benefits, self-explorations, and others (Textbox 1). Participants were also invited to participate in 2 optional virtual investigator-participant meetings where they had a chance to meet the study team, get study updates, and ask the study team questions in real time, anonymously.

XSL•FO
RenderX

Textbox 1. Beta testing app themes collated from participants.

Functionality

- Are the study tools (study app, wearables, and smart devices) functioning the way they should based on their intended use—to enable the user to track diverse symptoms and modifiers of their condition and potentially provide insight into factors that impact symptoms and outcomes, or general health insight relating to their condition. Are there factors about the participants' conditions that are not being tracked that should be? Are there missing functionalities that could help achieve the study tools goals?

Usability

- Are the study tools usable? Are there internal or external factors that prevent the participant from using the tools for their intended use (eg, physical barriers such as mobility challenges, mental barriers such as fatigue or cognitive disturbances, and technological barriers such as WiFi connectivity)?

Benefits

- Are there reported benefits from using the study tools? Do participants perceive value in using the study tools? Benefits might include factors such as improved health insight and awareness, or positive behavior modification.

Harms

- Are there reported harms from using the study tools? Harms might include factors such as increased anxiety or other mental health concerns from tracking certain symptoms or being asked certain questions at high frequencies, irritability from task burden, or injuries from using the wearable/smart devices.

Self-explorations

- How are participants using the app to learn about themselves and conduct self-explorations? How specifically are they using the compass feature? For example, are they using this feature to track specific symptoms/features, to track specific modifiers of symptoms (eg, diet), or to try to learn associations between factors that impact symptoms?

Ethical Considerations

This study was approved by Advarra IRB (Pr00082545) and all participants digitally provided informed consent and parental authorization (where appropriate). All personal data were kept confidential by the internal research team. The study data collected were stored in deidentified form (stripped of personal identifiers) and attached to a unique identifier. Participants received US $50 for every month of participation in the form of a gift card and were also offered to keep the Oura ring at the end of the study.

Prioritizing Participant Feedback

Participants communicated their feedback to their engagement specialists through text, email, video calls, and, where appropriate, sent screenshots. Participant feedback was documented systematically by engagement specialists, which was then collated by the app development team and reviewed with PDGs for prioritization. This project had time and funding constraints, meaning that not all participant suggestions could be implemented. Suggestions were condensed from duplicates across participants, and by setting aside those that were out of scope (ie, could not be achieved within the current time frame, or within the current budget). PDGs were asked to rate each feedback from least desired, desired, to most desired. The app development team worked to determine which of the desired and most desirable suggestions could feasibly be implemented within the allotted time frame and budget. This synthesis was conducted in 2 waves during the beta study, with the goal of having time to implement most suggestions so that the participants could view and test themselves. Suggestions that were not possible to implement were documented and are made available to others wishing to view (see Data Availability section).

App Development Process

App development was undertaken by the technology partner (AgileOps) using an iterative, Agile workflow aligned to the multiphase co-design program. Requirements were derived from phase 1 specification documents and UX exercises, translated into shared low- and high-fidelity Figma prototypes for rapid validation with the project team and ultimately all the stakeholders involved in the co-design exercise, and then implemented in short, time-boxed iterative development sprints (recurring unit of time by which the development process is organized) of an approximate length of 2 weeks each with traceability to the originating workshop artifacts. Every app change was mapped to a requirement or user story traceable to co-design artifacts (workshop outcomes, spec docs, and Figma frames). Weekly product reviews with PDGs and the sponsor confirmed scope, prioritized participant-reported issues, and aligned releases with IRB amendment needs. All 5 study apps were developed natively for iOS and Android and distributed via the Apple App Store and Google Play Store. The supporting backend services were deployed on cloud infrastructure to enable secure survey delivery and wearable data acquisition. Continuous integration and delivery followed trunk-based development with mandatory code review, automated linting and tests, and staged promotion (development → staging → production). Mobile releases used internal/beta channels for rapid usability checks prior to public availability during phase 3. A server-driven "study engine" delivered survey schemas, schedules, notifications, and visualization configurations by remote configuration, allowing same-day adjustments while

XSL•FO
RenderX

preserving data integrity through schema versioning. This engine enabled real-time incorporation of participant feedback during active use.

In terms of accessibility and performance, frontends follow web content accessibility guidelines–informed patterns (contrast, type scaling, and motion reduction). Mobile apps are optimized for low-bandwidth scenarios with appropriate error and conflict handling. The Compass Chart experience specifically used progressive data loading and elastic queries to keep visualizations responsive even as longitudinal data grows.

Quality and safety practices included a testing pyramid (unit, integration, and end-to-end), synthetic monitors of critical user journeys (enrollment, consent, survey completion, and device synchronization), centralized observability (logs/metrics/traces), and auditing of administrative and export actions. All network communication used transport layer security; storage and secrets followed cloud key-management and least-privilege access controls. These measures supported the usability study while meeting governance needs associated with IRB-approved procedures.

Architectural Stack and Methodology

A key element that facilitated the continuous development process was the methodological and technological stack adopted for the project, which was intentionally fine-tuned for quick prototyping, iterative development, and continuous release without compromising the quality and security of the output. This was achieved by combining modern development frameworks (specifically Ruby on Rails application layer exposing versioned application programming interfaces), web consoles for research/clinical use, and native iOS/Android apps for participants to support robust device integrations and accessibility features, all backed by a cloud-first infrastructure containerized and orchestrated on Amazon Elastic Kubernetes Service (Kubernetes) to support isolated workloads, horizontal scaling, and controlled rollouts. Data from surveys, active tasks, and connected devices were normalized through event-driven extract, transform, load pipelines and indexed in Elasticsearch to enable longitudinal visualization and query of symptoms and objective signals.

Analysis

Phase 1 of this co-design involved building out app specification documents. All of the resulting app prototype themes/attributes and outcomes are described in tabular format. Participant insight and feedback from phase 3 were collected through regular phone discussions every 2 weeks with study engagement specialists, in addition to an exit interview after completing the study. A thematic analysis [25,26] of qualitative data captured during these interactions was conducted to identify themes for app improvement. Participant engagement was measured through calculating retention rates (number of dropouts/total enrolled) and median adherence to study activities over study follow-up. Adherence to app-related tasks was defined as the proportion of tasks completed divided by the total number of tasks that could have been completed over each participant's unique study follow-up. For example, all apps included a daily quick activity. For a participant with a follow-up of 4 months, the total expected number of daily quick activities is 120. If a participant completed 95 daily quick activities, their adherence to this specific task would be 79%. Adherence to the check-in calls every 2 weeks was defined as the number of calls completed divided by the total number of expected calls over a unique participant's follow-up period. Medians and ranges were used as adherence distributions were nonnormally distributed. Adherence to the wearable/smart devices was estimated using different daily wear criteria. For Oura ring data, daily wear was defined as the presence of an "Oura Sleep Score." For the Lumia device, daily wear was defined as the presence of at least one "heart rate" value. For the Empatica device, daily wear was defined as the presence of at least one "electrodermal activity (EDA)" value. For the MIR Spirometer, daily wear was defined as the recording of any spirometry data.

Results

Co-Design Outcomes

Multimedia Appendix 6 outlines the codeveloped app goals and specifications for each prototype app. While there was overlap in unique goals, themes, and key symptoms to track across the prototype apps, each app included unique content. Each group had an interest in building longitudinal symptom maps and having the ability to share symptoms with clinicians. Further, all groups had an interest in enabling the user to follow aspects of burden of disease, routines, and potential triggers that modify symptoms or disease outcomes. This stage in co-design was critical for deciding on the prototype app's key functionalities and features to ensure that the tool could achieve the common and specific objectives. While most groups included a target age range of >18 years, given the mostly adult onset of symptoms, the PCD app included a minor app version (aged 14-17 years) in light of the presence of symptoms earlier in life.

Select wearable/smart devices were selected for each group to capture objective measures of key symptoms (section 4B in Multimedia Appendix 6). All groups used the Oura ring as a measure of daytime activity and sleep quality. Groups that had a specific interest in following the symptom of pain additionally included the Empatica EmbracePlus smart wristband device, owing to its ability to track EDA (skin conductance), which could reflect an objective proxy of pain. Additionally, the long COVID-19 group had an interest in following dysautonomia (dysregulation in the autonomic nervous system), for which EDA could be a useful measure. The Lumia ear device was additionally used in the long COVID-19 group owing to its unique ability to capture blood flow to the head as another useful potential measure of dysautonomia. Groups that had an interest in following symptoms relating to breathing, or respiratory function, additionally included a spirometer (MIR Spirobank Spirometer). Please see Multimedia Appendix 5 for a detailed description of selected wearables and smart devices. Taken together, other than design and targeted symptoms (which defined the app survey/task content and wearable/smart device selection), the apps were similar in design with the same core features.

XSL•FO
RenderX

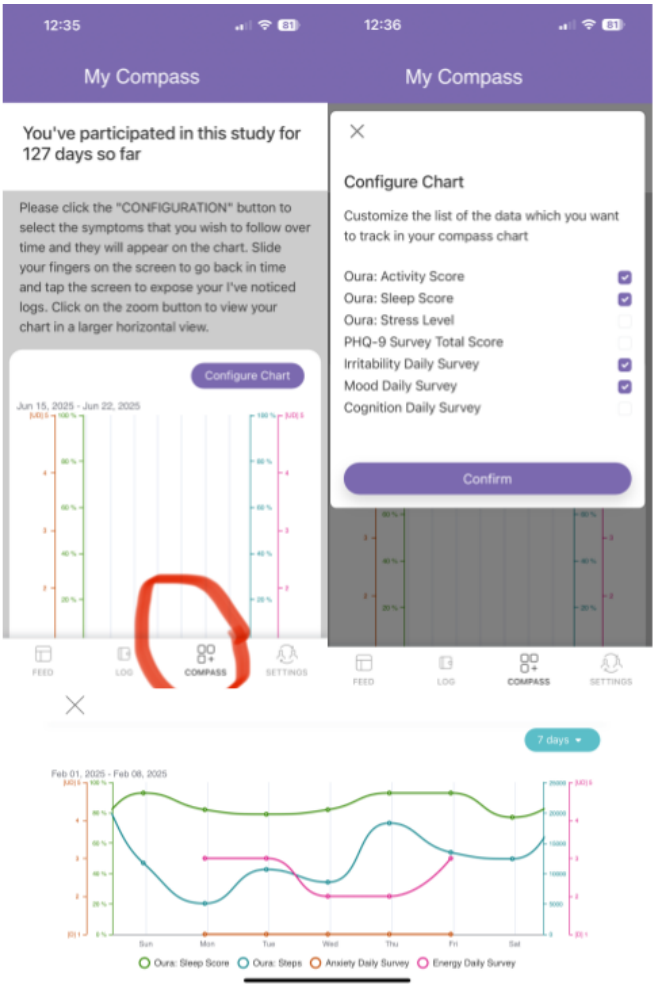
Prototype Apps and Their Features

Specific app features were developed to accommodate the intended app themes and goals. All prototype apps included daily and intermittent prompted surveys and active tasks to collect subjective self-reported information from participants that were intended to capture each symptom in order to build longitudinal symptom maps across conditions (Figure 3).

In keeping with many group themes of enabling better abilities to track and understand certain symptoms and have the ability to better understand triggers and modifiers of symptoms and disease, additional optional app features were co-designed. These included the "I've Noticed..." feature, the "Reflections" feature, the Compass Chart, and Compass Log.

The "I've Noticed..." feature (section 5A in Multimedia Appendix 7) enables the end user to tag momentary experiences at any time in the app in either a written text format, or audio or video recording. The logged experiences from the I've Noticed feature are then time-stamped and logged in an additional diary format feature called "Compass Log" (section 5B in Multimedia Appendix 7), where the end user can return to these logged experiences and even edit them. Participants were instructed to try to use this feature to log in-the-moment potential triggers/modifiers that could help explain fluctuations in their symptoms, or for logging dynamic changes in their symptoms. For example, for the VCP group, this feature was useful for logging falls and near falls when they occurred. This feature was developed to enable a user to tag momentary context in their day or night that could lend insight into potential triggers or modifiers of their condition.

The "Reflections" feature (section 5C in Multimedia Appendix 7), while similar in format to the "I've Noticed..." feature, served a different purpose. The "Reflections" feature was designed to empower the user to have a space within the app to take the time to consider certain aspects of their condition and reflect on certain aspects that improve or deteriorate their condition. This feature prompted participants daily to complete a reflection where they could write a written note, or complete an audio or video recording. Prior to completing a reflection, this feature instructed participants to complete a grounding exercise, such as meditation, going for a walk, etc, to help prepare themselves to make a reflection about their day or their week in relation to their condition. The logged reflections were made available in the end users' Compass Log, where they could revisit their logged entries. This feature was developed to empower the end user to reflect on a deeper level of possible triggers and modifiers of their condition.



The Compass Chart (Figure 4) feature enabled participants to view select symptoms or wearable/smart data streams retrospectively over time. Participants could select from a dropdown menu of up to 10 items to track and were able to view 4 of these items in their chart at a time. This feature was designed to provide the user with a tool to follow, and potentially learn new insights about their condition in terms of symptom patterns and factors that improved or worsened their condition.

Beta Testing Pilot Study Results

Overview

A total of 239 end user participants participated in the beta testing pilot study that was conducted between February 2025 and June 2025. See Multimedia Appendix 8 for specific enrollment flow details of each group. Enrollment and retention rates were high, ranging from 94% to 100% and 92.2% to 100%, respectively (Table 2). In most disease groups, exit interview completion was high (long COVID-19: 47/50; pancreatitis: 35/44, 80%; sarcoidosis: 44/50, 80%; VCP: 42/44, 95.4%) except for the PCD group (23/51, 45.1%), who were mostly minors. Demographic characteristics can be found in Multimedia Appendix 9. In all but the sarcoidosis cohort, beta testing participants were predominantly White and female. Mean age was in the middle age category (40-55 years) in all groups except for the PCD cohort, which included minors, with a mean age of 31 (SD 15) years.

XSL•FO
RenderX

Table 2. Median adherence rates for study activities across disease groups.

	Long COVID-19 (n=49)	Pancreatitis (n=44)	PCD[a] (n=51)	Sarcoidosis (n=50)	VCP[b] disease (n=44)
Study weeks, mean (SD)	14.2 (3.6)	14.5 (3.2)	11.9 (3.5)	18.0 (0.6)	13.7 (3.1)
Retention, n (%)	49 (100)	42 (95.5)	47 (92.2)	47 (94.0)	44 (100)
Biweekly check-in calls (%), median (IQR)	100 (100-100)	85.7 (61.7-100)	71.4 (46.4-92.9)	85.7 (71.4-100)	100 (100-100)
Daily quick activities (%), median (IQR)	36.8 (22.1-60.3)	39.9 (23.5-68.2)	39.8 (24.2-55.4)	51.2 (25.1-67.3)	43.1 (29.7-64.2)
Weekly in-app survey (%), median (IQR)	90.9[c] (73.3-100)	97.2[c] (89.2-100)	100[c] (80.2-100)	—[d]	72.4[e] (54.2-80.0)
Biweekly in-app survey (%), median (IQR)	100[f] (75-100)	100[f] (88.9-100)	100[f] (79.2-100)	100[f] (89.5-100)	100[f] (100-100)
Oura ring use (%), median (IQR)	89.3 (71.4-95.0)	67.1 (46.2-92.5)	26.3 (15.5-50.4)	66.4 (52.6-82.1)	83.9 (65.1-94.1)

[f]9-item Patient Health Questionnaire.

Participant Adherence

Table 2 includes median adherence to study activities by disease group. With the exception of the PCD group, all groups demonstrated excellent adherence to participating in biweekly check-in calls with research staff and to weekly and biweekly in-app surveys. Adherence to using the study smart devices demonstrated acceptability, with participants using the Lumia ear device >60% of the time, Oura ring use >65% of the time (except for the PCD group), Empatica use >55% of the time, and MIR Spirometer use >50% of the time. All devices except the Oura ring had a delayed integration into the study, meaning that the time that participants had to interact with these devices was shorter than the entire study duration. The PCD group was the only group that included minor participants (aged 14-17 years). This disease group demonstrated consistently lower adherence to most study activities.

As this was a pilot beta testing study, the app was undergoing modifications, and a number of active tasks and features had periods of malfunction. Accordingly, the adherence estimates relating to the app tasks should be interpreted with caution, as some of the low adherence may be attributable to app error as opposed to noncompliance.

Participant Beta Tester Feedback

During the participant beta testing phase, 215 unique participant reports of prototype app issues were documented, while 112 unique participant reports of wearable/smart device issues were reported. There were 257 unique participant suggestions of how to modify or improve the study app experience. User feedback was coded into the following core themes: 81 functionality, 51 usability, 28 benefits, 20 harms, 71 self-explorations, and 6 others. Several features were implemented during the beta testing period, and some shortly after the study closed, based on participant feedback. For example, new surveys or new items to existing surveys were included, screening questions, and features to instruct participants not to complete tasks when they cannot safely be completed (eg, walk tests) to ease user burden, color contrast improvements, including a dark mode option for users with visual impairments, labeling features with emojis to improve ease and personalized “I’ve noticed”/”reflection” entries. See Multimedia Appendix 10 for all features implemented.

Over 90% (175/191) of participants across all disease groups (who completed an exit interview) reported that they received some benefit from using the prototype apps and associated wearable/smart devices (long COVID-19: 42/47, 89.4%; pancreatitis: 34/35, 97.1%; sarcoidosis: 41/44, 83.2%; VCP: 38/42, 90.5%; PCD: 20/23, 87.0%). Overall, 71.2% (136/191) of all participants rated their likelihood to use their respective app in the future between 7-10, on a 1-10 rating scale, with 10 being the most likely to use the app (Multimedia Appendix 11). Participants reported benefits of the prototype apps and associated wearable/smart devices, including increased self-awareness of symptom modifiers (eg, sleep and stress patterns that trigger exacerbations) and behavior modification through the encouragement of health-promoting behaviors. Participants indicated an appreciation for the comprehensive symptom tracking that empowered them to feel accountable for making healthier choices and the desire to share their health data with others. Participants also reported that they felt supported in participating in the beta testing study. Frequent check-in calls with engagement specialists and intermittent virtual progress meetings with the investigator team were viewed positively by participants.

XSL•FO
RenderX

While benefit was reported by the majority of participants, a number of subthemes emerged during the beta testing usability period (Multimedia Appendix 12). There was a desire to improve the functionality of the apps through better personalized notifications when tasks are due, better task instructions, and better app navigation through the app's core features. There was some overlap in feedback between the core themes of functionality and usability, where, for example, more personal customization was a desire, which alters initial functionality, but would likely lead to better usability. Numerous participants had different opinions on how frequently they wanted to complete certain surveys. For example, all prototype apps included a daily quick activity survey that prompted the user to report on their mood, energy, cognition, pain, and other symptoms. A number of participants suggested they track these symptoms multiple times a day to capture daily variations in fluctuating symptoms, while others preferred a longer cadence (eg, weekly), and some participants suggested tracking additional symptoms, not present in the quick activity. A solution would be to enable participants to set their own cadence and even the content of some surveys. However, in making these decisions, one must weigh the consequences of enabling too much customization where data cannot be harmonized across users for health research, or returned data are no longer useful for the individual. There were unique usability preferences from the long COVID-19 group, many of whom reported vision problems. These reports included enabling a dark mode option or better color contrast.

There were 20/239 (8.4%) unique participant reports of nonserious harms associated with using the prototype apps and associated wearable/smart devices (10 long COVID-19, 5 pancreatitis, and 5 VCP). Most of these were related to frustration relating to unclear instructions on certain tasks and having to complete tasks that did not feel relevant to the user. Many of the prototype apps used select ResearchKit's active tasks (eg, 2-minute walk task). Many of these "plug-in" tasks are not customizable, which introduces challenges to include adequate instructions to tailor these tasks for each end user population. There were also some reports of burden and fatigue from too many tasks, particularly when symptoms were static. A small number of participants reported a negative emotional impact from using the prototype apps and associated wearable/devices. For example, there was a report that the use of the Oura ring and returned summary scores made a participant feel worse about their health (VCP participant). For some, persistent, daily tasks felt like reminders of disease progression and were emotionally draining.

In addition to these reported harms, there were several reports of skin irritation issues associated with wearing the Empatica EmbracePlus wristband at the site of wear that appeared to be mostly the result of contact dermatitis. This was investigated with the device company, and Empatica has reported 0.1% skin irritation rate for EmbracePlus, according to tests performed following the ISO 10993 standard series. Both of the populations using this device may experience heightened autonomic activity from pain (pancreatitis) and from other unknown causes (long COVID-19) that could have contributed to a higher number of reported irritations than typical for this device. Participants were instructed to stop wearing the device if skin irritation occurred.

Participants were encouraged to use the prototype app Compass feature to log experiences and symptom modifiers, and use the Compass Chart to track certain symptoms over time. This feature also overlaid select feature streams from some of the wearable/smart devices. The goal of this feature was to enable the end user to start to self-explore their condition, and potentially start to make some insights into what makes them better or worse. There was again overlap in feedback themes, with this core theme relating to the desire for customization in what participants were enabled to track via the app, and how this was transmitted back to them via the app. Participants' desires for what and how to transmit via the app were heterogeneous. However, there was a general consensus that personalized labeling (eg, using icons and color coding) within the Compass Chart would be useful, and ways to export and share data with others for a deeper review of personal health data.

PDG Co-Designer Experience

The participating PDGs reported positive experiences relating to being able to shape an app, learning from other PDGs and from an app development team, exploring the use of P-DHT data that is important to patients, and providing patient communities with the opportunity to pilot test an app for them.

Negative experiences were reported relating to mismatches in project objectives. Some of the PDGs anticipated that the data could be used to inform insights about each condition or the use of the tools for following certain symptoms—there was an expectation that direct benefit would be translated to the participating communities. This highlights the critical importance of repeating and discussing project objectives throughout the entire co-design process. To effectively co-design and beta test a prototype app, end users must use and interact with the app, which means data is produced. However, with dynamic changes occurring within the app, and the resolving of early app bugs that can result in significant gaps in data, the data produced from such early prototype stages is not advisable to be used for making health-related insights that one would make from an observational study.

PDG groups were heavily involved in the first 2 project phases, but were less involved in phase 3—the beta testing study, which was more focused on end user involvement. There was a general desire from PDGs to be more involved in the beta testing study to relay updates back to their community, and to better understand insights from the data in near real time.

Some PDGs reported wanting more one-on-one time with the development team. A number of group workshops were held, but all co-designers felt that more time was needed to work through questions and complex ideas.

App Development Team Co-Designer Experience

The app development team found benefit in the co-design approach in producing a prototype app that could have taken multiple usability studies to achieve. The initial PDG input on app goal and specifications was instrumental in yielding an

XSL•FO
RenderX

early prototype that already had elements of disease-specific personalization. This allowed the beta testing period to focus on more nuanced features of the app as opposed to common user feedback on relevance. In the engagement of ~50 end user beta testers for months, the sheer volume of detailed app improvement input was overwhelming, much more than the app development team has experienced from past P-DHT studies. Further, while the app development team has reported high retention and adherence rates from past P-DHT studies [1], the observed enrollment and retention rates of end users in this pilot study were exceptionally high.

The app development team underestimated the time and resource burden of the co-design approach, especially in the development of 5 different apps. There was an expectation that more overlap in needs across the disease groups would be present; however, the initial co-design phase highlighted each group's unique needs, which surpassed the app development team's initial expectations.

Discussion

Overview

In this paper, we describe a patient-led, user-centered, and collaborative personal health app plus wearable plug-in co-design methodology. Five prototype apps were developed for end users with long COVID-19, pancreatitis, sarcoidosis, PCD, and VCP disease. End users were placed at the center of the design process alongside other multidisciplinary partners driven by nonprofits and community-based organizations, including app design and development experts, UX experts, clinicians, and PDGs. Using a "by each other for each other" approach, this co-design process included facilitators to guide the co-design process for disease experts; however, all partners were considered experts in the process in their own respective roles. After the development of the prototype apps, this approach included a 3- to 5-month usability testing period with 239 end users across different rare or complex conditions. A flexible study engine was built that facilitated real-time and frequent app modifications while the app was in active use. This flexible study engine accelerated and empowered the co-design process.

While this co-design methodology required significant effort and time from all partners involved, it yielded deep insights into end user driven prototypes. Beta tester participants demonstrated exceptionally high enrollment rates, retention, and acceptable adherence to using the apps and devices for several months during the usability testing period. A total of 16 of 191 participants actively engaged in providing feedback on biweekly check-in calls, exit interviews, and virtual calls, while 327 unique P-DHT bugs and 257 unique suggestions to improve the app were reported. Collectively, participant suggestions resulted in numerous app fixes and improvements, many of which were implemented while participants were actively using the app, enabling them to see the result of their feedback. Further, pairing participants with an engagement specialist offered a mechanism to communicate complicated app/wearable-related concepts, which would not be possible without these frequent touch points.

While the impact of the co-design approach cannot be formally evaluated from this study, as there was no comparison, the app development team reported a more streamlined process in producing an early personal health app prototype that already included disease-specific personalization. This enables a deeper beta testing focus on more nuanced features of the app. Through both the engagement of the end user participants from the PDGs and the results of the initial co-design stage, the volume of app improvement suggestions was much more than the team had experienced from past P-DHTs studies.

A common participant feedback theme centered around customization of what the app tracked, how often it tracked, and how it transmitted this information back. Further, participants expressed a desire for more instructions and tailoring of certain tasks so that they were relevant to them and their situation. For example, in the VCP and long COVID-19 end user groups, some users experienced phases where they could not walk safely and expressed a desire to temporarily turn off certain app activities (eg, the walk test) so that they were not repeatedly prompted to complete them. A challenge for the co-design team in implementing participant feedback is balancing this feedback with the personal health apps' intended goals. If the app is purely for the participant, then the co-designer may increase the level of customization. However, if information from the app is intended to be shared with others (eg, clinicians or researchers for analysis), the co-designer has to balance the level of customization with the level of data harmonization that is required to meet the app's goals. This highlights the continued importance of repetitive grounding of the P-DHT intended goal and use for all co-designers involved.

The information collected from P-DHTs holds promise in providing clinicians with richer, higher-resolution data of their patients' health in between health care visits and new knowledge for PDG research. However, a key promise is in empowering patients with the tools to follow their health, and gain insight about what makes them better or worse, in their own unique context, without the sole reliance on health care visits [2,4]. This could be enabled by augmenting P-DHTs with artificial intelligence (AI) tools that give n-of-1 suggestions for improved health [27-29]. AI-driven insights from P-DHT n-of-1 data could yield new insights into rare or complex disease symptom trajectories, and modifiers of disease exacerbations that account for individual-level variability. However, challenges exist in enabling AI suggestion engines to work effectively. This suggestion engine requires adequate "label" context data from the user, which is notoriously difficult to capture, as it often requires a high burden from the user, and much user validation work is needed to determine the accuracy of these tools' suggestions.

There are additional challenges in the general use of P-DHTs. P-DHTs involve a certain level of digital literacy and usability to be feasible for use in the long term and integrated into patients' daily lives. Further, there are disconnects in values and approaches to bring a P-DHT from design to implementation, resulting from multiple stakeholders between health care and industry that often leave the end user at the outskirts of the process [14]. Finally, the existing health app market is saturated by companies with pay walls, and that hold

XSL•FO
RenderX

data in silos that can result in a health data market that takes advantage of patients and their sensitive data. Taken together, P-DHTs hold promise to increase patient agency, putting them in the driver's seat of their health. However, for this promise to become a reality, patients and community organizations must first be empowered and given the time to cocreate these tools for themselves, backed by the appropriate companies.

A number of robust P-DHT patient-centered and patient-led co-design approaches have emerged in the past 5-10 years [21-23,30,31]. A common challenge across these instances is how to adequately ground an end user (especially in a remote co-design environment) so that they are empowered to co-design along with other partners with expertise in app design/development, and digital health research [23]. Further, most existing frameworks do not extend the co-design period into the usability testing period and tend to use small user testing groups for short periods of time [12]. The value and shortcomings of a personal health app cannot be realized until significant usage, which is a key shortcoming of existing P-DHTs on the market and is likely in part the result of poor engagement after the first few weeks of use [11,13]. Accordingly, as opposed to using a mobile app rating scale as a fixed metric of user acceptability and usability, which is commonly applied in other app co-design approaches, we implemented a dynamic feedback system that incorporated user feedback over several months.

Limitations of Approach

The personal health app co-design approach implemented here yielded several lessons learned. While 6 months was allotted for the initial co-design to build out the first app prototypes that included 8 workshops and several break-out meetings, more time was needed to ground and work through complex processes. Some workshops could have been split into 2 or 3 additional workshops. Further, there were occasional mismatches in co-design objectives throughout the project period. For example, the objective of this co-design was to produce prototype apps and conduct usability testing to determine their initial feasibility, and while that objective was clearly communicated at the start of the process, there was disappointment from some PDGs that the pilot data could not be used to yield new information about the disease or to inform clinical decision-making. Revisiting co-design objectives more frequently and understanding stakeholder goals (and limitations) would be useful for grounding all partners back to the same objective.

This co-design process took a significant amount of time and effort from all partners (>1 year with considerable full-time equivalents from some partners). While this can be seen as a limitation, it may be the reality of co-designing a meaningful personal health app. This needed investment should be clearly defined at the outset to manage expectations appropriately. However, this up-front investment could yield a shorter time to implementation. Further, there was a benefit in the ability to have conversations across five different PDGs, where different disease areas were able to learn from one another.

Each app was iteratively modified, even during the beta testing usability period. This approach is uncommon in app development but has value by enabling the end user to see the result of their feedback and further usability testing of a new fix or improvement in real time. A consequence of this approach is that the release of a new or modified feature by a change in code can inadvertently impact functionality in another app feature. While this scenario occurred on a few occasions, the app development team anticipated this reality and had the appropriate resources ready to troubleshoot these inadvertent app bugs when they arose. In the end, this did not significantly impact the co-design timeline and demonstrates that an app does not necessarily have to be locked for modifications during active use. A further challenge with the aforementioned real-time modification approach is the need for frequent research ethics board modifications to amend study protocols, which, depending on the review board, can be associated with time delays and additional costs.

While the initial app prototypes offered benefit to many of the end user testers, there was a proportion of end users (8%) who did not report any benefit. There will likely always be a proportion of individuals who will not receive benefit from a P-DHT–delivered tool for health. A challenge for app co-designers is in defining the success of the personal health app and understanding which patients are most likely to engage and find benefit. In the context of the P-DHT space, broad benefit across a user population may not be a reality, and success may be defined under a different lens relating to narrower n-of-1 outcome definitions.

As evidenced by the low adherence to most tasks in the PCD group, there were challenges in engaging a minor population compared to an adult population. This cohort had a significantly lower completion rate of biweekly check-in calls (<40% of calls), compared to up to 100% for most other groups. This check-in call has been found to be essential in maintaining engagement in the participation in digital health research activities [1]. Minors may require alternate methods of checking in beyond a phone call. Further work is needed to better understand how to engage a youth population in the use of P-DHTs for health. As the sample size in each group was ~50 participants, the numbers were not high enough to examine differences in usability, adherence, or other feedback by factors such as sociodemographic characteristics. However, with the exception of the Sarcoidosis cohort, all beta tester participants were predominantly White. Therefore, these co-design outcomes cannot generalize to diverse populations.

Importantly, the initial purpose of the Rare As One project was to develop at a high level symptom tracking and transmitting apps. In light of this, the broad goal of each app was loosely already defined, and the grounding exercises were designed to aid in tailoring the goals for each unique disease group. For others wishing to use a similar framework, the goal framing workshops may include different grounding exercises (eg, tools that provide access to care or health knowledge) than those configured here.

Future Directions and Conclusions

This user-centered, collaborative, co-design work was intended to yield open-source code and usability data for 5 prototype apps for long COVID-19, pancreatitis, sarcoidosis, VCP disease,

XSL•FO
RenderX

and PCD. Our aim is to enable others to leverage this open-source work (all available via GitHub) to use the built study engine, prototype apps, extract specific features, or modify it for the same or different clinical populations. It is our hope that other PDGs, funders, or commercial entities might leverage these open-access tools, and if not, that this framework might be used and modified for additional use cases. More beta testing and co-design will likely be needed to further evaluate the potential benefit these apps could yield for end users.

Personal health app co-design is rooted in a complex digital landscape that requires a significant amount of up-front effort and time. Despite the up-front investment in time, taking this co-design approach may yield shortcuts in the longer-term implementation of a personal health app. For groups willing to provide this up-front investment, here we provide a co-design framework and the building blocks of five prototype personal health apps that could be leveraged for improving understanding of, and communicating symptoms of, rare or complex diseases. This reflects a potentially novel resource for PDGs and communities actively engaged in research. The ultimate goal of this personal health app co-design is to develop n-of-1 suggestion tools that could empower end users to glean insight into what day-to-day factors improve or exacerbate their condition, which could be transformative for personalized health care, particularly in the rare or complex disease landscape.

Acknowledgments

We would like to acknowledge all co-design partners, including Biohub, the patient-driven organizations (Patient-led Research Collaboration [long COVID-19], Mission Cure [pancreatitis], Foundation for Sarcoidosis Research [FSR], Cure VCP Disease, Inc, and the Primary Ciliary Dyskinesia Foundation), and device companies (Empatica, Lumia, MIR, and Oura). We would like to acknowledge and thank all of the end user co-designers who participated in the beta testing study. FSR is grateful to Biohub's Rare as One Initiative for providing a grant to support FSR's participation in this project.

Funding

This work has been made possible by Biohub through grant 2024-342789 from the Chan Zuckerberg Initiative donor advised fund, an advised fund of the Silicon Valley Community Foundation.

Data Availability

Among participants who opted in, coded study data (deidentified) are made available on the Synapse platform [32] at Sage Bionetworks [33] and other platforms to be announced with 4YouandMe's website [24] and can be freely accessed by any researcher who becomes "qualified" by becoming a registered and certified Synapse user [34], and by meeting the specific conditions of use that require submitting an intended data use statement alongside an institutional review board–approved protocol. The specific Synapse Project page can be found on [35] among registered Synapse users.

Source code for the prototype apps is available at the following reproducibility Github link and website page: iOS shared codebase [36], Android shared codebase [37], and web codebase [38].

The investigators encourage others to access, modify, and build upon these open-source prototype apps.

Authors' Contributions

SMG wrote the manuscript and coled the co-design development and beta testing study. EK managed the beta testing study. RY conducted the data analysis. MS, PG, CO, DV, and JW were engagement specialists for the beta testing study. JP and MT developed the mobile apps. MF, YR, HW, MG, DM, MM, RM, TS, EH, AP, NP, and ZY were patient-driven organization partners and coled the co-design development and drove recruitment. HB-P and AS, representing the funders, coled the co-design development. SAS, DA, EA, RG, DH-G, NH, CK, and MO were beta testing participants and provided comments on the written manuscript. SF led the co-design development. All authors contributed to the editing of the manuscript.

Conflicts of Interest

TS and EH from the Foundation for Sarcoidosis Research (FSR) received funding support from numerous pharmaceutical companies associated with program implementation, and patient-centered clinical trial design and recruitment. FSR receives funding from numerous nonprofit organizations and community-based and family foundations. HB-P is Director at Biohub that funded this research. AS is Program Manager at Biohub that funded this research.

Abstract

Background: Self-monitoring technologies are commonly used to promote health behavior change, with glanceable displays offering continuous feedback throughout the day. Yet, it is still unclear how various aspects of these glanceable representations affect their interpretability and usability.

Objective: This study aimed to investigate the effects of 3 design factors—stylization, granularity, and salience—on users' ability to understand glanceable smartwatch-based feedback on daily step goals.

Methods: We conducted an online simulation study to examine how 3 design dimensions—stylization, salience, and granularity—influence the effectiveness of glanceable feedback displays. Stylization and salience were crossed in a 2×2 factorial design, while granularity varied from 1% to 20% progress increments. A total of 202 Amazon Mechanical Turk participants were randomly assigned to 1 of 16 smartwatch display conditions. In each condition, participants viewed feedback on daily step progress and estimated the level of progress shown. We measured estimation error and questionnaire-assessed perceived usability and acceptability. The collected data were analyzed using generalized estimating equations and linear regression.

Results: High stylization reduced accuracy (+4.52 error points; $P<.001$) and negatively affected perceptions across 6 dimensions, including comprehension ($P=.003$), complexity ($P<.001$), and usability ($P=.001$). Granularity had a nonlinear effect: error was lowest around 5%-10%, with sharp increases at 20%. The 10% level also received the most favorable ratings, for example, comprehension (+0.656; $P=.003$). Salience had no effect. Previous smartwatch users were less accurate than never-users (+7.46 points) but rated displays as more useful ($P=.002$) and easier to focus on ($P<.001$). Current users gave similarly positive ratings on attention and usefulness.

Conclusions: These findings could help researchers design effective glanceable smartwatch feedback displays and expand the design space for glanceable feedback.

KEYWORDS

glanceable displays; health informatics; mobile health; physical activity; smartwatches

Introduction

Self-monitoring is widely used to support behavior change in health-related contexts, and meta-analyses have found self-monitoring to be highly effective for physical activity, diet, and weight loss [1-4]. Increasingly, mobile devices such as smartphones and smartwatches have become a common way of providing self-monitoring interventions [5-8]. One of their key strengths for supporting self-monitoring is that they enable users to see self-monitoring feedback frequently—increasing its salience and, thus, its potential to shape users' behavior. Mobile devices can increase feedback frequency by leveraging multiple modalities, including inside apps, push notifications, text messages, and, crucially, glanceable displays such as lock screens (phones) and clock faces (smartwatches).

XSL•FO
RenderX

Glanceable displays refer to the designs that present important, noncritical information in an always-visible but nonintrusive form, allowing data to move seamlessly from the periphery of a user's awareness to the focus of attention and back again [9]. Glanceable displays are a promising approach to supporting self-monitoring, as they enable researchers and intervention designers to create feedback representations that a person can see throughout the day without having to remember to go into an app. By ensuring feedback is always visible, these displays allow users to maintain awareness of their health metrics throughout the day without the burden of needing to navigate to an app or manage incessant push notifications [10-12].

As the smartwatch market has matured, health and fitness have become key domains supported by these devices, and glanceable displays are a central medium through which smartwatches support self-monitoring of health-related metrics. For instance, the Apple Watch includes a complication, which is an element of the clock face that displays information other than the time, for the Activity app, shown by default on most built-in clock faces, which displays feedback on minutes of activity, calories burned, and the number of hours of nonsedentary time. Similarly, most default Fitbit clock faces display step count and heart rate. The information provided in such feedback displays is visible every time the user looks at the watch, providing ongoing awareness about one's level of activity. Moreover, Apple Watch, Fitbit, Garmin, and Wear OS platforms all support some level of clock face customization, enabling a range of feedback—as well as forms of that feedback—to be incorporated into the clock face. Given how frequently watch wearers glance at their watches each day, for a growing number of smartwatch users, feedback shown on their watches represents a powerful way to benefit from self-monitoring without the burden of receiving incessant notifications.

However, little is known about what makes a glanceable display effective, and, specifically, what design dimensions influence the understandability, usability, and behavioral impact of such displays. Prior research has demonstrated the potential of glanceable displays but has often yielded ambiguous results regarding design specifics. For instance, in the *UbiFit Garden* study, researchers found that a stylized virtual garden wallpaper effectively supported physical activity over 3 months [10], and the *BeWell* system successfully used animated sea creatures to represent sleep and social contact [12]. However, in other studies, such as *Gardy* [11], researchers found that highly stylized displays (eg, growing trees and mushrooms) were less effective than lower-stylized versions. Qualitative data from *Gardy* suggested that the issue might not have been stylization itself, but rather a lack of granularity—the inability of users to extract accurate progress data from the image. Because previous designs have varied across multiple dimensions simultaneously, it remains unclear how different dimensions of glanceable displays individually impact the understandability and usability of health feedback.

This question is particularly important in the context of smartwatch displays, which are constrained by the small screen size, the need to display time clearly first and foremost, and the very brief interactions with the feedback. To optimize the design of smartwatch-based feedback displays so that these displays can effectively support health-behavior change and be sufficiently well-liked so users are willing to keep them on their watches, we need better evidence for how different aspects of the feedback design affect how they are perceived and used.

In this paper, we report on a web-based factorial experiment with 202 participants that aimed to begin filling this knowledge gap by systematically examining the influence of 3 design dimensions—granularity of feedback, its salience, and whether the feedback is stylized—on the effectiveness of a smartwatch-based glanceable display to communicate progress on a daily step goal. Representing progress on health goals—for physical activity, sleep, diet, etc—is a common use of feedback displays on smartwatches, so the findings from our study may be applicable to other domains of health behavior change beyond physical activity.

On a methodological note, while our simulation-based study could not examine the impact of the tested design dimensions on behavior change—a research question that would require a field experiment—the size of the study, which was powered to detect small effect sizes, enabled us to examine perceptual properties and subjective judgments of the tested design dimensions with a level of rigor that could not be achieved in small-scale field deployments that are feasible for early-stage design research. As such, this study presents an example of resource-efficient optimization research that is increasingly advocated for in health and behavioral sciences [13-15].

Methods

Overview

To begin to understand how design affects usability and effectiveness of glanceable displays, we conducted an online simulation-based experiment that manipulated 3 design dimensions of glanceable feedback displays: stylization, salience, and granularity. In the experiment, stylization and salience were crossed in a 2×2 factorial structure, while granularity was varied across multiple levels, ranging from showing progress in 1% to 20% increments. A total of 202 Amazon Mechanical Turk (MTurk) participants were randomly assigned to 1 of 16 interface conditions. In each condition, participants were presented with a smartwatch display showing feedback on progress toward a daily step goal and were asked to estimate the level of progress that was shown.

The primary aim of the study was to investigate how the design dimensions influenced users' accuracy in assessing goal progress displayed on a smartwatch at a glance. The primary outcome was the error in participants' estimates of the displayed progress. A secondary aim was to examine how each design dimension affected perceived usability and acceptability.

Rationale for the Use of an Online Simulation-Based Experiment

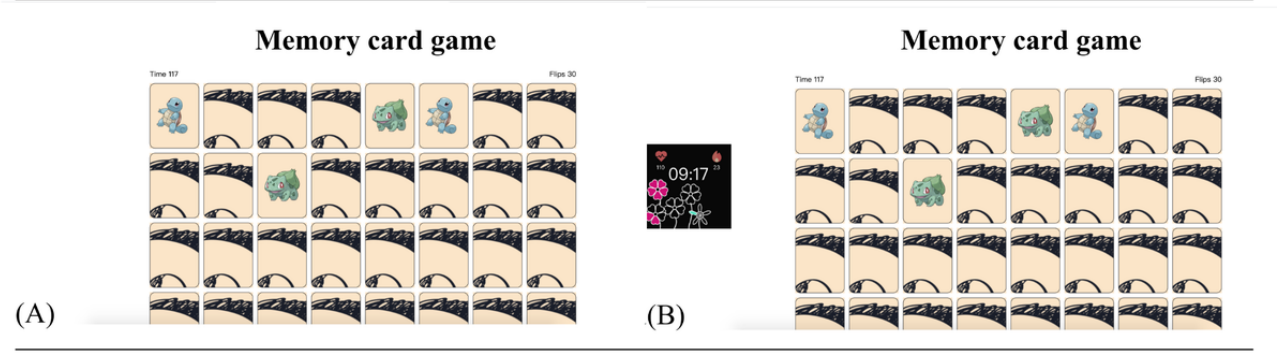
Given our goal of systematically evaluating the impact of design variations on users' ability to rapidly comprehend step goal progress at a glance, we opted to conduct an online simulation-based experiment. Like any research methodology, this approach presents a set of trade-offs. Its most obvious

XSL•FO
RenderX

limitation is the lack of ecological validity—the fact that participants did not interact with a real smartwatch in their natural environments. However, given our research question, this limitation is less critical than it might first appear, and it is made up for by the method's advantages, including feasibility and scalability. Our rationale for using an online experiment was threefold.

First, the primary question addressed by this study is how variations in design influence participants' ability to accurately perceive the level of progress toward a goal. This question concerns visual perception (ie, the ability to perceive small differences between representations) and interpretability of different types of visualization (ie, the ability to tell what the feedback display is trying to show). Such questions have routinely been studied using surveys and online experiments, including in the context of graphical representations for communicating health risks and results from medical tests [16-21]. Importantly, for our research question, an online experiment provides a *conservative* measure of the potential impact of different feedback designs, since participants are able to focus their attention on the experimental task without the distraction of other tasks that may interfere with how accurately they perceive feedback in the midst of everyday life.

Second, an online experiment enabled us to feasibly study the impacts of design with a high level of statistical rigor. Because we were concerned that small details of each design could impact performance in unforeseen ways, we created a total of 16 different interfaces. Since we expected the differences in objective performance across interfaces to be fairly small, we determined that over 200 participants would be needed to estimate these effects (power calculations are presented below), and that such a number could only be reasonably obtained by using an online platform such as Amazon MTurk. Conducting an equivalent study in the field would be prohibitively expensive, with the time and resource costs far outstripping the importance of the research question the study was trying to answer.



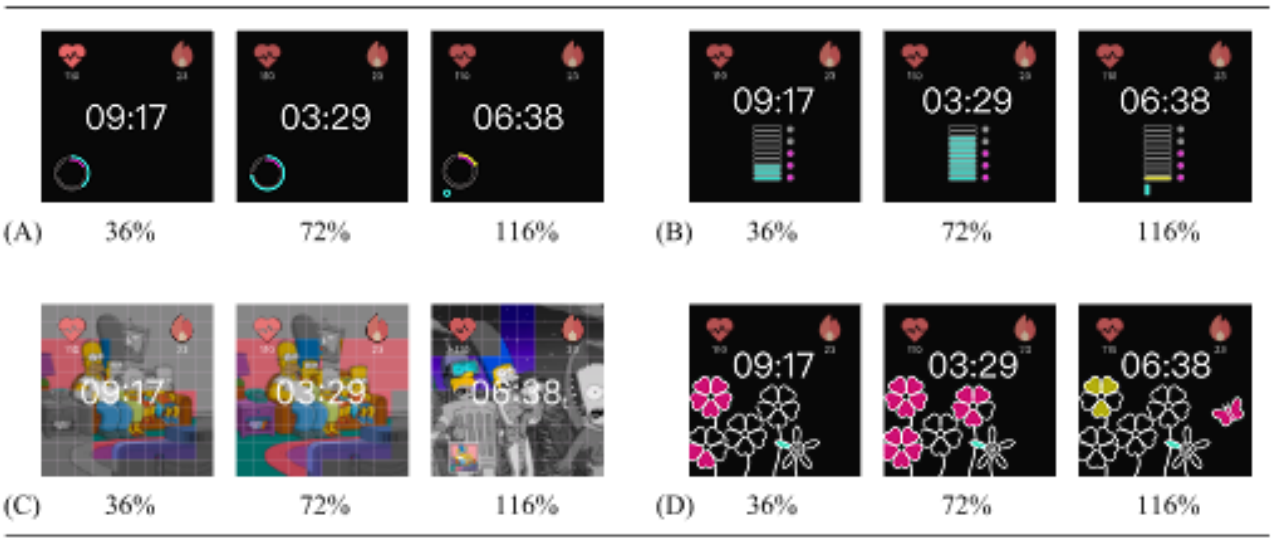
Third, using a simulation greatly facilitated our measurement approach. To measure user performance, we needed to compare participants' estimates of their step goal progress to a "true" value; in addition, we needed to be able to ensure that participants were making a reasonable effort to adhere to the study procedures. Given this need for the objective "ground truth" for comparison and to know the precise state of the watch display when the participant was engaging with the experimental task, we determined that a simulation was necessary. Controlling the "glancing" behavior in the wild would be impossible, and while moderated sessions in a user testing laboratory could have been used in place of a simulation, they would not allow us to scale effectively without huge expenses that would not be merited by the expected significance of the results.

Experimental Task

To frame the overall experiment, participants were told that they had recently bought a smartwatch, and they were using it to track their steps as they tried to increase their activity and walk 10,000 steps per day. Each experimental task was further set up with a brief scenario: participants were told that they had an important video call in a few minutes and that while they were waiting for the meeting to start, they decided to play an online game of Memory. To make sure they were not late for the meeting, they were asked to tap the spacebar a few minutes after they started playing the game to check the time, as they were told that the simulation time did not flow at the same rate as real-world time.

Tapping the spacebar brought up an image of a smartwatch that displayed time and step-goal progress using the design for the condition to which the participant was randomized. The image of the display was sized to approximate the size of a smartwatch viewed from a foot and a half (50 cm) away, the approximate distance of the wrist from the eyes when a person looks at a watch. The smartwatch image remained on the screen for 5 seconds, after which it was hidden to mimic the act of putting the arm down (Figure 1). As soon as they saw the time and activity progress, participants could resume playing the game (ie, the game remained active even while the smartwatch display was showing) in order to mimic the return to the primary task after glancing at a watch. Overall, 15 seconds after the smartwatch display was hidden, the game was interrupted, and participants were shown a 2-question questionnaire asking them to report (1) the time they saw on the display and (2) the percentage of completion of the daily step goal shown on the watch.

Figure 1. (A) Web screen without the display. (B) Web screen with the display.



XSL•FO
RenderX

Study Procedures

All study procedures were hosted on a study website, which was linked from the task we created on the Amazon MTurk platform. When they entered the study website, participants were presented with consent information that described the study procedures, after which they were presented with a brief training that explained the display design for their assigned condition. After reading the training material, participants were given a training task where they were asked to estimate the progress on the daily step goal shown on the display that used their assigned design. After they entered their estimate, the system provided the correct answer to further assist with learning how to interpret the display accurately.

Following the training, participants were presented with 3 experimental tasks. Each experimental task followed the structure outlined in the *Experimental Task* section. However, each scenario was contextualized to represent a different time of day—morning, midday, or afternoon—and featured a distinct level of step-goal completion when the smartwatch was displayed (Figure 2). After they completed all 3 experimental tasks, participants were asked to complete a questionnaire that assessed their perceptions of the usability and interpretability of the smartwatch display they used in the experiment.

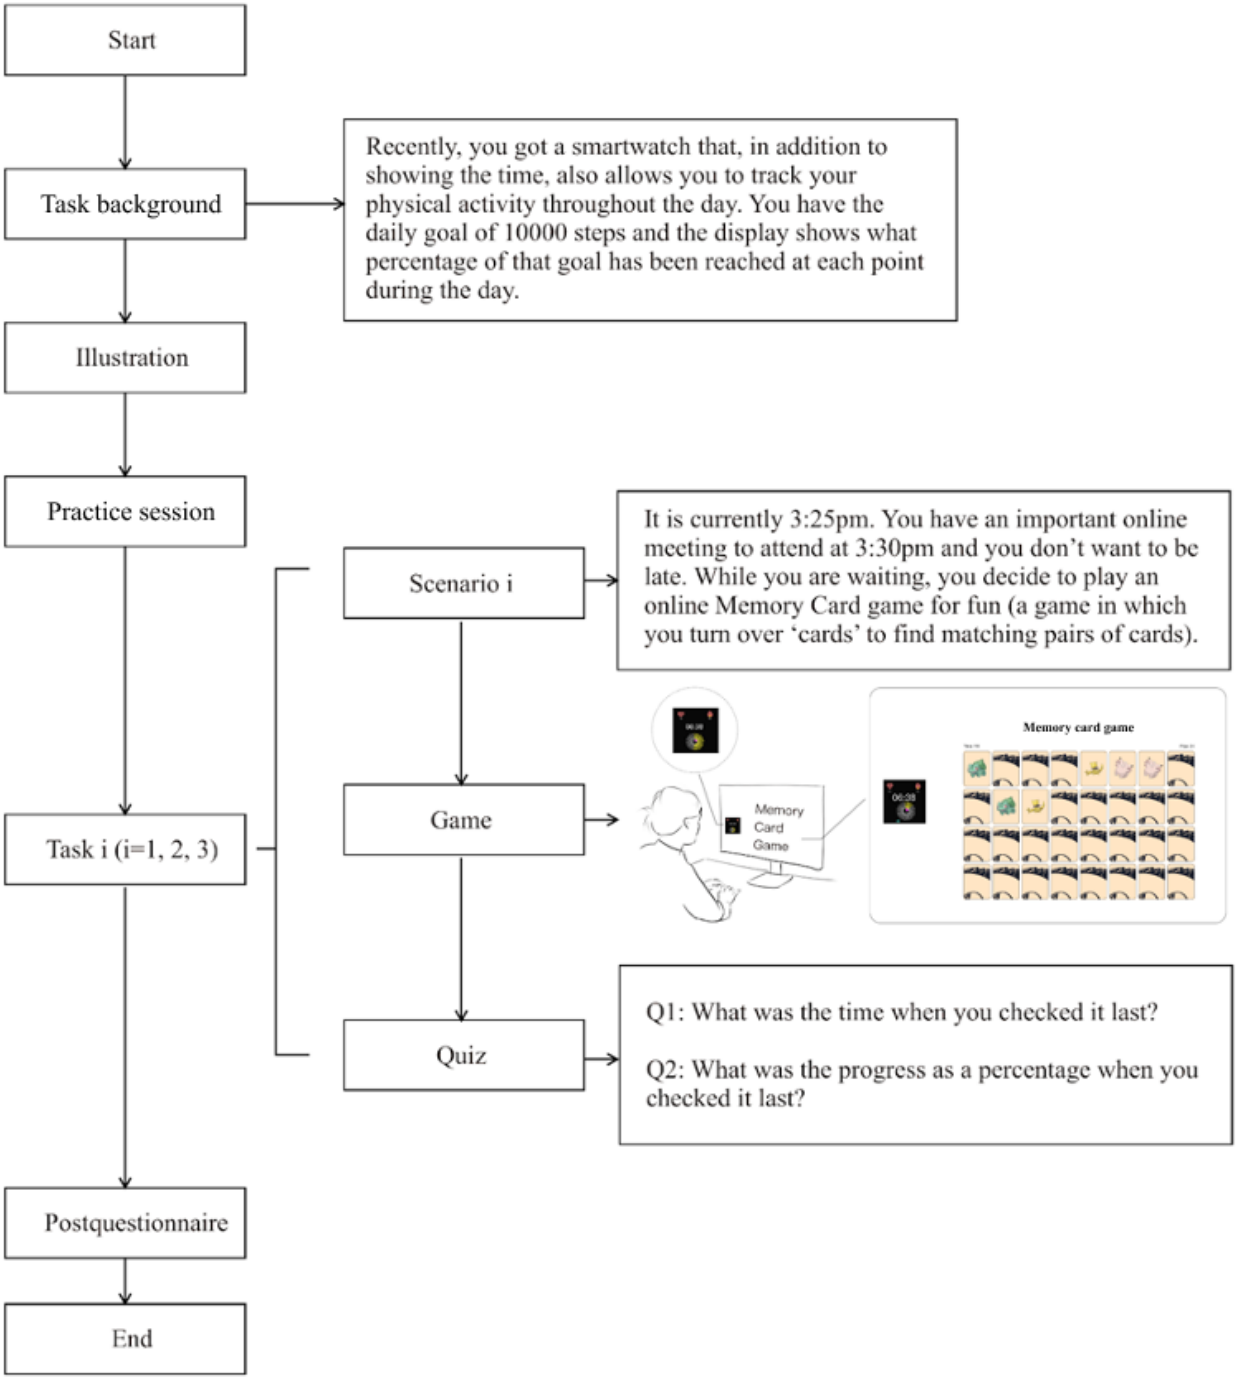


Figure 2. Four example displays shown at different times of day (morning, midday, and afternoon), each paired with varying levels of step-goal completion. Practice sessions were provided to help participants learn how to interpret the progress indicators. (A) Panel E in Figure 4: 1% increments. Progress turns from blue to yellow at 100%, with a small blue circle added when the goal is exceeded (eg, 116%). (B) Panel C in Figure 4: 10% increments. At 36%, 3 bars are filled. Upon overreaching the goal, the color changes to yellow and a small blue bar appears. (C) Panel N in Figure 4: 1% increments. A grayscale Simpsons image gradually regains color square by square. Exceeding the goal triggers a new image, and a small completed image appears below. (D) Panel K in Figure 4: 5% increments. Each pink flower has 5 petals; only full 5% units are shown. Beyond the goal, the flower turns yellow, and a pink butterfly appears.

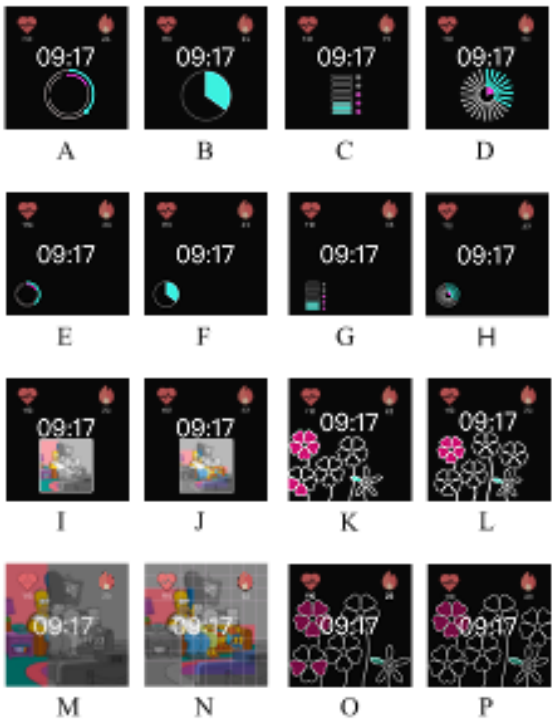
After they submitted the questionnaire, participants were issued a code that they could enter in the MTurk task form to request payment for completing the task. Participants were compensated US $2.50 for completing the experiment. The compensation was chosen to match a US $15/hour wage, adjusted for the duration of the task (~10 minutes). The full flow of the experiment is shown in Figure 3.

XSL•FO
RenderX

Figure 3. Study flow depicting participants' progress through the training session, 3 experimental tasks, and the poststudy questionnaire.



Intervention

Overview

The main manipulation in the experiment was the design of the display shown to each participant. We designed 16 unique interfaces by varying 3 design dimensions: stylization (low, high), salience (low, high), and granularity (1%, 4%, 5%, 10%, 20%). Stylization and salience were manipulated at 2 levels each, while granularity varied across 5 uneven levels (Figure 4). The design dimensions tested in the experiment were as follows:

XSL•FO
RenderX

Figure 4. A total of 16 unique interfaces used in the study: (A) Apple Watch–inspired design using a progress circle that directly reflects the current value. (B) Apple Watch-inspired design using the pie chart that directly reflects the current value. (C) Ten horizontal bars, each representing 10% progress (eg, 36% colors 3 bars and 72% colors 7 bars). (D) Bars arranged in a circle, each representing 4% (eg, 36% colors 9 bars and 72% colors 18 bars). (E-F) Low-salience versions of panels A and B, with reduced size. (G-H) Low-salience versions of C and D, with reduced size. (I) A Simpsons figure progressively colored from left to right in 1% increments. (J) Simpsons figure divided into 100 squares; each 1% of progress colors 1 square. (K) Flower petals representing 5% each (eg, 36% of progress colors 7 petals and 72% colors 14 petals). (L) Whole flowers representing 20% each (eg, 36% of progress colors 1 flower and 72% colors 3 flowers). (M-P) Low-salience versions of panels I-L, featuring reduced saturation and brightness, along with increased transparency.

interface	stylization	salience	granularity

M,N	high	low	1%
O	high	low	5%
P	high	low	20%

Stylization

Stylization refers to the use of "signs that have an intermediate degree of transparency to the signified object" [9]. In mobile health, stylized feedback is sometimes used to obscure the nature of the metrics that are being tracked, in order to display health information on displays that may be visible to other people while maintaining user privacy. We used metaphors, such as the use of flowers as iconic signs, to signify the information in the feedback displays. We chose to test stylization due to its potential to increase engagement, as high-stylized displays can be designed to be attractive and can be highly customizable [22]. In addition, high-stylized displays can be privacy-preserving, making them a good match for displaying feedback on sensitive types of health information. On the other hand, interpreting high-stylized displays requires learning, and they may not be as precise for displaying progress as graphs commonly used for data visualization. In our experiment, low-stylized displays used standard graphical formats such as bar charts, pie charts, or circles (eg, panel A in Figure 4). The selection of these charts aligns with prior research in glanceable displays, as these formats are efficient for rapid information retrieval and quick understanding on smartwatches [23-25]. High-stylized displays (eg, panels J and O in Figure 4) incorporated more expressive visuals, including cartoon characters and flowers. Inspired by the customizable cartoon interfaces on the Apple Watch, such as Snoopy, we chose pictures from "*The Simpsons*"—a widely watched cartoon in the United States—to represent progress in the high-stylized condition. Additionally, drawing inspiration from the *Ubifit Garden* [26], we used flowers as an alternative high-stylized representation to design a visually engaging form of feedback.

Granularity

Granularity refers to the size of the increment used to display progress. High-granularity feedback can represent small changes (eg, each 1% of goal attainment), while low-granularity feedback represents larger increments (eg, every 10% or 20% of progress). Due to the small size of the smartwatch screen and the need to display multiple pieces of information, including time, designers may be tempted to design smartwatch feedback that uses lower data granularity in order to satisfy aesthetic considerations and feedback readability. On the other hand, high-granularity feedback has been shown to aid progress estimation and increase physical activity motivation [27,28].

To evaluate these effects, we selected 5 granularity levels: 1%, 4%, 5%, 10%, and 20%. These levels are not evenly spaced, as they are exploratory design choices based on our design inspirations and established user interface paradigms in the wearable market. The 1% granularity level represents the high-precision displays found in Apple Watch and Garmin designs, where progress is mapped to exact pixel or degree

XSL•FO
RenderX

movements. The 4%, 5%, and 10% levels reflect common progress bar increments found in Fitbit interfaces (eg, progress lights in the Fitbit Flex), where progress is often discretized into "steps" or blocks to enhance glanceability. Finally, the 20% level was inspired by HCI designs such as the *UbiFit Garden* [26], which uses discrete icons (eg, 1 flower) to represent the completion of a significant sub-goal. We chose the 20% step for this purpose as it represents a moderately large increment (ie, 1/5th) commonly used to represent goal progress.

Salience

Salience refers to the degree to which a stimulus captures attention by standing out from its environment. Rather than being a single attribute, salience is a composite of visual factors—such as contrast, size, and positioning—that determine how much "attentional grab" a display exerts [29-31]. Salience is known to influence the perception of peripheral displays [32], yet operationalizing this concept for smartwatch interfaces proved nontrivial, as different design styles required different levers to manipulate user attention.

For low-stylized displays, which used standard graphs, we operationalized salience primarily through size and chart position [29]. High-salience interfaces featured progress feedback centered on the screen at a height exceeding 100 points, demanding immediate focus. Conversely, low-salience versions used a complication style—placed in the screen's corner at a height of 60 points—following Apple Watch Human Interface Guidelines. Here, the reduced size and peripheral placement minimized the display's ability to easily compete for the user's attention vs the time display.

The operationalization became more nuanced for high-stylized interfaces, where simply shrinking the designs would have rendered them unreadable due to their visual complexity. Instead, salience was manipulated by varying the relationship between the representation and the background. The high-salience condition used a centrally positioned 128-point display that remained a distinct, foreground element (eg, panel I in Figure 4). In contrast, the low-salience condition used a 300-point display that covered the entire screen but was designed to recede into the background (eg, panel M in Figure 4). By reducing the saturation and brightness while increasing transparency, this larger display was made less visually prominent to avoid distracting from the watch's primary timekeeping function.

Randomization

When they entered the experiment, each participant was automatically randomized, with the probability of 1 out of 16 (6.25%), to 1 of the 16 experimental designs of progress feedback. All instructions for interpreting the display, the test session at the start of the experiment, as well as each of the 3 experimental tasks used the feedback design to which the participant was randomized.

Each participant completed 3 experimental tasks that used different levels of step-goal progress: 36%, 72%, and 116%. The numbers were chosen to represent low, moderate, and goal-met-and-exceeded progress on the daily step goal, and to not be round, easily guessable numbers. To control for order effects, the order of the 3 tasks was randomized for each participant. This meant that, for instance, a participant may see the interface that represents 116% goal attainment first, followed by interfaces that show 36% and 72% goal attainment. Each level of progress was shown to each participant only once.

Measures

The objective of our study was to find out how the tested design dimensions affect the ability of participants to accurately assess the smartwatch progress feedback display at a glance. Consequently, our primary outcome was the absolute error of the participants' progress estimates, calculated as the absolute difference between the progress estimate and the true progress value, which allowed us to assess the overall accuracy of participants' ratings without taking into consideration whether their ratings were above or below the true value of the goal progress.

Our secondary outcomes included the self-reported ratings of the displays' usability and usefulness. These were assessed using a questionnaire that participants completed after they completed all 3 experimental tasks. The questionnaire was based on the System Usability Scale [33] and a questionnaire used by Shami et al [34] to assess the perceived strengths and weaknesses of glanceable displays. The constructs assessed and the questions used are shown in Textbox 1. Questions Q6-Q7 and Q12-Q14 were adapted from the System Usability Scale; questions Q1-Q5 and Q8-Q11 (except Q10) were adapted from Shami et al [34]. All questions were assessed on a 5-point Likert scale that ranged from *strongly disagree* to *strongly agree*. Q10 was an attention check question that we used to filter out Amazon MTurk workers who were answering questions without paying even minimal attention.

XSL•FO
RenderX

Textbox 1. Poststudy questionnaire. Constructs and corresponding question items are listed below.

Noticeability

- Q1: I could easily notice the progress display.
- Q2: I could notice the change in my progress across 3 scenarios.

Comprehension

- Q3: I felt confident in being able to understand the information regarding my progress.
- Q4: I felt confident in being able to understand the information in the progress display just by glancing at it.

Relevance

- Q5: The display provided me with the information I needed to track my progress.

Complexity

- Q6: The smartwatch display showed too much distracting information.
- Q7: I found the smartwatch display unnecessarily complex.

Division of attention

- Q8: I was able to maintain focus on playing the game while checking the time and my progress.
- Q9: I was able to shift my attention between playing the game and checking the smartwatch display easily.

Attention check

- Q10: Please skip this question and move to the next one. This is just to screen out random clicking.

Attractiveness

- Q11: I found the design of the smartwatch display attractive.

Usability

- Q12: I think the way the progress was shown is useful.
- Q13: I think that I would like to use this smartwatch display on an ongoing basis.
- Q14: I would imagine that most people would learn to use this system very quickly.

Statistical Analysis

Sample Size and Power

The study was powered to detect the main effects of the 3 design dimensions on the primary outcome, the absolute value of the error in progress ratings. While we could not find any existing literature that would readily provide data on the sizes and distributions of the likely effects for the measure we were interested in, we started with the data from the work of Gouveia et al, who designed 21 glanceable displays for showing activity progress [1]. To derive a functional baseline, we examined their *Goal Completion* condition (mean 5340, SD 4528), which emulates established commercial standards (eg, Fitbit Flex), and compared it against their most divergent design, the *Gardy* condition (mean 3760, SD 3511). Using the pooled standard deviation method, this comparison yielded an estimated effect size of approximately d=0.39. However, to remain conservative and ensure the study could detect even subtler differences between our own design iterations, we assumed a small effect size of d=0.2. Further, we assumed a moderate, 65% correlation between repeated measures. With 90% power and the alpha level set to .05, the required sample size was 204.

Analysis

For the analyses of the progress estimation error rates, we used the generalized estimating equation (GEE), which is an extension of linear regression that takes into account the nested nature of repeated-measure data. Given that stylization and salience had 2 levels, but granularity had 5 levels, we estimated the main effects for stylization and salience in a single model, as is typically done in factorial experiments, but we fit a separate model to estimate the effect of granularity. To improve model fit, in all analyses, the estimated error was square-root transformed—that is, the dependent variable was defined as:

Diagnostic plots for the GEE model were assessed to ensure valid statistical inference. The observed striations in the residuals vs fitted plot were confirmed to be artifacts of the discrete, integer-based nature of the raw data rather than model misspecification. The residual distribution confirms that the model appropriately accounts for the data structure.

To examine responses from the poststudy questionnaire, we first created scores for each construct measured by the questionnaire (ie, noticeability, comprehension, relevance,

XSL•FO
RenderX

complexity, division of attention, attractiveness, and usability) by averaging each participant's answers to the questions for that construct. We then fitted linear regression models that used these construct scores as dependent variables and indicators for the design dimensions as predictors.

In line with best practices for factorial experiments [35], models analyzing the stylization and salience design dimensions used effect coding to code design-dimension indicators. With effect coding, 1 level of a factor (eg, high-salience) is coded as +1, and the other level of the factor (eg, low-salience) is coded as –1 in the models. The use of effect coding enables a marginal interpretation of the main effects for each factor: if the β coefficient for a particular design dimension (eg, salience) is found to be significant, that finding can be interpreted as indicating that that design dimension has an impact on the dependent variable (accuracy of progress estimation, usability, etc) averaging across other tested factors and other measured and unmeasured influences.

Eligibility, Recruitment, and Data Integrity Verification

Recruitment was done through the Amazon MTurk platform. We created an MTurk task that linked to the study website that hosted the experiment. Eligible participants were required to be 18 years of age or older and could take part in the experiment only once. Attempts at participating more than once were recognized based on the MTurk worker ID and were filtered out prior to the data analysis.

To ensure high data quality—MTurk workers sometimes click through a task to get paid without actually engaging with the task [36,37]—prior to conducting the experiment, we developed 2 attention checks that we used as criteria for *a priori* exclusion of participants from the dataset. The first check used a metric called string edit distance [38], which measures the similarity of 2 strings in terms of the number of operations (insertions, deletions, etc) that are required to transform one string into the other. In our pilot work, we found that the edit distance of 2 effectively identified responses to the goal-progress estimation that were clearly fallacious (eg, the same number was provided as an answer to all 3 experimental tasks). We, therefore, removed from the analytical data set all participants for whom the edit distance between their estimates of goal progress and the correct answer was greater than or equal to 2. The second exclusion criterion used the attention check question in the poststudy questionnaire (Q10 in Textbox 1). The question asked participants to skip the question and leave it unanswered. Participants who answered the question (ie, who clicked on any radio button on the Likert scale for that question) were excluded from the dataset.

The study protocol was approved by our university's Behavioral and Social Sciences Institutional Review Board.

Results

Participants Sample

We recruited 400 participants on Amazon MTurk, targeting adults who were interested in smartwatches and physical activity. Participants were recruited in 4 waves of 100 participants each. Each wave of recruitment was followed by the exclusion of participants who violated one of the criteria for data integrity validation. We would then start the next wave if the required number of participants had not been reached.

After applying data integrity criteria, 202 participants remained in the final dataset. Of these, 35.64% (n=72) identified as female. In terms of smartwatch usage, 29.2% (n=59) were current users, 38.61% (n=78) were former users, and 32.18% (n=65) had never used a smartwatch. The age distribution was skewed toward younger and middle-aged adults. The largest age group was 25-34 years (n=87, 43.07%), followed by 35-44 years (n=57, 28.21%) and 45-54 years (n=33, 16.34%). Participants aged 18-24 years accounted for 6.93% (n=14) of the sample, while those aged 55-64 years and older comprised 3.47% (n=7) and 1.98% (n=4), respectively.

Stylization Negatively Affects the Accuracy of Progress Assessment

Table 1 presents the results of the GEE analysis examining the effects of salience and stylization on the accuracy of participants' goal-progress estimates. Since the outcome variable was square-root transformed, the reported β coefficients should be squared to interpret effects on the original scale. To make the results interpretable, we note that the median absolute error across all conditions was 14 (IQR 4-47) points. Our findings indicate that stylization significantly reduces the accuracy of progress assessments. Compared to low-stylized representations, high-stylized ones led to an increase in error by 4.52 points, rising from 8.98 for low-stylized conditions to 13.50 points for high-stylized conditions. We found no significant impact for salience, however.

Nonlinear Effects of Granularity on Estimated Absolute Error

Table 2 presents the results of a GEE analysis examining the effects of salience, stylization, and granularity on the accuracy of participants' goal-progress estimates. By including all 3 factors in a single model, we isolated the marginal impact of each variable. In this combined linear model, granularity demonstrated a marginally significant independent effect on estimation error (P=.08). However, because granularity was unevenly distributed across feedback designs—with half of the panels using the finest granularity level (1%)—and preliminary diagnostics suggested a nonlinear relationship, we conducted a follow-up analysis. As reported in Table 3, we used a model specifically parameterized with a quadratic term to account for this complexity. These results revealed a U-shaped relationship: error decreased as granularity *decreased*, up to a point, after which further decreases in granularity led to higher error.

Table 2. Generalized estimating equation model results examining the effects of stylization, salience, granularity, age, gender, and user status on the accuracy of progress estimates (square-root transformed outcome).

	Coefficient	SE	z	*P* value	95% CI
Intercept	3.230	0.541	5.973	<.001	2.170 to 4.290
Stylization	0.311	0.124	2.507	.01	0.068 to 0.554
Salience	–0.007	0.121	–0.056	.96	–0.248 to 0.226
Granularity	0.033	0.019	1.732	.08	–0.004 to 0.070
Age	0.020	0.012	1.652	.10	–0.004 to 0.043
Gender	0.034	0.124	0.272	.79	–0.210 to 0.278
Current user	0.254	0.335	0.759	.45	–0.402 to 0.911
Previous user	0.961	0.283	3.396	.001	0.406 to 1.515

Table 3. Generalized estimating equation model results examining the nonlinear effects of granularity on the accuracy of progress estimates (square-root transformed outcome).

	Coefficient	SE	*z*	*P* value	95% CI
Intercept	4.599	0.214	21.465	<.001	4.179 to 5.019
Granularity	–0.114	0.071	–1.599	.11	–0.254 to 0.026
Granularity squared	0.008	0.003	2.437	.015	0.002 to 0.015

We examined 5 levels of feedback display granularity: 1%, 4%, 5%, 10%, and 20%. Given that the outcome variable was square-root transformed, predicted values were squared to interpret error on the original scale. Decreasing granularity from 1% to 4% reduced the predicted error from 20.19 to 18.24, a decrease of 1.95 points. A further decrease in granularity from 4% to 5% resulted in a smaller reduction of 0.36 points, lowering the predicted error to 17.88 at the 5% granularity level. Transitioning from 5% to 10%, the error began to increase slightly, rising by 0.26 points to 18.14 at 10% granularity. When granularity decreased from 10% to 20%, the predicted error sharply increased by 12.32 points, reaching 30.46. These findings reveal a U-shaped relationship between granularity and error, suggesting that when feedback is presented on smartwatch-sized screens, moderate levels of granularity enhance accuracy, whereas high granularity and overly coarse representations hinder users' ability to estimate goal progress correctly.

According to the model, the optimal granularity level is around 7.1%. Since this value was not directly tested in our feedback designs, it suggests that the lowest predicted error would occur at a granularity level of 5% or 10%.

Stylization Negatively Affects Perception of Comprehension, Relevance, Complexity, Attention, Attractiveness, and Usability Ratings

As shown in Textbox 1, we grouped the subjective perception items from the postquestionnaire into 7 categories: noticeability, comprehension, relevance, complexity, division of attention, attractiveness, and usability. To examine the impact of stylization and salience on participants' subjective perceptions of the feedback displays, we conducted linear regression analyses.

Tables 4-9 present the results of the linear regression analyses examining the effects of stylization and salience on participants' perceptions of the interfaces, including comprehension, relevance, complexity, division of attention, attractiveness, and usability (see Table S1 in Multimedia Appendix 1 for the impact of stylization on noticeability). Perceptions were measured using a 5-point Likert scale across 7 categories. Stylization was found to negatively influence 6 of the 7 dimensions of user perceptions: comprehension, relevance, complexity, attention, attractiveness, and usability. When using high-stylized feedback designs, participants reported greater difficulty comprehending the information (–0.486 points; P=.003), perceived the interface as more complex (–0.690 points; P<.001), and felt that less relevant information was provided (–0.476 points; P=.002).

XSL•FO
RenderX

Additionally, they found it harder to maintain focus or shift attention between the interface and the game (–0.378 points; *P*=.022), and rated the interfaces as less attractive (–0.338 points; *P*=.047) and less usable (–0.532 points; *P*=.001).

10% Granularity Yields the Most Favorable Perceptions

Compared to modeling granularity as a continuous predictor, treating it as a categorical variable provided a clearer understanding of how different granularity levels impacted subjective responses. Tables 10-12 present the results of linear regression analyses examining the effects of granularity on participants' perceptions of the interfaces, including comprehension, complexity, and division of attention (see Tables S2-S5 in Multimedia Appendix 1 for the impact of granularity on noticeability, relevance, attractiveness, and usability).

Table 10. Linear regression analysis of the effects of granularity on comprehension scores (reference group: 1% granularity).

	Coefficient	SE	*t* test (*df*)	*P* value	95% CI

XSL•FO
RenderX

Table 12. Linear regression analysis of the effects of granularity on division of attention scores (reference group: 1% granularity).

	Coefficient	SE	*t* test (*df*)	*P* value	95% CI
Intercept	3.295	0.117	28.121 (197)	<.001	3.064 to 3.526
Granularity=4%	0.305	0.244	1.250 (197)	.21	–0.176 to 0.786
Granularity=5%	–0.390	0.281	–1.387 (197)	.17	–0.945 to 0.164
Granularity=10%	0.523	0.235	2.224 (197)	.027	0.059 to 0.987
Granularity=20%	0.038	0.300	0.128 (197)	.90	–0.553 to 0.630

Among the 5 granularity levels (1%, 4%, 5%, 10%, and 20%), the 10% granularity level yielded the most favorable perceptions. Relative to the 1% granularity group, participants in the 10% group reported the interface as easier to comprehend (+0.656 points; *P*=.003), less complex (+0.766 points; *P*=.005), and easier to maintain focus on (+0.523 points; *P*=.03).

To further evaluate the performance of the 10% group, we reran the analysis using the 10% group as the reference category (Tables S6-S12 in Multimedia Appendix 1). Consistent with the previous comparison, we found that participants in all other granularity groups rated the feedback designs as harder to comprehend (1%: –0.656; *P*=.003; 4%: –0.591; *P*=.04; 5%: –1.091; *P*<.001; 20%: –0.702; *P*=.03). Participants in the 1% (–0.766 points; *P*=.005) and 5% (–1.195 points; *P*=.002) groups also perceived the feedback designs as more complex compared to the 10% group. Similarly, participants in the 1% (–0.523 points; *P*=.03) and 5% (–0.913 points; *P*=.006) groups found it more difficult to maintain focus, compared to the 10% group. Additionally, compared to the 10% group, participants in the 5% group perceived the feedback design as harder to notice changes in (–0.634 points; *P*=.024), less informative (–0.779 points; *P*=.009), and less useful overall (–0.848 points; *P*=.006).

Effects of Smartwatch Experience on Accuracy and Subjective Perceptions

Prior smartwatch experience was associated with decreased accuracy in progress assessment. As shown in Table 1, compared to people who have never used a smartwatch before, being a previous smartwatch user—but not a current user—increased the error by approximately 7.46 points, with the error rising from 11.13 to 18.59 points (median absolute error 14, IQR 4-47 points).

Despite exhibiting lower accuracy in progress estimation compared to participants who had never used a smartwatch, previous smartwatch users reported more favorable subjective perceptions across several measures. As seen in Tables 6, 8, and 9, compared to participants who had never used a smartwatch, previous smartwatch users found the interface easier to maintain focus on (+0.874 points, *P*<.001) and more useful (+0.566 points, *P*=.002). However, they also perceived the feedback displays as more complex, rating them 0.754 points lower in simplicity *P*=.001). In Table 13, compared to current smartwatch users, previous smartwatch users also perceived the feedback design as harder to notice changes in (–0.773 points, *P*=.001).

Table 13. Linear regression analysis of the effects of stylization and salience on noticeability scores (reference group: current smartwatch user).

	Coefficient	SE	*t* test (*df*)	*P* value	95% CI
Intercept	3.253	0.407	8.003 (195)	<.001	2.452 to 4.055
Stylization	–0.689	0.184	–3.745 (195)	<.001	–1.052 to –0.326
Salience	0.061	0.180	0.339 (195)	.73	–0.294 to 0.416
Age	0.004	0.009	0.426 (195)	.67	–0.014 to 0.021
Gender	0.168	0.190	0.885 (195)	.38	–0.207 to 0.544
Never used user	–0.019	0.229	–0.084 (195)	.93	–0.472 to 0.433
Previous user	–0.773	0.224	–3.449 (195)	.001	–1.215 to –0.331

Current smartwatch users did not show significant differences in accuracy compared to participants who had never used a smartwatch, but reported more positive subjective perceptions. Specifically, as seen in Table S1 in Multimedia Appendix 1, Tables 7 and 9, they rated the feedback designs as easier to notice changes in (+0.354 points; *P*=.053), easier to maintain or shift attention (+0.559 points; *P*=.007), and more useful (+0.512 points; *P*=.007), all on a 5-point scale.

Discussion

Principal Results

Our study examined how variations across 3 design dimensions—stylization, salience, and granularity—influenced participants' ability to interpret glanceable smartwatch feedback displays.

Results showed that high stylization negatively affected the accuracy of progress assessments. Regarding granularity, levels of 5% and 10% could be seen as a sweet spot, resulting in lower interpretation errors. Participants in the 10% granularity group

XSL•FO
RenderX

also reported more favorable subjective perceptions compared to those in other granularity conditions. Salience did not influence either the accuracy of interpreting progress or participants' subjective perceptions.

Interestingly, participants who had previously used a smartwatch but were no longer actively using one performed worse in assessing progress compared to those who had never used a smartwatch. However, both previous and current smartwatch users reported more positive subjective evaluations of feedback displays than participants who had never used a smartwatch.

Increased Interpretation Errors Caused by Stylization Present Design Trade-Offs

Our results indicate that high stylization negatively affected interpretation accuracy, increasing progress errors by 4.52 points. This finding should be considered alongside several factors that may influence the real-world viability of stylized displays. First, the observed accuracy gap might narrow with increased familiarity; while our study used a brief practice period, long-term use of a specific stylized interface could result in users learning to better interpret its visual patterns, potentially improving performance over time. Second, stylization may serve as a privacy-preserving layer, offering users a degree of discretion by preventing onlookers from easily discerning personal data. Third, the aesthetic qualities of such interfaces might boost user engagement and check frequency, which could enhance overall effectiveness [22,39,40].

In contrast, low-stylized displays are preferred when feedback precision is critical for decision-making. This is particularly relevant in safety-critical contexts or data-driven health management, such as monitoring blood glucose levels [41] or tracking caloric balance. In these scenarios, the requirement for high levels of precision makes stylized feedback a suboptimal choice. Ultimately, the use of stylization involves a trade-off between the necessity for interpretative accuracy and the user's potential preference for discretion and aesthetic engagement.

Finding the Sweet Spot in Granularity for Glanceable Displays

We found that the relationship between granularity and accuracy in progress assessment is nonlinear. Accuracy initially increases as granularity decreases (eg, from 1% to 5%), but the rate of increase slows down between 5% and 10% and then reverses direction. This pattern indicates the presence of an inflection point—an optimal granularity level, estimated at 5%-10% in our data—at which accuracy peaks. Beyond this point, accuracy declines as granularity increases further.

These results are not completely unexpected, as there are situations where high levels of feedback granularity may not be helpful. For instance, in very small feedback displays, such as smartwatch complications, feedback granularity can quickly exceed users' ability to visually discriminate between states of the display. In such situations, a lower-granularity display may more effectively convey changes in the state through more easily perceived jumps than a high-granularity display. Similarly, in many contexts, there are limits to the level of granularity that is needed for decisions. For instance, Hawley et al [16] and Zikmund-Fisher et al [20] found that variations in the granularity of the graphs about the risk of taking different medications did not have a significant impact on people's choices of which medicine to take. The researchers used n-in-100 (ie, among 100 people, the number of people who have side effects) as low granularity and n-in-1000 as high granularity. Their results indicated that when the level of granularity met the upper limit of the demand, participants' assessments became unaffected by further increases in granularity.

Our result shows that the sweet spot for goal-progress feedback displays may be at 5% or 10% granularity, which aligns with previous research. For instance, Kong et al [42] observed that participants estimating the proportion between 2 rectangles (displayed in a constrained space) tended to round their answers to multiples of 5. Our results showed the same tendency—participants frequently reported progress estimates in multiples of 5. This suggests that interfaces designed with 5% or 10% granularity may support faster and more accurate assessments, as users can more easily map perceived progress to familiar reference points.

Taken together, these results suggest that pursuing very high granularity does not necessarily improve users' ability to notice changes or make informed decisions. Conversely, very low granularity may increase errors in progress assessment and fall short in contexts where greater precision is required [41]. A granularity level of 5% or 10% appears to strike an effective balance—supporting precision, enabling users to notice changes, and reducing estimation errors.

Prior Use Followed by Abandonment May Reflect Interpretation Difficulties

Lastly, our results indicate that previous smartwatch users made more errors in perceiving progress compared to those who had never used a smartwatch. Specifically, their error was 7.46 points higher—representing the largest effect on interpretation accuracy observed in our study. While we are not sure why this discrepancy exists, one intriguing possibility is that people who are less effective at interpreting information displayed on smartwatches are more likely to abandon them. This possibility might be reflected in participants' subjective perceptions. Compared to individuals who have never used a smartwatch, previous smartwatch users rated the feedback display as more complex (–0.754 points; P=.001; Table 6). Even when compared to current smartwatch users, previous smartwatch users still perceived the feedback display as more complex (–0.773 points; P=.001; Table 13). However, as shown in Table 7 and Table 9, previous smartwatch users also found the interface more useful (+0.566 points; P=.002; Table 9) and reported it was easier to maintain focus while using it (+0.874 points; P<.001; Table 7). Current smartwatch users similarly rated the feedback display as more useful (+0.512 points; P=.007; Table 9) and easier to focus on (+0.559 points; P=.007; Table 7). Notably, current users did not report any statistically significant negative perceptions of the feedback display interface.

If this is the case, researchers who develop smartwatch-based interventions may want to use prior smartwatch use as a tailoring variable for providing additional training or using alternative forms of intervention feedback. Investigating how predictive

XSL•FO
RenderX

this variable is for other intervention effects could be an interesting avenue for future research.

Challenges in Operating Design Dimensions From Theories to Practices

Our experience in constructing these interfaces suggests a broader challenge regarding how to cleanly operationalize design dimensions when transitioning from theories to practical applications. While design dimensions such as granularity, stylization, and salience are conceptually distinct, their implementation in a real-world context like smartwatch displays may be inherently constrained by practical requirements.

For instance, the tension between exact estimations and low-granularity designs reflects the trade-off between accuracy and interpretability. For glanceable displays, while providing accurate data is important, designs need to remain interpretable to be efficiently accessed under cognitive load. While asking participants to estimate the range of progress might have aligned more naturally with low-granularity interfaces, using an exact estimation task across all conditions allowed us to observe how different designs influence this cognitive balance. This indicates that practical constraints can make it difficult to cleanly separate a single design dimension from its functional impact on performance. Another operationalization challenge for stylization and granularity is further discussed in the Limitations section.

These observations suggest that design dimensions that are theoretically distinct are often not orthogonal in practice. Operationalizing a single dimension in isolation, without accounting for these functional interdependencies, risks producing interfaces that are either visually incoherent or practically irrelevant.

Limitations

Methodological Limitations

As we note in the Method section, the main trade-off of our decision to use an online experiment involves sacrificing some ecological validity for the increased statistical rigor and feasibility of studying many design variations for feedback displays. One other notable limitation of the study is that it did not allow us to study additional questions about the influence of time and attentional context on display interpretation. In real-world use, over time, users are likely to learn how to interpret any (reasonable) type of feedback display. So, it is possible that the differences in interpretation accuracy we found in our study for unfamiliar displays would gradually decrease with repeated use. Similarly, how accurately a person interprets a feedback display at any given time is likely to have to do in part with why they are looking at the watch. If the person is in a hurry and just wants to see what time it is, they may not notice the feedback display at all. If they are trying to check goal progress, they would pay closer attention to the display. While our study was closer to the latter setting, carefully studying how exactly time and context affect feedback interpretation would require a different study design. Whether a simulation could still be used to study those processes is an interesting question that would be worthwhile for design researchers to consider. The answer will likely depend on the exact processes that are being studied and whether a simulation could incorporate the key factors hypothesized to influence those processes. Determining this involves thinking carefully about the causal processes that underlie the phenomenon of interest.

Design Space Constraints

Another limitation of this work concerns the interdependence of the design dimensions in practice. While we conceptually defined granularity, stylization, and salience as distinct factors, they were not always perfectly decoupled in our experimental stimuli. For instance, changes in granularity were occasionally tied to shifts in representation type, such as transitioning from a circular progress ring to a segmented bar chart to accommodate higher data resolution.

This confounding reflects a considered trade-off between experimental control and the practical applicability of the stimuli. Given the exploratory nature of mapping this design space, we aimed to present participants with functional and coherent interfaces that mirror the types of glanceable displays that can be used in everyday contexts. Strictly isolating a single dimension by increasing granularity without adjusting the visual representation could have resulted in artifacts that were visually awkward or practically illegible. While this approach prioritized the holistic integrity of the designs, we acknowledge that it limits our ability to isolate the independent impact of each individual dimension. Future work could build on these findings by employing more constrained experimental setups to further disentangle these interconnected factors.

Conclusions

In this paper, we presented a study that tested 16 glanceable feedback displays to examine the effects of 3 design dimensions—stylization, salience, and granularity—on the accuracy of progress assessment. Our findings show that stylization negatively affected both the accuracy of assessing goal progress and perceptions of comprehension, relevance, complexity, attention, attractiveness, and usability. In contrast, granularity levels of 5% and 10% may be optimal for displaying smartwatch feedback. We found no significant differences between high-salience and low-salience interfaces in terms of interpretive accuracy and subjective perceptions. Interestingly, participants who had previously used a smartwatch but were no longer using one exhibited larger errors in interpreting progress feedback. However, both previous and current smartwatch users reported higher subjective perceptions compared to those who had never used a smartwatch. Our results extend the research on glanceable feedback and can help researchers design effective glanceable smartwatch feedback displays.

Abstract

Background: Mobile health (mHealth) apps have become important tools for HIV/AIDS management. Although the Mobile App Rating Scale and its user version are widely used, how different stakeholder groups combine quality dimensions into overall judgments remains unclear. Discrepancies between researcher and patient evaluations may affect app adoption and clinical effectiveness.

Objective: This exploratory study aimed to compare configurational pathways associated with high subjective quality ratings of HIV/AIDS apps between researchers and patients using fuzzy-set qualitative comparative analysis.

Methods: Twenty-one Chinese HIV/AIDS mobile apps from early 2023 were evaluated by 3 researchers using the original Mobile App Rating Scale and 2 HIV-positive patients using the user version of the Mobile App Rating Scale. Six conditions were examined: engagement, functionality, aesthetics, information quality, privacy protection, and developer type. Necessary and sufficient configurations were identified for both groups. Wilcoxon signed-rank tests compared raw ratings between groups. Sensitivity analyses covered 4 calibration anchor sets, 4 raw-consistency cutoffs, 4 proportional reduction in inconsistency cutoffs, and multivalue operationalization of privacy protection.

Results: Researcher and patient ratings differed significantly for functionality (median difference 0.50, IQR 0.00 to 0.63; P=.003) and engagement (−0.20, IQR −0.40 to 0.10; P=.04), but not for aesthetics (P=.16), information (P=.07), or subjective quality (P=.06). Five sufficient configurations were identified for researchers (solution consistency=0.981, coverage=0.649) and 4 for patients (solution consistency=0.998, coverage=0.796). Configurations including privacy protection appeared only among researchers; its absence appeared in 3 patient configurations, reflecting the rarity of protection in the sample (5/21 apps) rather than lower patient ratings for protected apps. For patients, functionality (0.907) and information quality (0.915) exceeded the necessity threshold but were strongly correlated (r=0.816), so functionality was retained on substantive grounds rather than as an independent necessary condition. Illustrative cases were Wu Ai Fang Hua and Ai Yi Jian for the researcher-oriented pathway and Chabei for the patient-oriented pathway. Sensitivity analyses left the configurations unchanged across all anchor sets and raw-consistency cutoffs; 1 researcher configuration did not survive the stricter proportional reduction in inconsistency cutoffs, and the patient necessity result was anchor-dependent.

Conclusions: The 2 evaluator panels' assessments of HIV/AIDS mHealth apps appeared to follow different configurational logic in this sample, with several equifinal pathways to high subjective quality in each group. Because the patient panel comprised 2 evaluators, and 21 apps were analyzed with 6 conditions, the findings should be read as hypothesis-generating rather than representative of people living with HIV. The findings nonetheless suggest that both expert and end-user perspectives are needed during mHealth development, and that, because privacy protection was rare and not required for a favorable patient judgment, its provision in a population highly vulnerable to disclosure-related harm needs to be ensured by developers and regulators rather than left to user demand.

KEYWORDS

HIV/AIDS; mobile health; mHealth; app quality; fsQCA; patient evaluation; MARS; uMARS; qualitative comparative analysis; fuzzy-set qualitative comparative analysis; Mobile App Rating Scale; user version of Mobile App Rating Scale

Introduction

Background

The global HIV/AIDS epidemic continues to pose significant public health challenges, with approximately 39 million people living with HIV worldwide as of 2022 [1]. Mobile health (mHealth) apps have emerged as innovative tools to support HIV prevention, treatment adherence, and self-management [2,3]. These digital interventions offer potential benefits including improved medication adherence, enhanced patient-provider communication, and increased access to health information [4,5]. Health app use is now widespread, but the behavioral functionality actually implemented in these apps varies widely [6,7].

The quality of mHealth apps is crucial for their effectiveness and user adoption [8,9]. Various stakeholders, including researchers, health care providers, and patients, evaluate app quality from different perspectives, potentially leading to divergent assessments [10]. Researchers typically use standardized evaluation frameworks emphasizing technical functionality, evidence-based content, and privacy protection [11,12]. In contrast, patients may prioritize usability, engagement features, and personal relevance [13,14].

The Mobile App Rating Scale (MARS) has become a widely adopted tool for assessing mHealth app quality across 4 dimensions: engagement, functionality, aesthetics, and information quality [15]. The user version of the Mobile App Rating Scale (uMARS) was subsequently developed to enable end users to evaluate apps from their own perspective [16,17]. While both versions provide comprehensive evaluation frameworks, they do not explicitly address how different evaluator groups weight these dimensions or how they combine to produce overall quality judgments. In HIV/AIDS care, this omission is consequential, because apps in this field must simultaneously deliver clinical utility and protect a health status that carries a high risk of stigma and discrimination [18,19].

Theoretical Framework

Overview

Three complementary theoretical perspectives motivate the comparison undertaken here and were used to select conditions and to interpret results.

Task-Technology Fit and Technology Acceptance

Task-technology fit theory holds that a technology improves performance to the extent that its capabilities match the requirements of the user's task [20]. The unified theory of acceptance and use of technology (UTAUT) and its consumer extension (UTAUT2) further specify performance expectancy, effort expectancy, and hedonic motivation as proximal determinants of use intention [21,22]. For a person living with HIV, the salient tasks are concrete: booking an anonymous test, obtaining reliable information, tracking medication. Performance expectancy and effort expectancy therefore map closely onto the MARS functionality and engagement dimensions and predict that these should dominate patient judgments. Researchers, who rate apps without a personal task to accomplish, are instead trained to apply normative criteria, so their judgments should weight information quality and safeguards more heavily.

Privacy Calculus and the Privacy Paradox

Privacy calculus theory models disclosure as a trade-off in which anticipated benefits are weighed against perceived risk [23]. The trade-off is systematically asymmetric when risks are abstract and delayed while benefits are immediate and concrete, producing the well-documented gap between stated privacy concern and observed behavior [24]. This framework predicts that privacy protection will function as a normative criterion for expert raters but will be discounted by end users, and it makes the direction of any observed divergence theoretically interpretable rather than merely descriptive.

eHealth Literacy and the Evaluator Effect

eHealth literacy encompasses the skills required to appraise and apply digital health information [25]. Features such as data-minimization practices and consent mechanisms are largely invisible in the interface and require appraisal skills that end users typically lack; visible features such as layout and interactivity do not. Independently of literacy, the usability literature documents an "evaluator effect": trained evaluators applying the same instrument to the same artifact reach substantially different conclusions [26]. Together these perspectives imply that expert and user ratings should not be treated as interchangeable estimates of a single latent quality, which is the assumption implicitly embedded in current app-recommendation practice.

Configurational Logic

Each of the 3 perspectives outlined in the Theoretical Framework section describes a combination rather than an isolated effect: fit depends on functionality and content matching a task; the privacy calculus depends on risk relative to benefit. Conventional regression estimates the average, independent, symmetric contribution of each predictor [27,28] and cannot represent such conjunctions. Set-theoretic methods represent them directly through equifinality, conjunctural causation, and asymmetry [29-32].

Gap in Knowledge

Despite growing recognition of the importance of patient perspectives in mHealth evaluation, few studies have systematically compared how researchers and patients evaluate app quality using configuration-based approaches [17]. Previous research has examined individual predictors of app quality ratings [33,34] but has not addressed: (1) whether multiple

XSL•FO
RenderX

combinations of conditions are associated with high quality ratings (equifinality), (2) whether the same condition contributes differently depending on the conditions it is combined with (conjunctural causation), and (3) how evaluation patterns differ between professional researchers and end users. Studies in the HIV/AIDS app domain specifically have quantified mean quality scores and interrater agreement [35-39] but have not examined how dimensions combine. Furthermore, HIV/AIDS populations face disease-related stigma, acute privacy concerns about sensitive health information, and specific self-management needs that may shape their quality perceptions differently from general user populations [18,19,40].

Study Objectives

This exploratory study aimed to: (1) identify the configurational pathways associated with high subjective quality ratings in HIV/AIDS apps as evaluated by researchers and by patients; (2) compare necessary and sufficient conditions between the two evaluator groups; (3) examine the degree of alignment or divergence in evaluation patterns; and (4) derive design-relevant propositions for HIV/AIDS app development that address both normative rigor and the user-side priorities observed in this panel. Given the panel and case numbers described in the Evaluator Panels and Sample Size Considerations section, the objective is to generate structured hypotheses about how quality judgments are formed, not to estimate population-level parameters.

Methods

Study Design

Overview

This cross-sectional study used a comparative evaluation design to assess HIV/AIDS mobile apps. Two distinct evaluator groups were recruited: (1) professional researchers with expertise in medical informatics, computer science, and social medicine; and (2) individuals living with HIV/AIDS. The study was conducted between February and May 2023, following PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines for systematic app selection [41]. The ratings analyzed here were collected for, and descriptively reported in, a previous quality evaluation of the same 21 apps [35]; the present study is a secondary, configurational analysis of that dataset, but the fuzzy-set qualitative comparative analysis (fsQCA), Wilcoxon, and sensitivity analyses reported here are new.

Unit of Analysis and Human Participation

Two distinct matters are addressed separately here. First, the unit of analysis is the mobile app: the 21 apps are the cases on which every datum is indexed, and all calibration, necessity, sufficiency, and coverage parameters refer to sets of apps rather than to sets of people. The evaluators are not cases; within this design each evaluator functions as a measurement instrument applied to every app, which is why evaluator reliability is assessed as interrater agreement rather than treated as sampling error. Second, and separately, 5 individuals produced those measurements, 2 of them people living with HIV. The first point concerns how the ratings are analyzed; the second concerns what was owed to the individuals who produced them. The first is set out in the Evaluator Panels and Sample Size Considerations section, and the second in the Recruitment and Eligibility, Data Collected, Basis on Which Prospective Ethics Review Was Not Sought, and Protections Applied sections.

Recruitment and Eligibility

The 2 patient evaluators were recruited entirely through the HIV prevention and control team of the local Center for Disease Control and Prevention (CDC), which is the institution that maintains the follow-up records for people living with HIV in this region. The research team specified the eligibility criteria; the CDC team applied them within its own records, identified individuals who met them, and invited participation. The research team did not receive the follow-up register, did not screen or select individuals, and did not at any stage collect, request, verify or record the serostatus of either evaluator, nor their names, contact details, age, sex, place of residence or any other personal information. Serostatus was therefore never an item of information held by the research team: it was a condition applied by the CDC within data the CDC already held for its own statutory purposes. Written informed consent was obtained from both evaluators before participation; in order to protect their privacy, the consent process was conducted by the CDC team, which collected and retained the signed consent forms on behalf of the study, so that no document bearing a participant's name passed to the research team. What the research team received were completed rating forms, identified by a study code.

Data Collected

The data generated in this study were MARS and uMARS scores for apps that are publicly listed in Chinese app stores and in WeChat. No biological sample, medical record, clinical measurement, health-record extract, or laboratory result was obtained from any evaluator, and no demographic, behavioral, or health variable describing an evaluator entered the dataset or any analysis. The research team therefore collected no personal information of any kind about the evaluators; the only data collected were ratings of publicly available software, held under study codes on an encrypted institutional server.

Basis on Which Prospective Ethics Review Was Not Sought

Prospective ethics review was not applied for, and the basis for that is stated here so that readers can assess it. The applicable instrument is the Measures for Ethical Review of Life Science and Medical Research Involving Humans, issued jointly by the National Health Commission, the Ministry of Education, the Ministry of Science and Technology, and the National Administration of Traditional Chinese Medicine (Guo Wei Ke Jiao Fa [2023] No. 4) [42] and in force from 18 February 2023, that is, for the whole of the evaluation period. Article 3 defines the scope of the Measures as research conducted with human beings as subjects, or conducted using human biological samples or personal information data, including health records and behavioral data; Article 50 defines a research participant correspondingly as a person who provides biological samples, information data, health records or behavioral data for the

XSL•FO
RenderX

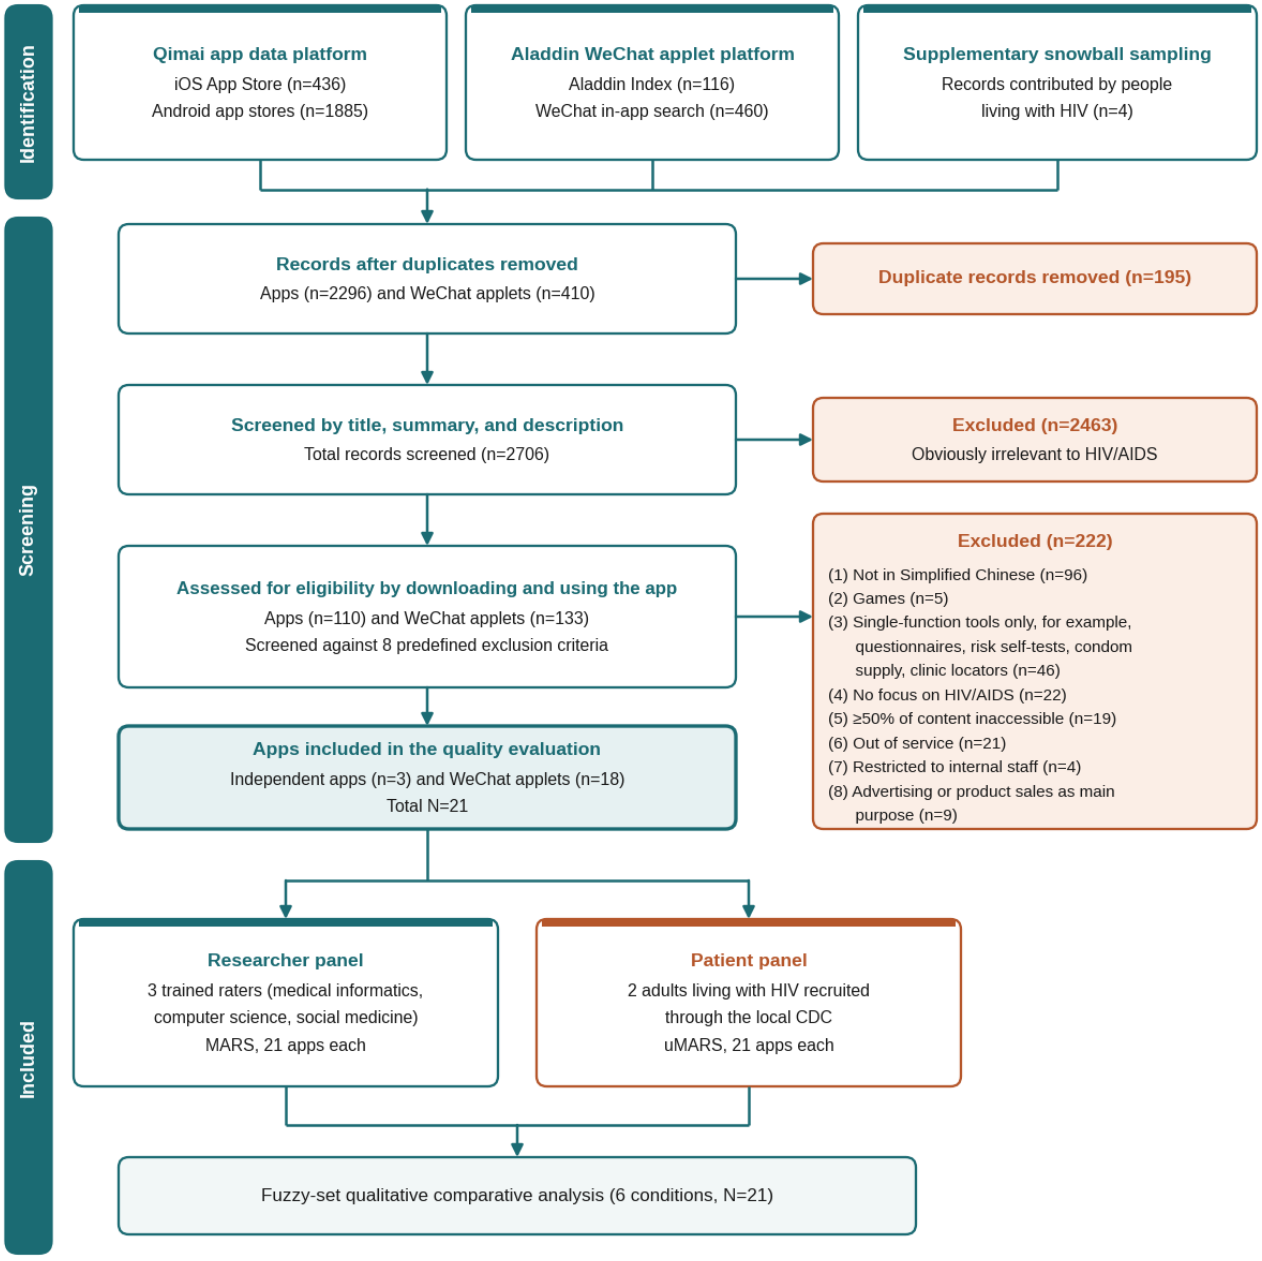
research. On both definitions, this study lies outside the scope of the Measures: no human being was a subject of investigation, no biological sample was used, and no personal information data, health record, or behavioral record of any evaluator was provided to, held by, or analyzed by the research team. What the evaluators supplied were ratings of external artifacts, which are properties of the apps rather than information about the raters. Alternatively, were the ratings to be regarded as information data supplied by identifiable individuals, Article 32(2) provides that research using anonymized information data may be exempt from ethics review where it causes no bodily harm and involves neither sensitive personal information nor commercial interest; each condition is satisfied here, since ratings were coded at source, no procedure was applied to any person, no sensitive personal information reached the research team, and the study had neither commercial sponsorship nor commercial interest. The risk to participants was no greater than the minimal-risk threshold at which Article 31 permits review by expedited procedure.

This reporting position is the prevailing one in the MARS/uMARS app-quality literature. App-quality evaluations of this design are routinely published without prospective ethics review on the ground that the object of evaluation is publicly available software rather than persons [43], and the same holds where lay end users rather than experts complete the instrument: in the Greek validation of the uMARS, in which 91 informed participants each rated an app twice, the authors reported that ethics approval was not required because the study consisted of completion of the uMARS and involved no clinical procedure [44].

Protections Applied

Although the study lies outside the scope of mandatory review, the protections owed to participants were applied in full and in accordance with the principles of the Declaration of Helsinki. Both patient evaluators were informed of the purpose, procedures, and time commitment of the study and of their right to withdraw at any point without giving a reason and without consequence for their care, and both gave written informed consent before participating; the signed forms were collected and retained by the CDC team on their behalf. Recruitment through the CDC follow-up channel was chosen because it is the only route by which people living with HIV in this region can be approached without their status being disclosed to a third party. No information capable of identifying an evaluator appears in this article or in any associated data file.

App Selection and Data Collection



A systematic search was conducted on the Qimai app data platform, Aladdin WeChat applet data platform, and WeChat from February 18-19, 2023. Search terms included “HIV”, “AIDS”, “Human Immunodeficiency Virus”, “Acquired Immunodeficiency Syndrome”, and their Chinese equivalents. The Qimai Keyword Expansion Assistant was used to identify relevant apps with a relevance score exceeding 50% and a search index surpassing 4605.

WeChat applets, lightweight apps embedded within the WeChat platform, were included due to their widespread use in China. The Aladdin Index platform was used to identify relevant WeChat applets. Additionally, a snowball sampling method was implemented through collaboration with local CDC HIV prevention teams to identify apps commonly used within the HIV/AIDS community but potentially missed by platform searches.

The exclusion criteria for this study were the following: (1) non-Simplified Chinese language, (2) games, (3) apps with limited functionality, (4) apps not primarily focused on HIV/AIDS content, (5) more than 50% inaccessible content, (6) terminated services, (7) apps restricted to internal use, and (8) apps primarily intended for advertising or product sales. Following systematic screening, 21 HIV/AIDS apps were included for evaluation. The selection process and the subsequent 2-panel evaluation design are shown in Figure 1 [35].

Evaluation Tools: MARS and uMARS

Two versions of the MARS were used in this study to accommodate the different evaluator groups. The original MARS was used for researcher evaluations, while uMARS was used for patient evaluations [15,17].

The original MARS is a validated 23-item scale designed for expert assessment of app quality across four objective dimensions: (1) engagement (entertainment, interest, customization, interactivity, and target group); (2) functionality (performance, ease of use, navigation, and gestural design); (3) aesthetics (layout, graphics, and visual appeal); and (4) information (quality, quantity, credibility, and evidence-base). Each item is rated on a 5-point scale (1=inadequate to 5=excellent). MARS also includes a subjective quality subscale, which served as the outcome variable in this study [15].

The uMARS is a 20-item adaptation designed for end user evaluation, retaining the same 4 dimensions but with simplified language and reduced technical terminology to enhance accessibility for nonexpert raters [17]. Both MARS and uMARS have demonstrated good reliability and validity across diverse mHealth apps and languages [45-47]. The use of parallel instruments allowed for meaningful comparison between expert and user perspectives while ensuring each group could evaluate apps using an appropriate tool.

Evaluator Panels and Sample Size Considerations

Researcher Panel

Three researchers conducted the app evaluations using the original MARS and were purposively selected to cover the 3 competence domains that MARS scoring requires: health information content, software engineering, and app-quality

XSL•FO
RenderX

methodology. Rater 1 holds a master's degree in Medical Informatics with extensive experience in medical information analysis. Rater 2 holds a master's degree in Computer Science with software development expertise. Rater 3 holds a PhD in Social Medicine with substantial experience in mobile app evaluation.

Before formal evaluation, all 3 raters completed MARS training by reviewing instructional videos and conducting pilot evaluations on 4 randomly selected apps (2 WeChat applets and 2 independent apps). For the formal evaluation, raters 1 and 2 independently assessed all 21 apps. To ensure consistency, evaluators completed assessment of all apps for dimension N before proceeding to dimension N+1. When discrepancies occurred between raters 1 and 2, rater 3 reassessed the app, and a consensus score was reached through structured discussion.

Patient Panel

A total of 2 patient evaluators were recruited through collaboration with local CDC HIV prevention and control teams. Eligibility criteria, applied by the CDC team within its own follow-up records rather than by the research team, were the following: (1) confirmed HIV-positive diagnosis on the CDC follow-up register; (2) age ≥18 years; (3) ability to read and understand Simplified Chinese; and (4) experience using mobile apps. Both participants provided written informed consent, which the CDC team collected and retained on behalf of the study to protect their privacy, and both were assured of anonymity and data confidentiality; no serostatus information and no personal identifiers were transferred to the research team at any stage (see the Study Design and Ethical Considerations sections). Recruitment was purposive rather than probabilistic, with the aim of obtaining evaluators whose lived experience made them able to judge the apps as intended users.

Recruiting patient evaluators proved substantially more difficult and time-consuming than recruiting expert raters, and the size of the patient panel reflects that difficulty rather than a design preference. People living with HIV are a small and highly stigmatized minority in China, and they attach exceptional importance to the confidentiality of their serostatus. The dominant concern voiced by those who were approached and declined was not the time required by the rating protocol but the possibility that participation would create a record linking them by name to HIV-related research, however strong the assurances of anonymity. Recruitment could proceed only through the local CDC's routine follow-up visits, which is the sole channel through which people living with HIV in this region can be approached without their status being disclosed to a third party, and a considerable period elapsed before 2 individuals willing to take part were identified. No demographic detail about the 2 participants is reported, because none was collected: in a 2-person panel recruited through a single follow-up program, age, sex and city in combination would be potentially identifying, and the research team therefore asked the CDC team not to transfer such details.

Patient evaluators completed the uMARS rather than the original MARS. They were provided with brief uMARS training materials adapted for nontechnical users, emphasizing the evaluation of user experience rather than technical specifications. Patients independently evaluated all 21 apps over a 4-week period and submitted their ratings through a secure online platform. Adequate time was provided for patients to thoroughly explore each app before rating. Patient scores were averaged across the 2 evaluators for each app and dimension.

Sample Size Considerations

Two aspects of sample size warrant explicit justification: the number of evaluators and the number of apps.

Number of Evaluators

The use of 2 to 3 trained raters is not a constraint specific to this study but the established design convention of the MARS/uMARS app-quality literature, including in this journal. The MARS was developed and validated on independent ratings by a small expert panel and reported excellent interrater reliability under those conditions (intraclass correlation coefficient [ICC]=0.79) [15]. The convention has been maintained consistently since. Table 1 summarizes evaluator panel size across published MARS-based app-quality evaluations in *JMIR mHealth and uHealth* and closely related outlets, spanning instrument-validation studies, single-disease app reviews, and cross-national comparisons.

XSL•FO
RenderX

Table 1. Evaluator panel size in published MARS[a]-based app-quality evaluations. Studies are ordered by the number of apps evaluated.

Study	Health domain	Instrument	Apps evaluated (n)	Evaluators (n)
Miró and Llorens-Vernet [48], 2021	Chronic conditions (interrater reliability study)	MARS, MAG[b]	4	8
Fernández-Sánchez et al [36], 2025	HIV and STI[c] prevention	MARS	6	2 (plus a third for disputes)
Shen et al [49], 2021	Drug-drug interaction checking	MARS	7	2
Schmeelk et al [50], 2022	COVID-19 symptom monitoring	MARS	20	2 (5 for calibration)
This study	HIV/AIDS	MARS, uMARS[d]	21	3 researchers; 2 patients
Mani et al [51], 2015	Mindfulness	MARS	23	2 (second rater on 30% subset)
Amor-García et al [52], 2020	Genitourinary cancer	MARS	46	2
Yamamoto et al [53], 2022	Mental health (instrument validation)	MARS-J[e]	50	2
Messner et al [47], 2020	Mental health (instrument validation)	MARS-G[f]	104	2 per app

[a]MARS: Mobile App Rating Scale.

[b]MAG: Mobile App Development and Assessment Guide.

[c]STI: sexually transmitted infection.

[d]uMARS: user version of the Mobile App Rating Scale.

[e]MARS-J: Japanese version of the Mobile App Rating Scale.

[f]MARS-G: German version of the Mobile App Rating Scale.

Two features of this evidence are relevant here. First, panel size does not scale with the number of apps: 2 raters were used whether 6, 7, 20, 23, 46, 50, or 104 apps were evaluated [36,47,49-53]. This is because the rater in this paradigm functions as a measurement instrument applied to each app rather than as a sampled unit of analysis. The unit of analysis is the app; the psychometric requirement is demonstrable agreement between raters, not a large rater sample. Reliability is accordingly evaluated as interrater agreement, as reported in the Interrater Agreement section, rather than treated as sampling error. Second, 3 raters—the number used for our researcher panel—is at the upper rather than the lower end of the distribution [35,54]; most comparable studies use two. Beyond the studies tabulated, the same convention is evident across app domains in this journal, including drug-drug interaction checkers [55], medication adherence apps [56], apps for deaf and hard-of-hearing users [57], hematological condition apps [58,59], traditional vs modern medicine apps in China [60], noncommunicable disease management apps [61], and apps for men who have sex with men in China [39], as well as in the Korean [46] and Arabic [62] MARS validations, in reviews of depression apps in German app stores [34] and of commercial weight-management apps [63], and in the 2 published MARS-based evaluations of HIV/AIDS apps [37,38].

The patient panel requires a separate justification, because the logic that supports a small expert panel does not transfer directly to end users: experts are trained to converge on a normative standard, whereas end users are informative partly because they differ from one another. Three considerations support the present design. First, HIV-positive status is a stigmatized and legally protected attribute in China, and recruitment is correspondingly difficult: people living with HIV could be approached only through CDC follow-up visits, and the prevailing reason for declining was concern that participation would create documentation linking the individual to HIV-related research. Second, both patient evaluators rated all 21 apps on all dimensions, so the design is complete rather than sparse: there are no missing cells, and each app is evaluated by the same evaluators, which is the condition under which paired comparison with the researcher panel is valid. Third, agreement between the 2 patient raters was examined empirically rather than assumed, and the limits of agreement were narrow relative to the rating range (see Statistical Analysis). We therefore treat the patient results as characterizing the configurational structure observed in this panel and frame them as exploratory and hypothesis-generating throughout.

Terminology

Because a 2-person panel cannot stand for a population, a fixed vocabulary is used throughout. The patient panel and the 2 patient evaluators refer to the 2 individuals who completed the uMARS; patient configurations and patient-side pathways refer to configurations recovered from those 2 evaluators' averaged ratings of the 21 apps; and statements about the researcher panel are likewise restricted to the 3 raters described in the Researcher Panel section. No expression in this paper is intended to characterize the preferences of people living with HIV in China as a population, or of Chinese app users generally. Where the text refers to patient evaluations, it refers to this panel.

Number of Apps

Twenty-one apps are the complete set of Chinese HIV/AIDS apps meeting the inclusion criteria at the time of the search, identified from 2901 screened records. This is not a sample drawn from a larger population, but a census of an intentionally narrow population, and the small size is itself a substantive finding about the Chinese HIV/AIDS app market [35].

XSL•FO
RenderX

Comparable app-quality evaluations in this journal have analyzed as few as 4, 6, and 7 apps (Table 1), and evaluations of 20 apps have supported published quality conclusions [50].

For the configurational analysis specifically, qualitative comparative analysis (QCA) was developed for small- and intermediate-N designs and is conventionally applied to 10-50 cases, where intimate case knowledge is available, and each case can be interpreted individually [64,65]. With N=21, the present study lies within this range and, unlike most regression-based designs, permits every case to be inspected individually against its configuration. Six conditions with 21 cases nevertheless produce substantially limited diversity: of the 64 logically possible configurations, only 14 (researcher data) and 15 (patient data) contained at least one case with membership above 0.5. We therefore report the intermediate solution, which uses only easy counterfactuals [66,67]; interpret configurations alongside the specific apps that instantiate them; and report the sensitivity analyses described in the Robustness and Sensitivity Analyses section.

Privacy Protection Assessment

Privacy protection was coded by 2 researchers independently from the apps themselves and their store listings. An app was coded as protected (code 1) only if it met all three of the following criteria: (1) a privacy policy accessible from within the app; (2) explicit disclosure of what data are collected and how they are used; and (3) user control over personal data, such as account or data deletion. All other apps were coded as unprotected (code 0). Coding disagreement occurred for 2 of 21 apps and was resolved by discussion with reference to the app interface; agreement before discussion was 90.5% (19/21).

We acknowledge that this binary treatment simplifies a multidimensional construct. Comprehensive instruments for privacy assessment in mHealth evaluate policy fairness against data-protection regulation, permission and data-sharing behavior, and technical safeguards, and they yield graded rather than dichotomous scores [68-71]. Two considerations motivated the binary coding here. First, the empirical distribution was strongly bimodal: apps either provided all 3 elements or none of them, and no app in this sample provided partial protection in the sense of a policy without disclosure or without user control. Second, a graded index estimated from 21 cases would add analytic flexibility without adding usable variance. To test whether this choice drove the results, we repeated the entire analysis with privacy specified as a 3-level fuzzy set (0=no protection; 0.5=policy, disclosure, and user control; 1=the preceding elements plus an in-app privacy password), reported in the Alternative Privacy Operationalization section.

fsQCA

Conditions and Outcome

Six conditions were examined: engagement, functionality, aesthetics, and information quality (continuous, from MARS/uMARS); privacy protection (binary); and developer type (binary: 1=government organization, 0=nongovernment). The outcome was the subjective quality rating. Conditions were selected from the MARS/uMARS framework and from prior literature on determinants of mHealth app quality [11,15,33].

Calibration

Calibration transforms raw scores into fuzzy-set membership between 0 and 1 [66,72]. Continuous conditions were calibrated using the direct method with 3 anchors set at the 95th percentile (full membership), the 50th percentile (crossover), and the 5th percentile (full nonmembership). Percentile-based anchoring is standard where no external substantive benchmark exists for the measure, and is recommended when scores are instrument-specific and their absolute values are not interpretable against a criterion [73,74]. This applies here: a MARS engagement score of 3.0 has no external meaning as a threshold of “high engagement,” whereas its position within the observed distribution of HIV/AIDS apps does. Anchors were derived separately for the researcher and patient datasets, since the 2 instruments produce different rating distributions and a common anchor would confound instrument scaling with evaluator judgment. Membership scores falling exactly at 0.50 after calibration were adjusted upward by 0.001, so that no case was left at the point of maximum ambiguity; this mattered most for patient functionality, since 14 of the 21 apps received the same functionality rating and that rating is the crossover value. Where a percentile anchor coincided with the crossover, which occurred only for patient functionality under the wider anchor sets used in the sensitivity analysis, the affected anchor was set to the nearest observed value beyond the crossover. Binary conditions were retained as crisp sets. Because the choice of percentile anchors is a researcher decision rather than a property of the data, its consequences were examined explicitly in the sensitivity analysis.

Necessity

A condition is necessary if the outcome cannot occur without it [66,75]. Necessity was assessed by consistency, with the conventional threshold of 0.90 [67], and evaluated jointly with coverage to guard against trivial necessity. Both the presence and the absence of each condition were tested.

Sufficiency

Truth tables were constructed for both datasets. A frequency cutoff of 1 was applied, as is standard for small-N designs [64], together with a raw consistency cutoff of 0.80 and a proportional reduction in inconsistency (PRI) consistency cutoff of 0.70. Boolean minimization produced complex, parsimonious, and intermediate solutions; the intermediate solution is reported as the primary result [67]. Following Fiss [76], conditions appearing in both the parsimonious and the intermediate solution are designated core, and those appearing only in the intermediate solution are designated peripheral.

Robustness and Sensitivity Analyses

Four sets of checks were performed, following current QCA reporting recommendations [64,74,77]. First, all analyses were repeated under 4 calibration anchor sets (95/50/5, 90/50/10, 85/50/15, and 80/50/20 percentiles). Second, the truth table analysis was repeated across raw consistency cutoffs of 0.75, 0.80, 0.85, and 0.90 crossed with PRI cutoffs of 0.65, 0.70, 0.75, and 0.80. Third, the analysis was repeated with the 3-level privacy set described in the Privacy Protection Assessment section. Fourth, necessity consistencies were recomputed under

XSL•FO
RenderX

each anchor set. The results are considered robust where the set of configurations and their substantive interpretation are unchanged, and consistency remains above the 0.80 threshold; any specification under which this does not hold is reported explicitly.

Statistical Analysis

Overview

Descriptive and comparison statistics were computed in Python 3.12; calibration, necessity analysis, and truth-table analysis were conducted in fsQCA (version 4.1; University of California). Descriptive statistics were computed for all variables. Because the 2 evaluator groups rated the same 21 apps, differences in raw dimension scores were tested with Wilcoxon signed-rank tests, with the matched rank-biserial correlation as the effect size; the nonparametric test was chosen because dimension scores were bounded, skewed, and drawn from a small sample. Agreement between groups was quantified with Pearson and Spearman correlations. Given 5 prespecified comparisons, *P* values should be interpreted descriptively rather than as confirmatory tests.

Interrater Agreement

Agreement was examined within each panel separately, and because the 2 panels completed different instruments, no estimate reported in this section combines researcher and patient ratings. Within the researcher panel the 2 independent raters were raters 1 and 2, each of whom scored all 21 apps on the original MARS before any discrepancy was referred to rater 3 and before consensus scores were formed; Bland-Altman analysis of that MARS dataset [35,78] gave a mean difference of 0.01 (SD 0.10; 95% limits of agreement −0.19 to 0.21) for app quality and 0.07 (SD 0.49; 95% limits of agreement −0.89 to 1.03) for subjective quality. Within the patient panel, the 2 independent raters were the 2 patient evaluators whose ratings are analyzed in the present paper, each of whom scored all 21 apps on the uMARS before the 2 sets of scores were averaged; Bland-Altman analysis of that uMARS dataset gave a mean difference of 0.13 (SD 0.26; 95% limits of agreement −0.38 to 0.64) for app quality and 0.23 (SD 0.45; 95% limits of agreement −0.66 to 1.12) for subjective quality. Both uMARS estimates therefore derive specifically from the 2 patient evaluators included here, and no researcher rating enters them; conversely, the 2 MARS estimates derive only from raters 1 and 2, and no patient rating enters them.

Limits of agreement for the 2 app-quality scores are narrow relative to the 1-5 rating range, indicating close agreement within both panels; the wider limits for the single-item subjective quality scores are consistent with the greater variability expected of subjective judgments. Bland-Altman analysis was the prespecified agreement method in the parent evaluation, and it is the appropriate choice for 2 raters because it quantifies both systematic bias and the range of disagreement on the original measurement scale rather than expressing agreement relative to between-app variance [78]. An ICC could not be computed retrospectively for either panel, because the archived dataset retains only the postconsensus researcher scores and the averaged patient scores; the rater-level score files are no longer available, and the Bland-Altman estimates reported in this section are those computed in the parent evaluation while those files were still held [35]. Future apps of this design should archive rater-level scores so that both agreement statistics can be reported.

Ethical Considerations

This study evaluated publicly available mobile apps. The data analyzed were MARS and uMARS ratings of those apps; no biological sample, clinical record, health record, or personal information of any evaluator was collected, held, or analyzed by the research team. The serostatus of the 2 patient evaluators was neither collected nor verified by the research team: eligibility was applied by the collaborating CDC HIV prevention and control team within its own follow-up records, and no identifier or personal detail was transferred to the research team. Prospective ethics review was not sought, on the basis set out in the Methods: the study lies outside the scope defined in Article 3 of the Measures for Ethical Review of Life Science and Medical Research Involving Humans (Guo Wei Ke Jiao Fa [2023] No. 4) [42] and would in the alternative fall within the exemption in Article 32(2) of the same instrument. This position is consistent with comparable app-quality evaluations, including those in which lay end users completed the instrument [43,44]. The study was nonetheless conducted in accordance with the principles of the Declaration of Helsinki: both patient evaluators were informed of the purpose and procedures of the study and of their right to withdraw at any time without consequence, and both provided written informed consent, the signed forms having been collected and retained by the CDC team on behalf of the study to protect the participants' privacy.

Results

Descriptive Statistics and Group Comparison

Twenty-one HIV/AIDS apps were evaluated by both researcher and patient groups. Table 2 presents the descriptive statistics for all variables. Researcher ratings demonstrated moderate variability across conditions, with functionality receiving the highest mean score (4.28, SD 0.39) and engagement the lowest (mean 2.40, SD 0.53). Subjective quality ratings from researchers averaged 2.47 (SD 0.65), ranging from 1.13 to 4.13.

Table 2. Descriptive statistics for researcher (Mobile App Rating Scale) and patient (user version of the Mobile App Rating Scale) ratings of 21 HIV/AIDS apps [35].

Variable	R[a] mean (SD)	R min[b]	R max[c]	P[d] mean (SD)	P min	P max
Engagement	2.40 (0.53)	1.60	3.60	2.56 (0.63)	1.80	4.70
Functionality	4.28 (0.39)	3.25	4.75	3.84 (0.59)	1.50	4.50
Aesthetics	3.40 (0.49)	2.33	4.17	3.22 (0.48)	1.67	4.17
Information	3.83 (0.33)	3.33	4.33	3.90 (0.74)	1.75	4.75
Subjective quality	2.47 (0.65)	1.13	4.13	2.75 (0.61)	1.00	3.75

[a]R: researcher.

[b]min: minimum.

[c]max: maximum.

[d]P: patient.

Patient evaluations showed similar patterns but with notable differences. Patients rated engagement slightly higher than researchers (mean 2.56, SD 0.63), though still the lowest among all dimensions. Information quality received the highest patient rating (mean 3.90, SD 0.74), followed by functionality (mean 3.84, SD 0.59). Patient subjective quality ratings averaged 2.75 (SD 0.61), ranging from 1.00 to 3.75, indicating somewhat higher overall satisfaction compared to researchers.

Wilcoxon signed-rank tests on the paired ratings (Table 3) showed that the 2 groups differed significantly on functionality, which researchers rated substantially higher than patients (median difference 0.50, IQR 0.00 to 0.63; W=14.0, P=.003, rank-biserial r=0.82), and on engagement, which patients rated slightly higher (median difference −0.20, IQR −0.40 to 0.10; W=57.5, P=.04, r=−0.50). Differences in information quality (P=.07), subjective quality (P=.06), and aesthetics (P=.16) did not reach significance. Rank correlations between the groups were moderate for engagement (ρ=0.64, P=.002) and information (ρ=0.63, P=.002) but near 0 for functionality (ρ=0.20, P=.38). Functionality is thus the dimension on which the groups both differ most in level and agree least in ordering, whereas engagement is rated similarly and ranked consistently. This pattern provides the empirical warrant for analyzing the 2 groups separately rather than pooling them. Dimension-level differences between the 2 groups are displayed in Figure 2.

Table 3. Comparison of researcher and patient ratings across the same 21 apps (Wilcoxon signed-rank tests and rank correlations).

Dimension	R[a] mean (SD)	P[b] mean (SD)	Median difference (IQR)	W[c]	P value	Rank-biserial r	Pearson r	Spearman ρ
Engagement	2.40 (0.53)	2.56 (0.63)	−0.20 (−0.40 to 0.10)	57.5	.04	−0.50	0.71	0.64
Functionality	4.28 (0.39)	3.84 (0.59)	0.50 (0.00 to 0.63)	14.0	.003	0.82	0.06	0.20
Aesthetics	3.40 (0.49)	3.22 (0.48)	0.17 (−0.17 to 0.51)	67.5	.16	0.36	0.23	0.32
Information	3.83 (0.33)	3.90 (0.74)	−0.21 (−0.42 to 0.01)	56.0	.07	−0.47	0.48	0.63
Subjective quality	2.47 (0.65)	2.75 (0.61)	−0.38 (−0.75 to 0.25)	54.0	.06	−0.49	0.39	0.45

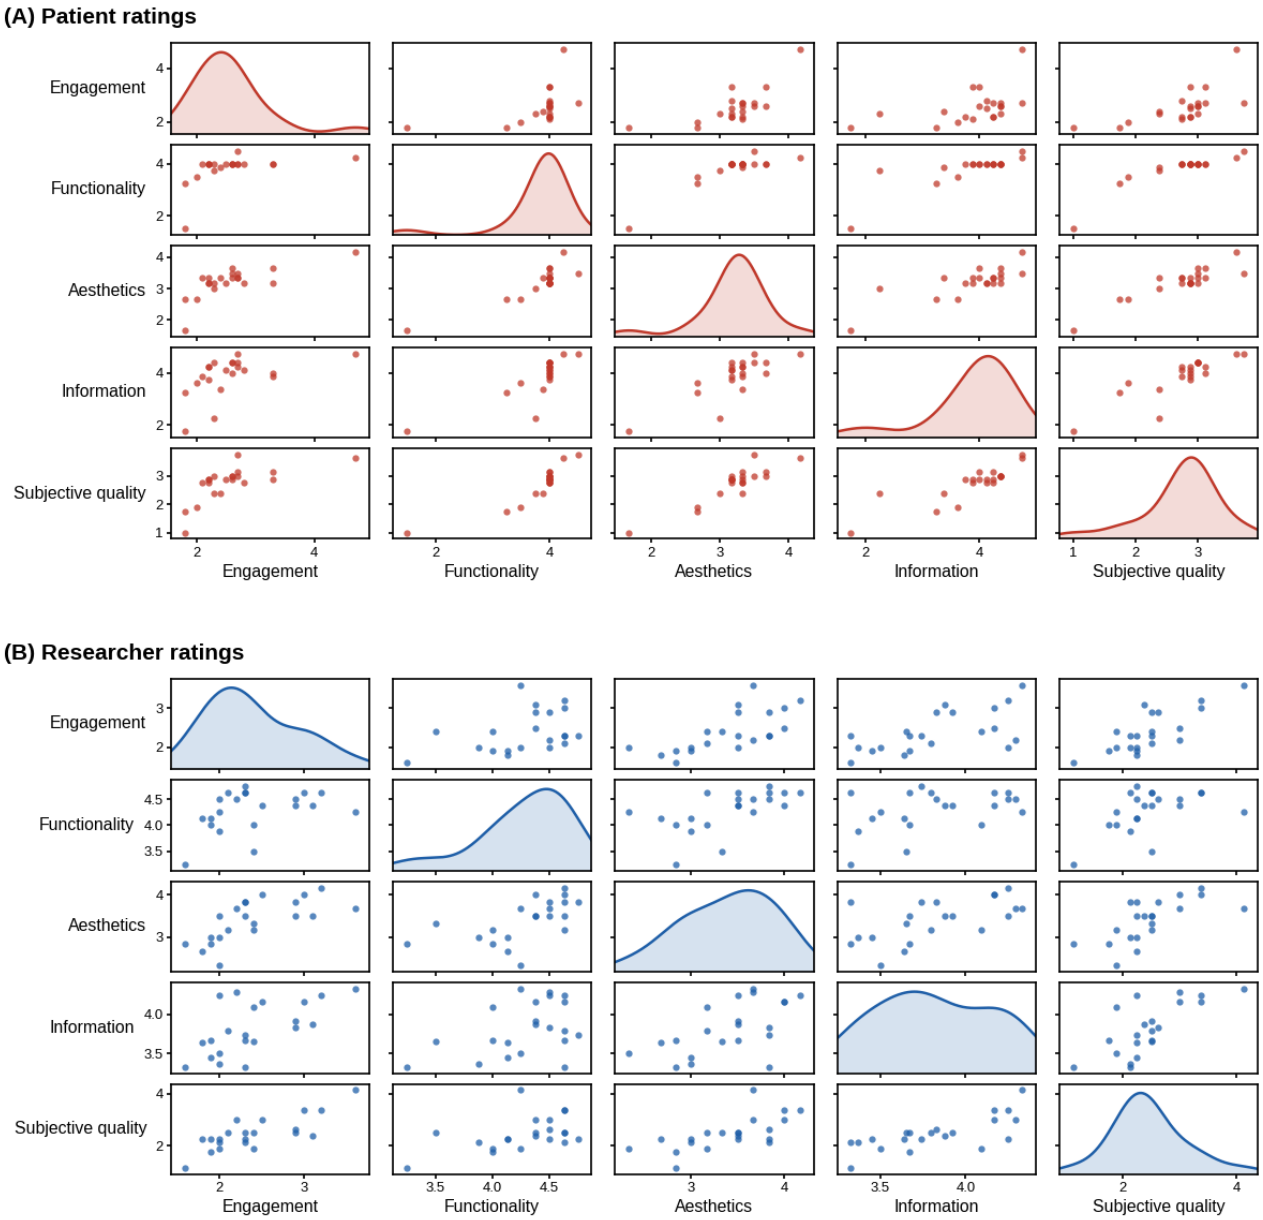
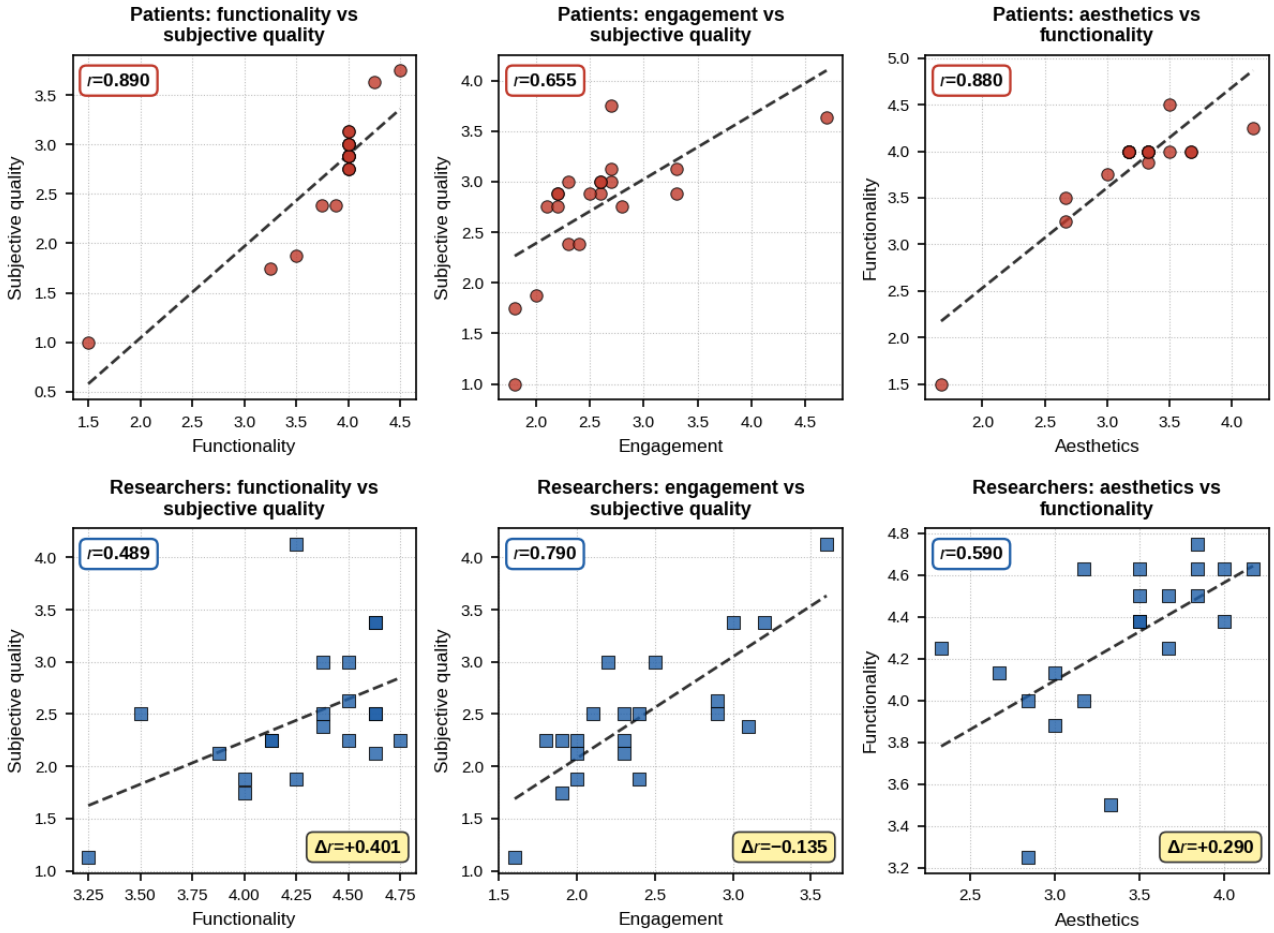
Figure 2. Dimension-level comparison of researcher and patient ratings.



Association Structure Within Each Group

Scatter matrix analysis (Figure 3) revealed divergent evaluation frameworks. Patient ratings showed tight linear patterns, most notably for functionality-subjective quality (r=0.890; P<.001). In contrast, researcher ratings exhibited greater scatter for this relationship (r=0.489; P=.02, n=21; Δr=0.401), indicating more compartmentalized assessment. Patient judgments were therefore more strongly organized around a single evaluative axis, while researcher judgments were more compartmentalized across dimensions. The bivariate relationships that differ most between the 2 groups are shown side by side in Figure 4.



XSL•FO
RenderX

Figure 3. Scatter matrices for patient (A) and researcher (B) ratings.

XSL•FO
RenderX

Figure 4. Key bivariate relationships compared between groups.

Calibration

Calibration anchors differed between researcher and patient datasets, reflecting distinct rating distributions (Table 4). For researchers, the full membership threshold for engagement was 3.20, compared to 3.30 for patients. Functionality calibration showed more pronounced differences: researchers' full membership threshold was 4.63 vs 4.25 for patients. Information quality thresholds demonstrated the greatest divergence: researchers set full membership at 4.29, whereas patients used 4.75. For the outcome variable (subjective quality), full membership thresholds were 3.38 for researchers and 3.63 for patients.

Table 4. Calibration anchors.

Variable	Type	R[a] full[b]	R crossover	R nonmem.[c]	P[d] full	P crossover	P nonmem.
Engagement	Continuous	3.20	2.30	1.80	3.30	2.50	1.80
Functionality	Continuous	4.63	4.38	3.50	4.25	4.00	3.25
Aesthetics	Continuous	4.00	3.50	2.67	3.67	3.33	2.67
Information	Continuous	4.29	3.80	3.33	4.75	4.13	2.25
Privacy	Binary	1	N/A[e]	0	1	N/A	0
Developer type	Binary	1	N/A	0	1	N/A	0
Subjective quality	Continuous	3.38	2.38	1.75	3.63	2.88	1.75

[a]R: researcher.

[b]full: full membership.

[c]nonmem.: full nonmembership.

[d]P: patient.

[e]N/A: not applicable.

These calibration differences underscore the importance of group-specific analysis in fsQCA, as identical raw scores may represent different levels of membership in the fuzzy set of "high quality" depending on the evaluator group's reference

XSL•FO
RenderX

frame. They should not be read as evidence that one group applied a stricter standard than the other in any absolute sense, since MARS and uMARS items are not scaled to a common metric.

Necessary Conditions

Necessity analysis results are presented in Table 5 and Figure 5. For researcher evaluations, no single condition met the conventional threshold (consistency ≥0.90) for being considered necessary. Information quality demonstrated the highest necessity consistency (0.845), followed by functionality (0.821) and aesthetics (0.820). Engagement showed lower necessity (0.795), while privacy protection (0.322) and government developer type (0.242) were far below the threshold. Their negations showed moderate consistency, indicating that nongovernmental apps without formal privacy features could still receive high researcher ratings.

Table 5. Necessity analysis for high subjective quality.

Condition	R[a] cons.[b]	R cov.[c]	R ~[d]cons.	R ~cov.	P[e] cons.	P cov.	P ~cons.	P ~cov.
Engagement	0.795	0.807	0.490	0.460	0.829	0.844	0.594	0.547
Functionality	0.821	0.719	0.456	0.501	0.907	0.940	0.721	0.653
Aesthetics	0.820	0.815	0.506	0.484	0.841	0.870	0.627	0.568
Information	0.845	0.804	0.482	0.482	0.915	0.862	0.594	0.588
Privacy	0.322	0.660	0.678	0.434	0.269	0.546	0.731	0.463

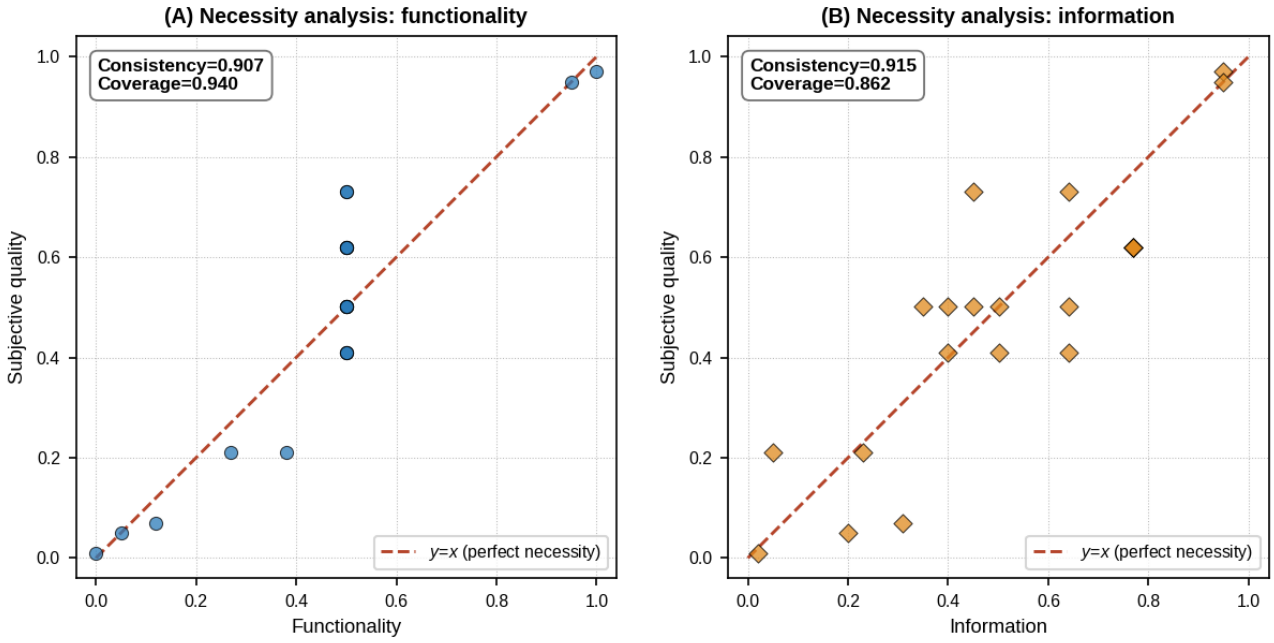
[a]R: researcher.



[b]cons.: consistency.

[c]cov.: coverage.

[d]~: negation of the condition.

[e]P: patient.

Figure 5. Necessity XY plots.

For patient evaluations, functionality (0.907) and information quality (0.915) both exceeded the threshold. However, these 2 conditions were highly correlated in the patient data (r=0.816), which means they cannot be treated as independent necessary conditions; a high correlation between candidate necessary conditions is a known source of overidentification in necessity analysis [67]. Following Schneider and Wagemann [67], we resolved this on substantive grounds: functionality is the precondition for reaching content at all, since a user must be able to navigate an app before its information can be judged, and information quality is best read as an extension of that access rather than a separate requirement. Functionality is therefore reported as the single candidate necessary condition for patients. We emphasize that with 21 cases and 1 panel, this should be treated as a proposition for testing rather than as an established necessity claim. Aesthetics (0.841) and engagement (0.829) approached but did not meet the threshold; privacy (0.269) and government developer type (0.283) did not.

XSL•FO
RenderX

Sufficient Configurations: Researchers

Sufficiency analysis was conducted to identify configurational pathways leading to high subjective quality ratings. Five sufficient configurations were identified for high subjective quality ratings among researchers (Table 6). The overall solution consistency was 0.981, and solution coverage was 0.649. These values exceed the recommended threshold of 0.80 for consistency and indicate acceptable empirical coverage.

Table 6. Sufficient configurations for high subjective quality—researchers.

Configuration	Causal path	Consistency	Raw coverage	Unique coverage
R1	~[a]Developer × privacy × engagement × aesthetics × information	1.000	0.159	0.033
R2	~Developer × privacy × functionality × aesthetics × information	1.000	0.163	0.037
R3	~Developer × engagement × functionality × aesthetics × information	0.985	0.463	0.293
R4	Privacy × engagement × functionality × aesthetics × information	1.000	0.175	0.049
R5	~Developer × ~privacy × engagement × ~functionality × ~aesthetics × ~information	0.942	0.110	0.066
Solution	N/A[b]	0.981	0.649	N/A

[a]~: negation of the condition.

[b]N/A: not applicable.

Configuration R3 (nongovernment developer × high engagement × high functionality × high aesthetics × high information quality) demonstrated the highest raw coverage (0.463) and unique coverage (0.293). This pathway accounted for the largest proportion of high-quality outcomes. The consistency of 0.985 indicates that this configuration almost always leads to high subjective ratings.

Configurations R1 and R2 both combined privacy protection with aesthetics and information quality, each at consistency 1.000, differing only in whether engagement or functionality completed the combination. Within this dataset, the two therefore behave as substitutable elements once privacy is present, though with a single case supporting each pathway, this substitutability is a description of these cases rather than a generalizable finding.

Configuration R4 combined all positive conditions (privacy, engagement, functionality, aesthetics, and information) without specifying developer type. This comprehensive pathway achieved perfect consistency (1.000) with moderate coverage (0.175).

Configuration R5 is a contrarian pathway: nongovernmental apps without privacy features, with engagement but low functionality, aesthetics, and information quality (consistency 0.942, raw coverage 0.110). Only one app instantiates it, and it is reported for completeness rather than as a recommended design route.

Sufficient Configurations: Patients

Four sufficient configurations emerged from patient evaluations (Table 7). The overall solution consistency was 0.998, and solution coverage was 0.796. Both metrics exceeded researcher evaluation results, indicating stronger explanatory power.

Table 7. Sufficient configurations for high subjective quality—patients.

Configuration	Causal path	Consistency	Raw coverage	Unique coverage
P1	~[a]Developer × ~privacy × engagement × functionality × aesthetics	1.000	0.285	0.018
P2	~Privacy × engagement × functionality × aesthetics × information	0.996	0.474	0.207
P3	~Developer × engagement × functionality × aesthetics × information	1.000	0.482	0.215
P4	~Developer × ~privacy × ~engagement × functionality × ~aesthetics × information	1.000	0.263	0.089
Solution	N/A[b]	0.998	0.796	N/A

[a]~: negation of the condition.

[b]N/A: not applicable.

Configuration P3 (nongovernment developer × high engagement × high functionality × high aesthetics × high information quality) demonstrated the highest coverage (raw=0.482, unique=0.215). This pathway closely mirrors researcher configuration R3,

XSL•FO
RenderX

suggesting one shared route to a favorable judgment across groups.

Configuration P2 (absence of privacy × high engagement × high functionality × high aesthetics × high information quality) achieved near-perfect consistency (0.996) with substantial coverage (0.474). The appearance of privacy absence as a component distinguishes patient from researcher solutions, but it should be read against the distribution of the condition: 16 of 21 apps lacked privacy protection, so most apps that were strong on the 4 MARS dimensions were also, necessarily, apps without it. It does not indicate that the patient panel rated protected apps lower. In set-theoretic terms, protected apps were slightly more consistently members of the high-rating set than unprotected ones (0.546 vs 0.463; Table 5), and the 2 apps the patient panel rated highest, Chabei and Hong Feng Wan, both offered protection.

Configuration P1 emphasized engagement, functionality, and aesthetics without requiring high information quality. This pathway indicates that visually appealing and functionally robust apps can achieve high patient ratings even with moderate information content.

Configuration P4 is compensatory: apps lacking engagement and aesthetics still achieved high ratings through functionality and information quality (consistency 1.000, raw coverage 0.263).

Comparison Across Groups

Table 8 presents a consolidated comparison of configurations across evaluator groups. Several patterns warrant attention.

Table 8. Configurational comparison—researchers and patients.

Antecedent condition	R1	R2	R3	R4	R5	P1	P2	P3	P4
Engagement	✓[a]	—[b]	✓	✓	✓	✓	✓	✓	X[c]
Functionality	—	(✓)[d]	(✓)	(✓)	X	(✓)	(✓)	(✓)	✓
Aesthetics	✓	✓	✓	✓	(X)[e]	✓	✓	✓	X
Information	✓	✓	✓	✓	(X)	—	✓	✓	✓
Privacy	✓	✓	—	✓	(X)	(X)	(X)	—	(X)
Developer type	X	X	X	—	X	X	—	X	X
Consistency	1.000	1.000	0.985	1.000	0.942	1.000	0.996	1.000	1.000
Raw coverage	0.159	0.163	0.463	0.175	0.110	0.285	0.474	0.482	0.263
Unique coverage	0.033	0.037	0.293	0.049	0.066	0.018	0.207	0.215	0.089
Solution consistency	0.981	N/A[f]	N/A	N/A	N/A	0.998	N/A	N/A	N/A
Solution coverage	0.649	N/A	N/A	N/A	N/A	0.796	N/A	N/A	N/A

[a]✓: core condition present.

[b]Em dashes indicate that the condition may be either present or absent.

[c]X: core condition absent.

[d](✓): peripheral condition present.

[e](X): peripheral condition absent.

[f]N/A: not applicable.

First, functionality appeared as a core or peripheral condition in most configurations for both groups. For patients, functionality was present in all 4 configurations. For researchers, functionality appeared in 3 of 5 configurations. This finding aligns with necessity analysis results showing functionality as highly important for both groups.

Second, privacy protection plays different roles. It is a core condition in 3 researcher configurations, whereas its negation appears in 3 of 4 patient configurations. Since privacy protection was present in only 5 of 21 apps, both patterns rest on few cases. The contrast is a difference in configurational role, not a difference in valuation: the negated condition enters the patient solution because unprotected apps dominate the sample, and protected apps were, if anything, rated slightly more consistently highly by the patient panel (Table 5). The skewed distribution of this condition is a limitation of the sample rather than a finding about the evaluators.

Third, engagement carried different weight in the 2 panels. Three of 4 patient configurations included engagement as a core condition, and in 2 of those it is one of only 3 core conditions. For researchers, engagement was a core condition in 4 of 5 configurations, but in 3 of those it appeared alongside 3 or 4 further core conditions.

Fourth, nongovernmental development appears across both groups' high-performing configurations. Because government-developed apps in this sample were predominantly county-level CDC applets with limited interactive design, this condition plausibly indexes development resources and design intent rather than ownership as such.

Fifth, solution coverage differed substantially between groups (researchers: 0.649; patients: 0.796). The higher patient coverage indicates that the identified configurations account for a larger proportion of the outcomes rated highly by the 2 patient evaluators.

XSL•FO
RenderX

Robustness and Sensitivity Analyses

Calibration Anchors

Recomputing every configuration under 4 anchor sets left the configurational structure unchanged (Table 9). Across all anchor sets, every configuration retained consistency at or above 0.942, and solution-level values remained high (researchers: consistency 0.966-0.983, coverage 0.639-0.679; patients: consistency 0.997-1.000, coverage 0.582-0.796). The baseline column of Table 9 is the set of values reported in Tables 6 and 7. Coverage was more anchor-sensitive than consistency, and most so for the patient configurations, which is expected because relaxing the full-membership anchor rescales membership scores in the outcome.

Table 9. Sensitivity of configuration consistency and raw coverage to calibration anchors[a].

Config.[b]	Cons.[c] 95/50/5	Cons. 90/50/10	Cons. 85/50/15	Cons. 80/50/20	Cov.[d] 95/50/5	Cov. 90/50/10	Cov. 85/50/15	Cov. 80/50/20
R1	1.000	1.000	1.000	1.000	0.159	0.159	0.159	0.167
R2	1.000	1.000	1.000	1.000	0.163	0.159	0.152	0.166
R3	0.985	0.982	0.987	0.959	0.463	0.454	0.422	0.442
R4	1.000	1.000	1.000	1.000	0.175	0.167	0.154	0.162

[a]Values were recomputed from the calibrated data using identical procedures; the 95/50/5 column reproduces Tables 6 and 7.

[b]Config.: configuration.

[c]Cons.: consistency.

[d]Cov.: coverage.

Necessity Across Anchors

Necessity consistencies were recomputed under each anchor set. For researchers, no condition reached 0.90 under any specification, so the conclusion that no single condition is necessary for researcher judgments is not an artifact of the anchors. For patients, functionality (0.907) and information quality (0.915) exceeded the threshold at the baseline anchors only; under the three wider sets neither reached it (functionality 0.744-0.804; information quality 0.824-0.860). Two features of the patient data account for this. First, patient functionality ratings are concentrated at 4.00, so that the 80th, 85th, and 90th percentiles coincide with the crossover, and the full-membership anchor had to be set to the nearest observed value beyond it. Second, widening the anchors compresses membership scores toward the crossover and thereby lowers necessity consistency for conditions whose upper values are closely spaced. The patient necessity result is therefore anchor-dependent, which reinforces rather than qualifies the caution stated in the Necessary Conditions section: functionality is offered as a proposition for testing and not as an established necessary condition. Privacy protection remained far below threshold in every specification for both groups (0.264-0.343). The full necessity sensitivity results are given in Table 10.

XSL•FO
RenderX

Table 10. Necessity consistency for high subjective quality under 4 calibration anchor sets[a].

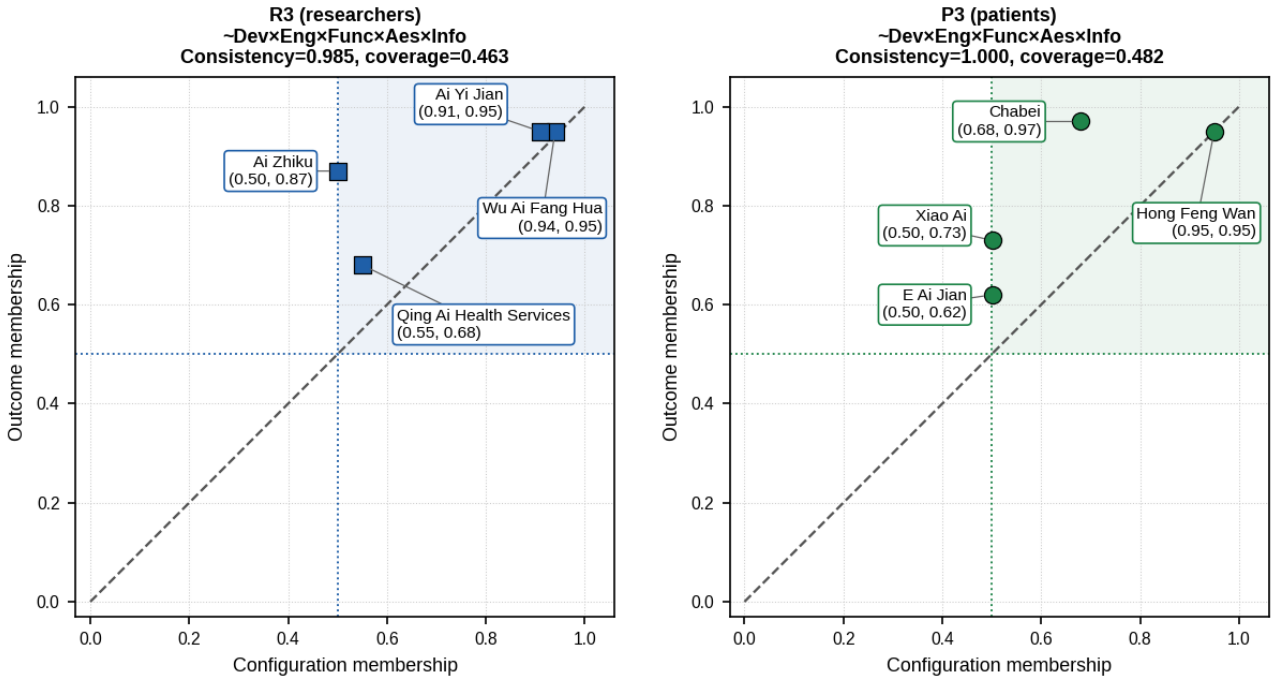
Group	Condition	95/50/5	90/50/10	85/50/15	80/50/20
Researchers	Engagement	0.795	0.787	0.767	0.783
Researchers	Functionality	0.821	0.780	0.738	0.756
Researchers	Aesthetics	0.820	0.809	0.806	0.811
Researchers	Information	0.845	0.850	0.804	0.839
Researchers	Privacy	0.322	0.329	0.326	0.343
Researchers	Developer type	0.242	0.236	0.238	0.226
Patients	Engagement	0.829	0.730	0.788	0.765
Patients	Functionality	0.907	0.804	0.795	0.744
Patients	Aesthetics	0.841	0.805	0.738	0.645
Patients	Information	0.915	0.849	0.860	0.824
Patients	Privacy	0.269	0.266	0.277	0.264
Patients	Developer type	0.283	0.284	0.279	0.288

[a]Values are necessity consistencies. The conventional threshold is 0.90. Column headings give the percentile anchors used for full membership, crossover, and full nonmembership.

Consistency and PRI Thresholds

Fourteen of the 64 truth table rows were empirically instantiated in the researcher data and 15 in the patient data. Under the baseline cutoffs, 6 researcher rows and 5 patient rows met both criteria. Across the 16 combinations of raw consistency cutoffs (0.75, 0.80, 0.85, 0.90) and PRI cutoffs (0.65, 0.70, 0.75, 0.80), the retained set was invariant in the patient data. In the researcher data, it was invariant with respect to the raw consistency cutoff, but the row instantiated by the Beijing AIDS Association applet, whose PRI consistency is 0.712, dropped out at PRI cutoffs of 0.75 and above, which removes configuration R5 from the solution. R5 is the contrarian pathway, is instantiated by that single case, and has the lowest consistency and the lowest raw coverage of the configurations reported; the other 4 researcher configurations were unaffected at every combination tested. The solutions are therefore insensitive to the raw consistency cutoff, and sensitive to the PRI cutoff only in respect of R5.

Alternative Privacy Operationalization



Re-running the analysis with the 3-level privacy set left every configuration unchanged in substance: the truth tables retained the same rows, Boolean minimization returned the same 5 researcher and 4 patient configurations, and the parsimonious solutions were identical. Consistency shifted by at most 0.018 (patient P4: 1.000 to 0.982), and no configuration fell below 0.947. Coverage changes were likewise small, the largest being increases of 0.052 in the raw coverage of patient P1 (0.285 to 0.337) and of 0.051 in that of P2 (0.474 to 0.525). Necessity consistency for privacy protection remained low under the graded specification (researchers 0.278; patients 0.223). The limited role of privacy in the patient configurations is therefore not an artifact of dichotomization: only 5 apps offered protection of any kind, only 2 of those added an in-app privacy password, and grading the 5 does not alter how privacy combines with the other conditions.

Case-Level Analysis

XY plots were constructed to visualize the cases instantiating the highest-coverage configurations, R3 and P3 (Figure 6). All illustrative cases demonstrated configuration membership scores above 0.5 with corresponding outcome membership scores above 0.5, confirming sufficiency at the case level. No deviant cases were identified.

XSL•FO
RenderX

Figure 6. XY plots for case-level analysis of configurations R3 (researchers) and P3 (patients). Both configurations share the same structure (~Dev×Eng×Func×Aes×Info) and are the highest-coverage pathway for each evaluator group. Each point is an app; the values in parentheses are configuration membership and outcome membership, and values shown as 0.50 are 0.501 after the adjustment described in the Calibration section. Aes: aesthetics; Dev: government developer; Eng: engagement; Func: functionality; Info: information quality; ~: negation of the condition.

For researchers, configuration R3 contained the most cases (n=4), including Wu Ai Fang Hua (0.94, 0.95) and Ai Yi Jian (0.91, 0.95). For patients, configuration P3 was best exemplified by Chabei (0.68, 0.97).

R3 and P3 share an identical structure (~developer [~ denotes negation of the condition] × engagement × functionality × aesthetics × information), yet different apps sit at the top of each. This indicates that the same combination of dimensions is satisfied by different apps depending on who is rating. These apps are presented as illustrations of each pathway, not as validated exemplars: with 1 to 4 cases per configuration, they show what a configuration looks like in practice and support interpretation, but they do not constitute evidence that these are the best available apps.

Discussion

Principal Findings

Configurational pathways to high subjective quality in HIV/AIDS apps were examined using fsQCA. Three key findings emerged. First, equifinality was demonstrated: 5 configurations were identified for researchers, and 4 for patients, and no single pathway was required for high-quality ratings. Second, the 2 panels' evaluation priorities differed in this sample. Privacy protection was a core condition in 3 researcher configurations and appeared as a present condition in none of the patient ones, whose configurations instead combined engagement, functionality, aesthetics, and information quality with the absence of privacy protection. Third, functionality emerged as foundational: it reached the necessity threshold in the patient data and appeared in most configurations for researchers. Wilcoxon tests independently confirmed that functionality is where the 2 groups diverge most in level and agree least in rank order.

These findings are broadly consistent with the theoretical framework outlined earlier, with one important qualification. The prominence of functionality and engagement in patient configurations matches the task-technology fit and performance-expectancy predictions [20-22]: for a person managing HIV, an app earns a favorable judgment by letting them accomplish something. The privacy calculus prediction that end users discount abstract, delayed risks [23,24] is not, however, supported by these data. Privacy protection was absent from the patient pathways because it was absent from most apps, not because protected apps were rated lower; the 2 apps the patient panel rated highest both offered protection. What the data do show is that protection was not required for a favorable patient judgment, which is consistent with the eHealth literacy account that such features are hard for end users to appraise [25], but equally consistent with users valuing protection when it is present. The compartmentalized structure of researcher ratings, in contrast, is what one would expect from trained raters applying a normative checklist rather than pursuing a task.

Interpreting the Divergence

Three nonexclusive mechanisms may explain the divergence, and they carry different implications.

If the mechanism is appraisal capacity—privacy features are simply not visible or assessable to end users [25,69]—the appropriate response is disclosure design: making protective

XSL•FO
RenderX

features legible at the point of use, as nutrition labeling does for food.

If the mechanism is privacy calculus—users perceive the features but discount them against immediate benefit [23,24]—disclosure alone will not change judgments, and the appropriate response is to reduce the cost of the protective option rather than to inform users about it.

If the mechanism is displaced trust—users infer safety from health-service branding or from CDC association—then the risk is concentrated precisely in the apps that appear most institutionally credible, and the appropriate response is certification rather than user education.

The present data cannot distinguish these mechanisms, because no qualitative data on evaluator reasoning were collected. This is a limitation of the design and the most important priority for follow-up work: think-aloud protocols or postrating interviews with a larger patient panel would discriminate among the three, and the practical recommendation differs substantially depending on which holds.

Illustrative Cases and Design Implications

Case-level analysis identifies apps that instantiate each pathway and, more usefully for developers, the concrete features they share; these features are the level at which user-centered design guidance for HIV apps has previously been formulated [79].

Wu Ai Fang Hua and Ai Yi Jian illustrate the researcher-oriented pathway R3. Common features include a structured knowledge base with attributed sources and update dates, medication and follow-up reminders, and a web-based community component. The design lesson is not "score highly on four dimensions," but that content credibility signals—visible sourcing, dating, and institutional attribution—are what distinguish these apps from otherwise similar applets.

Chabei illustrates the patient-oriented pathway P3. Its distinguishing features are a shallow navigation hierarchy in which testing appointment booking is reachable in 2 taps from launch, plain-language content without clinical jargon, and a peer community area. Its high outcome membership (0.97) relative to its configuration membership (0.68) suggests that features outside the MARS/uMARS subscales contribute to patient satisfaction—most plausibly the anonymity and low-friction access that a WeChat applet affords, since no download, registration, or app-store trace is required.

Configuration P4 is the practically relevant pathway for resource-constrained developers: high ratings from this patient panel were achieved through functionality and information quality alone, without investment in engagement or visual design. For county-level CDC teams building service applets on limited budgets, this suggests that reliable booking and accurate, current content are the necessary investments, and that gamified or visually elaborate features are optional rather than foundational.

Conversely, configuration R5 contained a single marginal case (Beijing AIDS Association: 0.58, 0.59) whose recognition rested on engagement despite low scores elsewhere, a reminder that expert endorsement does not transfer automatically to user acceptance.

Recommendations for Developers

Overview

The configurations and the illustrative cases translate into a small number of concrete design decisions. They are stated below at feature level, because that is the level at which a development team acts, and recommendations that follow directly from the observed cases are distinguished from those that are proposals consistent with the findings but not themselves tested here. Table 11 sets each against the configuration from which it derives.

XSL•FO
RenderX

Table 11. Feature-level design recommendations derived from the observed configurations and illustrative cases[a].

Configuration (panel)	Illustrative cases	Observed feature pattern	Recommendation	Evidential status
P3, P4 (patients)	Chabei	Core service task 2 taps from launch; content readable without registration	Keep booking, reminders, and result checking within 2 taps; allow anonymous reading	Follows from observed cases
R3 (researchers)	Wu Ai Fang Hua; Ai Yi Jian	Attributed and dated knowledge base; reminders; community area	Show source, date, and reviewing institution on every content item; keep a visible update log	Follows from observed cases
R1, R2, R4 (researchers) vs P1-P4 (patients)	—[b]	Privacy protection core in 3 researcher configurations; present in none of the patient configurations	Enable protection by default; keep notification text free of HIV-related content; summarize storage on one screen at first launch	Proposal consistent with the finding
P4 (patients)	—	High ratings from functionality and information quality alone	Fund booking reliability and content currency first; treat engagement and visual design as later increments	Follows from observed cases
R5 (researchers)	Beijing AIDS Association	Engagement present, other dimensions low; single marginal case	Do not treat engagement as a substitute for the service task: this route appeared only in the researcher solution	Single marginal case; researcher side only
P3 (patients)	Chabei	Outcome membership (0.97) above configuration membership (0.68); applet format	Consider applet delivery where feasible, treating the absence of download, icon, and store record as a privacy feature	Interpretation; not directly measured
Across panels	—	Divergence between panels in the appraisal of privacy protection	Prefer platform- or CDC-level privacy certification to user-facing privacy education	Policy proposal consistent with the finding

[a]Recommendations marked as proposals are design implications consistent with the observed configurations but not themselves tested in this study. Configuration labels follow Table 8.

[b]Not available.

Keep the Primary Service Task Within 2 Taps of Launch

Functionality entered all 4 patient configurations and 3 of the 5 researcher ones, and it is the condition retained as the candidate necessary condition for the patient panel; Chabei, the illustrative case for the patient pathway P3, placed testing appointment booking 2 taps from launch. Appointment booking, reminder setting, and result checking should not sit behind a menu tree, a splash sequence, or a sign-in screen.

Do Not Require Registration to Read Information

Information quality entered every patient configuration except P1, and registration is the point at which an identifiable record is created. The recruitment experience reported in Methods indicates how heavily that possibility weighs on this population. Content should be readable anonymously, with account creation required only for functions that cannot operate without it.

Make Content Provenance Visible on Every Item

The 2 apps illustrating R3, Wu Ai Fang Hua and Ai Yi Jian, were distinguished from otherwise similar applets by a knowledge base whose entries carried attributed sources and update dates. Each content item should therefore name its source, carry a publication or revision date and, where applicable, identify the institution that reviewed it, with an in-app record of when the content set was last updated as a whole.

Treat Protective Settings as Defaults Rather Than as Options

Privacy protection was a core condition in 3 researcher configurations and appeared as a present condition in none of the patient ones. Whatever the mechanism, a design that requires the user to seek protection out will under-protect this population. Proposals consistent with this finding, though not tested in this study, are to enable any available protection by default rather than on request, to write notification and reminder text that never names HIV status or medication, and to present what is stored and where on a single plain-language screen at first launch rather than within a terms-of-use document.

Fund Function and Content Before Engagement and Visual Design

Configuration P4 reached high ratings in the patient panel on functionality and information quality alone. For a county-level team, this makes booking reliability and content currency the first 2 line items and gamified or visually elaborate features later increments. Configuration R5 makes a related point from the other side. One app reached a favorable researcher judgment on engagement alone, with functionality, aesthetics, and information quality all low; but that route appeared only in the researcher solution, rests on a single case, and has the lowest consistency and the lowest raw coverage of any configuration reported. Engagement can carry an expert's overall impression of an app, and on the evidence here it does not stand in for the service task on the user side.

XSL•FO
RenderX

Consider an Applet Build Where the Service Permits It

The outcome membership for Chabei (0.97) exceeded its configuration membership (0.68), which suggests a contribution from something outside the rated dimensions, most plausibly that a WeChat applet requires no download, leaves no icon on the home screen, and creates no app-store record. Where the service can be delivered in that format, the distribution format is itself a privacy feature. This reading is an interpretation of a single case rather than a measured effect.

Prefer Certification to User-Facing Privacy Education

Because privacy protection did not appear as a present condition in any patient pathway, publishing more privacy information is unlikely on its own to alter user-side judgments. A visible privacy label issued at platform or CDC level would place the appraisal burden where the capacity to carry it lies. This is a policy proposal consistent with the observed divergence rather than a finding of the study.

Comparison With Prior Research

Prior MARS-based work has documented correlational differences between expert and user ratings [35,80] and has evaluated HIV/AIDS apps against mean-score benchmarks [36-38]. The present study extends this literature by describing how each group's judgments are organized rather than only whether they differ: the same dimensions enter different combinations for different evaluators.

The centrality of functionality is consistent with usability findings across health app domains, including behavioral intervention technologies [81] and mental health apps [82]. This supports the interpretation that functional performance serves as a baseline requirement rather than a differentiator.

The privacy finding aligns with the broader digital health literature documenting weak privacy practice and limited user appraisal of it [68-71,83], and with the privacy paradox [23,24]. For HIV/AIDS populations, the stakes are higher than in most app categories, since disclosure carries risks of stigma, relationship loss, and discrimination [18,19].

Limitations

Overview

Several limitations bound the claims that can be made from these data.

Patient Panel Size

The patient perspective rests on 2 evaluators whose ratings were averaged. Although a 2-person panel is consistent with the evaluator conventions of this literature (Table 1), and although both evaluators completed the full protocol for all 21 apps with narrow limits of agreement, 2 end users cannot capture the heterogeneity of people living with HIV in China. It is therefore not possible to determine from these data whether the patient configurations reflect preferences shared across this population or the perspectives of these 2 individuals. The patient findings are accordingly presented as exploratory and hypothesis-generating: the claim supported by these data is that a configurational logic distinct from the expert one is observable, not that it is the logic of the patient population.

Case Number and Conditions

Twenty-one apps with 6 conditions produce pronounced limited diversity: only 14 of 64 logically possible configurations (researcher data) and 15 of 64 (patient data) contained empirical cases. Several configurations rest on one or two apps, and unique coverage values below 0.05 (R1, R2, R4, and P1) indicate pathways with little independent empirical weight. The sensitivity analyses show the solutions are largely stable under alternative analytic choices, with the exceptions reported in the Robustness and Sensitivity Analyses section of the Results, but stability under respecification is not the same as generalizability to other app populations.

Rater Panel Composition

Researcher ratings came from 3 individuals from 2 institutions; although interrater agreement was close, evaluator effects cannot be excluded [26], and a differently composed expert panel might weight dimensions differently.

Absence of Qualitative Data

No interview or think-aloud data were collected, so the mechanisms proposed for the observed divergence—appraisal capacity, privacy calculus, displaced trust—are interpretations consistent with theory rather than findings.

Privacy Measurement

Even under the graded specification, privacy was assessed from user-facing artifacts. Actual data handling, third-party sharing, and permission behavior were not examined, and apps that display a policy may not comply with it [70,71].

External Validation

Quality was operationalized as rated subjective quality. No downstream outcome—sustained use, adherence, testing uptake, or clinical benefit—was measured, so the configurations describe pathways to a favorable evaluation, not to health impact.

Context and Time

Only Simplified Chinese apps available in early 2023 were examined. The market changes quickly, WeChat applets are a China-specific format, and quality drivers may differ in other linguistic and regulatory settings.

Future Research Directions

Priorities follow directly from the limitations. Recruiting a substantially larger and more diverse patient panel, ideally stratified by age, sex, time since diagnosis, and eHealth literacy, would allow the patient configurations reported here to be tested rather than proposed. Adding qualitative data would discriminate among the mechanisms proposed for the privacy divergence. Extending the analysis to a larger app corpus, or pooling across countries, would reduce limited diversity and permit conditions to be added without exceeding what the case number supports. Linking configurational membership to downstream use and clinical outcomes would establish whether pathways to high perceived quality are also pathways to benefit. Finally, experimental manipulation of specific features would move the design implications from association toward causal evidence.

XSL•FO
RenderX

Conclusions

Researcher and patient evaluations of Chinese HIV/AIDS mobile apps followed different configurational logics in this exploratory study. Privacy protection entered only the researcher pathways to high subjective quality, whereas the patient panel's pathways combined engagement, functionality, aesthetics, and information quality with its absence; functionality entered all 4 patient configurations and 3 of the 5 researcher ones, and met the necessity threshold in the patient data at the baseline calibration. Multiple equifinal pathways were identified in each group, so no single feature combination is required for a favorable evaluation.

These patterns were largely stable across calibration anchors, consistency thresholds, and an alternative graded operationalization of privacy; the exceptions are that 1 researcher configuration did not survive the stricter PRI cutoffs and that the patient necessity result held only at the baseline anchors. They rest, however, on 21 apps rated by 3 researchers and 2 patients, and the patient findings in particular should be read as hypotheses about how end users form quality judgments rather than as estimates of what people living with HIV prefer.

Two implications are nonetheless warranted. First, expert and end user assessments are not interchangeable, and app recommendation and development processes that rely on either alone risk producing apps that are respectively unused or underprotected. Second, privacy protection was rare in this market and was not required for a favorable patient judgment, although the apps the patient panel rated highest did offer it. In a population for which the cost of unrecognized disclosure risk is not measured in inconvenience, protection therefore needs to be ensured by developers and regulators rather than left to user demand.

Acknowledgments

The authors sincerely acknowledge the editors and anonymous reviewers for their insights and comments to further improve the quality of the paper. The authors also thank the HIV prevention and control team of the Bengbu Center for Disease Control and Prevention, which carried out the recruitment of the patient evaluators, applied the eligibility criteria within its own follow-up records, and collected and retained the consent documentation on behalf of the study. The authors declare that no generative AI tools were used in the preparation of this paper.

Data Availability

The datasets used and analyzed during the current study are available from the corresponding author upon reasonable request.

Funding

This work was supported by the Youth Project of the Anhui Provincial Social Science Planning Fund (AHSKYQ2025D110). The funder had no involvement in this study's design, data collection, analysis, interpretation, or the writing of this paper.

Authors' Contributions

PL, CY, and FW conceived the research idea and jointly developed the study design. PL prepared the first draft of the paper. FW supervised the study. CY was responsible for data curation and reanalysis. All authors contributed to revising the paper and approved the final version for submission.

Conflicts of Interest

None declared.

Abstract

Background: Driven by technological advancements, the proliferation of mobile sports and health apps has revolutionized health management by improving efficiency, cost-effectiveness, and accessibility. While the widespread adoption of these platforms has transformed public health practices and social well-being in China, emerging evidence suggests that inadequacies in their privacy policies may compromise personal information (PI) protection.

Objective: This study aimed to conduct a systematic evaluation of privacy policy compliance among 286 mobile sports and health apps in the Chinese Mainland, benchmarking them against the Personal Information Protection Law and associated PI regulatory guidelines.

Methods: This study develops a privacy policy compliance indicator scale based on the information life cycle and the legal framework for PI protection in the Chinese Mainland. This scale consists of 5 level 1 indicators and 37 level 2 indicators that assess the privacy policy compliance.

Results: The privacy policy compliance of 286 sports and health apps generally performed worse, with only a minimal number (n=11, 3.8%) of apps scoring above 90 points (rated as excellent), nearly half (n=121, 42.3%) of apps scored below 60 points (rated as unqualified). Among the 5 level 1 evaluation indicators for privacy compliance in sports and health apps, the compliance rate for PI collection (mean 74%, SD 25.8%) is the highest, while the compliance rate for PI storage (mean 53.5%, SD 28.4%) is the lowest. The compliance rates for privacy policies across the remaining 3 level 1 evaluation indicators, such as PI usage (mean 54.2%, SD 24.4%), PI entrusted processing, sharing, transferring, and disclosing (mean 62.2%, SD 19.8%), and PI security and feedback (mean 61.7%, SD 21.3%), fall around 60%. Out of 37, 17 level 2 evaluation indicators show a compliance rate below 60%. The compliance rate with privacy policies for 5 level 2 evaluation indicators is exceptionally high, including collection subject (mean 97.2%, SD 16.5%), collection type (mean 99%, SD 10.2%), collection purpose (mean 96.2%, SD 19.3%), reasons for sharing, transferring, and disclosing PI (mean 91.6%, SD 27.8%), and feedback channel (mean 93.4%, SD 24.9%). Notably, 3 indicators exhibit compliance rates below 20%, including sensitive information storage (mean 14%, SD 34.7%), constraints of automatic decision-making (mean 9.4%, SD 29.3%), and deceased user rule (mean 5.2%, SD 22.3%). Authorization for sensitive information (mean 29.4%, SD 45.6%) lagged behind general information (mean 83.6%, SD 37.1%).

Conclusions: Although some apps have established commendable policies, there are gaps that compromise the efficacy of PI protection. Considering this, this paper proposes targeted actions for 3 stakeholders: users, regulators, and legislators. Only through coordinated action can the app ecosystem close the compliance gaps, reduce PI protection risks, and restore user trust in digital services.

KEYWORDS

sports and health apps; personal data; sensitive information; privacy policy compliance; personal information protection; regulatory reform

Introduction

With the popularity of mobile phones and people's increasing interests in sports and health management [1-3], mobile sports and health apps, which are closely related to physical exercise and provide exercise knowledge, assist with physical activities, track workout data, and support health management, have emerged and are constantly growing [3-7]. Currently, the app stores on the 2 major mobile operating systems, Android (Google) and Apple iOS, offer a vast array of apps related to

XSL•FO
RenderX

health monitoring [8,9], calorie management [10-12], fitness guidance [13,14], health consultation [15,16], and other sports and health services [17]. These apps have enhanced the efficiency, cost-effectiveness, and accessibility of sports and health management, enabling people who are concerned about health through sports to learn exercise programs in real-time, track their diet, and improve their overall health condition using the apps [18-21]. It is reported that the extensive usage of these apps has significantly enhanced the social and public health landscape in China [22].

However, the rapid growth of mobile sports and health apps poses a threat to users' personal privacy and data security [23-26]. Streaking privacy, which occurs when sports and health apps collect, process, and use personal exercise and physical health information without authorization, has caused serious legal issues and attracted widespread social attention around the world [27-29]. For instance, the US Federal Trade Commission ordered the Easy Healthcare Corporation to pay a $100,000 civil penalty for its Premom app collecting and sharing a significant amount of users' personal information (PI) with third-party advertisers in violation of privacy protection, eavesdropping, and other applicable laws and regulations [30]. A Norwegian nonprofit organization has discovered that 10 of the most popular apps on Google Play Store, including sports and health apps, transmit users' sensitive PI to third parties without their permission [31]. In China, these challenges are more acute. In December 2018, China's Cyberspace Administration carried out a special regulatory action targeting numerous apps, including those related to sports and health, and discovered that 3496 apps were illegally collecting and using PI [32].

As a response, many countries, including the United States [33,34] and the European Union [35-37], have enacted bills to strengthen PI protection [38]. The United States has enacted laws such as the Health Insurance Portability and Accountability Act [39], the Health Breach Notification Rule [40], and the Children's Online Privacy Protection Rule [41], which stipulate the obligation of health care organizations to safeguard health data, require health care organizations to establish a consent mechanism for sharing patients' health data with third parties, outline the data breach notification mechanism for health care organizations and the legal responsibilities for disclosing patients' sensitive data [42]. The European Union protects PI and privacy in a unified manner through the General Data Protection Regulation, grants 8 rights to users, and requires data processors to process personal data under the individual consent mechanism [43].

In response to the risks of PI leakage and privacy abuse posed by sports and health apps, China's PI protection legal system adopts an approach [44], aiming to protect users' privacy data and promote market development [27]. In 2019, the Cyberspace Administration of China made policies, such as methods for determining illegal collection and use of personal information by apps and provisions on the scope of necessary personal information for common types of mobile internet applications, to regulate the collection and use of PI by apps [45]. In light of the noncoercive nature of these policies and in view of the urgent need for PI protection [46], China enacted the Personal Information Protection Law (PIPL) in 2021 [47]. While public reports held that the PIPL has established a basic legal framework for PI collection, processing, and usage [48-50], academic scholars still argue that the PIPL should be significantly improved [51-54]. Meanwhile, since December 2021, the National Technical Committee 260 on Cybersecurity of Standardization Administration of China has successively made voluntary national standards, such as the Practical Guide to Cybersecurity Standards—Guidelines for the Classification and Grading of Network Data [55], the Information Security Technology - Personal Information Security Engineering Guidelines (PI Guidelines) [56], Information Security Technology—Implementation Guidelines for Notices and Consent in Personal Information Processing [57], and Information Security Technology—Guide for De-identifying Personal Information [58] to classify and grade PI for protection. Additionally, the Ministry of Industry and Information Technology of China regularly reports and requires rectification of apps that violate users' rights and interests [59]. According to public reports, a total of 297 apps were required to rectify their illegal collection of PI in 2024 [60].

Under the above legal requirements, mobile sports and health apps, which collect and use users' PI as the premise of their normal operation, need to establish an internal compliance management system for personal privacy and data security [44]. In this system, developing privacy policies stands in the foreground, because the formulation and implementation of privacy policies ensures that the apps' market operation behavior meets the requirements of laws and regulations, thereby achieving a balance between internal self-discipline and external supervision. As required by PIPL and PI Guidelines, a legitimate and valid privacy policy is comprised of the collection, storage, use, entrusted processing, sharing, transfer, disclosure, consultation, and feedback of PI [61,62]. Accordingly, this paper attempts to measure these aspects of mobile sports and health apps' privacy policy because the degree of PI protection is correlated with how well the app's privacy policy conforms with PIPL and PI Guidelines.

There is a well-established body of work on privacy policies and PI protection in existing studies. For example, Tangari et al [4] explored free fitness apps on the Google Play Store in Australia and found that 88% of the apps will potentially collect user data. Parker et al [63] investigated and rated medicine-related apps for the Android mobile platform available in the medical store category of Google Play in the United Kingdom, United States, Canada, and Australia. Grundy et al [64] explored the risks posed by rated medicines-related apps when sharing user data. Alfawzan et al [65] emphasized the privacy policies of 23 most popular apps on women's health in the Apple operating system and the Android system. Shipp and Blasco [66] assessed the privacy practices of a set of 30 Android menstruation-related apps that track users' reproductive cycle, sex life, and health. Although research on the privacy policy compliance of mobile health (mHealth) apps is expanding, studies specifically examining the privacy policy compliance of mHealth apps closely related to sports still require further in-depth investigation. Scholars have conducted comparative in-depth research on the privacy policy compliance of China's

XSL•FO
RenderX

mHealth apps [67-69], focusing primarily on mobile mental health [29,70,71], mobile hospitals [28,72,73], contact tracing [74,75], traditional Chinese medicine treatments [76], and chronic disease management [22,77]. Research on the privacy policy compliance of Chinese mobile sports and health apps remains limited. Current research on privacy policy compliance for mobile sports and health apps is limited to a few jurisdictions, with a significant lack of attention still directed toward the privacy policy compliance issues of Chinese mobile sports and health apps. Currently, China boasts an exceptionally large user base for mobile sports and health apps. These apps collect users' PI, particularly sensitive data, such as gender, location, exercise routes, heart rate, workout duration, weight, and exercise frequency. If the PI collected by these mobile sports and health apps is not gathered, used, and shared in a lawful, transparent, and trustworthy manner, it not only jeopardizes users' personal privacy and safety but also poses a threat to national data security. Therefore, privacy policy compliance for mobile sports and health apps requires thorough analysis in the Chinese Mainland.

In order to comprehensively evaluate the compliance rate of privacy policies of sports and health apps in the Chinese Mainland, this paper deploys scenario-based contextual analysis [78] and information life cycle theory [79]. Nissenbaum [78] argued that the contextual integrity theory should serve as the cornerstone of privacy protection, because different contextual frameworks shape the norms of information flow across various scenarios, and these norms determine the legitimacy of information processing. There are typically 2 types of PI protection scenarios. The first type vertically categorizes different types of information based on the varying levels of processing risks, and the other type horizontally focuses on the different stages of information processing. Regarding the former, both domestic and international legislation generally adopt a dichotomy to differentiate between sensitive PI and general PI. This paper also follows this classification to evaluate their respective levels of protection compliance. For the latter, combining with the information life cycle stipulated in the PIPL, this study proposes 5 stages of PI collection, PI storage, PI usage, PI entrusted processing, sharing, transferring, and disclosing, and PI security and feedback, and further uses them as 5 primary indicators in the scale.

This study uses the legal framework for PI protection to develop a privacy policy compliance indicator scale and evaluate the compliance degree of privacy policies of 286 sports and health apps. In the Methods section, we focus on selecting, collecting, and analyzing sample apps, developing a compliance indicator scale, and designing the scoring process. In the Results section, we examine the level of PI protection of each privacy policy and report the results of the compliance assessment. In the Discussion section, we summarize the overall landscape and existing shortcomings in privacy policy compliance among sports and health apps and propose regulatory reforms to strengthen PI protection.

This study aims to (1) select, collect, and analyze privacy policies of sports and health apps developed for users in the Chinese Mainland, (2) establish a privacy policy compliance indicator scale based on the PIPL and PI Guidelines [22,27] (3) evaluate the compliance level of privacy policies of sports and health apps by scoring each indicator, and (4) provide suggestions on how to improve PI protection in the Chinese Mainland. This study enhances the discourse on balancing personal information protection with sustainable innovation in sports and health apps. By underscoring the necessity of enhancing privacy policy compliance and offering improvement suggestions, it offers insights for policymakers, developers, operators, and users across various nations regarding PI protection.

Methods

Study Design

We first comprehensively collected 714 apps from the app stores of Google Android and Apple iOS, the 2 mobile phone operating systems in the Chinese Mainland, between August 2 and August 6, 2025. Then we proceeded to examine the program description of apps to review their features and locate their privacy policies on August 6, 2025. Subsequently, we downloaded the privacy policies of the remaining apps, eliminating those that either did not allow a privacy policy download or lacked a privacy policy altogether between August 7 and August 8, 2025. Finally, we analyzed the compliance level of privacy policies of 286 valid sports and health apps with the PIPL and PI Guidelines and further proposed improvement suggestions regarding the gaps identified in the process of compliance evaluation from August 10 to August 20, 2025.

Sample Selection and Inclusion Criteria

This study focused on the privacy policy compliance of sports and health apps. We selected the apps from the app stores of Android and Apple, the 2 popular mobile operating systems in the Chinese mainland. We opened the app stores (Yingyongshangdian in Chinese) section, selected the function of app category (Fenlei in Chinese), and put in keywords "sports and health" (Yundong Jiankang in Chinese) to filter apps. Through the comprehensive collection and search methods described above, we have gathered the initial sports and health sample apps. Then, we carefully reviewed the feature descriptions of each of the initial sports and health sample apps we collected, while simultaneously downloading their privacy policy documents. The apps included in the sample must meet the following 2 criteria. First, they must be explicitly designed for a diverse user base to offer sport guidance, real-time exercise data tracking, fitness education, and other sports and health services, and second, they must be intended for ordinary individuals rather than for sports and health management organizations or governments. The apps with the following criteria were excluded from the sample. First, the app provides only low-fat food options, recipes, and dietary control recommendations. Second, the app provides only psychological issue diagnosis, stress relief, and emotional support functions. Third, the app provides only sleep aid and sleep quality monitoring functions. Fourth, the app solely collects physical data, analyzes health issues, and provides fitness recommendations. Fifth, the app exclusively offers exercise instruction content and videos, along with coaching services. Sixth, the app solely provides virtual fitness game services.

XSL•FO
RenderX

Seventh, the app exclusively offers sports event booking, live streaming, and participation services. Eighth, the app solely provides massage services. Ninth, the app either lacks a privacy policy or its privacy policy web page fails to display effectively. By searching, analyzing, and filtering sports and health apps, we obtained the final number of sample apps used for privacy policy compliance analysis.

Development of the Privacy Policy Compliance Indicator Scale

We constructed a privacy policy compliance indicator scale from the perspective of the scenario-based requirement [78] and the information life cycle [79] to assess the compliance between the privacy policies of sports and health apps and the PIPL and the PI Guidelines. The process of developing the privacy policy compliance indicator scale is as follows.

We first comprehensively reviewed the provisions of the PIPL and PI Guidelines and then extracted an appropriate privacy compliance evaluation legal framework applicable to sports and health apps, from which we produce level 1 evaluation indicators. According to the information life cycle, sports and health apps operate through the processes of collection, storage, usage, processing, sharing, transfer, disclosure, information consultation, suggestion, and feedback of PI [22,27]. In light of this, we argue that the legal framework is comprised of five stages: (1) the collection of PI (Articles 6, 13, 14, 17, 28, 29, and 30 of the PIPL; and Articles 2, 4, and 5 of the PI Guidelines); (2) the storage of PI (Articles 17, 19, 39, and 40 of the PIPL; and Article 6 of the PI Guidelines); (3) the use of PI (Articles 6, 14, 15, 16, 24, 45, 46, 47, 48, 49, and 50 of the PIPL; and Articles 7 and 8 of the PI Guidelines); (4) the entrusted processing, the sharing, the transfer, and the disclosure of PI (Articles 21, 22, 23, 26, 27, 38, and 39 of the PIPL; and Article 9 of the PI Guidelines); (5) the consultation and feedback on PI (Articles 50, 57, and 65 of the PIPL; and Article 10 of the PI Guidelines). In accordance with this legal framework, we set 5 level 1 evaluation indicators: the collection of PI, the storage of PI, the use of PI, the entrusted processing, the sharing, the transfer, and the disclosure of PI, and the consultation and feedback on PI.

To conduct a more precise evaluation of the privacy policy, we further divide the 5 level 1 evaluation indicators into 37 level 2 evaluation indicators, thus establishing our privacy policy compliance indicator scale (Table 1). The level 1 evaluation indicators include PI collection, PI storage, PI usage, PI entrusted processing, sharing, transferring, and disclosing, and PI security and feedback. Specifically, the level 1 evaluation indicator of PI collection comprises 9 level 2 evaluation indicators. They are the collection subject, policy update, app scope, collection type, collection purpose, processing rule, authorization for general information, authorization for sensitive information, and exceptions for explicit authorization. Another level 1 evaluation indicator of PI storage consists of 4 level 2 evaluation indicators: storage time, storage place, PI deidentification, and sensitive information storage. We further break down the level 1 evaluation indicator of PI usage into 14 level 2 evaluation indicators, including PI access control, deidentified display and use, purpose restrictions for PI usage, authorization for the usage purpose change, constraints of automatic decision-making, query right, correction right, deletion right, copy right, account cancelation right, withdraw or change authorization, asking response right, deceased user rule, and complaint mechanism. Concerning the level 1 evaluation indicator of PI entrusted processing, sharing, transferring, and disclosing, we further categorize it into 5 level 2 evaluation indicators: requirements for entrusted controller processing PI, reasons for sharing, transferring, and disclosing PI, security measures of sharing, transferring, and disclosing PI, special circumstances without consent, and cross-border transmission requirements. The last level 1 evaluation indicator is the PI security and feedback, which encompasses 5 level 2 evaluation indicators of security incident response mechanism, security event notification mechanism, feedback channel, feedback period, and external dispute resolution mechanisms.

RenderX

Table . Level 1 and level 2 evaluation indicators of privacy policy compliance of sports and health apps.

Level 1 evaluation indicator	Level 2 evaluation indicator
PI[a] collection	• Collection subject • Policy update • Application scope • Collection type • Collection purpose • Processing rule • Authorization for general information • Authorization for sensitive information • Exceptions for explicit authorization
PI storage	• Storage time • Storage place • PI deidentification • Sensitive information storage
PI usage	• PI access control • Deidentified display and use • Purpose restrictions for PI usage • Authorization for the usage purpose change • Constraints of automatic decision-making • Query rightCorrection right • Deletion rightCopy right • Account cancelation right • Withdraw or change authorization • Asking response right • Deceased user rule • Complaint mechanism
PI entrusted processing, sharing, transferring, and disclosing	• Requirements for entrusted controller processing PI • Reasons for sharing, transferring, and disclosing PI • Security measures of sharing, transferring, and disclosing PI • Special circumstances without consent • Cross-border transmission requirements
PI security and feedback	• Security incident response mechanism • Security event notification mechanism • Feedback channel • Feedback period • External dispute resolution mechanisms

[a]PI: personal information.

The PIPL and PI Guidelines are of significant importance for the protection of personal data and privacy. These provisions are legally mandatory rules that must be strictly adhered to. Therefore, we treat all 5 level 1 evaluation indicators equally and assign them a value of 1. It means that if these 37 level 2 evaluation indicators are accurately and effectively stated in the privacy policy of the sports and health app, they are assigned a value of 1, and if not, they are assigned a value of 0.

After classifying the level 1 evaluation indicators and applying the scoring rule, we got a total score (37 points) for each app's privacy policies. Then, the final score is calculated on a 100-point scale. This means each app's privacy policy score (on a 37-point scale) is converted to a 100-point scale to determine the final score. The evaluation results were further divided into 4 levels: excellent for a compliance score above 90 points, good for a compliance score in the range of 80 - 90 points, qualified for a compliance score in the range of 60 - 79 points, and unqualified for a compliance score below 60 points. The privacy policy compliance tiering of sports and health apps is illustrated in Table 2.

Finally, we calculated and summarized the score of each level 2 evaluation indicator for all sample apps. From August 21 to December 25, 2025, 2 independent raters (RG and FC) participated in the scoring process. This process was divided into 2 stages. To ensure reliability and consistency of the scoring results, in the initial scoring stage, all raters independently evaluated 30 randomly selected apps (10.5% of the total), achieving a correlation coefficient of 0.983 (P<.001) among different raters within the same group, indicating that the evaluations were closest to consistency. After evaluation, the raters gathered together to discuss the differences and reasons for the initial scoring and ultimately formed an almost consistent scoring standard. In this way, subjectivity in scoring is limited, although not eliminated. In the second scoring stage, we divided the sample apps into 2 groups of 143 each. Each rater randomly selects a group of apps to score independently.

Final score for apps	Privacy policy compliance tiers
≥90	Excellent
80-90	Good
60-80	Qualified
<60	Unqualified

Results

Sample Collection

From August 2, 2025, we conducted the collection, selection, evaluation, and analysis of the privacy policies of the sports and health apps. We gathered an initial set of 714 sports and health apps from the Android App Store and Apple App Store.

We collected 328 sports and health apps from the Android App Store. After excluding 118 apps due to reasons such as irrelevance to sports and health management services, the final valid count was 210 apps. The reasons and numbers for the 118 excluded apps are as follows: (1) 11 apps were excluded for providing only diet control and fat loss services, (2) 5 apps were excluded for providing only body data collection and testing services, (3) 27 apps were excluded for offering solely exercise instruction and learning services, (4) 17 apps were excluded for providing only virtual gaming services, (5) 35 apps were excluded for offering only sports event booking and live streaming services, (6) 5 apps were excluded for providing only sports venue booking services, (7) 16 apps were excluded for other reasons, and (8) 1 app was excluded because its privacy policy web page could not be accessed.

We collected 386 sports and health apps from the Apple App Store. After excluding 273 apps unrelated to sports and health management services, 113 valid apps remained. The reasons and quantities for excluding the 113 apps are as follows: (1) 28 apps were excluded for providing only dietary control and fat loss services; (2) 45 apps were excluded for offering solely psychological counseling and mental health guidance; (3) 36 apps were excluded for providing only sleep issue monitoring and sleep aid services; (4) 44 apps were excluded for offering exclusively physical data collection and health monitoring services; (5) 3 apps were excluded for solely providing exercise instruction and learning services; (6) 1 app was excluded for solely providing virtual gaming services; (7) 11 apps were excluded for solely providing massage and relaxation services; (8) 10 apps were excluded for solely providing traditional Chinese medicine consultation and treatment services; (9) 59 apps were excluded for other reasons including menstrual cycle prediction and care, vaccination, parenting, etc; (10) 5 apps were excluded for failing to open their privacy policy webpage; and (11) 31 apps were excluded for lacking a privacy policy. Therefore, we excluded 391 apps whose functions were not centered around sports. The reasons and number of apps excluded are listed in Table 3; the names, reasons, and number of apps excluded are presented in Multimedia Appendix 1. Ultimately, we collected 323 valid sports and health apps (the characteristics of the 323 valid sports and health apps are illustrated in Multimedia Appendix 2). The characteristics of the 323 valid sports and health apps are presented in Table 4.

Table . The reasons and number of apps excluded.

Reasons for apps excluded	Apps excluded (n=391), n
Dietary control	40
Mental health	45
Sleep monitoring	36
Body monitoring	49
Physical education	30
Video games	18
Massage services	11
Traditional Chinese medicine diagnosis and treatment	10
Sports events	35
Venue booking	5

RenderX

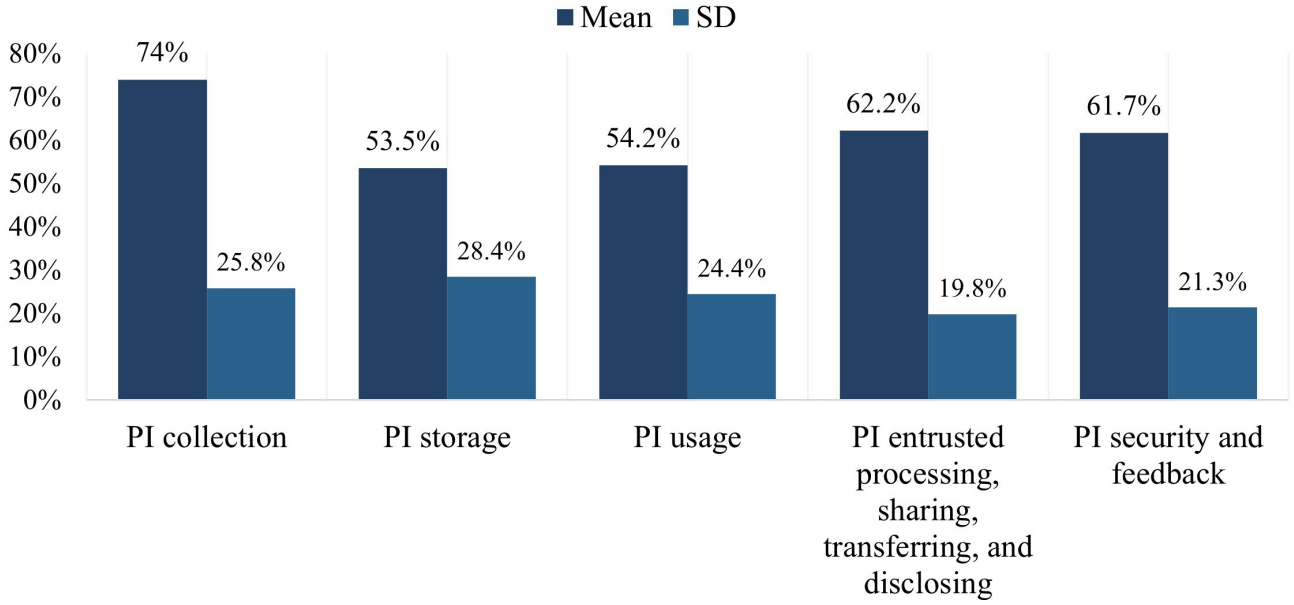
After carefully verifying the app names and company names of 323 valid sports and health apps, we found that among the 210 valid Android apps and 113 valid Apple iOS apps, 37 apps belonged to the same company and shared identical privacy policies. Therefore, we only need to count the privacy policies of duplicate apps from 1 operating system's app store. Since accessing privacy policies on Apple devices is more user-friendly than on Android devices, the privacy policies for these 37 duplicate apps were collected from the Apple App Store and included in the total count of apps collected from the Apple App Store. We subsequently removed these duplicate apps from the Android App Store, resulting in a final count of 286 apps. The methods and procedures for collecting, selecting, and excluding sample apps are presented in Figure 1. By entering the introduction pages of 286 sports and health apps one by one, we downloaded the privacy policy texts. After that, we thoroughly and carefully read the privacy policy documents of these apps from August 10 to August 20, 2025.

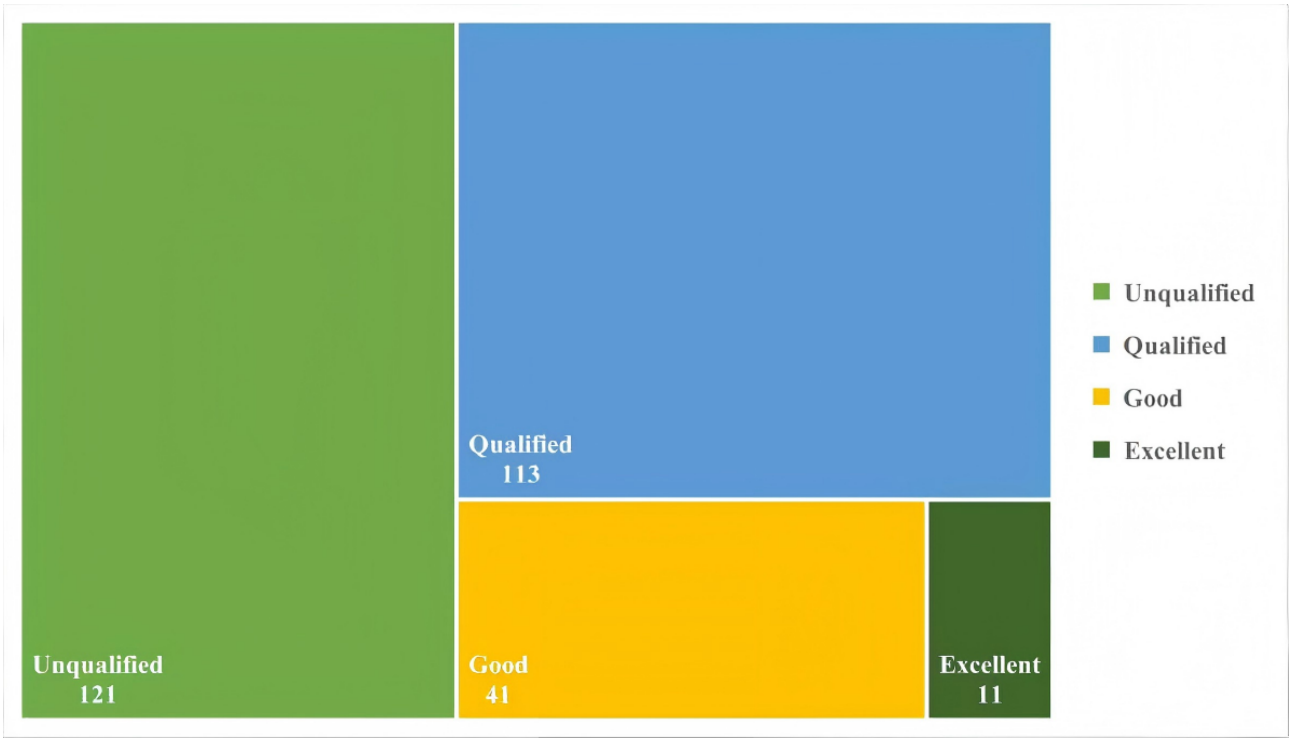
This study examined the privacy policies of 286 sports and health apps and assessed whether these privacy policies comply with the PIPL and the PI Guidelines in the Chinese Mainland. The names, compliance indicators, and scores of sports and health apps are presented in Multimedia Appendix 3. Our findings reveal a complex landscape of privacy policy compliance among sports and health apps. Among 286 sports and health apps examined, we observed a spectrum ranging from commendably high privacy compliance to moderate compliance and to a surprisingly poor compliance rate.

Figure 1. Flow diagram of the privacy policy collection and identification process.



XSL•FO
RenderX

Compliance Evaluation



The privacy policy compliance of 286 sports and health apps exhibits significant variation overall (Multimedia Appendix 3). The privacy policy compliance rate for level 1 evaluation indicators across these apps exhibits a tiered pattern. Among level 1 evaluation indicators, PI collection had the highest privacy policy compliance rate (mean 74%, SD 25.8%), while PI storage had the lowest compliance rate (mean 53.5%, SD 28.4%). PI usage also scored low in compliance (mean 54.2%, SD 24.4%). PI security and feedback (mean 61.7%, SD 21.3%) and PI entrusted processing, sharing, transferring, and disclosing (mean 62.2%, SD 19.8%) scored relatively higher. The overall privacy policy compliance status of these level 1 evaluation indicators is illustrated in Figure 2.

Figure 2. Compliance evaluation results of level 1 evaluation indicators of the apps' privacy policies. PI: personal information.

In general, after categorizing the privacy policy compliance scores of 286 sports and health apps into 4 levels (excellent, good, qualified, and unqualified), it was found that 3.8% (n=11) of apps achieved excellent compliance, 41 apps scored good, 113 apps scored qualified, while nearly half (n=121, 42.3%) scored unqualified. Compliance evaluation results on the overall compliance level of the apps' privacy policies are illustrated in Figure 3.

Figure 3. Compliance evaluation results on the overall compliance level of the apps' privacy policies.

XSL•FO
RenderX

From the perspective of the information life cycle [58], the privacy policy compliance of sports and health apps exhibits significant diversity in level 2 evaluation indicators for the information life cycle. This reflects significant variations in the implementation of privacy policy compliance among sports and health apps, with some rules being poorly enforced. The level 2 evaluation indicators' scores of sports and health apps' privacy policy compliance are reflected in Table 5.

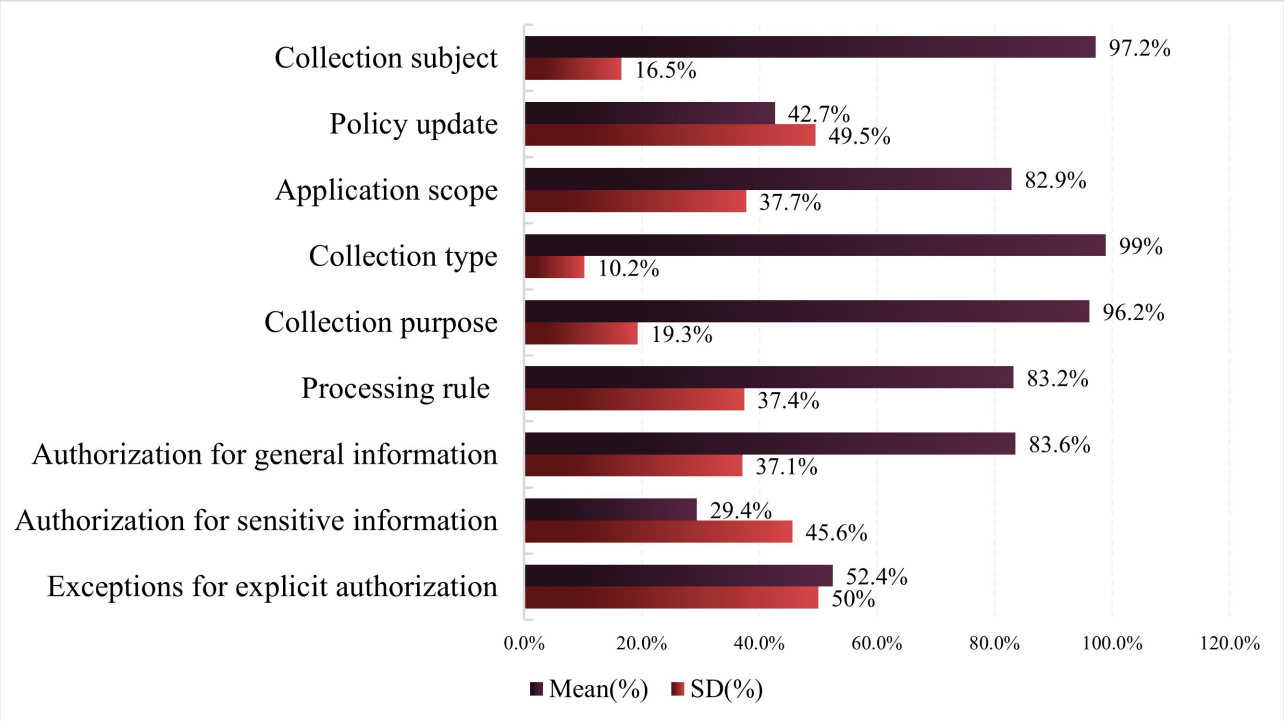
RenderX

Table . Level 2 evaluation indicators of privacy policy compliance score.



Level 1 and level 2 indicator	Mean (SD)
PI[a] collection	74% (25.8%)
Collection subject	97.2% (16.5%)
Policy update	42.7% (49.5%)
Application scope	82.9% (37.7%)
Collection type	99% (10.2%)
Collection purpose	96.2% (19.3%)
Processing rule	83.2% (37.4%)
Authorization for general information	83.6% (37.1%)
Authorization for sensitive information	29.4% (45.6%)
Exceptions for explicit authorization	52.4% (50%)
PI storage	53.5% (28.4%)
Storage time	69.6% (46.1%)
Storage place	78% (41.5%)
PI deidentification	52.4% (50%)
Sensitive information storage	14% (34.7%)
PI usage	54.2% (24.4%)
PI access control	67.5% (46.9%)
De-identified display and use	34.6% (47.7%)
Purpose restrictions for PI usage	77.6% (41.8%)
Authorization for the usage purpose change	53.5% (50%)
constraints of automatic decision-making	9.4% (29.3%)
Query right	80.1% (40%)
Correction right	70.6% (45.6%)
Deletion right	79.7% (40.3%)
Copy right	46.5% (50%)
Account cancelation right	61.4% (48.8%)
Withdraw or change authorization	75.2% (43.3%)
Asking response right	45.1% (49.8%)
Deceased user rule	5.2% (22.3%)
Complaint mechanism	51.7% (50.1%)
PI entrusted processing, sharing, transferring, and disclosing	62.2% (19.8%)
Requirements for entrusted controller processing PI	52.4% (50%)
Reasons for sharing, transferring, and disclosing PI	91.6% (27.8%)
Security measures of sharing, transferring, and disclosing PI	63.6% (48.2%)
Special circumstances without consent	65.4% (47.7%)
Cross-border transmission requirements	37.8% (48.6%)
PI security and feedback	61.7% (21.3%)
Security incident response mechanism	68.5% (46.5%)
Security event notification mechanism	55.6% (49.8%)
Feedback channel	93.4% (24.9%)
Feedback period	55.6% (49.8%)
External dispute resolution mechanisms	35.3% (47.9%)

RenderX

[a]PI: personal information.

For level 1 evaluation metric PI collection, PI collection demonstrated the highest level of privacy policy compliance (mean 74%, SD 25.8%) (Figure 4). This indicates that sports and health apps generally prioritize compliance in PI collection, informing users about the methods and purposes of personal information gathering, thereby fundamentally ensuring users' right to know regarding the collection of their PI. This promotes users' understanding of how their PI is used and enhances the transparency, integrity, and security of personal data usage within sports and health apps. The level 1 evaluation indicators PI collection showed significant differences in privacy policy compliance scores across its 9 level 2 evaluation indicators. Collection type demonstrated the highest privacy policy compliance (mean 99%, SD 10.2%), indicating that sports and health apps place strong emphasis on disclosing the types of PI collected to users, ensuring users are aware that their data, particularly sensitive data, have been gathered. Sports and health apps also exhibit high privacy policy compliance rates for collection subject (mean 97.2%, SD 16.5%) and collection purpose (mean 96.2%, SD 19.3%). This indicates that the vast majority of such apps clearly state the name of the data controller and the purpose of data collection within their privacy policies. Informing users about the collection subject and collection purpose enables them to understand who collects their PI and for what processing activities it is used, thereby assisting users in future legal actions regarding PI breaches. The compliance rate for application scope (mean 82.9%, SD 37.7%), processing rule (mean 83.2%, SD 37.4%), and authorization for general information (mean 83.6%, SD 37.1%) all exceeded 80%. Policy update (mean 42.7%, SD 49.5%) and exceptions for explicit authorization (mean 52.4%, SD 50%) showed lower compliance rates, approaching half. The privacy policy compliance rate for authorization for sensitive information was the lowest (mean 29.4%, SD 45.6%), indicating that the vast majority of sports and health apps lack effective provisions in their privacy policies regarding consent mechanisms for collecting sensitive PI. Since sports and health apps inevitably collect users' sensitive PI, the absence of consent mechanisms for such data collection leaves personal sensitive information highly vulnerable and susceptible to leakage.

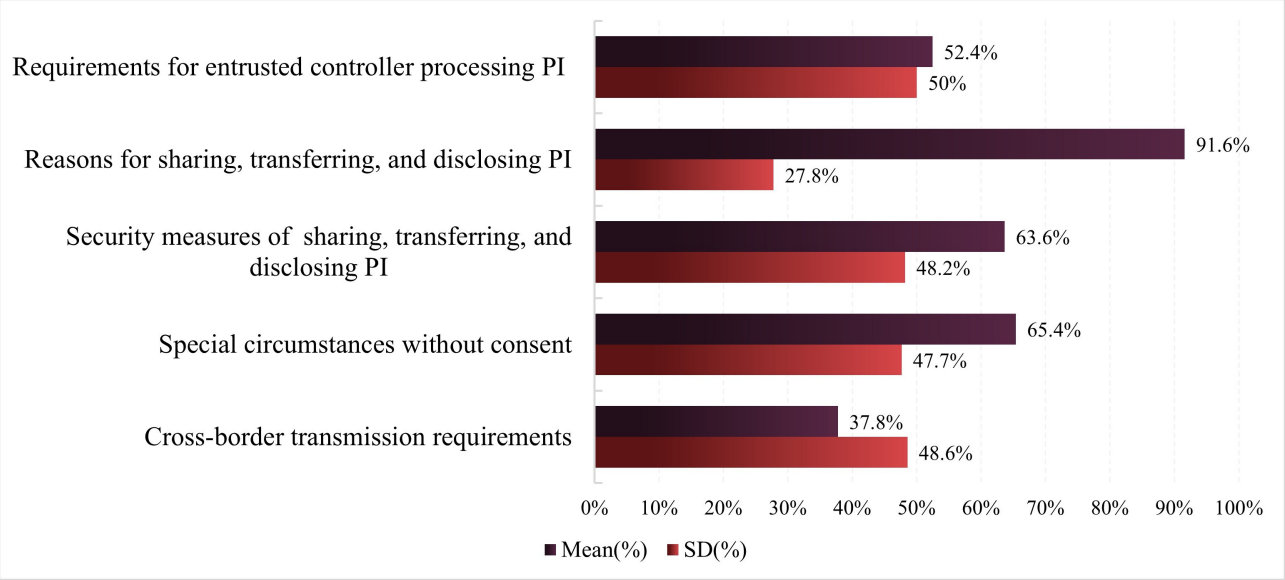

Figure 4. Privacy policy compliance evaluation results of personal information collection.

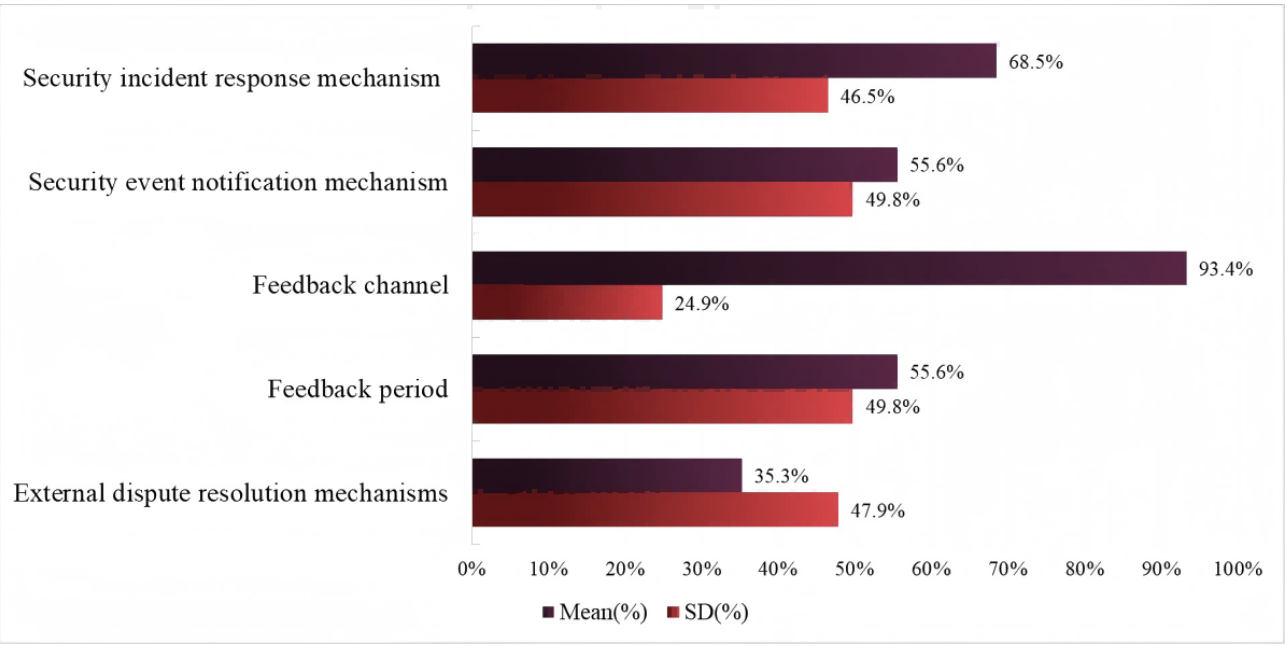
The level 1 evaluation indicator PI entrusted processing, sharing, transferring, and disclosing also demonstrated high privacy policy compliance (mean 62.2%, SD 19.8%) (Figure 5). Except for cross-border transmission requirements (mean 37.8%, SD 48.6%), the privacy policy compliance rate for level 2 evaluation indicators under level 1 PI entrusted processing, sharing, transferring, and disclosing exceeded 50%. The privacy policy compliance rate for reasons for sharing, transferring, and disclosing PI was the highest (mean 91.6%, SD 27.8%), indicating that sports and health apps highly prioritize explaining these reasons to users. This assists in safeguarding users' right to informed consent during the sharing, transferring, and disclosing of PI. The compliance rates of privacy policies for sports and health apps in the requirements for entrusted controller processing PI (mean 52.4%, SD 50%), security measures for sharing, transferring, and disclosing PI (mean 63.6%, SD 48.2%), and special circumstances without consent (mean 65.4%, SD 47.7%) all exceed one-half.

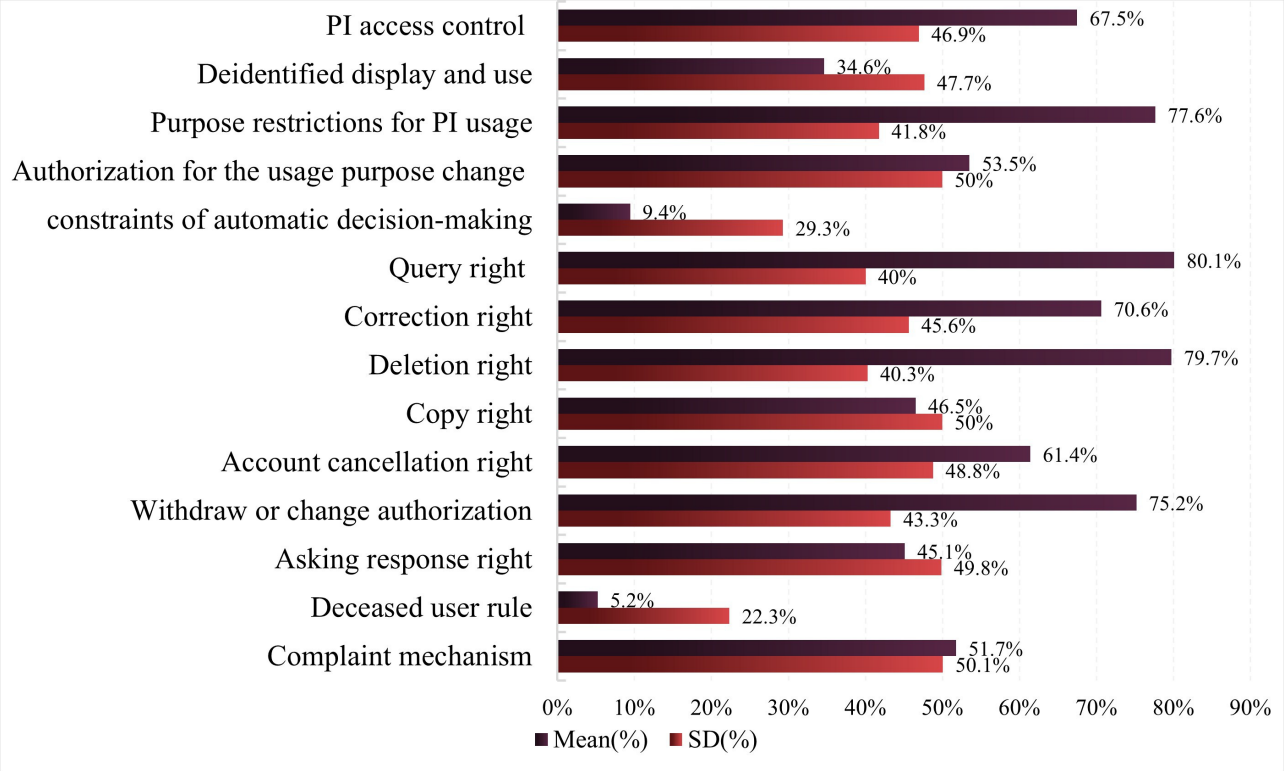


XSL•FO
RenderX

Figure 5. Privacy policy compliance evaluation results of personal information entrusted processing, sharing, transferring, and disclosing. PI: personal information.

Regarding level 1 evaluation indicators, PI security and feedback, the privacy policy compliance rate of sports and health apps in PI security and feedback exceeds half (mean 61.7%, SD 21.3%) (Figure 6). The privacy policy compliance score for the level 2 evaluation indicator feedback channel is the highest (mean 93.4%, SD 24.9%), reflecting that sports and health apps pay great attention to providing users with effective feedback channels in case of disputes regarding the collection, use, and processing of PI. In terms of privacy policy compliance, more than half of the sports and health apps meet the level 2 evaluation indicators: security incident response mechanism (mean 68.5%, SD 46.5%), security event notification mechanism (mean 55.6%, SD 49.8%), and feedback period (mean 55.6%, SD 49.85%). This indicates that over 50% of sports and health apps have established PI security protection mechanisms and security incident reporting procedures, ensuring the safety of users' PI and their right to be informed in the event of information leakage. The compliance of external dispute resolution mechanisms in privacy policies is very poor, with one-third of sports and health apps not having established external resolution mechanisms for PI disputes, which means they do not clearly inform users that they can sue in court if a dispute occurs.

Figure 6. Privacy policy compliance evaluation results of personal information security and feedback.



The level 1 evaluation indicator PI usage is relatively low (mean 54.2%, SD 24.4%) for privacy policy compliance. This indicates that nearly half of the sports health apps do not strictly enforce the protective regulations for PI usage (Figure 7). Sports and health apps generally provide good protection for users' PI rights, with the compliance rate for the query right being the highest (mean 80.1%, SD 40.0%). Compliance rates for the correction right (mean 70.6%, SD 45.6%), deletion right (mean

XSL•FO
RenderX

79.7%, SD 40.3%), account cancelation right (mean 61.4%, SD 48.8%), and withdraw or change authorization (mean 75.2%, SD 43.3%) also exceed half, indicating that the vast majority of sports and health apps can effectively protect users' basic PI rights. However, in terms of user personal information rights, the privacy compliance rates for copyright (mean 46.5%, SD 50%) and asking response right (mean 45.1%, SD 49.8%) are relatively poor, especially for the deceased user rule, which has the worst privacy compliance (mean 5.2%, SD 22.3%). On the other hand, the privacy compliance rates for level 2 evaluation indicators such as PI access control (mean 67.5%, SD 46.9%) and purpose restrictions for PI usage (mean 77.6%, SD 41.8%) are relatively good. The privacy policy compliance rate for authorization for the usage purpose change (mean 53.5%, SD 50%) and the complaint mechanism (mean 51.7%, SD 50.1%) have both exceeded half. Only one-third of sports and health apps meet privacy policy compliance requirements in deidentified display and use (mean 34.6%, SD 47.7%). It is particularly noteworthy that the compliance rate of privacy policies regarding constraints of automatic decision-making is very low (mean 9.4%, SD 29.3%), indicating that the vast majority of sports and health apps do not have restrictions on the automatic decision-making mechanism. This is detrimental to users' ability to decide how their PI is used and processed, leading to negative impacts on the security of PI and users' peace of mind [80].

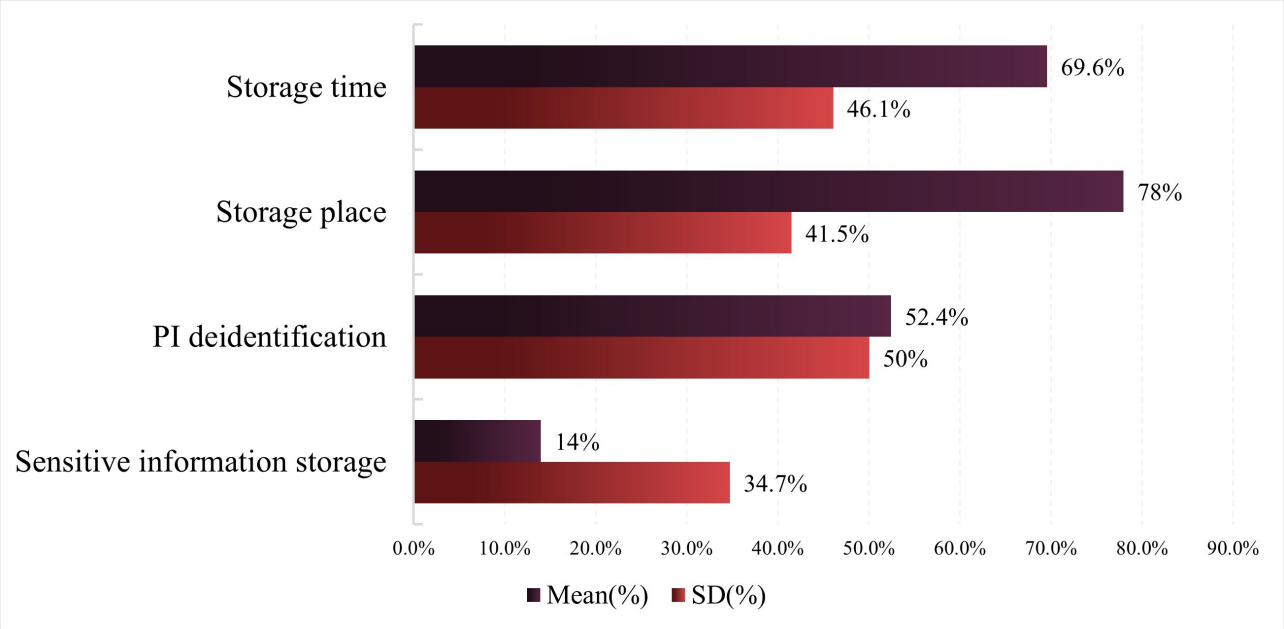


Figure 7. Privacy policy compliance evaluation results of personal information usage. PI: personal information.

The compliance rate of privacy policies for sports and health apps regarding the level 1 evaluation indicator PI storage is the lowest (mean 53.5%, SD 28.4%), with about half of the apps failing to meet the compliance requirements for PI storage (Figure 8). The compliance rate of privacy policies for sports and health apps regarding the level 2 evaluation indicator storage place is the highest (mean 78%, SD 41.5%), while the compliance extent for storage time (mean 69.6%, SD 46.1%) and PI deidentification (mean 52.4%, SD 50%) also performs relatively well. However, the compliance rate of privacy policies for sensitive information storage is the worst among sports and health apps, indicating that the vast majority of apps do not have specific provisions and settings for the storage of users' sensitive PI, which is detrimental to the protection of users' sensitive PI and data security.

XSL•FO
RenderX

Figure 8. Privacy policy compliance evaluation results of personal information storage. PI: personal information.

Discussion

Principal Findings

We developed a privacy policy evaluation scale by integrating scenario-based contextual analysis theory and information life cycle theory, grounded in the provisions of the PIPL and PI Guidelines, to assess privacy policies of mobile sports and health apps. Our defined context encompasses scenarios where users use these apps to record physical activity data, exercise routes, and fitness instructions, all directly related to physical exercise.

This study's findings demonstrate that 286 evaluated apps in the Chinese Mainland are failing to meet core PI protection requirements, with critical gaps in the overall compliance of the 286 apps, policy update, sensitive PI protection, key user rights, PI transferring, and PI security management.

First, our analysis indicates that the overall compliance level of privacy policies among 286 sports and health apps is not high. The compliance levels varied (mean 61%, SD 24.3%), with a minority of apps demonstrating strong compliance while others showed lower compliance. Sports and health apps with low compliance primarily violate the PIPL and PI Guidelines, which share common principles with many other jurisdictions. Furthermore, low privacy policy compliance of apps can have several direct and indirect negative consequences for users, including security risks, loss of control, and intrusive marketing. This indicates the need to strengthen PI regulatory oversight for sports and health apps and establish standardized, actionable practices.

Second, data analysis suggests that PI collection has the highest level of compliance. According to Article 14 of the PIPL, if the collection purpose, method, or types are changed, a separate consent shall be obtained from users. However, data analysis indicates that compliance rates regarding privacy policy updates are unsatisfactory, with only 122 out of 286 apps adhering to this requirement. Indeed, many app developers operate under the assumption that continued use equates to user consent, rather than proactively seeking explicit approval. This lack of compliance undermines both user dignity and security, increasing the risk of data misuse and breaches. To address this, we argue that apps should instead secure explicit consent through clear pop-up notifications, much like during the initial sign-up process. Users should be required to actively confirm their agreement; otherwise, access to the app's services should be limited or denied.

Third, we found that the privacy policies of sports and health apps exhibit significant shortcomings in protecting sensitive PI. It should be noted that the PIPL (especially Chapter II, Section 2) and the Guidelines (especially Article 5.4) provide special protection for the collection of sensitive PI. Substantively, Article 28 of the PIPL specifies the substantive conditions for processing sensitive PI, namely, PI processors can process sensitive PI only when there is a specific purpose and when it is of necessity, under the circumstances where strict protective measures are taken. Procedurally, Articles 29 and 30 of the PIPL and Article 5.4b of the PI Guidelines require that a processor processing sensitive PI shall notify the individual of the necessity of processing their sensitive PI and the impact it has on their rights and interests," and that sensitive PI processors must obtain informed, voluntary, specific, clear, unequivocal, and separate consent from PI subjects. The substantive and procedural requirements have also been highlighted by the Notice of the Ministry of Industry and Information Technology on Further Enhancing the Service Capacity of Mobile Internet Applications [81]. However, our data analysis shows that the compliance rate of sensitive PI protection (mean 29.4%, SD 45.6%) is significantly lower than that of general PI protection (mean 83.6%, SD 37.1%). This disparity not only indicates how inadequate the present security measures are for protecting sensitive PI, but it also continuously lowers users' awareness of security when providing sensitive PI. Additionally, it is also important to note that although a total of 40 apps referenced sensitive PI storage, none comply with the storage requirements

XSL•FO
RenderX

of the PI Guidelines, which mandate encryption (Article 6.3.a) and, in principle, the elimination of original personal biometric data (Article 6.3.c), including samples and photographs. In the 40 apps, one just lists the types of sensitive PI, such as personal identity information and biometric information. The other apps fail to explicitly state the protection measures for sensitive PI; instead, their statements imply that adequate protection measures have been taken and that they would do their best to protect sensitive PI. This reveals a serious security concern, because if sensitive PI is leaked, tampered with, or used illegally, it may endanger the user's personal or property safety.

Fourth, our analysis indicates that comprehensive compliance with the protection of users' PI rights remains weak. In terms of user rights, although most apps effectively list a series of user rights, including query rights, correction rights, deletion rights, withdraw or change authorization rights, and account cancellation rights, less than half of the apps give users the right to obtain a copy of PI and ask for a response. Notably, only 27 of the 286 apps provide users with the right to refuse using automated decision-making mechanisms. Currently, personalized recommendation technologies and artificial intelligence technologies are advancing rapidly. Automated decision-making mechanisms based on algorithms have been widely adopted in the operation of sports and health apps. The vast majority of these apps do not grant users the right to opt out of automated decision-making processes. This results in the infringement of users' autonomy over the collection, use, and processing of their personal information, violating the principles of legitimacy and transparency enshrined in PIPL. Consequently, users may be misled in their app usage, experience improper collection of their information, and face frequent disruption from app notifications. Fewer apps have provided deceased user rules, that is, unless otherwise arranged by the deceased before their death, their close relatives have the rights to access, copy, correct, delete, and other rights related to the deceased's relevant PI. This will trigger disputes over the usage and inheritance of deceased individuals' digital assets, hindering the normal operation and development of sports and health apps.

Fifth, our findings reveal that privacy policies for sports and health apps require further refinement regarding regulations on sharing, transferring, and disclosing PI. While most apps state the reasons for sharing, transferring, and disclosing PI, significantly fewer of them will take technical measures to ensure information security and obtain the user's separate consent. Notably, even fewer apps' privacy policies specify that when PI is shared or transferred to overseas processors, the user should be separately informed of the purpose of data export and the receiver, and the user's authorization should be separately obtained. This is obviously lower than the standards stipulated in Article 23 of the PIPL and Article 9 of the PI Guidelines, which may damage the users' ability to monitor the whole PI processing process, their security awareness of transferring PI, and their trust in apps, and the principle of informed consent.

Finally, our analysis reveals that sports and health apps do not provide users with clear response times for feedback. User data collection occurs in real time, and this frequent gathering inevitably leads to issues or disputes during usage. At such times, a timely and effective feedback and dispute resolution mechanism becomes crucial for resolving problems, maintaining user retention, and helping apps build a positive reputation. However, many sports and health apps merely provide feedback channels without establishing timelines for addressing concerns. This lack of accountability discourages apps from proactively and effectively resolving feedback issues and disputes. Additionally, many sports and health apps lack robust PI security safeguards and reporting mechanisms, making personal data vulnerable to infringement and posing serious risks of data breaches. This will lead to a decline in users' trust in the app's privacy protection, making users more cautious about providing personal information, especially sensitive personal information, and may lead to users uninstalling the app.

Recommendations

The study's findings collectively demonstrate that 286 evaluated apps are failing to meet core PI protection requirements. Critical gaps in PI protection are primarily attributed to 3 factors. First, there is a deficiency of awareness among users regarding PI protection, reducing incentives for app developers to prioritize privacy. Second, existing PI guidelines lack legally binding force, resulting in inconsistent adherence and voluntary compliance. Third, insufficient regulatory oversight and weak enforcement mechanisms fail to deter noncompliant practices. These factors collectively undermine the effectiveness of current PI protection frameworks, highlighting the need for targeted action from 3 stakeholders: users, regulators, and legislators. We argue that only through coordinated action can the app ecosystem close the compliance gaps identified in this study, reduce PI protection risks, and restore user trust in digital services.

First, to strengthen app privacy compliance, it is essential to enhance users' PI rights awareness [82]. We argue that interventions can be scenario-embedded and accessible. For example, app developers are encouraged to integrate snapshots of PI rights into app onboarding when users consent to privacy policies, paired with visual resources that translate legal jargon into simple guidance [83]. This ensures users learn rights when they interact with PI-related features, not just through disconnected policy texts. Additionally, official complaint channels should be easily accessible to hold apps accountable for noncompliance, which can drive industry-wide improvement [84].

Second, the regulatory mechanism for sports and health apps should be standardized. Under the current legal framework, the regulatory mechanism for apps can be characterized as self-regulation by app operators, with government oversight as a supplementary measure. Moreover, in terms of the institutional framework in the Chinese Mainland, regulators are dispersed across many different government departments, resulting in a lack of enthusiasm for law enforcement and of technical capacity for supervision. As a result, the regulation of apps in practice is inadequate. In this context, we recommend creating a unique data regulator to assess and oversee the privacy protection of apps and raising the industry's entry barrier through the issuance of compliance identification or certifications [64]. This regulator can strengthen enforcement of low-compliance areas, such as

XSL•FO
RenderX

sensitive PI storage and policy updates, through regular audits and penalties for noncompliance [63].

Finally, laws and regulations for the protection of personal health information should be improved. The Civil Code [85], the Cybersecurity Law of China [86], the Law of the People's Republic of China on Basic Medical and Health Care and the Promotion of Health [87], and the PIPL formulate the legal framework for protecting personal health information. While these laws are comprehensive, the majority of them contain oath and principle clauses that are not applicable in specific cases. Although many of these principles and oath clauses are further crafted in the PI Guidelines, these guidelines do not have the force of law; instead, they are merely recommended standards and are not mandatory by nature. In this regard, we suggest that the legal effect of adopting the PI Guidelines should be clarified in laws and regulations. In this way, the app operator should specify in the first part of the privacy policy whether the PI Guidelines are adopted, and once adopted, they will be legally binding [66].

Contributions

This study holds significant implications for both policymakers and scholars. First, based on the principal findings—particularly that the privacy protection requirements established by the PIPL demonstrate a higher level of compliance compared with the PI Guidelines—we propose that legislation should strengthen the binding force of the PI Guidelines, thereby providing guidance for legislative reform. Second, the current low compliance with privacy policies may be linked to inadequate regulatory enforcement. In response to the fragmented regulatory oversight in practice, we recommend the establishment of an independent regulator to enhance the effectiveness of privacy protection enforcement. Finally, this study addresses a gap in the existing literature. While existing studies have explored the relationship between health apps and privacy protection in Australia [4,88], between mHealth apps and privacy protection [89-93], and between health code apps and privacy protection in China [94,95], the legal compliance of sports and health apps with the PIPL and PI Guidelines, as well as China's legislative framework for PI protection, was not thoroughly examined in these studies. This study fills this gap by examining the privacy policies of 286 sports and health apps across 37 evaluation dimensions and assessing whether these privacy policies comply with the PIPL and PI Guidelines.

Limitations

However, this study also has limitations. Although we developed an indicator scale to assess the compliance level of privacy policies of the 286 sports and health apps, this evaluation process does not concern the actual implementation of different technical measures, resulting in the omission of evaluation criteria and the lack of targeted recommendations for improvement from a technical point of view [96]. For instance, an app may explicitly state in its policy that it encrypts sensitive PI during storage but may not actually implement consistent encryption protocols in its backend systems. We hope that future research can treat this study as a starting point to further analyze the processing of PI and the design and implementation of PI protection measures in the information system, by using technical methods, such as network traffic analysis or third-party data flow auditing, and adopting the research method of interviewing relevant personnel including product managers, research and development engineers, PI protection officers, legal personnel, system architects, security administrators, operation and maintenance personnel, human resources personnel, system users, and so on.

Conclusions

The extensive usage of sports and health apps is significantly enhancing the social and public health landscape in the Chinese Mainland. Nonetheless, the security threats to PI protection arising from privacy policy compliance have not received adequate attention. This paper's assessment of the overall compliance level of 286 sports and health apps and the individual evaluation of 37 privacy policies reveals a complex picture of PI protection. Although some apps establish commendable compliance policies, there are some shortcomings. These shortcomings not only pose security threats to app users but may also hinder operators in optimizing and developing app functionalities. In light of this, this paper puts forward suggestions for improvement from the perspectives of user awareness, regulatory enforcement, and legislative reforms.

Abstract

Background: Digital health tools are increasingly used in mental health care to passively collect patient data and analyze health status outside of clinical settings. While technologies such as digital phenotyping, affective computing, and computational behavioral analysis offer new insights into symptom manifestation in daily life, they generate large volumes of potentially sensitive data that raise significant data privacy concerns, requiring high levels of patient awareness and consent. Empirical research is lacking on stakeholder understandings toward the sensitivity of these data and expectations for data stewardship, perspectives that are critical for developing robust informed consent and data protection policies for digital health data use.

Objective: This study aimed to explore key stakeholder perspectives on the sensitivity of computer perception (CP) data, trust in existing data protections, willingness to share CP data externally, and desire for transparency of CP data transactions outside of the clinical space.

Methods: As part of a larger, multisite study, we conducted qualitative interviews (n=40) via Zoom (Zoom Communications, Inc) with 20 adolescents (aged 12 - 17 years) familiar with CP tools and their caregivers (n=20). Interviews consisted of a series of open-ended questions regarding stakeholders' perspectives on privacy, data security, and the use and exchange of CP data. We developed a qualitative codebook to identify and label thematic patterns in responses to questions addressing the topics above, using thematic content analysis to identify themes inductively. Each interview was coded by merging work from at least two separate coders, and several team members contributed to qualitative analysis.

Results: Most adolescents and caregivers viewed CP data as highly sensitive and expressed a reluctance to share these data beyond their clinical teams. While many participants expressed trust in existing data protections to protect CP data, they often misunderstood or overestimated the extent of protections to safeguard CP data.

Conclusions: Our findings underscore the critical need for clear and effective patient communication and education about the risks, benefits, and protections associated with CP data through informed consent protocols. To promote greater transparency, understanding, and trust, we recommend 5 strategies: educating patients about data protection; studying secondary data exchange and reidentification risks; strengthening transparency regulations; improving data traceability mechanisms, such as distributed ledger technologies, to enhance data traceability and auditability; and adopting dynamic consent models.

Introduction

Mental health care is undergoing rapid change as researchers and clinicians adopt digital tools and mHealth (mobile health) apps to support diagnosis and monitoring. Approaches such as digital phenotyping [1-5], affective computing [6,7], and computational behavioral analysis [8,9] involve algorithmic analysis of continuously and passively collected data from patients outside of clinical settings in an attempt to offer more ecologically valid insights into how symptoms manifest in daily life. We refer to these approaches as computer perception (CP) technologies, a term that builds on computer vision but reflects a broader set of sensing methods, including voice, movement, location, and physiological signals (eg, heart rate and skin

XSL•FO
RenderX

conductance). Despite their nuanced distinctions [5], these CP approaches generate large volumes of potentially sensitive data to enable various forms of clinical inference, particularly when triangulated and used alongside remotely administered self-report measures ("ecological momentary assessments"), often via mHealth platforms. Given their promise for data-centric and value-based care, CP technologies are increasingly applied across psychiatry and other areas of medicine (eg, cardiology [10], pain management [11], maternal health [12], and asthma [13]) that benefit from insight into behavioral patterns outside the clinic.

At the same time, CP tools also introduce significant ethical and privacy concerns, necessitating robust approaches to informed consent and data protection that directly respond to how individuals understand the sensitivity of these data and how they are—or should be—protected. A major challenge in digital health is the misalignment between stakeholder expectations and actual data governance practices [14-16]. Individuals may assume these data are safeguarded under existing health privacy laws, such as the HIPAA (Health Insurance Portability and Accountability Act), even when these data fall outside formal regulatory coverage [17-19]. Prior work shows that when perceived safeguards prove illusory, this misalignment can erode trust, reduce willingness to share data, and compromise sustained engagement with digital health tools [20].

This paper builds on this literature by presenting results from in-depth interviews exploring stakeholder understandings of the sensitivity of CP data, trust in existing data protections, willingness to share CP data for clinical or research purposes, and preferences for transparency around CP data transactions outside the clinical space. Although our empirical data were collected in the United States and reference US health privacy frameworks, the ethical and practical challenges we examine are not unique to North America. Across jurisdictions, rapid growth in digital health and sensing technologies has outpaced public understanding of how personal data is governed, shared, and reused. Even under the European Union's General Data Protection Regulation (GDPR), which provides broader formal protections for certain categories of personal data, enforcement gaps, limited transparency, and user misunderstandings persist, particularly for passively collected behavioral and biometric data [21].

Many CP data are not directly clinical in nature. Unlike traditional medical data, CP data may be collected for clinical purposes while remaining usable for nonclinical applications, such as marketing or profiling [19,22]. Importantly, CP data often fall between established categories of personal data, combining elements of identity data (eg, location, voice, facial features, and device identifiers) and clinical data (eg, inferred symptoms or functional states), even when they are not explicitly diagnostic on their own. Public perspectives on digital health data indicate that users may not perceive their self-tracked health information with the same sensitivity as traditional personal health information (PHI), despite the fact that these data can reveal sensitive information about a person's health or reproductive status [19].

As these data are not always classified as PHI, these "nontraditional health" (NTH) data often receive weaker legal protections, particularly in jurisdictions where health privacy laws apply narrowly to clinical records and covered entities. In the United States, for example, many CP data fall outside the scope of HIPAA, whereas in other jurisdictions, such as the European Union, broader data protection frameworks such as the GDPR may apply, at least in principle, to biometric and behavioral data. However, this regulatory ambiguity creates gaps in transparency, accountability, and user awareness [23,24]. Additionally, public misunderstandings regarding GDPR's scope in relation to biometric or behavioral tracking data contribute to ongoing challenges in ensuring informed consent and ethical data management [25].

We argue that this misalignment reflects a more fundamental lack of computational mechanisms, alongside supportive regulatory frameworks, that enable transparent tracking of patient and consumer data. This lack of visibility into how data moves across clinical, research, and commercial contexts perpetuates misunderstandings, power imbalances, and trust gaps between individuals, institutions, and technology systems, leading to collective vulnerabilities in privacy, autonomy, and equitable access to digital health benefits.

These ambiguities leave NTH data vulnerable to unwanted or undisclosed forms of data access and exchange by third-party data controllers (eg, large technology companies), particularly given that many mHealth apps lack adequate data security and confidentiality assurances [26]. Further, because many CP data are generated in the context of research-industry partnerships, uncertainties persist around what may be done with these data, to which entities control or claim ownership rights, where data are stored (eg, hospital vs corporate servers), and who holds decision-making authority over data access and exchange (eg, researchers, companies, or data brokers). A growing body of research suggests that public trust in data protection measures varies by institutional affiliation, with greater skepticism toward commercial data handlers [27].

Such concerns extend across data types, ranging from PHI to NTH data, collected within health care [19,22,28,29] as well as outside of health care, including browser history and consumer behavior data used for targeted marketing and personalization [29,30]. Extensive empirical literature documents public concerns about data privacy, transparency, and control and a desire for greater authority over what personal information is collected and who has access to it [27,31-35]. While numerous studies have examined perspectives on privacy, security, and confidentiality in mHealth apps [36-38], and others have explored attitudes toward CP technologies in relation to acceptability, adoption of, and adherence [37-45], few specifically investigate how individuals understand the handling of CP data after collection or how these understandings align with the realities of health information exchange (HIE) in the United States and elsewhere.

Patients and research participants may assume these data constitute PHI when collected in clinical or research settings, leading to misinterpretations of the degree to which these data are protected under data privacy laws—much as consumers

XSL•FO
RenderX

often assume their personal data are protected by default on websites or mobile apps without reading the terms of service or privacy policies [46-48]. Such misinterpretations are compounded by limited transparency about the benefits and risks of collecting CP data at the time of consent, as computational analysis capabilities continue to expand.

Examining alignment or misalignment in understandings about the nature and governance of CP data is therefore critical for developing patient education and informed consent protocols that clearly articulate potential benefits and risks. In this paper, we present findings from a qualitative investigation of adolescents' and caregivers' perspectives on sharing passively collected CP data. Our study aimed to explore key stakeholder perspectives on: (1) the perceived sensitivity of CP data; (2) trust in existing data protections governing CP data; (3) willingness to share CP data for clinical or research purposes; and (4) preferences for transparency around CP data practices and transactions—with the goal of informing more robust informed consent protocols and data governance recommendations for CP and related digital health technologies. We focus on CP data collected in settings where research and clinical care increasingly overlap, such as clinical trials embedded in health care systems, validation studies for tools intended for clinical deployment, and digital health platforms developed through academic-industry partnerships. While research and clinical contexts are governed by distinct ethical and regulatory standards, participants' expectations about data protection and use often span, or fail to distinguish between, these domains. We conclude by offering targeted recommendations to improve transparency and informed consent practices surrounding the collection and exchange of CP and other digital health data.

Methods

Study Design

This research aimed to explore ethical considerations for translating CP technologies into clinical care. Through in-depth, semistructured interviews, we explored perspectives on benefits, risks, and concerns around the integration of CP technologies, which also involved a supplementary exploration of specific concerns around privacy, data security, and perspectives toward the use and exchange of CP data.

Participants

As part of a multisite study funded by the National Center for Advancing Translational Sciences (R01TR004243), we recruited 40 participants between January 2023 and August 2023. Participants were recruited from a sister research study (R01MH125958) conducted within a clinical research setting, focused on validating CP tools designed to quantify objective digital biobehavioral markers of socioemotional functioning. Participants in our sister study were recruited from a clinical care setting in a large academic medical center using word of mouth. As part of that study, CP data were collected in a laboratory setting for research purposes with the stated goal of informing future clinical applications. As such, participant perspectives reflect experiences situated at the boundary of research and clinical care. Our choice to recruit from this sister study was also to ensure familiarity with and exposure to the collection of CP data, to enhance the ecological validity of our findings. Participants included adolescents (n=20) aged 12 - 17 years and their caregivers (typically biological parents, see Table 1). The adolescents had previously received neurodevelopmental (ie, autism) and/or psychiatric diagnoses of autism, anxiety, or depression and potentially diagnoses that often accompany these (eg, attention deficit/hyperactivity disorder or obsessive compulsive disorder). Diagnostic presentations for all adolescents were confirmed through the administration of standardized clinician interviews. Participants were told about this study by a research coordinator from our sister study. Individuals who expressed interest in participating were referred to this study by the sister study's coordinator and then contacted by a research assistant (RA) via phone or email to schedule a virtual interview. Our response rate was approximately 63% for patients and caregivers (63 people were contacted and 40 people agreed to participate).

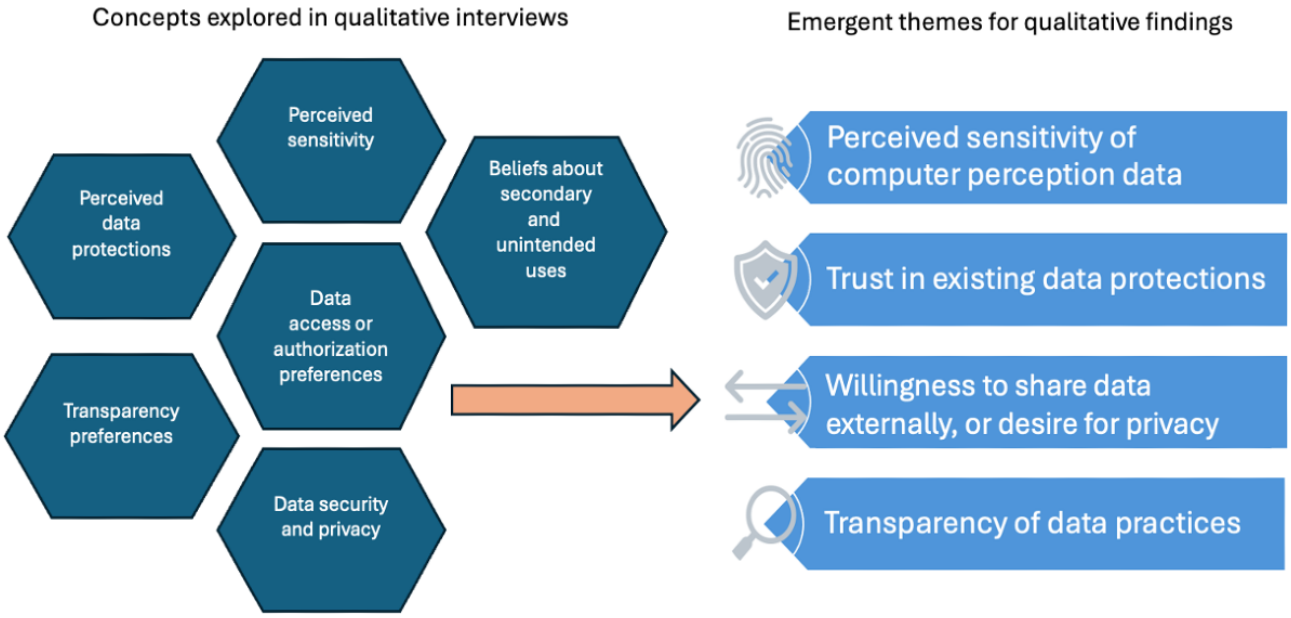
Data Collection

We developed separate interview guides for adolescents and their caregivers (Multimedia Appendices 1 and 2), exploring the same constructs across both groups with appropriate variations in wording. Guides were informed by prior work exploring user perspectives in data privacy and governance [14,15,17,19,20,22,27,29-38] and with the guidance of experienced bioethicists, child mental health experts, and computational scientists who develop these algorithms. Constructs included data security and privacy issues, regarding perceived sensitivity of this type of data and data collection, beliefs about the potential for unintended uses and current data protections, thoughts on secondary usage of their data and access authorization, and transparency needs or preferences of their personal data and its transactions or security processes. Initial drafts of the interview guides were piloted with two psychologists specializing in adolescent mental health, resulting in minor clarifications in wording. Interviews were conducted by RAs (authors CD, AS, and MEH) with extensive training in qualitative interviewing and analysis. Interviews were held via a secure videoconferencing platform (Zoom for Healthcare [Zoom Communications, Inc]) and lasted an average of ≈45 minutes. Before beginning the interview, each participant was presented with a 7-minute primer video (Multimedia Appendix 3) explaining the nature and intended use of CP data in clinical research and health care (ie, a basic, 8th grade-level understanding of how CP technologies collect and analyze data and how they might be used during a clinical encounter), including the different types of CP technologies available and the types of data they collect (eg, different types of wearables, smart devices, and sensors that stakeholders would likely be familiar with and that can collect vocal, facial, accelerometry, GPS, heart rate data, and more). The primer video was developed to ensure informed responses from patients and caregivers who are likely to be less familiar with this suite of technologies. Additionally, the RA stopped the video at key predesignated intervals (eg, after the original explanation of how CP collects and analyzes patient data, after providing an example of what the integration of these tools into a traditional clinical assessment could look like, etc) to assess understanding and elicit clarifying questions from participants to ensure comprehension. Recruitment continued until we observed significantly diminished novel informational returns from each subsequent interview ("saturation"). Operationally, research team members reviewed transcripts to identify novel insights not present in prior interviews. Saturation was determined when successive interviews within a stakeholder group yielded no new insights, which occurred in around 20 interviews per stakeholder group.

Ethical Considerations

This study was reviewed and approved by the Baylor College of Medicine Institutional Review Board (H-52233), which also waived a requirement for written consent due to research procedures involving minimal risk to participating stakeholders; thus, participants provided verbal consent. Minors provided assent with parental consent. Identifying participant information was stored in a password-protected system with 2-factor authentication behind a university firewall. All results are reported in the aggregate and are not linked to identifiable participants. Each participant received a US $50 gift card as compensation for their time.



Data Analysis

Interviews were audio-recorded, transcribed verbatim, and analyzed using MAXQDA (VERBI GmbH) software. Led by a qualitative methods expert, team members developed a qualitative codebook to identify and label thematic patterns in adolescent and caregiver responses to questions addressing the topics above. Codebook development followed a hybrid inductive–deductive approach. We formed an initial set of broad analytic domains informed by prior literature on digital health ethics, data governance, trust, privacy, and informed consent [19,23-27,29-38], which served as sensitizing concepts rather than fixed categories. Within these domains, codes were developed inductively through our familiarity with the interview content (all team members listened to all interview recordings) and a close review of a subset of transcripts to capture emergent concepts. Codes and definitions were iteratively refined in collaborative team meetings, and subsequently used to identify patterns in the data using thematic analysis [49]. Specifically, outputs for each code were further analyzed by progressively abstracting relevant quotes, an inductive process that entails reading every quotation to which a given code was attributed, paraphrasing each quotation (primary abstraction), and further identifying which constructs were addressed by each quotation (secondary abstraction). These constructs mapped onto a core set of thematic findings across four emergent domains (see Figure 1). Each of the concepts in these four domains was further categorized along a scale of "high," "medium," or "low" (eg, "high" need for transparency) to examine relationships between beliefs and perspectives, informational needs and preferences, and trust. These designations reflect consensus-based qualitative judgments by the research team, grounded in close analysis of coded excerpts, rather than participant ratings or a formal scale. Each interview was coded by merging work from at least two separate coders to reduce interpretability bias and enhance reliability. To ensure the validity of our findings, all abstractions were validated by at least one other member of the research team before calculating thematic frequencies to characterize stakeholders' responses and obtain a sense of the proportion of stakeholders raising or discussing each concern/theme. In rare cases where abstractions reflected conflicting interpretations, members of our research team met to reach consensus. Frequencies were used as a descriptive aid to convey the relative salience of perspectives across participants, consistent with pattern-based thematic analysis, and were not intended to suggest statistical significance or quantitative generalizability [49]. Frequencies account for participants who expressed perspectives that were ambiguous or context-dependent (eg, perceiving CP data to be highly sensitive in some situations but not in others) and were calculated when respondents expressed views across the high, moderate, and low categories. Frequencies and percentages reflect only reported information and therefore do not always

XSL•FO
RenderX

sum to 100%, as some respondents did not express perspectives across all themes.

Figure 1. Transformation of qualitative inquiry domains into thematic findings.

Results

Overview

The results are organized around four analytic domains identified through thematic analysis of transcripts from 20 adolescents and 20 caregivers (total N=40; see Table 1). These domains include the following: (1) perceived sensitivity of CP data; (2) trust in existing data protections; (3) willingness to share data externally and desire for privacy; and (4) transparency of data practices (see Table 2). Within each domain, we describe the range of perspectives expressed by participants and use qualitative descriptors (eg, high, moderate, and low) to summarize relative emphasis and salience, illustrated with representative quotations (eg, higher to lower perceived sensitivity and higher to lower trust in existing data protections). Frequencies and percentages of expressed views across these domains are presented in Table 2, intended to aid interpretive comparison between and across groups. Taken together, our results indicate that most caregivers and adolescents view CP data as moderately to highly sensitive, are reluctant to share these data beyond their clinical teams, and expressed a desire to have visibility into or control over both primary and secondary uses of their data. Notably, adolescents expressed higher trust in existing data protections compared to caregivers. Most caregivers shared that they were less willing to share data externally compared to adolescents. The following sections elaborate on and summarize these findings, complemented by illustrative quotes.

[a]CP: computer perception.

[b]Dashes throughout the table represent areas where no participant expressed perspectives that fall into those categories (eg, no adolescents or caregivers viewed computer perception data to be “low sensitivity”).

[c]This category was only present for these 2 themes but represents significant ambivalence among certain participants who expressed views across each level.

Perceived Sensitivity of Passive Continuous Monitoring Data

Most participants (15 adolescents and 14 caregivers) perceived CP data to be highly sensitive. Participants commonly understood CP data as revealing intimate aspects of identity, emotion, and daily life, leading many to view continuous monitoring as intrusive even when collected for clinical purposes. Some characterized it as an “invasion of privacy” (A16) because such data capture the “emotions and feelings of a person” (A16) or “who you are on the inside” (CG03; see Table 3). Some caregivers characterized continuous monitoring as “unnerving” (CG08) or “debilitating” (CG03), or likened it to “big brother” surveillance (CG19). More than half of all participants expressed a desire to pause or disable monitoring

XSL•FO
RenderX

during moments they considered private. These moments included private conversations, conflicts with family members, funerals, intimate situations, or emotionally vulnerable situations. Both stakeholder groups expressed a view that the potential negative impacts of collecting CP data may be especially pronounced in the context of physical and socioemotional changes associated with adolescence (eg, "where it would affect [their] self-image" CG07).

By contrast, a smaller number of participants (5 adolescents and 1 caregiver) viewed CP data as less sensitive, with one adolescent stating that it felt "sort of like wearing a Fitbit" (A07), particularly when perceived clinical benefits were salient (as noted by 6 adolescents and 9 caregivers).

Some stakeholders (3 adolescents and 5 caregivers) expressed ambivalence. For example, one caregiver shared that while the data itself did not seem invasive, since "our watches collect and our phones collect this kind of stuff all the time" (CG01), they would nevertheless be bothered if the data were shared with third parties (eg, insurance companies and future employers) without their knowledge (see also Willingness to Share CP Data section below).

XSL•FO
RenderX

Table . Quotes illustrating varying levels of perceived sensitivity of CP[a] data.

Perceived sensitivity: stated rationales	Adolescent quote	Caregiver quote
Highly sensitive		
CP data deserves greater protection than biological data	"It is a little bit more sensitive because it feels a lot more with the emotions and feelings of a person. So I do think they should be treated with a little bit of extra care." A16	"We need to have more protection [for CP data]. Because it's just different information. That's the voice, the facial expressions, again, that it's not going to be used for wrong purposes." CG16
CP data deserves the same high legal protections as other medical data	"It should be treated equal, because all medical information, unless you actually disclose it to somebody, it's not supposed to be known." A01	"Probably about the same [amount of protection]... Certainly not less." CG01
CP captures highly sensitive (personal) information: emotions, facial expressions, etc	"I think some people would maybe be reluctant to do things like this... Maybe people are afraid that something…may get exposed or… don't want someone examining their facial expressions [or] they don't want other people to know about something [a condition] they may or may not have." A01	"The physician has access to your naked body. But with emotions it's like having access to the naked naked because it's really who you are on the inside too. Things that you are unable to express. A machine that would be able to intimately know where you are, it's absolutely debilitating, it's scary." CG03
Passive continuous data collection is invasive and unsettling	"I wouldn't necessarily want it to monitor everything that I say. I would think that would be a bit invasive." A02 "It feels kind of invasive because I feel like it would just depend on the situation. You don't know, maybe there's a reason you aren't telling people about it and if they know without asking...it just seems invasive sometimes." A14	"So her DNA test says…she has a 40% higher chance than most people of developing, in the future, age related macular degeneration. That was helpful. So she takes lutein and ocuvite because it's progressive through time. But that was very easy to do. It was private. Blood test. She knows. I know. Her doctor knows, but it's not as invasive as what you're proposing." CG07
CP data collection is especially sensitive for adolescents	"If I was getting in a fight with my siblings or stuff like that, maybe I wouldn't want that to be recorded." A13	"When they hit high school. It gets very difficult. You've got all of those other complexities, the peers and society, I'm trying to figure out how I fit. It's really complex. When you're talking personal intrusiveness, I don't know. I'm a little sketchy on that." CG11
Moderately sensitive		
CP is invasive but justified by clinical benefits	"It's a little invasive. I personally wouldn't want my doctor to see like every single emotion and feeling that I'm having throughout the day. But at the same time, if there's someone who's unable to tell their feelings or emotions or what they're feeling properly, then it could be great help. It's helpful at the same time." A04	"If we come to the doctor and they explain, 'Hey, this is going to be better to help me, help you,' then sure, but unless we specifically come with a very specific issue... That's probably overkill. They deserve some privacy." CG04
Prefer ability to turn off continuous data collection in certain circumstances	"I feel actually most places I would probably just have it turned off because I don't like the idea of people knowing where I am at all times in case that data gets out… That just seems like a weird thing to me." A07 "When I'm going to the restroom or something like that." A17 "Probably when I'm taking a shower or something." A05 "Probably just my sleep." A04	"What if she wants to get intimate with her partner or to take a bath or she's having a really hard bowel movement that day. Those are certain things that might raise your heart rate that you don't necessarily want anybody to know about. It's very personal and doesn't necessarily need to be part of her diagnosis process... I think there should definitely be times you're allowed to take it off." CG05
CP data is more vulnerable to misinterpretation (needs context, can be subjective, etc)	"I guess the eye tracking and the listening to my voice**…**it's all being processed by maybe someone else or AI or something like that. And maybe someone else interprets what you're feeling differently than what you are actually feeling. Maybe you're trying to hide something and they just don't see it." A02	"I just worry that it could be wrong because sometimes computers don't know everything. They're not human. And it would be messed up for it to say, oh, well this person is feeling this and that person is not feeling that. It could mess up something. Oh, your child's feeling sad, to the point where they want to kill themselves. And [your kid is] like, 'No, that's not what I feel.' So I just worry about the error rate." CG08
Less sensitive		

XSL•FO
RenderX

Perceived sensitivity: stated rationales	Adolescent quote	Caregiver quote
No strong desire to turn off continuous monitoring in certain situations	"I mean there's nothing that's insanely private. I mean, [there aren't any moments where I would not want it to collect data in the moment], not that I can think of off the top of my head at least." A12	"Again, without being in that moment, no... I can't think of a thing where I would want total and utter privacy." CG10
Views CP as having a similar (low) sensitivity as other wearable or smartphone data	"I don't have that huge of a problem with it. I think it's sort of like wearing a Fitbit where it counts your steps and things like that. My only concern would be privacy, being shared with other people." A07	"Our watches collect and our phones collect this kind of stuff all the time. I think that if that's being transmitted to your insurance company or potential life insurance or disability insurance companies and they're going to rate you based on things like that, I guess that would probably bother me to some extent. But you don't want to get paranoid about it, you just want to be realistic about it." CG01

[a]CP: computer perception.

Trust in Existing Data Protections

Most participants (14 adolescents and 14 caregivers) expressed moderate to high trust in existing data protections governing CP data (see Table 4). This trust was largely grounded in confidence in clinicians and health care institutions, often accompanied by assumptions that CP data are protected under established health privacy laws. Several adolescents stated they had no concerns about CP data being shared beyond their doctor (eg, A11 and A13), while others emphasized that clinicians "are there to help you" and therefore could be trusted with sensitive data (A16). Some caregivers explicitly assumed that CP data were protected under HIPAA, stating that they "would expect the same type of privacy laws to apply" (CG03). This subset expressed more cautious trust, noting that while they had "no major concerns," they still wanted reassurance that data protections were "following HIPAA" (CG05). Notably, no respondents expressed low or no trust in existing data protections.

Table . Quotes illustrating varying levels of trust in existing data protections.

Trust: stated rationales	Adolescent quote	Caregiver quote
High trust		
Few, if any, concerns or perceived harm from sharing CP[a] data	"I think it depends on who it would be shared to, but I don't think for the majority I would have a problem with that being information being shared." A02	"I'm not sure what kind of problems could really arise from that [information collected potentially be shared with people other than their doctor]." CG09
Less concerned about unauthorized and harmful external data sharing because they trust or expect that it is kept safe/secure	"With every bit of information being locked down with multiple encrypted passwords, and everything's double encrypted, I have no concern." A09	"I know it's a very confidential doctor patient kind of relationship so there's no harm to my child's reputation." CG20
Expects/assumes HIPAA[b] already protects this type of user-generated data	"I guess it really depends on who it's getting shared to, but I guess it would be the same as what HIPAA is for. It would just be sent to the people that would be able to act upon it super fast..." A19	"I feel like it would be a part of their health information, so it would be private. I'm not any more worried about the technology specifically as opposed to overall somebody knowing he has an anxiety or OCD." CG18
Moderate trust		
Wants to be reassured of HIPAA protection	"What I would need though as a very firm understanding of the boundaries of the utilization of that data because HIPAA's a pretty big thing... I would want to know could anything in this data be not protected, why and how." CG12	"I want to know that it's HIPAA approved and although there's always a risk for a leak data because it's not a perfect world and there's a lot of hackers out there, just knowing that it's as safe as possible." CG05
Limited trust of technology developers to respect privacy (fear of technology)	"Even though you said that it wouldn't, I feel like I would always be nervous that it is tracking the things that I'm saying and what I'm actually doing, like even though it says it isn't, I feel like that would just be a fear." A14	"Right, the privacy aspect of it. Is it actually collecting texts or voicemails or recording conversations? We're always questioning whether our Alexa is actually listening to us." CG14
Low trust	—[c]	—

Willingness to Share CP Data

Most participants were reluctant to share CP data beyond their immediate clinical teams. Reluctance to share reflected concerns about privacy, loss of control, and potential misuse of data, particularly among caregivers responsible for their children's information. Participants frequently emphasized ownership and control, with one adolescent stating, "It's my information, keep it that way" (A05). Caregivers expressed near-universal hesitancy about external sharing, particularly with commercial entities. Notably, twice as many caregivers (n=18, 90%) expressed this reluctance as adolescents (n=9, 45%) (Table 2).

Their rationales (see Table 5) centered around a common view of these data as invasive and sensitive. At the same time, some participants expressed ambivalence or conditional willingness, acknowledging that CP data could be "helpful" (A16) or valuable for research while simultaneously asserting that such data "should be mine and my doctor's, and that's it" (A07). Some adolescents and caregivers stated a preference to be able to vet or control what information their doctors could access. A small number expressed resignation or apathy, suggesting that data sharing "does not make much difference" given the broader data ecosystem (A02).

XSL•FO
RenderX

Table . Quotes illustrating varying willingness to share CP[a] data.

Desire for privacy and willingness to share: stated rationales	Adolescent quote	Caregiver quote
Most willing to share		
Positive attitudes toward secondary uses	"I think it's probably going to be really helpful for future researchers if they can better whatever they're trying to research and figure something out that could help a lot of people, then I'm all for it." A16	—[b]
Moderately willing to share		
Secondary uses must come with stipulations (informed consent, intended use, reputation, and compensation)	"Yes (I would be willing if I knew) just what they're using it for, how long they're going to hold onto it, who gets to see it and is the company or whatever who's accessing the data from a reputable source." A04	"I'm comfortable with it as long as, if there is a way to let the participants know that, 'Hey, there's a chance that your information is going to be used in another study.' And identify that study." CG04
Willing to share if given control over data-sharing decisions	"I would be more willing to share if I have complete control over it." A03	"If I have the ability to say no, I might be a little more open-minded about who wants to see it for why. But again, I would need to have that information." CG02
CP data should be kept private, on a need-to-know basis with medical personnel (and treated like other medical data—not shared widely)	"I do think they should be kept private for a good amount... Not everybody has to see it except for my doctor and other people who me, my doctor, give authorized access to. But other than that should be pretty private." A16	"I think that it should probably not go to future employers or colleges, it's personal information. And I think too that now in this day and age… [data] is it sold somewhere to advertisers to then manipulate you? I mean, you can get paranoid about it, but I think that there is some level of that concern about what happens to that data." CG01
Reluctant to share CP data when it oversteps relationship boundaries	"I feel like [I would] maybe [be worried about sharing this data with] my parents, I don't know. If I'm trying to deal with something and I don't want them on my back about it, I feel like I wouldn't want them to know." A14	"I could see that with the younger population. But then again, we have that crossover when they get to be young adults. It's so intrusive and you would probably produce battles that you wouldn't really want… there's a certain level of that's his right to not talk about it. It really sucks when I don't know…But you have to really be careful on when they get older, there's more permission that they have to give. It's been hard to balance that…" CG11
Prefer to vet what doctors can see	"I think I'd have to know that it would show me the results first and then ask if I'm okay with sending it to the doctor, instead of just sending it to the doctor first and then the doctor telling the things. You get what I'm saying?" A07	"Can the doctor themselves go in and listen to a conversation because I wouldn't like that. Now, if the data's being analyzed in a way that the doctor doesn't have access to and it's shooting off reports, I'm far less troubled by that." CG12
Least willing to share		
Would "not" influence willingness to share because control/privacy does not seem feasible, or they are not interested	"I don't think it [sharing] would make much of a difference. I mean, there's some stuff that's probably already out there... But if it was something that really influences my health or just my mental wellbeing, if it really matters that much to me, I would probably care about it. But just in general, probably not." A02	"I just don't see that there's really any safety valves in place that are 100% secure... So I say, yes, this person can have it… if they're on a research team with the other person is going to see the data anyways... You have the researchers starting public companies…and then that information that they received under a secure process has now moved from academia out into the public sector…I just don't see that this is ever going to be really safe. That's concerning." CG01

[a]CP: computer perception.

[b]Not applicable

Transparency of Data Sharing

Most participants expressed a desire for greater transparency regarding how CP data are collected, used, and shared. Transparency was valued as a means of maintaining trust and agency, though participants varied in whether transparency alone was sufficient without accompanying control. Participants (6 adolescents and 6 caregivers) sought clarity about what data were collected and when, asking "what information it's gathering, when it's gathering it, what it's tracking" (CG07; see

XSL•FO
RenderX

Table 6). Others focused on secondary use, questioning "Where is this going? Who are you sharing it with? What are we doing with this information?" (CG04). Some participants (8 adolescents and 7 caregivers) emphasized the importance of knowing how access was authorized, asking, "Who authorizes that sharing?" CG15; "How is it controlled? What happens if somebody who isn't supposed to see it, [sees it]?" A16), and how transactions will be tracked ("How are you going to document?" CG11).

XSL•FO
RenderX

Table . Quotes illustrating varying preferences for transparency in CP[a] data exchange practices.

Transparency preferences: stated rationales	Adolescent quote	Caregiver quote
Strong desire for transparency		
Desire for transparency of what data CP collects	"I think I would definitely want to know what information is being tracked and how or where the information is going and how it's being used." A02	"I'd want to know exactly what information it's gathering, when it's gathering it, what it's tracking." CG07
If given the chance, they would audit their data transactions frequently	"[I would check] Pretty often I suppose. Mainly because it is a lot about me [that] not a lot of people know about**,** so having a lot of people look at it, I would probably be like, oh, this is out there and let me make sure it's people I trust and approve of seeing it." A04 "I'd want to know just what it's [that data] going to. I wouldn't like say, no, you can't use this information… But I would want to know just who's using it. I would just check up every now and then to see okay. What's happening with it?" A02	"I would expect there would be an alert, some notification that that is happening. And maybe check it once a week anyway myself, kind of like what I do with my bank accounts, just go check and see if the charges are what I made. That's something that I would feel comfortable with… [then] I would be able to reach out that much sooner to the research institute and start asking questions." CG04
Desire for transparent data sharing policy (eg, at time of consent)	"…mainly just with the privacy, but how it's being stored and who gets to review it and also just the development. If that information is given out early on, then I'll be like, 'Oh, feel more secure using the tracking and such.'" A16	"I would want to know what they were collecting and for how long. If they're going to do it for six weeks, I would want to know some assurance that at six weeks it's no longer collecting data. And then how they were going to protect the information... Who had access to it, I guess. And that they had some steps in place to protect the information." CG17
Desire for transparency about data protections	"How is it controlled? Who gets to see it? When are they able to see it and do the person who gave the data have control over who gets to see it? And then…what happens if somebody who isn't supposed to see it sees it and stuff like that." A16	"[I would want to know] the privacy or the security of that data, that it wouldn't fall into the wrong hands, misused. I mean, collecting data for me, is wonderful. You get a different picture combined with the actual person's thoughts, ideas, it's more meaningful, but it's more about the security to that, I would always have a concern about." CG16
Moderate desire for transparency		
Value transparency, but only if accompanied by opportunities for control	"If I'm not able to do anything about it and I see that there's a company that's using my data in a way that I don't want, then I'd rather not know about it. But if there is something that I can do about it, then I'd like to be updated on it and know about it and check it often." A07	"I don't think there's any point in [transparency]…when you know something [that] you can't do anything about." CG01
Might have negative reactions to discovering unwanted data transactions	"I'd be pretty weirded out if I didn't know about it or I wasn't made aware of it. And I think I'd be pretty upset if it was used by a company to make a product that I don't support or something like that." A03	"Well, if they're getting access to it and I didn't give them consent to it, I'd be very upset. If I don't recognize it, I would like to be able to ask somebody who it is. But if it's just a company that just buys and sells data, no, I would not be very happy about that." CG02
Moderately interested in transparency and, if given the chance, would only audit their data transactions once in a while	"I think if I looked at [transparency of data transactions] too much, I'd be obsessed and paranoid about it. So I'd try to keep a limit on it." A03	"I think that would be interesting. I don't know that I would want it because I want keep track of who all has the information, but **just to kind of see, 'Oh, this company is using this and they're getting this out of it,**' kind of thing. Just out of curiosity, not out of need to know. [I would check] very randomly and probably pretty rarely." CG20
Low desire for transparency	—[b]	—

[a]CP: computer perception.

[b]Not applicable

XSL•FO
RenderX

Additionally, participants (6 caregivers and 2 adolescents) also desired reassurance through transparency of data security processes. For example, specific reassurances included wanting transparency around "how they were going to protect the information" (CG17), along with "how safe and secure the information is" (CG10) and also "some assurance [that] it's no longer collecting data" when it is physically turned off (CG17). Other participants (3 caregivers and 3 adolescents) shared that they would feel "weirded out" (A07), "upset" (CG09), "disappointed" (CG16), "angry" (CG07), and "violated" (A16) if shown transactions with their data that they did not explicitly consent to.

Other participants (n=4) expressed that transparency without the ability to intervene would be frustrating or distressing, noting they would "rather not know" if no action were possible (A03). As one caregiver put it, "I don't think there's any point… when you know something [that] you can't do anything about" (CG03). Another adolescent participant reasoned that "[they'd] rather not know about it" if they could not act on the knowledge (A03).

Discussion

Participant Perspectives Toward Current Data Protections

A majority of adolescents and caregivers view CP data, that is, data collected through wearable digital sensors, as sensitive information, characterizing clinical assessments using CP as "invasive" (a term used by multiple participants). Many felt that such data could enable insights into patients' emotions and overall well-being. This is, of course, the clinical rationale for collecting these data; however, many respondents expressed privacy concerns, particularly around the potential for stigma or discrimination in cases of unintended or unwanted disclosure, given that participation was connected to their mental health condition. Some respondents stated that CP data thus deserve as much as or greater protection than other personal health data, which should be kept private and deidentified before sharing, as previous studies have found. Consistent with other research findings [50-52], participants from our study said they would feel distressed upon discovering that their data were being used in ways they did not explicitly consent to, especially for commercial purposes. Their concerns are broadly echoed in the literature around CP technologies [53-55], as well as for nonhealth-related data [31,56-59].

Importantly, however, most participants believe that CP data already receives high levels of protection and security. Many stated they highly trust their clinicians and hospitals to protect CP data once collected and expressed confidence that CP data fall under HIPAA protections as with other medical information. Others said they would seek "reassurance" that this is the case, revealing that they consider HIPAA protection to be the default. Respondents were generally unaware that many, if not most, forms of CP data are not classified as protected health information (PHI). CP data often falls outside traditional health privacy protections for two reasons. First, many tools are developed by companies that are not covered health care entities under HIPAA. The data generated by these technology products is instead subject to other data protection laws at the federal level (eg, Gramm-Leach-Bliley Act, Federal Trade Commission Act, and Family Educational Rights and Privacy Act) and state level (eg, California Consumer Privacy Act, California Privacy Rights Act, and Virginia Consumer Data Protection Act). However, critics [60,61] have characterized these as a "patchwork" of data protections that are too specific to certain data types or entities or contain various loopholes that create data protection gaps for citizens, especially for consumer-facing health apps and wearables.

Second, many of these data types (eg, GPS, accelerometry, call logs, message logs, or content) are not directly related to a patient's health or diagnostic status, even if they may in some cases be collected in service of clinical objectives. As other scholars [18] have noted, these forms of NTH data occupy an ambiguous or gray area in health data protections, even more so when they are uncoupled from the 18 identifiers that define HIPAA-protected PHI, as HIPAA does not cover deidentified information. This gap in legal protections for deidentified data becomes increasingly problematic as the ability to reidentify data grows, or when certain types of data, such as facial expressions and voice, are increasingly hard to deidentify. These concerns around privacy have been widely debated in the context of insurance, genomics, and other domains of data governance [62]. A burgeoning industry devoted to reidentifying personal data using machine learning technologies (eg, for marketing purposes or other forms of profiling) increasingly enables unwanted disclosure of personal data. The potential for reidentification is especially high for NTH that is subject to data exchange decisions that are outside of patients' (and even many physicians' and researchers') control.

An important takeaway from our findings in this context is that most patients and caregivers erroneously believe that HIPAA protections guard them from unwanted disclosure of their PHI and may not recognize the limitations of existing data protection frameworks [63]. Importantly, participants rarely differentiated between research and clinical data-sharing frameworks, despite these contexts being governed by different standards for consent, oversight, and commercial use. This lack of differentiation reflects the reality that CP data are often collected and reused across translational pipelines in ways that obscure whether data are governed by research ethics approvals, clinical privacy regimes, or commercial data practices. This ambiguity contributes to epistemic vulnerability and complicates their ability to make informed decisions about whether to consent to the use of CP technologies in clinical care or research. When individuals later learn that protections are weaker or more fragmented than assumed, this mismatch can undermine trust, reduce willingness to share data, and negatively affect adoption and sustained engagement. These findings echo broader public concerns about digital privacy beyond health care, where individuals often misunderstand the extent of their data protections [64-66]. Similar trends exist in consumer data ecosystems, particularly in digital marketing, where data collection occurs without explicit user awareness [30]. To bridge the gap between perceived and actual protections, it is critical to educate individuals about the limitations of data protections across these domains and the circumstances under which their

XSL•FO
RenderX

data may be used without their consent. Education can help to promote greater reflection about potential threats to the security and privacy of the information that individuals agree to have collected and managed. The use of decision aids and other decision support approaches (eg, shared decision making) offers frameworks to ensure patients and caregivers receive sufficient risk/benefit information to engage in informed consent. However, as we discuss below (see "Clearly Communicating (and Knowing) Risk"), certain factors limit the efficacy of education as a primary approach to achieving informed consent.

Challenges to Patient Education and Informed Consent About CP Data Collection

Clearly Communicating (and Knowing) Risk

Several factors challenge the feasibility of effectively educating participants about health data protection and data-sharing. One major challenge is the elusive nature of data sharing. Hospitals, research institutes, data brokers, electronic health record companies, and other entities that comprise the HIE market often engage in transactions that are not made public or fully transparent to individuals who are the subjects of that data [67]. This lack of transparency endures despite findings, including those from the present study, that most individuals desire greater visibility into the nature and extent of secondary data sharing. Similar demands for transparency and accountability have been observed in nonhealth contexts, such as media personalization and digital marketing [33]. Other studies likewise suggest that people—especially young people—want an active, participatory role in decision-making about data sharing [50]. While most (deidentified) data exchanges are permitted under HIPAA, their notorious opacity (regarding with whom, why, how often, and for what profit) complicates the ability of researchers and clinicians to adequately inform participants about the risks associated with participating in research studies that capture sensitive data. Often, clinicians and researchers themselves are unaware of the nature and extent of potential risk in ways that would enable them to clearly communicate them to research participants, as required by most institutional review boards. Greater empirical insights are urgently needed into the impacts of collecting these data in practice. For example, what percentage of these data are deidentified and exchanged only to be reidentified? What percentage of these reidentified data, in turn, lead to patient harms, and what kinds of harm (eg, dignity-related, financial, physical, emotional, social, political, etc)? Answering such questions requires forensic analysis that traces data from its source as it moves across the HIE landscape. Such an endeavor could be facilitated by various technologies that enable transparent tracking of provenance and transaction histories, as we have argued elsewhere [68,69].

Currently, however, HIE transactions remain critically understudied. While new federal legislation has been proposed (eg, American Privacy Rights Act, American Data Privacy Protection Act, and Consumer Online Privacy Rights Act) to address consumer privacy concerns, to ensure greater control over personal information, and to establish robust enforcement mechanisms to hold companies accountable for data sharing practices, federal funding for empirical research into the nature and extent of secondary data exchange is still lacking. Critics argue that HIE remains largely unaddressed and unregulated due to fragmented state and federal laws [70,71], lobbying by powerful electronic health record companies seeking to maintain market dominance, and fears that regulation may stifle innovation in bioinformatics. The result is an enduring unawareness among most individuals, including experts, about what happens to their health (and other types of) data once collected.

One remedy might be to mandate greater visibility into health data transactions, such that patients and research participants can follow who sees their data, how often, and for what purposes (eg, data sharing between researchers, data exchange for profit, etc). We have described elsewhere some computational avenues (eg, distributed ledger technologies) for enhancing the transparency and auditability of data exchanges [68,69]. However, even if these mechanisms are put in place, our findings suggest that many participants have mixed feelings about being able to see transactions involving their health information; some express enthusiasm, while others point out that such transparency would only frustrate them if unaccompanied by the ability to intervene in or control those transactions. To date, limited mechanisms exist to empower such control. Approaches such as dynamic consent, which enable participants to continuously monitor, manage, and update their consent preferences over time, may be appealing to individuals who want to actively track transactions involving their data (in this study, three-quarters of our participants). Notably, dynamic consent mechanisms are still not common in clinical research outside of certain contexts, for example, genomic or long-term biobanking, where data may be repurposed numerous times for multiple research agendas. In most areas of research, traditional forms of consent prevail, particularly "broad" consent where patients consent once at the start of a study or treatment and cannot modify stated permissions thereafter. Despite affording participants almost no insight into secondary use applications, broad consent enjoys widespread support from the scientific community [72,73], as it can help to facilitate data sharing and drive scientific progress. However, it requires high trust in data controllers to make decisions that align with data subjects' preferences. Our findings show that trust is indeed high among most research participants, but perhaps it should not be, not necessarily because data controllers do not act in good faith when stewarding participant data, but because the current legal landscape offers limited protection for health and NTH data that may enter into a cascade of secondary data exchanges that are difficult for primary data controllers to forecast, trace, or control.

Avoiding Undue Aversion and Consent Refusal

Determining the appropriate level of risk information for clinician researchers to communicate to participants is not only challenged by a lack of clarity about the extent and nature of harms but also by researchers' awareness that highlighting such (uncertain) risks may generate risk aversion and lead to consent refusal. The inability to assuage potential participants' concerns is exacerbated by the difficulty of auditing or assessing when unwanted disclosure and associated harms do occur. Individuals may be reluctant to consent to secondary uses of their data if they fear potential harms will go unnoticed and continue to

XSL•FO
RenderX

perpetuate indefinitely. Balancing disclosure of potential risks while encouraging participation remains a complex challenge. Improved ethical frameworks are needed to communicate uncertain risk without "scaring off" potential research participants who may benefit from integrating CP into their clinical care or contribute significantly to scientific discovery and research. For example, in the context of genomic sequencing, Koplin et al [74] argue that appropriately informed consent may be a fitting alternative to fully informed consent in cases where risks are uncertain. Koplin et al [74] argue that focusing consent procedures on satisfying four morally important goals that informed consent is meant to achieve, including (1) respect for personal autonomy, (2) promotion of autonomy and (3) well - being, and (4) preservation of trust in medicine, may help individuals to make decisions that align with their values, even without a full picture of potential risks. Further work is needed to explore how each of these goals may be achieved in the context of participant consent to CP data collection. For example, what mechanisms may be put in place to ensure autonomy over decisions to share data within and/or beyond a participant's clinical team? What information is needed to clearly convey the potential benefit of CP data collection for participants' well-being, especially given that most CP technologies remain investigational? These questions deserve greater attention as CP and mHealth technologies continue to gain traction in health care and research.

Pathways Forward

Given these uncertainties, it remains unclear how clinicians and researchers should proceed with informed consent. On the one hand, they are ethically obligated to communicate risks associated with the use of CP in research or care, but they themselves lack sufficient insights into these risks. Further, they must be careful not to over- or understate risks, balancing awareness against the potential to affect individuals' willingness to participate in research or integrate technologies that may ultimately benefit patients. Greater visibility into the nature and extent of transactions may only partially solve the problem of informed consent, as it may lead to distress if accompanied by opportunities for intervention or control. However, data controllers (ranging from researchers, institutions, companies, and data brokers) currently have little incentive to offer such control if legal mandates are not in place (and there is no indication they will be anytime soon). A key arena to watch for developments around such mandates is the newly created federal Trusted Exchange Framework and Common Agreement (TEFCA; 2024), which aims to facilitate nationwide, query-based data sharing and to improve patient access to health information as mandated by the 21st Century Cures Act (2016) [75]. Mandel et al [76] recently argued that three principles should be put in place by the time TEFCA launches, including that patients can (1) query for data about themselves, (2) know when their data are queried and shared, and (3) configure what is shared about them. TEFCA launched in 2024, and so far, while it does appear to support patient access to their own health information, TEFCA does neither specifically mandate that patients be notified each time their data are queried or shared, nor do all constituent health information networks offer the capacity for patient-configurable data-sharing controls. Research to identify and validate procedures and technologies that may provide the necessary infrastructure for such controls should be prioritized at the federal level to evolve alongside emerging data privacy legislation.

Limitations

This study has several limitations. First, our qualitative sample was drawn from adolescents and caregivers already enrolled in a research study embedded within a clinical research setting. Participants may thus have higher baseline trust in clinicians and institutions than individuals engaging with direct-to-consumer digital health tools, potentially limiting generalizability to other populations or contexts. Second, participants' perspectives reflect experiences at the intersection of research and clinical care; while this overlap is increasingly common for CP technologies, findings may not fully capture attitudes in purely clinical or purely commercial settings. Third, although the primer video was designed to ensure a shared baseline understanding of CP technologies, it may have influenced participants' framing of risks and benefits. Finally, as with all qualitative research, our findings are not intended to quantify prevalence or establish causal relationships, but rather to identify salient themes and ethical concerns that warrant further empirical investigation.

Conclusions

Our findings highlight the need for clearer communication, stronger data governance, and consent models that better reflect how digital health data are used in practice. These data hold strong potential to provide ecologically valid insights into patients' health conditions beyond the clinic, but also pose significant privacy risks that remain understudied. While clinicians and researchers have a unique responsibility to safeguard participant and patient data, they cannot effectively do so without a better understanding about the nature and extent of these risks or how to effectively mitigate them. To promote greater visibility, understanding, and trust (when justified) in digital tools that have strong promise to promote patient health, we advocate for five key strategies, including: (1) educating patients on the limitations of existing data protections; (2) conducting targeted research, including forensic analyses, into secondary data exchanges and identifying privacy breaches or reidentification risks; (3) enacting regulations that mandate greater transparency in health data transactions; (4) implementing computational mechanisms, such as distributed ledger technologies, to enhance data traceability and auditability; and (5) adopting dynamic consent models that allow patients to continuously manage and update their consent preferences. These strategies may help to better balance the promise of CP technologies and insights from wearables and mHealth apps with the ethical imperative to protect patient privacy, fostering greater trust and responsible innovation in digital health care.

Abstract

Background: Fatigue and chronic fatigue syndrome (CFS) have a considerable impact on quality of life, thus motivating people to develop skills for better management of their fatigue. While the number of commercial apps in this domain has increased, there has been limited exploration of their functionalities.

Objective: This paper aims to address this research gap through a functionality review of 17 top-rated iOS and Android apps for fatigue, with the aim to articulate design implications for technologies focused on supporting the management of fatigue.

Methods: We conducted a systematic search on the 2 most common app marketplaces, which resulted in the initial identification of 427 Apple apps and 1218 Google apps. From these, 17 apps were selected for review after applying a screening process to shortlist the top-rated apps. The functionalities of these apps were then coded through a week-long usage of each app for an expert evaluation leveraging authors' human-computer interaction (HCI) expertise. We looked for functionalities such as tracking and visualization seen in previous research on functionality reviews, in addition to interventional functionalities, which were informed by research on fatigue.

Results: Findings reveal the prevalence of functionalities for tracking fatigue (8/17, 47%), related symptoms (8/17, 47%), for visualizing tracked content (10/17, 59%), for assessing the user's condition (2/17, 12%), and for providing interventions for the management of fatigue (12/17, 71%). Functionalities providing interventions for self-management of fatigue are surprisingly limited, with the most relevant ones including pacing (2/17, 12%) alongside energy estimation (2/17, 12%).

Conclusions: The top-ranked apps for fatigue in the major marketplaces support 3 main functionalities under the scope of tracking fatigue along with related data, and visualizing such data, with limited provision of self-management interventions. Drawing from these findings, we articulate implications for the sensitive design of technologies to support the management of fatigue, including supporting hybrid tracking, combined visualizations to support sense-making of fatigue data with related factors, and supporting energy estimates and pacing interventions.

KEYWORDS

chronic fatigue syndrome; fatigue; mobile apps; tracking; self-management; interventions; pacing

Introduction

Background

Overview

Fatigue and particularly chronic fatigue syndrome (CFS) are conditions with a strong impact on quality of life. Crook et al [1] define fatigue as "more profound than being overtired; it is unrelenting exhaustion and a constant state of weariness that reduces a person's energy, motivation, and concentration." Within human-computer interaction (HCI) research on physical health, fatigue has been less explored, although recent work, focused on lived experiences of long COVID, has started to emerge [2]. In parallel to academic research, there has been a growing number of mobile apps targeting fatigue. Mobile apps for physical or mental health, and in particular, those highly rated by their users, are likely to reflect valuable design principles which benefit from being articulated as implications for design. Similar efforts have been made for apps for depression [3], digital well-being [4,5], and anxiety [6], but less so for fatigue. To address this gap, we report a functionality review of 17 top-rated apps for fatigue from the Apple App Store and Google Play Store, together with an analysis of their descriptions on marketplaces. Findings indicate that the main functionalities of these apps are tracking fatigue and its symptoms, visualizing tracked content, assessing symptom

XSL•FO
RenderX

impact on everyday life, and providing interventions. We conclude with 5 design implications for better support of people living with fatigue, which include supporting hybrid tracking to balance the validity of self-reported fatigue with low-burden automatic tracking of symptoms, contextualizing fatigue data with symptoms and associated factors through combined visualizations for sense-making, and supporting energy estimates and pacing interventions.

To support our exploration and understanding of the functionalities, we draw on the limited but emerging area of HCI work on fatigue, comprising the tracking of symptoms, the design of technologies supporting their management, and the emerging area of research that has engaged in the analysis of apps created for this purpose.

HCI Studies Around Technology Usage for Individuals With Chronic Conditions

A key area that we first needed to understand was the behaviors of individuals with CFS surrounding their use of technology to have a better idea of any ramifications that may arise from the condition, and consequently how they can be designed around. Paymal and Homewood [7] conducted a study to identify how CFS impacts technology usage in day-to-day life, in which they make use of their findings to present design recommendations. Their findings include the reduction of technology use on days where participants feel better, the increased usage of technology to help with tasks when symptoms were more noticeable, the avoidance of technology by some participants when their symptoms were more severe, and the usage of apps for tracking and self-management purposes. While the researchers identified how self-management technologies were used by this group, their reasons for turning to these technologies, and their criticisms regarding their usage experience, the researchers' findings could be further supported by detailing the different functionalities offered.

Virtual reality (VR) is also an area that has been the focus of research; Best and Butler [8] investigated the use of VR as a support space for individuals with CFS. They discovered that CFS symptoms would prevent users from engaging with the technology for extended periods of time; however, this led to users improving their energy management to use their limited reserves more efficiently, in addition to optimizing their physical spaces and the technology they use to minimize fatigue triggers. This highlights the interplay between their energy levels and their self-tracking efforts, and is a key area of concern when designing for this group of users.

Davies et al [9] investigated the experiences of patients with chronic fatigue regarding their usage of technology for disease management, and a key area of interest was the participants' usage of apps for self-management. In their study, they set forth design guidelines that are centered around the symptoms that patients want to manage the most, including features that assist users in identifying maximum and minimum energy thresholds, adding activity pacing functionality coupled with routine establishment, providing support for fatigue tracking by exploring automated logging methods to reduce effort expended, and finding ways to make self-management apps more engaging and motivating such as by gamification. Their findings can better inform our evaluation as the guidelines provide a frame of reference to examine the apps against.

Understanding Technologies for Individuals With CFS

Research has also delved into understanding how to support users with energy-limiting conditions (ELCs) through technology. For instance, Børsting and Culén [10] applied a sense-making process for complex domains in order to explore the design of technologies for supporting young individuals with CFS. The approach is a combination of a literature review, mapping techniques, and user research. The results of the user research, which was conducted with CFS experts, led to suggestions targeting self-management, namely, providing interventions discovered by other individuals with CFS, offering reminders for both resting and general purposes, providing functionalities to track and warn users of noise levels, providing social support technologies, and finally, providing the logging of symptoms coupled with tracking technologies suited for CFS.

Another strand of work has focused on technologies for supporting the management of chronic conditions. For instance, Sas et al [2] reported findings from workshops with individuals affected by long COVID, suggesting design implications for tracking and sense-making of fatigue and postexertional malaise (PEM), as well as self-management aimed at PEM prevention. Their findings stressed the importance of lightweight capture of data to prevent symptoms worsening among users, conjointly with reducing the burden of identifying both triggers and the PEM-approaching stage by making use of machine learning (ML) techniques or noninvasive items such as heart rate variability (HRV) tracking, and finally, supporting self-management of fatigue based on the stage of PEM that a user is at.

We also note the study of Homewood and colleagues [11] who co-designed through asynchronous communication with the aim of catering to the needs of individuals with ELCs. The researchers discovered that this method helped participants to only engage with the study when their energy levels were sufficient to partake; in addition, they were able to extract meaningful insights into improving the support for individuals with ELCs. These included designing technologies that improve communication with their social networks, implementing automatic tracking of their fatigue levels and associated symptoms, and using crip approaches in future studies dealing with ELCs.

Studies have also found that if participants' fatigue symptoms reached more severe levels, they may avoid interaction with technology to prevent overwhelming them [7,9,12]. For this reason, designing around the potential fluctuations in their energy levels is paramount [2,9,10,13,14], and one such way this can be achieved is by including automated logging methods, especially in scenarios where users track numerous types of data [2,9]. In the same vein, Mack et al [14] proposed tenets to improve the accessibility of technology, and from these, one tenet called for designs that account for rises in fatigue levels post exertion and consider the consequences of a task on an individual's energy reserves.

XSL•FO
RenderX

The findings detailed in this section can be used to better evaluate the current design space of commercial apps and provide more informed implications for future app designs.

Better Design of Online Resources for Individuals With CFS

Other areas of HCI research targeting chronic conditions have focused on the usage of online resources to support CFS, as in the study of Brigden et al [15]. This study, along with several others, found that social media could be of value to individuals with chronic conditions as a means of discussion and social support surrounding their condition [7,10,15-17]. These studies highlight the importance of observing for social media–based functionalities in the apps to be reviewed.

Another study is by Best and Butler [12], where they sought to identify the physiological effects experienced by individuals with CFS when socializing in a virtual world. Their findings also include the previously mentioned user behavior where they withdraw from technology as their fatigue levels worsen, so as to prevent further deterioration [7,9,12]. As such, the level at which users must interact with the apps could be a useful metric to evaluate the apps and think of further design implications.

HCI Research on Technologies for Long COVID

PEM is also known to be a characteristic of conditions such as long COVID [2]; therefore, the research in this field has value for the area of fatigue management. From the works in this field, we note the study of Homewood [13], who undertook an autoethnography where they used a Fitbit device for activity pacing purposes to manage their long COVID symptoms. This is also one of the studies that highlighted the importance of designing around the potential fluctuations in energy levels [2,9,10,13,14].

Another study of interest is that of Homewood et al [16], who conducted interviews with participants who had long COVID and made use of wearables for disease management, with findings highlighting the need for designs that are tailored to account for individual differences.

In addition, Pater and colleagues [17] carried out a 3-month-long cohort study on patients with long COVID, which involved the collection of both objective and subjective data. The authors emphasized that cognitive symptoms may make data gathering difficult, with participants finding it challenging to enter survey data regularly due to forgetfulness, which also made interviews burdensome [17]. They also posited that gaps in data tracked during their study were caused by participants forgetting to charge their wearable devices.

Finally, Mehdipour and Aharari [18] conducted a literature review along with case studies to analyze the marrying of the fields of AI, HCI, and Internet of Things (IoT)—which is defined by Kelly et al [19] as “a system of wireless, interrelated, and connected digital devices that can collect, send, and store data over a network without requiring human-to-human or human-to-computer interaction”—in regard to the analysis of data surrounding COVID. Their findings highlight that these fields aided the process of understanding large health datasets built from the data of numerous individuals.

These findings reveal the need for flexibility in tracking options to prevent overwhelming the user, and this exploration can be aided with HCI principles.

HCI Research on Technologies for Chronic Pain

We also draw from research on chronic pain, as it is a condition for which self-tracking is used for self-management. Adams and colleagues [20] investigated preferences regarding the self-assessment of pain for the purpose of self-managing chronic pain, through which they also discovered the previously mentioned importance of tailoring designs to suit individual differences [16,20].

Singh et al [21] carried out a study to explore the use of movement sensing and sonifying wearables by individuals with chronic pain in their undertaking of functional activity. The researchers found that the device challenged the user’s initial beliefs on their limits by improving their bodily awareness, and this led to users feeling more confident in trialing activity pacing methods. This highlights the importance of tracking and identifying limits for their self-management efforts.

Personal Informatics for the Support of Chronic Conditions

Personal informatics is an interdisciplinary research area within the broader HCI discipline, focusing on how people use personal technologies in life to collect, organize, and use information about their daily lives, in order to support personal goals in a range of domains such as productivity, learning, well-being, and health [22]. In the space of chronic conditions, this research area contributes design principles for digital health technologies such as mobile apps aimed at supporting fatigue. HCI work on chronic conditions has focused on tracking symptoms [23,24] or data related to physical activity [22,25,26], heart rate [27,28], sleep [22,29], and various other general health aspects [23,24,30].

Personal informatics also has value in supporting interventions; for instance, Felipe et al [29] found that it can greatly supplement the intervention of pacing, which is commonly undertaken by individuals with ELCs [2,9] and/or chronic pain [29,31]. In addition, individuals with chronic migraines also made use of personal informatics to identify if their condition is worsening in order to take preventative measures [32], which is known to be an important aspect of pacing [2].

Moreover, personal informatics can help users with chronic health conditions understand their condition better [24,29,32], offload the burden of monitoring their condition [29], improve communication and discussions with clinicians [24,32], help identify when their condition worsens, which is essential for taking preventative action in time [32], and finally, aid users in managing and monitoring their condition in the long term [32].

Objectives

Despite the numerous works focused on chronic conditions, limited research has drawn design implications for supporting fatigue by exploring the breadth of functionalities offered by top-rated apps in this space. In our research, we will highlight how our findings compare with existing apps for supporting the management of chronic fatigue syndrome, in terms of items

XSL•FO
RenderX

tracked and interventions. To this end, we put forth the following research objectives:

1. Conduct a systematic search on the top-rated commercial apps supporting fatigue
2. Explore and detail the range of functionalities offered by these apps
3. Identify whether the apps inform users of their theoretical or empirical underpinnings
4. Discern how the apps handle user data through the app's privacy policies and cookie notices
5. Inform design guidelines drawing from the functionalities discovered

We aim to address that gap by conducting a systematic search and a functionality review on the top-rated apps from today's marketplaces. To inform the methodology and paper structure, this paper draws on work done on app reviews in the areas of mindfulness [33], depression [34], goal setting [35], and digital wellbeing [4].

Methods

Overview

This section presents the process of selecting the apps and the description of functionality review, as well as analysis of app description and privacy terms.

Apps Selection Process

We conducted a systematic app search, for which we used a PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) search strategy [36], similar to previous research on app reviews [4,33-35,37-39] including some in JMIR journals [4,34,38,39]. The search was conducted in the autumn of 2024 on the app's store descriptions, using the keywords "chronic fatigue syndrome," "chronic fatigue syndrome," "fatigue," "ME/CFS," "CFS," "myalgic encephalomyelitis," and "pace or pacing." This search was completed on the 2 most common marketplaces, which is also consistent with prior app reviews [4,33-35,37-39].

From the returned apps, we removed duplicates from both platforms, and for the remaining apps, we applied an inclusion criterion of having an average rating score higher than 3.0 and a number of ratings higher than 10. By screening the resulting apps, we further excluded apps that did not use any of the keywords or used them irrelevantly, as well as those not in English or requiring a subscription to use without even a free trial.

We chose to review apps that are top-rated (rating scores above 3.0) as they reflect positive user experiences of interacting with the apps, in addition to having a robust set of functionalities that the users appreciated and most likely found useful. From an HCI perspective, exploring these functionalities is beneficial as we can infer design principles and identify how we can improve the future design of such apps [4,33-35,37]. In addition, we chose to review apps that are free to access, similar to prior work [4,33,35,40], as they are more likely to provide better accessibility to the general population and fairness, as some users may not be able to afford the subscriptions [41], which is especially important in the health care context. In addition to being free, these apps might also have functionalities that are problematic, which our review aims to identify.

Functionality Review

As noted by Hossain et al [42], functionality review is an increasingly common HCI method used to explore current technologies and their main features, particularly commercial mobile apps [4,33-35], which authors identified as being descriptive, that is, merely describing the functionalities, or critical, that is, involving deeper analysis and integration [42].

For this, the first author engaged with the apps twice a day for at least 1 week, using both an Android 14 version phone and an iPhone iOS 18.1.1 version phone. This ensured that each app was used for a total cumulative time ranging from 70 to 140 minutes. The second author reviewed 3 out of 17, for a duration of 3 days. This was to add independent codes, ensure the codes are clear and consistently used by independent raters, and validate the coding process. The proportion of apps assigned to the second coder is consistent with similar studies such as the review of goal apps [35] and the review on depression apps [34].

The coding process was hybrid [43], involving both deductively identified functionalities such as tracking [33-35], visualizing [33-35], and interventions [33,34] for self-management, common in previously reported HCI work on app reviews, while the inductively identified ones emerging from the reviewed apps included subfunctionalities regarding the content being tracked, such as fatigue and its symptoms. We also coded characteristics such as the theoretical and scientific underpinnings of the app's functionalities plus their privacy policies and cookie notices. When coding the former, if we did not find the information pertaining to this while using the app, we sought it in the app's help pages and websites.

With regard to interventions for fatigue management, Davies et al [9] highlighted the importance of "pacing" in order to help people remain within limits of their energy level, promoting routinization, and tending to their mental health. Pacing has also been found to be used in complement with the participant's energy management efforts [9]. For this reason, the authors searched for functionalities specifically revolving around these concepts as part of their coding.

Interrater agreement—which was done only on the codes concerning tracking and interventional functionalities due to the large number of codes—using Cohen κ [44] showed almost perfect agreement for 149 out of 188 (79.3%) codes, fair agreement for 5 out of 188 (2.7%), and slight agreement on 34 out of 188 (18.1%) codes. The grouping and labeling of these codes into almost perfect, fair, and slight agreement were informed by the study of Landis and Koch [45]. From these, the authors revised the codes with fair or lower agreement.

The codes with slight agreement were mostly related to the tracked items captured along with their modalities. The main reason for the difference was due to a greater usage length being required to fully capture all the codes, especially with regard to the vast number of items tracked along with their recording

XSL•FO
RenderX

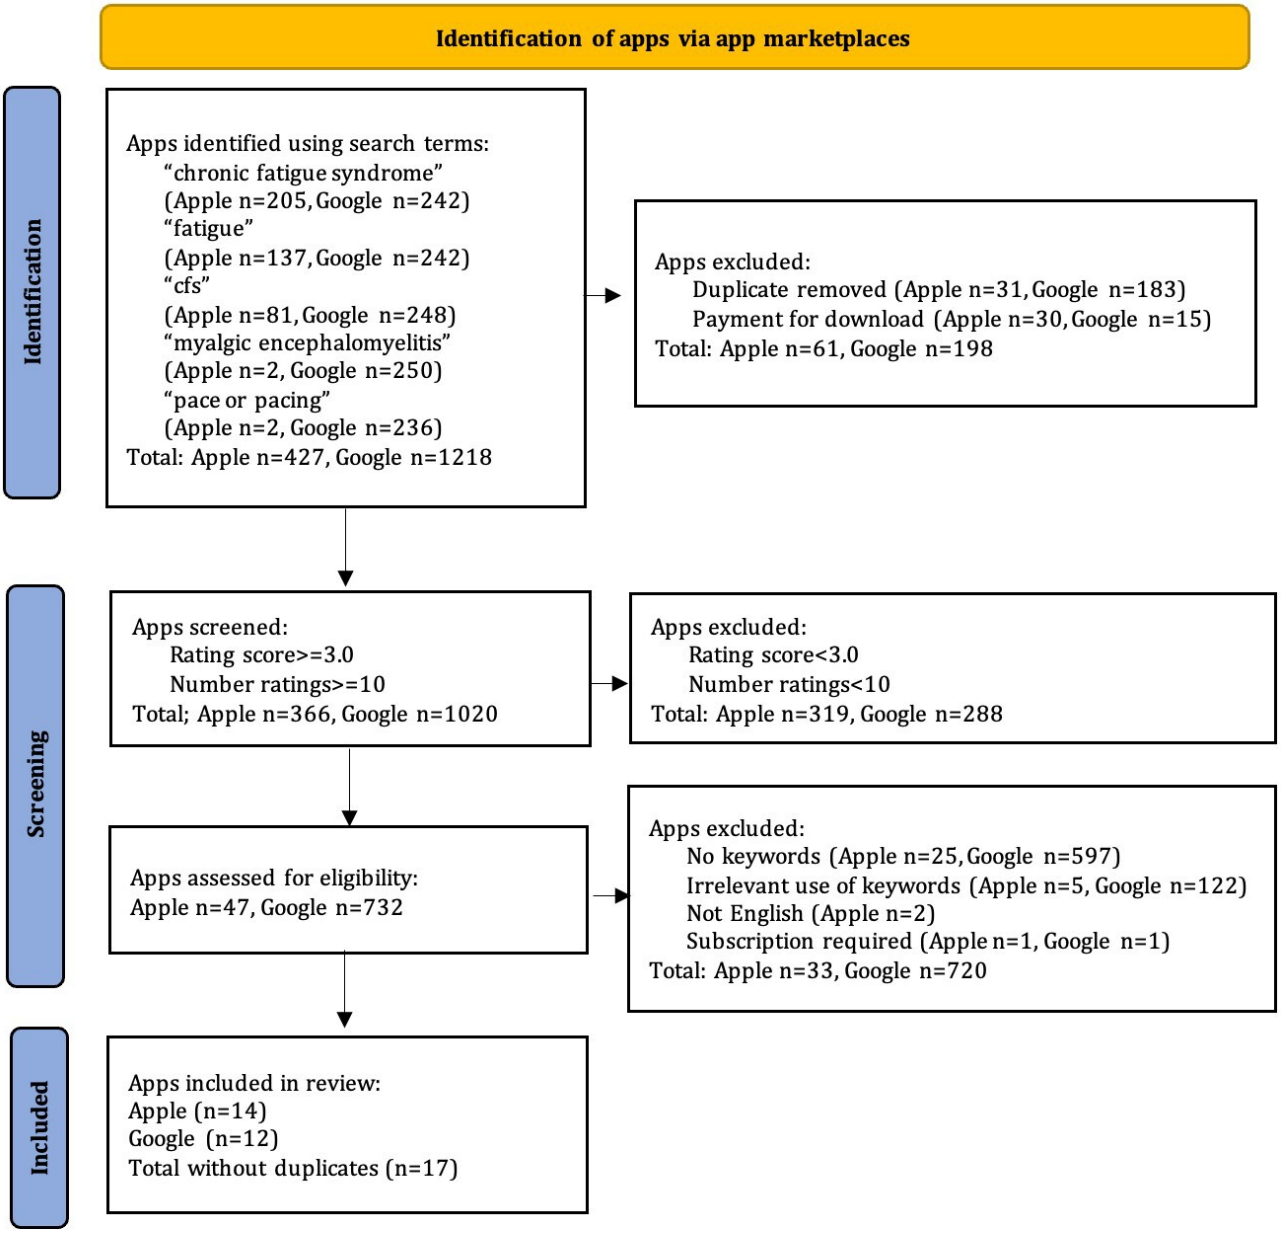
frequencies. As such, information gleaned from the longer usage duration was used to revise the codes into agreement.

Ethical Considerations

No human subjects participated in the research. For apps offering social media functionalities, we did not analyze any user-submitted content. Neither primary nor secondary human-related data were collected for this submission, which focuses exclusively on the description of the apps found on marketplaces and their functionalities.

Results

Overview



The app selection process resulted in a final set of 17 top-rated commercial apps from the Apple App Store and the Google App Store. Findings highlight that the identified apps not only include tracking functionalities but also support interventions for the management of fatigue, which involves managing energy levels and preventing crashes. The identified functionalities can be grouped into the main categories of tracking, visualizing, assessing, providing interventions, and ensuring privacy. Tracking functionalities comprise the collection of fatigue data and other related symptoms. Functionalities for visualization aim to represent the data in a manner that the user can understand and use toward the management of their condition. Assessment functionalities gauge the impact of the user's symptoms through validated scales. Intervention functionalities aim to help users manage their condition, and this can involve assisting with energy management and crash prevention. Finally, in the section highlighting the app's privacy measures, we will identify how apps handle users' data, the usage of cookies along with their purpose, and the age groups targeted. The full codebook has been supplied in the form of a Microsoft Excel sheet for viewing all codes and most of the subcodes (Multimedia Appendix 1).

App Selection Results

The initial search returned 427 apps on the Apple App Store and 1218 on the Google Play Store (Multimedia Appendix 2), and from these, we removed 214 duplicates from both platforms. Applying our inclusion criteria resulted in 366 apps from the Apple App Store and 1020 from the Google Play Store. By screening these, we further excluded apps that were less relevant, required a subscription, or were not in English, leading to 14 Apple apps and 12 Google apps. After accounting for duplicates across the 2 platforms, our final set comprised 17 apps: 5 from the Apple App Store, 3 from the Google Play Store, and 9 from both. The PRISMA diagram in Figure 1 [36] shows the selection process.

XSL•FO
RenderX

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) diagram for app extraction, detailing inclusion-exclusion criteria alongside app numbers included or excluded at each stage.

App Characteristics

A summarized view of the app characteristics has been presented in Multimedia Appendix 3.

While all selected apps had rating scores above 3, most apps from both stores had rating scores above 4.0 (13/14 for Apple apps and 10/12 for Google apps). Among the Apple apps, 4 apps had more than 100 reviews, and 2 apps had more than 1000 reviews. Most of the selected Google apps had more than 100 reviews (9/12 apps), with 5 apps having more than 1000 reviews. Our exclusion criteria removed apps that required either a one-time payment or a subscription; however, we included 3 apps with subscription models since they offered free trials.

Functionality Review Results

Overview

We now report on the findings from the functionality review, namely, the functionalities of tracking, visualizing, assessing, providing interventions, and ensuring privacy. Table 1 provides the main functionalities found in each app.

XSL•FO
RenderX

Table . Main functionalities that arose from the evaluation presented for each app.

Apps	Tracking	Visualizing	Providing interventions	Ensuring privacy
Bearable - Symptom Tracker	For tracking fatigue, symptoms, and associated factors	For visualizing tracked data	__[a]	For informing the user of their data handling
CareCircle - Health Platform	For tracking fatigue, symptoms, and associated factors	—	For social support	For informing the user of their data handling
Chronic Insights	For tracking fatigue, symptoms, and associated factors	For visualizing tracked data	—	For informing the user of their data handling
Curable: Chronic Pain Relief	—	—	For neuroeducation	For informing the user of their data handling
Elite HRV	For tracking associated factors	For visualizing tracked data	For energy estimation, psychoeducation	For informing the user of their data handling
Fibromyalgia Magazine	—	—	For psychoeducation	For informing the user of their data handling
Freeme: ME/CFS and Long COVID	—	—	For neuroeducation	For informing the user of their data handling
Guava: Health Tracker	For tracking fatigue, symptoms, and associated factors	For visualizing tracked data	—	For informing the user of their data handling
Gupta Program Brain Retraining	—	—	For neuroeducation, social support	For informing the user of their data handling
Turnto - Daily Breakthroughs	—	—	For social support, psychoeducation	For informing the user of their data handling
Visible: Pacing for illness	For tracking fatigue, symptoms, and associated factors	For visualizing tracked data	For energy estimation, psychoeducation	For informing the user of their data handling
Wave Health: Treatment Journal	For tracking fatigue, symptoms, and associated factors	For visualizing tracked data	—	For informing the user of their data handling
icompanion: understand your MS	For tracking fatigue, symptoms, and associated factors	For visualizing tracked data	For psychoeducation	For informing the user of their data handling
Ada - check your health	For tracking fatigue, symptoms, and associated factors	—	—	For informing the user of their data handling
SpoonieDay	For tracking associated factors	For visualizing tracked data	For pacing and energy estimation	For informing the user of their data handling
ME/CFS Pacing	For tracking associated factors	For visualizing tracked data	For pacing	—
Juva Stress and Migraine	For tracking associated factors	For visualizing tracked data	For biofeedback	For informing the user of their data handling

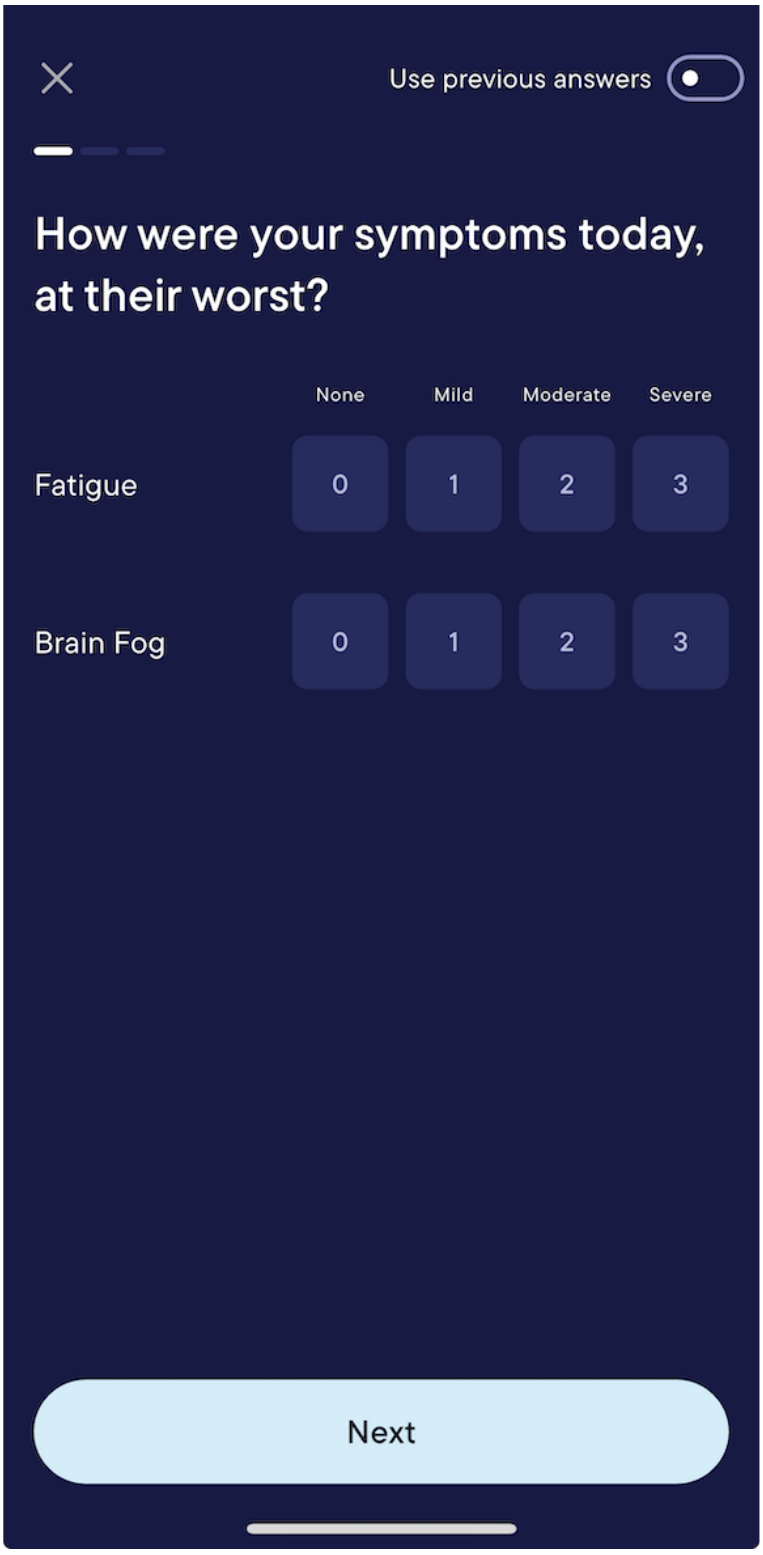
[a]Functionalities that are not available in the apps.

Tracking Fatigue, Symptoms, and Associated Factors

Overview

In this section, we explore the subfunctionalities that emerge under the main functionality of tracked content. At the first level of branching, we see fatigue tracking, symptom tracking, the tracking of associated factors and interventions, and finally modalities of the listed data as seen in Multimedia Appendix 4. The codes for the functionalities are also provided in Multimedia Appendix 5.

Tracking Fatigue



An important outcome is that from the 17 top-rated fatigue apps that we reviewed, less than half track fatigue (8 apps), and most of these (6 apps) track general fatigue, with the remaining 2 tracking physical fatigue. In addition, none of the apps offer a means of tracking fatigue automatically. This is important, indicating the potential of extending support for self-reporting of fatigue, and extending the measures of general fatigue to reflect other dimensions of fatigue: physical, cognitive, and mental or emotional. The apps that support self-reporting of fatigue do so through measures of trait fatigue or fatigue extended over time (5 apps), and state fatigue as fatigue momentarily experienced at the time of measurement (4 apps). The lack of usage regarding measures for state fatigue from half of the apps is also surprising, given the affordance of mobile apps for prompting its capture and thus tracking it through time.

Tracking fatigue is of great value to users with chronic fatigue, as this can be used to identify energy limits for the intervention of pacing [9] and thus, we believe the method of data capture and its granularity are important to be represented. To this end, we highlight that the few scales of fatigue used by the apps involve 1 item for each one, captured through 4-point (1 app) as seen in Figure 2 from the Visible: Pacing for illness app

XSL•FO
RenderX

(Visible Health Inc) [46], 5-point (2 apps), 7-point (1 app), 10-point (1 app), and 11-point (1 app) Likert scales, numerical scales (1 app), that is, 0.0 - 10.0 and semantic differential scales (1 app), that is, 3-point: mild, moderate, and severe level. From the apps that track fatigue only as a state, the scales can be completed at least once per day with no maximum (3 apps). No apps provide information on the validity of the used fatigue scales. Future app designs could better support ecological momentary assessment of fatigue states by using validated measures of state fatigue involving both general fatigue and its physical, cognitive, and mental aspects [2,47,48].

Figure 2. A screenshot showing a Likert scale used to capture data to track fatigue and other symptoms such as brain fog (image used with permission from the app's developer).

Besides fatigue, apps also track fatigue-related constructs such as energy level (4 apps), although there is surprisingly limited support for tracking exertion (2 apps) or crashes (1 app), which are essential for anticipating PEM and are much needed for

XSL•FO
RenderX

managing chronic fatigue [49]. Each of these constructs is captured manually, for energy levels through 5-point Likert scales (3 apps) and a semantic differential scale with 5 levels (1 app), exertion through 4-point Likert scales (2 apps), and crashes (an incidence of PEM) through a yes or no check augmented with a text entry for additional notes. Regarding the frequency option for daily manual entering of energy levels, this can be exactly once (1 app), at least once per day (2 apps), or 3 times per day (1 app). Interestingly, these self-reported measures of energy, exertion, and crashes can benefit from being contextualized with spatiotemporal and activity data [2], which may be automatically tracked. However, few apps (3 apps) supported such integration of self-reported and automatically tracked measures related to fatigue, and from the data mentioned, only activity data were leveraged.

Fatigue Symptoms

Findings indicate rich support for tracking 4 main types of fatigue symptoms: cognitive (8 apps), emotional (8 apps), physical (8 apps), and behavioral symptoms (5 apps). Multimedia Appendix 1 provides the top 40 most commonly tracked symptoms.

Most commonly tracked cognitive symptoms include brain fog (5 apps), difficulty with concentration (6 apps), or remembering (3 apps). Apps tracking emotional symptoms target mostly anxiety (8 apps), depression (7 apps), irritability (4 apps), pessimism (3 apps), sense of dread (3 apps), discouraged mood (1 app), disconnection or detachment from oneself and the surrounding world (ie, derealization or dissociation; 3 apps).

An important outcome is the prevalence of and range of bodily symptoms tracked by most apps. Such symptoms include most commonly pain (8 apps) and sensory symptoms (8 apps) such as numbness (6 apps) and sensitivity to light (6 apps), followed by specific ones concerning skin (6 apps), circulatory (7 apps), digestive (7 apps), muscular (5 apps), ocular (6 apps), respiratory (7 apps), reproductive (6 apps), or urinary systems (5 apps). Thus, most apps support a rich set of symptoms that could be tracked, which ranges between 76 and 155 different symptoms. While useful, tracking many symptoms, particularly manually, can be taxing [2], especially since many apps provide limited support for reducing such burden.

An interesting outcome is the various behavioral symptoms, with the most commonly tracked ones including nail biting (4 apps), restlessness (4 apps), fidgeting (3 apps), impulsivity (3 apps), skin picking (2 apps), and stimming (2 apps). A closer look at these indicates they are predominantly repetitive body movements [50], which previous work described as supporting self-regulation of sensory sensitivity in autism spectrum disorders [51], albeit also contributing to autistic fatigue [52].

Symptom Checkers

While the large number and diversity of the symptoms available to track is useful, it can also be overwhelming. Two apps use symptom checkers such as Ada's symptom assessment functionality and Isabel (used in the CareCircle – Health Platform app) for supporting users to report their symptoms. While developed to support clinician diagnosis, symptom checkers implemented on mobile apps have also started to be explored by researchers investigating user perspectives for usability and acceptability [53,54]. Recent work has also explored AI-augmented symptom checkers with findings showing effective diagnosis, but problematic triage, and thus their use by unsupervised patients may be harmful [53].

Factors Associated With Fatigue

The reviewed apps also support tracking of additional factors which may impact fatigue and thus may allow people to better understand their fatigue experiences. Such factors include health data (7 apps) such as manually entered medical information (4 apps), medication intake (6 apps), or acute conditions such as flu and cold (1 app). From these, medication is tracked either by automatic logging after a one-off entry (3 apps) or through manual logging with either daily entries (1 app) or recording in a list (2 apps). Other health data were also tracked through the same list style of recording (4 apps). The modality of data capture is interesting from an HCI perspective, as HCI research on ELCs has called for tracking apps with a low impact on users' energy levels [2,9]. In addition, since these users most likely have other symptoms alongside fatigue [55], this becomes particularly important. This opens up design opportunities toward implementing automatic tracking methods, as it would be the least taxing for this demographic. Health data were also automatically tracked, such as heart rate (6 apps), HRV (5 apps), resting heart rate (3 apps), oxygen saturation (2 apps), or breathing rate (2 apps). For the capture of health data, some apps leveraged the OS's health app (6 apps), while other apps made use of the phone camera (1 app) or additional wearables such as heart monitors or smartwatch sensors.

Apps tracking physical activity focused mostly on step count (6 apps) or exercise duration (4 apps), captured automatically (6 apps), directly from the OS's health app (6 apps), while 4 apps provide the option to manually enter step count. Mood was another important associated factor (6 apps), captured through a 5-point Likert scale (3 apps), augmented with emotion tags (1 app), a 10-point Likert scale with emotion tags (1 app), or merely a dropdown emotion list (1 app).

Another associated factor was sleep, captured through manually entered data using a 4- or 5-point Likert scale for sleep quality (1 app each), a dropdown list of factors impacting sleep (1 app), a time picker for daily entry of sleep duration (2 apps), or automatically tracked through the OS's health app (2 apps). Other associated factors include weight (4 apps) and lifestyle data such as stress, caffeine consumption, or alcohol consumption (3 apps).

Moreover, a total of 5 apps offer the option to track well-being activities such as journaling (3 apps), meditation (3 apps), mindfulness (3 apps), and yoga (3 apps).

The use of scales may result in the loss of contextual data [56], which may aid sense-making; however, some apps have attempted to remedy this by offering the option for notes (5 apps) with each recording of most or all data types. The optionality of this feature is important, as this lowers the burden on users by allowing them to keep their data collection simple if their energy reserves are low.

XSL•FO
RenderX

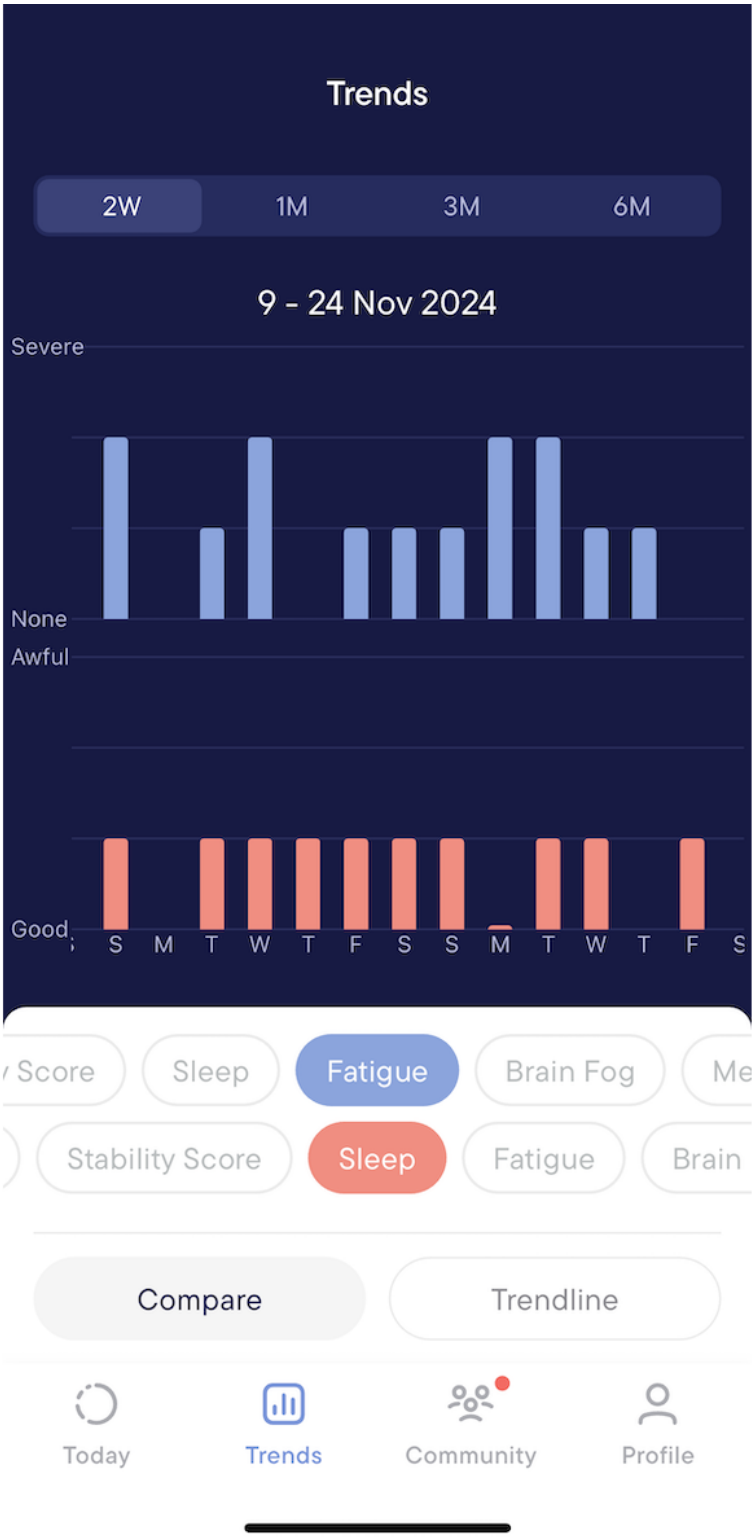
Visualizing Tracked Data

Overview

The daily use of the apps during the expert evaluation provided a sufficient amount of data for the assessment of their visualization functionalities. The findings from this reveal the provision of visualizations of tracked fatigue, symptoms, and associated data through charts representing different types of data, color-coded symptom severity, temporal aspects, and data summaries (Multimedia Appendices 6 and 7).

Types of Charts for Visualizing Fatigue

Findings show that the most common charts for fatigue visualization are line charts (4 apps) and bar charts (2 apps), although not all apps visualized tracked fatigue data (2 apps), despite users' interest in understanding their tracked fatigue for the purpose of self-management [9].



Types of Data Represented in Charts

Fatigue is known to have numerous factors [2,9], and for this reason, users will want to reflect on other data sources as well. Findings indicate that 9 apps provide visualizations of a single data type, such as fatigue scores (6 apps). In addition, as the factors are known to be interdependent [2,9], users would benefit from being able to compare the data on the same chart. To this end, apps also offer visualizations integrating different tracked data (7 apps): most often fatigue data + symptom data (4 apps), fatigue data + health data (4 apps), health data + health data (5 apps), symptom data + symptom data (4 apps), symptom data + health data (4 apps), fatigue data + mood data (3 apps), symptom data + mood data (3 apps), physical condition + mental condition (1 app), or morning + evening mood (1 app). It was also noted that 3 of these apps providing visualizations of combined data do not have the option of integrating fatigue, which may limit users' ability to better understand their fatigue by discerning factors that could affect it [9].

With respect to the number of different data used for such combined visualizations, most apps involve only 2 *y*-axis variables per visualization (6 apps), while 1 app allows an unlimited number of variables integrated in one app, which for numbers larger than 3 may be difficult to understand if not designed in an effective manner. Combined visualizations are often represented through multiple line charts, that is, one line for each *y*-axis variable (4 apps), combined bar and line charts (3 apps), combined scatter charts (1 app), parallel bar charts (1 app) as seen in Figure 3 from the Visible: Pacing for illness app [46], combined bar charts (1 app), and bar and dot combo charts (1 app). Of these, the most frequently used visualization was found to be combined line charts (4 apps). Given the interdependency of various aspects of fatigue [2,9], it is surprising that these visualizations do not look at them altogether in contrast to the isolated view, and this could be an area which future work could investigate. Finally, findings highlight that 1 app does not show combined visualizations, despite tracking different data.

XSL•FO
RenderX

Figure 3. Screenshot showing a combined visualization of 2 *y*-axis variables for comparison (image used with permission from the app's developer).

Use of Color-Coded Symptom Severity in Visualizations

From the 8 apps that provide visualizations for symptom tracking, half of the apps use warm colors such as red to indicate negative symptoms or high severity level (4 apps), while the others do not use such color codes (4 apps). The former highlights severity level, which can increase one's concerns and be perceived as judgmental [9].

Temporal Aspects of Visualizations: Timescale and Historic Versus Real-Time Data

All 9 apps providing visualizations for historic data do so with a range of timescale options such as the last 7 days (1 app), last 2 weeks (1 app), last month (3 apps), last 2 months (2 apps), last 3 months (3 apps), or a custom timescale ranging from the last 10 weeks to the last 7 years (1 app), any 7 days (3 apps), any 2 weeks (1 app), any month (2 apps), any year (1 app), as well as a custom scale with a start and end at any 2 points in

XSL•FO
RenderX

time (1 app). These various timescales are beneficial, with the most recent past supporting understanding while leveraging the memory of recent events impacting the displayed fatigue scores, and the far past supporting understanding broader patterns of how fatigue changes over time [57]. Moreover, findings show that 7 apps display only historic data, 1 app displays both historic and real-time data, and another app displays only real-time data. From the 2 apps that show real-time data, both apps use it for biofeedback interventions. In addition, the real-time data are measured with an HRV monitor for one app and with both a camera and an accelerometer for the other. Finally, one app visualizes HRV, and the other visualizes heart rate and breathing rate.

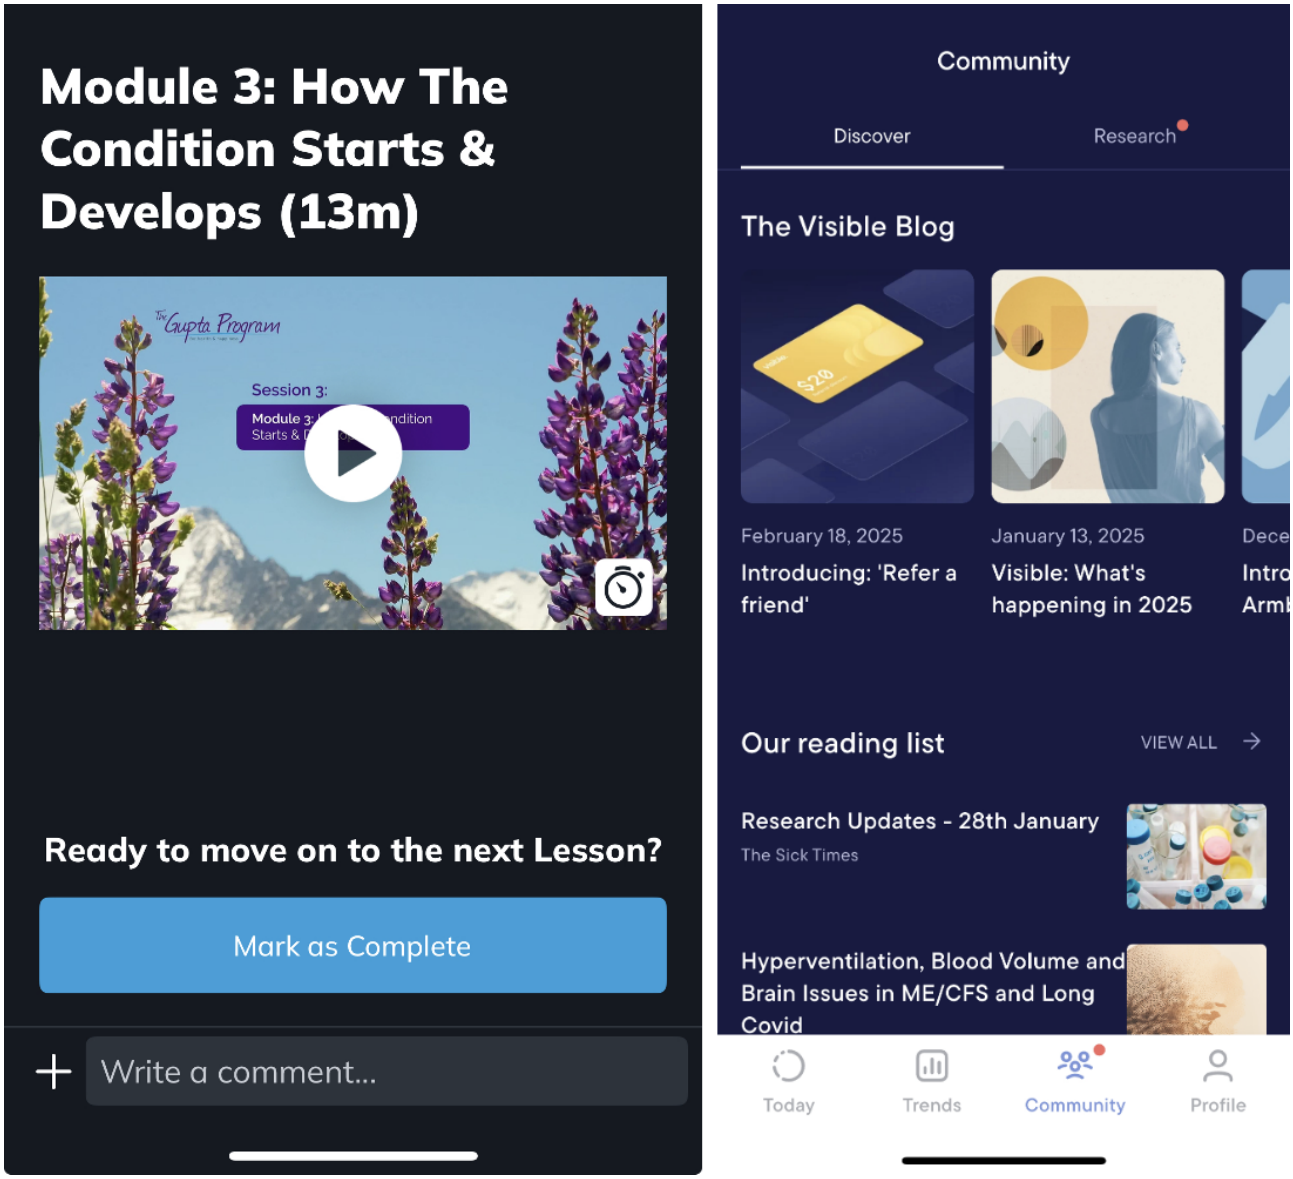
From the apps that visualized fatigue, we note that 2 apps represented all data points per day on the chart, while the other 4 apps represented one data point per day. While 2 of the latter only record 1 fatigue score per day, the other apps either average the score (Guava: Health Tracker) or show the highest score for the day (Bearable - Symptom Tracker). This may be either a benefit or a drawback to self-trackers who deal with chronic fatigue. On one hand, representing all the data points could take more mental effort to digest, which could be remedied by per-day summaries; however, they hide the changes in fatigue, diminishing the insights obtainable from their tracking efforts. This highlights the value of visualizing a minimum of 3 data points a day, with options to show fatigue data before and after activities, as users typically seek to understand the impacts of activities for pacing purposes [9].

Presentation of Distinct Summaries of Some or All Data

Findings reveal that 4 apps display data summaries. One app shows averages of any tracked variable within a chosen timescale. A second app shows the averages of symptoms and steps over a weekly or monthly period. A third app shows averages of morning and evening mood over 7, 30, or 90 days. The fourth app shows averages of daily scores within a yearly view visualization, and averages of monthly scores within a monthly view. These data summaries are important, as providing users a more condensed form of data could reduce the cognitive load of understanding their fatigue, which is important in preventing the apps from exacerbating their condition [2].

Assessment Tools

Regarding symptoms, 2 apps provide valid scales to assess the symptoms' impact on everyday life (Multimedia Appendices 8 and 9). One is the Functional Capacity in ME/CFS (FUNCAP) [58] (David Davies-Payne), whose development was informed by patients living with fatigue. This tool effectively accounts for the impact of PEM on completing activities. In its short version, it consists of 27 items covering 8 domains from personal hygiene to concentration. The other tool is Quality of Life in Neurological Disorders (Neuro QOL) [59,60], consisting of 8 or 9 items for each of 13 domains from physical to mental health. Both tools are retrospective reports as they require reflection on past experiences to complete [61].



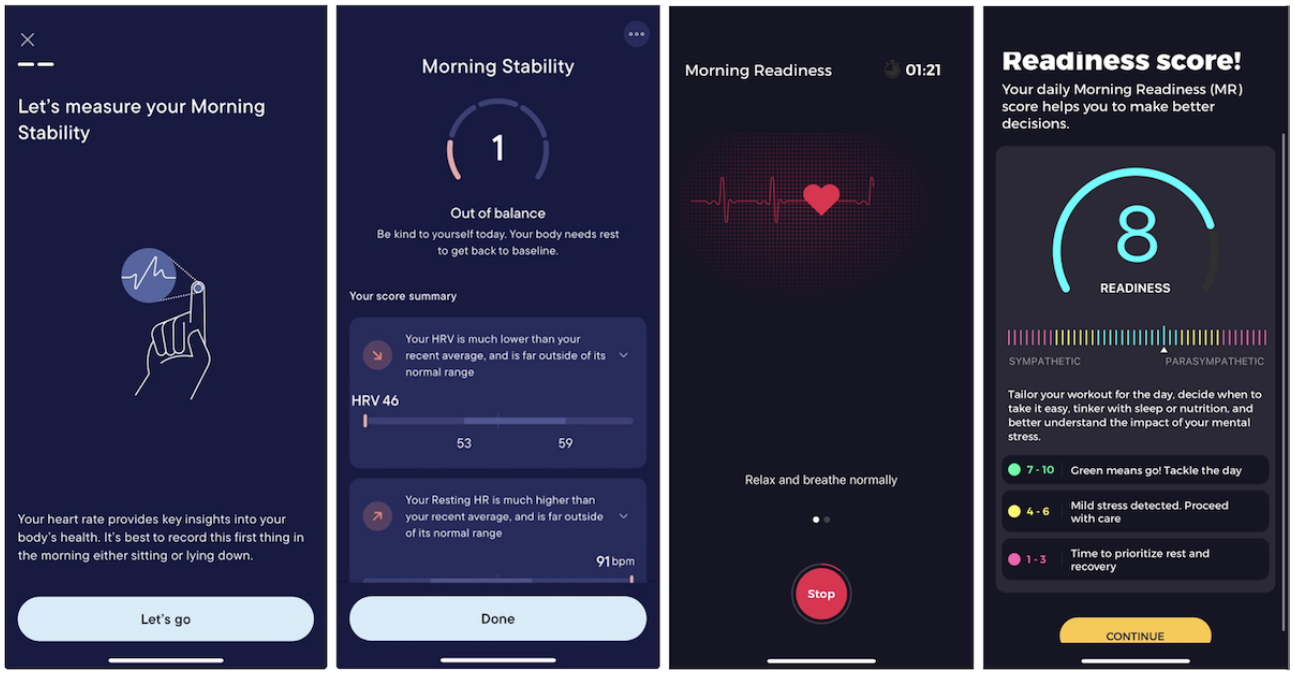
Interventions for Managing Fatigue

Overview

Despite the rich set of symptoms and tracked data, the top-rated apps for fatigue provide limited interventions for the self-management of fatigue, and in particular, those leveraging tracked data (Multimedia Appendices 10 and 11). Findings highlight a range of interventions provided by the apps, one of which is neuroeducation (3 apps); a treatment approach that aims to improve user well-being via educational lessons and exercises built around neuroscience concepts [62]. The apps in our review chose an approach centered on the concept of neuroplasticity and one such app is the Gupta Program Brain Retraining (Harley Street Solutions LTD) [63], as seen in Figure 4. Another intervention is psychoeducation (5 apps), which is delivered through articles informing users of their condition along with possible treatments and informing them of new advancements in research surrounding their condition, as seen in the Visible: Pacing for illness app [46] in Figure 4. Functionalities for social support (3 apps) were also implemented, in the form of community engagement through forum posts and social networking. These functionalities offer value to users with ELCs by providing them with a space for support while promoting discussion around their condition [7,10,15-17]. Moreover, 2 apps included biofeedback-based therapy, which aims to regulate the nervous system to reduce symptoms through the use of deep breathing (2 apps) or muscle relaxation (1 app) exercises, the latter of which has been known to reduce fatigue and may help individuals with CFS [64]. Finally, 2 apps were found to offer functionalities supporting pacing (2 apps).

XSL•FO
RenderX

Figure 4. Screenshots showcasing interventions provided by 2 different apps (psychoeducation on the left, and educational support on the right [images used with permission from the apps' developers]).



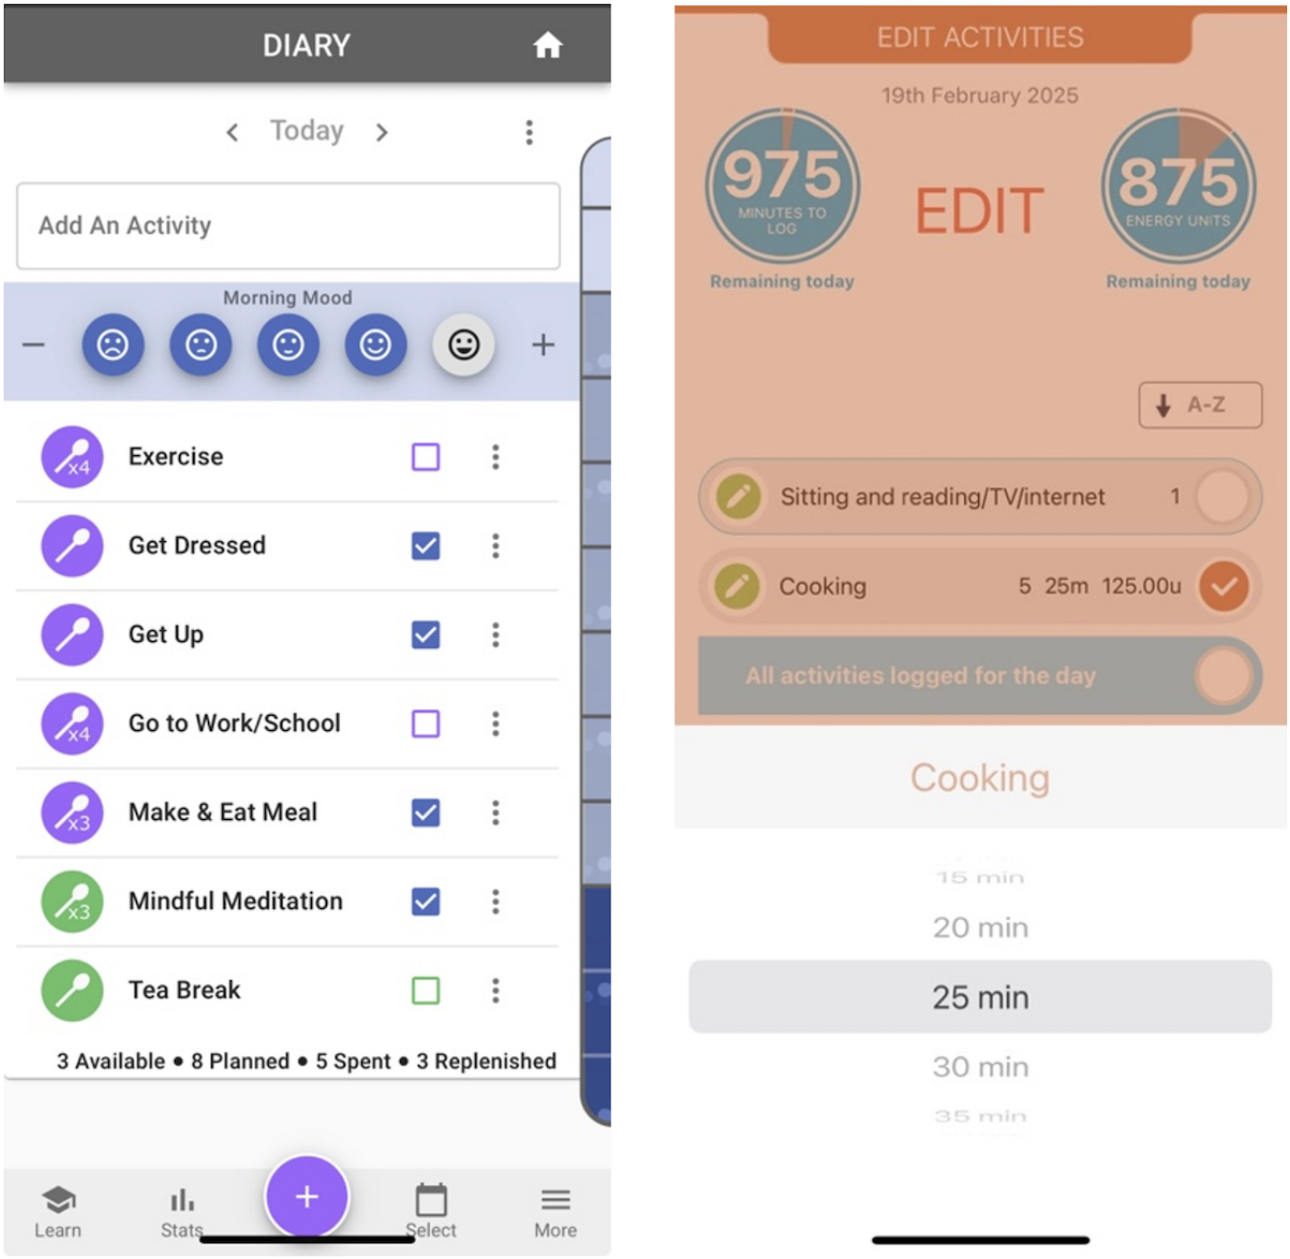
Pacing is an important intervention, tailored for fatigue [1], which involves planning and allocating one's energy toward activities to be completed based on their energy demands [9] through the so-called spoon management [9,65] or energy envelope approaches [9,66]. Pacing involves identifying what activities one can do, in addition to the extent that such activities can be carried out [67]; additionally, it entails stopping activities when breaching PEM and can also integrate the act of estimating energy levels [68]. Previous findings indicated the value of pacing interventions for managing fatigue in addition to preventing overexertion and PEM [1]. While not an intervention per se, 3 apps also provide support for energy estimates, which is important as it can provide input for pacing interventions.

Energy Estimation Using HRV and Pacing

Estimates of energy are manually tracked through self-reports (1 app), which is the traditional approach as a prerequisite for pacing. Interestingly, another 2 apps use a method of tracking daily energy estimates through HRV measurement in the morning, which is compared to the user's baseline to provide either a stability score by one app (Figure 5) [46], or a readiness score by the other (Figure 5) [69]. These scores are used to notify the user of potential flare-ups of their conditions and, as mentioned before, can inform their pacing decisions [68].

XSL•FO
RenderX

Figure 5. Screenshots showing energy estimation approaches by 2 different apps (images used with permission from the apps' developers).



Previous work suggested the potential of HRV data as an indicator of fatigue [70,71], albeit its use to estimate energy has been less explored. Such approaches to estimate both fatigue and energy levels are crucial to lower the burden of tracking and its cognitive load, which is especially beneficial for an individual who may be approaching PEM [2]. Interestingly, however, not all apps estimating energy also provide pacing interventions.

Pacing Interventions

These interventions are provided only by 2 apps using different energy units. One app uses spoon management [9,65] as seen in Figure 6 [72], and the other leverages energy envelope approaches [9,66] as seen in Figure 6 [73]. The former has a maximum daily energy level set to 12 spoons, while the latter uses a less conventional and finer-grain maximum daily amount of 1000 energy units. Both apps provide predefined and customizable activity lists with predefined energy impacts for each of the listed activities, as well as gamification in the form of a limited-quantity source [74] to track and account for energy as a resource. Additionally, they both use traffic light–style red and green coding to visualize energy usage as positive and negative [75], and to deliver cautionary feedback as a consequence of extending one's energy beyond the daily threshold amount.

XSL•FO
RenderX

Figure 6. Screenshots from apps providing spoon management (left), and an energy envelope approach (right; images used with permission from the apps' developers).

Planning daily activities based on one's energy can support not just pacing, but also structure and order, or routinization, with previous findings indicating its benefits for people living with CFS [9]. Routinization could be further supported by automatically prefilling in activity fields on apps to further reduce the user's burden. This is important as a previous study has shown that fatigue symptoms can impede user engagement with self-management apps [9].

Theoretical and Empirical Underpinnings of Interventions

Our findings show that 6 of the apps offering interventions such as psychoeducation, neuroeducation, energy estimation, and biofeedback had provided either theoretical or empirical groundings of their methods and informed the user either through app help pages or the app's website. From these, 4 of the apps cite academic work to support the efficacy of the intervention that they provide neuroeducation (Gupta Program Brain Retraining [Harley Street Solutions LTD]); pacing (Visible: Pacing for illness [Visible Health Inc.]), an energy estimation app; biofeedback (Juva Stress and Migraine [Juva Health Inc.]); and HRV-based interventions (Elite HRV [Elite HRV Inc]), respectively. However, only 2 of these apps (Visible: Pacing for illness [Visible Health Inc.] and Gupta Program Brain Retraining [Harley Street Solutions LTD]) provide empirical evidence supporting the effectiveness of the app itself. Two other neuroeducation apps (Freeme: ME/CFS and Long COVID [Freeme Health Ltd], and Curable: Chronic Pain Relief [Curable Inc]) cite academic work supporting all or some of the information provided to users in their educational material.

RenderX

Data Extracted From App Privacy Policies and Cookie Notices

Overview

We now report on data from app privacy policies and cookie notices through 3 main identified themes, namely the target age groups of the apps, information surrounding the handling of data, and the usage and purpose of cookies (Multimedia Appendices 12 and 13).

Target Age Group for App Use

Findings reveal that the majority of the apps (10 apps) restricted their use to nonadult individuals. From these, 7 apps mention that they do not provide services to users younger than 18 years, 2 apps do the same for users younger than 16 years, and 1 app restricted nonadult users unless the legal guardian or carer provides consent.

Information Surrounding the Handling of Data

Findings indicate that for 11 apps, their developers disclosed that they stored data gathered through the app on company servers, while 1 app stored it with a third-party site called Sentry Inc. The latter has stated in its privacy policy that this is done only for anonymized crash data.

As the apps store their data outside the user's device, it is important to reveal the parties with whom the data are being shared. Findings show that via the use of the app, users consent to sharing data with advertisers for 4 apps, 2 of which have revealed that personal data will be shared. Other parties with whom data will be shared in this manner include analytics (3 apps), anonymous crash data processing as mentioned earlier (1 app), and research (2 apps), but in an anonymized form.

Outside of the previously mentioned data, some apps also offered the option to opt-in to third-party data sharing with advertisers (1 app), analytics (1 app), the OS's health app (1 app), third-party backup storage providers (1 app), and 5 apps present the option to share data with researchers, of which 2 apps claimed that the data will be anonymized, and a third app revealed that the data will be used for product development and health research. It is worth noting that opting in with advertisers, the OS's health app, and backup storage providers involves the sharing of personal data.

Another important finding is the information surrounding the sale of user data; 3 of the apps were found to sell data, one of which revealed that they only sell personal information with the user's permission. Seven other apps offered no information surrounding the sale of data, and the remaining 6 apps revealed that they do not sell. Regarding the latter, 4 of them explicitly stated no, 1 app claimed that they do not sell the information covered by the policy, and the final app revealed that it does not sell data from Californian residents. Meanwhile, 2 of the 3 apps selling data informed that the data were being sold to advertisers (2 apps) and analytics providers (1 app). Data surrounding the sale of information were mostly easy to find, with the majority (6 apps) highlighting the information under clearly labeled headings and subheadings, while 2 apps detailed that they do not sell it without highlighting or obfuscating the information. However, one app that sold personal data did not state it on the main page of the privacy policy and was instead presented on a separate page for Californian and US residents. While this page was linked in the privacy policy, the document did not point to the information regarding the sales being there and thus appears hidden to users outside the United States, as they may not explore sections irrelevant to them. This emphasizes the importance of clearly highlighting information regarding sales to users through the use of subheadings to improve discoverability.

Regarding ownership of data, only 1 app's privacy policy offered information surrounding this, and it revealed that the developer is the data owner.

Usage and Purpose of Cookies

We also analyzed the app's privacy policies and cookie notices for information surrounding cookies and have found that 8 apps used cookies for analytics purposes, with one of the apps only enabling cookies outside of app and website areas requiring a log-in to use, to protect their users' health data. A total of 6 other apps stated that they made use of cookies for both advertisement and analytics, while the remaining 3 provided no information surrounding the use of cookies.

Discussion

Principal Results

Within the main tracking functionality, our findings highlight a rich set of tracked content on fatigue, its symptoms, and associated factors, whose understanding is supported by various visualizations. Regarding interventions, however, a limited number of apps leveraged this rich and diverse tracked data to support pacing of estimated energy. In light of these outcomes, we articulate 5 design implications capturing both the strengths of some of the top-rated apps for fatigue, as well as how such apps can be further improved, along with the broader design of technologies for fatigue.

Supporting Hybrid Tracking: Balancing Validity of Self-Reported Fatigue With Low Burden Automatic Tracking of Symptoms

Two key outcomes are the limited use of validated scales for capturing and tracking fatigue, which limits the validity of tracked data and its value for recommending interventions. Validated scales come with potential drawbacks regarding lower engagement due to their burden [56]. Information might also be less personally meaningful to the participant as the level of data collected is restricted to that elicited by the scale; however, the burden can be reduced by using scales that are short and simple [56]. In addition, the loss of meaningful contextual data can be remedied by offering the option to add notes with every entry, as 5 apps in this review have done. Therefore, we strongly recommend the use of validated fatigue scales, both for trait and state fatigue. The former can be used before and after an intervention program, while the latter can be used for frequent tracking of fatigue. To identify such valid scales, we can draw from a previous systematic review [76], showing that the most commonly used trait scale includes the Modified Fatigue Impact Scale (MFIS) [77], and for state scale we could use the 1-item

XSL•FO
RenderX

Samn-Perelli Fatigue Checklist [78], or the 4-item Fatigue State Questionnaire (FSQ) [79], which is also used in ecological momentary assessment with digital technologies [80]. The latter state scales are not only valid but also consist of a small number of items, representing an important consideration for lowering user burden for daily tracking. Moreover, we have seen emerging efforts to capture fatigue through HRV data both in some of the apps via commercial heart rate sensors (which include chest straps such as the Polar H10) capable of HRV capture by the Elite HRV app, and photoplethysmography [81] conducted through the smartphone camera by the Visible: Pacing for illness app (Visible Health Inc.), along with scholarly work [70,71] typically focusing on electrocardiogram (ECG) data. If these approaches can be scaled to an automatic process, this could offer substantial support to users seeking to lower the burden of tracking. In addition, the automatic tracking of fatigue has even been found to be desired by participants in co-design workshops tackling pacing technologies [11]. The implementation of a hybrid tracking system using low-effort or even automatic capture of fatigue through both self-reported measures of scales and HRV data can explore and ensure the validity of the latter, while lowering the burden of the former [2]. For this, we can also think of novel, low-cost tracking methods on smartwatch interfaces, possibly ML-powered [2].

Findings also indicate the vast number of symptoms available to be tracked, which can be much needed to inform the management of fatigue, albeit they may be taxing to track and understand. To mitigate this downside, we propose the use of free-form conversational interfaces supported by natural language processing (NLP); this can reduce the mental load on users while also allowing for richer data input and capture [82]. We further suggest hybrid tracking of such symptoms, leveraging low-burden self-reported data with lower frequency, augmented by automatically tracked data [2,9] through the app, or phone itself, as well as smartwatch sensors via the OS's health apps paired with heart rate monitors. We have also seen emerging efforts to integrate symptom checkers such as Ada and Isabel to support users in navigating their symptoms. This opens up new design opportunities for AI-augmented symptom checkers, although ethical implications need to be carefully considered, as despite their usability and acceptability [83], the value of AI checkers for unsupervised patients may be harmful [53].

Contextualizing Fatigue Data With Symptoms and Associated Factors: Combined Visualizations for Sense-Making

Findings reveal that while most apps support the tracking and visualizing of fatigue data, only half support combined visualizations, some of which show fatigue data shown alongside other tracked symptoms or associated factors, while others combine different symptoms with or without associated factors, albeit without fatigue data. Combined visualizations highlighting fatigue data against symptoms or associated factors are, however, crucial for understanding if and how the latter may have impacted changes in state fatigue over time. Integrating different data types in one ready-to-understand visualization is not trivial. For this, we suggest low complexity ensured by combining fewer data types, such as fatigue and steps, for instance, through visualizations with 1 or 2 line charts augmented with additional information such as one's location. The selection of data types, possibly powered by AI, would be best informed by data types with the strongest impact on the changes in fatigue scores. Visualizations may also include data summaries over time, some already supported by a small number of apps. Color-coded symptom severity levels may be avoided to lower users' emotional concerns, and more subtle ways of informing severity levels can be instead explored. With respect to timeline, we suggest providing options with complementary value: visualizations of the most recent past benefit from memory of recent events to support recall of key factors impacting fatigue and changes in daily scores, while those of the far past can highlight broader patterns of changes in fatigue over time [57].

Normalizing the Inclusion of Energy Estimates and Pacing Interventions in Apps Targeting Fatigue

While many of our reviewed apps support interventions, only a few provide support for the intervention of pacing. This is surprising, given the rich body of work indicating its effectiveness for the self-management of fatigue [2]. This opens up a design space for pacing interventions for which we suggest drawing from spoon management [9,65] or energy envelope approaches [9,66]. We can think of novel interfaces which leverage the spoons concept as energy units for energy estimates, scaffold users' planning of energy estimates to daily activities, and provide subtle rather than punitive guidance when an energy threshold is exceeded to help users prevent crashes. The latter is important, as crashes can cause people's energy levels to remain depleted over time, that is, days [2] or even months [49]. As shown by the apps "SpoonieDay" (Blackburn Labs) and "ME/CFS Pacing" (Emerge Australia Inc), one approach to mitigate this is for users to identify at the start of the day their available overall energy, prioritize the main activities that can be covered with it, and allocate the available energy toward core activities, while monitoring that their expenditure remains within the allocated limits. Although users can try to estimate this via methods such as spoon management [9,65] and energy envelope approaches [9,66], they may still underestimate their energy usage needs, and therefore, a warning system may be more useful.

Planning daily activities based on one's energy can support not just pacing, but also structure and order, or routinization, with previous findings indicating its benefits for people living with CFS [9]. Routinization could be further supported by automatically prefilling in activity fields on apps to further reduce the user's burden. This is important as a previous study has shown that fatigue symptoms can impede user engagement with self-management apps [9].

We have also noted the limited use of tracking crashes (PEM events), which can be highly useful, as these happen when participants go over their limits. Identifying one's own limits is one of the foundational aspects of pacing, and this can be further supplemented by contextualizing the data with activity data and spatiotemporal information.

XSL•FO
RenderX

Most importantly, findings revealed that the apps that offer pacing functionalities do not provide energy estimation functionalities, and vice versa. Users would benefit from these functionalities being put together, as energy estimation would give them more information to work with for pacing, and could especially support decision-making (when planning activities) on days when they are more cognitively fatigued.

Comparisons With Prior Personal Informatics Research in the Space of Chronic Conditions

We compared the findings to those of previous works in the field of personal informatics, as they can serve as valuable evidence given the common ground they share. The main difference that we noted is that the apps we reviewed track a much larger range of symptoms and health data compared to the works in the space of personal informatics. Due to fatigue being impacted by a wide range of interrelated factors [2,9], this level of tracking could be needed by users to understand their condition. While tracking a substantial number of symptoms will eventually overwhelm users [2], lightweight tracking solutions, as discussed earlier, could help negate this.

With regard to interventions, pacing is a unique approach that has received some focus from the field of personal informatics. For the purpose of pacing, while historic data are useful, Felipe et al [29] reported that users with chronic pain desired to see their data in real-time to identify if they were exceeding their limits. However, we have found that only a limited number of apps support this feature. Future apps could implement functionalities to show a live view of tracked data, as this could be useful for identifying if users are approaching PEM.

Limitations

The main limitations of the study are that our app review did not include non-English apps, apps outside the UK app stores, and finally, paid apps. Regarding the latter, as mentioned earlier, and aligned with previous work [4,33,35,40], we focused on apps that were either completely free or offered free trials because, in the health care context, accessibility and fairness are vital, especially since vulnerable users may not be able to afford subscriptions [41]. Nevertheless, other apps such as paid ones, non-English apps, and apps outside the United Kingdom are indeed likely to include additional valuable features, and future work could explore these to identify any further design insights on supporting the management of fatigue via apps.

Conclusions

This paper presents a functionality review of 17 fatigue apps selected as top-rated apps from the Google Play Store and the Apple App Store. Findings indicate 3 main functionalities pertaining to tracking fatigue, its symptoms, and associated factors, visualizing tracked content, and providing interventions for the self-management of fatigue. Our findings informed 3 implications for sensitive design of technologies for people living with fatigue, which include supporting hybrid tracking to balance the validity of self-reported fatigue with low-burden automatic tracking of symptoms, contextualizing fatigue data with symptoms and associated factors through combined visualizations for sense-making, and normalizing the inclusion of energy estimates and pacing interventions in apps targeting fatigue.

Abstract

Background: Health care professionals must consider multiple dimensions of prevention when consulting with adolescents. Identifying risky behaviors early in adolescence is crucial for reducing both morbidity and mortality. General practitioners are increasingly eager to incorporate digital tools for prevention into their consultations with adolescents; however, the relevance and clinical validity of these digital tools are not always established or well-known. Consequently, primary care professionals require guidance and support in selecting relevant mobile health (mHealth) tools.

Objective: The aim of this study is to identify relevant and useful digital apps to help primary care professionals detect at-risk adolescents across all recommended areas of prevention: orthopedics, mental health, substance abuse, risk behaviors, sexual health, vaccinations, social relationships, and nutrition.

Methods: A systematic review of smartphone apps, with an analysis of content quality, was carried out by 4 researchers using the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) checklist. The App Store and Google Play Store platforms were surveyed. The inclusion criteria were as follows: free of charge, date of last update, availability in French or English, relevance of the preventive approach to adolescents, and scientific validation. Four health care professionals assessed the apps: 2 selected the apps relevant to health care professionals, then 3 analyzed these apps using the French version of the Mobile App Rating Scale (MARS-F). Intraclass correlation coefficient, model (2,1) (2-way random effects, absolute agreement, single measures); standard error of measurement; and mean absolute error were also calculated.

Results: A total of 976 apps were identified, 49 of which had disappeared from the platforms prior to analysis. Nine apps were retained. Seven (0.72%) were included after evaluation using the MARS-F: 2 on mental health and 5 on sexual health (including 3 on contraception only). The mean MARS-F interrater score ranged from 2.5/5 to 3.8/5. The global MARS-F score demonstrated a pooled SD of 0.60 and an intraclass correlation coefficient (2,1) of 0.0003, resulting in a calculated standard error of measurement of 0.60. The average discrepancy between raters was a mean absolute error of 0.53.

Conclusions: No similar studies have been identified in the literature that specifically focus on mobile apps designed to support health care professionals in delivering preventive care to adolescents. Of the 8 areas of prevention identified as relevant for adolescents, only 3 are addressed by the apps validated through our methodology (5 focus on sexual health). Consequently, current apps are insufficient to support health care professionals in their overall preventive work with adolescents. Such a review should be conducted systematically prior to the development of any new tool to prevent duplication and channel creative efforts toward truly innovative digital solutions. Furthermore, a thorough analysis of relevant, recommended websites is essential, as these resources complement the use of mobile apps designed for health care professionals.

Introduction

Adolescence is a period of transition from childhood to adulthood. Adolescents are subject to many biopsychosocial changes, including the desire for autonomy and experimentation, the need to identify with peers, and risk-taking [1-6]. Health care professionals must consider a wide range of preventive domains during consultations with adolescents: sexual health, mental health, substance abuse and addiction, diet, physical activity, orthopedic disorders, vaccinations, screen use, and social relations [6-11]. Preventive actions are difficult for health care professionals to implement because of the complexity of consultations with adolescents [10-15]. Early identification of risky behaviors in adolescents is essential for reducing morbidity and mortality [11,16]. Although various recommendations and predominantly nondigital tools exist to support adolescent preventive care during consultations [8,9,14,17,18], health care professionals often find them difficult to implement effectively in practice.

The World Health Organization (WHO) defines eHealth as "digital services for human well-being," that is, the application of information and communication technologies to health and well-being [19,20]. Mobile health (mHealth) covers medical and public health practices based on mobile devices (mobile phones, patient monitoring systems, personal digital assistants, and other wireless devices) [19,21]. The development of health-focused websites and smartphone apps has contributed significantly to improving both the quality of care and patient health outcomes [20]. Digital tools are used in routine care by health care professionals and patients. In 2021, over 327,000 mHealth apps were listed in digital stores [21]. French general practitioners generally view mHealth apps and devices favorably and express readiness to integrate them into their clinical workflows [15,22]. In a qualitative study carried out among French general practitioners, the need for a preventive tool in consultations with adolescents was identified, with a preference for a practical digital tool [15]. Despite the desire of general practitioners to use these digital tools, the relevance of these tools is not always established or known [15,17].

Many apps are easy to use during consultations, and general practitioners often do not have the skills or time to select from the wide range on offer. General practitioners need guidance to choose relevant apps. The main aim of this study was to identify relevant and useful digital apps to help primary care professionals detect at-risk adolescents across all recommended areas of prevention: orthopedics, mental health, substance abuse, risk behaviors, sexual health, vaccinations, social relationships, and nutrition.

Methods

Study Design

A systematic review of smartphone apps with an analysis of content quality was carried out by 4 researchers. One general practitioner resident (CB) and 1 experienced general practitioner (EM) carried out the search for apps on search engines and the initial selection. Two general practitioner residents (MK and LP) and 1 experienced general practitioner (EM) evaluated the apps using the French version of the Mobile App Rating Scale (MARS-F) [23]. The study protocol was designed following the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines (items not relevant to a systematic search of apps were considered not applicable; Checklist 1) and the PRISMA-S (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Literature Search Extension) guidelines (Checklist 2) [24,25]. We took into account the specialized reporting items suggested by the PASSR (Protocol for App Store Systematic Reviews) guidelines (Checklist 3) to address the unique challenges of searching and analyzing mobile app stores [26]. The complete and detailed study protocol is provided in Multimedia Appendix 1.

Search Strategy

A systematic search was performed on the 2 major digital platforms: the Apple App Store and the Google Play Store. These platforms are used by approximately 99% of smartphone users to download their apps [27]. Two similar searches, using the same method, were conducted between August 2022 and March 2023, and then between March 2023 and May 2023. The platforms were queried in French and English using keywords related to adolescent prevention areas derived from MeSH terms [28]. MeSH terms were preidentified in a literature review according to prevention themes (Table 1). MeSH terms were replaced with non-MeSH synonyms when a search did not find any relevant results. The choice of words was discussed between the 2 researchers, CB and EM. Each keyword was used individually on the app platforms. CB and EM carried out the search on an iPhone 11 smartphone running iOS 15 (Apple), an ASUS VivoBook computer (ASUSTeK Computer Inc), and a Google Pixel 7 smartphone with the S91xBXXS1AWD1 update. The search ended when the search engines no longer provided new apps: keywords were entered into the search tool, followed by an exhaustive review of the descriptions of the apps offered.

Table . English keywords.

Prevention areas	English keywords
Orthopedics	• Kyphosis • Spinal curvatures • Vertebral body • Lordosis • Spinal or vertebral column • Scoliosis • Back pain • Osgood-Schlatter disease[a] • Osteochondrosis • Scheuermann disease[a] • Patellofemoral pain syndrome
Substance abuse, screens, and addictions	• Alcohol • Nicotiana • Drug • Cannabis • Heroin prevention[b] • Cocaine • Ecstasy • Screen time
Mental health	• Sleep-wake disorders • Anxiety • Depression • Suicide • Attention-deficit/hyperactivity disorder • Psychosis • Autism
Nutrition	• Obesity • Deficiency diseases • Feeding and eating disorders
Sexual health and puberty	• Sexually transmitted infection • Unsafe sex • Contraception • Puberty
Social relations and violence	• School dropout • Harassment, bullying[a] • Friend • Violence
Vaccinations	• Vaccination

[a]Non-MeSH words.

[b]The term “heroin” was not retained because the search results yielded only games.

Selection Process and Eligibility Criteria

The selection by EM and CB followed a 2-stage process. First, EM and CB screened the apps based on their titles, descriptions, and metadata provided in the app stores. Second, the shortlisted apps were downloaded and tested for full eligibility. The initial selection of apps was based on inclusion and exclusion criteria from digital platforms. In cases of doubt about an exclusion criterion, the decision was made through discussions between CB and EM.

To meet our inclusion criteria, the apps had to (1) relate to one of the selected areas of prevention (orthopedics, mental health, substance abuse, risk behaviors, sexual health, vaccinations, social relations, nutrition); (2) be relevant to facilitating the preventive approach of health care professionals during consultations with adolescents; (3) be available in French or English; (4) have been scientifically validated (developed by health care professionals or a learned medical society and/or based on scientific or government recommendations); (5) be free (apps free for only a trial period were not selected); (6) have been updated within the 3 years preceding the end of the search, at least by 2020 (since 2022, the Google Play Store has removed apps that have not been updated for more than 2 years [29], and for the App Store, this period is 3 years for apps with few downloads in the last 12 months [30] but not all catalogs have yet been updated).

XSL•FO
RenderX

The exclusion criteria were as follows: (1) lack of information about the scientific data used to design the app's content, (2) games without medicoeducational content, (3) wallpaper apps, (4) religious apps, (5) apps that offer links to medical appointments, and (6) advertising apps.

Inclusion criteria were based on the data available on each app's presentation page: the title, description, images, and general information about the app. If any data were missing, the apps were opened to search for the missing information. Apps were excluded after download if they were no longer available in app stores at the time of evaluation by one of the evaluators. We chose to focus on free apps to ensure that the tools identified are accessible to all health care professionals, regardless of institutional funding or individual socioeconomic status, thereby promoting digital health equity regardless of which health care professional a patient consults [31]. Health care professionals have already invested in costly practice tools such as business software and telecare tools. We therefore wanted to offer them apps with no impact on their professional workloads. The high cost of an app is one of the main reasons why it is not downloaded [32,33]. Selecting free apps also limits the risk of commercial bias or conflicts of interest that can be associated with paid models.

As these digital tools are intended for use in clinical consultations, scientific rigor is nonnegotiable. Using unvalidated tools poses an ethical risk to the patient-provider relationship and the safety of care.

Quality Appraisal and Data Extraction

MK, LP, and EM evaluated apps using the MARS-F [23]. The MARS and its French version (MARS-F) have been validated for the overall quality assessment of apps in the field of mHealth [23,34,35]. The app evaluations took place between December 2023 and January 2024.

The MARS-F assesses four objective quality dimensions: (1) Engagement (entertainment, interest, customization, interactivity, and target group), (2) Functionality (performance, ease of use, navigation, and gestural design), (3) Esthetics (layout, graphics, and visual appeal), and (4) Information (description accuracy, goals, information quality or quantity, visual information, credibility, and evidence base). A subjective quality score and an app-specific section were also proposed. Each item is rated on a Likert scale from 1 ("inadequate") to 5 ("excellent").

When specific objectives were not delineated and information was lacking, the respective items were rated as "not attributable" (NA). Consequently, these items were excluded from consideration in the overall scoring process. In total, MARS-F is a total score out of 5, corresponding to the average of these 4 sections. For each evaluator, an average for each section (A, B, C, and D) from 1 to 5 was calculated, followed by an interevaluator average for each section. An overall average of the interrater MARS-F score was used to evaluate the apps. To ensure the selected apps were suitable for clinical practice and met the needs of health care professionals working with adolescents, specific quality cut-off scores were applied during the screening phase. Apps were excluded if they failed to meet the following minimum thresholds across the MARS-F sections (Multimedia Appendix 1). Apps were excluded if MARS-F ratings were below 3 for target group relevance (Item 5, Section A), below 2 for all technical usability items (Section B: Functionality), or if ratings were insufficient within the Information Quality domain (Section D: Item 15 <2 or NA, Item 16 <2, Item 17 <4). During the quality appraisal, if an exclusion criterion was found by only 1 of the 2 evaluators for the final evaluation score, the third researcher (BL) was asked to discuss the results, and consensus was sought.

From the apps selected on digital platforms by EM and CB, 3 researchers took part in evaluating them: the 2 general practitioner residents (MK and LP) divided up the prevention themes for analysis, and the experienced general practitioner (EM) analyzed all the apps in a blinded manner. All 3 completed the MARS-F [23] separately. A common table was then filled based on these MARS-F results. To ensure rating consistency, LP and MK underwent a structured calibration process led by the veteran expert (EM). During the 2-session calibration process, informal reliability checks were conducted to ensure rater alignment. The 3 researchers independently scored a pilot sample of test applications. Discrepancies and borderline cases were thoroughly discussed until a 100% consensus was reached on all criteria. However, no formal statistical reliability metrics, such as a training intraclass correlation coefficient (ICC), were computed during this preliminary phase." The training consisted of two 2-hour sessions. The first session involved a comprehensive review of each MARS-F item and its scoring criteria. In the second session, conducted 3 weeks later, the 3 researchers independently and blindly evaluated 2 apps randomly selected from the initial search results. Discrepancies were discussed collectively, and scoring rules were clarified under the supervision of the researcher EM. Throughout the formal evaluation period, raters had access to expert guidance to resolve technical queries. Specific apps were not discussed until the final consensus meeting to maintain blinded assessment integrity. While a formal training ICC was not calculated, this iterative calibration was designed to minimize subjective bias.

Statistical Analysis

MARS-F scores were presented as means and SDs. To assess the reliability of the MARS-F ratings (global and subscales), we used a multimetric approach. Interrater reliability was calculated using the ICC, model (2,1) (2-way random effects, absolute agreement, single measures), along with the SD. To address measurement precision, we calculated the standard error of measurement (SEM) using the formula $SEM=SD\times\sqrt{(1-ICC)}$. Descriptive statistics, including the mean and SD, were generated for each app and for each global scale or subscale to characterize the distribution of quality ratings. We analyzed the expert's ratings (EM) against the residents' ratings (MK or LP). Since the ICC is a ratio of intersubject variance to total variance, the lack of variability between subjects in a small sample could mathematically deflate the ICC, even when raters are in close agreement. To provide a more accurate assessment of rater reliability, we also calculated the mean absolute error (MAE). The MAE represents the actual average point difference between raters on the 5-point scale.

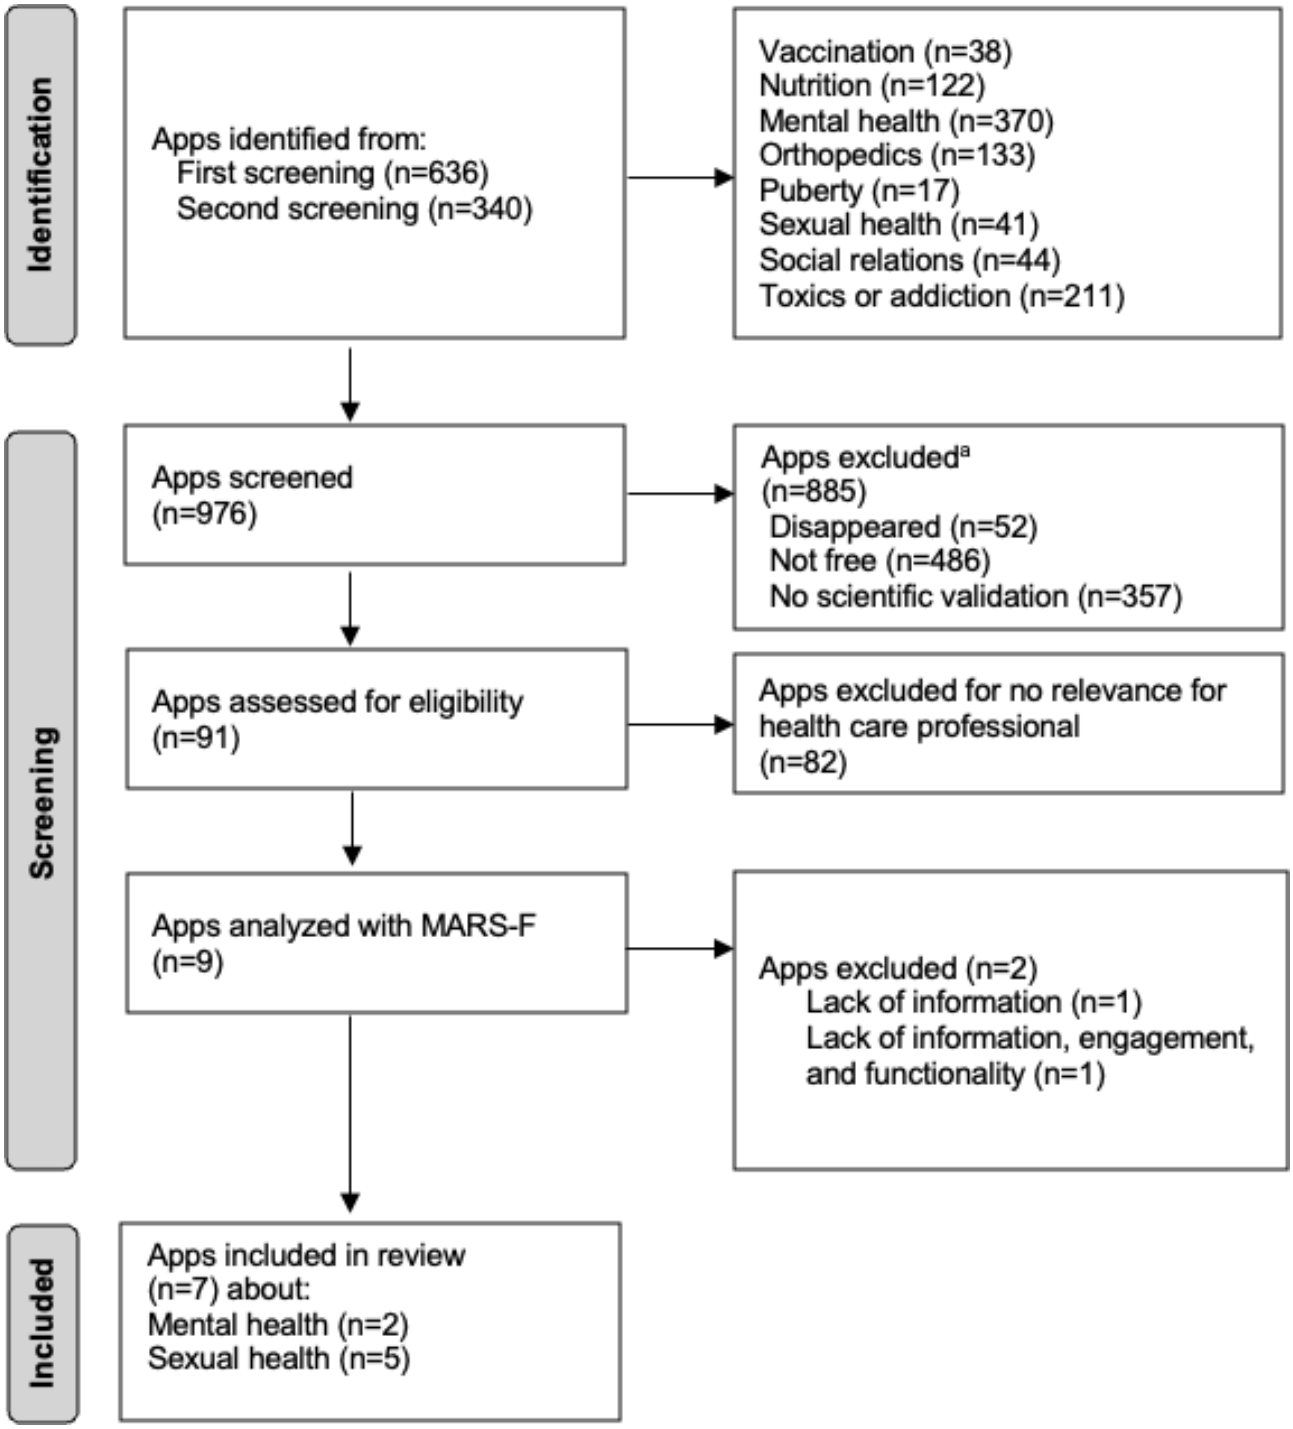
XSL•FO
RenderX

An ICC above 0.75 was considered excellent, good between 0.60 and 0.74, fair between 0.40 and 0.59, and poor if below 0.40. We have applied an interpretation threshold for MAE: excellent (<0.5), good (0.5 - 0.75), fair (0.75 - 1.0), and poor (>1.0).

ICC analyses were performed using JASP (version 0.96; 2026; University of Amsterdam), and MAE, SD, mean, and SEM were calculated in Microsoft Excel.

Ethical Considerations

A request for authorization has been made to the Data Protection Officer of the University of Montpellier. In addition, the study did not require authorization from the "*Comité de la Protection des Personnes*" (Personal Protection Committee), as it did not involve experimentation on individuals and did not fall within the scope of the General Data Protection Regulation and, therefore, of MR004. This study complies with the rules of the Helsinki Declaration [36].



Results

App Selection

Using the preidentified keywords, the double screening identified 976 apps. Forty-seven apps had already disappeared from the platforms between the 2 screenings and at the time of the first analysis by CB and EM; 2 more disappeared during the final evaluations by LP, MK, and EM, giving a total of 52 apps that had disappeared during the search. In the end, 9 apps were retained. After evaluation with the MARS-F, 7 were included (Figure 1). The mean MARS-F interrater score ranged from 2.5/5 to 3.8/5 (Table 2).

Quality of Apps Based on MARS-F

The evaluation scores for the 9 evaluated apps were listed in a table (Multimedia Appendix 2), and a summary of the content of the apps was produced for the apps not excluded from the analysis (Multimedia Appendix 3). We provide a summary of the MARS-F scores for the 7 included apps (Table 2) and a short summary of these apps.

Some items in MARS-F have been rated NA. We describe the NA items present in the apps evaluated by MARS-F in Table 3.

[d]NA: not attributable.

Reliability Evaluation

The global MARS-F score demonstrated a pooled SD of 0.60 and an ICC (2,1) of 0.0003, resulting in a calculated SEM of 0.60. The average discrepancy between raters remained low, with an MAE of 0.53. Across subscales, the SEM ranged from 0.41 (Engagement) to 0.79 (Functionality) (Table 4).

Table . Reliability table[a].

Scale or subscale	ICC[b] (95% CI)	Global SD	Min-Max	SEM[c]	MAE[d]
Global MARS-F[e]	0.0003 (−0.51 to 0.61)	0.60	2.55 - 3.92	0.60	0.53
Engagement	0.54 (−0.12 to 0.88)	0.61	1.60 - 3.80	0.41	0.4
Functionality	0.00 (−0.46 to 0.61)	0.79	2.50 - 4.75	0.79	1.03
Esthetics	0.33 (−0.35 to 0.79)	0.70	1.66 - 4.33	0.57	0.75
Information	0.26 (−0.15 to 0.72)	0.59	2.66 - 4.50	0.51	0.66

[a]ICC (2.1) values are affected by range restriction (low intersubject variance) and low number of apps. MAE is provided to complement ICC analysis and clarify reliability.

[b]ICC: intraclass correlation coefficient.

[c]SEM: standard error of measurement

[d]MAE: mean absolute error.

[e]MARS-F: French version of the Mobile App Rating Scale.

The interrater reliability analysis comparing the veteran expert (EM) and general practitioner residents (MK and LP) yielded variable results across the MARS-F subscales (Table 4). As expected, the ICC (2,1) for the overall MARS-F score was poor at 0.0003 (95% CI −0.51 to 0.61). While ICC values for several subscales remained poor, ranging from 0.000 to 0.540, these findings are largely attributable to range restriction caused by the high homogeneity of app quality scores in our small sample (n=9). To account for this statistical artifact, we calculated an MAE to assess absolute agreement. The MAE for the global score was 0.53 (good), indicating that ratings differed by approximately half a point on the 5-point scale, which represents good clinical agreement.

Description of the Apps

Of the 976 apps identified, 37.9% (ie, 370) and 21.6% (ie, 211) were found using mood-related keywords and toxic consumption-related keywords, respectively, compared with only 13.6% (ie, 133) and 3.9% (ie, 38) for orthopedics and vaccination. Nine apps were subjected to double-blind analysis using the MARS-F, and 7 were included. The "*Bariatrique Québec*" app was excluded from Section D (Information); the "USPSTF Prevention TaskForce" app was excluded from 3 sections: A (Engagement), B (Functionality), and D (Information). Among the 7 apps selected from the 976 apps identified (0.72%), 71.4% (ie, 5) were related to sexual health, all of these sexual health apps (100%) dealt with contraception, and 60% of these apps (ie, 3) dealt very briefly with sexually transmitted infections (1 dealt with antiretrovirals and 2 with condom use). About 28.6% of the selected apps (ie, 2) were relevant to mental health. No apps were selected for the following themes: vaccination, nutrition, orthopedics, puberty, social or toxic relationships, and addictions.

XSL•FO
RenderX

We summarized the 7 apps selected for use by health care professionals to support prevention initiatives during consultation with adolescents as follows:

- *Agenda du sommeil antifatigue*: this French-language app allows patients to maintain a digital "sleep diary" to better understand their sleep habits and sleep efficiency, and potentially improve their sleep hygiene. The app serves as a clinical tool for physicians, enabling them to evaluate adolescents' sleep patterns, identify underlying sleep problems, and subsequently optimize the management of sleep disorders.
- mhGAP-IG 2.0 App: this app, available in several languages including English and French, is designed for health care providers around the world and is based on WHO recommendations. It serves as the electronic version of WHO's mhGAP Intervention Guide, version 2.0, for mental, neurological, and substance use disorders in nonspecialized health settings. The app provides information on mental, neurological, and substance-related disorders. It offers detailed descriptions of the diseases, questionnaires for identification and/or assessment, and recommendations for treatment. This app is highly valuable to physicians for detecting mental disorders and self-harming behaviors in adolescents. However, while the app met the minimum threshold for inclusion based on the MARS-F criteria, certain nonfunctional features may negatively affect its overall usability in clinical practice.
- WHO Contraception Tool: developed by the WHO, this app helps health care professionals select the contraceptive method that is best suited to the patient's medical history and characteristics and that complies with good-practice recommendations. Contraceptive methods are ranked from 1 to 4 according to the level of recommendation (1: "use possible," 2: "use possible with conditions," 3 and 4: "use not recommended"). This app uses the WHO 2015 recommendations and is available in several languages, including English and French. The app also allows providers to integrate patient preferences and delivers comprehensive information regarding emergency contraception, contraceptive efficacy, and antiretroviral drugs.
- Contraception Eligibility Tool: this app is the exclusive English version of the "WHO Contraception Tool" and is based on 2 WHO recommendations from 2015 to 2018. It has been developed for humanitarian professionals. It is a tool for selecting the recommended contraception according to the medical data and history of patients, with the same ranking key from 1 to 4 as the 2 previous apps. The app also provides additional clinical guidance on initiating contraception, infertility management, emergency contraception, contraceptive efficacy, the identification of victims of violence against women, and the management of missed pills.
- Contraception Point-of-Care: this app offers interactive clinical algorithms to assist health care providers in selecting the most appropriate contraceptive method for each patient. Updated in February 2025, it incorporates data on contraceptive costs in the United States, contraceptive adaptation, and natural contraceptive methods. This app uses a drop-down menu to aggregate static documents that cannot be navigated or interacted with.
- Practice Family Planning: this app was developed by the Global Health Media Project, a nonprofit organization specializing in the production of educational and preventive health videos. The app is available in French, English, and Spanish. The app offers approximately 40 videos tailored for both health care professionals and patients. Health care professionals can use them for self-training or to select and share with patients for information and education on sexual health and contraception. The videos were developed for developing countries or countries with special health conditions, but they can also be used in countries with a higher socioeconomic level. They teach professionals how to approach and present information on contraception. They also include educational videos for professionals on technical procedures such as intrauterine device insertion, implant insertion or removal, practice organization, and the prevention of nosocomial infections. The videos can be downloaded and viewed offline. This video directory is a useful tool to help professionals in their preventive actions, but some videos are of average quality and perform more reliably when downloaded locally.
- Learn Family Planning: this app, also developed by the Global Health Media Project, is very similar to the previous one. It offers videos to be shown directly to patients by professionals wishing to discuss contraceptive health. Developed for the same target audience as "Practice Family Planning," the videos can also be used in countries with higher socioeconomic levels. The topics covered are more targeted than those in "Practice Family Planning," as the videos are intended to be shared with patients: contraceptive methods, education on contraceptive use, method comparisons, pregnancy, and pelvic examinations.

Discussion

Main Results

This digital review of apps available on the Android and iOS platforms identified 976 apps addressing areas of prevention relevant to consultations between health care professionals and adolescents: vaccinations, orthopedics, drug use and addiction, mental health, nutrition, puberty, sexual health, social relations, and violence. Of these 976 apps, 7 (0.72%) were retained after analysis as recommendable to health care professionals for use in consultations to help them implement prevention measures with adolescents: 2 on mental health (including 1 sleep) and 5 on sexual health (including 3 contraception only). No apps specifically dedicated to adolescent prevention in any of the recommended areas were identified.

Method Discussion

In the MARS-F, NA ratings are described in great detail for each item within the subscales [23]. Since NA ratings are not included in the final scores, these ratings could artificially inflate the scores and lead to the inclusion of apps of insufficient quality. In our study, NA ratings were found only in subsection D (Information), items 14, 17, and 19, which could increase this risk. However, the researchers were rigorous in their

XSL•FO
RenderX

analyses, and this did not affect the selection of apps. We have analyzed these NA ratings found in the following:

- Item 14: Goals (Does the app have specific, measurable goals?). Only 2 apps (*Agenda du sommeil antifatigue* and *Bariatrique Québec*) received a numeric score on this item. The other 9 apps provide information but do not allow for any measurable goals.
- Item 17: Visual Information (NA=There is no visual information in the app; eg, it contains only audio or text). The NA rating is clear in this case.
- Item 19: Evidence Base (Scientific evidence: "Has the app been tested or evaluated, and is it supported by evidence in the published scientific literature?"). The NA is clear in this case. None of the apps has been evaluated in a published study. This item alone does not account for the scientific relevance of the app; item 15 (Quality of Information) supports the scientific quality of the information, as does the pre-evaluation screening of the apps (only apps that have been scientifically validated were included: inclusion criterion number 4).

Safety, Liability, and Ethical Considerations

The integration of Clinical Decision Support Systems, such as the WHO Contraception Tool or mhGAP-IG 2.0 App, into practice carries significant medicolegal and ethical implications. These tools are designed to support, not replace, professional expertise. The health care professional remains solely liable for the final clinical decision. Most apps include disclaimers stating that recommendations are based on global guidelines and may not account for individual patient complexities. A critical risk is "automation bias," in which a professional might overlook rare comorbidities or contraindications that are not programmed into the app's algorithms.

A scoping review published in 2023 examined studies of apps used by health care professionals in clinical practice [37]. This scoping review aimed to describe how physicians use smartphones and mobile apps in clinical settings. Ten studies were included, mainly using survey or focus group methods. Smartphones and mobile apps were used for communication, medical education and training, clinical decision-making, and accessing drug compendia in most studies. Health care professionals were concerned about patient privacy and confidentiality. In our study, only 1 app (*Agenda du sommeil antifatigue*) involved personal data, but it was nonnominative and confidentiality was guaranteed. In addition, this app stands out as a robust model, being managed by the Bordeaux University Hospital, validated by a Data Protection Officer, and hosted within a secure institutional framework ensuring General Data Protection Regulation compliance. While other apps lack transparency regarding data encryption and remote storage, they do not collect or store any personally identifiable information or nominative data within the app.

The absence of age-verification and crisis-response features represents a limitation in adolescent-focused care apps. However, as the apps in our study are professional-facing tools, they lack autonomous safety triggers by design. Consequently, the safety of vulnerable users relies on practitioners' expertise, with the clinical framework compensating for the absence of built-in safeguarding features.

Comparison With the Literature

mHealth Apps

No study similar to ours, focusing on the use of apps to facilitate preventive action by health care professionals among adolescents, has been found in the literature. One review of apps used a method similar to ours but focused on patient-facing medication management apps [35]. The aim of this 2024 study was to identify and evaluate the medication management smartphone apps available in France that send reminders to patients. Sorting apps using the MARS-F grid enables a meticulous and stringent selection of recommended apps. Our study selected 7 apps out of 976, while that of Toïgo et al [35] selected 49 out of 960. The authors stated that the quality of the apps was heterogeneous, with only 2 having been studied in a randomized controlled trial with positive results. In our study, none of the apps had been the subject of a randomized controlled trial. Choosing which apps are relevant for health care professionals is difficult, as the scientific data used to develop these tools are often lacking, as are analyses of real-life use. By using a rigorous and reproducible selection process, we have identified and recommended the most effective apps for daily clinical practice, tailored for both patients and health care professionals.

The existing literature primarily comprises scientific studies evaluating apps designed for either health care professionals or patients, typically using systematic, narrative, or scoping review methodologies. A 2012 systematic literature review examined articles addressing the design, development, evaluation, or use of smartphone apps for health care professionals, medical or nursing students, or patients [38]. The authors retained data on 57 apps for health care professionals focusing on, among other things, disease diagnosis, drug reference, medical calculators, clinical communication, medical training, and general health care apps. The disease diagnosis, drug reference, and medical calculator apps were reported as the most useful by health care professionals.

Apps specifically designed to assist health care professionals with adolescent preventive care during clinical consultations were rare in our study (7/976). Our search for apps on the subject of adolescent prevention for health care professionals enabled us to identify apps that were relevant to health care professionals. Of the 91 apps that met the inclusion criteria, only 7 were retained as relevant to health care professionals. The other 82 were intended for adolescents or their parents. Adolescents are connected and use their smartphones for an average of 4 to 8 hours a day [39-42]. Apps addressing prevention themes that concern them are more likely to be developed for them than for health care professionals. Our findings confirm a significant gap: while thousands of apps exist for patient self-management, there is a striking lack of tools designed to support providers during consultations (Decision Support Systems). This reflects a general lack of investment in "Professional mHealth," which is essential for preventive health care.

XSL•FO
RenderX

The small number of apps retained in our study was directly related to the specific inclusion and exclusion criteria established for our review. Notably, we chose to exclude paid apps to avoid imposing financial burdens on health care professionals and to preserve the absolute independence of our research, which is entirely free from conflicts of interest (ie, no recommendations of paid apps or of apps developed by the pharmaceutical industry). We would like all French and English-speaking health care professionals to be able to benefit, free of charge, from the results of our work. The exclusion criterion, which was also very selective, was the lack of explicit scientific backing for the development of an app. It was not appropriate to offer a health care professional a selection of apps that were not based on reliable scientific data. The MARS-F tool is widely used in the literature as a tool for assessing the quality of health apps: it is a simple, objective, and reliable tool for classifying and assessing the quality of mobile health apps [34,35]. The choice of this method for our work was, therefore, appropriate [34,43].

Many Areas of Prevention for Adolescents

There are many areas of prevention that need to be discussed with adolescents during a consultation with a health care professional. The development of apps designed to support health care professionals in their preventive work with adolescents does not always address current global public health challenges. Furthermore, the areas of prevention addressed by these digital tools are unevenly represented. A quantitative study carried out in France in 2021 confirmed that general practitioners mainly discussed orthopedics, sports activities, vaccinations, and contraception, but had more difficulty discussing the prevention of sexually transmitted infections or addiction when consulting an adolescent [7]. Two hundred eleven (21.6%) of the 976 apps were related to addictions and substance abuse, which could meet adolescents' needs. No apps were selected because they had to be paid for or because they lacked scientific validation. The development of these apps may have been guided by a marketing and financial objective (paid apps) rather than by a public health interest (no scientific validation). General practitioners in the French 2021 study readily and spontaneously discussed orthopedics, vaccination, and contraception [7]. Of the 976 apps found in our screening, only 133 (13.6%) and 38 (3.9%) concerned orthopedics and vaccination. No apps were selected for health care professionals. As general practitioners are already involved in preventive work on these topics, the development of relevant and scientifically valid apps on these subjects was probably not a priority. No apps related to vaccination were selected. However, vaccination coverage among adolescents remains insufficient today. Despite the need for digital interventions on vaccination, high development costs and the necessity for frequent updates could represent significant barriers for developers. General practitioners need tools to discuss sexual health, but seem to find it easier to discuss contraception with adolescents. Only 41 apps about sexual health (4.2%) were identified out of the 976. At the final inclusion, sexual health apps accounted for 5 (71.7%) of the 7 apps selected as relevant for health care professionals. These 5 apps all deal with contraception, but other areas of sexual health are not covered, or only to a limited extent. This may be due to historical market trends, whereby sexual health was an early adopter of digital formats, as well as the ongoing need to improve adolescent reproductive health worldwide. Despite constant progress in contraception, the rate of unwanted pregnancies worldwide has changed little. Already in 2015, among 4793 sexually active American students, 488 (10.2%) said they only used the withdrawal method, and 594 (12.4%) used no contraceptive method at all [44]. Two Canadian studies in 2017 and 2019 found a prevalence of adolescent pregnancy ranging from 3.9% to 14.1%, depending on the group studied [45,46]. A 2024 French study entitled "The context of sexuality in France," conducted from 2019 to 2023, reported some worrying results [47]. Among 18 - to 29-year-olds, use of the pill fell from 54.3% to 36.6% between 2016 and 2023, use of the intrauterine device increased from 10.9% to 19.3%, but the absence of contraception rose from 4.3% to 8.7% [47]. The mental health of adolescents is a constant and indeed growing concern in France and around the world. This situation has worsened since the COVID-19 pandemic [48]. However, no mental health apps were included in our study. Although 370 (37.9%) of the 976 apps were related to mental health, no apps were selected because they had to be paid for or because they lacked scientific validation. Developers have adapted to the market and to the needs of health care professionals in relation to public health issues. However, the cost of the apps and ethical concerns about offering an app that has not been scientifically validated mean that no tool was selected.

Implications for Policy and Practice

Analysis of the MARS-F subdomains reveals that the apps had higher scores in Information and Functionality (mean scores of 3.5 for both), while Engagement and Esthetics received lower ratings (mean scores of 2.0 and 2.5, respectively). This suggests that current apps are often developed as "digital brochures" rather than interactive tools. This situation is frequently observed in mHealth literature [49], where institution- or professional-facing apps prioritize clinical evidence and technical reliability over visual appeal or gamification. For a health care provider, a tool that is difficult to navigate during a consultation is unlikely to be adopted, regardless of the quality of its medical evidence. This implies the need for development frameworks. These frameworks have to integrate optimal user-centered design and esthetics to encourage users to engage with an app, so that tools can be more effective in clinical settings. Our findings align with the recent update by the High Authority for Health on the evaluation framework for mHealth apps [21]. The High Authority for Health confirmed that medical expertise and scientific evidence are mandatory for digital tools to be integrated into official health care pathways. However, our study shows that very few prevention-focused apps currently meet these high standards, particularly for the adolescent population. Medical societies and health authorities should establish certification labels or "official app libraries" to guide health care professionals. This would reduce the "search burden" for clinicians and ensure the quality of tools used with adolescents.

XSL•FO
RenderX

Strengths and Limitations

Method

This is a systematic digital review, as all the apps were scanned to exhaustion during the initial 2 screenings. A solid methodology involving 7 researchers and the drafting of the study based on the PRISMA, PRISMA-S, and PASSR checklists reinforce the methodological rigor [24-26]. Finally, the use of a blind analysis based on a validated tool (MARS-F), combined with a detailed analysis of reliability, ensures the validity of the results by limiting selection bias.

Fifty-two apps disappeared during the course of the study. The ephemeral nature of the apps partly explains the small number of results and must be taken into account when sharing the results of our study, as with similar research projects. The disappearance of 52 apps during our study period highlights the high volatility of the digital health market, a major challenge for health care professionals seeking stable clinical tools and a structural limitation for any systematic digital review. Even though the selected apps successfully advanced through all screening stages, several of them still exhibit technical deficiencies that may negatively impact their clinical utility and usability. Although the strict exclusion criteria may have omitted certain apps with potential use for health care professionals, the fact that the selected apps are free, commercially independent, and scientifically validated significantly strengthens the clinical relevance and validity of our findings.

Reliability

A key strength of this study is the transparency regarding measurement error. By reporting the SEM and MAE alongside the ICC, we provide a realistic context for the quality scores. The fact that the SEM (0.60) is often larger than the score gaps between top-rated apps indicates that these tools are of comparable quality within the limits of the MARS-F scale's precision. Since the ICC is a ratio of intersubject variance to total variance, the lack of variability between subjects in our small sample mathematically deflates the ICC, even when raters are in close agreement. The low ICC in some dimensions does not reflect poor rater performance but rather a "range restriction" effect, as the selected apps were homogeneously high in quality. This is confirmed by the good global MAE (0.53), indicating that, on average, raters differed by only half a point on a 5-point scale. This confirms that the ratings are clinically consistent and that the differences between the veteran expert and the residents represent an acceptable margin of measurement error rather than systematic disagreement.

The "Engagement" subscale had the highest statistical reliability (fair ICC=0.540 and excellent MAE=0.40), while the "Functionality" subscale exhibited the greatest rater divergence (poor MAE=1.03). Overall, the low absolute error across most dimensions confirms that the ratings provided by the residents are consistent with expert judgment for practical evaluation purposes.

While our rater calibration involved rigorous independent scoring and iterative consensus sessions, no formal statistical reliability metrics (such as a training ICC) were computed during this phase. This lack of a quantitative baseline check represents a limitation. It may explain why certain complex domains, specifically the Functionality subscale, demonstrated lower scoring homogeneity in the main evaluation, as reflected by an MAE of 1.03.

The global MARS-F score yielded an SEM of 0.60, providing essential context for comparing the evaluated apps. Given that the differences between the mean scores of several apps (eg, 3.5 vs 3.2) are smaller than this measurement error (Multimedia Appendix 2), this indicates that variations should be interpreted as qualitative trends rather than statistically significant differences in app quality (Table 4). The inclusion of the SD and range for each app further demonstrates the distribution of ratings and confirms that the observed consistency remains within acceptable clinical margins despite the small sample size.

Language

This study examines English and French apps evaluated by French health care providers. A selection was made to ensure the tools were applicable to clinical settings within these linguistic spheres. However, we acknowledge that perceptions of "clinical relevance" and "quality" are inherently shaped by national guidelines and cultural nuances. Consequently, while our findings offer robust insights for Western clinical contexts, they should be viewed as a foundation for further cross-cultural research across diverse linguistic and regulatory environments.

Perspective

Our study conducted a rigorous selection of existing apps covering all areas of prevention recommended for adolescents during consultations with a health care professional. This type of review should be carried out systematically before any new tool is developed to avoid duplication and focus creative energy on innovative digital tools. Another study will look at existing websites that are relevant to helping health care professionals with their prevention work with adolescents during consultations. Similar to this study, it will examine websites in all the recommended areas of prevention, and the sites will be analyzed using a validated tool, Netscoring [50]. These 2 research projects (reviews of apps and websites) could be used as models for similar digital reviews prior to the creation of any new app or website. Finally, whatever tool is identified or designed, feasibility and acceptability studies by the professionals themselves will be necessary.

While the MARS-F scale offers a robust evaluation of information quality and credibility, it lacks explicit criteria for assessing clinical safety features. Future research should integrate specific safety frameworks to determine whether apps incorporate essential emergency protocols or risk-warning systems, particularly for users presenting with severe mental health symptoms.

Pending assessment of the acceptability and feasibility in clinical practice of the 7 apps selected in our study, we recommend 4 of these apps: "*Agenda du sommeil antifatigue*" and "mhGAP-IG 2.0 App" (with certain limitations linked to the technical shortcomings of "mgGAP-IG 2.0 App"); of the 5 sexual health apps, we recommend "WHO Contraception Tool," available in several languages, and "Practice Family Planning," which is richer in video content for health care professionals.

XSL•FO
RenderX

These 5 apps could be included in the recommended tools for health care professionals on the planned global website.

To provide a comprehensive operational framework for the 4 recommended apps, Table 5 categorizes them based on the following 6 key implementation parameters:

- Clinical scenarios define the specific medical contexts (eg, diagnosis, prevention, or follow-up), where the app is most effective.
- Time-efficiency per consultation estimates the duration required to use the tool during a standard medical visit, ensuring that it remains compatible with professional time constraints.
- Technical information covers the hardware and software requirements (eg, operating system compatibility and offline access).
- Integration describes the clinical workflow: how the tool is incorporated into the patient-provider interaction or synchronized with health data management.
- Engagement refers to the strategies used to motivate health care professionals' participation (eg, visual aids).
- Barriers to adoption include linguistic limitations, technical bugs, and cognitive load for practitioners.
- Mitigation strategies represent the proactive measures or professional safeguards proposed to minimize identified risks and overcome barriers, ensuring the safe and effective use of the digital tool within a supervised clinical framework.

XSL•FO
RenderX

Table . Guide for practical clinical implementation of the 4 recommended apps.

App name	Clinical scenarios and time efficiency per consultation	TI[a] and integration	Engagement and barriers to implementation	Mitigation strategies
Agenda du sommeil antifatigue	Scenarios: • Diagnosis of insomnia • Sleep hygiene education Time: 5 min	TI: • iOS (Apple) or Android (Google) • French Integration: • HCP[b] reviews data entered by the patient	Engagement • Active self-monitoring by the patient Barrier: • Patient forgetfulness in logging data	• The patient uses automated app notifications • HCP validates data entry during each clinical visit
mhGAP-IG 2.0 App	Scenario: • Assessment of mental or neurological disorders in nonspecialist settings • Information on various neurological and mental disorders Time: 15 min (questionnaire and flowchart) or much more for information	TI: • iOS or Android • Multilanguage • E-version of a WHO[c] guide Integration: • Decision support tool used during the clinical interview	Engagement: • Standardized assessment tool Barrier: • Some nonfunctional features	• HCP should cross-reference with the physical or PDF WHO manual for nonfunctional app links
WHO Contraception Tool	Scenario: • Selection of evidence-based contraception • Checking for contraindications to current contraception Time: 3 min during the prescription phase	TI: • iOS or Android • Multilanguage • Regularly updated Integration: • Point-of-care tool to match medical history with contraception method	Engagement: • Inclusion of patient preferences Barrier: • Requires medical history data entry	• Prepare a patient history checklist prior to app use to speed up data entry (patient or HCP)
Practice Family Planning	Scenarios: • Professional self-training for women's health consultations • Clinical procedure preparation (eg, IUD[d] insertion) • Direct patient education on contraceptive health Time: 5 - 15 min/video	TI: • iOS or Android • Multilanguage • Offline mode available Integration: • Preprocedural refresher for women health providers • Shared screen education during consultation	Engagement: • Visual learning • Short videos Barrier: • Average video quality • Requires significant storage space	• Preselect videos relevant to the practice of HCP • Download videos prior to clinical sessions to ensure smooth playback offline

[a]TI: technical information.

[b]HCP: health care professional.

[c]WHO: World Health Organization.

[d]IUD: intrauterine device.

Conclusions

There are many areas of prevention that need to be addressed with adolescents during consultations. Only 7 apps were relevant for helping health care professionals in their prevention work with adolescents. Five deal with sexual health, particularly contraception, and 2 with mental health. No apps have been validated for orthopedics, social relations, addictions, or vaccinations. Health care professionals are connected, especially online during consultations. A general online tool to help health care professionals with prevention among adolescents during consultations is relevant but currently nonexistent. Our study will contribute to the selection of relevant content for the development of such a tool, but further research is needed to ensure that it meets the needs of health care professionals.

Abstract

Background: Approximately 1 in 100 children worldwide are diagnosed with autism spectrum disorder (ASD), and 46% to 89% of those diagnosed experience significant feeding difficulties. Mobile health (mHealth) apps are a potential tool for scalable support. However, there is nascent literature on the quality and relevance of mHealth apps for managing ASD-related feeding challenges.

Objective: This study aimed at systematically identifying and reviewing the content, behavior change strategies, and quality of free English-language mHealth apps supporting the feeding of children with autism.

Methods: A systematic search was conducted on the Apple App Store and Google Play Store between September and October 2024 and updated between June and July 2026. Apps were included if they were free or freemium, in English, updated within the past year, and explicitly focused on the feeding of children with autism. Apps were excluded if they targeted clinicians rather than parents or children; could not be installed on the test devices; or primarily focused on learning or communication rather than feeding, despite descriptions suggesting relevance to feeding. We identified intervention strategies in the included apps using the behavior change wheel (BCW) framework and evaluated their quality using the Mobile App Rating Scale (MARS).

Results: The search returned 333 apps from both app stores. After removing duplicates and screening, only 2 iOS apps (EduKitchen-Toddlers Food Games and Autism Food Coach 2) met all inclusion criteria. 331 apps were excluded due to their focus on communication, early education, or other autism support that was not food related. EduKitchen-Toddlers Food Games provided child-centered interactive games and sensory-friendly visuals, while Autism Food Coach 2 provided structured caregiver tools, visual meal plans, and progress tracking. EduKitchen-Toddlers Food Games provided the BCW intervention functions of education, training, enablement, incentivization, and modeling, while Autism Food Coach 2 provided education, training, enablement, persuasion, incentivization, and environmental restructuring. The apps received MARS scores of 3.9 and 3.7, respectively, indicating acceptable quality. The apps' shortcomings included limited customization for diverse user needs and the absence of documented clinical validation.

Conclusions: There is a critical shortage of mHealth apps for feeding difficulties in children with autism that are both evidence-based and of high quality. Future development must integrate robust clinical validation and comprehensive, caregiver-centered support features to address this significant gap.

(JMIR Mhealth Uhealth 2026;14:e94908) doi:10.2196/94908

KEYWORDS

autism spectrum disorder; ASD; mobile health; mHealth; caregiver support; behavior change wheel; Mobile App Rating Scale; MARS

Introduction

Autism spectrum disorder (ASD) is a complex neurodevelopmental condition characterized by challenges in social interaction, communication, behavior regulation, and sensory processing. The global prevalence of ASD has increased significantly in recent decades; the US Centers for Disease Control and Prevention reports a 178% increase in autism prevalence since 2000 [1], and the World Health Organization estimates that approximately 1 in 100 children is diagnosed with ASD [2].

Among the various comorbidities observed in children with autism, feeding difficulties are especially common and underaddressed. Studies report prevalence rates ranging from

XSL•FO
RenderX

46% to 89% [3], with affected children exhibiting food selectivity, aversions to textures and flavors, rapid eating, and disruptive mealtime behaviors [4,5]. These challenges are linked to nutritional deficiencies, impaired growth, gastrointestinal disorders, and metabolic imbalances [6,7]. Children with autism experience feeding problems 5 times more frequently than their neurotypical peers [8]. This situation places a significant burden on caregivers and parents, who often serve as the primary facilitators of feeding interventions. They manage complex feeding routines while navigating children's behavioral and communication challenges. Given their central role in daily feeding routines and their intimate knowledge of their child's behaviors, parents represent a critical intervention point for addressing these challenges.

Parent-mediated interventions are a prominent model for supporting children with autism. Previous research indicates that parents can successfully learn and implement intervention strategies [9]. However, translating these interventions into community settings remains challenging due to persistent barriers in accessibility and scalability [10]. The emergence of mobile health (mHealth) apps presents a promising means to overcome these barriers. A growing body of research shows mHealth apps can effectively train parents and improve child outcomes in areas such as communication, socialization, and behavior management [11,12].

The success of these digital tools, however, is contingent upon their design and usability. Research indicates that parent engagement is directly linked to an app's perceived utility and its alignment with daily caregiving realities [13]. Poorly designed interventions that fail to account for parental needs, stress levels, and caregiving contexts may inadvertently exacerbate caregiver burden [14,15]. Indeed, systematic reviews of mHealth apps across domains such as child nutrition, child growth monitoring, and infant care show considerable variations in app quality [16,17]. Most apps have acceptable to good quality when evaluated with standardized tools such as the Mobile App Rating Scale (MARS) [18], largely due to lower engagement, usability, or quality of information scores. Other reviews have identified limited incorporation of evidence-based health information and behavior change practices in child health and parenting apps [16,17]. These findings highlight the necessity of systematically evaluating digital health interventions rather than assuming their effectiveness based on availability alone.

However, despite the growing interest in digital interventions for autism and the variable reported quality of mHealth apps, research has scarcely explored the range, support features, and quality of mHealth apps specifically designed to help parents manage feeding difficulties. The aim of this study was to conduct a systematic search and evaluation of the content, behavior change strategies, and quality of free English-language apps supporting the feeding of children with autism in the 2 major app stores (Google Play Store and Apple App Store). For included apps, we identified informational topics and app features and mapped them to the behavior change wheel (BCW) [19] to determine the scope and the supported behavior change intervention functions. The BCW provides a comprehensive theoretical framework for analyzing behavior change potential through intervention functions such as education, persuasion, and incentivization. Understanding the behavior change strategies embedded in an app is critical to evaluating its likely effectiveness. We then assessed the app quality using the MARS [18], a validated and widely used tool for evaluating mHealth app quality across 4 critical factors: engagement, functionality, aesthetics, and information quality.

Overall, this study answered the following research questions:

1. What is the availability of apps addressing feeding difficulties in children with autism in the 2 major commercial app stores?
2. What behavior change intervention functions are included in available apps?
3. What is the overall quality of available apps when assessed using the MARS?
4. What are the strengths and limitations of existing apps in supporting feeding-related interventions?
5. What actionable recommendations can guide the development of future mHealth apps that more effectively assist caregivers in managing ASD-related feeding difficulties?

Methods

Eligibility Criteria

Inclusion Criteria

We analyzed apps that met the following inclusion criteria: (1) the app is free to download (either fully free or freemium, ie, offering in-app purchases), (2) the content is written in English, (3) the app has been updated within the past year (to exclude defunct or outdated apps), and (4) the title or description explicitly addresses feeding in children with autism.

We limited inclusion to English-only apps, as it is the most widely spoken language worldwide when combining native and non-native speakers [20]. As researchers based in Africa, this choice also reflected local realities, as English is commonly used as an official or working language in many countries, with 26 countries in sub-Saharan Africa alone using English as an official language, either exclusively or alongside local languages [21].

Exclusion Criteria

Apps were excluded if they (1) targeted clinicians rather than caregivers or children; (2) primarily focused on learning or communication rather than feeding, despite descriptions suggesting relevance to feeding; or (3) could not be installed on the test devices (iPhone 12 Pro Max for iOS and Google Pixel 3a XL for Android) due to geographical restrictions, unsupported operating system versions, or other installation challenges.

Information Sources

Searches were conducted on the Google Play Store and Apple App Store. The Google Play Store holds more than 70% of smartphone apps market share [22], while the Apple App Store is considered the second largest app market store [23].

XSL•FO
RenderX

Search Strategy

We conducted a systematic search of the Apple App Store (iOS) and Google Play Store (Android) to identify mHealth apps related to feeding, food, meal planning, or nutrition for children with autism. The search was performed between September and October 2024 and updated between June and July 2026. All researchers were based in Rwanda, East Africa, during the study. The search terms used included: "child autism food," "kids autism food," "toddler autism food," "child autism nutrition," "kids autism nutrition," "toddler autism nutrition," "child autism meal prep planning," "kids autism meal prep planning," "toddler autism meal prep planning," "child autism feeding," "kids autism feeding," "toddler autism feeding," "child autism mealtime," "kids autism mealtime," and "toddler autism mealtime." These terms were entered directly into the Apple App Store and Google Play Store search interfaces with no filters or limits applied. The searches were conducted using an iPhone 12 Pro Max (iOS) and a Google Pixel 3a XL (Android) to simulate a typical end-user experience on each platform. All returned results were saved in a Microsoft Excel file for deduplication and screening.

Selection Process

After removing duplicates, 2 members of the research team independently screened the apps. We undertook a 2-phase screening process. In the first phase, the apps' information pages (screenshots and textual description) were screened against the inclusion and exclusion criteria. Apps with a clearly unrelated scope (eg, communication support only) were excluded. Apps that included child feeding as 1 of several features or suggested a broader scope of features than those listed on the page were moved to phase 2. In this phase, the apps were downloaded and installed on the test devices. They were then screened to determine if they contained feeding-related content. Apps that had feeding-related content were included in the final analysis. The screening results were compared, and disagreements were resolved by discussion or by consulting with a third member of the research team.

Data Collection Process and Data Items

Data was independently extracted by the same 2 members of the research team who conducted screening, with 1 reviewer focusing on the Apple App Store and the other on the Google Play Store. Reviewers independently navigated all freely accessible pages and recorded the informational content and features in a Microsoft Excel file and then validated each other's lists. The following data items were recorded per page: informational content (using article headings), interactive features, and whether each feature was free to access or paywalled. To ensure reliability, the reviewers cross-validated each other's assessments by switching platforms after the initial evaluations.

Deductive coding was then conducted using the BCW [19], with each feature mapped to 1 of the 9 intervention functions: education, persuasion, incentivization, coercion, training, restriction, environmental restructuring, modeling, and enablement. In a preparatory session, both reviewers reviewed the BCW framework and discussed descriptions of the intervention functions to ensure a shared understanding of the categories. They also created examples of app features to ensure consistent coding. Discrepancies were discussed until consensus was reached; when consensus was not possible, a third reviewer was consulted. A deductive approach was selected to assess the extent to which app content aligned with established behavior change theory, rather than to generate novel thematic categories.

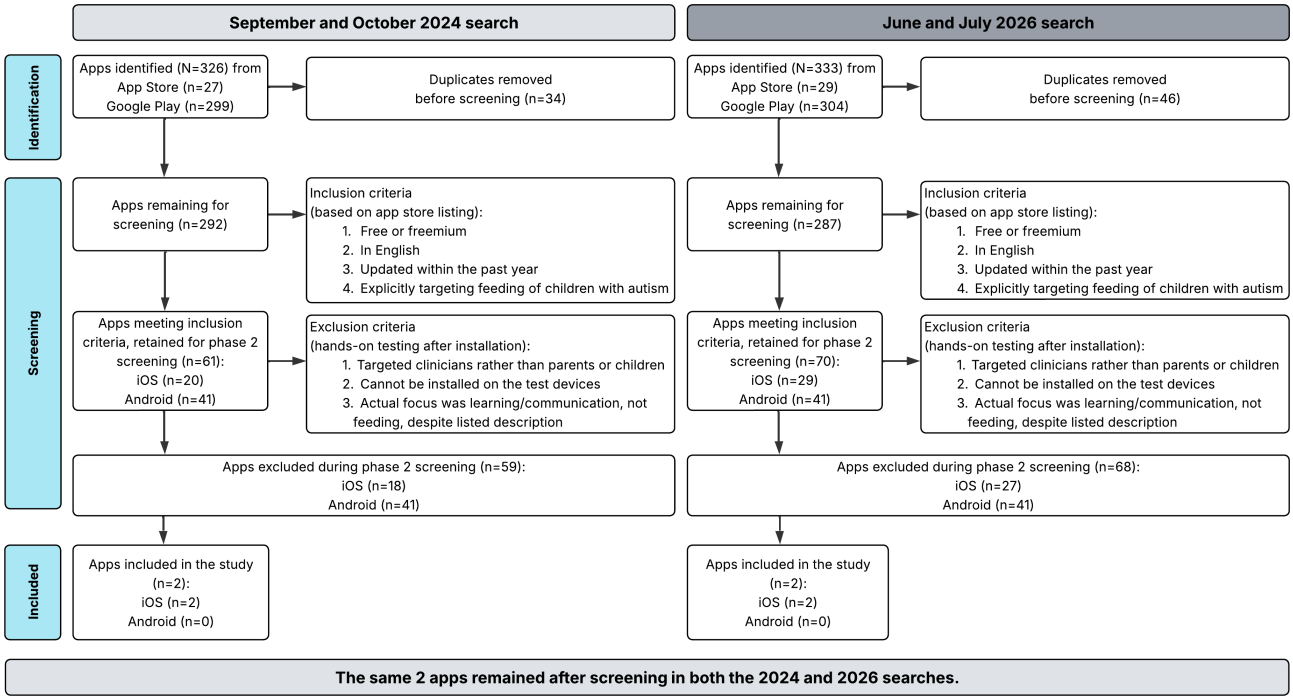
App Quality Assessment

The quality of the apps was assessed using the MARS [18], a validated tool for the evaluation of mHealth apps. MARS evaluates apps on 4 dimensions: engagement (user interest and interaction), functionality (performance and usability), aesthetics (visual design), and quality of information (accuracy, relevance, and credibility of content). Each dimension is rated on a 5-point Likert scale. Two reviewers independently rated each app. Both reviewers have a background in mobile app design and development and had worked on mHealth projects over the past year. The reviewers also completed the official MARS training to ensure consistent interpretation of the scale. Following the independent rating phase, the 2 reviewers discussed their evaluations to reach a consensus score for each MARS item. These final consensus scores were used in the analysis.

Ethical Considerations

The study did not require any ethics review.

Results



App Search and Selection

The initial search (conducted in September and October 2024) yielded 326 apps (27 iOS apps from the Apple App Store and 299 Android apps from the Google Play Store). From these 326 apps, 34 duplicates were removed, leaving 292 apps for phase 1 screening. After this stage, 61 apps were retained for phase 2 screening. The remaining apps were excluded because their focus was preschool education (eg, learning the alphabet, numbers, and animals), communication skills support, or emotional regulation through games or musical therapy. During phase 2 screening, a further 59 apps were excluded, as they had a similar focus on learning and communication. Overall, only 2 iOS apps (EduKitchen-Toddlers Food Games and Autism Food Coach 2) were found to address feeding challenges in children with autism, indicating a critical shortage on the number of available apps for supporting caregivers in the home management of feeding difficulties in children with autism.

Our updated search from June to July 2026 returned 333 apps, with 46 duplicates removed. After applying the inclusion and exclusion criteria, no additional apps were included in the study, showing no improvement in the availability of feeding support apps. We consider the implications of this in the Discussion section. A complete list of the screened apps, including their platform and primary focus, is provided in Table S1 of Multimedia Appendix 1. Figure 1 presents the app selection process following PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines [24].

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram of mobile health (mHealth) app selection for the systematic review.

Description of the Selected Apps

Both EduKitchen-Toddlers Food Games and Autism Food Coach 2 are commercial apps, with the former developed by Cubic Frog Apps and the latter by Aidan's Apps. EduKitchen-Toddlers Food Games is a child-facing app. Its stated aim is to provide a set of kitchen games that encourage wiser food knowledge while also enhancing the cognitive skills emphasized in preschool curricula, such as sorting and matching. Meanwhile, Autism Food Coach 2 is a caregiver- and child-facing app that was developed by a parent to promote slower chewing behavior in their child. Neither of the apps reports any scientific studies conducted during app development or any evaluation studies conducted on efficacy. Similarly, there was no report on the evidence used to inform content and feature selection.

Evaluation of App Features and Content

EduKitchen-Toddlers Food Games targets early childhood learners and supports preschool cognitive skills of counting, sorting, sequencing, and related cognitive skills alongside building food familiarity through interactive play. The app (Table 1) includes 18 free mini-games focused on cooking and kitchen tasks, for example, frying and counting eggs (Figure 2A) and sorting food-related waste (Figure 2B). The foods covered in the app included whole foods such as eggs, fruits (eg, apples, bananas, and strawberries), vegetables, cereals, bread, and fruit juices, along with processed foods such as cookies, ice cream, popsicles, and sugar-sweetened soft drinks. Although there were no lessons around distinguishing healthy from unhealthy foods, we did note that healthy foods were more prominently represented.

Table . Core features and access models of the selected apps.

App name	Access model	Target audience	Core features
EduKitchen-Toddlers Food Games	One-time purchase	• Toddlers/preschool children including children with autism • Parents/caregivers who configure the app (secondary audience)	• Gamified food-related activities (eg, sorting, matching, and counting) • Reinforcement through animations and in-app rewards • Customizable settings for sensory preferences and learning levels • Engaging, child-friendly interface with cartoon visuals
Autism Food Coach 2	Subscription (£49.99/month)[a]	• Parents and caregivers of children with autism who have feeding difficulties • children with autism who participate in feeding routines (secondary audience)	• Structured mealtime routines with visual schedules • Meal tracking and progress dashboards for caregivers • Customizable feeding plans for behavioral and sensory needs • Motivational prompts, goal setting, and reward systems

[a] £1=US $1.32 as of October 5, 2026.

XSL•FO
RenderX

Figure 2. Screenshots from EduKitchen-Toddlers Food Games, developed by Cubic Frog Apps, obtained via the Apple App Store. The app features food-themed games intended to build early familiarity with food through sorting, counting, and categorization. Example games include (A) frying and counting eggs and (B) sorting food-related waste.

Children can interact with the app through touch-based activities guided by voice instructions, with multiple languages supported, while parents can customize the app to select the language, adjust the difficulty level of activities, and unlock the full set of educational games through the premium version. Since the app targets young children, there was no informational content provided.

Autism Food Coach 2 is designed for caregivers and children with autism, providing a structured approach to support feeding routines. As shown in Figure 3, the app includes motivational messages that encourage emotional reflection and sensory modulation during meals. For example, Figure 3A advises users to "notice the effects food has on your feelings," while Figure 3B suggests playing relaxing music during meals to enhance enjoyment. The app includes additional functionalities, such as progress tracking, visual schedules, and personalized meal planning tools, that allow systematic tracking of mealtime behaviors. Motivational prompts and sensory regulation suggestions (eg, relaxing music or emotional reflection) are also provided to create calmer mealtime environments.

Although both apps incorporate food-related content, they diverge considerably in functional purpose and clinical utility: one offers indirect exposure to foods and feeding support through child-led play, while the other provides direct support for caregiver-led interventions. This section evaluates the extent to which the apps support structured feeding interventions, promote adaptive mealtime behaviors, and guide caregiver decision-making.

We formalize this analytical comparison in Textbox 1, which categorizes app features based on their ability to provide actionable guidance to support caregivers during feeding interventions. The analysis confirms that only Autism Food Coach 2 includes features that align with caregiver-mediated feeding interventions.

XSL•FO
RenderX

Figure 3. Screenshots from Autism Food Coach 2, developed by Aidan's Apps, obtained via the Apple App Store. The app includes prompts that, for example, (A) encourage users to reflect on how food affects their feelings and (B) promote calm sensory environments by suggesting soft background music during meals.

XSL•FO
RenderX

Textbox 1. App features categorized by caregiver decision support capabilities.

Features with caregiver decision support

- *Instant feedback and rewards* reinforce positive child behaviors, allowing parents to adjust strategies in real time.
- *Parent support tools* offer structured feedback, coaching prompts, and meal tracking to help manage feeding routines.
- *Customizable progress monitoring* provides visual progress charts and behavior tracking to support informed parental decisions.

Features without caregiver decision support

- *Interactive child engagement* focuses on engaging the child through games and narratives but lacks direct caregiver guidance.

Intervention Function Mapping Using the BCW Framework

The BCW provides a systematic model for designing interventions based on behavioral determinants. Table 2 summarizes the BCW intervention functions identified in each app. We identified 7 of the 9 BCW functions across the 2 apps. It is worth noting that neither app incorporated coercion nor restriction.

Table . Behavior change wheel intervention function mapping for the 2 reviewed apps.

Intervention function	EduKitchen-Toddlers Food Games	Autism Food Coach 2
Education	✓	✓
Training	✓	✓
Enablement	✓	✓
Persuasion	✗	✓
Incentivization	✓	✓
Modeling	✓	✗
Environmental restructuring	✗	✓
Coercion	✗	✗
Restriction	✗	✗

EduKitchen-Toddlers Food Games mapped onto 5 BCW functions: education, training, enablement, incentivization, and modeling overall, but food-related content mapped onto only 3 interventions. These were education, delivered through interactive lessons introducing food types; incentivization, seen through gamified rewards (eg, praise animations); and modeling, in the use of animated characters demonstrating appropriate feeding behaviors. Features mapped to training and enablement primarily supported preschool learning outcomes. For instance, training is embedded in mini-games that reinforce skills such as sorting and categorization, and enablement is supported via customizable gameplay settings to accommodate diverse sensory or developmental needs.

Autism Food Coach 2 incorporated 6 intervention functions: education, training, enablement, persuasion, incentivization, and environmental restructuring. The app provides educational content through guidance on balanced nutrition and mindful eating. Training is facilitated through structured visual schedules that model consistent feeding routines. Enablement includes personalized meal planning and caregiver-facing tracking tools. Persuasion is operationalized through motivational messages and positive affirmations. Incentivization is achieved through visual progress tracking and behavioral goal setting. Environmental restructuring is implemented through tools that help caregivers create predictable low-stress mealtime environments (eg, use of music, calming messages, and visual schedules).

MARS Quality Assessment

We present the results of the MARS evaluation for the 2 selected apps. EduKitchen-Toddlers Food Games achieved an overall MARS score of 3.9, reflecting good usability and design quality. It performed strongest in functionality (4.0) due to its stable performance, intuitive navigation, and simple touch-based interactions that allowed young children to complete activities with minimal assistance. A similarly high score was achieved for aesthetics (4.0) because of its colorful, child-friendly interface, large interactive objects, high-contrast visuals, and consistent use of animated characters that maintained children's attention while reducing visual complexity. The app also incorporated clear audio instructions, simple layouts, and uncluttered screens, making interactions appropriate for preschool-aged children and potentially supportive for children with autism who may benefit from predictable visual environments and multimodal cues. Engagement (3.7) and information quality (3.9) also received strong ratings because the app used a variety of age-appropriate gamified activities, including cooking, counting, sorting, and matching games, to reinforce learning through repeated interaction rather than text-based instruction. However, the information score was slightly lower because educational content was embedded within gameplay and there were no caregiver resources, nutritional

XSL•FO
RenderX

guidance, or evidence-based informational materials. The app received a subjective quality score of 4.0, reflecting its suitability as an engaging educational app for young children.

Autism Food Coach 2 achieved an overall MARS score of 3.7, interpreted as acceptable to good usability and design quality. It received its highest ratings for information (3.95) and engagement (3.75). The information score reflected the inclusion of educational modules on mindful eating, digestion, eating pace, emotional awareness during meals, and strategies for improving mealtime experiences, together with interactive features such as personalized eating timers, bite pacing, and meal-type selection. These features encouraged active user participation and supported behavior change throughout the eating process. Functionality (3.8) was rated highly because of the app's intuitive navigation, responsive performance, and customizable meal timer that could be adapted to different food types or user preferences. Aesthetics (3.3) received the lowest score due to its relatively simple and utilitarian interface, which prioritized functionality over visual engagement. Although the app included clear graphics and a consistent layout, it offered limited animation, interactive visual elements, and child-oriented design features. The app received a subjective quality score of 4.0, reflecting its perceived usefulness as a behavioral support tool for improving eating pace and mindful eating habits.

Table 3 summarizes the scores for the apps across the 4 MARS quality dimensions, that is, engagement, functionality, aesthetics, and information, along with the overall mean and subjective quality ratings. The table highlights a significant difference in the aesthetics dimension, in which EduKitchen-Toddlers Food Games received a substantially higher score (4.0 compared to 3.3). In contrast, both apps performed comparably in engagement, functionality, and information, with differences of 0.2 points or less.

Table . Mobile App Rating Scale results for the 2 reviewed apps. Each dimension was scored on a 5-point scale.

Characteristic and dimension	EduKitchen-Toddlers Food Games	Autism Food Coach 2
Platform	iOS	iOS
Overall score (mean)	3.9	3.7
Engagement	3.7	3.75
Functionality	4.0	3.8
Aesthetics	4.0	3.3
Information	3.9	3.95
Subjective quality score	4.0	4.0

Discussion

Principal Findings

This review examined the Apple App Store and Google Play Store for mobile apps that address feeding challenges in children with autism. Our most significant finding is the scarcity of feeding support apps. Only 2 of more than 300 identified apps met our inclusion criteria, and the same 2 qualified in both search rounds (2024 and 2026). Most excluded apps focused on communication, early education, or other autism support that was not food related. Delayed speech, language impairments, and difficulty with reading and writing are common in autism. Around 30% of children with autism remain nonverbal [25], and many perform worse academically than their IQ would predict [26]. These challenges are serious [27], but feeding difficulties also affect a large share of children with autism, with prevalence estimates of 46% to 89% [3]. Poor nutrition affects physical growth and is linked to long-term cognitive impairment [28]. The emphasis on communication and learning among the autism apps we screened does not match the daily reality of raising a child with autism. Feeding is a daily need for many families, but almost no evidence-based digital support exists for it; mHealth should give feeding the same priority as communication and learning.

The 2 included apps differ in target users and intervention logic. Neither provided a theoretical basis for its features, and we found no documentation of efficacy. Both mapped to 4 core BCW functions: education, training, enablement, and incentivization. For EduKitchen-Toddlers Food Games, training and enablement served preschool learning rather than feeding. These functions match needs described in prior work. Education and training target the capability barriers of teachers and caregivers, who report limited knowledge of feeding strategies for children with autism [29-31]. Enablement helps reduce structural barriers to professional care, which are common in lower-resource settings [32]. Even so, broad BCW coverage did not produce broad support. EduKitchen-Toddlers Food Games used child-centered gamification to build food familiarity, and Autism Food Coach 2 offered basic caregiver tools for meal planning and mindful eating. Established programs such as BUFFET (Building Up Food Flexibility and Exposure Treatment) [33] and the Autism MEAL (Managing Eating Aversions and Limited Variety) Plan [34] combine family-based therapy, gradual food exposure, and sensory integration [35]. The apps offered far less. Limited evidence-based content is also common in nutrition and infant feeding apps more broadly [16].

Both apps also had acceptable but not high-quality scores on the MARS. EduKitchen-Toddlers Food Games scored 3.9 and Autism Food Coach 2 scored 3.7. Earlier MARS evaluations of child nutrition and feeding apps reported overall scores of about 3.0 to 4.0 out of 5 [16,17,36], so our evaluated apps fall in the upper part of that range. Those studies also reported limited engagement features, weak evidence-based content, poor aesthetic design, and little personalization. We found

XSL•FO
RenderX

similar limitations (Table 4). Neither app reported clinical validation. EduKitchen-Toddlers Food Games offered basic customization, and Autism Food Coach 2 had the lowest aesthetics score (3.3), reflecting a simple, utilitarian interface.

Table . Strengths and limitations of the 2 reviewed apps.

	EduKitchen-Toddlers Food Games	Autism Food Coach 2
Strengths	Provides an engaging and interactive learning experience with high-quality graphics and food-themed mini-games; includes basic caregiver customization	Offers tailored meal plans, progress tracking, and structured coaching tools that support caregiver-led feeding interventions
Limitations	No scientific validation; limited features for caregiver-led interventions or clinical feeding challenges	Limited visual design quality; lacks empirical validation through clinical trials

Closing this gap starts with bringing established feeding programs such as BUFFET and the Autism MEAL Plan into digital tools. Building an effective mHealth app requires several stakeholders. Clinicians, such as dietitians and occupational and speech therapists, can keep the clinical content faithful to the original programs. Caregivers know what fits into daily mealtimes, and poorly designed tools can add to their burden [14,15]. Developers can turn this input into features that families find easy and engaging to use. Researchers should then evaluate the tools.

We make 3 recommendations to support this work. First, developers should use structured co-design frameworks (eg, IDEAS [integrate, design, assess, and share] [37]) so that clinical experts and caregivers shape the tools from the start. This helps apps combine evidence-based strategies with informative, engaging features that serve caregivers and children. Second, quick reference guides and practical tutorials on behavioral theory would help developers and stakeholders during rapid ideation sessions, because comprehensive frameworks and training manuals can be hard to navigate. Third, researchers and developers should document feature efficacy through mixed methods evaluations. Quantitative measures, such as food variety and mealtime behavior, show whether a tool improves feeding outcomes. Qualitative methods show how caregivers and children use each feature and why some work better than others. Both are needed because clinical strategies do not always work the same way when delivered digitally [38].

Evidence to guide app design also remains limited, particularly across cultural contexts. Preferences for gamification vary widely with cultural values and social norms [39,40], but little is known about which gamification and engagement features work best in mHealth apps in different settings. Evidence is also thin on how to balance personalization with privacy for different users, such as privacy-conscious users and open sharers. Future research should address these questions. This work is most urgent in low-resource settings, where in-person feeding services are scarce [32] and digital tools could reach families who cannot access them [10-12]. This review provides a baseline against which to track how the app market changes.

Limitations

While this review provides a structured assessment of the current landscape, several limitations must be considered when interpreting these findings. App search results vary depending on the geographic location. As the research was conducted in Rwanda, the apps available are likely different from those accessible from other countries and regions. This search also used English keywords and only included apps available in English. To fully understand the scope of apps available to the African population, the search should be expanded to include French, Portuguese, Arabic, Spanish, and local languages. Although extensive search terms were used, some relevant apps may have been missed due to alternative labeling by developers. Furthermore, restricted features behind paywalls could not be fully evaluated. Lastly, while MARS provides a standardized assessment from a rater perspective, it may not fully capture caregiver preferences and usability. Future work could consider user-centered measures, such as the user version of the Mobile App Rating Scale (uMARS) [41], to assess app acceptability and perceived usefulness.

Future research should broaden the search strategy to mitigate geographic sampling bias, for example, by using multiregion app store accounts to more comprehensively capture global app availability. Co-design approaches that involve parents, clinicians, and speech or occupational therapists will be crucial in ensuring that future apps address both clinical needs and contextual realities. Particularly in resource-constrained settings, culturally tailored and clinically validated mHealth apps are urgently needed to support caregivers to manage ASD-related feeding challenges. Longitudinal studies evaluating behavioral outcomes and caregiver burden can further establish the real-world impact of these digital interventions.

Conclusions

This study highlights a critical shortage of mHealth apps specifically designed to support feeding challenges in children with autism. Using the BCW and MARS frameworks, we evaluated the functional strengths and theoretical underpinnings of the 2 eligible apps. Although both apps incorporated behavior change techniques and demonstrated moderate to high usability, neither was grounded in clinically validated feeding interventions. These findings underscore the need for user-centered, evidence-based app development that integrates behavioral, sensory, and skill-building supports tailored to the diverse needs of children with autism. Expanding access to effective, clinically validated, and culturally responsive mHealth tools is essential for advancing digital health equity, particularly in low-resource settings where traditional intervention services may be limited.

Abstract

Background: As the world's population ages, the prevalence of chronic low back pain (CLBP) is increasing, placing a substantial burden on individuals and health care systems. Mobile health (mHealth) apps offer a potentially scalable solution to support self-management, but little is known about how, why, for whom, and under what circumstances such tools work in real-world settings.

Objectives: This study aimed to test and refine 3 program theories—developed through a previous realist review—on how mobile apps support CLBP self-management. The goal was to understand the key contextual factors and mechanisms that influence when and why a digital self-management intervention may succeed or fail.

Methods: A realist evaluation was conducted using one-on-one telephone interviews with 9 participants who had used the Curable app for 3 months to self-manage their CLBP. Realist interviews followed a teacher-learner cycle to explore, test, and refine the program theories. Abductive and retroductive analysis was used to develop context-mechanism-outcome configurations (CMOCs), which were synthesized into refined theories of digital self-management in chronic pain.

Results: A total of 20 CMOCs were constructed, supporting 3 overarching program theories centered on empowerment, self-management burden, and timing. First, the app was empowering when it offered credible and accessible knowledge that helped participants understand their pain, build confidence, and reduce reliance on health care providers. However, engagement depended on individual beliefs and expectations: those with strong biomedical views struggled to connect with the app's psychosocial framing. Second, while the app could ease the burden of self-management by offering support between appointments, it could also increase burden during flare-ups, when users lacked the capacity to engage. Features such as proactive content delivery and low-demand interfaces were viewed as essential for continued use. Third, timing emerged as a key factor. Early introduction was beneficial for some, but others needed to first accept the chronicity of their condition before they were ready to engage with self-management tools. Trust in the source recommending the app also influenced engagement. While clinician endorsement was often valued—especially early in the self-management journey—participants who had experienced unmet needs or disillusionment in clinical encounters reported that peer recommendations or nonclinical sources held greater weight. This highlights the importance of aligning recommendations with individuals' evolving relationships with authority and trust.

Conclusions: Mobile apps like Curable (Curable Inc) can support empowerment and continuity of care in CLBP, but their success depends on personalization, timing, and relational dynamics. To prevent feelings of abandonment, such tools should be introduced as an adjunct to—rather than a replacement for—ongoing clinical support.

Introduction

In 2020 nearly 10% of the world's population (approximately 619 million people) suffered from low back pain [1]. Studies estimate that between 5% - 15% of people will go on to develop chronic low back pain (CLBP; pain lasting longer than 3 months) [2,3]. People with CLBP are frequent health care users, which places a significant strain on medical services [3,4]. This demand is expected to rise as the global population grows older and the prevalence of CLBP increases with age [5]. Mobile health (mHealth) apps are becoming powerful tools in assisting health care services meet the rising demand of caring for people with chronic health conditions [6-8].

XSL•FO
RenderX

mHealth apps are software programs designed to be downloaded and run on smartphones or tablets with the aim of maintaining, improving, or managing the user's health [9]. mHealth apps have been recognized as a promising way of delivering timely, cost-effective, and individualized care [10]. It has been suggested that using mHealth apps to treat people with CLBP could reduce the number of general practitioner visits, provide quicker virtual consultations, promote self-management, and improve the psychological impact of pain [11]. Studies suggest that self-management apps for CLBP can be effective in reducing pain and disability [12-15].

However, recent reviews evaluating mHealth interventions for self-managing low back pain highlight mixed findings and persistent challenges. While some studies report improvements in pain and function, others point to inconsistent evidence, low methodological quality, and poor engagement [16,17]. Many apps reflect a narrow biomedical focus, lacking personalization and theoretical underpinning, and often fail to incorporate psychological and social dimensions of pain management. This limits their potential impact, particularly for people with complex, long-term conditions like CLBP [18]. These limitations underscore the need for theory-led research to better understand how, for whom, and in what contexts mHealth interventions work.

The Medical Research Council (MRC) encourages a theory-based approach to evaluation when reviewing complex interventions [19]. Theories can help identify behavioral mechanisms and contexts likely to bring about a desired outcome and, in so doing, potentially increase the effectiveness of both the intervention and its implementation [20]. This type of research is arguably of greater value to policy makers and program developers as the results go beyond reporting on effect sizes, which may be difficult to translate into real-world implementation [21,22]. Realist evaluations are a theory-led approach to evaluation designed to provide guidance on how to implement a program in a particular setting while avoiding potential obstacles along the way [23].

This study addressed the gap in theory-based research on self-management apps for CLBP. Aligned with the MRC's guidance on evaluating complex interventions, a realist evaluation was used to explore a commercially available self-management app. We selected Curable (Curable Inc.), a generic pain management app ranked among the top 3 in a systematic review of 19 chronic pain apps [24], notable for its embedded pain education—a key component of effective self-management [25]. Unlike apps specifically targeting musculoskeletal or low back pain, Curable's broader biopsychosocial approach aligns with current understanding that chronic pain, including CLBP, requires multifaceted management [26]. Rather than evaluating Curable's effectiveness, the app was used as a case study to test and refine program theories developed in a previous realist review [27]. This study aimed to extend their applicability by evaluating these theories in a real-world setting with individuals living with CLBP. Ultimately, the evaluation sought to refine existing theories and contribute to a more robust framework explaining who benefits from a self-management app for CLBP, why, and under what circumstances.

Methods

Ethical Considerations

The study received ethical approval from the University of the Highlands and Islands Research Ethics Committee (ETH2122-0819) and was conducted in accordance with the principles of the Declaration of Helsinki. Written informed consent was obtained from all participants before data collection. Participants were informed of the nature and potential consequences of the study and of their right to withdraw at any time without consequence. All data were anonymized before analysis and confidentiality was maintained in accordance with UK data protection legislation (UK GDPR). While no honorarium was provided, participants were offered a 12-month subscription to the Curable app as a noncoercive form of compensation, allowing continued access beyond the 12-week study period should they choose to continue using the app.

Theoretical Framework

Two substantive theories were used in this study to inform the testing and evaluation of the program theories: burden of treatment theory and empowerment theory. The burden of treatment theory, developed by May et al [28], focuses on the physical and emotional demands that patients face in managing chronic conditions, highlighting the work involved not only for the patients themselves but also for their relational networks (eg, family and health care providers). This theory was selected due to its emphasis on the complexity of managing CLBP within a health care system that increasingly expects patients to take responsibility for their care. It provided a useful lens for exploring how the structural, institutional, and professional dynamics interact with the experience of self-management in this context.

The empowerment theory used here draws from Lee and Koh's [29] model, which combines both the behavioral and psychological dimensions of empowerment. This theory was selected because it helps to explore the role of health care professionals (HCPs) in empowering patients to take control of their self-management, aligning with the goal of understanding how digital health tools, like the Curable app, might influence patient empowerment in managing CLBP. These theories guided the development of program theories by providing conceptual frameworks to understand the interactions between health care systems, patient behaviors, and technology. They also helped to identify key themes in the data, particularly around the concepts of support, control, and autonomy, which were central to understanding how participants engaged with the app. The use of substantive theories in this way is typical in realist research, as it allows for a richer, more contextually grounded exploration of program theories and the mechanisms at play [30].

Clarification of Key Terms

To ensure conceptual clarity and consistency throughout the review, we outline below how key terms have been defined and operationalized. This includes our understanding of context, mechanism, and outcome within a realist framework, as well

XSL•FO
RenderX

as how we have defined self-management, which is central to the intervention under study.

The following key terms are used consistently in this paper and are defined as follows:

1. Self-management: our definition of self-management was informed by a number of key papers in the field of self-management of chronic conditions, including Barlow et al [31] Bodenheimer et al [32], Lorig et al [25], and Wagner et al [33]. In this study, self-management was defined as the ability of an individual—supported by health care providers, family, and community—to acquire the skills and confidence to manage their chronic condition on a daily basis. This process was considered dynamic, allowing individuals to adapt to the fluctuating nature of CLBP and the changing intrinsic and extrinsic factors in their lives.
2. Context: the dynamic and influential conditions or circumstances that shape how an intervention operates. Contexts are not static backdrops but active forces that determine whether and how mechanisms are triggered. These may include individual factors (eg, psychological state and previous knowledge), social or environmental conditions, or institutional settings, all of which influence how participants engage with and respond to the intervention.
3. Mechanism: the underlying processes that explain how and why an intervention works (or does not). Mechanisms involve the interaction between the resources provided by the intervention (eg, app features) and participants' responses to these resources (eg, changes in confidence, engagement, or self-efficacy). Mechanisms are context-dependent and are activated based on the specific conditions in which they operate.
4. Outcome: the results or effects produced by the intervention, which occur because of the activation of mechanisms within a specific context. Outcomes may include changes in behavior, attitudes, or health status.

The definitions of context, mechanism, and outcome used in this study are drawn from our previously published work on realist methodology [34]

Study Design

A realist evaluation of a commercially available chronic pain self-management app was undertaken to test and refine program theories, derived from a previous realist review [27]. A realist evaluation is a systematic approach to studying how people respond to social programs delivered in real-life complex environments and how this influences program outcomes [35]. Realist logic is grounded in the concept of generative causation, which suggests that observable outcomes are brought about by underlying, often unseen, causal mechanisms that operate differently depending on context [36]. These mechanisms help explain why some people may benefit from an intervention and others may not. Context-mechanism-outcome configurations (CMOCs) are central to realist research, providing a way to understand how and why an intervention works (or does not) in specific contexts [37]. Another way to understand CMOCs is as testable propositions that explore the interaction between context, mechanisms, and outcomes, offering an evidence-based framework for explaining why different results might emerge in varying settings or populations [38]. Using a specific case study to test and refine theoretical understandings is a recognized and valuable application within realist research, particularly when evaluating complex interventions like mobile health apps for CLBP [39]. The aim of a realist evaluation is to develop theories as to who might benefit from an intervention or program, why, and in what circumstances.

The study was carried out remotely in Scotland with 9 participants living with CLBP. Participants were given licenses to use a commercially available app (Curable) for 12 weeks to help them self-manage their condition. No restrictions or limitations were placed on how the participants used the app. At the end of 12 weeks, participants engaged in one-to-one, semistructured realist interviews. The study adhered to the RAMESES II (Realist And Meta-narrative Evidence Syntheses: Evolving Standards II) reporting standards for realist evaluation [40] (refer to Multimedia Appendix 1)

Intervention

The Curable app, developed by the US-based company Curable Inc, is a commercially available digital health intervention designed to support individuals in the self-management of chronic pain. It delivers content via a smartphone or web browser through a combination of audio lessons, written articles, and interactive exercises. The app's program is grounded in pain neuroscience education and incorporates elements from cognitive behavioral therapy, mindfulness-based stress reduction, and expressive writing. Users are guided through the content by a virtual chatbot, which provides personalized recommendations and prompts based on user input. Interactive features include reflective journaling, symptom tracking, quizzes, and meditative or breathing exercises. The app encourages daily engagement, and its structure allows users to progress at their own pace through thematic content modules that address the psychological, emotional, and neurophysiological aspects of chronic pain [41].

Recruitment

Participants were recruited through 3 concurrent channels. In the first stream, individuals who had participated in the previous realist synthesis and consented to future contact were emailed directly by the lead researcher. In the second stream, an online advertisement was posted on a study-specific Twitter account (@RealBackstory), and interested individuals responded via email. In the third stream, several pain charities and third-sector organizations shared the study advertisement on their websites and/or in their digital newsletters. Recruitment was entirely conducted online, with participants self-identifying by emailing the lead researcher to express their interest. As such, most participants were self-selected. However, to ensure diversity in experience and explore rival theories, purposive sampling was used to include a small subset (n=3) of individuals identified by a third-sector organization as having had particularly positive experiences with in-person self-management programs for CLBP. This purposive sampling allowed us to examine potentially contrasting perspectives, enhancing the explanatory power and trustworthiness of the findings [42].

XSL•FO
RenderX

Eligibility Criteria

The inclusion and exclusion criteria are shown in Textbox 1.

Textbox 1. The inclusion and exclusion criteria.

Inclusion criteria:

- Any sex
- Aged 18 years or older
- Self-managing chronic low back pain (defined as pain in the lower back lasting >3 months)
- Have seen a medical practitioner about their back pain prior to being involved in this study
- Not receiving active medical treatment for back pain (surgery, physiotherapy, scans, etc)
- May still be taking prescribed analgesia for their low back pain
- Have a smartphone capable of running the Curable app
- Able to participate in a telephone interview

Exclusion criteria:

- Lacking capacity to provide informed consent
- Chronic pain condition that does not include low back pain
- Unable to commit to a 12-week study

Data Collection and Analysis

In line with realist methodology, the number of interviews was guided by the principle of providing rich and relevant data for theory testing rather than aiming for saturation [43]. Data collection ceased once participants had contributed sufficient conceptual depth to meaningfully explore and refine program theories. This approach is consistent with realist evaluation practice [44] and supported by the concept of information power [45], which recognizes that the more relevant and information-rich the data, the fewer participants are needed.

One-to-one, semistructured realist interviews were conducted via telephone by the lead researcher (RH), a chronic pain specialist physiotherapist with qualitative interviewing experience and training in realist methodology. The realist interviews used a teacher-learner cycle, which is a key approach in realist evaluation [44]. In the teacher-learner cycle, the interviewer initially adopts a “teacher” role by presenting a program theory for the interviewee to consider. The interviewee then engages with the theory, drawing on their lived experience to confirm, refute, refine, or elaborate on it. Through this interaction, the interviewer becomes the learner, and the interviewee becomes a co-constructor of knowledge, actively contributing to theory refinement [46]. This cyclical dynamic enhances theoretical sensitivity and contributes to the trustworthiness of the realist research process [46] Interviews were audio recorded with consent and transcribed by a third party. The interview guide was based on the theories from a previous realist review (refer to Multimedia Appendix 2).

Data from the transcripts were analyzed to test the 3 program theories developed from the preceding realist review. These program theories were underpinned by 16 CMOCs; CMOCs are used in realist evaluation to explain how and why particular outcomes occur in specific contexts [34]. Transcripts were coded via repeated rounds of direct, indirect, and holistic coding to identify key causal mechanisms and contextual factors. This coding framework was based on training received from the Center for Advancement in Realist Evaluation and Synthesis (CARES; Jagosh, unpublished data, 2020).

Direct coding was used sparingly and involved a “cut and paste” approach, where brief but pertinent passages from the transcripts were extracted and added to a mind mapping software (XMind; version 22.10). These excerpts typically served as key quotes to support or challenge the CMOCs from the realist review. Indirect coding involved annotating sections of the transcript in the margins, with these annotations extracted and added to the mind map under the relevant CMOC. Each annotation was linked to the original data with participant ID and line numbers for transparency. Holistic coding examined larger sections or entire transcripts to create broader inferences, which were similarly extracted and placed in the mind map.

Inferences were made from the data using retroductive and abductive logic [47,48]. Retroduction refers to reasoning backward from observed outcomes or phenomena to theorize about the underlying causal mechanisms, often combining both inductive and deductive reasoning [48]. Abduction has been described as a form of “reading between the lines” to imagine the underlying causal mechanisms that are typically not directly observable [49]. Jagosh [48] refers to abduction as the creative process of generating inferences to hypothesize what might be happening beneath the surface. It involves reasoning based on “educated guesswork” and “informed hunches,” where researchers draw on existing knowledge to propose plausible explanations for observed phenomena.

The analytical process involved testing the CMOCs with both confirming and disconfirming data extracted from the transcripts. Confirming data referred to instances where the findings aligned with the proposed theory, supporting the link between context, mechanism, and outcome. Disconfirming data presented cases that contradicted the expected outcomes, challenging the initial theory. These contrasting pieces of

XSL•FO
RenderX

evidence were placed side by side in the mind map to refine or adjust the CMOCs. Additionally, counterfactuals were explored—looking for instances where the absence of a certain context or mechanism led to a different outcome than expected. In cases where these contradictions or counterfactuals highlighted different theoretical possibilities, the CMOCs were split or revised to incorporate rival theories. This ensured the complexity of the data was preserved and not flattened out to create uniform themes [50]. The rigor of the final theories was judged using the principles of explanatory coherence [42,51] and was strengthened through an iterative comparison of evidence across participants. This involved assessing how well the findings aligned with existing literature and considering alternative explanations. Additional rigor was supported by ongoing discussions within the research team and peer review. While formal stakeholder engagement was not undertaken at this stage, informal discussions with a participant—who later became a Patient and Public Involvement (PPI) lead in follow-on research—also helped sense-check emerging interpretations.

Realist Review Overview

A realist review was conducted before this evaluation to develop program theories about how and for whom self-management apps might work for people with CLBP. The review, published elsewhere [27] drew on 57 sources, including peer-reviewed literature, UK government policy documents, national pain charity resources, and nontraditional materials such as blogs, social media, and book chapters to capture a broad range of perspectives. To further enhance the depth and relevance of the findings, 19 realist interviews were conducted with people with CLBP, clinicians, and digital health designers. These interviews were integrated directly into the analysis to ensure that the voices and lived experiences of people with CLBP were central to theory development. The review generated 16 CMOCs, which were grouped into 3 overarching program theories: empowerment, self-management burden, and timing. These are summarized in Table 1 and referenced throughout the results section, where they were further tested and refined.

XSL•FO
RenderX

Table . Context-mechanism-outcome refinement.

Realist synthesis CMOCs[a]	After testing	Realist evaluation CMOCs	Sources	Example quote
CMOC 1. Convenience, accessibility, and choice Traditional NHS-led[b] self-management programs for CLBP[c] provide participants with little choice in how, when, and where they are delivered (C). A self-management app for CLBP can be accessed at a time and location that is convenient to the user (M), which restores a person's sense of control and autonomy (O).	Refined	*CMOC 1. Choice and flexibility* When a person with CLBP has distinct preferences and varying levels of motivation for self-management (C), the app being adaptable and flexible enough to accommodate the user's wants (I) leads to the patient experiencing a sense of agency, choice, and control over their self-management program (M), ultimately resulting in sustained use of the app and adherence to their self-management program (O).	Participants: 2,5,7,9	***...****having time to go out for a walk and listen to it* [the app] *was quite useful. But some of the content wasn't great when you're actually on the move*. [Participant 7] *...it just didn't suit me and my lifestyle*. [Participant 5]
CMOC 2. Knowledge and self-reliance Many people with CLBP rely on HCPs for support because they do not know how to manage their symptoms (**C**). By providing the user with knowledge, advice, and strategies to self-manage CLBP, a mobile app enables the user to gain confidence and agency (**M**) to manage their condition on their own (**O**).	Split	*CMOC 2. Knowledge is empowering.* For people with CLBP who feel dependent on health care professionals due to a lack of confidence in managing their symptoms independently (C), being offered an app that provides accessible information and practical self-management strategies leads them to feel more empowered and confident in their ability to manage their condition (M). As a result, they become more self-reliant and reduce their dependence on healthcare professionals (O). *CMOC 3. Knowledge reduces fear* For people with CLBP who experience fear and anxiety related to the uncertain causes of their ongoing pain (C), an app that provides education about CLBP can increase their sense of understanding, control, and agency over their condition (M), ultimately leading to greater confidence and engagement in self-management (O).	Participants: 2,3,4,6,7 Participants: 1,4,6,7	***...****I've gone to them* [GP's] *looking for solutions an come away with nothing so I'm disappointed. Whereas when I found out about it* [pain] *myself, I could understand it more*. [Participant 3] *...managing that fear is absolutely critical to pain management itself and an app can help with that, without a doubt*. [Participant 4]

XSL•FO
RenderX

Realist synthesis CMOCs[a]	After testing	Realist evaluation CMOCs	Sources	Example quote
CMOC 3. Personalisation A person with CLBP needs to be able to recognize themselves in the advice and information the app provides (**C**) so that they can trust what they are being told (**M**) otherwise they unlikely to engage with the app because they do not consider it as being relevant to their situation (**O**).	No change	*CMOC 4. Personalisation* For a person with CLBP to engage with the app, they need to see the advice and information as personally relevant to their situation (C). This recognition fosters trust in the app's recommendations (M), which in turn leads to increased engagement because the individual perceives the app as a useful tool for managing their condition (O).	Participants: 1,4,5,6,7,9	*I'm not going to turn it* [the app] *on because I've started to hear more stuff that doesn't mean anything to me. It doesn't resonate with me*. [Participant 7]
CMOC 4. Hope If a mobile the app fails to provide the user with options that have not been tried before (**C**) then the initial hope they may have felt at being offered something that might alleviate their pain (**M**) can turn to bitterness, disappointment and sometimes anger (**O**).	Refined	*CMOC 5. Biomedical mindset* For people with CLBP who have a biomedical mindset (C), a self-management app that presents an alternative approach to understanding and managing CLBP may lead to frustration, annoyance, and disappointment (M), as the solution offered does not align with their expectations for managing their pain (O).	Participants: 1,5,6,8,9	*Pain is pain - the pain is not in my head – I have a diagnosis..I gave up on it because I just thought 'this is ridiculous.' I just felt that it wasn't teaching me anything I didn't already know. It wasn't helping me.* [Participant 6]
CMOC 5. Adjunct to care If a self-management app was used as an adjunct to care and not a replacement (**C**) then HCPs[d] are likely to welcome the tool as it helps them to deliver ongoing support remotely (**M**) thereby enabling them to treat more patients in their limited clinic time (**O**).	Refined	*CMOC 7. Enhancing Patient Confidence Between Appointments* Between healthcare appointments, when reduced contact can leave people with CLBP feeling vulnerable (C), giving them a self-management app can lead to the patient feeling reassured that they have timely and convenient access to ongoing support and answers (M), ultimately increasing their confidence to go longer before they need to see a HCP (O).	Participants: 8,9	***...****it* [the app] *helps until they maybe get an appointment.until maybe they go and have a onceover with a professional or a doctor – absolutely, great!* [Participant 8]

XSL•FO
RenderX

Realist synthesis CMOCs[a]	After testing	Realist evaluation CMOCs	Sources	Example quote
CMOC 6. Burden of care If people with CLBP lack the internal and or external resources to engage with a self-management app (**C**) then this can cause further stress and frustration (**M**) which adds to their burden of having to manage long term back pain (**O**).	Split	*CMOC 8. Proactive support* For individuals with CLBP experiencing severe symptoms that inhibit their ability to engage mentally with tasks (C), an app that proactively selects and plays content they have found helpful in the past reduces cognitive fatigue and the stress of decision-making (M), thereby making it easier to engage with the app, particularly during flare-ups (O) *CMOC 9. Voice activation* For individuals with CLBP experiencing severe flare-ups that impair their ability to engage physically or mentally with tasks (C), an app with voice activation (resource) reduces physical effort and fatigue (M), enabling continued access to support even during extreme pain (O).	Participants: 2,7,9 Participants: 2,7,9	*...at times when you are in so much pain.you just want some sort of reassurance or someone to come with an idea, because you can't think of anything for yourself.* [Participant 9] *Voice activation is probably the only chance you've got because sometimes the pain is so unbearable. the only way I could actually unlock it* [the app] *would be voice activation.* [Participant 7]

XSL•FO
RenderX

Realist synthesis CMOCs[a]	After testing	Realist evaluation CMOCs	Sources	Example quote
CMOC 7. Monitoring Monitoring their progress with a mobile app and sharing this data with a HCP (**C**) can help a person with CLBP convey more of a 'complete picture' of how they are managing their condition (**M**) and thereby improve the communication and quality of a healthcare consultation (**O**).	Refined New New	*CMOC 11. Improved communication* During healthcare consultations, when people with CLBP find it challenging to accurately recall and articulate the details of their condition and management (C), using an app to record and share this data with an HCP can lead to the patient feeling less stressed and more in control (M), which improves their ability to communicate and enhances the quality of the healthcare consultation (O). *CMOC 6. HCP buy-in needed* When a HCP does not see the value in the app's recorded data or dismisses its utility (**C**) then this disempowers the person with CLBP by devaluing their contribution to the consultation (**M**) which can adversely affect the therapeutic relationship from the patient's perspective (**O**). *CMOC 12. Monitoring is burdensome* For people with CLBP who are constantly aware of their pain and benefit from strategies that allow them to mentally switch off from it (C), repeated prompts by an app to record symptoms can disrupt this mental disengagement, adding an additional burden to self-managing CLBP and serving as a constant reminder of their ill health (M), which can worsen the pain experience (O).	Participants: 1,2,4,9 Participants: 1,4,7 Participants: 3,5	*...you have to make them* [healthcare professionals] *believe you, and it creates so much stress in that interaction, and if you were doing than on an app then you're taking the stress out of it.* [Participant 4] *...when I took that to my neurologist he just went 'but how do I know that that is genuinely like the right information?'"* [Participant 1] I found it [monitoring] very difficult to do and it actually made the pain worse because I was focusing on it. [Participant 5]
CMOC 8. Meaningful consultations Using an app to record and share their data with an HCP (either before or during the appointment) (**C**) can maximize limited consultation time (**M**) and thereby reduce the frustration felt by patients' valuable consultation is wasted bringing HCPs 'up to speed'(**O**).	Refined	*CMOC 10. Making consultations more effective/efficient* In healthcare settings with short patient appointments (eg, 10 min) where patients face the burden of using that time to provide background information (C), using an app to record and share pertinent data with an HCP ahead of time can lead to the patient feeling a sense of reduced frustration due to the expectation of a more efficient and focused consultation (M), ultimately leading to a more satisfactory consultation (O).	Participants: 4,5,6,7,9	…when you go and see him [the GP], he's got the information there [on the app]… so I think there's an opportunity for the GP to use it and save them a lot of time and a lot of work. [Participant 9]

Realist synthesis CMOCs[a]	After testing	Realist evaluation CMOCs	Sources	Example quote
CMOC 9. Abandonment By providing support as well as a means by which to contact a HCP if needed (**C**) a self-management app provides users with the reassurance of a 'safety net' should they feel they need additional support (**M**) thereby mitigating feelings of abandonment (**O**). *CMOC 10. Safety net* A self-management app that enabled a person with CLBP to maintain contact with a HCP (**C**) can provide a reassuring 'safety net' (**M**) leaving them more confident to be discharged from the healthcare service (**O**).	Merged	*CMOC 13. Ongoing support* After discharge, a person with CLBP needs occasional reviews from a HCP in addition to a self-management app (**C**) to reassure them that they have not been left to manage their condition on their own (**M**) and prevent feelings of abandonment (**O**).	Participants: 1,3,4,5,	A follow-up with a real live person is always a good idea in my book, just to see how they're getting on. I wouldn't want them to be given the app and say 'There you are, bye bye'. [Participant 3]
CMOC 11. Social Isolation In the absence of supportive 'real life' relationships (**C**) a self-management app with a chat bot feature that has been designed to communicate in a human-like way to offer comfort and reassurance (**M**) can help someone with CLBP feel less alone (**O**).	Split	*CMOC 14. Chatbot is supportive* For people with CLBP who experience social anxiety, fear of judgment, or find social interaction draining (C), the non-judgmental and socially undemanding nature of an app's chatbot (Intervention Feature) can reduce feelings of shame, guilt, and loneliness (Mechanism), ultimately helping to reduce feelings of social isolation (Outcome). *CMOC 15. Chatbot is poor proxy* For people with CLBP who find connecting with fellow human beings to be supportive and emotionally beneficial (C), the lack of warmth and empathy from an app's chatbot (Intervention Limitation) can lead to the patient experiencing the interaction as fake, cold, and devoid of meaning (Mechanism), making the chatbot an inadequate substitute for human support (O).	Participants: 1,3,4,7,8 Participants: 1,7,8	*...if you've been isolated for so long then the very act of meeting someone, getting to know them.can be quite intimidating.whereas I suppose something, you know, that is not quite real would be easier in some regards.* [Participant 3] *...it's the personal thing, that's the difference.it's* [the chatbot] *not real, you're not seeing facial expressions of somebody, how they react to you. The A.I* [artificial intelligence] *it's robotic basically.,it's cold*. [Participant 8]
CMOC 12. Acceptance If a person with CLBP remains steadfast in their search to find a cure for their back pain (**C**) and are unwilling to accept an active role in self-managing their condition (**M**) then they are likely to be disappointed with a self-management app because it does not rid them of their pain (**O**).	Refined	*CMOC 16. Expectations of a cure* For people with CLBP who are still seeking a cure for their back pain (C), a self-management app may not meet their expectations (M), leading to disappointment and a lack of engagement (O	Participants: 2,3,9	*Once you accept it and adjust your lifestyle around it and work with it not against it, any sort of information you can gather through the app* [is helpful]. *But it's acceptance. A lot of people won't accept that they've got a long-term issue*. [Participant 9]

[c]CLBP: chronic low back pain.

[d]HCP: health care professional.

Results

A total of 9 participants, aged between 35 and 70 years and all living with CLBP for a minimum of 3 years participated in the study. A total of 3 were female and 6 were male. The 16 CMOCs from the preceding realist synthesis were tested and refined by the realist evaluation to produce 20 CMOCs (see Table 1).

These 20 CMOCs were refined, but did not fundamentally alter, the 3 program theories identified in the preceding realist review [27]. The groupings of the CMOCs and subsequent program theories were informed by Burden of Treatment theory [28] and Lee and Koh's conceptualization of empowerment [29]. The evaluation revealed deeper insights into contextual factors and causal mechanisms that explain who might benefit from a self-management app for CLBP, why, and in what circumstances.

Program Theory 1: Empowerment

Program theory 1 (see Textbox 2), informed by Lee and Koh's [29] model of empowerment, was developed from 7 CMOCs: choice and flexibility (CMOC1), knowledge is empowering (CMOC2), knowledge reduces fear (CMOC3), personalization (CMOC4), biomedical mindset (CMOC5), HCP buy-in is needed (CMOC6), and reduce HCP workload (CMOC7).

Textbox 2. Program theory 1: empowerment

People with chronic low back pain can feel empowered by a self-management app if the app is personal and relevant to their situation, can be accessed when and where they need it, and is presented as an adjunct to ongoing care.

Participants highlighted the importance of having choice and flexibility in how they accessed self-management support. While the app was designed to be convenient (CMOC1), many felt its rigid content delivery did not meet their situational needs. This refined the original concept of "convenience" by suggesting that flexibility in interaction style—not just availability—is key to fostering a sense of control and agency.

The app's educational content was widely seen as a means of empowerment, particularly when it provided new insights or helped fill perceived gaps in HCP knowledge (CMOC2). Beyond information acquisition, knowledge also had an important emotional impact in that it reduced the fear associated with chronic pain and helped participants shift from passive coping to active self-management (CMOC3).

However, this process was moderated by the app's capacity to personalize its content. Participants expressed frustration at the generic feel of the Curable app, noting that it did not sufficiently tailor responses to individual experiences (CMOC4). This was particularly problematic for users who expected content to reflect their specific pain history or emotional context.

Engagement with the app was also shaped by participants' underlying pain beliefs. Those with a strong biomedical orientation struggled with the app's psychological framing, interpreting it as invalidating their pain (CMOC5). By contrast, participants who had already begun to reconceptualize their pain found the app aligned with their thinking and were more likely to benefit.

A recurring theme across CMOCs was the continued importance of HCPs. Participants expressed a need for HCP buy-in and endorsement to validate the app's credibility and reinforce its content (CMOC6). In addition, the app was perceived as potentially useful in reducing demand on HCPs by enabling patients to self-manage more confidently between appointments (CMOC7). However, this potential was conditional on the app's responsiveness and the willingness of HCPs to engage with its outputs.

XSL•FO
RenderX

Together, these CMOCs refined Program Theory One by demonstrating that empowerment in self-management is not solely a function of delivering knowledge. It depends on how that knowledge is delivered, who it is validated by, and how well the system supports both user autonomy and relational trust.

Program Theory 2: Self-Management Burden

Program theory 2 (see Textbox 3), developed from 9 CMOCs and informed by May colleagues' [28] burden of treatment theory, explores how self-management apps can either alleviate or intensify the burden of managing chronic low back pain (CLBP). The theory was refined to highlight that this burden is shaped not only by external resources, such as digital access, but more critically by internal capacities, especially during periods of heightened pain.

Textbox 3. Program theory 2: self-management burden

If people with chronic low back pain (CLBP) have the capacity to engage with a mobile app, then it can reduce the burden of having to self-manage CLBP by providing ongoing support, facilitating communication with health care professionals, and mitigating feelings of abandonment.

During acute flares, participants described a significant drop in cognitive and emotional bandwidth, making any self-management activity—even app use—challenging. The evaluation introduced two new CMOCs to address this context: voice activation (CMOC8) and proactive support (CMOC9). Participants suggested that voice control could reduce interaction effort, while a more proactive app—one that nudges rather than waits for user input—could better meet their needs during these episodes of intense pain.

Beyond these flare-specific adaptations, several CMOCs addressed how the app's design intersected with routine management and interaction with HCPs. A recurring theme was the desire for data collection and sharing functionality, which participants believed would enhance the efficiency and focus of medical consultations. This supported and refined the review's theory that digital tools can reduce the frustration of updating HCPs during limited appointment time (consultations, CMOC10). Participants felt that pre-shared data would allow consultations to center on interpretation and planning rather than recounting.

This aligns with CMOC11, which focused on improving communication. The app was perceived as a potential aid in memory and articulation, allowing users to convey details that might be difficult to express during face-to-face consultations. Importantly, some participants valued objective data as a way to counteract perceived skepticism from HCPs when symptoms were not outwardly visible—reducing the pressure to "look sick."

However, not all interactions with data were beneficial. For some, symptom monitoring (CMOC12) backfired. Participants who had used other apps with frequent tracking prompts described heightened focus on pain, emotional distress, and even symptom worsening. For these users, digital tracking increased—rather than reduced—the burden of self-management.

Participants also discussed the app's role as a source of ongoing support (CMOC13), particularly following National Health Service (NHS) discharge. While Curable provided a sense of continuity, it was not viewed as a replacement for professional input. Many still desired periodic reassurance and oversight from HCPs, highlighting that an app alone was insufficient to maintain confidence or alleviate feelings of abandonment.

The app's conversational agent, Clara, further divided opinion. For some, the chatbot was supportive (CMOC14)—a nonjudgmental, low-effort interaction partner that offered comfort without the social labor of human connection. In contrast, others saw Clara as a poor proxy (CMOC15) for genuine empathy. The absence of emotional nuance, spontaneity, and body language left these participants feeling disconnected, reinforcing the view that digital tools can offer support but rarely replace relational care.

Collectively, these CMOCs refine Program theory two by emphasizing that the burden of self-management is not only shaped by how much a person must do, but also how sensitively digital tools respond to their physical, cognitive, and emotional capacity. Apps must strike a careful balance: offering timely, tailored, and low-effort support while avoiding features that may inadvertently intensify distress or isolation.

Programme Theory 3: Timing

Program theory 3 (see Textbox 4), informed by both burden of treatment theory [28] and the empowerment model, emphasizes that the timing of introducing a self-management app is a key factor in determining whether it is embraced by users. The theory is underpinned by five key CMOCs: expectations of a cure (CMOC 16), a proper diagnosis (CMOC 17), trust the messenger (CMOC 18), reassurance (CMOC 19), and the early stage in the journey (CMOC 20).

Participants reflected on how the NHS, historically centered around finding cures and fixing ailments, shaped patients' expectations. This cultural backdrop led to an assumption that health issues like CLBP should be resolved, rather than managed over the long term. For many patients, this expectation made it difficult to accept self-management solutions like mobile apps. However, participants noted that once individuals moved beyond the expectation of a quick fix, typically after receiving a thorough diagnosis and reassurance, they were more receptive to long-term management strategies, such as using a self-management app (CMOC 16).

XSL•FO
RenderX

Textbox 4. Programme theory 3: timing

A person with chronic low back pain is likely to benefit from a self-management app early on in their patient journey but not before they feel believed and reassured by health care professionals and have accepted their condition cannot be cured (CMOCs 16-20).

This shift in mindset was facilitated by key moments in the care journey. First, receiving a "proper" diagnosis—a concrete explanation of their pain—was seen as vital for helping patients accept their condition (CMOC 17). However, participants stressed that this diagnosis alone was not enough; they also needed reassurance from a HCP to ensure their pain was not indicative of something serious (CMOC 19). Only when these needs for validation and reassurance were met did participants feel ready to consider self-management tools, such as the app.

The introduction of the app was considered most effective when it occurred after these key steps had been completed. Timing was seen as especially critical—if the app was introduced too early, before a proper diagnosis or reassurance, it could be perceived as a "brush-off" or a superficial solution. But when the app was introduced at the right moment—typically after a thorough clinical assessment and reassurance—it was viewed as a supportive tool that could help users build self-management skills earlier, improving their quality of life sooner (CMOC 20).

Trust also played a significant role in whether participants engaged with the app. As highlighted in CMOC 18, recommendations from a trusted individual—often, though not always, a HCP—were more likely to lead to acceptance. However, when trust in HCPs was eroded due to unmet needs for validation or reassurance, some participants sought advice elsewhere, including from peers or alternative sources, who then became the preferred recommenders. This underlines the importance of introducing the app at the right moment, and through the right source, based on the patient's journey and their current relationship with healthcare professionals.

Together, these CMOCs refine Program theory three by emphasizing that successful engagement with self-management apps is contingent on timing—not simply early in the journey, but at the right point in a person's clinical and emotional trajectory. This includes when expectations of a cure have softened, when the individual feels their pain has been properly explained and validated, and when reassurance has been offered by a trusted source. The refined theory shifts away from a generic call for early intervention and instead highlights that the effectiveness of app-based self-management depends on readiness, which is shaped by how the health system meets core psychological and relational needs.

Discussion

Principal Findings

The aim of this realist evaluation was to test and refine 3 program theories developed during a preceding realist review on the use of mobile apps for the self-management of CLBP. These program theories centered around the concepts of empowerment, self-management burden, and timing, and were each underpinned by a set of CMOCs. They were informed by two key substantive theories: May and colleagues' [28] burden of treatment theory and Lee and Koh's [29] model of empowerment. Using the Curable app as a case study, this evaluation explored how, for whom, and under what circumstances such a digital self-management tool might work—or not—in everyday life. This study found that mobile apps like Curable can empower individuals with CLBP by providing accessible knowledge and reducing reliance on HCPs. However, the effectiveness of these tools is contingent on personalization, timing, and relational dynamics with health care providers. The success of such tools also depends on their introduction as an adjunct to ongoing care rather than a replacement, with careful consideration given to users' evolving trust and readiness for self-management.

Our evaluation showed that digital self-management tools like the Curable app can support empowerment in people with CLBP by providing accessible and credible knowledge that fosters confidence, agency, and a reduced reliance on HCPs—a finding that echoes Lee and Koh's [29] model of empowerment and aligns with Lim and colleagues' [52] work showing that people with CLBP want information to manage their condition. Knowledge provided via the app helped participants understand their pain and reduce fear, confirming the empowering potential of education in chronic pain management [25]. However, empowerment was not universally experienced. Participants with a strong biomedical mindset struggled to engage with the app's psychosocial framing, perceiving it as invalidating or insufficient—a reflection of the enduring influence of the biomedical model in shaping patient expectations [53]. This supports findings by Stenner et al [54] and Van de Velde et al [55], who argue that acceptance of pain is a prerequisite for engaging with self-management. These results highlight the need for apps to be personalized, both in content and delivery, to match users' readiness for behavioral change—a key mechanism of engagement reflected in the technology acceptance model [56,57] and the unified theory of acceptance and use of technology [58].

Participants also believed that the app could help them rely less on HCPs between appointments, particularly when they felt the information was relevant and trustworthy—suggesting a role for digital tools in extending continuity of care. However, when HCPs failed to acknowledge app-related efforts or patient-generated data, participants felt dismissed, leading to disempowerment. This reinforces Lee and Koh's [29] assertion that empowerment is relational and shaped by the behavior of those in power. For digital tools to fully realize their empowering potential, HCPs must validate and incorporate these tools into consultations. This aligns with existing research, which demonstrates that apps designed to track and share health data have improved consultations in the management of conditions like irritable bowel syndrome [59], chronic pain [60], and heart failure [61]. Taken together, these findings challenge the assumption that digital tools are inherently empowering and instead suggest their success is conditional on user beliefs, professional endorsement, and contextual fit. App developers should prioritize personalization and create tools that support

XSL•FO
RenderX

a staged, user-centered journey toward empowerment, while health systems must formally recognize and accommodate digital self-management tools within routine care.

The evaluation highlighted that while self-management apps can ease the burden of care, they also risk amplifying it if poorly designed or insufficiently integrated with broader health care support. Findings align with May and colleagues' [28] burden of treatment theory, which asserts that the capacity to engage with self-management depends on an individual's personal resources and the demands placed upon them. Participants emphasized that during acute flare-ups of CLBP, the cognitive and physical effort required to interact with apps like Curable became a significant barrier. This underscores the importance of designing features that minimize interactional demands during times of distress—such as voice activation and proactive content delivery—echoing calls in the literature for "low-friction" digital health tools [62]. Although data-sharing capabilities were absent in Curable, participants voiced a strong desire for features that allow symptom tracking and integration into consultations, viewing the proactive sharing of health information with health care providers before consultations as beneficial. This aligns with Holt and colleagues' [63] research, which demonstrated that previsit data collection enhances patient-provider communication, particularly in areas like respect, care, and perceived physician time, suggesting a pathway for better integrated health care support.

However, symptom tracking also revealed potential harms: for some, it became a persistent reminder of their condition, reinforcing pain salience [64]—a finding echoed in pain psychology literature cautioning against hypervigilance [64]. The app's chatbot, Clara, was also polarizing. While some participants found its nonjudgmental, low-demand interaction helpful—aligning with its intended purpose—others felt it lacked the emotional depth of human connection, reflecting early observations in the literature on the limitations of artificial intelligence–driven relational agents in fully replicating therapeutic rapport [65]. However, more recent research suggests that humans can form meaningful emotional bonds with chatbots [66], which can help alleviate feelings of social isolation and loneliness [67]. This prompted participants to consider the potential for improvement: they envisioned that with more sophisticated programming and algorithms enabling greater empathy and responsiveness, a chatbot like Clara could potentially foster a more supportive relationship. Despite these possibilities, however, the majority of participants felt that the app alone was not sufficient for ongoing support after discharge from the health care service. While some found Clara helpful for building confidence between appointments, they agreed that a follow-up with an HCP was ultimately necessary. This perspective mirrors findings from a large cross-sectional online survey, which revealed that most people prefer using health apps as a complement to, rather than a substitute for, in-person doctor visits [68]. These results highlight that, although digital self-management tools can extend care between appointments, they are generally seen as supplementary to, not a replacement for, the ongoing expertise of health care professionals.

Program theory 3 focused on the role of timing in shaping a person's readiness to engage with a self-management app for CLBP. While this theory was not explicitly framed around a single substantive model, it was informed by both the burden of treatment and empowerment frameworks. These concepts helped illuminate how the shifting emotional, cognitive, and relational context of living with CLBP influences when and how individuals feel capable of self-managing.

Our findings align with previous research, highlighting that patient engagement with self-management is more likely when individuals feel validated, reassured, and well-informed about their condition. For example, Toye et al [69] found that people with CLBP often struggle to engage with self-management until they have redefined their identity in relation to pain, a process that takes time and often requires credible explanation and validation from a trusted source. Similarly, Ong et al [70] found that people with sciatica were unable to emotionally adjust or cope with their symptoms until they received a credible diagnosis and explanation, which helped them make sense of their suffering. These findings echo the importance our participants placed on receiving a "proper" diagnosis and reassurance from an HCP before engaging with the app.

The concept of "timing" also reflects broader discussions in the literature around readiness for behavior change. Prochaska and DiClemente's [71] transtheoretical model of change suggests that interventions are more effective when matched to a person's stage of readiness—something that emerged clearly in our evaluation. Offering a self-management app too early, before patients feel they have been taken seriously or ruled out serious pathology, can create resistance rather than engagement.

Trust in the person recommending the app emerged as a key factor influencing engagement, aligning with Greenhalgh and colleagues' [72] finding that patients are more likely to adopt health technologies when introduced by someone perceived as credible and caring. However, our study suggests that the timing of such a recommendation is equally important. For users early in their journey, a trusted clinician may be an ideal introducer. But for others who have experienced unmet needs, disillusionment, or frustration in clinical encounters, the same recommendation may be disregarded or even resisted. In these cases, peer recommendations or alternative sources carried more weight. This highlights that the right source of recommendation must come at the right time, tailored to the user's current relationship with health care authority and trust.

While Program theory 3 does not rest on a distinct theoretical framework, its development was shaped by the same constructs underpinning the burden of treatment and empowerment theories. Specifically, it adds a temporal dimension—showing that empowerment and the capacity to shoulder treatment burdens are not static traits but unfold over time. Understanding when individuals are ready to self-manage is, therefore, essential in aligning support tools, like self-management apps, with patients' evolving needs and expectations.

Limitations

This study was guided by the RAMESES quality and reporting standards for realist evaluation [40] to ensure the research was undertaken with rigor and transparency. However, there are some limitations to be noted.

XSL•FO
RenderX

The Curable app did not have some of the functionality that was initially theorized to be beneficial, which meant some theories from the realist review could not be tested. However, to address this gap, participants used their experience with other health apps to help refine and develop theories.

Participation in the study was voluntary, which introduces a risk of selection bias. To address this, purposive sampling was used to ensure a variety of views toward self-management were represented. In addition, the study had a small number of participants and only evaluated the Curable app, which limits the claims that can be made about how representative its findings are for other self-management apps. However, the results have been presented as middle-range theories [30]. That is, the theories are at a level of abstraction whereby readers can judge whether they might be transferable to their context.

Conclusions

mHealth apps have the potential to help people with CLBP self-manage their condition. This is important considering the growing number of people affected by this condition and the likelihood that the numbers will increase as the world's population ages. This realist evaluation identified several key contextual factors and causal mechanisms to determine who may benefit from a self-management app and why. First, patient acceptance of their condition is important. Second, HCPs buy-in and personalized, adaptable content are essential for promoting sustained user engagement. Finally, to fully address patient needs, self-management apps should ideally be used in conjunction with ongoing support from HCPs. This integrated approach can help alleviate feelings of abandonment that may arise when solely relying on a mobile app.

Acknowledgments

We sincerely thank all participants who generously shared their experiences for this study. We are also grateful to Pain Association Scotland, Let's Get On With It Together, and Affa Sair for their valuable support with participant recruitment. Additionally, we acknowledge the use of ChatGPT (ChatGPT-4) for light text editing and proofreading during the preparation of this manuscript. We confirm that no original content, figures, or data were generated by this artificial intelligence tool, and we retain full responsibility for the paper's content, accuracy, and integrity.

Funding

RH's work was supported by the Inverness and Highland City Region Deal Studentship Award (2018).

Data Availability

The datasets generated or analyzed during this study are not publicly available due to privacy and ethical restrictions but are available from the corresponding author on reasonable request.

Authors' Contributions

RH, TG, and MB conceptualized the study and developed the methodology. RH conducted the investigation, including data curation and formal analysis, while TG and MB supervised the project and validated the findings. RH drafted the manuscript, and TG and MB critically reviewed and edited it.

Identifying and Evaluating Patient-Centered Mobile and Web Apps for Patients With Chronic Spontaneous Urticaria: Systematic Search and Content Analysis

Abstract

Background: Chronic spontaneous urticaria (CSU) is characterized by recurrent wheals or angioedema lasting for more than 6 weeks and substantially affecting the quality of life. Given its fluctuating course, accurate symptom monitoring is essential. Mobile health apps (MHAs) offer promising tools for real-time symptom tracking, patient education, and communication. Systematic evaluation of existing MHAs for CSU is critical to inform the development of effective, patient-centered digital solutions.

Objective: This study aimed to identify and evaluate publicly available MHAs for patients with CSU, assessing their quality, usability, and alignment with the needs of both patients and physicians to guide the development of future patient-centered apps.

Methods: A systematic search of app stores and the internet was conducted to identify MHAs for CSU. Inclusion required German or English language support and patient-centered content. Apps were excluded if they contained advertisements; lacked patient-centered content, designed to assist patients in the self-management and care of their condition; or were focused on clinical trials or health care professional use. After screening, 1 app, CRUSE Control, met all criteria and was evaluated by 23 physicians and 16 patients with CSU using the German versions of the Mobile Application Rating Scale (MARS and end-user version of MARS) and the mHealth App Usability Questionnaire. Participants' technical affinity was assessed using the affinity for technology interaction scale and the Mobile Device Proficiency Questionnaire. Additionally, they completed a custom questionnaire on their personal needs and expectations for CSU-specific MHAs.

Results: Fifteen MHAs were identified, with 12 available on both platforms. Eleven apps were excluded due to lack of specificity to CSU (n=10) or not being patient-centered (n=1). One app, CRUSE Control, met all inclusion criteria and was selected for final evaluation. CRUSE Control received similar mean (SD) quality ratings from physicians (MARS 4.03, SD 0.45) and patients (end-user version of MARS: 4.06, SD 0.40; *P*=.83). Among the MARS subcategories, functionality was rated significantly higher by patients than by physicians (4.75, SD 0.41 vs 4.47, SD 0.55; *P*=.04). Usability, measured using the German mHealth App Usability Questionnaire (assessing effectiveness, efficiency, and satisfaction), showed no significant difference between physicians (5.85, SD 0.71) and patients (5.76, SD 0.41; *P*=.64). Technology affinity was comparable between groups, with physicians scoring 3.50 (SD 0.66) and patients 4.00 (SD 0.88) on the affinity for technology interaction (*P*=.05). Proficiency with mobile devices, assessed via the Mobile Device Proficiency Questionnaire, also showed similar results (physicians: 4.81, SD 0.26; patients: 4.74, SD 0.45; *P*=.60).

Conclusions: Few high-quality MHAs for CSU are currently available, and only 1 met the inclusion criteria. Patients and physicians rated the app highly, though patients placed greater emphasis on functionality. High technology affinity in both groups supports adoption. Patients prioritized features that facilitate disease management. Although limited to a single app, these findings suggest that MHAs may support CSU care.

Introduction

Background

Urticaria is a common skin disorder characterized by the sudden onset of wheals and/or angioedema. Wheals (urticaria) typically presents with three key features: (1) sharply demarcated, superficial swellings of the skin of variable size and shape, usually surrounded by a reflex erythema; (2) intense pruritus or, less commonly, a burning sensation; and (3) a transient course, with lesions usually resolving within 30 minutes to 24 hours.

In around 40% of cases, episodes of urticaria are accompanied by angioedema, primarily affecting the face, but also the hands and feet [1]. Angioedema is defined by (1) rapid-onset, pronounced swelling in the deeper dermis, subcutis, or mucous membranes, often erythematous or skin-colored; (2) a sensation of tingling, burning, or tension and sometimes pain rather than itch; and (3) a slower resolution, typically lasting 72 hours. According to current guidelines, urticaria is classified by duration as either acute (≤6 wk) or chronic (>6 wk) and by trigger as spontaneous (no identifiable cause) or inducible (triggered by specific stimuli) [2,3].

The lifetime prevalence of urticaria is estimated to range between 10% to 20%, indicating that a substantial proportion of the population experiences at least one episode during their lifetime [2,4]. Chronic urticaria (CU) has a lifetime prevalence of approximately 1% to 2% among adults in Europe, the United States, and worldwide, with chronic spontaneous urticaria (CSU) being the most common subtype [4-6]. It most frequently manifests between the third and fifth decades of life [5,7,8] and affects women twice as often as men [8].

The impact of CSU on patients and their social environment is substantial and far-reaching [9]. Quality of life is markedly impaired, comparable to other severe dermatological conditions such as hidradenitis suppurativa or advanced atopic dermatitis [10]. The unpredictability of symptoms—such as itching, swelling, and wheals, which can lead to sleep disorders—contributes to emotional distress, particularly anxiety and depression [11-14].

CSU is primarily a clinical diagnosis, typically first assessed by general practitioners. A comprehensive diagnostic evaluation includes a detailed medical history, structured around the "7 C's" (Confirm, Cause, Cofactors, Comorbidities, Consequences, Components, and Course), as well as the assessment of disease activity, impact on patient's life, and disease management [2,15]. CU may also be triggered by circulating immune complexes and activation of the complement system. In cases persisting for several months or longer, autoimmune thyroiditis should be ruled out [16,17]. Standardized tools such as the urticaria activity score (UAS), Urticaria Control Test (UCT), and the Chronic Urticaria Quality of Life Questionnaire are recommended for quantifying disease burden and monitoring fluctuations over time [2,18].

Due to the episodic nature of CSU, which may persist for months or even years [19], symptom fluctuation is common and can make it difficult for health care providers to fully assess the disease's burden.

To bridge this gap, mobile technologies have gained traction in dermatology. Clinical photography has been used for documenting disease progression and supporting diagnostic accuracy [20], and messaging tools and teleconsultation already support remote assessment and communication [21]. This offers additional benefits in improving treatment monitoring and enhancing patient education [22]. A recent study has demonstrated the feasibility and high acceptance of teledermatologic disease management in a cohort of patients with CSU [23]. Building on these existing digital tools, mobile health apps (MHAs) offer promising opportunities for the management of CSU. As the demand for accessible and flexible health care grows, they are becoming increasingly relevant in disease management, enabling real-time symptom documentation, remote monitoring, and timely interventions [24-27]. Their portability, good availability, and widespread use make MHAs particularly valuable for managing health issues, as reflected in the growing digital health market. By the third quarter of 2020, the Apple App Store offered 48,608 medical mHealth apps (up from 44,384 in Q3 2019) and a total of 82,633 health and fitness apps [28].

In Germany, MHAs can be certified as digital health apps (DiGAs), making them eligible for prescription and reimbursement through public health insurance since 2019 [29,30]. As part of the Digital Healthcare Act—the first law worldwide to integrate digital therapeutics into public care—DiGAs support patient self-management, improve therapy adherence, and facilitate communication by enabling the sharing of patient-generated data [29].

Challenges such as reimbursement issues, digital literacy, and variable acceptance among health care providers and patients limit the use of DiGAs, and currently, no certified DiGA or high-quality app exists specifically for CSU [31,32]. Given the clinical need and patient demand, identifying and evaluating existing MHAs for CSU is essential to guide the development of effective, user-centered digital solutions.

Objective

The aim of this study was to identify MHAs currently available for patients with CSU, evaluate their quality and usability, and assess the technological preferences and needs of both patients and physicians. Based on these insights, recommendations for the development of future patient-centered CSU apps were derived.

Methods

Ethical Considerations

This analysis was approved by the Ethics Committee of the University of Würzburg (reference: 20230918 02) in accordance with the ethical standards established by the Declaration of Helsinki. All participants gave informed consent. Data was fully anonymized; no personal information was collected. No compensation was provided to the participants.

XSL•FO
RenderX

The reporting of this study followed established principles for transparent and structured reporting of research: STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) guidelines (Checklist 2).

App Screening

Between January 1 and March 31, 2024, 2 independent dermatologists with expertise in the management of urticaria conducted a systematic search of the Apple App Store, Google Play Store, and the internet using search engines (eg, Google and Safari) for mobile apps designed for patients with CU. Search terms used were "urticaria," "spontaneous urticaria," "hives," "itching," "angioedema," "wheal," and "swelling." Inclusion criteria were defined as (1) availability on at least 1 of the specified platforms (Apple App Store, Google Play Store, or internet-based) and (2) language support in either German or English. Exclusion criteria comprised the (1) presence of advertisements, (2) a lack of patient-centered content—meaning content that primarily focuses on supporting the care and self-management of patients, or (3) a primary focus on clinical trials or scientific conferences. Apps containing advertisements were excluded in order to avoid potential disruptions to user experience and to control for confounding effects on usability [33]. Each app was assessed individually and independently. Discrepancies between reviewers were resolved through discussion. No automation tools were used during the screening process.

The primary outcomes for which data were sought included app functionality (eg, symptom tracking, disease activity scores, and medication reminders), user engagement features (eg, personalization and notifications), and data protection or privacy measures. All available features and descriptions provided in app store listings or within the apps themselves were reviewed. All data reflected the app status at the time of assessment.

For each app, the following variables were collected, if available: app name, platform availability (Apple App Store, Google Play Store, Google, and Safari), search term used, app topic (primary focus or intended purpose), total number of hits per search term, supported languages (German and English), app store rating and number of user ratings, target user group (patients and health care professionals), cost (free or paid), presence of advertisements, date of access, and inclusion of specific features such as symptom scores or disease monitoring tools.

A total of 15 apps were identified. After applying the inclusion and exclusion criteria, only one app, the CRUSE Control app, met the required criteria. The app was available on both Apple App Store and Google Play Store and supported German and English languages.

This study focuses on comparing app quality and usability between patients and physicians, rather than providing absolute ratings of individual apps.

Raters' Characteristics

Patients were randomly selected from our outpatient clinic to reduce selection bias and obtain a diverse user perspective. Similarly, physicians were randomly selected among those working in the same outpatient clinics and regularly treating patients with CSU. As the primary aim of the study is to assess app quality and usability, detailed information on participants' social background, educational level, and clinical characteristics (eg, comorbidities or urticaria subtype) was not collected. This decision was made to minimize participant burden and maintain focus on the usability aspects of the app within the scope of this exploratory investigation.

Patients and physicians tested the CRUSE Control app version corresponding to the operating system available on their personal smartphones (iOS or Android). If they did not own a mobile device, they used a provided iPhone.

Evaluation of App Quality

The Mobile Application Rating Scale (MARS) is a widely used tool for evaluating the quality of mobile apps [34]. It consists of 19 items across four categories: engagement, functionality, aesthetics, and information. Each item is rated on a 5-point Likert scale, with higher scores indicating higher quality. The overall MARS score is calculated as the mean value of these four subscale scores. In addition, there is a separate "subjective" section to capture the user's personal impression of the app.

For this study, the validated German version of Mobile Application Rating Scale (MARS-G) [35] and the end-user version of Mobile Application Rating Scale (uMARS) were applied to assess the quality of MHAs. The uMARS represents a simplified version of the MARS designed for end users and has been shown to reliably assess the quality of MHAs [17]. The MARS-G includes an additional section, which evaluates therapeutic quality and safety across 4 dimensions: patient benefit, therapist benefit, potential risks, and transferability to routine care. It is referred to as the Psychotherapy Section in the questionnaire provided by Messner et al [35].

Although the German translation of the uMARS used in this study has not been formally published, its items are identical to those of the validated MARS-G. A comparative analysis between physicians' and patients' MARS and uMARS was conducted.

For clarity, the term "MARS" or "uMARS" is used throughout the manuscript to refer to this German version.

Evaluation of App Usability

The G-MAUQ (German mHealth App Usability Questionnaire), the German validated version of the MAUQ, is a usability assessment tool for MHAs [36]. With 18 questions in 3 subcategories, it assesses the user's perspective of the app's ease of use, interface, and overall satisfaction and usefulness.

A total of 23 physicians assessed the app, appropriate for patients with CSU, using MARS-G to evaluate quality and G-MAUQ to assess usability. Simultaneously, 16 patients with CSU rated the same app, applying the uMARS for quality assessment and the G-MAUQ for usability evaluation. Prior to completing the evaluations, all participants were instructed to test each app for at least 10 minutes. A comparative analysis between physicians' and patients' G-MAUQ was conducted.

XSL•FO
RenderX

Evaluation of Technical Affinity

The physicians' and patients' technology affinity was assessed using the affinity for technology interaction (ATI) scale and the Mobile Device Proficiency Questionnaire (MDPQ-16). The ATI is a well-established and widely used measure of an individual's general affinity for technology consisting of 9 questions [37]. The 16-question MDPQ-16 is also used to assess technology affinity specifically related to the use of mobile devices [38].

Spearman rank correlation coefficient and Pearson correlation coefficient were used to correlate the ATI scale and MDPQ-16 score with ages of physicians and patients and the MDPQ-16. A comparative analysis between physicians' and patients' ATI and MDPQ-16 was conducted.

Statistical Analysis

The calculations were performed using SPSS, version 23 (IBM Deutschland GmbH). Following the testing of the data for normal distribution with Shapiro-Wilk, either the Mann-Whitney *U* or *t* test was used. *P* values less than .05 were considered statistically significant. Correlation analysis was conducted using both the Spearman and Pearson correlation coefficients.

Evaluation of Patients' Need for a Patient App

Both physicians and patients completed a questionnaire specifically designed for this analysis. This questionnaire included open-ended questions regarding MHAs and their needs and expectations regarding such apps.

Results

App Screening and Selection

A total of 15 urticaria-related apps were identified: 14 in the Apple App Store and 13 in the Google Play Store. Of these, 12 were identified in both App Stores, and 11 of these apps were excluded for the following reasons: not specific to CSU (n=10) and not patient-centered (n=1; Figure 1).

Figure 1. App selection.

Only 1 currently available patient-centered urticaria app was identified: the CRUSE Control Urticaria app, a CU self-evaluation app available in both Apple App Store and Google Play Store. It was developed by Urticaria Centers of Reference and Excellence and is available in English and German. We tested version 1.0.69, last updated in November 2023.

The app offers patients with CU the opportunity to receive support in managing their condition. It provides a platform for daily documentation of symptoms and impact on quality of life within a few minutes. By sharing data with the treating physician, the efficacy of the current therapy and treatment can be optimized.

The app comprises 6 principal sections, each of which provides distinct functionality to assist patients with CU. In the "Daily Documentation" section, patients are required to evaluate the impact of urticaria over the preceding 24 hours. The questions are based on established scales, including the UAS and the Angioedema Activity Score. Additionally, patients are queried on a monthly basis regarding disease management, with questions based on the UCT and the Angioedema Control Test. The impact on the patient's quality of life is assessed using the Chronic Urticaria Quality of Life Questionnaire and the Angioedema Quality of Life Questionnaire. Furthermore, daily medication intake and dosage are recorded.

The "Results Review" section enables users to monitor their daily progress in relation to the UAS and Angioedema Activity Scores, as well as their long-term disease management via the UCT, Angioedema Control Test, and quality of life indicators. In the "Profile View" section, patients may view and update their personal information. The "Preparation for Doctor's Visit" section allows patients to prepare relevant information and questions for their upcoming appointment. Furthermore, patients

XSL•FO
RenderX

have the option of uploading images of their urticaria in this section. A reminder function is provided to ensure that important appointments and medication dosages are not overlooked. Ultimately, the "Information about Urticaria" section offers valuable, patient-oriented material to facilitate comprehension of the condition. The link to the "Hello Professor" function provides valuable medical information that expands patients' knowledge and increases their confidence in dealing with the disease.

The data collected can be summarized in a report for the physician, which may be transmitted via email or shared through a QR code. The integration of these elements facilitates uninterrupted and comprehensive observation of the condition, while also enhancing communication between patients and health care professionals (Table 1).

Table . Overview of patient-centered features in the CRUSE Control app.

Section/feature	Description/functionality	Notes/relevance to patient care
"Daily Documentation"	Daily symptom tracking (UAS[a], AAS[b]), monthly disease management (UCT[c], AECT[d]), quality of life (CU-Q2oL[e], AE-QoL[f]), medication intake	Enables monitoring of disease activity and therapy efficacy
"Results review"	Visualization of progress and long-term disease control	Supports self-management and gives insight into therapy outcomes
"Profile View"	View and update personal information	Personalization of patient data
"Preparation for Doctor's visit"	Upload images, prepare questions, reminders for appointments and medication	Enhances communication with physician and appointment readiness
"Information about Urticaria"	Educational content about the condition, "Hello Professor" cross-reference	Improves patient understanding and confidence
"Data Sharing"	Generate report for physician via email or QR code	Facilitates continuous monitoring and physician feedback

[a]UAS: urticaria activity score.

[b]AAS: angioedema activity score.

[c]UCT: urticaria control test.

[d]AECT: angioedema control test.

[e]CU-Q2oL: Chronic Urticaria Quality of Life Questionnaire.

[f]AE-QoL: Angioedema Quality of Life Questionnaire.

Raters' Characteristics

The app was evaluated by 23 dermatologists and 16 patients with CSU. Mean age was 34.0 (SD 9.7) years in physicians and 40.0 (SD 13.4) years in patients. The physicians' group was comprised of 6 men and 17 women, while the patients' group included 6 men and 10 women. All patients experienced multiple episodes of urticaria per month, lasting at least 12 weeks in total. Additionally, they reported sleep disorders and anxiety related to their condition.

Evaluation of App Quality, Including Comparative Analysis of Patients' and Physicians' Data

Only the CRUSE Control app met the inclusion criteria and was included in this analysis. The results of the MARS and uMARS scores for the app are shown in Tables 2 and 3.

Table . MARS[a] score of the CRUSE Control app assessed by 23 physicians. Maximum MARS score: 5 points. In addition to the validated German version of Mobile Application Rating Scale core sections, the table includes the psychotherapy section—an extension in the German MARS that evaluates therapeutic quality across 4 dimensions (patient benefit, therapist benefit, risks, and transferability to routine care) as described by Messner et al [35].

	CRUSE Control app, mean (SD)
MARS score	4.03 (0.45)
Engagement score	3.67 (0.71)
Functionality score	4.47 (0.55)
Esthetics score	4.10 (0.56)
Information score	3.86 (0.49)
Subjective quality	3.49 (0.42)
Psychotherapy score	3.83 (0.61)

[a]MARS: Mobile Application Rating Scale.

XSL•FO
RenderX

Table . uMARS[a] score of the CRUSE Control app assessed by 16 patients with urticaria. Maximum uMARS score: 5 points.

	CRUSE Control app, mean (SD)
uMARS score	4.06 (0.40)
Engagement score	3.55 (0.62)
Functionality score	4.75 (0.41)
Esthetics score	4.10 (0.45)
Information score	3.82 (0.81)
Subjective quality	3.35 (0.60)

[a]uMARS: end-user version of Mobile Application Rating Scale.

The quality of the CRUSE Control app was evaluated by both physicians and patients using the MARS or its user version (uMARS). Physicians and patients provided similar ratings, with an average score of 4.03 (SD 0.45) out of 5 for physicians and 4.06 (SD 0.40) for patients (*P*=.83), suggesting an overall high quality of the app. In most subcategories, including engagement (*P*=.58), esthetics (*P*=.97), information (*P*=.86), and subjective quality (*P*=.64), the ratings were closely aligned between the 2 groups. However, patients rated the functionality of the app significantly higher than physicians, with an average score of 4.75 (SD 0.41) compared to 4.47 (SD 0.55; *P*=.04). The subcategory measuring "Psychotherapy" was only included in the MARS for physicians. This section addresses the quality criteria for apps with respect to patient safety, the use of the app's presentation, and the quality of the therapeutic offerings. They scored it with an average of 3.83 (SD 0.61).

Evaluation of App Usability, Including Comparative Analysis of Patients' and Physicians' Data

The usability of the CRUSE Control app was assessed similarly by both physicians and patients. Using the G-MAUQ to measure usability, physicians gave an average score of 5.85 (SD 0.71) out of 7, while patients rated it slightly lower with an average score of 5.76 (SD 0.41) out of 7. No significant difference was found between the 2 groups (*P*=.64), as shown in Table 4. In the subcategories of G-MAUQ, both physicians and patients rated "Ease of Use" (6.27, SD 0.68 vs 6.45, SD 0.57), "Interface and Satisfaction" (6.04, SD 0.68 vs 6.00, SD 0.52), and "Usefulness" (5.30, SD 0.98 vs 4.91, SD 0.87) similarly. However, when looking at the absolute scores, patients rated "Usefulness" 0.39 points lower than physicians, though this difference was not statistically significant (*P*=.20).

Table . Evaluation of the CRUSE Control app with G-MAUQ[a] and G-MAUQ subscales by physicians and patients. Maximum G-MAUQ score: 7 points.

	Physicians (n=23), mean (SD)	Patients (n=16), mean (SD)	*P* value
G-MAUQ	5.85 (0.71)	5.76 (0.41)	.68
Ease of use	6.27 (0.68)	6.45 (0.57)	.51
Interface and satisfaction	6.04 (0.68)	6.00 (0.52)	.83
Usefulness	5.30 (0.98)	4.91 (0.87)	.20

[a]G-MAUQ: German mHealth App Usability Questionnaire.

Evaluation of Technical Affinity, Including Comparative Analysis of Patients' and Physicians' Data

The ATI score and the MDPQ-16 score, which evaluate the users' affinity for technology, were recorded for both patients and physicians.

Physicians achieved a mean ATI score of 3.50 (SD 0.66) out of 6 points and a MDPQ-16 score of 4.81 (SD 0.26) out of 5 points. Patients, on the other hand, had a mean ATI score of 4.00 (SD 0.88) and a MDPQ-16 score of 4.74 (SD 0.45; *P*=.05). Although there were no statistically significant differences between the 2 groups, both groups considered themselves highly experienced in mobile device usage, as indicated by their similar MDPQ-16 scores (physicians: 4.81, SD 0.26; patients: 4.74, SD 0.45; *P*=.60), as shown in Table 5.

Table . Evaluation of technical affinity using the ATI[a] scale and short version of MDPQ-16[b] score. Maximum affinity for technology interaction score: 6 points; maximum MDPQ-16 score: 5 points.

	Physicians (n=23), mean (SD)	Patients (n=16), mean (SD)	*P* value
ATI	3.50 (0.66)	4.00 (0.88)	.05
MDPQ-16	4.81 (0.26)	4.74 (0.45)	.60

[a]ATI: affinity for technology interaction.

[b]MDPQ-16: Mobile Device Proficiency Questionnaire.

XSL•FO
RenderX

The Spearman correlation coefficient revealed a slight negative correlation between the ATI score and age for both physicians (−0.224; *P*=.30) and patients (−0.290; *P*=.28). The younger the physicians and patients were, the more likely they were to consider themselves technology-savvy (ATI).

A small positive correlation was observed between the ATI score and MDPQ-16 score, with a coefficient of 0.256 (*P*=.24) for physicians and 0.322 (*P*=.22) for patients.

When analyzing both groups together, the Spearman correlation between ATI score and age was −0.206 (*P*=.21), and between ATI score and MDPQ-16 score, it was 0.309 (*P*=.06).

Patients' Expectations and Comments

The open-ended questionnaire provided valuable insights into patients' expectations and preferences regarding MHAs for managing urticaria. The 16 patients expressed a high level of openness to using MHAs to support their condition. Key functionalities that patients found particularly important included symptom tracking (n=14, 88%), photo documentation (n=15, 94%), medication management (n=14, 88%), and a note-taking and question feature (n=14, 88%). Almost half of the patients indicated a desire for an introductory guide to the app and technology training, as well as a digital companion to assist with navigation and provide encouragement. Additionally, 10 (63%) patients expressed interest in having a chat function with their doctor and a platform to connect with other individuals affected by urticaria.

A majority of the 16 patients (n=11, 69%) also requested a feature that would help organize and remind them of appointments. Other specific areas where patients sought support included information and educational content (n=11, 69%), tips for symptom management (n=11, 69%), psychosomatic support (n=5, 32%), and holistic treatment approaches (n=10, 63%).

To ensure regular use of the app, patients indicated that it would need to offer tangible improvements in their care, particularly by helping them manage their condition more effectively. Under these conditions, patients were open to using the app more than three times a week.

Additional patient wishes included "disease progression documentation," "symptom tracking," "support during acute flare-ups," "therapy suggestions," "features for identifying triggers," "emergency support features," "behavioral guidance for daily living," and "user-friendly interface."

Regarding the design of the CRUSE Control app, 14 (88%) out of 16 patients rated it at less than or equal to 7 out of 10 points. The information content was rated favorably by 12 (75%) out of 16 patients (≥7/10 points), while the usability and functionality were also rated positively by 12 (75%) and 10 (63%), respectively.

Discussion

Principal Findings

This study provides the first systematic analysis of MHAs for patients with CSU available in the App Stores and online. The patient cohort (mean age 40, SD 13.4 y; 6 men and 10 women) reflected the typical demographic pattern in CSU, with women being affected approximately twice as often as men [5,7,8]. The physician cohort (mean age 34, SD 9.7 y; 6 men and 17 women) represented the younger and predominantly female demographic commonly observed among university hospital staff in dermatology [39]. Despite broad inclusion criteria, only 1 out of 15 identified CSU apps met all predefined requirements. This highlights a substantial gap in the digital support landscape for CSU and underscores the need for targeted research and development of high-quality, evidence-based apps.

The episodic nature of CSU presents significant challenges for an accurate assessment of disease severity and activity [2]. Physicians rarely have the opportunity to observe patients during active flare-ups and rely on retrospective patient reports, photographs, and time-consuming interviews, which may result in misclassification and suboptimal treatment decisions. However, current guidelines recommend regular monitoring, ideally daily to weekly, using validated instruments such as the UAS and UCT to guide therapeutic adjustments [15]. MHAs have the potential to provide the solution. They constitute promising tools for continuous real-time symptom documentation, consolidating data into overviews to support both patients and physicians, and enhancing patient self-management and confidence. As their use in health care is becoming increasingly popular and steadily expanding, there is a growing need for their comprehensive and standardized evaluation [40]. A systematic review and evaluation of available medical apps, as provided by this study, using established and validated evaluation tools, is essential to gather feedback from both users (patients) and physicians (prescribers). This feedback will play a critical role in the ongoing development of MHAs [24,41]. The more closely an MHA is aligned with the needs of its users, the greater the likelihood of sustained engagement and long-term use [42].

The identified app, the CRUSE Control app, received high ratings across all MARS subdomains, including engagement, functionality, esthetics and information, with mean ratings of 4.03 (SD 0.45) on the MARS and 4.06 (SD 0.40) on the uMARS. However, high-quality ratings alone do not necessarily ensure sustained use [43]. Research has consistently shown that many MHAs, even those with favorable initial evaluations, experience a sharp decline in user engagement over time. In a mental health app, for instance, retention rates dropped to as low as 3.3% after 30 days [44]. Long-term adherence poses a major challenge in digital health [45] but is essential for achieving meaningful clinical outcomes. This is particularly important for chronic conditions such as CSU, which require ongoing monitoring of symptoms.

The positive evaluation of the CRUSE Control app is promising. Its high functionality and intuitive design facilitates rapid symptom documentation. This can reduce time burden and potentially support sustained user engagement, a factor consistently recognized as essential for long-term adherence in previous studies [46,47].

Although a user-friendly design may enhance initial engagement, sustained engagement ultimately depends on the app's ability to meet the specific needs of its target users [47].

XSL•FO
RenderX

In this study, the differing priorities of consumers were reflected in the evaluations.

Physicians rated the functionality of the CRUSE Control app significantly lower than patients (P=.04) [41,48]. They rather emphasized clinical relevance, accuracy, reliability, and integration into workflows. Their focus was on precise data collection, treatment support, and evidence-based decision-making to ensure that the app meets medical standards and functions without errors. Clinical quality was also confirmed by the physicians' rating of the psychotherapy subcategory (mean 3.83, SD 0.61). It was relatively high, indicating favorable assessments of patients' safety, the suitability of app-based delivery, and the quality of therapeutic content.

In contrast, patients valued ease of use, intuitive navigation, and practical features for daily self-management. Rapid symptom documentation, completed within minutes, was seen as a major advantage. It reduced user burden and likely promoted adherence and sustained engagement. In subcategory functionality, patients appreciated particularly its usability and its role in everyday health management.

The G-MAUQ usability score reflects this positive perception of both groups. Physicians and patients alike rated the CRUSE Control app highly for usability, with "ease of use" and "user satisfaction" scores nearing 6 out of 7 on the G-MAUQ. The ratings of the app's "usefulness" were slightly lower, though the differences between the groups were not significant.

Despite differences in priorities and usability needs, these high ratings indicate that both groups find significant value in the app: physicians for its clinical use and patients for its support in self-management.

Both patients with CSU and physicians demonstrated high technological affinity and competence in using mobile devices, as reflected by high ATI and MDPQ-16 scores. Hence, MHAs can be adopted and used effectively by this group [49,50]. A slight negative correlation between age and technological affinity was observed. This indicates that younger individuals tend to be more comfortable with digital tools. Older users may need additional support to ensure equitable access and sustained engagement.

Patient feedback in the open-ended questionnaire demonstrated a clear willingness to use MHAs for managing CSU, particularly if the app offered real benefits such as symptom tracking, photo documentation, and medication management. Patients wish for psychosocial support, education, and communication features. A future app could integrate community and peer support functionalities through health care professional–moderated forums or support groups, aiming to reduce patient isolation and encourage sharing personal experiences.

Limitations

Data collection focused on app ratings, without detailed clinical data such as disease severity or duration, which limits potential correlations with app use. The short-term evaluation of a single app without direct comparison to other CSU apps may have introduced some bias. The relatively young study population also limits the generalizability of the findings to older patients.

A major limitation of this study is that only 1 app met the predefined inclusion criteria at the time of the search, potentially introducing selection bias. The findings primarily reflect the characteristics of this single app and should be interpreted with caution regarding the broader CSU mHealth landscape. Because CRUSE Control is a well-developed and medically guided app, there is a possibility of performance or reporting bias, which could have led to an optimistic assessment of the potential of mHealth for CSU.

Future studies should include broader clinical data, longer follow-up, and direct comparisons across multiple CSU apps to reduce bias and enhance generalizability.

Conclusions

Despite broad search criteria, only 1 app met all inclusion requirements, highlighting a significant gap in digital support for patients with CSU. Both patients and physicians rated the app highly in terms of quality, usability, and information content. Patients rated functionality significantly higher, reflecting differing priorities between ease of daily use and clinical rigor. High technological affinity among both groups suggests favorable conditions for MHA adoption. Patients expressed clear interest in features supporting symptom tracking, medication management, and psychosocial support, emphasizing the need for patient-centered designs and onboarding assistance. Overall, MHAs show great potential to enhance CSU care.

While these findings are limited to a single app, they indicate that MHAs may have the potential to enhance CSU care. Future research should incorporate broader clinical parameters, longer follow-up, and diverse patient populations to further assess app effectiveness and optimize digital health tools for CSU management.

Acknowledgments

The authors sincerely thank all the patients and physicians who participated in this study. Their input was essential in advancing our understanding of mobile health apps for managing chronic spontaneous urticaria. No generative artificial intelligence tools were used in the writing or editing of this manuscript.

Abstract

Background: Exercise prescription is a structured and individualized intervention that requires appropriate progression, tailoring, and behavioral support to ensure safety and long-term effectiveness. With the expansion of mobile health technologies, exercise prescription apps are increasingly used to support the remote delivery of prescribed exercise programs. However, the extent to which widely adopted apps align with established clinical standards remains unclear.

Objective: This study aimed to evaluate the clinical usability of popular, no-cost exercise prescription apps from a professional perspective, focusing on clinical integrity, intervention fidelity, behavioral mechanisms, and clinician-assessed digital usability.

Methods: A systematic search of Google Play and the Apple App Store identified widely adopted apps that enable clinician-directed exercise prescription. Eligible apps were evaluated using established frameworks, including the frequency, intensity, time, and type (FITT) and FITT, volume, and progression (FITT-VP) principles; the Consensus on Exercise Reporting Template (CERT); the Behavior Change Technique Taxonomy version 1 (BCTTv1); and the Mobile App Rating Scale (MARS). Descriptive analyses and interrater reliability assessments were performed.

Results: Six apps met the inclusion criteria. All satisfied the basic FITT requirements; however, none incorporated explicit guidance on exercise progression or individualized adjustment consistent with the FITT-VP principles. CERT evaluation demonstrated comprehensive reporting of structural components but a consistent absence of progression logic, tailoring strategies, and adverse event documentation. Although multiple behavior change techniques were identified, several techniques considered important for graded progression and sustained adherence in unsupervised settings were infrequently implemented or absent. Overall app quality was moderate, characterized by strong functionality but limited engagement. Only 2 apps reported evidence of scientific evaluation.

Conclusions: Widely adopted exercise prescription apps meet fundamental structural requirements but do not fully support the progressive and individualized processes central to clinical exercise prescription. These findings highlight a gap between structural prescription delivery and independent clinical exercise management. Exercise prescription apps may therefore be most appropriately positioned as adjunctive tools within clinician-guided or hybrid care models. Future development should prioritize transparent progression mechanisms, individualized adjustment, and the implementation of clinically relevant behavior change strategies to enhance safety and long-term effectiveness.

Introduction

Exercise prescription is a structured and individualized program of exercise, systematically designed to improve health or functional capacity, and these programs are commonly developed by specialists on the basis of patients' clinical status, goals, and needs [1]. Physicians in physical medicine and rehabilitation, as well as in primary care, routinely prescribe exercise as both treatment and secondary prevention for a broad range of conditions, including musculoskeletal, cardiovascular,

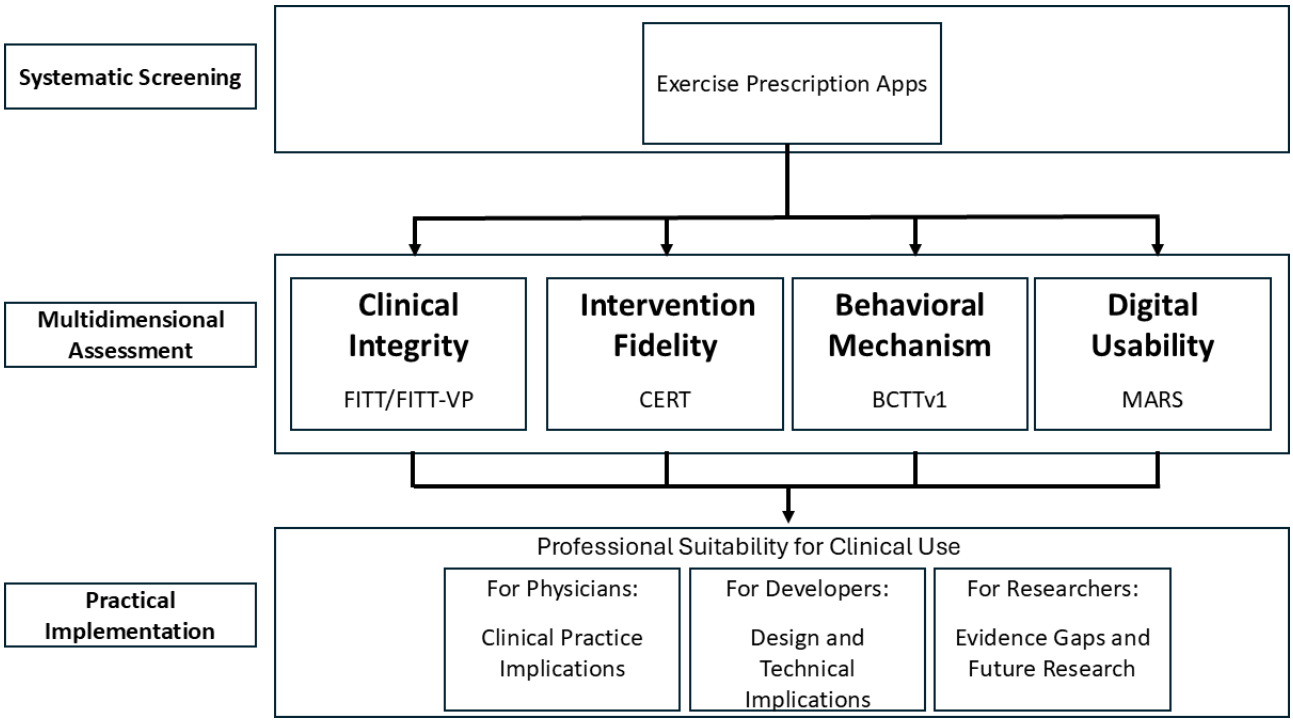
XSL•FO
RenderX

neurological, and pulmonary diseases [2-9]. Given this wide scope of application, precision is essential to ensure both safety and effectiveness. According to the American College of Sports Medicine (ACSM), exercise prescription should specify exercise frequency, intensity, time, and type (FITT), with additional consideration of volume and progression (FITT-VP) to support appropriate physiological adaptation and minimize the risk of adverse events [10]. When these elements are appropriately defined and individualized, exercise therapy can deliver evidence-based benefits while reducing the likelihood of exercise-related harm [11].

With the expansion of mobile health (mHealth) technologies, exercise prescription apps have emerged as tools to support the remote delivery of prescribed exercise programs. These systems typically consist of a clinician-facing prescription platform and a patient-facing app, enabling clinicians to design structured exercise programs that patients can access via mobile devices or computers. Prior studies indicate that digitally supported exercise interventions can be feasible, cost-effective, and minimally disruptive to daily life while maintaining patient satisfaction with outpatient services [12-15]. Randomized controlled trials have further demonstrated improvements in adherence to home exercise programs and increased confidence in exercising [16]. Since the COVID-19 pandemic, the growing adoption of digital health solutions has also expanded the use of online training platforms and home-based exercise apps [17-20]. Moreover, app-supported exercise prescription has shown potential benefits in specific clinical populations, including individuals with sarcopenia [21], myocardial infarction [22], or long COVID [23].

Despite growing evidence supporting the feasibility and effectiveness of digitally delivered exercise interventions, concerns remain regarding the professionalism and completeness of exercise prescriptions generated by mobile apps [24]. Compared with face-to-face care, mobile platforms may limit the delivery of detailed instructions, real-time biomechanical feedback, and hands-on correction, all of which are integral to safe and effective exercise prescription. From a professional perspective, the suitability of exercise prescription apps depends on their ability to support clinicians in prescribing, monitoring, and adjusting exercise programs in accordance with established clinical standards. Key considerations include whether exercise prescriptions adequately address essential ACSM components, whether intervention delivery is transparent and reproducible, and whether behavioral strategies are incorporated to support adherence in unsupervised or remote settings. In addition, the rapid development cycles of commercial apps raise concerns regarding usability, consistency, and quality from a clinical perspective [25]. While existing evaluations of health apps often focus on general users, single-disease outcomes, or basic activity tracking [26-30], evidence remains limited regarding the extent to which widely used exercise prescription apps meet professional requirements for clinical prescription and implementation.

To address these gaps, this study adopted a clinician-centered, multidimensional evaluation framework to assess whether popular, no-cost exercise prescription apps are suitable for professional clinical use. The evaluation focused on 4 complementary domains reflecting core requirements of exercise prescription in real-world practice: clinical integrity of exercise prescriptions, intervention fidelity and transparency, behavioral mechanisms supporting adherence, and digital usability and overall app quality. These domains were operationalized using established and validated instruments, including the FITT and FITT-VP principles, the Consensus on Exercise Reporting Template (CERT), the Behavior Change Technique Taxonomy version 1 (BCTTv1), and the Mobile App Rating Scale (MARS). By integrating these perspectives, this study extends beyond general app quality or user-centered evaluations and provides a structured professional assessment of exercise prescription apps intended for clinician-guided care.



Methods

Study Design and Conceptual Framework

This study adopted a clinician-centered, cross-sectional evaluation design to assess exercise prescription apps intended for professional use. A multidimensional evaluation framework was applied to reflect the key components of clinical exercise prescription practice (Figure 1).

XSL•FO
RenderX

Figure 1. Conceptual framework for clinician-centered evaluation of exercise prescription apps. BCTTv1: Behavior Change Technique Taxonomy version 1; CERT: Consensus on Exercise Reporting Template; FITT: frequency, intensity, time, and type; FITT-VP: frequency, intensity, time, type, volume, and progression; MARS: Mobile App Rating Scale.

The framework included four domains: (1) clinical integrity, (2) intervention fidelity, (3) behavioral mechanism, and (4) digital usability. These domains were operationalized using established instruments: the FITT and FITT-VP principles, CERT, BCTTv1, and MARS.

Ethical Considerations

This study did not involve human participants, human data, or human biological materials. Therefore, institutional ethics board review and approval were not required.

App Identification and Search Strategy

This review adhered to the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) protocol, as detailed in the PRISMA 2020 statement (Checklist 1) [31]. A systematic search of Google Play and the Apple App Store was conducted on July 13, 2024, using Taiwanese regional settings. The following search terms were used: “exercise prescription AND doctor,” “exercise prescription AND therapist,” and “exercise prescription AND rehabilitation.” Duplicate apps were removed.

Apps were eligible if they were free, available in English or Chinese, designed for adult users, and not disease specific; did not require additional equipment; and allowed clinicians to prescribe exercise programs. To ensure market relevance, only apps available on both platforms with more than 10,000 downloads were included. A comprehensive and transparent description of this search process is provided in Multimedia Appendix 1.

Evaluation Framework and Domains

Clinical Integrity (FITT and FITT-VP)

Clinical integrity was assessed using the FITT and FITT-VP principles [10]. Apps were considered to meet the FITT criteria if all 4 core components were explicitly specified within the prescribed exercise programs. In addition, adherence to FITT-VP required explicit progression rules or defined mechanisms for adjusting the exercise volume or intensity over time.

Intervention Fidelity (CERT)

Intervention fidelity was evaluated using CERT, a 16-item checklist designed to assess the completeness and transparency of exercise interventions [32,33]. The CERT domains include materials, provider qualifications, delivery procedures, setting, dosage, tailoring, and adherence. Apps were assessed using a checklist approach to determine whether each CERT item was addressed. Achievement rates were calculated for individual items. The primary outcome was the achievement rate for individual CERT items.

Behavioral Mechanism (BCTTv1)

Behavioral mechanisms were evaluated using BCTTv1, a standardized framework for identifying discrete behavior change techniques (BCTs) within interventions [34]. The taxonomy includes 93 techniques and has been extended in mHealth apps to encompass 102 techniques [35]. Each app was systematically reviewed to identify the presence of BCTs according to BCTTv1 definitions. Achievement rates were calculated as the proportion of apps implementing each technique.

In this study, a predefined subset of BCTs within the BCTTv1 was designated as critical BCTs. These techniques were selected on the basis of prior studies examining strategies associated

XSL•FO
RenderX

with exercise initiation, maintenance, and physical activity promotion in digital or remote interventions [36-38]. The selected techniques were grouped into three functional categories: (1) behavior initiation, (2) behavior maintenance, and (3) promotion of physical activity (Multimedia Appendix 2). Achievement rates for this predefined subset were calculated separately.

Digital Usability (MARS)

Digital usability and overall app quality were evaluated using MARS, which assesses engagement, functionality, aesthetics, and information quality on a 5-point scale [39,40]. To assess the evidence base component of information quality, supporting scientific literature was identified through database searches in PubMed and Google Scholar, as well as through app descriptions and developer websites. Each item was independently rated by 2 reviewers.

Sample Assessment Procedure

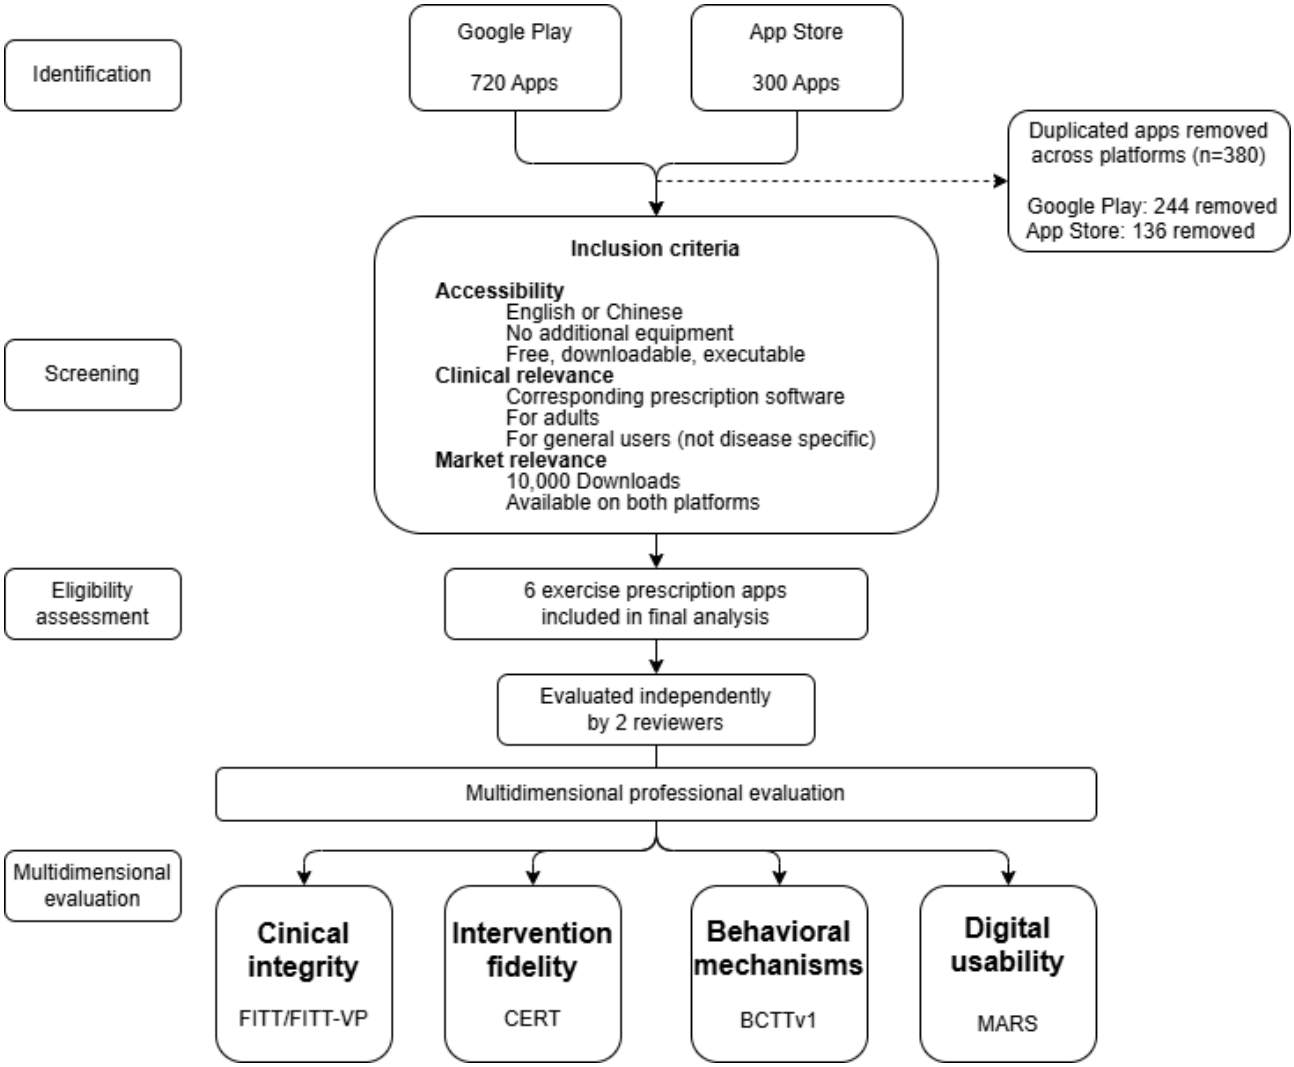
All included apps were evaluated using their full range of patient-facing functions. Web-based prescription platforms were not assessed.

Each app was independently reviewed by 2 clinicians (CHW and CNC), both resident physicians with more than 3 years of clinical experience and extensive experience using Android and iOS systems. Prior to evaluation, both reviewers completed formal BCTTv1 training and certification and familiarized themselves with the CERT and MARS protocols. To calibrate scoring interpretations, 5 additional health and fitness apps not included in the final sample were jointly reviewed before data collection.

All apps were installed on an Apple iPhone 8 running iOS version 16.3.1 and a Samsung SM A5360 running Android version 13. Reviewers examined all available features for at least 30 minutes per app. Discrepancies in coding were resolved through discussion, and a third reviewer (YCC) was consulted when consensus could not be reached.

Data Extraction and Statistical Analysis

For our study, descriptive data were gathered from Google Play on July 29, 2024, using a Taiwanese account and regional settings. We collected information on app titles, developers, versions, and download numbers directly from the app listings. We chose not to include data from the App Store, as it closely mirrored the information available on Google Play but was less extensive. Ratings and review counts were also excluded from our analysis due to their significant variability across different countries, which complicates comparisons due to the apps' broad international user base. All statistical analyses were conducted using MedCalc Statistical Software (version 22.0.21; MedCalc Software Ltd). Given the exploratory design, descriptive statistics were primarily employed to present the findings. Interrater reliability was also assessed using Cohen κ or intraclass correlation coefficient (ICC) to determine the level of agreement between the 2 raters [41].



Results

App Identification and Selection

The initial search yielded a total of 1020 apps (each search term yielded 240 apps on Google Play and 100 on the App Store). After removing duplicates and applying the inclusion and exclusion criteria, 6 exercise prescription apps were included in the final analysis (Figure 2). All included apps were available on both platforms; were free to download; supported clinical exercise prescription; and had exceeded 10,000 downloads at the time of assessments.

App Characteristics

As of July 29, 2024, the 6 apps included in our study demonstrated a wide range of installations, with numbers ranging from 10,000 to 1 million downloads (Table 1). The app developers were based in the United Kingdom, United States, Canada, and Australia. All apps were initially released between 2017 and 2020 and had all been updated in 2023 or 2024.

Table . Characteristics of included exercise prescription apps (N=6; July 29, 2024).

Clinical Integrity Assessment Based on FITT and FITT-VP Principles

All 6 apps met the FITT criteria, as they explicitly specified the exercise frequency, intensity, time, and type within prescribed exercise programs (Table 2). In contrast, none of the apps met the FITT-VP criteria. Across all apps, explicit guidance on progression of exercise volume or intensity over time was absent, and no app provided decision rules for adjusting exercise prescriptions based on user performance or program duration.

Table . Multidimensional evaluation results of included exercise prescription apps (N=6; July 29, 2024).

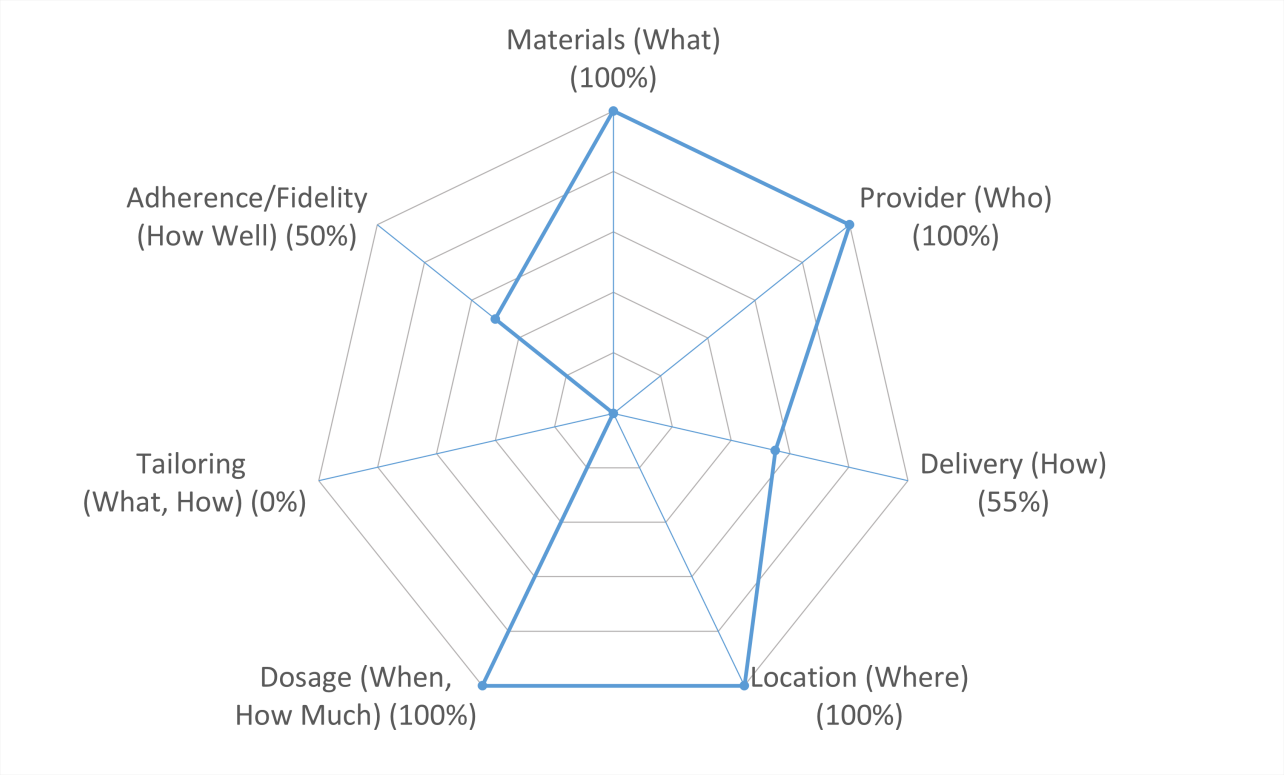
	PhysiApp	MedBridge GO for Patients	Wibbi	TrackActive Pro - Patient App	Rehab Guru Client	Telehab
Clinical integrity						
FITT[a]	Yes	Yes	Yes	Yes	Yes	Yes
FITT-VP[b]	No	No	No	No	No	No
Intervention fidelity						
CERT[c]	10	10	10	8	9	10
Behavioral mechanism						
BCTTv1[d]	18	16	15	14	15	19
Digital usability						
MARS[e]	3.82	3.85	3.36	3.36	3.55	3.99

[a]FITT: Frequency, intensity, type, time. “Yes” denotes full adherence to all 4 elements.

[b]FITT-VP: Frequency, intensity, type, time, volume, progression. “Yes” denotes full adherence to all 6 elements.

[c]CERT: Consensus on Exercise Reporting Template. Score indicates number of checklist items met (maximum=16).

[d]BCTTv1: Behavior Change Technique Taxonomy version 1. Number of identified behavior change techniques.



[e]MARS: Mobile App Rating Scale. Mean overall score on a 5-point scale.

Intervention Fidelity Assessment Based on CERT

Intervention fidelity varied across CERT domains (Table 3 and Figure 3). All 6 apps (100%) achieved complete reporting for core structural elements, including materials, provider qualifications, exercise setting, and dosage. Within the delivery domain, all apps specified whether exercises were performed individually or in groups and whether sessions were supervised or unsupervised. Of the 6 apps, 5 apps (83%) reported methods for assessing exercise adherence, and 4 apps (67%) included nonexercise components such as educational or dietary content.

XSL•FO
RenderX

Figure 3. Domain-level reporting patterns of the Consensus on Exercise Reporting Template across exercise prescription apps (N=6; 2024).

XSL•FO
RenderX

Table . Item-level achievement rates for the Consensus on Exercise Reporting Template (CERT) across included exercise prescription apps (N=6; 2024).

Abbreviated item description of CERT	Achievement rate
Materials (what)	
Detailed description of the type of exercise equipment	100%
Provider (who)	
Description of qualifications/expertise/training of instructor	100%
Delivery (how)	
Description of whether exercises are performed individually or in a group	100%
Description of whether exercises are supervised/unsupervised	100%
Description of the measurement/reporting of adherence to exercise	83%
Detailed description of motivation strategies	0%
Detailed description of the decision rule(s) of exercise progression	0%
Detailed description of how the exercise program was progressed	0%
Description of each exercise to enable replication (eg, illustrations and photographs)	0%
Description of any home programmed component	100%
Description of any nonexercise component	67%
Description of the type/number of adverse events that occurred during exercise	0%
Location (where)	
Description of exercise setting	100%
Dosage (when and how much)	
Description of exercise intervention and dosage	100%
Tailoring (what and how)	
Description of whether exercises are generic or tailored to the individual	0%
Detailed description of how exercises are tailored to the individual	0%
Decision rule for starting level of exercise	0%
Adherence/fidelity (how well)	
Description of how adherence or fidelity to the exercise intervention is assessed/measured	100%
Description of the extent to which the intervention was delivered as planned	0%

In contrast, no app (0%) reported motivational strategies, decision rules for exercise progression, or descriptions of how exercise programs were progressed over time. Similarly, none of the apps described whether or how exercises were tailored to individual users or how starting exercise levels were determined. Reporting of adverse events was absent across all apps, and none documented whether the prescribed intervention was delivered as planned. The comprehensive table with respective scoring can be found in Multimedia Appendix 3. Interrater reliability for CERT assessment was high (Cohen κ=0.88).

Behavioral Mechanism Assessment Based on BCTTv1

Overall Implementation of BCTs

Across the 6 included apps, a limited but heterogeneous set of BCTs was identified. When assessed against the original 93-item BCTTv1 taxonomy, the mean number of techniques implemented by apps was 13.2 (SD 1.77; range 11 - 16). When extended mHealth categories were included (102 techniques), the mean number of techniques increased to 16.2 (SD 1.77; range 14 - 19). The interrater reliability for BCT coding was high (Cohen κ=0.85).

Fourteen techniques were implemented across all apps (100% achievement), including goal setting (behavior), action planning, feedback on behavior, self-monitoring of behavior, instruction on how to perform the behavior, demonstration of the behavior,

XSL•FO
RenderX

and behavioral practice or rehearsal. Additional techniques were implemented in a subset of apps. The full list of identified BCTs and their achievement rates is presented in Table 4, and detailed coding results, including the extended 102-technique classification, are provided in Multimedia Appendix 4.

Table . Achievement rates of behavior change techniques (BCTs) identified from the full BCTTv1[a] taxonomy across included exercise prescription apps (N=6; 2024), ordered by frequency of implementation.

BCTTv1 code	BCT	Critical BCT[b]?	Achievement rate
1.1	Goal setting (behavior)	Yes	100%
1.4	Action planning	Yes	100%
1.5	Review behavior goal(s)	No	100%
2.1	Monitoring of behavior by others without feedback	No	100%
2.2	Feedback on behavior	Yes	100%
2.3	Self-monitoring of behavior	Yes	100%
4.1	Instruction on how to perform a behavior	Yes	100%
6.1	Demonstration of the behavior	Yes	100%
8.1	Behavioral practice/rehearsal	Yes	100%
9.1	Credible source	No	100%
12.6	Body changes	No	100%
17.1	Tailoring to demographic characteristics	No	100%
17.2	Tailoring to health status	No	100%
17.4	Adjusting intervention content to performance	No	100%
5.1	Information about health consequences	No	66%
10.4	Social reward	No	50%
1.3	Goal setting (outcome)	Yes	33%
1.7	Review outcome goal(s)	No	33%
2.5	Monitoring outcome(s) of behavior by others without feedback	No	33%

[a]BCTTv1: The Behavior Change Technique Taxonomy version 1. It comprises 102 distinct techniques. Only techniques identified in at least 1 app are presented; all remaining BCTTv1 items had an achievement rate of 0% across the evaluated exercise prescription apps.

[b]Critical BCTs were defined a priori as techniques with established relevance to exercise initiation, long-term maintenance, or physical activity promotion in digital or remote intervention contexts.

Predefined Clinically Relevant BCTs

Table 5 shows the predefined critical BCTs grouped into 3 functional categories: behavior initiation, behavior maintenance, and promotion of physical activity. Within behavior initiation, demonstration of the behavior and behavioral practice or rehearsal were incorporated by all apps (6/6, 100%), whereas biofeedback and graded tasks were not identified (0/6, 0%). For behavior maintenance, action planning and instruction on how to perform the behavior were universally implemented (6/6, 100%), while prompts or cues, graded tasks, and self-reward were absent (0/6, 0%). Among techniques associated with physical activity promotion, goal setting (behavior), action planning, feedback on behavior, and self-monitoring were consistently implemented, whereas social support, restructuring the physical environment, and framing or reframing were not identified.

XSL•FO
RenderX

Table . Achievement rates of predefined critical behavior change techniques across functional roles among included exercise prescription apps (N=6; 2024).

Functional category and behavior change techniques (BCTTv1[a] code)	Achievement rate
Behavior activation	
6.1 Demonstration of the behavior	100%
8.1 Behavioral practice/rehearsal	100%
2.6 Biofeedback	0%
8.7 Graded tasks	0%
Behavior maintenance	
1.4 Action planning	100%
4.1 Instruction on how to perform a behavior	100%
8.1 Behavioral practice/rehearsal	100%
7.1 Prompts/cues	0%
8.7 Graded tasks	0%
10.9 Self-reward	0%
Physical activity promotion	
1.1, 1.3 Goal setting (behavior and outcome)	100%
1.4 Action planning	100%
2.2 Feedback on behavior	100%
2.3, 2.4 Self-monitoring of behavior with its outcome(s)	100%
10.1 - 10.11 Items in group “Reward and threat”	50%
3.1 - 3.3 Items in group “Social support”	0%
12.1 Restructuring the physical environment	0%
13.2 Framing/reframing	0%

[a]BCTTv1: The Behavior Change Technique Taxonomy version 1.

Digital Usability Based on MARS

Assessment of overall app quality using MARS yielded a mean score of 3.66 (SD 0.25) across the 6 apps, with individual app scores ranging from 3.36 to 4.00 (Table 6 and Figure 4). Among MARS domains, engagement received the lowest ratings, with a mean score of 2.50 (SD 0.28; range 2.10 - 2.80), indicating limited use of interactive, motivational, or personalized features. In contrast, functionality was rated highest, achieving a mean score of 4.36 (SD 0.22; range 4.00 - 4.63), reflecting stable performance, ease of navigation, and technical reliability across all apps. Aesthetic quality was rated moderately to highly, with a mean score of 3.89 (SD 0.48; range 3.17 - 4.50), and information quality was rated similarly, with a mean score of 3.90 (SD 0.18; range 3.58 - 4.07). Comprehensive tables with both reviewer and respective scoring results are provided in Multimedia Appendices 5 and 6. The interrater reliability of MARS was assessed using the ICC (2-way random effects, absolute agreement, average measures). The resulting ICC was 0.71 (95% CI 0.59 - 0.81), indicating good reliability.

XSL•FO
RenderX

Figure 4. Radar chart illustrating the Mobile App Rating Scale scores of the 6 included exercise prescription apps (N=6; 2024).

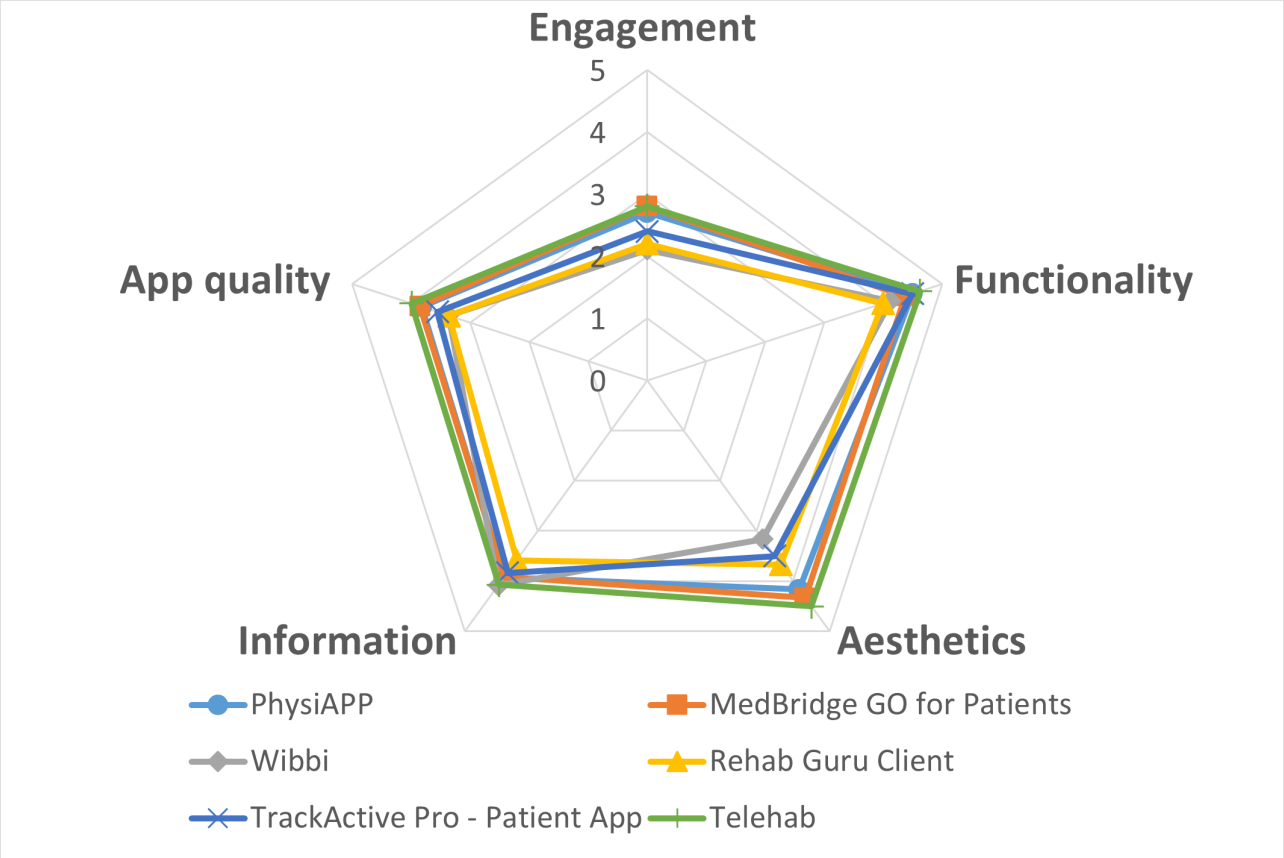


Table . Digital usability and quality scores of included exercise prescription apps (N=6; 2024) assessed using the Mobile App Rating Scale (MARS).

MARS domain	PhysiApp	MedBridge GO for Patients	Wibbi	TrackActive Pro - Patient App	Rehab Guru Client	Telehab	MARS score, mean (SD)[a]
Engagement	2.70	2.80	2.10	2.20	2.40	2.80	2.50 (0.28)
Functionality	4.50	4.38	4.13	4.00	4.50	4.63	4.36 (0.22)
Aesthetics	4.17	4.33	3.17	3.67	3.50	4.50	3.89 (0.48)
Information	3.93	3.92	4.08	3.58	3.83	4.07	3.90 (0.17)
Overall quality	3.82	3.86	3.37	3.36	3.56	4.00	3.66 (0.25)

[a]The maximum possible MARS score is 5.0, based on a 5-point Likert scale ranging from 1 (inadequate) to 5 (excellent).

Our review of the evidence item revealed that by July 2024, only 2 apps among the cohort had undergone scientific evaluation, suggesting a lack of empirically validated health apps in the current market.

Discussion

Principal Results

This study uses an integrated, clinician-centered, multidimensional evaluation framework to provide a novel professional perspective on how exercise prescription apps operate in real-world clinical contexts. Overall, popular, no-cost exercise prescription apps were found to meet the basic structural requirements for exercise prescription but fell short of key standards required for independent clinical use. Although prescriptions consistently specified core FITT elements, the absence of explicit progression and individualized adjustment limited alignment with established clinical practice. While multiple BCTs were identified, those critical for sustaining exercise behavior in unsupervised or remote settings were frequently lacking. Despite strong technical functionality and high information quality, low engagement scores suggest that usability alone is insufficient to support long-term adherence.

When considered collectively across domains, these apps nonetheless demonstrate operational strengths, including structured translation of prescriptions into actionable tasks, continuous visibility of adherence, low cognitive load instruction delivery, and delegation of routine monitoring. Taken together, these findings highlight a gap between clinical expectations for exercise prescription and the current capabilities of widely used digital tools, supporting the role of exercise prescription apps as adjuncts within clinician-guided care rather than as stand-alone prescribing solutions.

XSL•FO
RenderX

Conceptual Foundation and Innovation of the Multidimensional Evaluation Framework

This study introduces a clinician-centered evaluation framework that integrates clinical exercise prescription standards, behavior change theory, and digital usability into a unified, practice-oriented model. Unlike prior evaluations of physical activity and mHealth apps that have primarily examined usability, engagement, or behavior change features in isolation [26-28], this framework situates app assessment within the logic of real-world clinical exercise prescription and decision-making. By aligning established instruments with sequential stages of professional practice, including prescription structure and progression logic (FITT and FITT-VP), transparency and reproducibility of intervention delivery (CERT), support for exercise initiation and maintenance (BCTTv1), and interface quality and engagement (MARS), the framework enables clinicians to directly compare app features with clinical expectations. In doing so, it provides a shared reference to guide both informed clinical selection and future app development.

Adherence to FITT Principles and the Need for Enhanced Program Progression in Exercise Apps

Unlike general physical activity apps that often fail to meet the basic FITT criteria [24,42], the specialized apps in our study successfully incorporated these fundamental elements. However, the primary clinical limitation lies in their failure to satisfy the full FITT-VP framework, specifically regarding structured progression and individualized adjustment. In established exercise prescription practice, progression is essential for achieving physiological adaptation while minimizing injury risk, particularly by avoiding abrupt increases in exercise volume or intensity [43,44]. Clear guidance on how and when to advance exercises is also critical for informed consent and may facilitate patient engagement and adherence.

In addition, limited support for tailoring exercise programs to individual needs constrains the safe use of these tools in populations such as older adults and individuals with chronic diseases, for whom inappropriate exercise loading may increase the risk of adverse events [45]. The absence of explicit information regarding potential exercise-related risks further complicates informed decision-making by both clinicians and patients. To optimize the integration of exercise prescription apps into clinical practice, more comprehensive and transparent intervention descriptions are required to support individualized care and the effective translation of evidence-based exercise prescription into real-world settings.

Intervention Fidelity and Clinical Transparency in App-Based Exercise Prescription

The evaluation of intervention fidelity via the CERT domains revealed a stark disparity between the reporting of static structural elements and dynamic clinical processes. While all apps achieved 100% compliance in describing core components such as materials, provider qualifications, and settings, there was a universal failure (0%) to report motivational strategies, progression logic, or tailoring mechanisms. This deficiency mirrors findings from previous systematic reviews in pregnancy [46] and musculoskeletal rehabilitation [47], which similarly identified a pervasive lack of customization features in mHealth tools. Crucially, the absence of documented decision rules for exercise progression limits the transparency of the intervention. As highlighted by Hansford et al [48] and Conrado Ignacio et al [49], detailed reporting of intervention components—beyond simple dosage parameters—is essential for ensuring reproducibility and clearly defining the functional mechanisms of the prescribed therapy. Consequently, while digital platforms successfully deliver standardized content, the lack of explicit reporting on how exercises are adjusted obscures the clinical reasoning necessary to ensure safety and effectiveness throughout the rehabilitative trajectory.

Furthermore, the total lack of information regarding baseline determination and individual tailoring (0%) highlights a fundamental challenge in digital health. According to updated preparticipation health screening recommendations [50], a comprehensive evaluation of a patient's physical status and functional capacity is the indispensable prerequisite for ensuring safety before initiating any exercise program. The inability of current apps to document how starting levels are calibrated or adjusted to individual constraints suggests a reliance on generic protocols rather than precise clinical titration. Coupled with the complete omission of adverse event reporting, these findings indicate that current apps function as digital exercise libraries rather than sophisticated therapeutic tools, falling short of the safety and individualization standards required for clinical populations.

Enhanced BCTs With Challenges in Addressing Supervision and Adherence in Exercise Apps

The exercise prescription apps reviewed in this study incorporated a higher number of BCTs than reported in previous app evaluations [29,30]; the specific selection of strategies remains highly consistent with the broader mHealth literature [29,51-54]. The predominance of self-monitoring, feedback, goal setting, and action planning in our sample mirrors the most frequently identified features in recent content analyses, confirming that these specialized tools adhere to the standard design patterns observed in general physical activity interventions. However, consistent with established behavior change theory, the mere presence of multiple techniques does not ensure effective behavioral support if their selection and configuration are not aligned with the clinical requirements of long-term exercise adherence [55].

From a clinical perspective, several predefined critical BCTs for sustaining exercise behavior in unsupervised or remote settings were absent or infrequently implemented. These included graded tasks, biofeedback, prompts or cues, and self-reward—mechanisms closely associated with progression, self-regulation, and adaptive feedback over time. Their limited representation suggests that current exercise prescription apps are primarily optimized for exercise initiation and short-term compliance rather than for dynamic adjustment and sustained behavior change, which are central to clinical exercise prescription.

Conversely, several frequently implemented techniques that were not classified as critical were consistently present across all apps, including presentation of a credible source, routine

XSL•FO
RenderX

review of behavioral goals, monitoring without feedback, and repeated behavioral practice. Although these techniques may have limited independent effects on long-term adherence, they may provide complementary clinical value by reinforcing professional authority, standardizing instruction, and supporting structured follow-up [56,57]. Taken together, these findings indicate that while current exercise prescription apps insufficiently implement several clinically critical BCTs, their operational strengths may still augment clinician-guided or hybrid care models, although they may not effectively function as stand-alone behavioral interventions.

Digital Usability in Exercise Apps

In our analysis, the exercise prescription apps achieved an average MARS quality score of 3.66 (SD 0.25), consistent with prior studies by Paganini et al [58] and Simões et al [59], which reported moderate overall quality scores for physical activity apps. Paganini et al [58] found the average quality score to be 3.60, with variations across different subcategories: information averaged 3.24; engagement, 3.19; aesthetics, 3.65; and functionality, the highest at 4.35. Simões et al [59] reported a slightly higher overall MARS score of 3.88, with functionality again scoring the highest at 4.30, followed by aesthetics, information quality, and engagement.

Notably, in our study, the score for information quality was higher at 3.90, whereas the engagement score was considerably lower at 2.50. This discrepancy may reflect the more specific and task-oriented nature of our evaluated apps compared to the broader range of apps included in other studies, which might engage users differently. Despite substantial download figures, the apps we reviewed showed limited evidence of effectiveness, a finding that corroborates previous evaluations [60-62], which consistently highlighted a shortage of evidence-based content and professional guideline adherence in the mHealth landscape.

Clinical Implication

From a clinical perspective, the findings of this study indicate that currently available exercise prescription apps should not be used as stand-alone prescribing tools but rather incorporated into clinician-guided or hybrid care models. Although these apps consistently deliver structured exercise instructions and provide visibility of patient adherence, the absence of explicit progression logic, individualized adjustment, and several clinically critical BCTs limits their capacity to independently support safe and effective exercise prescription. Consequently, clinicians remain essential for determining appropriate starting levels, explaining progression criteria, and managing exercise-related risks, particularly in older adults and individuals with chronic diseases [63].

At the same time, the operational features that are consistently implemented across apps such as standardized exercise demonstrations, routine goal review, adherence tracking, and low cognitive load instruction delivery may still offer complementary clinical value. When used alongside professional judgment, these features can reduce instructional burden, support treatment consistency, and facilitate structured follow-up between clinical encounters. In this context, exercise prescription apps may function as digital extensions of clinician-led care rather than autonomous therapeutic systems.

For developers, these findings underscore the need to move beyond technically feasible features toward closer alignment with clinical exercise prescription standards. Enhancing transparency around progression rules, incorporating mechanisms for individualized adjustment, and prioritizing BCTs associated with long-term adherence may improve the clinical relevance of future applications. Most importantly, adopting a co-design approach—actively involving both clinical practitioners and end users in the development process—is essential to bridge the gap between technical implementation and real-world clinical utility [64,65].

Limitations

This study has several limitations. First, search results were inherently transient and geographically specific due to localized app store algorithms and the rapidly evolving mobile market [66]. While our semantic search strategy targeted popular, clinically relevant apps rather than an exhaustive catalog, the findings represent a 2024 snapshot, and the currency of these results may diminish, as apps undergo frequent updates. Second, while the interrater reliability was high for CERT and BCT assessments, the MARS evaluation yielded relatively lower consistency, reflecting the subjective nature of aesthetic and engagement metrics; however, all discrepancies were resolved through rigorous consensus-based discussion to ensure data validity.

Third, the CERT and BCTTv1 frameworks, originally designed for research interventions, may not fully capture modern app functionalities such as automated feedback, potentially creating a structural mismatch in scoring. Fourth, we identified the presence of BCTs but did not evaluate the quality of their implementation or their actual impact on user behavior. Furthermore, the lack of longitudinal adherence and clinical outcome data limits our assessment of real-world therapeutic impact.

Future Direction

While our study establishes fundamental professional quality and usability benchmarks for exercise prescription apps, it serves primarily as a foundational step mapping the current landscape. Future work should build upon these findings by transitioning from quality assessment to rigorous clinical verification.

Specifically, longitudinal randomized controlled trials are needed to determine if the high-scoring, professionally vetted apps identified in this study translate to better patient adherence and health outcomes compared to traditional methods. Furthermore, considering that the effectiveness of digital exercise prescription systems may vary significantly across conditions, these investigations should target specific clinical cohorts—such as patients with cardiac conditions, neurological disorders (eg, poststroke rehabilitation), or musculoskeletal issues (eg, sarcopenia)—rather than general users.

Crucially, to match the complexity of clinical needs, efficacy trials must move beyond self-reported measures and incorporate objective physiological outcomes, such as laboratory data (eg,

XSL•FO
RenderX

inflammatory markers and glycemic control) and body composition metrics assessed via bioelectrical impedance analysis. Finally, integrating wearable sensors for real-time biofeedback represents a promising frontier for ensuring that these digital prescriptions are delivered safely and effectively.

Conclusions

Using a clinician-centered, multidimensional evaluation framework, this study systematically assessed the clinical usability of popular, no-cost exercise prescription apps. Although these apps consistently met basic structural requirements and demonstrated strong technical functionality, they lacked essential features related to progression, individualization, intervention transparency, and sustained behavior change support. As a result, their capacity to independently deliver clinically appropriate exercise prescriptions remains limited.

Nevertheless, the standardized delivery of exercise instructions, structured translation of prescriptions into actionable tasks, and support for adherence monitoring suggest that these apps may still add value within clinician-guided or hybrid care models. Future development should prioritize a co-design approach involving both clinicians and users to bridge existing gaps. This collaborative strategy is essential to align apps with clinical standards and behavior change principles, thereby enhancing their safety, effectiveness, and clinical relevance.

Funding

The article processing fee was supported by intramural funding from Taipei Veterans General Hospital, Taiwan, and Chang Gung Memorial Hospital, Taiwan. These funding sources had no role in the interpretation of the study results. No external funding was received for this study.

Abstract

Background: Previous research suggests that 14.4% of the general population is affected by tinnitus. For some of those affected, the ear noise is bothersome or associated with severe distress. There are various treatment options such as cognitive behavioral therapy (CBT), sound therapy, or hearing aids. In addition to browser-based online interventions, mobile apps have been introduced as novel treatment approaches. Previous studies have identified several apps aimed at supporting users with tinnitus. Yet, knowledge about the content of tinnitus apps is limited.

Objective: This study aimed to provide an overview of apps specifically developed for tinnitus by analyzing general app characteristics, as well as app content, focusing on intervention components and behavior change techniques (BCTs).

Methods: A systematic search using 7 search terms (eg, tinnitus and ear noise) was conducted in the Google Play Store and the Apple App Store. Apps designed specifically for tinnitus and available in German or English met the inclusion criteria. Two independent trained raters assessed general app characteristics (eg, age group and costs) using the app description section of the German version of the Mobile App Rating Scale. In addition, raters analyzed app content using the BCT taxonomy (v1) and a list of typical intervention components in tinnitus treatment. Differences in ratings were discussed, and a third trained rater was consulted if no consensus was reached.

Results: A total of 1198 apps were identified in the systematic search. Of those, 69 apps were included in the final analysis. Fifty-two apps were available for free, 23 of which offered in-app purchases. Among the 17 paid apps, costs ranged between €0.69 (US $0.81) and €450 (US $527) per 12 months. Fifty-eight of 69 apps provided sounds (eg, white noise and nature sounds). Many apps assessed tinnitus characteristics (n=38) and provided information about tinnitus (n=27). The most frequently used BCTs were “instruction on how to perform the behavior” (n=25; eg, audio instructions for relaxation techniques), “feedback on behavior” (n=11), “behavioral practice/rehearsal” (n=11), “information about health consequences” (n=11), “information about emotional consequences” (n=11), and “prompts/cues” (n=11). The number of BCTs implemented varied widely across apps (0 - 18 per app).

Conclusions: Most tinnitus apps offer sound-based interventions (eg, white noise and nature sounds). Notably, CBT elements (eg, cognitive restructuring, attention training, and relaxation training) are implemented less frequently, despite CBT being recommended in tinnitus treatment guidelines. Further research on the efficacy of tinnitus apps is needed. Transparent reporting of intervention techniques may help clarify mechanisms of action and support the replication of effective interventions. Given the large number of readily accessible apps, this study provides an overview relevant to both researchers and health care professionals.

Introduction

Tinnitus is often described as a hissing, sizzling, or ringing in one or both ears or within the head and is defined as an auditory perception without corresponding external sound [1]. Recent meta-analytic findings point to a pooled prevalence of 14.4% for any tinnitus in adults [2]. For a smaller proportion, the ear noise is bothersome or related to severe distress. For example, 1.2% of the participants in a European Tinnitus Survey reported severe tinnitus [3,4]. Sleep disturbances and concentration difficulties, as well as depression and anxiety, can be associated with the ear noise [5-7].

Both patients seeking treatment and practitioners encounter numerous options with a varying base of evidence (eg, medication, hearing aids, cognitive behavioral therapy, or sound therapy) [1,8]. Digital innovation has paved the way for new methods to deliver treatment by providing internet- and mobile-based interventions (IMIs) [9]. IMIs have the potential to provide access to evidence-based interventions on a larger scale. They may accompany traditional interventions, potentially enhancing their effects or reducing costs [10]. Nevertheless, questions and potential risks arise when implementing IMIs, for example, concerning data security or the efficacy of stand-alone smartphone apps [10-12].

In recent years, especially internet-based interventions that provide cognitive behavioral strategies to people affected by tinnitus have been developed. These interventions target the reduction of tinnitus distress and have shown promising effects in several studies [9,13]. In addition to these web-based interventions, a range of smartphone apps aimed at alleviating burdensome tinnitus are easily accessible on app stores [14,15]. An understanding of what is being offered in these interventions may foster the replication of effective interventions, help identify potential mechanisms of action, and inform future intervention development [16]. However, to date, information and studies on the content and aims of tinnitus apps remain scarce.

A primary approach to providing an overview of app content is to categorize the intervention components used (eg, sounds, relaxation training, and information on tinnitus). Previous reviews of tinnitus apps have mostly focused on providing a brief summary on app content, for example, by sorting apps into categories (eg, “tinnitus education, awareness, and prevention,” “tinnitus relief,” “sound therapy,” or “individual therapy”) [14,15,17]. Two of these reviews additionally provide brief descriptions of what individual apps offer, without necessarily distinguishing the specific intervention components implemented (eg, offering sounds to mask tinnitus, providing individual therapy for tinnitus) [15,17]. Sereda et al [18] provided a detailed description of intervention components and functions of apps. However, the group did not systematically search the app stores but rather analyzed some of the apps that people affected by tinnitus reported using in their daily life [18]. We wanted to add to this line of research by using a systematic approach to differentiate individual intervention components (as described in treatment guidelines or handbooks on tinnitus therapy), thereby providing a detailed overview of the intervention components used.

A second approach for categorizing app content is to identify the behavior change techniques (BCTs) used [19]. Michie et al [19,20] developed a cross-domain taxonomy that includes 93 BCTs (eg, “self-monitoring of behavior”), allocated to 16 categories (eg, “feedback and monitoring”). This approach, rooted in health psychology, may be a useful second perspective to understand what might enhance active tinnitus management by fostering health behavior change. Prior studies on tinnitus have documented the BCTs used in an internet-based intervention by applying the behavior change wheel [21]. Furthermore, BCTs, alongside other measures, were assessed to describe the intervention content of a single internet-based intervention and several self-help interventions [16,22]. The authors concluded that intervention coding fostered the understanding of potential mechanisms of action and may be used to guide future developments [16,21,22]. BCTs have not yet been investigated in tinnitus apps.

Taken together, our study focused on the following research questions:

- How many German and English apps specifically developed for tinnitus are available on the Google Play Store and the Apple App Store?
- Which intervention components are provided in tinnitus apps?
- Which BCTs are used in tinnitus apps?

Findings on the quality and content of a subsample of the apps included in this study, namely 21 German apps, have previously been published in German to contribute to ongoing discussions specific to the German health care system [23]. Based on an updated systematic search, we aim to provide a broad overview of current app content in both English and German apps. To advance tinnitus-specific research and intervention development, and to inform researchers, practitioners, and future tinnitus app development, we focused exclusively on apps explicitly developed for people affected by tinnitus.

Methods

Systematic Search

The project was registered at the Open Science Framework [24]. The German Google Play Store and Apple App Store (iTunes) were searched to identify both paid and free Android and iOS apps. The following search terms, as well as their German equivalents, were used: “tinnitus,” “ear ringing,” “ear noise,” “ear buzzing,” “Ohrenklingeln,” “Ohrgeräusch,” and “Ohrensausen.” The search was performed by one of the authors (AR) from November 2020 to April 2021 and updated in February 2023 (conducted by MK and AR). The search strategy was designed to prioritize sensitivity over specificity to ensure a comprehensive capture of all potentially relevant apps. As our aim was to provide an overview of apps explicitly developed for tinnitus, we established strict inclusion and exclusion criteria detailed below to ensure the quality of the final sample.

Inclusion and Exclusion Criteria

In the first step, identified apps were screened based on information provided in the app store (title, description, user comments, and screenshots). The following inclusion criteria

XSL•FO
RenderX

were used: specifically developed for tinnitus and available in German or English. Apps were excluded if one of the following criteria applied: (1) duplicate; (2) app no longer available on the app store; (3) apps with limited functions with a full version of the app being included; (4) app bundles, that is, a group of apps offered together; and (5) app not developed for smartphones but for tablets. If an app was available on both stores, the iOS version was included. App screening for the initial search was performed by one of the authors (1073 apps, AR). In cases where the app screening was inconclusive, a second rater was involved (91 apps, LL; screening for updated search, 125 apps, by AR and MK). In the second step, the remaining apps were tested for eligibility by AR. For this purpose, apps were downloaded and tested again for inclusion criteria. Apps were excluded if either criteria (1) or (2) or one of the following criteria applied: (6) analysis not feasible due to technical shortcomings, (7) app has no app-specific functionality (eg, solely offers eBooks or articles), (8) app in development or test phase only, (9) no access to the app (eg, no purchase via the app store feasible, no user account provided by the app developer upon request), and (10) app offers no intervention itself but accompanies a therapy via earpiece.

Measures

General Characteristics

General app characteristics were assessed using the app description section of the German version of the Mobile App Rating Scale (MARS-G) [25]. We slightly adapted this section for the purpose of our study. The following factors were assessed: platform, cost, affiliations, age group, category in the app store, technical aspects of the app, embedding into routine care, type of use, type of treatment, support, certification, data safety, and barrier-free.

Intervention Components

To categorize app content, a list of typical intervention components in tinnitus treatment was developed by the authors (AR, DL, and CW). This list was built based on studies on the components of interventions for tinnitus [26], the German treatment guideline for chronic tinnitus [27], reviews on tinnitus treatment [9,28,29], as well as a handbook on cognitive behavioral therapy for tinnitus [30]. Furthermore, the evidence-based health information guideline was used [31]. The guideline, among other aspects, names criteria on how patients should be informed prior to the start of an intervention. The component "information on the intervention" was developed to capture several of the criteria described. For the list of typical intervention components in tinnitus treatment used to categorize app content, see Multimedia Appendix 1. Moreover, raters analyzed which of the identified intervention components were a key component in the app's concept (ie, important messages or key skills that are trained when using the app).

Behavior Change Techniques

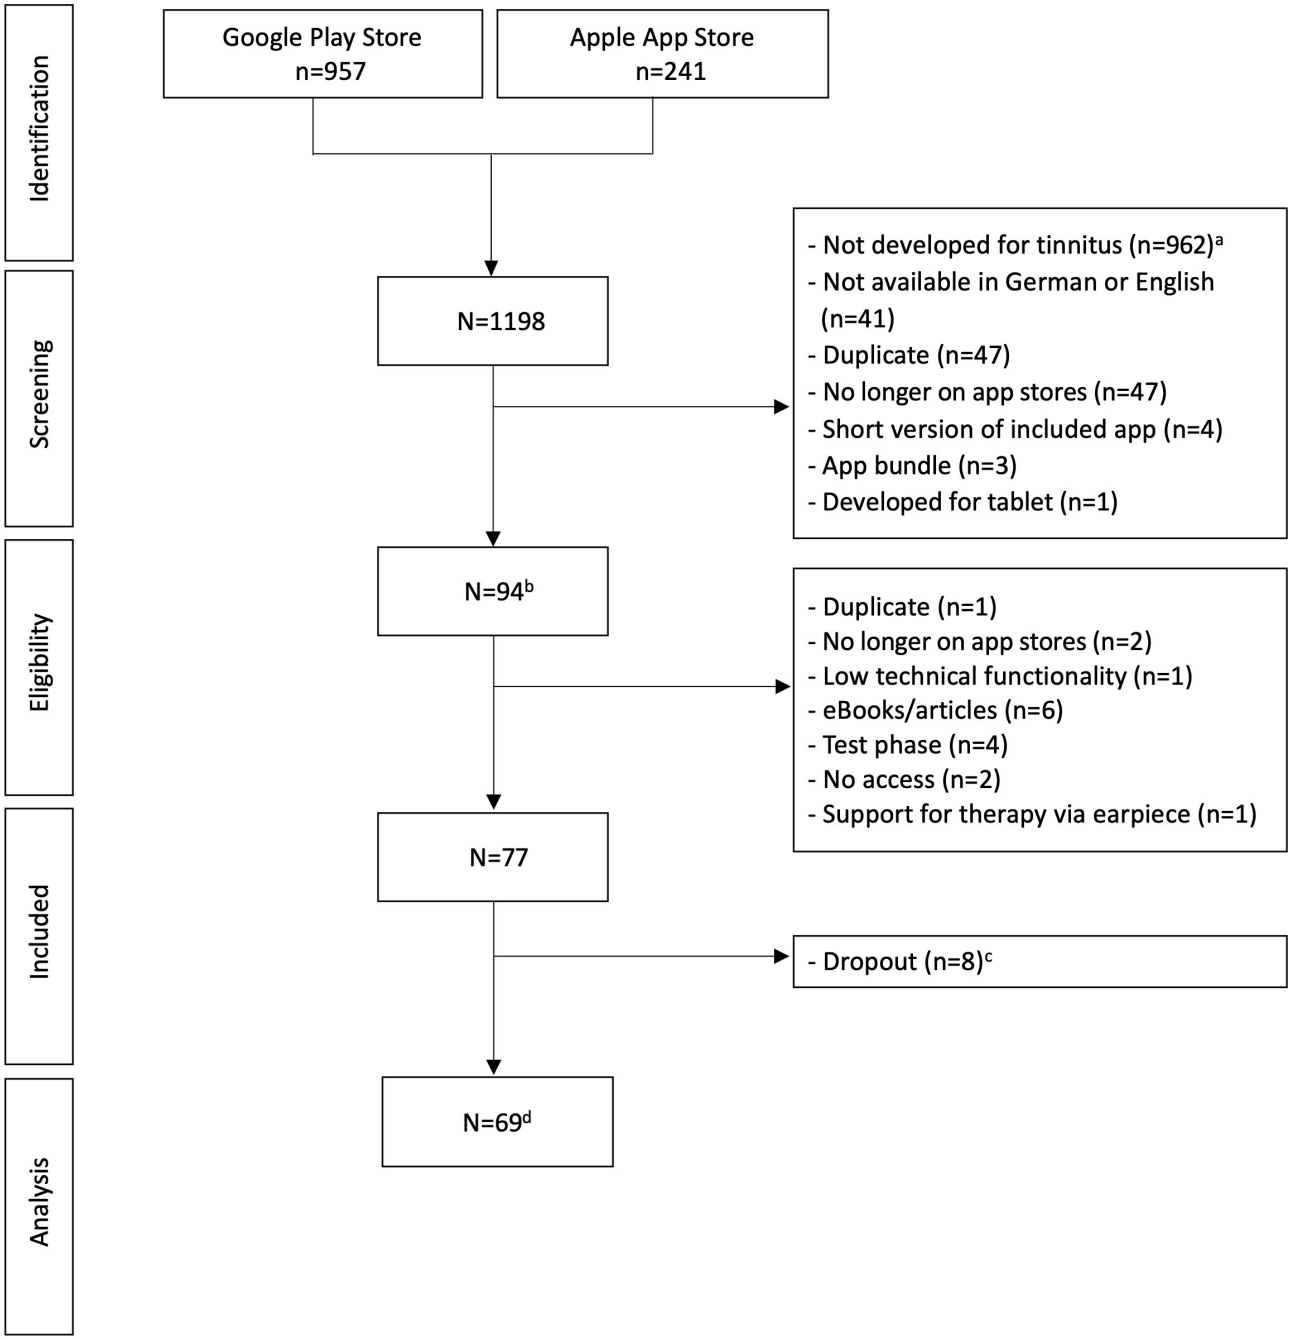
To assess which techniques were used to encourage changes in behavior, the BCT taxonomy (v1) [19] was used. This taxonomy includes 93 techniques that might be used in behavior change interventions (eg, "self-monitoring of behavior" or "action planning"). These are allocated to 16 categories (eg, "feedback and monitoring" or "goals and planning"). For each app, raters analyzed which of the 93 techniques described in the BCT taxonomy (v1) were implemented.

Rater Training

Five raters with a bachelor's or master's degree in psychology were trained prior to the app ratings. The training consisted of several steps. First, the raters watched a video introducing the German version of the Mobile App Rating Scale rating, as provided by the authors [25]. As this video contains an example of how to rate a tinnitus app, this specific part was excluded, and instead, the raters viewed parts of the training video created by the authors of the original scale (which included an example of how to rate an app) [32]. Second, the raters used exercises offered on the BCT Taxonomy v1 online platform to train categorizing BCTs (all raters: "Practices"; rater 1: online-training) [33]. Third, to become familiar with the taxonomy, the raters developed and jointly discussed examples of how each BCT might be implemented in a tinnitus app. As a final step, the raters independently analyzed 5 apps developed for pain management and subsequently discussed their results until agreement was reached.

Procedure and Data Analysis

Two raters independently tested each app for at least 20 minutes and then proceeded to rate the app. The full versions of the apps (including all app features) were tested. Each rater was provided with a list of apps, which had to be rated in descending order. The order specified differed between raters to minimize potential order effects. Once all apps were analyzed, raters discussed the results based on differences in the ratings of general characteristics, intervention components, and BCTs. If no consensus was reached, a third rater participated in the discussion. Descriptive statistics (eg, frequencies of individual BCTs) were calculated using IBM SPSS Statistics version 28 [34].



Results

Systematic Search

The initial search using the 7 search terms mentioned above yielded 1198 apps on the app stores (Google Play Store: n=957; Apple App Store: n=241). Of these, 1105 apps were excluded during screening. Most of the apps (n=962) were excluded as they were not explicitly developed for tinnitus (n=809 addressed topics other than tinnitus, eg, decibel meters; n=153 apps mentioned tinnitus but were not explicitly developed for it, eg, apps accompanying hearing aid devices; Figure 1). The remaining 94 apps were downloaded and tested for eligibility. Of these, 17 apps were excluded (eg, due to low technical functionality), leaving 77 apps that fulfilled all inclusion criteria. During the app testing, a further 8 apps had to be excluded (eg, no longer available on the app stores). Accordingly, 69 apps were included in the final analysis. Figure 1 displays the flowchart of the systematic search and inclusion process for tinnitus apps, and the caption provides further detailed information on the selection process. The list of all apps included in the final analysis can be found in Multimedia Appendix 1.

XSL•FO
RenderX

Figure 1. Systematic search and inclusion of tinnitus apps. [a]809 apps were not developed for tinnitus, for example, apps offering a decibel meter; 153 apps did mention tinnitus but were not explicitly designed for tinnitus: 115 apps offering sounds for sleep, to foster concentration, to accompany meditation or yoga praxis, to reduce stress, for tinnitus; 17 apps for hearing aid devices offering tinnitus programs; 21 apps mentioning tinnitus in the app title or description (eg, information on different diseases of the ear, nose, or throat; frequency generator; and listening to a tinnitus tone). [b]Inclusion of the full version of an app following a suggestion of the app developer. [c]Six apps no longer on app stores, 1 app with low technical functionality, 1 link to website, and 1 duplicate. [d]One app was no longer available on the Apple App Store, but still offered on the Google Play Store, so the Android version was tested instead; one app was tested with limited functions (no full version or access to the app store description available).

App Characteristics

A total of 45 iOS and 24 Android apps were analyzed. Fifty-two apps were free, with 23 of them offering in-app purchases. The price for 17 paid apps ranged between €0.69 (US $0.81) and €450 (US $527) per 12 months. The majority of tinnitus apps were offered in the app store categories medical (n=29 apps) or health and fitness (n=28 apps). For 29 apps, we were not able to identify the developers or providers. Sixty-six apps offered a treatment, with 1 app additionally including content for prevention. One app aimed to track symptoms and 1 app offered an assessment of the tinnitus tone. Three apps had an app community (eg, motivational notifications can be sent to other users), and 3 apps offered an exchange with others via social media or messenger apps. Almost all apps were not by design embedded into routine care (n=63). Only 3 apps allowed for the sharing of information (eg, user statistics) with a health care professional. Few apps provided support for users (n=8), most of them regarding potential technical issues (n=6). For a full overview of app characteristics, see Table 1.

[b]n=2 cost coverage by German health insurance company.

[c]USK: German Entertainment Software Self-Regulation Body.

[d]For 1 app, categories were not assessed, as the app store description was no longer available.

[e]One app listed “mental well-being” as a second app category.

[f]n=2 usage primarily within the context of study participation; n=2 further guidance, customized therapy, or online training are offered on the app`s website.

[g]n=1 tracking symptoms, n=1 assessment of tinnitus tone, and n=1 additionally assessing sleep quality and problematic internet use.

[h]n=1 developed in accordance with norms IEC 62304 and IEC 82304 as well as the “Good Automated Manufacturing Practice 5” (GAMP 5).

[i]CE: Conformité Européenne.

Intervention Components

Intervention components were assessed using a list of components in tinnitus treatment developed by the authors. Most frequently used intervention components were sounds (eg, white noise, nature sounds, and music), which were implemented in 58 of 69 apps. In 52 apps, sounds were a key element. An assessment of tinnitus characteristics was offered by 38 apps (key element in 22 apps). Furthermore, information on tinnitus (n=27, key element in 16 apps) and the provision of information on, or assessment of risk factors for tinnitus (n=23) were implemented in several apps. Less than a third of the apps assessed tinnitus distress (n=18) or provided information on or assessed further otological symptoms (n=16). Further intervention components typically used in CBT were implemented in a smaller number of apps: relaxation training (n=16), techniques to improve sleep (n=12), identification of maladaptive thoughts (n=8), restructuring maladaptive thoughts (n=8), attention training (n=4), and exposure to tinnitus (n=1). Besides, a larger part of the apps (n=39) informed users about the aim of the intervention, while only a few apps offered information on uncertainties and missing evidence (n=7). Across all apps, we identified 41 different intervention components. Apps highly differed in the number of intervention components they included, ranging from 2 to 20 intervention components per app. For full details on the identified intervention components, see Table 2.

[a]Intervention components were assessed using a list of typical intervention components in tinnitus treatment developed by the authors (AR, DL, and CW; Multimedia Appendix 1). Components identified in at least 1 app are depicted.

[b]Not applicable.

[c]Based on the guideline for evidence-based health information, namely requirements regarding the content of information for patients about a treatment [31].

[d]Developed by app community, no information provided by the app developers.

[e]For details on further intervention components identified in only one app, see Multimedia Appendix 1.

[f]For example, focus on strengths and successes, gratitude exercises, assessment of important motives and needs—setting life goals.

Behavior Change Techniques

BCTs were categorized using the taxonomy by Michie et al [19]. In total, 36 out of 93 BCTs were identified in at least 1 app. The most frequently implemented BCTs were "instruction on how to perform the behavior" (n=25, eg, audio instructions on how to perform a relaxation technique), "feedback on behavior" (n=11), "behavioral practice/rehearsal" (n=11, eg, prompting users to practice mindfulness-based exercises), "information about health consequences" (n=11), "information about emotional consequences" (n=11), and "prompts/cues" (n=11, eg, app reminders to engage in pleasant activities). Apps highly differed in the number of implemented BCTs (none to 18 BCTs per app), with 32 apps including no BCTs at all. See Table 3 for a full overview of BCTs identified.

Discussion

Principal Findings

In this systematic review, we assessed intervention components and BCTs [19] used in tinnitus apps and provided a detailed summary of the content of available apps. We analyzed a total of 69 apps available in English or German, all of which were easily accessible via 2 major app stores.

Within the 69 apps included in our study, numerous intervention components were identified (eg, relaxation, assessment of tinnitus distress, or techniques to improve sleep). The most frequently implemented intervention component was sounds (eg, white noise and nature sounds). Furthermore, many apps offered an assessment of tinnitus characteristics or tinnitus distress and provided information on tinnitus, risk factors, and the basics of the intervention offered (eg, its aim). One possible reason for focusing on these components is that they are relatively easy to implement. Our findings are consistent with previous research reporting the frequent use of sound therapy in tinnitus apps [14,15] and patients' preference for such apps [18]. In a recent health service evaluation, sound therapy (including hearing aids) was found to be the most frequently available intervention in both northern and southern Europe [35]. At the same time, clinical guidelines differ on whether they recommend sound therapy, given the lack of evidence or the risk of bias in previous studies [8,36]. Although meta-analytic evidence clearly supports the efficacy of CBT for treating tinnitus distress [8,36,37], CBT intervention components (eg, cognitive restructuring, relaxation training, and attention shifting) were implemented in only a small number of apps. In contrast, when analyzing CBT apps for depression, Martinengo and colleagues identified a variety of apps offering, for example, cognitive restructuring [38]. Thus, it seems possible to realize even more complex CBT components in smartphone apps. Interestingly, a closer look at the intervention components revealed considerable differences in how certain components were implemented. For example, 1 app addressed typical maladaptive thoughts by naming several maladaptive thoughts, briefly elaborating on their potential negative effects, and suggesting alternative thoughts. In another app, users were asked to name individual debilitating thoughts and were then provided with techniques to develop a more helpful thought.

Our second aim was to assess the BCTs used in available tinnitus apps, as up-to-date knowledge on this topic is limited. In our study, we identified 36 of the 93 BCTs defined by Michie et al [19]. The 6 most frequently identified BCTs were "instruction of how to perform the behavior," "information about emotional consequences," "information about health consequences," "feedback on behavior," "behavioral practice/rehearsal," and "prompts/cues." Only a few other studies have assessed BCTs used in tinnitus interventions. Greenwell et al [16] analyzed BCTs in 5 studies on self-help interventions for tinnitus, and 2 studies reported on BCTs used in individual online interventions [21,22]. The techniques most frequently identified in our study are likely common because they are straightforward to implement in an app. For example, to promote relaxation behavior, users were instructed on how to perform a breathing exercise ("instruction on how to perform a behavior"), motivated to practice relaxation with audio recordings ("behavioral practice/ rehearsal"), or sent reminders to complete an exercise ("prompts/cues"). Interestingly, social support techniques were identified in only 4 out of 69 apps. This aligns with Greenwell et al [16] findings that social support components were largely absent in self-help interventions for tinnitus. In previous research on tinnitus support groups and group therapy, features such as the exchange of information, a sense of belonging, and validation of the tinnitus experience were identified as central helpful elements [39,40]. Including peer support in apps could therefore benefit tinnitus users, and smartphone apps offer various ways to provide this digitally. Moreover, goal setting was implemented in only a few apps. From a clinical perspective, prompting users to set goals and review them ("goal setting behavior," "goal setting outcome," "review behavior goals," and "review outcome goals") could enhance motivation. Reviewing these goals, according to Michie et al [19], may lead to adapting goals or modifying the behavior change strategy based on prior achievements. This process would allow users to evaluate whether they have met their goals using the app or if adjustments to the goal are needed. Additionally, normalizing the adaptation of goals or strategies may further support user motivation.

XSL•FO
RenderX

In addition to numerous apps focusing on the provision of sounds and a small number of apps offering various CBT strategies, we identified apps offering, for example, acoustic neuromodulation or tailor-made notched music therapy. This highlights the general problem that tinnitus sufferers searching for an app are confronted with treatment approaches supported by varying levels of evidence [29,37,41]. It is likely that most app users are unaware of this. Furthermore, while a few tinnitus apps have been tested for efficacy, many apps lack scientific evaluation [42-47]. This aligns with our findings from a subsample of the apps included in this study [23]. In the current study, we also found only a few apps providing information on uncertainties or missing evidence regarding the intervention provided. As a basic requirement, app developers should inform users about the evidence base of the treatment approach and whether the app has been scientifically evaluated. Additionally, information on alternative treatment approaches should be provided to enable informed decision-making. This would also provide guidance to users if they are unable to reach their goals using the app. Similarly, Sander et al [48], in their review on posttraumatic stress disorder apps, proposed that apps categorized as medical or health apps should inform users that the app is not a replacement for standard treatment and provide guidance on accessing other treatment options. Correspondingly, other groups have called for evidence-based information in medical and health-related apps [49,50]. In our subsample analysis, we identified a few intervention components that could have negative effects if used without guidance from a clinical expert (eg, insufficient instructions for a training designed for users with hyperacusis) [23]. This is consistent with previous research highlighting potential negative effects when certain exercises are used without support [18]. Remarkably, none of the apps were categorized as "barrier-free." However, we only screened for app features aimed at reducing barriers using a single yes or no item. In light of our findings and the large number of available tinnitus apps, health care professionals should ask patients whether they are using tinnitus apps and evaluate app content together. This may help patients assess whether the interventions offered are evidence based. In addition, potential shortcomings and negative effects can be identified, and professionals can provide guidance on the proper use of certain strategies. This aligns with recommendations by Brown et al [50], who call for increased awareness of potential negative effects among users and health care professionals. Assessing apps used in daily life also offers the opportunity to integrate exercises into a broader treatment plan. For example, a patient may use relaxation training offered in an app but struggle to practice it regularly. In this case, a health care professional can help identify barriers and develop strategies to overcome them.

This review provided several key insights into the current landscape of tinnitus apps. Using a broad and systematic search strategy, we identified a large number of tinnitus-specific apps and evaluated each app in detail, rather than focusing only on the most popular ones. This approach allowed us to provide a comprehensive overview of the intervention components and BCTs currently implemented in tinnitus apps. A key strength of this review is the high sensitivity of the initial search. By using a broad search strategy, we accounted for nonclinical terminology often used by developers in app store metadata. During the screening phase, a significant number of hits had to be excluded because the apps were not related to tinnitus (eg, offering a decibel meter). Probably due to the app store search algorithms using a multitude of criteria (eg, screening title, description, and keywords), 153 apps (eg, accompanying hearing aid devices or generic sound or relaxation apps that lacked tinnitus-specific content) were further retrieved. While these apps might have used "tinnitus relief" as a keyword in their metadata to, for example, increase visibility, they were not specifically designed for tinnitus and were, therefore, excluded from the final analysis. Although the broad search strategy resulted in a high exclusion rate of apps, it ensured that no dedicated tinnitus-specific interventions were overlooked, providing a more reliable overview of the current digital health landscape for tinnitus.

Our findings show that sounds were by far the most frequently implemented intervention component, whereas evidence-based CBT components were present in only a small proportion of apps, despite strong evidence for CBT in the treatment of tinnitus distress. Furthermore, only 36 of the 93 BCTs defined by Michie et al [19] were identified across all apps, indicating a limited use of established BCTs. By systematically mapping these components, we highlight which BCTs are currently under-represented and discuss their potential relevance for future app development. In addition, our results underscore the lack of transparent information on the evidence base of the treatment approaches offered in many apps and the need for scientific evaluation. Regular assessment of tinnitus apps by health care professionals may help identify potential shortcomings, support informed use of apps, and facilitate their integration into a broader treatment plan.

Limitations and Future Directions

Besides these strengths, several limitations should be considered. First, the systematic search was last updated in 2023. Accordingly, newly developed apps may not be included in the analysis. Furthermore, some of the included apps may no longer be available on the app stores, or their content might have changed substantially since the time of data extraction, limiting the temporal validity of our findings. Moreover, more recently developed apps might include more complex CBT components or a greater variety of BCTs. We searched 2 major app stores (Google Play Store and Apple App Store) but did not search app libraries (eg, ORCHA App Library) or other app stores (eg, Windows Store). Thus, the coverage of available apps may be incomplete. It is also possible that additional tinnitus apps were unavailable on the German app store but accessible to users in other countries. Second, we only analyzed apps available in English or German. Therefore, our findings may not be generalizable to apps in other languages and potential cultural or regional differences in app design and content are not captured. Third, as we used tinnitus-specific search terms and focused solely on apps explicitly developed for tinnitus, this review does not cover other apps that might potentially be beneficial for people suffering from tinnitus. In particular, transdiagnostic or mental health apps (eg, targeting stress or sleep) that may indirectly address tinnitus-related distress were not included, which may limit the scope of the review. Fourth,

XSL•FO
RenderX

although we provide an overview of intervention components currently used in apps, no conclusions about the quality of their digital implementation can be drawn based on our data. Accordingly, we did not assess the mode of delivery for individual BCTs or how often they were used in each app. Our coding was based on the presence or absence of components rather than their depth or user engagement, which may vary substantially between apps. Fifth, based on our results, we cannot investigate associations between the implementation of a particular BCT or intervention component and the efficacy of an app. We did not incorporate user-level data (eg, adherence, engagement, or outcomes), which limits conclusions regarding the practical effectiveness of the apps and the identified components.

Future research is needed to determine which intervention components, BCTs, or combination of BCTs are most effective in promoting behavior change and reducing tinnitus-related distress, ideally by linking specific components to user engagement and clinical outcomes. Moreover, subsequent studies may clarify how complex CBT components, such as cognitive restructuring, can be realized in an app to be beneficial for the user. Such research should also include questions of usability, personalization, and appropriate guidance. Future research should also examine how intervention components need to be implemented to be used safely without professional supervision, and under which conditions additional human support may be required to ensure both safety and effectiveness.

Conclusions

In this review, we provide a detailed and systematic analysis of tinnitus app content by categorizing intervention components and BCTs. By applying an established BCT framework, this study offers a structured and theory-informed overview of current app-based interventions. A variety of intervention components were identified at least once (eg, relaxation training, sound therapy, and information on tinnitus). However, the component most frequently implemented was sounds (eg, white noise and nature sounds), highlighting a discrepancy between commonly implemented features and evidence-based treatment recommendations. Core CBT elements, which are recommended in tinnitus treatment guidelines, were offered less frequently. Patients with tinnitus searching for support in app stores are confronted with a large number of easily accessible apps, yet the content and theoretical grounding of these apps vary substantially. In light of the limited scientific evaluation of these apps, future research on their efficacy as well as potential negative effects is highly needed. Importantly, this review provides a transparent and reproducible foundation for such evaluations by systematically mapping existing intervention components and BCTs. Overall, this study provides an overview for research and practice by summarizing current tinnitus app content and identifying key gaps that can inform evidence-based app development and future research priorities.

Acknowledgments

The authors thank Marc Philipp Scheib and Sophie Helene Eg Pakleppa for their help in data collection, and Malin Keller as well as Lea Liebchen for support during the conduct of this study. No artificial intelligence tools were used for the purposes of information gathering, analyses, content creation, manuscript writing, and/or editing.

Abstract

Background: Lupus erythematosus (LE) is a chronic autoimmune disease that significantly impacts patients' quality of life. Photosensitivity is a key impairment that severely limits the quality of life, especially in cutaneous lupus erythematosus (CLE), where exposure to sunlight can lead to rashes, exacerbations, and pain. In systemic lupus erythematosus (SLE), other manifestations such as joint pain, fatigue, and organ damage may contribute to decreased physical function and emotional distress. Mobile health apps (MHA) offer potential support for comprehensive disease management for the symptoms mentioned above. However, there is a lack of systematic analysis of available lupus management apps.

Objective: This study aims to systematically identify publicly available German or English MHA for lupus management as well as to assess their quality by surveying both patients and physicians.

Methods: A systematic search and assessment of German or English mobile apps for patients with lupus, available in the Google Play Store and Apple App Store, was conducted independently by two reviewers. The two apps that met all relevant criteria were then reviewed independently by seven physicians using the German Mobile Application Rating Scale (MARS) and the System Usability Scale (SUS). Subsequently, they were reviewed by five patients (three with SLE and two with CLE), using the user version of MARS (uMARS) and SUS. Additionally, the Affinity for Technology Interaction (ATI) scale was collected from both patients and physicians to evaluate the technical affinity in both groups.

Results: In total, 29 apps were available on the Apple Store and 26 on the Google Store, with 18 apps being present and downloadable on both platforms. Of the 18 apps, 16 were excluded because they did not meet the inclusion and exclusion criteria. Only two apps, *Lupus Log* and *Lupus Minder* met all the required criteria and were included in the study. The mean MARS scores varied from 2.61/5 to 4.17/5 and mean SUS from 17.5/100 to 100/100 between physicians. The app with the highest mean overall MARS score was *Lupus Log*, which was rated with 3.91/5 on average by the physicians. Patients evaluated the app with a comparably mean uMARS score (3.95/5). Technical affinity, objectified by ATI, was higher in patients than physicians (3.9 vs 3.68).

Conclusions: Systematic identification and evaluation showed high-quality apps for patient-centered lupus MHA as indicated by MARS and uMARS scores greater than 3 for both *Lupus Log* and *Lupus Minder*.

Introduction

Background

Lupus erythematosus (LE) is a chronic autoimmune disorder with great heterogeneity of symptoms. It can affect multiple organs, including skin, kidney, heart, and the nervous system [1]. In cutaneous lupus erythematosus (CLE), inflammation is typically confined to the skin and does not affect internal organs. CLE is often worsened or even triggered by sun exposure [2]. Systemic lupus erythematosus (SLE) can present with many clinical symptoms of varying severity, including lupus nephritis, which can lead to kidney failure if left untreated. Therefore, SLE patients are treated with systemic corticosteroids and other immunosuppressants or immunomodulators, which can again

XSL•FO
RenderX

cause side effects and result in additional morbidity. In contrast, for CLE, topical treatments are often sufficient to relieve symptoms [3].

Due to chronic inflammation, patients experience a variety of physical limitations, including joint pain, fatigue, sleep disorders, photosensitivity as well as cardiovascular and pulmonary symptoms. Mental and emotional health is further impaired with patients showing high prevalence of depression, anxiety, and cognitive disorders [4]. Furthermore, SLE can also directly affect the central nervous system causing a wide variety of psychiatric symptoms [5]. Some patients experience a so called “lupus fog” with memory loss and difficulty concentrating, which further negatively impacts daily life and social interactions [6]. Corticosteroids and immunosuppressive drugs can cause weight gain, diabetes, osteoporosis, and increased risk of infection that are detrimental to patients’ quality of life [7].

In people living with LE, symptoms such as chronic fatigue, joint pain, and cognitive difficulties often occur unnoticed by others, making it hard for patients to feel understood and to receive empathy. This invisibility can lead to several emotional and social struggles such as frustration and a feeling of stigmatization [8]. The unpredictability of lupus flare-ups makes this disease more challenging. Even when the disease appears to be controlled, symptoms can suddenly return and cause fear and anxiety [9].

Since patients with lupus often experience fluctuating symptoms, it can complicate treatment adherence and monitoring. Therefore, mobile health apps (MHA) present an opportunity to support patients in managing their condition by providing accessible information, symptom tracking, and direct communication with health care providers [10]. However, there is a lack of robust evidence regarding the effectiveness of these apps for lupus patients, and high-quality studies are essential to assess their impact [11]. To date, comprehensive reviews of MHA for lupus management have been scarce [12], as they were restricted to evaluations conducted exclusively by health care professionals (with small reviewer samples) and without incorporating patient perspectives. To complement existing reviews, a comparative analysis using validated scoring systems and involving both health professionals and patients is needed to generate more robust data on the usability and quality of MHAs for lupus self-management. The Affinity for Technology Interaction (ATI) scale provides a reliable method for quantifying an individual’s technology affinity, providing important context for interpreting their app evaluations [13]. To subjectively assess app quality, the Mobile App Rating Scale (MARS) was developed, evaluating aspects such as engagement, functionality, esthetics, and information [14-16]. MARS has been applied in studies evaluating mobile apps related to various chronic diseases, including chronic wounds [17]. A user version (uMARS) allows app quality to be assessed from the patient perspective [16]. The System Usability Scale (SUS), a 10-item questionnaire, has been used broadly to assess the usability of systems, including mobile apps for conditions like dementia, depression, pediatric obesity, and smoking cessation [18].

Aim of This Study

This study aims to systematically identify and assess mobile apps available for lupus management. By using validated tools, such as the MARS and the SUS, this research seeks to provide a comprehensive evaluation of these apps from both professional and CLE as well as SLE patient perspectives.

Methods

Study Design and Setting

This was a cross-sectional observational study conducted at the Department of Dermatology, University Hospital Würzburg, Germany. The study involved a systematic search and comparative evaluation of MHAs for patients with LE by both patients and physicians.

Participants

Physicians were dermatologists involved in direct lupus patient care. Patients were adults (≥18 y) with a confirmed diagnosis of cutaneous or systemic lupus erythematosus, identified during routine outpatient visits.

Ethical Considerations

This study was conducted in accordance with ethical guidelines and standards, with approval from the ethics committee at the University of Würzburg (reference number 2022062501). All participants provided written informed consent. No personal identifiers were collected on the forms, and responses were manually entered by the study team. All data were deidentified at the point of analysis. No financial or material compensation was provided to participants for taking part in the study.

App Identification and Selection

Two independent reviewers systematically searched the Apple App Store and the Google Play Store in June and July of 2023 to identify patient-centered mobile health applications related LE. The search terms used were: “lupus,”, “lupus erythematosus,” “lupus erythematodes,” “systemic lupus,” “cutaneous lupus”. German and English apps were included in order to reflect the languages most used by the study population, and to ensure relevance to the target user group. To guarantee cross-platform usability and broader accessibility, only apps available in both app stores were considered. Additionally, it was required that apps were specifically designed for patients with LE, were free of charge, did not require user registration or community interaction, and did not contain advertisements. We excluded apps with advertisements to prevent disruptions in users’ experiences and to avoid the confounding effects advertisements can have on usability [19]. Advertisements can frustrate users, reduce the clarity and intuitiveness of an app’s interface, and make it difficult to compare apps’ performance or users’ experiences [20]. As part of the inclusion criteria, only apps with a publicly accessible privacy policy and evidence of basic data protection measures were included. This ensured alignment with good practice guidelines for mobile health evaluations.

XSL•FO
RenderX

Data Extraction and App Characteristics

The following information available in the app stores and on app websites was collected

- App name
- Target consumer group (eg, patients, medical personnel)
- Cost
- Platform
- Advertisement
- Features
- Search term used to identify the app

Evaluation

Mobile Application Rating Scale

The quality of the identified and included apps was evaluated by seven physicians using the MARS, which assesses the four domains: engagement, functionality, esthetics, and information. Each item is rated on a 5-point Likert scale, where 1 indicates "inadequate" and 5 indicates "excellent" performance. Higher scores reflect better app quality. The overall MARS score is calculated as the mean of the subdomain scores, with a maximum possible score of 5; a score above 3 is considered acceptable or good app quality. The apps were then further evaluated by five patients (three with systemic lupus erythematosus and two with cutaneous lupus erythematosus) using the user version of the scale (ie, uMARS), which uses the same scoring logic and dimensions but is adapted for the user perspective.

System Usability Scale

In addition, the SUS was applied to assess overall usability. SUS consists of 10 items rated on a 5-point Likert scale, with the total score converted to a 0 - 100 scale. Higher SUS scores indicate better usability. A SUS score ≥70 is generally considered acceptable, scores between 50 and 70 indicate marginal usability, and scores below 50 are interpreted as poor usability. Including both MARS and SUS allowed for a comprehensive assessment of app quality and usability from both the health care professional and the patient viewpoint.

Affinity for Technology Interaction

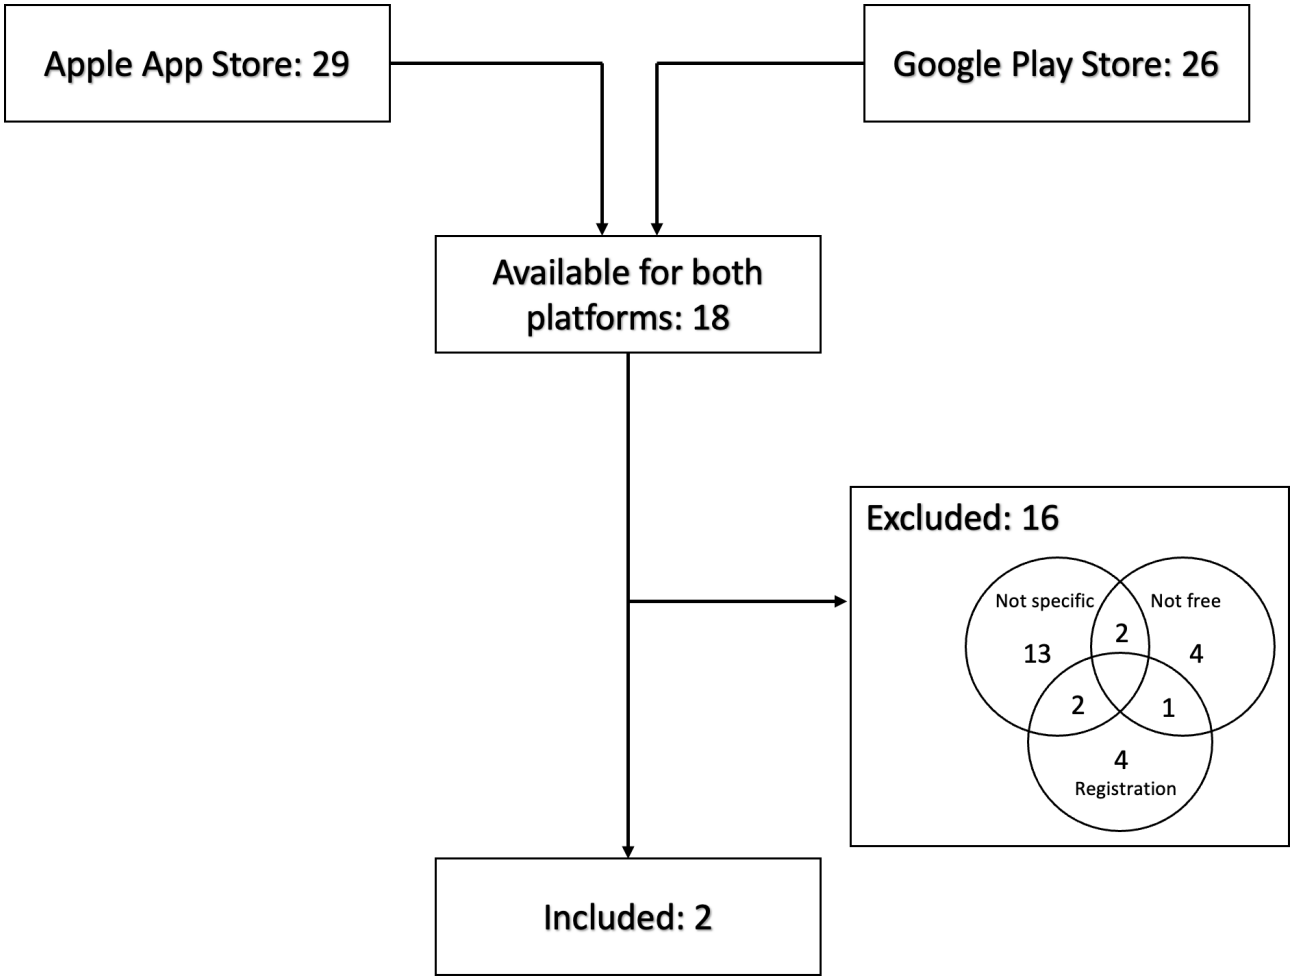
The ATI scale was used to gather information on the physicians' and patients' technical affinity. ATI consists of 9 items rated on a 6-point Likert scale, resulting in a score range from 1 (very low affinity) to 6 (very high affinity). Higher scores indicate a greater interest in interacting with technology. A score above three reflects average or moderate technology affinity, while a score above four is typically interpreted as high. Assessing ATI in both user groups provided context for interpreting their app ratings, particularly in terms of potential differences in expectations, familiarity, and digital literacy.

Evaluation Procedures

Each physician and patient received access to the same apps and tested them on their own smartphones or tablets (iOS or Android). Participants were instructed to test each app for at least ten minutes, explore all relevant features, and assess its usability, content, and overall functionality. To assist participants in understanding the rating process, an optional explanatory video describing the MARS/uMARS tool was made available via a QR code. Following app testing, participants completed the appropriate paper-based evaluation tools. All questionnaires were filled out on paper and collected by the study team for manual data entry and analysis.

Statistical Analysis

Descriptive statistics were used to summarize app quality scores and demographic data. The Mann-Whitney *U* test was used to compare scores between patients and physicians (eg, MARS vs. uMARS, SUS, ATI). The Wilcoxon signed-rank test was applied to compare differences between apps. *P* values below .05 were considered significant. The data analysis was performed using Python, with libraries such as Pandas, SciPy [21], NumPy [22], Matplotlib, and Seaborn [23].



Results

App Selection

In total, 37 potentially relevant mobile health apps targeting lupus patients were initially identified through the app store search. These apps were then reviewed independently by two authors to assess eligibility according to predefined inclusion and exclusion criteria. Of the 37, 18 apps were available in both the Apple App Store and Google Play Store (see Figure 1). Of these 18 apps, 10 were targeted at patients. Strict criteria were established for app inclusion: the apps needed to be specifically designed for LE, free of charge, and did not require registration/community connections, or advertising. Of the 18 apps, 13 were excluded because they were not specifically designed for LE. Additionally, 4 apps required payment after download or for full access, and 4 apps asked for registration, included ads, or had community connections. Some apps met multiple exclusion criteria. Ultimately, only 2 apps, *Lupus Log* and *Lupus Minder*, met all the required criteria and were included in the study.

XSL•FO
RenderX

Figure 1. Flowchart illustrating the screening process for identifying suitable mobile apps.

Evaluation of App Quality

A total of two apps —*Lupus Log* and *Lupus Minder* —met all inclusion and exclusion criteria and were evaluated by 7 physicians. *Lupus Log* and *Lupus Minder* are designed specifically for lupus patients, offering features tailored to disease management and symptom tracking. Both apps provided a user-friendly interface and allow for the creation of a personalized medication plan. *Lupus Minder* features a structured design with an intuitive layout. It offers general lupus information and a planner for medical appointments, which can be printed or exported. A daily symptom tracker is available, but it only includes a free-text field without predefined options. The app ensures data security through password protection. *Lupus Log* stood out for its well-structured design and includes a real-time, location-based UV index. Its daily symptom tracker allows users to select predefined symptoms, add custom categories (eg, fatigue, lesions, ulcers), and to attach notes or photos. The app also provides lupus-related tips, news updates, and access to personal health statistics. Additionally, push notifications can remind users to complete the symptom tracker, though medication reminders are not included.

The mean MARS scores (and SDs) of the physicians, including subcategory scores and SUS scores, are provided in Table 1, while the corresponding uMARS and SUS results from patient evaluations are shown in Table 2.

XSL•FO

Table . MARS[a] and SUS[b] scores of the *Lupus Log* and *Lupus Minder* app, as assessed by 7 physicians.

Scores	Lupus Log	Lupus Minder
MARS, mean (SD)	3.91 (0.42)	3.29 (0.38)
A: Engagement score, mean (SD)	3.69 (0.58)	2.86 (0.65)
B: Functionality score, mean (SD)	4.46 (0.37)	3.75 (0.46)
C: Esthetics score, mean (SD)	4.19 (0.72)	3.24 (0.66)
D: Information score, mean (SD)	3.48 (0.65)	3.43 (0.26)
SUS, mean (SD)	87.14 (4.43)	65.36 (27.59)

[a]MARS: Mobile Application Rating Scale.

[b]SUS: System Usability Score.:

Table . uMARS[a] and SUS[b] scores of the *Lupus Log* and *Lupus Minder* app, as assessed by 5 patients.

Scores	Lupus log	Lupus minder
uMARS, mean (SD)	3.95 (0.62)	3.32 (0.52)
A: Engagement score, mean (SD)	3 (0.94)	2.4 (0.52)
B: Functionality score, mean (SD)	4.35 (0.93)	3.8 (1)
C: Esthetics score, mean (SD)	4.41 (0.44)	3.74 (0.91)
D: Information score, mean (SD)	4 (0.5)	3.56 (0.43)
SUS	76 (29.18)	49.38 (34.18)

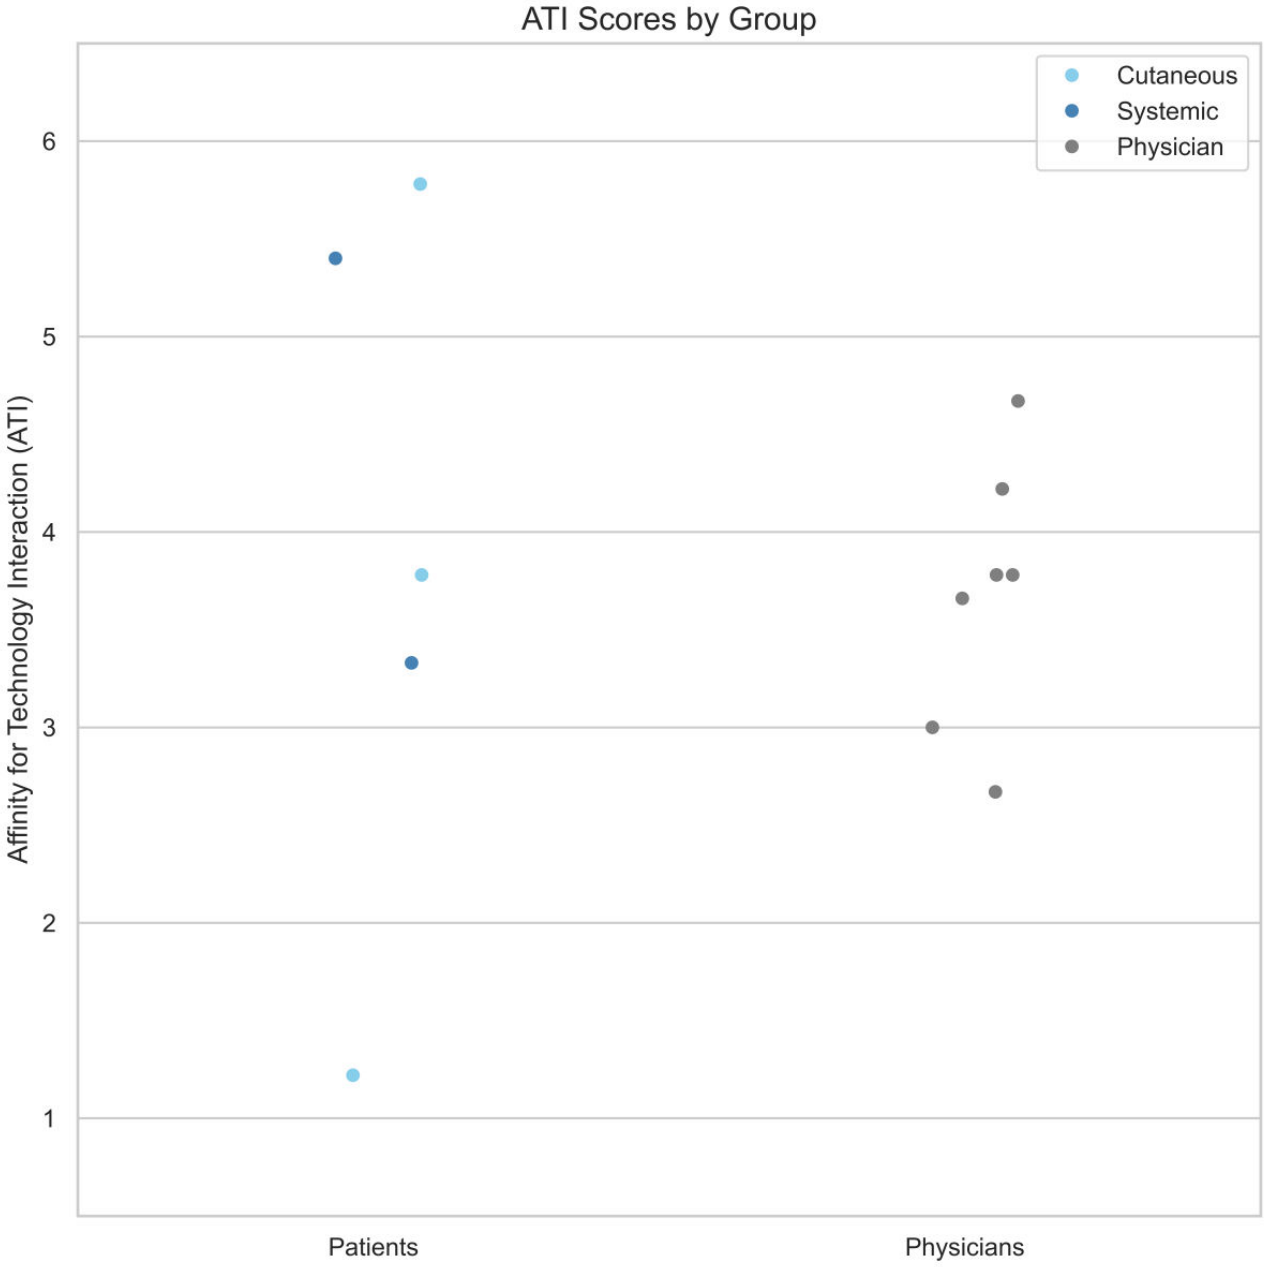
[a]uMARS: User version of Mobile Application Rating Scale.

[b]SUS: System Usability Score.

Lupus Log had the highest mean MARS (mean 3.91, SD 0.42 out of 5) and mean uMARS (mean 3.95, SD 0.62 out of 5). When Wilcoxon signed-rank test was applied *Lupus Log* had a significantly higher MARS score (P=.03*)* but not significantly higher uMARS scores (P=.125), possibly due to small size (see detailed information on demographics, uMARS, SUS and ATI scores of CLE and SLE patients in Multimedia Appendix 1). *Lupus Minder* had a lower mean MARS (mean 3.29, SD 0.38) and mean uMARS (mean 3.31, SD 0.52 out of 5). Mean SUS by physicians and patients scores were 87% and 76% for *Lupus Minder* and 65% and 49% for *Lupus Log*, respectively.

Comparative Analysis of Patients and Physicians Data

Lupus Log MARS (see Table 1) and uMARS (see Table 2) were almost identical and differences were not statistically significant (P=.76). In the subcategory engagement and information, mean scores differed most. Patients rated engagement with 3.0 lower than physicians 3.69 (P=.16). In contrast, information was rated higher by patients with a mean score of 4.0 than by physicians with a mean score of 3.48 (P=.19).



Lupus Minder's MARS (see Table 1) score and uMARS (see Table 2) were almost identical (P=.70). In the subcategory engagement and esthetics, mean scores differed most. Patients rated engagement with 2.4 lower than physicians with 2.86 (P=.30). In contrast, esthetics was rated higher by patients with a mean score of 3.74 than by physicians with a mean score of 3.24 (P=.40).

Evaluation of Technical Affinity

The physician group consisted of 5 females and 2 males, with an age range of 27 - 42 years (median: 30 y). The patient group included 3 patients with systemic lupus erythematosus (SLE) and 2 with cutaneous lupus erythematosus (CLE). Four patients were female, and one was male, with ages ranging from 35 to 67 years (median: 52 y). ATI scores ranged from 1.22 to 5.78 out of 6. An ATI score of >3 indicates average technology affinity, and a score of >4 indicates high technology affinity. Technical affinity was lower in physicians than in patients (3.68, SD 0.68 vs 3.9, SD 1.82) but this difference was not statistically significant (P=.74). A visualization of ATI scores in both groups is shown in Figure 2.

XSL•FO
RenderX

Figure 2. Individual ATI scores (range: 1 - 6) for patients with cutaneous (light blue) or systemic (dark blue) lupus erythematosus and physicians (gray). Patients showed slightly higher scores than physicians, though not statistically significant (P=.74, Mann-Whitney U test).

Discussion

Principal Findings

In this study, we first conducted a systematic search to identify smartphone apps specifically designed for patients with LE, following approaches used in previous evaluations of mobile health apps [24-26]. Among the included apps, *Lupus Log* received a significantly higher MARS score than *Lupus Minder* (P=.03), indicating a clear preference among physicians regarding overall app quality. However, no statistically significant differences were observed in the uMARS scores among patients (P=.*12*), nor between patients and physicians across most subdomains, possibly due to the small sample size and the limited power to detect subtle differences. Although several subgroup comparisons (eg, ATI scores between groups, SUS scores between apps) showed meaningful trends, they did not reach statistical significance.

High agreement among assessors, even for subjective measures, is an encouraging indicator of the reliability of the assessment. While the Enlight [27] framework is another feasible and validated tool for digital health app evaluation, MARS and uMARS were chosen for this study due to its established use in comparative assessments by both health professionals and patients [25], aligning with the study's focus on multi-stakeholder perspectives.

This study identified a limited number of high-quality lupus management apps that met our strict inclusion criteria. Both *Lupus Log* and *Lupus Minder* received decent ratings when rated by raters who can be considered affine to technology based on mean ATI scores greater than 3 for physicians and patients.

XSL•FO
RenderX

With a mean MARS score of 3.91 (SD 0.42), *Lupus Log* was rated highest by physicians. Likewise, it achieved a mean uMARS score of 3.95 (SD 0.62). In the subcategory ‚information', *Lupus Log* was rated higher by patients overall and in the subcategory 'engagement,' possibly due to offering additional information on UV index.

Previous studies have assessed the quality of lupus-related mobile health apps but were limited to evaluations conducted exclusively by healthcare professionals, often with only two raters per app. Ramasamy et al [11] evaluated 19 apps for systemic lupus erythematosus (SLE) and lupus nephritis, reporting that *Lupus Minder* received an overall MARS score of 2.96, with domain-specific scores of 2.9 (engagement), 3.5 (functionality), 3.1 (esthetics), and 2.35 (information). In a separate systematic review, Dantas et al [12] evaluated *Lupus Log*, which scored 2.7 overall, including 3.3 (engagement), 3.2 (functionality), 2.3 (esthetics), and 2.1 (information). While informative, both studies relied on assessments from only two health care professionals per app, without incorporating patient perspectives. In contrast, our study included a broader group of raters—seven physicians and five patients—and uniquely combines both clinical and user-centered evaluations. This dual-stakeholder approach provides a more comprehensive evaluation of app quality and usability. Compared to the previous reviews by Dantas et al and Ramasamy et al, which identified a larger number of lupus apps, our study applied stricter inclusion criteria focused on real-world usability; we included only apps that were free, available on both major platforms, and did not require registration or contain advertising. In contrast, both prior reviews allowed paid apps, iOS-only apps, and apps with limited accessibility.

The episodic nature of lupus makes assessing disease activity and severity challenging, as flare-ups are unpredictable and often go unobserved by physicians. Current evaluations rely on patients' memories, subjective reports, and occasional photos, which can lead to misjudgments and suboptimal treatment. Regular monitoring patient-reported outcome measures is therefore essential, as recommended by lupus management guidelines [28], which advocate for validated tools like LupusQoL [29] and SLAQ (Systemic Lupus Activity Questionnaire) [30] to assess disease control. A mobile health app can simplify this process by enabling continuous tracking of symptoms, severity, and flare-ups while providing an overview for both patients and physicians. This improves support, builds confidence, and enhances treatment precision for physicians and patients.

However, patient involvement in the app development process remains limited [31]. As the primary end users, patients should play a more active role in the co-design and development process to ensure usability, relevance, and engagement [32,33] Both patient-centered apps evaluated in this study, provided a diary function which serves both physicians and patients. While no prior studies have evaluated mobile apps for lupus erythematosus using both MARS and uMARS, comparisons with evaluations in other disease areas, such as mental health, are informative. A recent study using MARS to assess French-language mental health apps [34] reported a top MARS score of 3.85, which is comparable to the scores observed in our study. These findings suggest that the quality of our top-rated apps is on par with apps in better-studied domains, such as mental health.

Limitations

The study's limitations include a small sample size and the subjective nature of the evaluation tools. Future research should involve larger patient cohorts and consider randomized controlled trials to assess app effectiveness more robustly over a longer period. Other app platforms (eg, Huawei AppGallery, Samsung Galaxy Store, Windows Phone Store and Blackberry World) were excluded from the search to focus on the most used platforms—Apple App Store and Google Play Store—which dominate the mobile health app market in Western countries. This exclusion is acknowledged as a limitation of the study. By excluding apps with advertisements, some potentially relevant apps may have been omitted. This narrower inclusion strategy, while intentionally designed, likely contributed to the lower number of included apps compared to earlier reviews.

Conclusions

Lupus Log and *Lupus Minder* offer practical tools for tracking disease activity in both CLE and SLE. These apps have received positive feedback from patients and physicians, supporting disease control and promoting patient self-management. Their acceptance among patients highlights the need for further studies to evaluate long-term use and adapt the apps to meet the needs of both groups. Involving patients in the app design process can enhance usability and relevance, ultimately leading to better disease management outcomes.

Abstract

Background: Neglected tropical diseases disproportionately affect underserved populations, with snakebite envenoming (SBE) remaining one of the most overlooked, despite its significant global burden. Digital health applications (DHAs) offer potential to improve prevention, care, and resource management, especially when integrated into digital health interventions. However, despite growing interest, evidence and structured evaluations are limited, making it difficult to assess their impact without a clear overview of existing tools.

Objective: This scoping review aims to provide the first comprehensive mapping of DHAs for SBE, highlighting their potential to strengthen the World Health Organization (WHO) strategy while underscoring the urgent need for structured evaluation, improved quality, and strategic integration to enhance prevention, treatment, and coordination efforts.

Methods: This review followed the Joanna Briggs Institute and PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) guidelines, with a protocol registered on the Open Science Framework. We searched the PubMed database, app stores, and Google for DHAs between September 24 and 26, 2024, addressing snakebite prevention or treatment. To be included, the DHA had to be accessible via the recorded link, contain a description with snakebite-related features (eg, identification, first aid, and treatment), and allow user interaction. Descriptions had to appear in abstracts, app store listings, or website text. Results were grouped by type (mobile- or web-based) and by WHO region. Furthermore, we examined the 2 most common features: first aid and snake identification. First aid content was benchmarked against global guidelines, while identification methods were categorized, and selected artificial intelligence (AI)–based identification apps were exploratively tested using images of medically significant snakes.

Results: A total of 52 eligible results were included, of which 94.2% (49/52) were mobile apps and 5.8% (3/52) were web-based. Regional focus varied, with most apps targeting South-East Asia (n=11, 21.2%), the Americas (n=9, 17.3%), and the Western Pacific (n=5, 9.6%). However, these numbers largely reflect concentration in just a few countries, namely India (n=10, 19.2%), the United States (n=5, 9.6%), and Australia (n=5, 9.6%). The most frequent feature was snake identification support, for example, through photo upload and algorithm-based recognition. However, AI-driven identification often lacked clarity and performed inconsistently in testing. First aid guidance was also common, but only a handful of apps offered comprehensive, evidence-based advice, while others omitted key steps or recommended unsafe practices.

Conclusions: This review provides the first structured evaluation of DHAs for SBE and offers a reproducible framework for assessing digital solutions across neglected tropical diseases. By highlighting key gaps and proposing a foundation for integration into national strategies, it supports the development of equitable, evidence-based digital health innovation in underserved areas.

KEYWORDS

snakebite; neglected tropical diseases; digital health; mobile health; mHealth; digital health application; artificial intelligence; AI

Introduction

Snakebite envenoming (SBE) is currently classified by the World Health Organization (WHO) as one of the 21 neglected tropical diseases (NTDs). Even within the NTD portfolio, SBE receives limited attention and resources, despite global estimates of 2.7 million SBE cases annually and an estimated 81,000 to 138,000 deaths each year [1-3]. The WHO's snakebite prevention and control strategy aims to halve snakebite deaths and morbidity by 2030, by focusing on four priority areas: (1) empowering and engaging communities; (2) ensuring safe and effective treatment; (3) strengthening health systems; and (4) increasing partnerships, coordination, and resources [1]. Progress has been made since this goal was set in 2019, but it remains slow [4].

Digital health interventions (DHIs), which are specifically designed to address health functions through digital means, can enhance access to treatment, health care provider training, collaboration, and resource distribution [5]. DHIs often use digital health applications (DHAs), such as telemedicine, mobile apps, or web-based platforms [6]. Despite the recognized value of DHIs in advancing universal health coverage, evidence of successful implementation for NTDs, including SBE, remains limited [7]. One of the few well-documented examples is in skin NTDs, where mHealth apps, teledermatology, and artificial intelligence (AI)–driven detection tools have improved diagnosis and management in resource-limited settings [7-9]. Additionally, the WHO's "Skin NTDs app" demonstrates how targeted mHealth apps can support health care workers in making informed clinical decisions, which improve patient care [10].

In SBE, DHIs have the potential to strengthen all 4 WHO priority areas. First, they could empower communities by providing easily accessible first aid and prevention advice. Second, an easy-to-access digital guide outlining safe and effective treatment protocols can enhance the knowledge and capabilities of health care workers. Third, digital reporting applications could be used to collect data on cases that present to the health facilities, helping to fill existing data gaps. Fourth, DHIs could facilitate collaboration among hospitals, nongovernmental organizations, researchers, and patients, improving coordination, treatment, and data sharing. These advancements could streamline prevention, care, and resource management for better outcomes. Despite the rise of DHAs for SBE, there is a lack of evidence, integration within broader DHIs, and structured evaluations. In the absence of a clear overview of existing applications, assessing their impact remains a challenge. Therefore, a comprehensive review of the current landscape for SBE is essential to inform and guide future efforts.

This scoping review systematically identifies currently available DHAs for SBE management, maps their distribution by WHO region, and summarizes their functions. With this review, we aim to provide an overview of the existing DHAs for SBE, laying the foundation to reduce redundancy, foster collaboration, optimize priorities, and improve resource allocation in line with the WHO's goals.

Methods

This review was structured according to the Joanna Briggs Institute's *Manual for Evidence Synthesis on Scoping Reviews*, the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) checklist (Checklist 1), and design guidelines for scoping reviews, as outlined in the protocol registered with the Open Science Framework on August 2, 2024 [11-13].

Search Strategy

We searched PubMed database for literature on DHAs for SBE, as well as the Google Play Store, Apple App Store (using fnd.io [14]), and Google search engine for digital applications related to SBE. Search terms for PubMed database were ("snakebite" OR "snake bite") AND ("digital health" OR "telemedicine" OR "telehealth" OR "mHealth" OR "m-Health" OR "eHealth" OR "E-Health" OR "health app" OR "digital health intervention" OR "digital health technology" OR "healthcare app" OR "mobile health app" OR "remote healthcare" OR "digital diagnosis" OR "digital treatment" OR "digital tool" OR "digital surveillance" OR "digital monitoring" OR "AI"). As Boolean searching did not work in app stores, these were searched by each search term individually ("snakebite," "snake bite," "snake identification," "snake surveillance," "snakebite surveillance," "snakebite diagnosis," "snakebite treatment," "snakebite first aid," "snakebite education," "snakebite prevention"). The internet search was kept broad to try to capture as much as possible ("app" OR "digital health" OR "eHealth" OR "mHealth" AND "snakebite" OR "snake bite"). The complete search strategies and translations are detailed in Multimedia Appendix 1 (Search Queries). All searches were first conducted in English. The Google search was repeated in 13 languages. The first 50 nonsponsored results were selected from each Google search. Non-English results were translated using Google Translate or DeepL [15,16]. Applications known to the author team that were not retrieved through the user-centric search were subsequently added as expert knowledge and screened against the same eligibility criteria.

The searches were performed between September 24 and 26, 2024, from a German IP address. Further details are provided in the published protocol [13].

Selection Criteria

To be eligible for inclusion, the application had to be accessible through the recorded link and include a description that included features relevant to the treatment or prevention of snakebites in humans (eg, snake identification, snake information, first aid, and treatments). These descriptions had to be available in the abstract (for published literature), app store description or images (Google Play Store and Apple App Store), or website

XSL•FO
RenderX

text (Google search). Users had to be able to perform actions in the application through buttons, forms, or menus.

Study Selection

All search results were exported to a data extraction template in Microsoft Excel (Multimedia Appendix 2) with the following information: publisher or source name, app title (app name, website, or article title), link to the result, search type, and language. After removing duplicates within the searches and results with invalid links, the remaining results were screened for inclusion according to the selection criteria. If an application appeared in multiple searches, it was included only once. When identified in both an app store and through a Google search, the app store version was included in the results. If an app was available in both the Apple App Store and Google Play Store, only the latter was included. Excluded results were documented with exclusion reasons. Two reviewers conducted screening and extraction in duplicate.

Data Extraction

For the included applications, we extracted the data policy availability, associated access costs, features offered (grouped according to those with a human focus [prevention, first aid, and advanced treatment], snake focus [snake identification and habitat information], or other focus [eg, snake rescue]), the region and/or country if applicable, the platform type (mobile- or web-based), and whether the application was snake-specific or not. In addition to the data included in the original study protocol, we decided during the search to further record user ratings (count and stars), downloads (available for Google Play Store), app store category, device availability (iOS/Android), release date, and the last update before November 18, 2024, if available.

Data were extracted iteratively from online sources for more than 2 months. This resulted in missing values for some of the apps that became unavailable later in the extraction period. While all core variables, such as features and region, had already been recorded before the apps became inaccessible, assessments of AI and first aid information could not be performed for all apps.

Discrepancies were resolved through discussion and cross-verification. Data extraction was completed by November 19, 2024. Any deviations from the original protocol, along with their rationale, are detailed in Multimedia Appendix 3.

Ethical Considerations

This study synthesized information from publicly accessible sources (including app store listings and publicly available websites) and did not involve human participants, interventions, or individual-level identifiable data. Therefore, ethics approval, informed consent, and participant compensation were not applicable.

Synthesis of Results and Content Evaluation

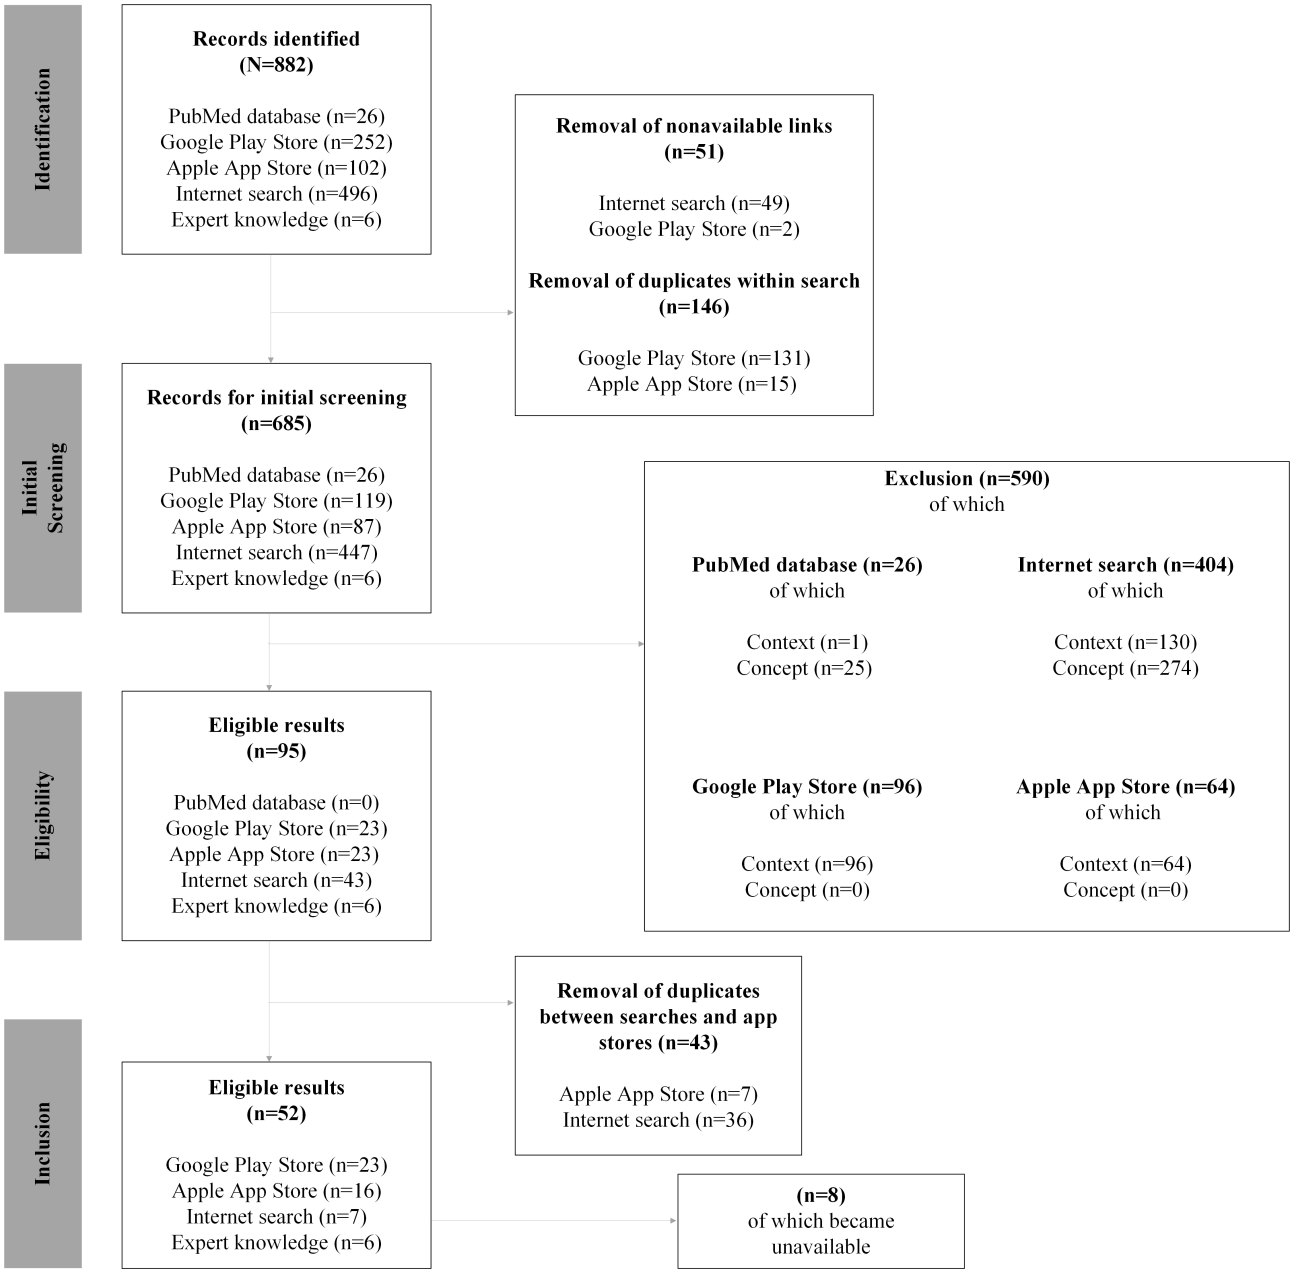
Because of regional download restrictions and the lack of a standardized evaluation framework, we were unable to assess all app features systematically. Instead, we focused on the 2 most common features: first aid and snake identification.

First aid content was compared with globally applicable guidelines from Health Action International and the Global Snakebite Initiative [17]. The results can be found in Multimedia Appendix 4. For snake identification features, we classified apps into different categories based on the methodology provided by the app provider. In cases where apps reported AI-based identification features, we reviewed publisher descriptions and user feedback.

We then conducted exploratory testing of 3 different AI-based identification apps to assess their performance. We selected and tested 3 apparently credible apps: the single available web-based app, one general reptile identification app, and one snakebite-specific identification app selected at random from the existing options. Apps with unrealistic claims or consistently poor user ratings were excluded, ensuring only reasonably credible applications were included. To cover a wide range of species from different regions, we used 2 images for each of the 12 most medically significant snake species (as defined by the WHO [18]), resulting in 24 test images. These species were (1) *Naja kaouthia*, (2) *Crotalus durissus*, (3) *Calloselasma rhodostoma*, (4) *Dendroaspis polylepis*, (5) *Daboia russelii*, (6) *Bitis arietans*, (7) *Echis ocellatus*, (8) *Naja haje*, (9) *Bothrops asper*, (10) *Pseudonaja textilis*, (11) *Oxyuranus scutellatus*, and (12) *Bungarus candidus*. We used verified photos from iNaturalist (with the appropriate use rights) that reflect what a typical user might upload [19]. Responses for each image were recorded as shown in Multimedia Appendix 5. We divided the results into 5 categories. The first category, “correctly identified,” was used when the species in the image was correctly named (eg, when an image of *Bitis arietans* was identified as *Bitis arietans*). The second category, “misidentified as a nonvenomous snake,” was used when a venomous species was incorrectly labeled as nonvenomous (eg, when *Bitis arietans* was misidentified as *Aspidites ramsayi*). The third category, “misidentified as another venomous snake,” included cases where the species was confused with another venomous species (eg, when *Bitis arietans* was identified as *Daboia russelii*). The fourth category, “misidentified as nonsnake,” was assigned when the image was classified as something other than a snake (eg, a worm). The fifth category, “NA,” was used when no response was generated due to technical issues.

The included applications were grouped according to their platform type (mobile- or web-based), regional focus (WHO regions), and features offered.

Results



Overview

A total of 882 results were identified, including those from the PubMed database (n=26, 2.9%), Google Play Store (n=252, 28.6%), Apple Store (n=102, 11.6%), Google Search (n=496, 56.2%), and expert knowledge (n=6, 0.7%; Figure 1). After removing duplicates within single searches (n=146, 16.6%) and results with nonfunctioning links (n=51, 5.8%), 685 (77.7%) records were screened using the eligibility criteria. All PubMed database (n=26, 2.9%) results were excluded either because they were not SBE-related or did not describe a DHA (eg, general publications about snakebites). App store results were

XSL•FO
RenderX

excluded for lacking snake or SBE-related content (n=160, 18.1%; eg, snake games), and internet search results were excluded for not being SBE-related or not being interactive DHAs (n=404, 45.8%; eg, news on snakebite victims). After removing cross-search duplicates (n=43, 4.9%), 52 (5.9%) results remained: 39 (39/52, 75%) from app stores (23/39, 59% Google Play Store and 16/39, 41% Apple App Store), 7 (13.5%) from the internet search, and 6 (11.5%) from expert knowledge (Figure 1). Of these, 94.2% (49/52) were mobile apps and 5.8% (3/52) were web-based platforms. Of the 49 mobile apps, the oldest was released in 2015, while 28 (57.1%) apps were released since 2019.

Figure 1. Flowchart of the digital health applications (DHAs) identified during screening. Reasons for exclusion were categorized as (1) context: not relevant for snakebite envenoming; (2) concept: not an interactive DHA; or (3) unavailable: not (or no longer) available (eg, broken link, 404 error, or security warning).

Of the 52 applications, 32 (61.5%) were snakebite-specific, while 20 (38.5%) were general applications that included snake-related content. Key features identified in these apps included snake identification (n=41, 78.8%), first aid advice (n=27, 51.9%), habitat information (n=18, 34.6%), prevention advice (n=8, 15.4%), and advanced treatment advice (n=7, 13.5%). A total of 18 (34.6%) applications included additional features, such as snake removal contacts or lists of hospitals with antivenom.

Mobile Apps

Most mobile apps targeted a specific WHO region: South-East Asia (11/49, 22.4%), the Americas (9/49, 18.4%), Western Pacific (5/49, 10.2%), Africa (3/49, 6.1%), and Europe (1/49, 2.0%); 20 (40.8%) were nonregion specific or the region was unclear. We divided these 20 apps into two categories: (1) worldwide region, which includes apps with a clear global focus as indicated by the provided information or images, and (2) unclear region, which includes apps for which the regional scope

XSL•FO
RenderX

could not be determined from the provided information or images. App details are summarized in Table 1.

South-East Asia

Eleven apps were identified for South-East Asia (India n=10, 90.9% and Bangladesh n=1, 9.1%), and all were freely accessible. The app for Bangladesh included information on snake species, first aid advice, hospital and snake removal contacts, and educational content [20].

For India, 5 (50%) apps were designed for nationwide use, while 3 (30%) were specific to Kerala, 2 (20%) to Odisha, and 1 (10%) to West Bengal. The countrywide apps featured AI-assisted snake identification [21], field guides [22,23], and apps for snakebite management, including hospital and snake removal contacts [24,25]. The Kerala apps included a field guide with expert support and resource lists [26], first aid advice and emergency contacts [27], and a hospital search app with information on antivenom availability [28]. The apps for Odisha [29] and West Bengal [30] offered local snake information, snakebite symptoms, first aid advice, and snake removal contacts. The West Bengal app also listed hospitals with antivenom. Download numbers were available for all apps, ranging from 500 [28] to 100,000 [26].

Americas

Nine apps were identified for the Americas (United States: n=5, Suriname: n=2, Mexico: n=1, and Brazil: n=1). Seven apps were free, and 2 for the United States had in-app purchases [31,32].

For the United States, 4 apps were designed for nationwide use, and 1 was specific to North Carolina. Three supported snake identification [31,33,34]: 2 field guides that also contained first aid advice [33,34], and 1 that claimed to offer AI-based snake identification with expert verification [31]. One app focused on prevention and first aid specifically for North American pit vipers [35], while the remaining app offered general first aid advice and information on snakebite prevention [32].

The apps for Mexico, Brazil, and Suriname provided first aid advice, expert contacts, and antivenom information. The Mexican app focused on venomous scorpions, spiders, and snakes, as well as expert contacts [36]. The Brazilian app offered SBE victims and medical personnel first aid advice and snake reporting [37]. One Suriname app offered first aid advice and treatment information for SBE victims and medical professionals [38], while the other was a field guide with first aid advice [39]. Download numbers were available for 4 of these apps, ranging from 10 [39] to 100,000 [31].

Western Pacific

All 5 apps for the Western Pacific were specific to Australia, with 1 specific to the state of Victoria. Most were free, with 1 snakebite-specific app available for US $6.99 [40].

Three apps offered snake identification features: 2 field guides [40,41], and 1 with additional educational resources, first aid advice, and prevention [42]. Two others offered general first aid advice, including specific advice for snakebites [43,44]. Download numbers were available for 4 of these apps, ranging from 100 [40] to 50,000 [40,42].

Africa

Three apps were identified for Africa: 2 were free [45,46], and 1 cost US $15.99 [47]. All offered first aid advice. Two apps were designed for Southern Africa (without defining specific countries). These included an interactive, comprehensive field guide [47] and a basic snake identification guide with expert identification and contacts for snake removal [45]. The third was a general first aid app for Africa, which included specific advice for snakebites [46]. Download numbers were available for 2 of these apps, ranging from 1000 [46] to 100,000 [45].

Europe

One app was identified for Europe, specifically designed for Sweden. This free app serves as a field guide offering snake identification, habitat information, and basic first aid advice [48].

Worldwide

All 4 apps identified for worldwide use offered snake identification features. Two were general AI-based identification apps with optional in-app purchases [49,50]; the other 2 were free and used crowdsourced identification, 1 included habitat information [51], and the other used gamification [52]. Download numbers were available for the 2 crowdsourced apps, ranging from 1 million [52] to 5 million [51].

Unclear

Sixteen apps had an unclear regional focus. Most were free, while 6 (37.5%) apps involved a cost. A total of 10 (62.5%) offered snake identification features: 8 (80%) were snake-specific [53-60], and 2 (20%) were general animal apps [61,62]. Five (31.2%) were general first aid apps, which included specific advice for snakebites [63-67], and 1 (6.2%) collected snakebite data and linked snakebite victims to hospital care [68]. Download numbers were available for 6 of these apps, ranging from 100 [68] to 100,000 [65,66].

Web-Based Platforms

Only 1 web-based platform was identified: “AI.Snakes,” which offered advanced treatment information, AI photo-based and clinical assessment–based identification, and regional risk assessments [69].

XSL•FO
RenderX

Two global platforms were added through author team expert knowledge [70,71], as they were not retrieved though the search strategy: the WHO's "Snakebite Information and Data Platform" with information for up to 373 snake species, including distribution maps, antivenom, and clinical guidance; and the "VAPAGuide," a free expert resource with emergency protocols, clinical flow charts, and species data. The web-based platforms and their functions are summarized in Table 2.

[a]Artificial intelligence–based photo identification.

Snake Identification

Of the 41 DHAs offering snake identification features, 17 (17/41, 41.5%) enabled photo uploads for identification, of which 2 (2/17, 11.8%) relied on expert identification [31,45], 2 (2/17, 11.8%) on identification by online communities [51,52], 13 (13/17, 76.5%) claimed to offer AI identification [21,49,50,53-59,61,62,69], 15 (15/41, 36.6%) displayed snake images or photos, 5 (12.2%) were field guides, and 1 (2.4%) used algorithms based on clinical symptoms and described snake morphology (eg, scale patterns) [24]. The identification process was not described in 3 apps (7.3%) [22,30,60].

For 4 AI-based DHAs, developer credentials and algorithm accuracy were unclear [21,54-56]. One claimed accuracy of more than 100% for each identification result [58], 4 apps were no longer available when we attempted to evaluate the feature [21,54-56], and some received user criticism in reviews based on the algorithm's randomness in the results [53].

On the basis of our explorative assessments of 3 selected AI-based snake identification applications, the performance of this feature was highly variable. The "AI.Nature" application failed to return a result for any of the 24 photos used. The "Snake ID – reptile identifier" correctly identified 2 images but failed to detect a snake in 5 images, misidentified the snake as nonvenomous in 10 images, and suggested the wrong venomous species in 7 images. The "Frog Identifier Reptile ID" app correctly identified 13 images but failed to detect a snake in 1 image, misidentified the snake as nonvenomous in 1 image, and suggested the wrong venomous species in 9 images. Performance results and images used are shown in detail in Multimedia Appendix 5.

First Aid

A total of 27 applications featured first aid advice for snakebites. These included 15 (55.6%) snake-specific apps, 9 (33.3%) general first aid apps with snakebite content, 2 (7.4%) general reptile guides, and 1 (3.7%) app on bites and stings. During the evaluation period, 5 (18.5%) apps were not accessible, and 2 (7.4%) were no longer available in the app store. Therefore, we were unable to evaluate them. This resulted in 20 (74.1%) apps being available for download and assessment. Of those, 3 (15%) covered all recommended first aid steps [23,24,26]. Most advised reassuring the bitten person, remaining calm, minimizing movement, and seeking medical care, but many omitted warnings about traditional or unsafe treatment (n=10, 50%) or the importance of moving away from the snake (n=12, 60%). Three (15%) apps incorrectly recommended washing the wound, and the "Army First App" advised killing the snake for identification and using a constricting band. Three (15%) apps provided minimal or no information [64,66,67]. Full details are provided in Multimedia Appendix 4.

Discussion

Principal Findings

This scoping review presents the first structured overview of DHAs for SBE and represents one of the earliest systematic efforts to characterize DHAs for NTDs with a breakdown of available features [13]. We identified 52 DHAs relevant to snakebite treatment or prevention, most of which were offered as snakebite-specific mobile apps. The most common features included snake identification and first aid advice.

Despite the number of apps available, their distribution does not align with the global burden of SBE. High-incidence regions, such as sub-Saharan Africa, remain underrepresented, with only 3 apps available for the region, while low-incidence countries, such as the United States and Australia have 5 apps each. This reflects the broader disparities in funding, research capacity, treatment infrastructure, and epidemiological data [72]. Most African countries lack reliable data on SBE, limiting effective policymaking and resource allocation [73]. This underrepresentation of the African continent extends to the nondigital space. Despite promising initiatives, snakebite management in Africa remains largely underfunded and underresourced [72]. Access to smartphones and reliable internet is increasing across the African continent, making DHAs increasingly useful, particularly for health care workers [74]. Nevertheless, access remains limited, especially in rural populations, which continues to restrict the utility of DHAs for those populations. This contrasts with better rural connectivity

XSL•FO
RenderX

observed in South Asia and the Western Pacific [75]. However, beyond India and Australia, these regions still face limited availability of snakebite-related DHAs.

First aid and snake identification were the most common features. Most apps' first aid features were aligned with established guidelines, and only one app included several contraindicated practices [63]. However, transparency around authorship, clinical validation, and accountability was often lacking, raising safety concerns. These apps could be improved by referencing international guidelines, linking sources, and warning against harmful practices. Because many people self-treat using unsafe methods, validated content could improve outcomes and support the WHO's pillar to empower communities with better knowledge and applications.

Despite reported advances, the availability of AI-based snake identification apps remains limited and user-facing performance is variable. Challenges, such as interspecies similarities, species variation, and poor image quality, make accurate identification difficult. Nevertheless, research prototypes trained on large image datasets have reported high classification accuracy across many species and in real-world images [76-78]. However, even occasional misidentifications pose serious risks if used for medical decisions after snakebites. In our exploratory assessment, using verified images loaded into 3 apps which claimed to use AI for snake identification, outputs were inconsistent, with frequent misidentifications or no results (Multimedia Appendix 5), suggesting limited real-world usability of current AI-claimed snake identification apps. None of the reviewed apps offering AI-based snake identification disclosed details on development or evaluation details (eg, training data, validation datasets, and versioning), and most relied on internally derived confidence scores rather than externally validated outcomes. These gaps highlight the mismatch between research-level AI and published apps [79].

Few apps disclosed their development purpose or process, and many were developed outside health systems, lacked regulatory oversight, and included liability disclaimers, indicating the need for stronger regulation. Several apps also lacked emergency-friendly interfaces, relying on long, unstructured PDFs that pose risks during time-sensitive situations. Despite these limitations, apps with expert input and clear scope hold promise, especially if further developed within regulatory frameworks. Only 1 app was described in a peer-reviewed publication, highlighting the general lack of scientific documentation or transparency in app development [80]. This manuscript was published after our analysis and was therefore not identified through our initial search.

Recommendations

The review identifies 4 priority actions to improve the quality, accessibility, and alignment of DHAs for SBE. Responsibility should be considered on multiple levels: national health authorities and professional societies can define minimum clinical content standards and integration pathways, app marketplaces can require baseline transparency fields as listing criteria, and global actors can support shared taxonomies and registries to improve discoverability and interoperability.

First, enforcing basic transparency and documentation standards, such as publishing development histories, data sources, and use context, would enable consistent assessment. Co-designing apps with target user groups, particularly underserved groups, would ensure relevance and usability. Second, a global digital health registry for SBE and other NTDs could enhance visibility, reduce duplication, support interoperability, and promote uptake. Third, incentivizing open collaboration (eg, co-design, open-source codebases, stakeholder involvement, or version control) would improve usability and trust. Fourth, aligning app development with national digital health strategies and systems would strengthen sustainability and institutional support.

Strengths and Limitations

This study has several limitations. First, reliance on real-time data extraction rather than app downloads may have led to the extraction of incomplete data. However, this only applies to data from apps no longer accessible, illustrating the app marketplace's volatility, particularly in niche or fast-growing areas. Second, the user-centric search strategy may have missed less visible resources. Notably, 2 expert platforms known to the author team were not identified in the search and were only included via expert knowledge [70,71]. The inability to find these platforms, despite using a very broad search strategy and searching in multiple languages, probably reflects challenges that typical users may also face. Visibility of apps and platforms is influenced by algorithmic ranking and varying levels of search engine optimization, and not by the quality of the DHA itself. End users and frontline health workers operating under time pressure and resource constraints are unlikely to find these platforms with a simple search and have even fewer cues to judge whether tools are trustworthy and fit for purpose, an especially acute challenge in neglected disease settings.

Furthermore, our search strategy may have overlooked digital tools without a direct web presence, such as chatbots running on platforms such as WhatsApp [81]. It also excluded other service-based digital solutions, such as remote consultation platforms, including the Remote Envenomation Consultancy Services in Malaysia [82]. Although this is a limitation, the lack of an online presence meant that this type of DHA could not be directly analyzed. Its content was not readily accessible and therefore falls outside the scope of this review, as this was an inclusion criterion. Finally, we did not download, evaluate, or compare all available apps, as currently no standardized framework exists for assessing snakebite apps, and any such comparison would have been inherently subjective. Despite these constraints, the gray-inclusive strategy and registered protocol support reproducibility. Findings align with WHO priorities on transparency, interoperability, and equity in digital health [5,83,84].

This review identified critical gaps in transparency, metadata completeness, standardized evaluation, efficacy metrics, and alignment of digital snakebite apps with health governance frameworks. Many apps lacked documented development processes, references to clinical standards, or integration with national health strategies. These deficits undermine long-term sustainability, impede user trust, and hinder integration into structured care pathways.

XSL•FO
RenderX

Geographic misalignment, particularly underrepresentation in high-burden regions such as sub-Saharan Africa, along with persistent digital inequities in low- and middle-income countries, further highlight the disconnection between needs and app availability. Without targeted efforts to strengthen DHA and address usability barriers in low- and middle-income countries, such apps risk reinforcing exclusion rather than improving access [7]. Infrastructure challenges, regulatory gaps, and poor interoperability further complicate integration into formal care systems.

Despite pervasive gaps in transparency, quality, and integration, the findings from this review provide a replicable foundation for future assessment and strategic planning of digital applications in the field of SBE. Scaling this framework across NTDs and embedding shared standards can support equitable, evidence-based digital innovation in neglected disease areas.

Acknowledgments

The authors would like to thank Anaïs Ludolph, Johanna Holm, Rangarirai Makuku, Ana Castiella García, Roselyn Kang'ara, Quy Quoc Bao Truong, Ahmad Junaedi, Ángela Duarte Pardo, Atishay Mathur, Helen Merin-Sostmann, Mohamed El Houboub, Jarntrah Sappayabanphot, and Jessica Lee for their support with the translations of the search terms. Generative artificial intelligence (AI) tools were used solely for language editing and condensation support under full author supervision. No sections of the manuscript were generated autonomously by AI, and all wording and content were reviewed and approved by the authors.

Funding

The review was supported with core funding from the Bernhard Nocht Institute for Tropical Medicine.

Data Availability

Detailed search terms can be found in Multimedia Appendix 2, and inclusion and exclusion criteria are available in the protocol. The main dataset and the final results generated from this review are available at Open Science Framework [85].

Authors' Contributions

Conceptualization: DH, OG, BK, PS, TATD
Data curation: DH, OG, TVT, TTTP
Formal analysis: DH, OG, JDR
Investigation: DH, OG
Methodology: DH, OG, LK, BK
Project administration: DH, BK

Abstract

Background: The use of mobile health (mHealth) apps can assist with the management of gestational diabetes (GDM). Although a number of studies have demonstrated their efficacy in improving maternal-fetal outcomes, opinions differ regarding their usability and overall quality. Poorly designed apps, with ill-conceived features or inappropriate content, may pose a threat to patient safety. Nevertheless, very few studies provide in-depth evaluations of app design quality, and the diversity of features and techniques used remains insufficiently explored.

Objective: We aimed to evaluate the quality and multifunctionality of commercially available mHealth apps for GDM.

Methods: This is a systematic app review guided by the TECH (target user, evaluation focus, connectedness, and health domain) framework and the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 checklist. Searches were conducted on the Apple App Store and Google Play. Apps were screened by name, description, and full navigation to identify inclusions. The quality of the apps was evaluated using the Mobile App Rating Scale and IMS Institute for Healthcare Informatics Functionality Score. Multifunctionality of the apps was evaluated using the GDM-adapted features and techniques list developed from the App Behavior Change Scale, NICE (National Institute for Health and Care Excellence) 2015 guidelines, and previous studies. The general features list, which contains instruction, data security, customization, and technical issues, was derived from previous studies.

Results: The search (June 2024) identified 23 commercially available apps from UK app stores. The overall app quality was evaluated to be satisfactory (Mobile App Rating Scale: mean 4.0, SD 0.36; IMS Institute for Healthcare Informatics Functionality Score: mean 5.83, SD 3.03). The multifunctionality evaluation found that the apps had a mean of 17.95 and SD of 7.31 across all 45 items. Overall, our findings suggested that mHealth apps for GDM achieved a certain level of multifunctionality. However, their feature types and supporting digital techniques are relatively basic. The apps focused on education and managing blood glucose control rather than integrating other self-monitoring data and pregnancy-relevant management into their design. The digital techniques used to achieve these features included text and manual operation, rather than other automated features.

Conclusions: This is the first app review to consider the relationship between app features and usability for women with GDM. Future app development should integrate a wide range of pregnancy-relevant information and more automated features and use advanced digital techniques to enable a holistic digital solution for women with GDM.

Introduction

Challenges in Gestational Diabetes Self-Management

The self-management of gestational diabetes (GDM) usually includes a series of complex lifestyle behavioral changes such as diet, exercise, and continuous self-testing of blood glucose [1]. This systematic approach aims to help women maintain optimal blood glucose levels and minimize complications for both mother and baby. However, previous research highlights the challenges for women with GDM, who find it hard to understand or follow the instructions from doctors [2]. Women have to make decisions on food choices daily, and this is done through effective cooking strategies [3]. It also challenges

XSL•FO
RenderX

women to understand the labels and nutritional values of food [4]. Guidelines across countries emphasize the importance of strengthening physical activities and regard aerobic activities as acceptable approaches [5]. However, this requires carefully choosing the level of intensity and the types of exercise [5].

Mobile Health Apps Help With Self-Management of GDM

GDM digital technologies have covered various areas of GDM management, providing features including aspects of educational information, health behavior coaching, data recording, and communication interfaces for women [6]. By analyzing the overall effectiveness, previous literature found that GDM digital technologies could provide comparable quality of care to face-to-face visits with health care professionals or midwives, manifesting in heightened maternal health conditions and increased rates of natural childbirth, alongside diminished occurrences of adverse maternal and neonatal outcomes [7-9].

There are various forms of digital technologies, such as mobile apps, webpages, and digital devices, among which mobile apps are one of the most common types of technology used [9]. The rise in global smartphone penetration has led to the evolution of mobile apps, which are now one of the most representative forms of GDM digital technologies [8-10]. Mobile phones possess advantages in terms of accessibility as they are portable devices, thereby facilitating women's access to digital services irrespective of their geographical locations [11,12].

Variation in Perceived Usability of Mobile Health Apps for GDM

However, unlike the overall optimistic results from the evaluation of effectiveness, our previous review and other studies found a variation in pregnant women's views on the app's usability [13,14]. Women had positive views of apps when they supported self-monitoring and viewed them as beneficial tools for obtaining information about GDM, making informed dietary decisions, and facilitating exercise regimens [13,15-17]. The technologies also led to increased levels of adherence, concentration, and satisfaction among women [7,14]. The apps offered platforms for the women and clinicians to keep continuous interaction, fostering the client-clinician relationship [16,18]. This mitigated various concerns that women encounter in managing their condition, demonstrating efficacy in facilitating women's self-management practices [7-9]. In the meantime, apps added to women's emotional burden with problematic features and content [13]. For example, redundant processes and frequent failures in data recording reduced women's motivation for using the technology [18,19]. The differences between the information provided by apps and clinicians confused the women [16]. Evidence suggests that mobile health (mHealth) apps might unintentionally lead to increased unhealthy behavior [20]. mHealth apps designed inappropriately may contain inaccurate or incomplete information that misleads users or provide insufficient support for managing high-risk behaviors, which could affect users' safety [21].

Challenges to Conducting a Comprehensive Evaluation of GDM Apps

To ensure that women are offered apps of the best quality, health care practices face challenges in evaluating and selecting suitable options. The current era is facing the results of unregulated mHealth markets, which flourish in the number of emerging mHealth apps but vary in quality [22]. The increasing study of app quality evaluation has triggered a discussion on the definition of app quality. Studies found that the criteria used for evaluating app quality were heterogeneous [23,24]. In addition, established criteria lack precise definitions, which hinders the assessment of app quality.

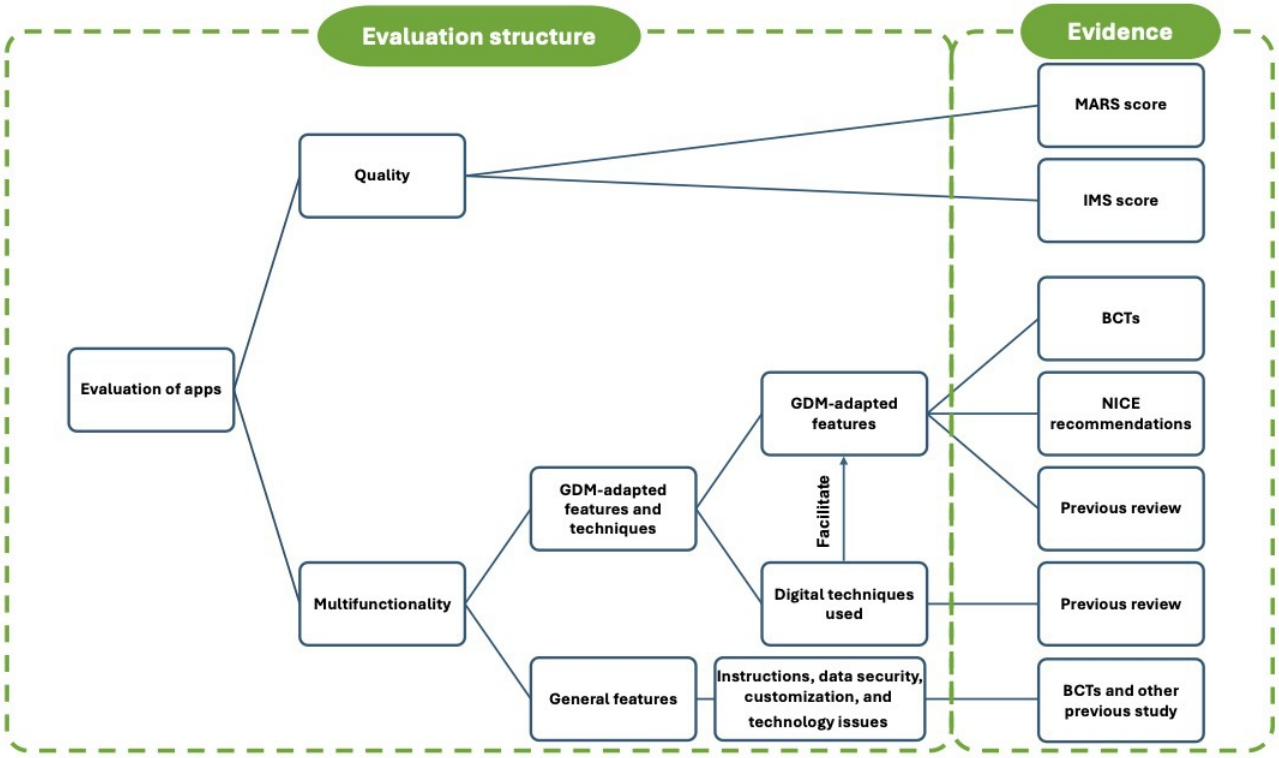
Two previous reviews have evaluated the functionality and usability of GDM mHealth apps [6,25]. Both reviews primarily relied on a single quality criterion: the Mobile App Rating Scale (MARS). However, neither study addressed how well app features are adapted to GDM self-management content. Similarly, they offered no practical insights to assist health care professionals in selecting apps that are both functional and user-friendly. What is missing from the current literature is an evaluation of how these apps contain features suitable for GDM care, and guidance that helps health care professionals when selecting usable apps.

Objectives

This study reviewed commercially available mobile apps to explore app quality and multifunctionality, targeted at antenatal care for women with GDM or pre-existing diabetes during pregnancy, available in the UK app market, and in the English language. This systematic evaluation only includes free-download apps and analyzes the available free-of-charge features, providing insights into the types of features that are most accessible for women with GDM. We assessed the quality of the apps using standardized evaluation scales. We evaluated the app's multifunctionality based on app features and content tailored specifically to the GDM population, as well as general features that affect the normal use of apps.

Methods

Study Design



This study followed the TECH (target user, evaluation focus, connectedness, and health domain) framework proposed by Gasteiger et al [26] (2023), which is tailored for the context of reviewing and evaluating the quality of commercially available mHealth apps as opposed to the systematic literature review methodology. Informed by the traditional systematic review process, the TECH framework aims to help conduct reviews on mobile apps by establishing search strategies, the use of eligibility criteria, and a comprehensive quality appraisal. It provides guidance to conduct a search, and has been applied in recent studies to evaluate mHealth apps, including risk assessment and self-management tools, by examining both their functionality and content [27-29].

This study consists of 2 major domains of evaluation: app quality and app multifunctionality. Figure 1 shows the structure of the evaluation elements and the evidence supporting the evaluation. The app quality evaluation in this study aimed to

XSL•FO
RenderX

explore the type of features being used in the included apps and used generalized tools to quantify the level of quality. The measurement was informed by the TECH framework and guidance by introducing both the MARS and the IMS Institute for Healthcare Informatics Functionality Score (IMS). The aggregation of the 2 quality appraisal tools helps to evaluate mobile apps more comprehensively.

Figure 1. Evaluation structure. BCT: behavior change technique; GDM: gestational diabetes; IMS: The IMS Institute for Healthcare Informatics Functionality Score; NICE: National Institute for Health and Care Excellence; MARS: Mobile App Rating Scale.

The multifunctionality evaluation aimed to conduct a GDM context-tailored assessment on the behavior change techniques (BCT) used in the apps, as well as other essential features needed to be enabled for normal app usage. Therefore, there were two elements in the multifunctionality evaluation: (1) the GDM-adapted features and techniques, which refer to the app features aligned with BCTs, along with the digital techniques used to enable the features; and (2) the general features, which refers to the essential features that enable the normal usage of apps, including instructions, data security, customization, and technical issues.

Eligibility Criteria

Following the guidance of the TECH framework, a scoping search on Apple App Store and Google Play in the UK context was run in March 2024 to identify eligibility criteria [26]. This study aims to identify apps that include GDM as one of the targeted user groups and that eligible apps must refer to GDM in their description to qualify for inclusion in this study. From this process, three potential types of mobile apps were identified: (1) mobile apps for GDM management, (2) mobile apps for pregnancy management with additional features for blood glucose control, and (3) mobile apps tailored for diabetes patients but claimed to be suitable for women with GDM. Additionally, the mobile apps were available in the UK context and the English language, free to download, running on Android (Google LLC) or iOS (Apple Inc). The eligibility criteria are listed as follows (Multimedia Appendix 1):

1. Target user (T): mobile apps tailored for GDM, pregnancy, and diabetes users, with GDM as one of the targeted user groups.
2. Evaluation focus (E): content of information, quality, and functionality of the mobile apps that are suitable for users with GDM.
3. Connectedness (C): mobile apps with external devices such as glucose meters and smartwatches.
4. Health domain (H): mobile apps suitable for antenatal behavioral change for women with GDM rather than prevention or postpartum care.

Search

The search keywords "gestational diabetes," "GDM," and "pregnancy diabetes" were applied in the search strategy. The final search was conducted by 3 reviewers on the Apple App Store and Google Play in June 2024. Due to the Apple App Store's online page design, it was not possible to export the search results into screening software to remove duplicates. Additionally, the mobile app search results were subject to frequent changes over time. To avoid unnecessary duplication in the search, all 3 reviewers searched and performed screening on the same day.

Screening

The screening process was guided by the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) checklist and the TECH methodology [26,30]. Two steps of

XSL•FO
RenderX

screening were applied, including title screening and full mobile app screening. The mobile app name and description screening process was conducted on the search results pages to identify potential mobile apps for inclusion. We contacted the app companies to access those apps with limited access during the retrieval process. A subsequent full mobile app screening was conducted to check the relevance and feature operability. To include the mobile apps which were usable at the technological level as well as suitable for the targeted population, the full mobile app screening process made a decision of inclusion when (1) the screened mobile app was available in English; (2) no constant technical glitch or crash occurred when operating; and/or (3) the mobile app mentioned GDM at least once in options, information, or features. A snowballing strategy was used after the full mobile app screening process to check the relevant-recommended apps generated within the search results pages of the final-included mobile apps, such as the "you might also like" and "similar apps" pages, to reduce missing mobile apps.

During the screening process, 2 pairs of authors independently screened the search results in Google Play and Apple App Store. The level of agreement between the reviewers was determined using Cohen κ to calculate interrater reliability. To minimize the potential for duplication inherent in app store searches, the analysis was based on the results from a single search term. Discrepancies between the paired authors were discussed and resolved. The results of eligible mobile apps were checked and agreed upon by the other authors. The devices used to search and screen the apps were iPhone 11 Pro Max (iOS 17.5), iPhone 11 (iOS 17.5), iPhone X (iOS 16.7.8), Samsung Galaxy J5 (Android v8.1 Oreo), and Huawei Mate 10 (HarmonyOS 4.0).

Quality Appraisal

Overview

Two quality appraisal tools, which are widely applied for mHealth evaluation, the MARS [26,31] and the IMS tool [32], were used to evaluate the mHealth apps. The MARS (26 items) was used to evaluate the technical design, and the IMS (11 items) to evaluate the number of functions.

The MARS was scored from inadequate to excellent with a corresponding score from 1 to 5 in the 5-point Likert scale. This review followed the recommendation of MARS to calculate MARS scores using the 16 items of app quality rating. The subjective quality and perceived impact items were combined as subjective quality (10 items) for evaluation in this review. The IMS [32] items were coded as 1 per item if app features were presented and otherwise 0 per item, generating a functionality score ranging from 0 to 11 for each app. The overall mapping scores representing the frequencies of applied features were presented in a radar graph as recommended [32].

Quality appraisal was conducted by 2 pairs of reviewers. The agreement rate between the reviewers using different scales was calculated, with interclass correlation coefficients (ICCs) for MARS results [33] and Cohen κ for the IMS results. The level of agreement in ICCs, which ranges between 0 (no agreement) and 1 (perfect agreement), was reported in the value and followed the level categorization as either poor (<0.40), fair (0.40 - 0.59), good (0.60 - 0.74), or excellent (0.75 - 1.0) [34]. The calculation was conducted using IBM SPSS (version 29; IBM Corp).

Data Extraction

Data extraction focused on two categories: (1) app characteristics, which included basic information such as the app operating system, version, and size; and (2) multifunctionality, which included GDM-adapted features and techniques, as well as general features. A list of uncategorized app features and techniques was initially extracted and used to inform the GDM-adapted features and techniques list and the general features list. The two lists contributed to the evaluation of the app's multifunctionality (Multimedia Appendix 2). After the development of the evaluation lists, the apps were reviewed again by 1 author and extracted for the items on the lists. The extracted features and techniques of individual apps were checked and discussed to reach an agreement in the author group.

The GDM-adapted features and techniques lists included types of app features (GDM-adapted features) and digital techniques (GDM-adapted techniques). GDM-adapted features refer to the app feature content, which served as a digital solution to clinical interventions for GDM management. For example, blood glucose data recording served as a digital solution to a paper diary for blood glucose documentation. GDM-adapted techniques are the digital techniques used to enable the app features. For example, Bluetooth (Bluetooth Special Interest Group) techniques and manual recording are both digital techniques used to enable the data recording app feature. General features referred to instructions, data security, and customization, which were extracted based on other studies [35,36].

The development of the GDM-adapted features and techniques list included app features aligned with BCTs [36], NICE (National Institute for Health and Care Excellence) 2015 recommendations [37], and our previous review on women's preferences [13]. BCTs include strategies such as education, goal setting, self-monitoring, feedback, and reinforcement that encourage healthy behaviors [36]. The 2015 NICE guideline recommends managing GDM through individualized diet and exercise, along with blood glucose monitoring [37]. It also includes pregnancy management guidance by including frequent antenatal visits and monitoring of fetal growth and well-being [37]. Our previous review found that women with GDM valued digital tools with education, personalized guidance, and easy data management [13]. It highlights the need for more usable technologies that support self-monitoring of GDM [13]. Integrating these sources created a clear framework for assessing app features, making sure the GDM-adapted features and techniques list reflects behavior change, clinical care, and women's needs when managing GDM. Additionally, some basic digital techniques, such as text-based educational information and data recording approaches, were added to the final list of app features without direct indications from literature or recommendations.

XSL•FO
RenderX

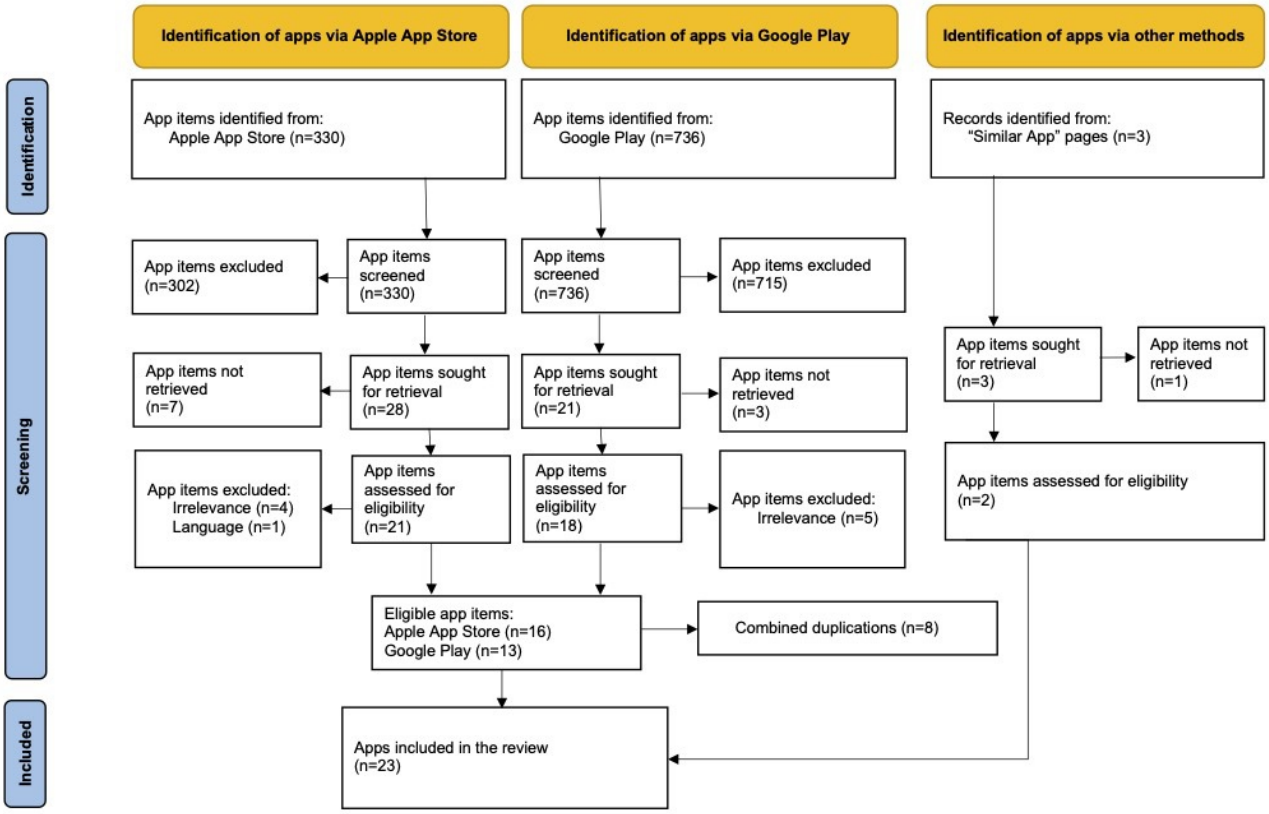
Data Analysis and Presentation

The extracted features and techniques of apps were analyzed and presented in aggregated data. Categorical data, including app characteristics items, GDM-adapted features, GDM-adapted techniques, and general features, were summarized as frequencies and percentages. Continuous data, including app size, MARS score, and IMS score, were presented as means with SDs. App characteristics, MARS score, GDM-adapted features and techniques, and general features were summarized in tables to provide a clear presentation of results. The IMS score was presented in a radar chart to illustrate the distribution of IMS functionalities across 10 domains.

Ethical Considerations

This study did not involve human participants, animals, or any collection of personally identifiable information. All data analyzed were publicly available in the Apple App Store and Google Play Store. Accordingly, institutional review board approval was not required. As no human subjects were enrolled, informed consent was not applicable.

Results



Search Results

The search identified 1066 apps, 330 from the Apple App Store and 736 from Google Play. Two paired authors independently screened the search results in both app stores, the Apple App Store, resulting in 28 eligible mobile apps from the Apple App Store, and 21 in Google Play. The interrater reliability in both pairs indicates a minimum of substantial agreement, with Cohen κ values of 0.62 and 0.91. The title and description screening process resulted in 49 potentially eligible mobile apps in the two app stores. The mobile apps available in both operating systems were not combined at this step.

The 49 eligible mobile apps were retrieved and installed before the full mobile app screening process. This process led to 10 exclusions due to activation (n=7), subscription (n=1), and technical crash issues (n=2). The retrieving, installing, and checking process led to 39 (n=21 in iOS, n=18 in Android) inclusions for the full mobile app screening. The full app screening led to 10 exclusions (n=5 in iOS, n=5 in Android). The reasons for exclusion included irrelevance (n=9) and language (n=1). Perfect agreement was identified between the 2 pairs of authors. Mobile apps available in both operating systems (n=8) were then combined in number, resulting in 21 eligible mobile apps.

A subsequent snowballing process generated the inclusion of 2 mobile apps (available in both operating systems). The search and screening process contributed to the eventual inclusion of 23 eligible mobile apps for this study. Figure 2 illustrates the PRISMA diagram for the screening process (Multimedia Appendix 3 for the enlarged PRISMA diagram).

Figure 2. PRISMA diagram. PRISMA: Preferred Reporting Items for Systematic Reviews and Meta-Analyses.

App Characteristics

Of the 23 reviewed apps, 56% (n=13) were adapted to both operating systems (iOS and Android), followed by 22% (n=5) of the apps which were exclusively for iOS, and 22% (n=5) of the apps which were exclusively for Android. Most (n=16, 70%) of the apps were updated in 2024. On average, the apps were of mean 66.43 and SD 53.46 MB, ranging between 6.2 and

XSL•FO
RenderX

223.4 MB. All the apps were free to download, with 48% (n=11) free to access all features, and 52% (n=12) required a subscription. The major targeted user groups of the apps were people with diabetes (n=12, 52%), women with GDM (n=7, 30%), followed by women who are pregnant (n=3, 13%) and women with diabetes who are pregnant (n=1, 4%).

We categorized the apps into 4 major types based on the characteristics of features: multipurpose, self-monitoring, educational, and communicational. Self-monitoring apps were identified by their ability to assist women's behavior for self-monitoring, such as recording data and reminding them of self-tests, with a total of 5 apps. Educational apps were identified by their ability to offer women information, with a total of 5 apps. Communicational apps were identified by their ability to provide a platform for women to communicate with their peers and health care professionals, with a total of 2 apps. The apps that used more than one of the mentioned characteristics of features were identified as multipurpose apps (n=11). All apps (n=23) were free to download, with all apps that were tailored for GDM or pregnant users (n=11) being free to access all features; meanwhile, the other 12 apps for general diabetes users needed to subscribe for full access. Table 1 shows the characteristics of the reviewed apps.

Quality Appraisal

Overview

Overall, the mean MARS score was 4.0 and SD 0.36, and the mean IMS score was 5.83 and SD 3.03 (see details in Multimedia Appendix 4). The mean MARS quality score indicates a satisfactory level of quality, which appears to be higher than the average MARS quality score reported for mHealth apps in the literature (mean 4.0, SD 0.36 vs mean 3.51, SD 0.71) [38]. Regarding individual MARS quality score domains, the MARS engagement domain, which is relevant to coaching and personalization features, scored the lowest (mean 3.56, SD 0.60) compared to other MARS domains (MARS functionality: mean 4.48, SD 0.72, MARS esthetics: mean 4.12, SD 0.48, MARS information: mean 4.02, SD 0.44). Apps were also evaluated based on their different types of functionality using the MARS quality score: the multipurpose apps, educational apps, self-monitoring apps, and communicational apps. Multipurpose (mean 4.06, SD 0.44) and self-monitoring (mean 4.02, SD 0.25) apps appeared to score higher than other types of apps (educational apps: mean 3.92, SD 0.37, communicational apps: mean 3.84, SD 0.47).

The mean IMS score indicated a moderate level of the number of app features. Multipurpose (mean 7.91, SD 2.12) and self-monitoring (mean 6.60, SD 1.14) apps tended to score higher than the other two types of apps. Figure 3 shows the radar graph of the distribution of features scored by the IMS. Among all the 10 IMS features, instructions (n=18), data management features (n=18), and information (n=13) were the predominant features used by the 23 reviewed apps. The guide feature scored lowest compared to other IMS features (n=5).

Figure 3. Distribution of features by IMS scores. IMS: The IMS Institute for Healthcare Informatics Functionality Score.

Reviewers had substantial agreement on their evaluation of iOS apps; IMS (κ=0.834, 95% CI 0.74-0.93, *P*<.001) and MARS (ICC=0.808, 95% CI 0.742 - 0.858) scores. A similar level of agreement was observed for Android apps, with IMS (κ=0.851, 95% CI 0.76-0.95, *P*<.001) and MARS (ICC=0.755, 95% CI 0.67 - 0.82).

Multifunctionality

The analysis of features and techniques was based on the exploration of features that would need to be integrated into an app to assist specifically with GDM. We incorporated the BCTs [36], NICE recommendations [37], and our previous review on women's preferred features [13]. The process generated a list

XSL•FO
RenderX

of GDM-adapted features and techniques (Table 2, details in Multimedia Appendix 5). The features were categorized into 5 domains: education, data management, coaching features, communication features, and pregnancy management.

XSL•FO
RenderX

Table . GDM[a]-adapted features and techniques (N=23).

Pregnancy progression education and management	N, P	4
Fetal monitoring	N, P	3

[a]GDM: gestational diabetes.

[b]Evidence: B: behavior change techniques; N: NICE (National Institute for Health and Care Excellence) recommendations; P: women's preferred features.

[c]GI: glycemic index.

[d]Not applicable.

[e]HCP: health care professional.

Table 3 summarizes the predominant GDM-adapted features and techniques applied by the reviewed apps. The analysis reveals a strong emphasis on educational content (n=18) and data management (n=16) within the mobile apps. The educational components of the apps focus on delivering content critical for GDM management, mainly including knowledge about GDM diagnosis (n=10) and low GI index food choices (n=15). Data management predominantly focuses on collecting blood glucose data, with over 50% (n=14) of apps, rather than food (n=8) and exercise tracking (n=7).

[a]GDM: gestational diabetes.

Text-based educational information was nearly ubiquitous, and core tracking features—particularly for blood glucose—were widely implemented. Text-based information delivery was the most common mode, used in over 50% (n=18) of apps. Manual data recording was predominant (used in 14 apps), and 12 used tables (text) to visualize the data. Among all 23 apps, Malama (a multifunctional, GDM-focused app) and Diabetes:M (a multifunctional, diabetes-focused app) cover all the predominant features and techniques.

We identified the features and techniques applied by fewer than 4 apps as the least applied features. The least addressed features included the provision of food recipes (n=4), abnormal symptom reporting (n=4), rewarding for milestone achievements (n=3), and pregnancy progression and education management (n=4). The least addressed techniques included video information delivery (n=4), automatic blood glucose data transmission (n=4), automatic exercise data transmission (n=3), image recognition techniques (n=3), combination charts (n=3), and personal-tailored information or suggestions (n=3).

General Features

Overall, most reviewed apps used general features which ensured normal app usage, with 23 apps addressing data security, 22 apps addressing instructions, and 19 apps addressing personalization. There were 5 apps identified as having technical issues that affect normal use, or distractions that disrupt user interactions. General features and technical issues are summarized in Multimedia Appendix 6.

XSL•FO
RenderX

Some general features were applied universally by the apps. These include consenting to privacy policies (n=23) and asking permission to access data (n=23), providing a quick step-by-step introduction (n=16) when users launch the apps. For personalization, collecting users' demographic data (n=16), asking their preferences for measurement units (n=14), and enabling customized features (n=16), such as reminder timing, were used. Very few apps mentioned the location of data storage (n=5) and the techniques (n=4) used to protect user data.

Additionally, of the 23 evaluated apps, there were 7 with issues that could affect normal user experience, including 5 multipurpose apps (MyManis, hug + u, myFetalLife, Blood Sugar - Diabetes App, and Diabetes:M) and 2 self-monitoring apps (Carbs & Cals and Diabetic diary-Glucose tracker). There were three major issues among these apps: (1) frequent technical glitches, (2) data management issues, and (3) frequent advertisements. Data management issues existed in 4 multipurpose apps, with frequent failure or errors of data recording (MyManis and Diabetes:M), limitations in the data recording feature when inputting decimals and time points (hug + u), and failure of displaying the recorded data in 1 app (myFetalLife). Frequent advertisements took place in 3 apps (Blood Sugar - Diabetes App, Carbs & Cals, and Diabetic diary-Glucose tracker), with advertisements showing up frequently when moving between screens or inputting data, leading to a sense of distraction. Technical glitches and crashes happened to 1 multipurpose app (myFetalLife). While this app contained various features suitable for the management of GDM, technical issues took place frequently and caused crashes and failures when recording the data.

Usable Apps

This review evaluated the app functionality based on the generated lists of GDM-adapted features and techniques, as well as general functionality, collectively with 45 evaluation items on features and content. On average, the apps applied a mean of 17.95 and SD of 7.31 of all 45 items across domains. For GDM-adapted features and techniques, the apps applied a mean of 10.82 and SD of 5.31 of the 32 items. For general functionality evaluation, the apps applied a mean of 7.13 and SD of 2.58 of the 13 items.

We considered apps usable when they contained features and content higher than the average value in each domain and the total average value, with no distractions or technical issues (Table 4). These 6 apps were either categorized in the multipurpose (n=4) or the self-monitoring (n=2) app type in this review.

Table . Usable apps and evaluation.

	App type	Health care domain	MARS[a] quality	IMS[b] score	Multifunctionality and content	General functionality
Full score or number of features	N/A[c]	N/A	5	11	32	13
Average score or addressed features, mean (SD)	N/A	N/A	4.0 (0.36)	5.83 (3.03)	10.82 (5.31)	7.13 (2.58)

[d]GDM: gestational diabetes.

[e]SMBG: self-monitoring of blood glucose.

Discussion

Overview

This study aimed to provide a comprehensive evaluation of the quality and multifunctionality of commercially available apps on their cash-free features for GDM self-management. By evaluating app quality using the MARS quality and IMS scales, the results showed that the overall app quality is at a satisfactory level. However, regarding individual MARS domains, the MARS engagement domain, which contains coaching and personalized content, was scored lowest among other domains. Following this, the multifunctionality of apps was evaluated by two elements: (1) GDM-adapted features and techniques, namely the app features that fitted into GDM management context, and the corresponding digital techniques used to enable the features, explored the variety of features used by the reviewed apps; (2) general features, which included instruction, data security, customization, and technical issues, explored the app features regarded as essential for basic app usage.

XSL•FO
RenderX

Primary Findings: Basic Features, Limited Content, and the Need for Advanced Design

The reviewed apps predominantly focused on GDM educational content and blood glucose data recording. In addition, the digital techniques used to enable such features were relatively basic. Most apps relied on text-based approaches for content presentation and required manual operation for data management. Moreover, their content reflected only the most fundamental requirement for GDM, focusing primarily on blood glucose management rather than addressing the broader pregnancy experience.

One of our primary findings is the narrow focus on blood glucose monitoring in the design of many apps. Many of the apps included in this review offered features that could support blood glucose self-management, such as educational resources on self-test skill education and dietary guidance, as well as data recording, digital feedback, and graphic visualization. These features were also identified in our previous study as being preferred by women with GDM, as they facilitated self-management [13]. For example, having educational information in a single app improved easy access and helped women recall information [13]. Initial digital feedback using colored labels, combined with graphic visualization, helped the women interpret their data and adjust their diet according to blood glucose trends [13]. However, most apps lacked a multidimensional approach to GDM management. Even though diet and physical activity are both essential for stabilizing blood glucose levels, very few apps in this review included relevant content and features.

Our findings suggest that features relevant to pregnancy progression management were lacking in available apps. In this study, only a small number of apps provided information or features to support pregnancy management and fetal monitoring. There were only 5 apps that included features or information relevant to pregnancy, such as informing about baby growth over time. The features and information about pregnancy and fetal well-being were more likely to be available in those apps designed for pregnancy care. However, the functionality of these pregnancy-tailored apps in blood sugar control was relatively underdeveloped, typically due to technical issues related to data recording and display. These findings indicated an imbalance in focus in app design, with limited integration of broader pregnancy-relevant needs.

In addition, automated features, including automated data transmission and app-generated behavior change suggestions, were used by only a few apps. Similar patterns are also observed in other mHealth apps for pregnancy care, where basic features and techniques still dominate the feature composition [39-41]. These apps tended to focus on either collecting users' personal and physiological data or providing normative and comprehensive information, rather than proactively facilitating women's behavior changes [39-41]. Automated features, such as rewarding on milestone achievements, identifying barriers for behavior change, or providing feedback for behavioral adjustment, are rarely incorporated into the design of pregnancy-related apps [39,40]. Instead, these tasks are sometimes managed through interactions with health care professionals and handled manually [41].

This indicates that the apps currently available and free to download appear to lag behind the evolving needs of women and health care professionals. Women seek tailored guidance for managing their blood glucose, which enhances women's self-awareness and supports their autonomy in self-management [13]. This is usually achieved through effective communication with health care professionals, where the women can receive one-to-one advice and personalized feedback on their blood glucose levels, diet, and lifestyle adjustment [42,43]. However, limited opportunities for antenatal consultations and the heavy workload of health care professionals have often resulted in limited advice on continuous behavior changes [42,43].

Implications for Designing Guidelines and Recommendations

Our findings highlight a gap between the potential of technology and its real-world application. Frontier automated techniques are advancing at an astonishing pace, such as deep learning, decision trees, and reinforcement learning, which have been explored for predicting blood glucose levels and providing personalized treatment recommendations [44,45]. These tools can continuously process data such as blood glucose levels, ketonuria, and dietary adherence, identifying patterns and making real-time adjustments [44]. However, our review revealed that many frontier technologies remain largely inaccessible to women with GDM.

To address this gap, it is essential to integrate broader pregnancy progression management into a condition-specific management app that requires thoughtful design to ensure relevance across different stages of pregnancy and to balance general maternal health management with condition-focused support. As recommended by the 2015 NICE guidance, pregnancy progression management is an important component of GDM management [37]. This requires additional attention on fetal growth and well-being, indicating that additional screening test results and fetal self-observation data recording should be considered [37]. Additional evidence found that women with GDM preferred mHealth technologies that were closely aligned with their pregnancy needs, such as reminders for antenatal visits and pregnancy stages, and they particularly valued educational information related to their pregnancies [16,46].

The findings emphasize the potential of digital tools to provide support for individualized care. It calls for greater integration of automated technologies into app design. This requires co-design approaches involving women and health care professionals to ensure that future apps move from basic features to personalized, interactive, and context-based support for GDM management. Additionally, further exploration is needed to evaluate the automated app feature designs regarding their usability, effectiveness, and safety in real-world contexts.

Recommendations for Development

Given the wide variation in features and techniques available in current GDM apps, and the range of factors that may influence app development, we adopted an evidence-based approach to summarize broadly applicable recommendations

XSL•FO
RenderX

for the development of apps for women with GDM (Textbox 1). These recommendations outline options for core functional design, while also identifying optional advanced features that may be incorporated where appropriate.

XSL•FO
RenderX

Textbox 1. App development recommendations.

Education

Information about gestational diabetes (GDM):

- Include information on the mechanism of GDM, its relevant risks, and impact on pregnancy. The information should aim to help women recognize the importance of monitoring their blood glucose levels.

Dietary management information:

- The rationale for dietary management and basic dietary strategies should be explained, with links to practical and reliable resources, such as guidance on low-glycemic index food choices.

Physical activity information:

- Provide information about the appropriate types of exercise for pregnant women, optimal timing for exercise, the importance of physical activity, and considerations for ensuring safety.
- Information should be provided on appropriate exercise duration and intensity, conditions in which exercise is not suitable, and when exercise should be stopped if certain symptoms occur.

Self-monitoring skills:

- Provide information about how to perform self-monitoring, including capillary blood glucose testing skills, appropriate timing of testing (for example, fasting, before or after meals, and before bedtime), and evidence-based target ranges for blood glucose levels.

Pregnancy-relevant information:

- Provide information on pregnancy progression, including the different stages of pregnancy and corresponding information about the baby, such as fetal growth.

Basic techniques:

- Text information delivery.

Advanced techniques:

- Graphs, pictures, and videos in information delivery.

Development considerations:

- The primary aim of providing information is to increase women's awareness of self-monitoring and, in turn, improve their skills. Information should be clear, easy to understand, and sufficient to support understanding.
- Aside from basic information, consider practical resources, such as food recipes or exercise tutorial videos, that support behavior changes.
- Resources provided should be evidence-based and reliable.

Data management

Types of data:

- Ensure blood glucose data is accurately recorded and clearly visualized in the app. Consider other essential data, including dietary intake, physical activity, symptoms, medication usage, fetal growth, and fetal well-being, to be recorded within the app.

Basic techniques:

- Manual data recording using text, data visualization using tables, and initial data evaluation by preset normal values.

Advanced techniques:

- Automated data transmission (eg, Bluetooth and image recognition techniques), graphic data visualization to show trends, combination charts to cross-check different types of data, and personalized suggestions based on recorded data.

Development considerations:

- Enable easy data recording, prioritizing automated digital techniques over manual text entry, and provide appropriate indicators and options to improve efficiency.
- Considering digital data analysis techniques to evaluate patients' recorded data, and where appropriate, to offer initial suggestions to support patients.

Communication

XSL•FO
RenderX

Features:

- Communication with health care professionals and peers.

Basic techniques:

- Easy-access contact buttons to start phone calls or send text messages.

Advanced techniques:

- Built-in chat box, online forum.

Development considerations:

- Ensure access to health care professionals within the app.
- The features should be designed to help address the women's questions in real time.
- Specific staffing roles should be considered to support and manage communication modules within the app.

Coaching, customization, and technical issues

Reminding and adherence:

- Basic reminders should be provided for blood glucose testing and other relevant activities.
- More advanced features may include reminders when tests are missed, motivational messages to acknowledge achievements, and rewards linked to milestones.
- Development considerations: the aim of developing such features should be to enable dynamic and intelligent tracking of women's behaviors, using reminders and notifications to help prevent unhealthy behaviors, support lifestyle adjustment, and encourage women's behavior change.

Customization:

- Recommended features: demographic data recording, personalized measurement units, customizable normal data ranges, multilanguage options, customizable self-monitoring goals, and a customizable data visualization dashboard.
- Development considerations: the diverse needs, demographic background, and levels of literacy of the women should be considered in app development.

Technical issues:

- Ensure the data details are accurately captured in the app, including numerical precision (for example, decimals), measurement units, and time of data entry.
- Ensure data visualizations are clear and well-organized, and that every recorded data point can be easily viewed.
- Minimize or eliminate connectivity issues and app crashes.

Strengths and Limitations

The strengths of this review include its standardized process and comprehensiveness of evaluation. Standardized evaluation tools were used to measure the quality and multifunctionality of mHealth apps for GDM. In addition, it extends the TECH framework by Gasteiger et al [26] by introducing a more context-based, user-informed, and evidence-informed approach, integrating BCTs, NICE recommendations, and women's preferences, enabling a detailed evaluation of app multifunctionality.

However, several limitations should be considered when interpreting the findings. First, the search was conducted only once on a single day. While this minimizes duplication of included apps, it may have resulted in an incomplete capture of all available apps due to the dynamic nature of app store listings, which can be influenced by advertising and other factors. Second, the decision to restrict the search to UK app stores, while ensuring consistency with UK-based NICE guidelines, may have limited the scope and breadth of the review by excluding insights from apps available in other regions. Third, our findings reflect the status of apps in June 2024. Given the high turnover and frequent updates of apps, their scores, features, and technical issues may have changed postreview, which may affect reproducibility.

Conclusion

This study explored the quality and multifunctionality of commercially available apps for GDM self-management, focusing on the cash-free features, following the TECH and PRISMA frameworks. Our findings highlight that GDM apps should provide more interactive features and support comprehensive pregnancy care, rather than being limited to glucose management and using basic digital techniques. Valuable insights can be drawn from other models of remote pregnancy care, especially those implemented under unavoidable circumstances, such as in rural settings or during the COVID-19 pandemic, where integration of data was required to collect from remote monitoring approaches [47,48]. On one hand, when designing digital technologies for a specific pregnancy complication, it is important to integrate general

XSL•FO
RenderX

pregnancy-related data, such as self-reported symptoms, so that they can be managed alongside the target condition [47]. On the other hand, efforts should be made to enable the in-person services and advice to be available online, ensuring that women receive adequate support while engaging in self-management [48]. Taken together, the evidence highlights an emerging research and design agenda for future mHealth app design—one that prioritizes the integration of comprehensive pregnancy progression management and data interconnectivity to better meet the complex requirements of GDM management.

Acknowledgments

We would like to thank Dr Helen Hawley-Hague for generously lending us the required device.

Authors' Contributions

QZ designed this study, with the support of DD and AC. QZ, YT, and LH reviewed the apps. QZ analyzed the data and wrote the first draft of this paper. QZ, DD, and AC participated in the interpretation of this study's findings and the preparation of this paper. All of the authors approved the final paper.

Abstract

Background: The use of mobile apps in oncology has been expanding rapidly, encompassing prevention, treatment, and patient support. These technologies hold significant potential to improve care delivery and enhance the efficiency of health care services. However, their integration into clinical practice faces important challenges. A key issue lies in the difficulties health care professionals (HCPs) encounter when selecting apps that adequately meet their specific needs and comply with appropriate standards of quality and clinical effectiveness. This lack of robust evidence on the availability, adoption, and evaluation of mobile apps designed for cancer care professionals not only hinders their wider adoption but also restricts their potential to serve as reliable tools in oncology practice.

Objective: This study aims to map the landscape of free mobile apps for cancer prevention, treatment, therapy, or support for HCPs, and assess the quality of the apps identified.

Methods: A systematic search was conducted on Google Play and Apple App Store in June 2023 and December 2024 using predefined oncology- and professional-related keywords, following PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines. Two independent reviewers (DL and AC) assessed the selected apps using the Mobile App Rating Scale (MARS), which evaluates engagement, functionality, aesthetics, information quality, and subjective quality on a 5-point Likert scale. Discrepancies in ratings were resolved by a third reviewer. Descriptive statistics summarized the app quality and characteristics.

Results: Out of 221 apps initially identified, 20 met the inclusion criteria and were evaluated. Most apps (15/20, 75%) supported both Android and iOS platforms, with 90% (18/20) commercially developed. The mean overall MARS score was 3.51 (SD 0.54), indicating moderate quality but with room for improvement. Only 2 apps, ONCOassist (Portable Medical Technology Ltd.) (mean

XSL•FO
RenderX

4.25, SD 0.26) and Oncology Board Review (mean 4.03, SD 0.39), surpassed the threshold of 4.0, considered good quality. ONCOassist stood out for its comprehensive functionality and high information quality, offering clinical decision support tools such as treatment protocols, prognostic calculators, and toxicity grading aligned with professional oncology practice. Prevention and support apps generally scored lower, particularly in engagement and interactive features. No app achieved a high score across all MARS domains.

Conclusions: The study highlights a fragmented landscape of free mobile apps for cancer care professionals, with predominantly low to moderate quality and limited evidence to support clinical effectiveness. ONCOassist emerges as a promising tool warranting further investigation. This underscores the urgent need for standardized evaluation frameworks, regulatory oversight, and sustainable development strategies to ensure the creation and adoption of reliable, evidence-based digital health tools in oncology.

KEYWORDS

mobile apps; neoplasms; technology assessment; biomedical; telemedicine; quality of health care

Introduction

Cancer is the second leading cause of premature mortality and morbidity in Europe, with 4.7 million new cases and 2.1 million deaths annually in the European Union [1]. The European Cancer Control Plan reflects this political priority, further emphasized by the inclusion of cancer as one of the 5 missions in the Horizon Europe program [2,3].

In recent years, partly accelerated by the COVID-19 pandemic, telehealth apps have grown rapidly, including mobile health (mHealth) apps designed for oncology [4,5]. These apps leverage the convenience of smartphones to support cancer prevention and diagnosis, symptom monitoring, and communication between health care providers and patients [4,6]. Although available to diverse audiences, nearly 45% are designed for health care professionals (HCPs), making them the most prominent target group [7]. Their primary functions are educational, with secondary roles in supporting clinical decision-making and patient care [7]. Mobile apps may be used as stand-alone interventions or in combination with additional support material as part of broader interventions [8].

There is growing evidence that digital health technologies, such as mobile apps, can support self-management, reduce symptom burden, improve cancer care management, and enhance quality of life for patients with cancer [4,9,10]. These apps, used on smartphones or tablets, may facilitate medication adherence, symptom tracking, and disease management [11], as well as promote healthy lifestyles and access to information [6]. Despite this potential, and although HCPs generally express positive attitudes toward their use [12], actual adoption in cancer care remains limited. Evidence from the United States and several European countries indicates a mismatch between the rapid proliferation of cancer-related apps and their real-world use among both professionals and patients [5].

The adoption of mHealth apps by HCPs is hindered by several barriers. First, HCPs face difficulties in identifying appropriate apps for their needs and in evaluating the extent to which scientific evidence supports their use [9]. Moreover, no tools are currently available to help cancer patients or professionals search for high-quality cancer apps [13], making it difficult for both digital laypersons and HCPs to identify reliable options [14]. The quality of existing apps for HCPs also varies and is generally low: systematic searches have found that almost half of the tested apps were rated as deficient or insufficient [15]. Another limitation is that most cancer care apps are not developed with the involvement of health providers, which complicates their implementation [13]. Finally, cost represents an additional barrier, as 77% of health app users rely exclusively on free apps [16,17]. Consequently, the most recent evaluations of health apps have focused only on those that are freely available [18].

Given these challenges, app evaluations can help clarify the landscape. There are several approaches to evaluating apps, including content analyses, usability testing, observational studies, and efficacy trials [19]. Among these, questionnaires and scales are the most common for assessing usability in eHealth apps, although they do not always identify the specific issues that need to be addressed [20]. However, despite the increasing number of cancer-related apps, evidence about the availability and quality of free apps specifically designed for HCPs remains scarce.

To address this gap, this cross-sectional study aims to map the landscape of free mobile apps for cancer prevention, treatment, therapy, or support for HCPs, and assess the quality of the apps identified. This analysis focuses on the characteristics and overall quality of these apps, thereby contributing to the evidence base and informing future development.

Methods

Study Design

This study was designed to evaluate the availability and quality of apps developed for the prevention, treatment, therapy, or support of cancer for HCP during the years 2023 and 2024. The decision to conduct the study over this period was informed by the dynamic nature of mHealth technologies, characterized by rapid advancements and frequent updates.

To achieve this, a systematic search was conducted across major app download platforms, followed by a peer evaluation of each identified app. It is part of the Digital Transition and Digital resilience in Oncology (TRANSiTION) project [21], which aims to develop advanced training to equip both clinical and non-clinical professionals (ie, health managers) with essential digital skills.

XSL•FO
RenderX

Search Strategy

A systematic search of mHealth apps related to cancer prevention, treatment, therapy, and support for HCPs was conducted in Google Play and the App Store. A completed PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 checklist is provided in Multimedia Appendix 1. For the purpose of this study, a cancer HCP is defined as any clinical professional (eg, oncologist and radiation therapist) or non-clinical professional (eg, manager and administrative staff) involved in cancer care.

The search strategy was based on methods used in previous studies [22,23]. The search was conducted using a Spain and Cyprus IP addresses. The initial search was performed in June 2023, with a follow-up search in December 2024, to compare the evolution of apps over 1.5 years. The search terms used were "oncology or cancer prevention" or "cancer treatment or cancer therapy" or "cancer support"; "health care professional*" or "doctor*" or "nurse*", "nursing*"; "health manager*". The terms and parameters used were identical to those used in the systematic review conducted by Cloconi et al [24], which aimed to review the digital health technologies used by HCPs and health managers in the academic literature on cancer care.

The inclusion and exclusion criteria used for the selection of apps are listed in Textbox 1.

Textbox 1. Inclusion and exclusion criteria for app selection.

Inclusion criteria

- Apps targeted at health care professionals providing cancer prevention, treatment, therapy, or support.
- Apps available on Google Play and the Apple App Store currently.

Exclusion criteria

- Apps that were not available in English.
- Apps that were not freely available.
- Apps with nonfunctional links.
- Apps not related to oncology.
- Apps addressing the needs of patients, but not of health care professionals.
- Apps with nonfunctional links. Apps not related to oncology.

To be included in the data extraction, apps had to meet all inclusion criteria and none of the exclusion criteria. Google Play apps were searched using a laptop (Windows 11) by systematically entering predefined keywords. The same process was applied for the App Store, through a desktop computer (macOS 13). This approach ensured the selection of apps that are directly accessible and functional for end users.

Data Extraction

Two independent researchers (DL and AC) collected data from descriptions of online apps (including app features and narrative text) available in the App Store and Google Play Store. The variables collected for each app included the following: app name and target group, category, objective, rating (out of 5), number of downloads, development company, cost, creation date, last update, availability, and whether an official source was cited. The technical aspects of the apps were also documented, including features such as the ability to share on social media, the requirement to log in, and the need for web access to function. Additionally, information was collected regarding potential commercial interests, including the presence of advertisements or options for purchasing services. The purposes of the apps were classified using an open-ended question that provided a brief description of the digital tool.

App Quality Evaluation

To assess app quality, the Mobile Apps Rating Scale (MARS) was used [25]. MARS is a tool specifically designed to evaluate the quality and content of mHealth apps. MARS consists of a total of 23 items covering five dimensions: (1) engagement (5 items: fun, interest, individual adaptability, interactivity, and target group), (2) functionality (5 items: performance, usability, navigation, and gestural design), (3) aesthetics (3 items: layout, graphics, and visual appeal), (4) information (7 items: accuracy of app, description, goals, quality of information, quantity of information, quality of visual information, credibility, and evidence base), and (5) subjective quality (4 items: recommendation, times of use, pay-per-use, and overall rating). Items are assessed on a 5-point Likert scale. Items assessing information quality can also be rated as not applicable (eg, in case of missing evidence or missing visual information). Each dimension's score is the average of its items. Therefore, the score for each dimension can range from 1 to 5 (1=inadequate, 2=poor, 3=acceptable, 4=good, and 5=excellent). MARS has excellent psychometric properties [26]. In this study, all the dimensions showed adequate internal consistency (Cronbach α=0.78-0.91).

The app evaluation procedure used was consistent with that of previous studies [27]. Apps were reviewed by 2 trained reviewers (DL and AC), selected randomly from a group of experts engaged in the European project TRANSiTION on e-skills training for cancer HCPs, as mentioned previously. The reviewer team consisted of professionals trained in family medicine, psychology, and nursing, with additional specialization in health technology assessment and digital education. Before conducting the MARS evaluation, reviewers piloted a review of one app and discussed each MARS item to

XSL•FO
RenderX

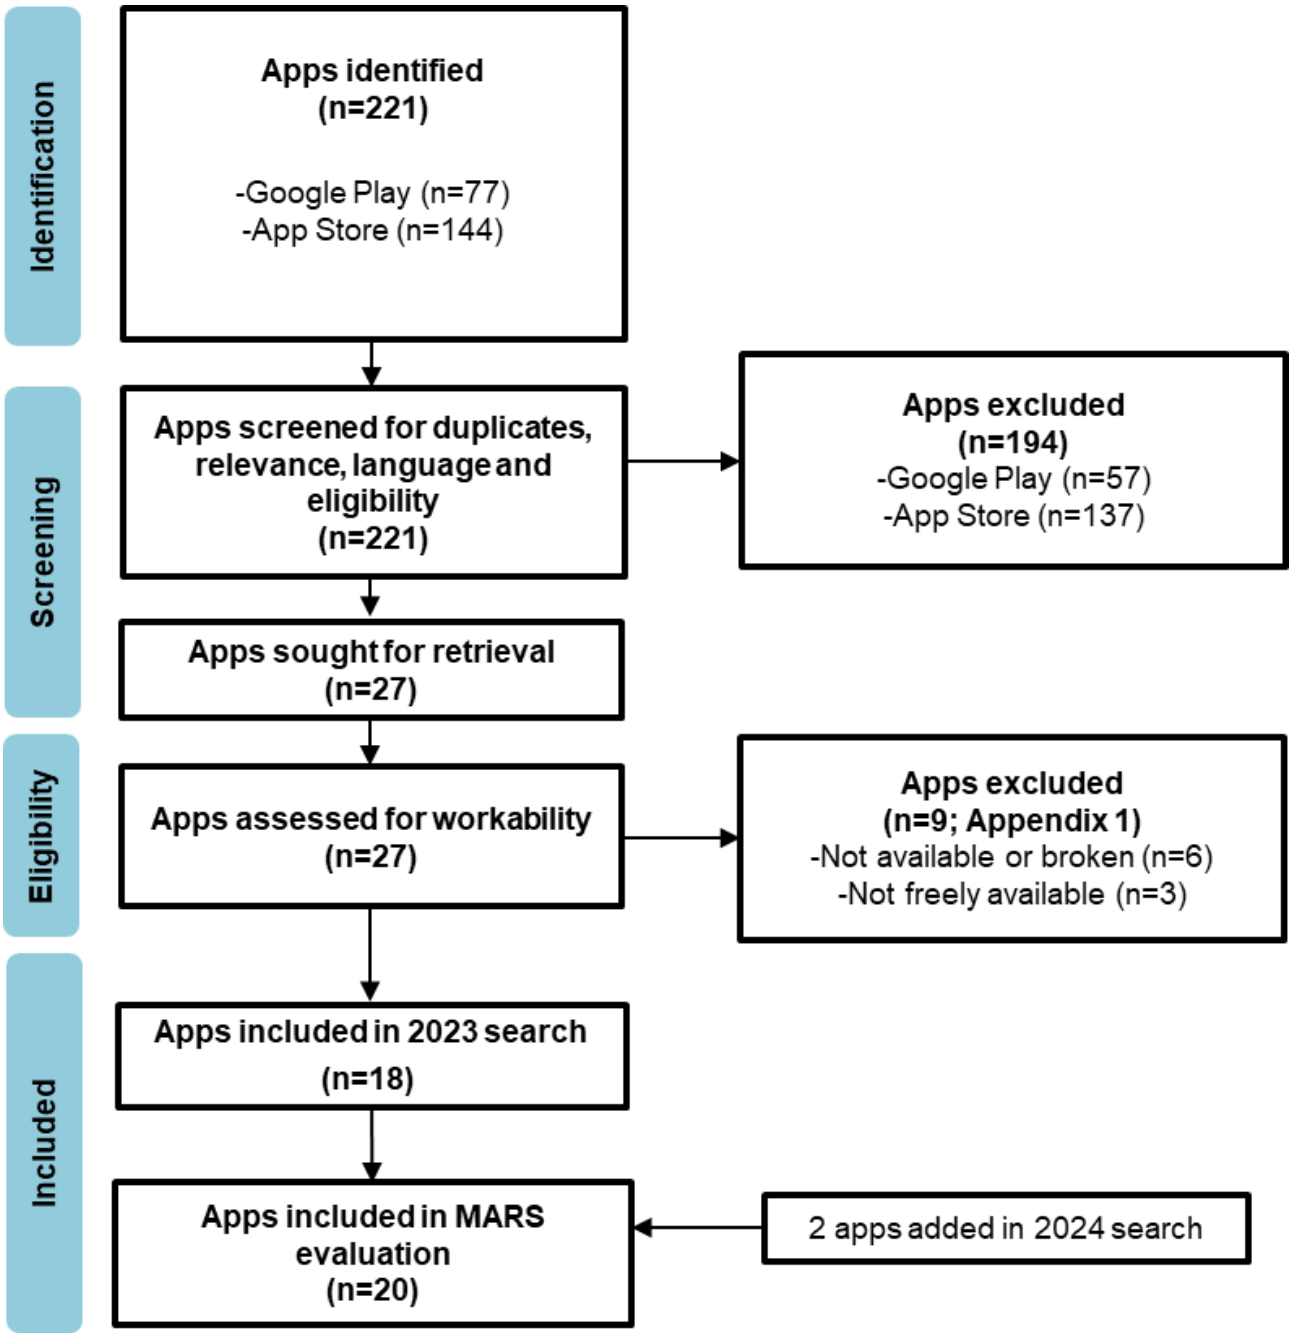
ensure an appropriate level of interrater consensus ratings in a hybrid session. In case the concordance between the reviewers was not reached (ie, a difference greater than one point in A, B, C, or D MARS dimensions), a third reviewer assessed the app. The lead researcher, an expert in digital health with extensive expertise in biotechnology, oversaw the MARS qualification process.

A descriptive analysis was developed, with continuous variables presented as means. Interrater reliability was examined using the intraclass correlation coefficient (ICC), calculated with a 2-way random-effects model and absolute agreement definition. The data generated were analyzed using IBM SPSS Statistics (version 25.0; IBM Corp).

Ethical Considerations

This study did not involve human participants or the collection of personal data. It was reviewed by the Pontevedra-Vigo-Ourense Research Ethics Committee (ref: 2023/309), which indicated that no formal evaluation was required.

Results



Description

Within the scope of this study, searches were conducted in June 2023 and December 2024. In the initial search, 221 apps were screened, of which 18 met the inclusion criteria. Among these 18 apps, 16 underwent version updates in 2024, with the exceptions being the European Society for Medical Oncology (ESMO) Interactive Guidelines and TNM Cancer Staging Manual.

The subsequent search in December 2024 identified 20 eligible apps, 18 of which had been initially detected in the June 2023 search and remained available. Consequently, this search marked the introduction of 2 new apps that were unavailable in the preceding year (Figure 1). The list of excluded apps can be found in Multimedia Appendix 2.

XSL•FO
RenderX

Figure 1. PRISMA flowchart of the identification, screening, and selection of free oncology mobile applications apps for health care professionals, based on searches conducted in Google Play and Apple App Store in June 2023 and December 2024.

Of the total, 75% (15/20) of the apps are available for Android and iOS. All apps had commercial affiliations, except for 2 (ESMO Interactive Guidelines and "NCCN Guidelines" [National Comprehensive Cancer Network]), which are affiliated with non-governmental organizations. Only 45% (9/20) of the apps were created after the COVID-19 pandemic.

The apps, while related to cancer, exhibited considerable heterogeneity with respect to their focus. Several were focused on teaching users about the treatment of the disease, while others intended to prepare users for an examination. Some cancer guidelines apps were also included. Other apps even extended beyond cancer to address a range of physical or mental illnesses. None of these apps has conclusive evidence of their validity and reliability for their purpose. The final list of analyzed apps is shown in Table 1, where it is specified the app's name, cancer type, platform, and year of creation are specified.

Interrater reliability indicated a moderate overall level of agreement (ICC=0.66). Reliability varied across MARS dimensions, ranging from excellent for engagement (ICC=0.90) to good for functionality (ICC=0.75), moderate for aesthetics (ICC=0.64) and information (ICC=0.52), and poor for subjective quality (ICC=0.38).

The combined results of the objective assessments (ie, engagement, functionality, aesthetics, and information evaluations) and the subjective assessments are presented in Table 2.

Table 2. Mobile Apps Rating Scale assessment of the included oncology mobile apps: dimension scores and overall quality.

Apps	A. Engagement (SD)	B. Functionality (SD)	C. Aesthetics (SD)	D. Information (SD)	App subjective quality (SD)	App quality, mean (SD) (A+B+C+D)/4
ONCOassist	4.10 (0.42)	4.87 (0.18)	3.66 (0.47)	4.37 (0.05)	3.75 (0.35)	4.25 (0.26)
Oncology Board Review	3.47 (0.31)	4.33 (0.38)	4.11 (0.51)	4.24 (0.41)	3.17 (0.76)	4.03 (0.39)
Hematology & Oncology Consult	3.07 (0.83)	4.50 (0.43)	4.22 (0.69)	4.12 (0.40)	2.92 (0.58)	3.98 (0.58)
Radiation Oncology Exam Review	3.73 (1.10)	4.17 (0.29)	3.55 (1.02)	4.25 (0.69)	3.08 (0.95)	3.92 (0.75)
NCCN Guidelines	3.20 (0)	3.62 (0.18)	3.83 (0.24)	4.75 (0.12)	3.87 (0.53)	3.85 (0.07)
ESMO Interactive Guidelines	3.60 (0.56)	4.62 (0.18)	3 (0.47)	4.10 (0.42)	3.87 (0.18)	3.83 (0.04)
Current Medical Diagnosis and Treatment	3.50 (0.14)	4.12 (0.53)	2.83 (0.71)	4.13 (0.38)	3.12 (0.88)	3.65 (0.37)
TNM Cancer Staging Manual	2.93 (0.12)	4.25 (0.25)	3.22 (1.02)	4.17 (0.60)	3.08 (1.01)	3.64 (0.33)
Pediatric Disease & Treatment	2.60 (0.57)	4.25 (0.35)	4.17 (0.24)	3.39 (0.15)	3.12 (0.88)	3.60 (0.25)
Radiation Oncology Q&A Review	2.93 (0.42)	4.17 (0.29)	3.67 (0.88)	3.59 (0.54)	2.66 (0.52)	3.59 (0.31)
Williams Manual of Hematology	3.20 (0.28)	4.37 (0.53)	3 (0.94)	3.58 (0.59)	2.62 (1.24)	3.53 (0.59)
All Diseases Treatments	2.50 (0.42)	4.62 (0.18)	4 (0.47)	2.95 (0.64)	2.50 (0.35)	3.52 (0.13)
Oncology Nursing Drug Handbook	3.07 (0.31)	3.75 (0.75)	3.78 (0.69)	3.11 (0.63)	2.66 (0.95)	3.43 (0.41)
Pharmacology for Nursing 2023	3.73 (0.76)	3.17 (1.42)	3.22 (1.07)	3.25 (0.66)	3.33 (1.38)	3.34 (0.91)
Washington Manual of Oncology	2.55 (0.66)	3.75 (0.54)	3 (0.82)	4.05 (0.71)	2.50 (1.43)	3.34 (0.59)
All Diseases Treatments 2023	1.90 (0.14)	4.37 (0.18)	3 (0.47)	3.20 (0.28)	2.37 (0.18)	3.12 (0.11)
Harrison's Manual of Medicine	2.60 (0.20)	3.67 (0.38)	3 (1)	3.15 (0.53)	1.83 (0.38)	3.11 (0.27)
Fitzpatrick's Color Atlas	2.60 (0.20)	3.33 (0.88)	2.78 (0.19)	3.12 (0.62)	2.58 (0.38)	2.96 (0.37)
Cervical Cancer Guide	2.10 (0.14)	3.50 (0)	2.67 (0.47)	3.25 (0.83)	2.13 (0.53)	2.87 (0.29)
Colon Cancer Guide	2.40 (0.28)	3.37 (0.18)	2.17 (0.24)	2.92 (0.35)	2.25 (0.71)	2.71 (0.17)
Overall mean	2.99 (0.68)	4.04 (0.65)	3.34 (0.80)	3.71 (0.69)	2.87 (0.86)	3.51 (0.54)

Notably, the scores were generally low, with an average of 3.51. Only 2 apps achieved an objective score higher than 4 ("good"), while in the subjective evaluations, none reached this threshold. The highest-rated app was ONCOassist (mean 4.25, SD 0.26). Oncology Board Review ranked second (mean 4.03, SD 0.39), followed by Hematology & Oncology Consult in third place (mean 3.98, SD 0.58). Reviewers noted that areas for potential improvement include aesthetics for ONCOassist and engagement for both Oncology Board Review and Hematology & Oncology Consult. The lowest-scoring apps were Colon Cancer Guide (2.71, SD 0.17), Cervical Cancer Guide (2.87, SD 0.29), and Fitzpatrick's Color Atlas (mean 2.96, SD 0.37). The domain with the lowest scores for these 3 apps was engagement and subjective quality evaluation. The results are discussed below according to the different dimensions of the MARS. It is noteworthy that none of the evaluated apps attained a score of 4 in all dimensions.

Apps' Engagement

The apps with the highest scores in engagement were ONCOassist (mean 4.10, SD 0.42), Radiation Oncology Exam Review (mean 3.73, SD 1.10), and Pharmacology for Nursing 2023 (mean 3.73, SD 0.76), while the lowest scoring apps were All Diseases Treatments 2023 (mean 1.90, SD 0.14), Cervical Cancer Guide (mean 2.10, SD 0.14), and Colon Cancer Guide (mean 2.40, SD 0.28).

XSL•FO
RenderX

Apps' Functionality

The apps with the highest scores for functionality were ONCOassist (mean 4.87, SD 0.18), ESMO Interactive Guidelines (mean 4.62, SD 0.17), and All Diseases Treatments (mean 4.62, SD 0.17). Conversely, the apps with the lowest scores were Pharmacology for Nursing 2023 (mean 3.17, SD 1.42), Colon Cancer Guide (mean 3.37, SD 0.17), and Cervical Cancer Guide (mean 3.50, SD 0).

Apps' Aesthetics

The apps with the highest aesthetics scores were Hematology & Oncology Consult (mean 4.22, SD 0.69), Pediatric Disease & Treatment (mean 4.17, SD 0.23), and Oncology Board Review (mean 4.11, SD 0.51). The apps with the lowest scores were Colon Cancer Guide (mean 2.17, SD 0.23) and Cervical Cancer Guide (mean 2.67, SD 0.47).

Apps' Information

The apps with the highest scores in information were NCCN Guidelines (mean 4.75, SD 0.12), ONCOassist (mean 4.37, SD 0.05), and Radiation Oncology Exam Review (mean 4.25, SD 0.69). Conversely, the apps with the lowest scores were Colon Cancer Guide (mean 2.92, SD 0.35), All Diseases Treatments (mean 2.95, SD 0.64), and Oncology Nursing Drug Handbook (mean 3.11, SD 0.63).

Apps Subjective Quality

The apps with the highest scores in this section are NCCN Guidelines and ESMO Interactive Guidelines (mean 3.87, SD 0.53, and SD 0.18). Next is ONCOassist (mean 3.75, SD 0.35), followed by Pharmacology for Nursing 2023 (mean 3.33, SD 1.38). In contrast, the app with the lowest subjective rating is Harrison's Manual of Medicine (mean 1.83, SD 0.38).

Discussion

Principal Findings

In this study, the app review identified 221 apps between June 2023 and December 2024 following the search strategy, keywords, and parameters outlined by Cloconi et al [24]. After the screening phase, 20 apps for cancer prevention, treatment, therapy, or support for HCPs were selected in the systematic search. To explore them further, this study evaluated these apps with the MARS, a scientifically validated instrument that assesses 5 key dimensions: engagement, functionality, aesthetics, information, and subjective quality.

As a result, the ONCOassist app achieved the highest score among all the apps. Endorsed by the European Scientific Organisations such as the ESMO [28] and the European Oncology Nursing Society [29], it obtained particularly strong ratings in functionality and information. Its feature set is closely aligned with daily oncology practice, offering toxicity criteria, staging tools, prognostic calculators, and adjunctive functions that streamline clinical workflows and reduce time spent switching between resources [30]. These tools are clinically relevant, for example, in grading adverse events during treatment, estimating prognosis through staging systems, or calculating chemotherapy dosing at the point of care, which may explain their advantage over guideline-oriented, exam-oriented, or single-purpose apps. ONCOassist has also been recognized as a best practice model for incorporating user feedback in its development [30] and is valued for enhancing performance by providing guideline-based recommendations that act as a safety net for clinical decision-making [31], as well as showing potential utility in frailty assessment [32]. Its integration into oncology practice is already being discussed within professional networks [33], and its uptake is evident in some regions. As an instance, Devnani et al [34] reported that nearly 60% of a sample of 155 Indian oncology professionals had used it for over a year. Nonetheless, the available evidence should be interpreted with caution due to small samples, non-probabilistic recruitment, and potential conflicts of interest, highlighting the need for future research with more robust designs to confirm its clinical effectiveness and real-world impact.

Despite the increasing relevance of mobile apps for cancer care and management, the number of apps identified in this study is lower than that reported in previous research. Comparatively, Lima et al [4] identified 34 mobile apps published between 2015 and 2022 aimed at patients with any type of cancer for diagnosis, prognosis, monitoring, and treatment. In any case, this study focused exclusively on free apps designed for use by health professionals. In this regard, although the study by Charbonneau et al [13] identified 123 apps for cancer intended for the general public, only 3 of them are aimed at professionals. Consequently, it is to be expected that the number of apps identified would be relatively limited. Importantly, this limited number is not only consistent with prior studies but also reflects a broader structural scarcity of oncology-specific mobile apps for professionals. Much of digital oncology innovation currently takes place through web-based platforms or tools integrated into electronic health records rather than stand-alone mobile apps, which narrows the availability of dedicated mobile solutions in app stores.

The assessment of apps indicates that the quality of the identified apps is generally poor. The mean score was 3.51 (SD 0.54), with only 2 apps (the aforementioned ONCOassist app and Oncology Board Review) exceeding the 4-point threshold, which is considered to indicate a "good" level of quality. These findings align with the existing literature. Amor-García et al [35] used the same tool to evaluate 46 apps designed for patients with genitourinary tumors, obtaining a mean score of 2.98 (SD 0.77). In their study, only 13% (6 out of 46) of the apps achieved a score exceeding 4 on the MARS scale [36]. In a similar vein, Böhme et al [15] used a tool based on the MARS scale, which indicated that 60% of the apps for cancer were rated as insufficient or deficient. Similarly, the mean MARS score for the overall quality of the 88 apps addressing hematological conditions (including hematological cancers among other pathologies) in the review by Narrilos et al [37] was 3.03 (SD 1.14). They concluded that more than half of the apps do not meet acceptable criteria for quality and content, with most providing only information about the conditions and lacking interactivity and personalization features. Scholz and Teetz [14], who analyzed the quality of 33 identified mHealth apps focusing on breast cancer, agreed with the findings of previous studies

XSL•FO
RenderX

as they also found problems with app quality. Additionally, results of studies that focused on the evaluation of mobile apps intended for cancer patients are similar to the results of studies that evaluated the quality of apps intended for HCPs [13]. This consistency in lack of quality in apps was also observed in this study, as none of the evaluated apps achieved a score of at least 4 across all dimensions of the MARS scale. The assurance of high-quality apps (eg, through the provision of user-friendly interfaces, the presentation of evidence to support them, or the involvement of users in their creation) would serve as a facilitator for the implementation of mHealth [38].

Beyond individual app performance, our findings also reveal differences across categories. Apps classified under prevention tended to focus on awareness and lifestyle recommendations, but they generally scored lower on functionality, reflecting a lack of interactive or decision-support features. In contrast, treatment-related apps offered more sophisticated functionalities such as toxicity grading, staging tools, or guideline-based recommendations, which explains their higher ratings in functionality and information. Finally, support apps showed strengths in accessibility and patient-oriented resources but often lacked the depth of evidence-based content required for professional use. Taken together, these patterns suggest that while treatment-oriented apps currently provide the most comprehensive toolsets for oncology professionals, prevention and support apps remain underdeveloped for clinical practice and represent important areas for future improvement. However, these comparative insights should be interpreted with caution, since the small number of apps included (n=20) restricts both the representativeness and the statistical power of the findings, as the limited sample constrains subgroup comparisons and increases the influence of outliers, making the results more descriptive than inferential. Taken together, these category patterns highlight the inherently heterogeneous nature of the digital oncology landscape. This heterogeneity can be understood as a structural feature of current app ecosystems, where tools differ sharply in purpose, evidence base, and alignment with clinical workflows.

This study is not without limitations. First, there may be additional apps not captured in this review. The keywords used for the review might not identify other relevant apps for cancer HCPs. Furthermore, while Google Play and the Apple Store account for approximately two-thirds of the mobile apps downloaded annually [39], there are other, less commonly used download platforms that were not included in this review. In addition, the review focused exclusively on free apps. While this approach reflects real-world usage patterns and aligns with the scope of the TRANSiTION project [16,17], it may also reduce the representativeness of the findings, since paid apps, which could differ in quality or functionality, were excluded. Limiting the search to English-language apps also excludes numerous potentially relevant apps in other languages, which may affect the generalizability of our findings. In particular, this restriction could underrepresent apps developed for and widely used within non–English-speaking European health care systems. However, this choice was consistent with the primary aim of the study, which is embedded in the TRANSiTION project, where the apps may be used as common resources for participants from 14 European countries. English was selected as the working language of the project and provided a common ground to ensure accessibility, comparability, and feasibility of evaluation across countries. Moreover, the number of apps evaluated after the screening process (n=20) is relatively small. This limits the representativeness of the sample and reduces the statistical power of the findings, as subgroup analyses could not be conducted, and outliers may disproportionately affect the results. Therefore, the study should be viewed primarily as descriptive. Future research with larger and more diverse samples, ideally through systematic surveillance and international collaborations, is needed to provide a more comprehensive and robust overview of oncology apps. Second, although the evaluation of the apps was conducted using a standardized procedure and a validated tool, the evaluators may be susceptible to response biases, as the assessment relies on subjective ratings. In addition, the MARS assesses the app's evidence base with a single item (item 19), which appears insufficient for determining whether an app should be included in an HCP's resource portfolio. These limitations imply that the validity and reliability of the quality scores may be constrained, since rater bias and the restricted appraisal of evidence can influence results. Consequently, MARS ratings should be understood as standardized indicators of app quality rather than definitive evidence of clinical effectiveness or robustness. Nevertheless, MARS is the most widely used among all app evaluation scales and is suitable for general public use [40]. Future research should therefore combine standardized quality assessments with empirical studies to determine the actual impact of oncology apps on professional performance, efficiency, and well-being.

Health apps are emerging technologies that handle sensitive personal health data, which can significantly impact health outcomes and are susceptible to cybersecurity threats [41]. This study highlights that while some apps have limited supporting evidence from previous studies, none have provided evidence of their validity and reliability for their intended purpose. In the study of Berger-Groch et al [42] that focused on identifying mobile apps that can be used in the treatment of patients with musculoskeletal tumors, only 3 scientific articles on mobile apps in orthopedic oncology were present, yet several more apps were available without scientific medical evaluation. Some of the justifications provided in the literature are that apps tend to become unavailable in app stores once the studies have concluded, or that a significant proportion of the papers do not reveal the specific apps that were used [11]. The lack of regulatory standards or frameworks for assessing the quality of these apps is, therefore, of serious concern [43] and has been described as the "Wild West of healthcare" [44]. There are some initiatives to regulate the quality of apps, such as those in the National Health Service [45], the Spanish Ministry of Health and Agència de Qualitat i Avaluació Sanitàries de Catalunya [46], or the ongoing European project ASSESS DHT [47], which focuses precisely on filling this gap.

In addition to these regulatory challenges, the predominance of commercially developed apps in our sample (18 out of 20) raises concerns regarding both content quality and sustainability. On the one hand, commercial investment may provide resources

XSL•FO
RenderX

for more advanced design and maintenance. On the other hand, it can introduce potential conflicts of interest, with content that may prioritize promotional goals over evidence-based practice. Sustainability is also uncertain, as the long-term availability of commercially driven apps depends on market viability, a factor that may explain why many oncology apps become unavailable after only a few years. Similarly, apps developed within the framework of publicly funded research projects may encounter comparable sustainability challenges. Although grounded in scientific evidence, their maintenance and updates are often limited to the project's duration, after which support may be discontinued, restricting their long-term utility. Prior research has shown that such discontinuity contributes to poor adoption rates and a lack of long-term sustainability, highlighting the need for evidence-informed methodological approaches that extend beyond funding cycles to ensure continuity and adoption in real-world practice [48]. These findings underscore the importance of regulatory oversight and sustainable development models to guarantee that oncology professionals can rely on digital tools with transparent, evidence-based, and durable content. Overall, the scarcity and heterogeneity identified in this review underscore the fragmented nature of the current digital oncology ecosystem and highlight the need for coordinated development and robust evaluation frameworks.

From a clinical perspective, our findings highlight the need for oncology professionals to exercise caution when selecting mobile apps, giving priority to those that demonstrate transparent evidence and functionalities that support clinical workflows. In this sense, the implementation of regulatory frameworks and validated quality standards will be crucial for transforming our results into practical guidance, ensuring that HCPs can safely rely on digital tools that enhance efficiency and patient care. In this context, this study, as part of the TRANSiTION project, which incorporates multiprofessional and patient perspectives from several European Union Member States into its design and implementation, as well as in the dissemination and communication of its outcomes, will contribute to initiating new research lines and developing apps with enhanced methodologies [49].

Conclusions

This study identified mobile apps available to cancer care HCPs and highlighted their limitations. Currently, there is insufficient evidence in the literature to support the effectiveness of any specific downloadable app. However, this review offers a structured evaluation of app quality and a comparative overview of each app's strengths and limitations, providing a baseline for future research and development in this field. While overall app quality was poor, the findings point to the potential usefulness of the ONCOassist app, which emerged as the highest-rated app in our assessment and merits further investigation through robust empirical studies. Continued monitoring, evidence-informed development, and the implementation of quality standards will be essential to ensure that mobile apps can reliably support oncology practice in the future.

Abstract

Background: Parents are increasingly using smartphone apps to help guide decision-making around aspects of caregiving, including safer sleep. However, it remains unclear whether the guidance provided aligns with best practice guidelines.

Objective: This review aimed to identify smartphone apps that provide safer sleep guidance and to assess their content, technical features, functionality, and quality. A secondary aim was to make recommendations on the improvements that existing and future apps can make to provide safer sleep guidance.

Methods: In January 2026, we searched the UK Google Play Store and Apple App Store for safer sleep guidance apps for parents and caregivers of newborns and infants (babies aged ≤12 months). Information regarding content, technical features, and functional features was extracted and summarized descriptively. Each app was evaluated by 2 raters using the Mobile App Rating Scale (MARS) and the IMS Institute for Healthcare Informatics functionality score. Adherence to best practice sleep guidance was assessed using bespoke criteria. Interrater reliability was calculated.

Results: A total of 1345 apps were identified, with 12 meeting the inclusion criteria. All were free to download, with 42% (5/12) containing in-app purchases. Only 17% (2/12) were affiliated with a professional health, medical, clinical, or government body. All 12 apps contained some information regarding safer sleep practices, although this was addressed and named differently (eg, calling it cot death, sudden infant death syndrome, or safe sleep). Of the 9 criteria relating to safer sleep best practice guidance, the apps mentioned an average of 6.75 (SD 1.71; range 3-9) criteria. Some promoted unsafe sleep practices (ie, around swaddling and cosleeping). The apps included an average of 5.4 of the 11 IMS functionality criteria (SD 2.5; range 2-9). The mean MARS score was 3.7 out of 5 (SD 0.43; range 2.92-4.13), and most (11/12, 92%) had a minimum acceptability score of 3 or above. Two had been formally trialed or tested. Although the language used was considered accessible (easy to understand), none of the apps allowed the language to be changed (beyond English), and very few (3/12, 25%) enabled users to change to night/dark mode, which would be considered essential when using these apps at night.

Conclusions: Several apps about safer baby sleep exist. Few discuss safer sleep guidance comprehensively or raise awareness about sudden infant death syndrome and its links with unsafe sleep. All the reviewed apps met the minimum acceptability criteria for quality; however, not many were formally trialed or tested. More long-term research should be conducted on the effectiveness of safer sleep apps on adherence to safer sleep guidance. We recommend that apps relating to infant and baby safety in general include information on realistic safer sleep practices that are informed by best practice guidelines and take a risk minimization approach.

Introduction

Safer sleep refers to a range of evidence-based practices that reduce the risk of sudden infant death syndrome (SIDS), an ongoing and significant public health concern. SIDS is defined as the sudden, unexpected, and unexplained death of an otherwise healthy infant occurring in babies aged 12 months or younger and most commonly within the first 6 months [1]. SIDS is listed in the *ICD-11* (*International Classification of Diseases, 11th Revision*) under the code MH11: sudden infant death syndrome and includes terms such as "cot death," "infantile sudden infant death syndrome," and related variants [2]. As the exact etiology of SIDS remains unknown and is believed to result from a combination of factors, current guidance focuses on implementing measures, such as safer sleep practices, that mitigate and reduce associated risks [1]. In the United Kingdom, safer sleep recommendations are primarily informed by guidance from The Lullaby Trust, the National Health Service (NHS), and the National Institute for Health and Care Excellence (NICE), all of which aim to reduce the incidence of SIDS.

The safest sleep environment for an infant is a separate sleep space, located within the same room as their carer [3]. Infants should be placed on their backs on a firm, flat, waterproof mattress, with their feet positioned closest to the foot of the cot or Moses basket. The cot or Moses basket should be kept free of objects and contain only the mattress and lightweight bedding [3-5]. They should be kept smoke-free, and the room temperature should be maintained between 16 °C and 20 °C, as overheating is a contributing factor to SIDS [3,6]. Current guidance recommends room sharing with their carer for at least the first 6 months [4]. This is central advice provided by professionals, and all parents should be given risk-reduction information on bed-sharing to support informed decision-making [6].

Parents should be advised not to bed-share if their baby has a low birth weight, weighs less than 2.5 kg, was born prematurely, or if either parent has consumed 2 or more units of alcohol, smokes, is taking medication that causes drowsiness, or has used recreational drugs [3,6]. Cosleeping should never occur on a sofa or armchair, as this significantly increases the risk of fatal sleep accidents and SIDS [7]. Parents should also assess the sleep environment for potential entrapment risks, including any gaps between the mattress and the bedframe or adjacent walls [8].

According to provisional data from the Office for National Statistics [9], a total of 164 unexplained infant deaths occurred in England and Wales in 2023, representing 7.1% of all infant mortality. Of these, 52% were classified as SIDS, equating to 0.14 sudden infant deaths per 1000 live births in 2023. Evidence indicates that hazardous sleep environments are present in most unexplained infant deaths in the United Kingdom, which is a key focus of national guidance [10].

While safer sleep campaigns, notably the "Back to Sleep" initiative launched in the 1990s, contributed to a 90% reduction in SIDS in England, this decline has plateaued in recent years [10,11]. Although the campaign was successful in targeting position-related SIDS, it has had less impact on deaths associated with cosleeping, which now accounts for approximately 30%-50% of all SIDS cases, mostly due to hazardous cosleeping environments, such as parental alcohol or drug consumption (which may cause drowsiness), smoking, preterm infants, or sofa or armchair use [3,10]. Additionally, didactic approaches that rely on fear, judgment, or inflexible ideal rules are often ineffective. Many parents report struggling to follow advice they perceive as unrealistic, particularly during periods of routine disruption [11]. In contrast, risk-reduction approaches acknowledge real-world circumstances and provide practical strategies that explain how and why safer sleep practices protect infants [11].

Messaging of safer sleep campaigns must be adapted and reinforced for the current generation of parents, as gaps remain in parental knowledge and adherence to safer sleep guidance, particularly in higher-risk groups. A cross-sectional survey conducted by Pease et al [12] in deprived areas of Bristol, United Kingdom, found that mothers in higher-risk groups were less likely to breastfeed, had more difficulty recalling 2 or more unprompted correct SIDS risk reduction strategies, and scored lower overall on prompted safer sleep scenarios. Notably, only 52% of the 400 mothers surveyed identified infant sleep position as a risk reduction strategy for SIDS [12].

In May 2024, UK adult smartphone users averaged 38 apps on their devices, and 32.5 million visited one of the top 10 health and well-being websites or apps [13]. Of the adult visitors to NHS websites that month, 57% were women [13]. Mobile health (mHealth) apps, which leverage the widespread use of smartphones, provide a cost-effective way to deliver accessible information and influence specific, health-related behaviors within targeted populations [14]. Additionally, with the increase in artificial intelligence (AI), many people, including parents, are turning to AI for information surrounding a multitude of topics; however, there are concerns about AI models such as ChatGPT because they draw their information from what is available on the internet, leading to the potential for misleading or incorrect data [15].

Technology, specifically mHealth apps, is increasingly influencing how parents make decisions about infant sleep. Lambert et al [11] found that most of their participants (28 families) relied on online resources, including sleep tracking apps, social media, and search engines, to guide their understanding of infant sleep, particularly when they perceived contact with health visitors was limited. Younger parents reported a stronger reliance on online sources and influencer content, preferring social media platforms over the NHS website, which they described as overly wordy or jargon-heavy. mHealth apps offer an opportunity to bridge the gap left by traditional services by providing resources that are collaboratively developed, accessible, and succinct, which can help parents plan for safer sleep and navigate routine disruptions, rather than relying solely on traditional didactic approaches [11].

Research surrounding systematic reviews of publicly and commercially available mHealth apps specifically targeting safer sleep for newborns and infants has not yet been conducted in the United Kingdom, although some research does exist on similar topics. For example, Simon et al [16] conducted a

XSL•FO
RenderX

content analysis of smartphone apps for children's sleep; however, they reviewed apps that offer sleep improvement strategies rather than safer sleep guidance for babies and infants. Virani et al [17] reviewed mHealth apps targeting new parents, specifically parents of newborns and infants; however, the study focused on apps that provided sleep tracking, sleeping aids, and photo sharing, and their target sleeping aid applications presented white noise and lullabies to soothe infants to sleep. They did not provide education on safer sleep guidance. Another review by Lee-Tobin et al [18] examined the educational information provided in sleep mHealth apps; however, it was not solely targeted toward newborns and infants. A final review by Grigsby-Toussaint et al [19] excluded apps targeting babies and included those used as sleep alarms. This suggests a gap in the availability of systematic evaluations of mHealth apps targeting parents of infants and newborns that provide guidance on safer sleep practices.

Safer sleep guidance is widely available on the internet, although it is difficult to access evidence-based, reliable guidance via an app without knowing the names of specific organizations or apps that provide this information. This is further emphasized by the increase in misinformation surrounding safer sleep on various social media platforms [20], making it difficult for parents of newborns, especially first-time parents, to access trustworthy information. This systematic mHealth app review will therefore seek to answer the question of what stand-alone safer sleep apps are available for parents and caregivers of newborns and infants in the United Kingdom and what their quality and functionality are. How accessible are they, and do they adhere to best practice guidelines?

Methods

Review Design

A systematic review of safer sleep mHealth apps available on the UK Google Play (Android) and Apple App Store (iOS) was undertaken. This review was conducted using the 7-step process, and the review question was informed by the TECH (target user, evaluation focus, connectedness, and health domain) framework [21] (Textbox 1). The protocol is registered on the Open Science Framework [22], and the review was reported using an initial version of the CAPPRRI (Consensus for APP Review Reporting Items) guidance [23], which was under development at the time of the review. Multimedia Appendix 1 contains the completed CAPPRRI checklist.

Textbox 1. The TECH (target user, evaluation focus, connectedness, and health domain) framework used to determine the review question.

Target user

- Parents and caregivers of newborns up to infancy

Evaluation focus

- Quality, functionality, accessibility, and adherence to best practice guidelines

Connectedness

- Stand-alone

Health domain

- Safer sleep

This review was conducted by a UK pediatric nursing student in her second year of study (SY) and a UK midwifery student in her second year of study (NM), under the guidance of 2 researchers with extensive experience in conducting systematic mHealth app reviews and digital health evaluation (NG and DD). One author is also a registered nurse (DD). The clinical training backgrounds of the reviewers (SY and NM) may have positively influenced the appraisal of app content, particularly with respect to infant safety, clinical credibility, and alignment with evidence-based guidance. To mitigate any potential biases (eg, favoring mHealth interventions), all stages of the review followed a predefined protocol, used explicit inclusion criteria, and applied standardized and reproducible appraisal methods.

Eligibility Criteria, Search, and Selection

As seen in Table 1, the eligibility criteria were determined through application of the TECH framework [21]. The target users were parents or caregivers of newborns and infants (0-12 months), including individuals and families, while apps targeting health care professionals, nurseries, care providers, or organizations were excluded. For the purpose of this review, infants were defined as children aged 12 months or younger, including the neonatal period (0-28 days) and postneonatal period (aged ≤12 months) [9]. The evaluation focus included app quality, functionality, accessibility, and adherence to best practice guidelines; privacy features were excluded because personal data were not expected to be collected. Eligible apps were required to be stand-alone and specifically address safer sleep by providing educational or informational content. Apps that functioned solely as sleep trackers, feeding or milestone trackers, or sound machines were excluded. Apps that cost to download were also excluded.

XSL•FO
RenderX

Table 1. Inclusion and exclusion criteria applied to the TECH (target user, evaluation focus, connectedness, and health domain) framework.

Domain	Inclusion criteria	Exclusion criteria
Target user	• Parents or caregivers of newborns up to infancy (aged 0-12 months) • Individuals or families	Health care professionals, nursery or care providers, or organizations
Evaluation focus	• Quality, functionality, accessibility, and adherence to best practice guidelines	Privacy (do not expect personal data to be collected)
Connectedness	• Stand-alone	Connected to wearable devices, EHRs[a], and health care services
Health domain	• Safer sleep apps (eg, sleep positions, bed set-up, sleep environment, and cosleeping) • Educational or informational	Sleep trackers, feeding, milestones, or sound machines

[a]EHR: electronic health record.

A preliminary search was conducted using no limits or filters and the following key terms: safe sleep, safe sleep guidance for babies, and safe sleep guidance for infants, on the UK Apple App Store and Google Play Store. This confirmed that the number of apps available was manageable for the review and ensured that relevant apps were not missed. These same search terms were used for the final search conducted between January 6 and 13, 2026. The search was done manually, without the use of automated tools.

The name and developer of each app were manually recorded in a Google Sheets spreadsheet. Three lists of apps were produced following the 3 key term searches, and deduplication of apps was conducted separately by both researchers across the keyword searches. One author then screened each app's eligibility based on its name and the written and image descriptions on the respective app store to assess whether it met the eligibility criteria. A second screening and deduplication stage then took place to identify duplicates between the stores and to screen eligibility after each app had been downloaded. Depending on platform availability, researchers downloaded each app onto 1 of 2 devices: an iPhone 11 (iOS system) and a Samsung S22 (Android system). Two researchers (NM and SY) then conducted independent eligibility assessments and reached a consensus. A third researcher (NG) helped resolve any disagreements. The screening of downloaded mHealth apps was conducted by both researchers on the same day to avoid changes in app store search results, which can vary from day to day. A flow diagram was developed to depict the search and screening process.

Apps available on both iOS and Android platforms were retained only once, to determine their multiplatform availability and to confirm which version was the most recent. Only 1 multiplatform app was included in the review, and this was evaluated on the Android device.

Data Extraction

Data were extracted into a predefined data extraction (coding) sheet created within Google Sheets. Descriptive characteristics were extracted, including app name, developer, version number, the app stores where they were available, cost of in-app purchases, size, average user rating, number of user ratings, and affiliation (name of professional health, medical, clinical, or government body affiliated with the app).

Quality was assessed using the 19-item Mobile App Rating Scale (MARS), which evaluates 4 dimensions: engagement, functionality, aesthetics, and information quality [24]. Each item was rated using a 5-point Likert scale: inadequate (1 point), poor (2 points), acceptable (3 points), good (4 points), and excellent (5 points). The authors evaluating the apps (SY and NM) used the step-by-step training video on YouTube to aid their use of MARS and received additional training from the supervising author (NG). The subjective quality scale was excluded to ensure that all evaluations remained fully objective.

Functionality was assessed using the IMS Institute for Healthcare Informatics Functionality Scale, with each of the following functions rated 1 (present) or 0 (absent): inform; instruct; record, collect data, share data, evaluate, intervene; display; guide; remind or alert; and communicate [25]. The researchers also recorded the presence of AI as present (n=1) or absent (n=0). A written summary was made of any AI features.

Readability metrics were used to evaluate accessibility features, including the Flesch-Kincaid metrics integrated within Microsoft Word. The Flesch Reading Ease score provided a value between 0 and 100, where higher scores reflect that the content is easier to read [26]. Alongside this, the Flesch-Kincaid Grade Level offered an approximate US school grade required to understand the text [27]. It was recorded whether the app enabled users to change the language and whether dark or night mode features were available, either by reflecting the default phone settings or allowing in-app adjustments. These features were considered important for parents using the app during nighttime care, as they may help to minimize sleep disruption.

Each app's adherence to best practice guidelines for safer sleep and cosleeping, defined as any shared sleep between an adult and a baby (eg, on a bed, sofa, or chair) [8], was evaluated using bespoke criteria informed by evidence-based guidance [4,5,28]. The presence of the following information was rated as present (n=1) or absent (n=0) and then summed for a total score:

- Lie your baby on their back
- Keep their cot clear

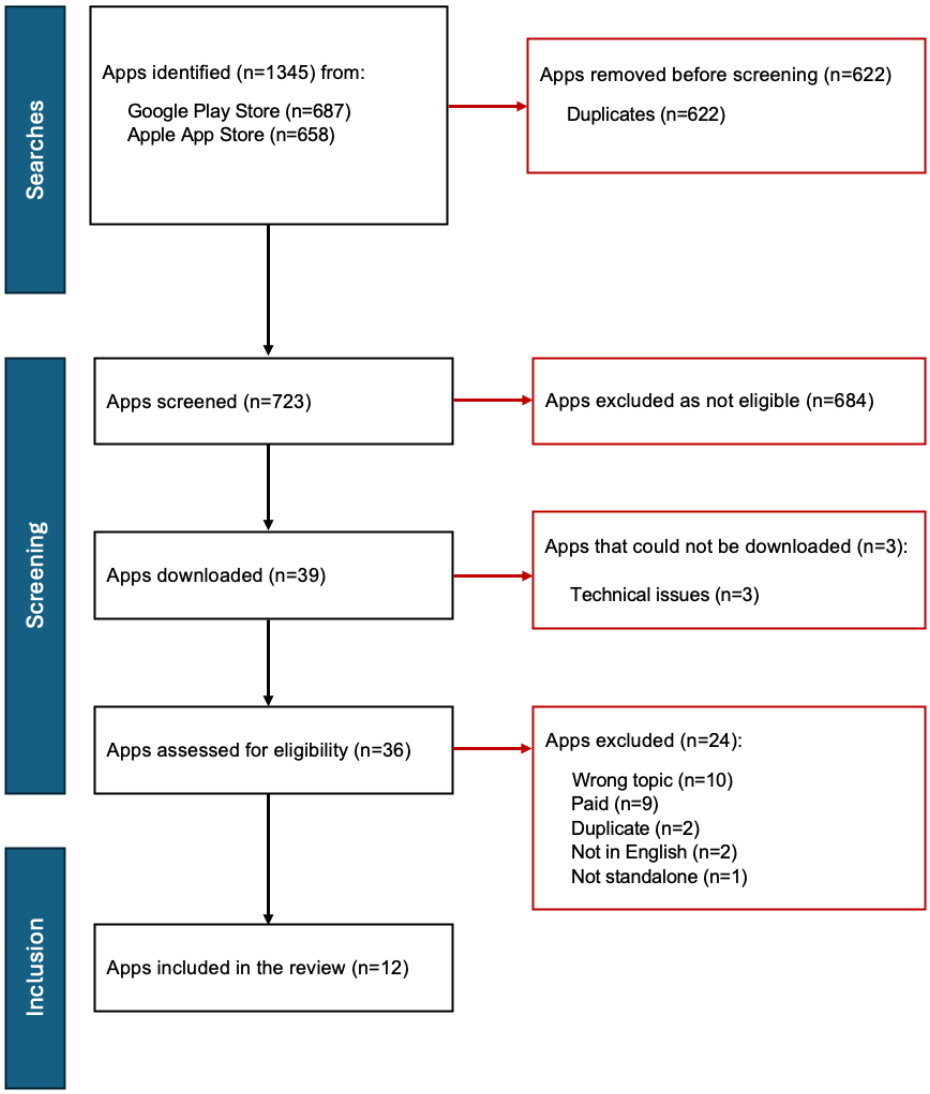
XSL•FO
RenderX

- Use a firm, flat, and waterproof mattress
- Recommend against bed-sharing (shared sleep between an adult and a baby on an adult bed for the majority of the night) if the baby has a low birth weight, or either parent has had 2 or more units of alcohol, smokes, is taking medication that causes drowsiness, or has used recreational drugs
- Avoid your baby getting too hot
- Sleep your baby in the same room as you for at least the first 6 months
- Do not sleep on a sofa or chair with the baby
- If bed-sharing: do not have pillows or duvets near the baby
- If bed-sharing: do not have other children or pets in the bed

Data Synthesis and Analysis

Descriptive statistics were calculated in Microsoft Excel for all relevant items related to app characteristics, quality, functionality, accessibility, and adherence to best-practice guidelines. Text-based summaries (eg, description of any AI features) were summarized using a content synthesis approach. Results were presented using tables and figures (eg, a radar graph), where applicable. The apps were cross-compared using criteria related to quality, functionality, and adherence to best-practice guidelines to identify the highest-scoring apps.

Interrater reliability was also calculated to determine levels of agreement between the researchers conducting the quality and functionality evaluations using MARS and the IMS Institute for Healthcare Informatics functionality scores. These were calculated using IBM SPSS. We calculated an intraclass correlation coefficient for all MARS items using an absolute-agreement 2-way mixed-effects, average-measures model [29]. Interpretations were as follows: <0.5 (poor), 0.5-0.75 (moderate), 0.75-0.90 (good), and >0.90 (excellent) [30]. As the IMS Institute for Healthcare Informatics functionality score uses a binary measure (categories: present=1 and absent=0), we calculated Cohen κ. Interpretations of agreement were <0 (poor), 0.01-0.20 (slight), 0.21-0.40 (fair), 0.41-0.60 (moderate), 0.61-0.80 (substantial), and 0.81-1.00 (almost perfect) [31].



Results

App Market Search and Screening

The initial search yielded 1345 apps. A total of 622 duplicates were removed: 297 from the Google Play Store, 286 from the Apple App Store, and an additional 39 identified between the 2 stores. A total of 723 apps were screened based on their names and the text and graphic descriptions in the app stores, leading to the exclusion of 684 apps as they did not meet the eligibility criteria. After this, 39 apps were downloaded for the second screening stage; however, 3 did not open or could not be accessed. Apps were excluded for the following reasons: addressing the wrong topic (n=10), requiring paid subscriptions or payments to access in-app content and features (n=9), not being in English (n=2), and not being stand-alone (n=1). Two others were duplicates; however, because the apps and developers had different names, they were not identified as duplicates during the initial screening stage. As a result, 12 apps were included in the review. Figure 1 presents the CAPPRRI flowchart summarizing the app search and screening process for the review.

Figure 1. CAPPRRI (Consensus for APP Review Reporting Items) flowchart presenting the app search and screening process.

Descriptive Characteristics

Of the 12 apps included in the review, 50% (n=6) were available on the Apple App Store, and 42% (n=5) were available on the Google Play Store; only 1 (8%) was available on both. All were free to download, although 5 (42%) contained in-app purchases to unlock premium or additional content. Two (17%) apps were affiliated with a professional health, medical, clinical, or government body. The average app size was 99.34 (SD 54.10) MB, ranging from 17.70 MB to 232.70 MB. Of the 10 apps that had been rated by users, the total number of user ratings was 571,016, ranging from 1 to 340,000. An average user rating score of 4.11 out of 5 was calculated. Table 2 provides a summary of the app characteristics, and Multimedia Appendix 2 provides a list of all 12 apps and a plain language summary of the review.

Table 2. Key characteristics and content of the reviewed apps (N=12).

Characteristic	Value
Market availability, n (%)	
Apple Store	6 (50)
Google Play Store	5 (42)
Both	1 (8)
Cost, n (%)	
Free to download	12 (100)
In-app purchases	5 (42)
Affiliated with a professional health, medical, clinical, or government body, n (%)	
Yes	2 (17)
No	10 (83)
The user can change the language, n (%)	
Yes	0 (0)
No	12 (100)
The user can change to night/dark mode, n (%)	
Yes	3 (25)
No	9 (75)
Sleep guidance mentioned, n (%)	
Lie your baby on their back	12 (100)
Keep their cot clear	10 (83)
Use a firm, flat, and waterproof mattress	11 (92)
Recommend against bed-sharing (shared sleep between an adult and a baby on an adult bed for the majority of the night) if the baby has a low birth weight, or either parent has had 2 or more units of alcohol, smokes, is taking medication that causes drowsiness, or has used recreational drugs	11 (92)
Avoid your baby getting too hot	12 (100)
Sleep your baby in the same room as you for at least the first 6 months	10 (83)
Do not sleep on a sofa or chair with the baby	8 (67)
If bed-sharing: do not have pillows or duvets near the baby	4 (33)
If bed-sharing: do not have other children or pets in the bed	3 (25)
Readability	
Reading ease score, mean (SD)	76.6 (SD 7.98)
Reading age (US grade level)	6.9

Sleep Guidance

While all 12 apps contained some information regarding safer sleep practices, this was addressed and named differently (eg, calling it cot death, SIDS, or safe sleep). Of the 9 criteria pertaining to safer sleep best practice guidance, the apps mentioned an average of 6.75 criteria (SD 1.71; range 3-9). Only 2 apps mentioned all the criteria.

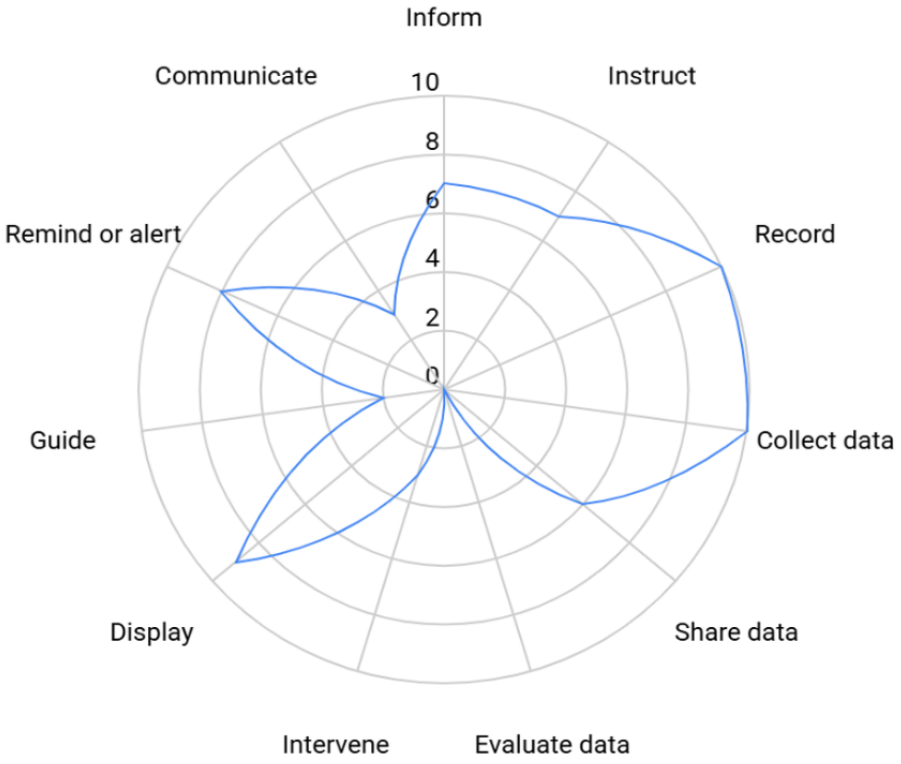
All 12 apps mentioned placing the infant on their back as well as avoiding the baby getting too hot. Additionally, 92% (n=11) of the apps addressed the importance of using a firm, flat, and waterproof mattress and 92% (n=11) recommended against bed-sharing (shared sleep between an adult and a baby on an adult bed for the majority of the night [8]) if the baby has a low birth weight or either parent has had 2 or more units of alcohol, smokes, is taking medication that causes drowsiness, or has used recreational drugs. Most (10/12, 83%) mentioned keeping the cot clear and sleeping in the same room as the baby for at least the first 6 months. However, only 33% (n=4) mentioned not having pillows or duvets in the bed if parents choose to bed-share, and only 25% (n=3) highlighted the importance of not having any other person or pet in the bed if parents choose to bed-share. Table 2 presents the criteria and how many apps mentioned each one.

Two (17%) of the apps contained information that contradicts safer sleep guidance. Both highlighted practices such as swaddling and cosleeping with no additional information on how to do so safely, for example, not swaddling above the

XSL•FO
RenderX

shoulders, keeping swaddles loose around the hips, and only cosleeping with 1 adult in the bed and no pillows or blankets.

Accessibility



The average reading ease score was 76.6 (SD 7.98; range 62.90-91.40). All apps scored above 60, meaning that most adults should be able to understand the content. The average reading age was US grade level 6.9, ranging from the fifth grade to the ninth grade. However, 1 app exclusively provided content in video format, and therefore, readability scores could not be generated. None of the apps provided the ability to change the language (beyond English), and only 3 (25%) could be switched to night/dark mode either through app settings or by automatically adapting to the device's settings.

Functionality

The IMS Institute for Healthcare Informatics functionality score was used to identify functions within each app. There was moderate agreement between the 2 raters (κ=0.494, 95% CI 0.353-0.635; *P*<.001). Consensus was met on all items.

The apps had an average of 5.4 (SD 2.5) functions. The range of functions was from 2 to 9. The 3 most common functions were record (10/12, 83%), collect data (10/12, 83%), and display (9/12, 75%). The 4 least common functions were evaluate data (0/12, 0%), guide (2/12, 17%), and communicate and intervene (both 3/12, 25%; Figure 2).

Figure 2. Radar graph showing app functionality using the IMS Institute for Healthcare Informatics functionality score for 11 items.

A total of 2 apps (Baby Buddy: Pregnancy & Parent and Pregnancy Tracker & Baby App) had 9 out of the 11 functions, and 3 apps (Little One, Baby+ Your Baby Tracker, and Infant sleep info) had 7 functions. There were 2 apps (SIDS Info and Baby Sleep Magic) that only had 2 out of the 11 functions. The remaining apps ranged from having 3 to 6 functions.

Only 1 (8%) app contained an AI assistant. The application, "Bounty: Pregnancy and Baby App," featured a "friendly AI Midwife Assistant" that was available to answer questions until a human midwife could answer between Monday and Friday from 10 AM to 2 PM.

Quality

All apps underwent an independent evaluation carried out by 2 raters using MARS. There was excellent agreement between the raters (intraclass correlation coefficient 0.96, 95% CI 0.948-0.969; *P*<.001).

The mean overall quality score was 3.7 (SD 0.43; range 2.92-4.13). Almost all applications, 92% (11/12) met the minimum acceptability score of 3. The apps "Little Ones" and "Baby Buddy: Pregnancy and Parent" had the highest overall rating (4.1), and "Asianparent: Pregnancy & Baby" had the worst rating (2.9). Mean scores for engagement, functionality, aesthetics, and information quality were 3.3 (SD 0.56; range 2.4-4.3), 4.1 (SD 0.58; range 2.88-5.00), 3.6 (SD 0.73; range 2.67-4.67), and 3.8 (SD 0.68; range 2.38-4.80), respectively. Half of the apps (6/12, 50%) scored the highest on the functionality dimension, 4 apps (33%) scored the highest on the aesthetics dimension, 2 (17%) scored the highest on the information quality dimension, and none scored the highest on the engagement dimension. Three apps (25%) scored the lowest on the engagement dimension, 1 (8%) scored the lowest on the functionality dimension, 4 (33%) scored the lowest on the aesthetics dimension, and 3 scored the lowest on the information quality dimension.

XSL•FO
RenderX

Only 2 (17%) apps, "Baby Buddy: Pregnancy & Parent" and "Bounty: Pregnancy and Baby App," had been formally trialed or tested. However, one yielded positive or partially positive results [32,33] while the other received critical results for its content as it provided contradictory information around avoiding alcohol consumption but also limiting this to 1-2 units once or twice per week [34]. It is important to note that we did not verify whether this contradiction has been amended or whether the app has been updated. None of the apps had been tested in randomized controlled trials.

Cross-Comparison of Highest-Scoring Apps

A cross-comparison of the apps with the highest IMS functionality and MARS scores was undertaken. The highest performing apps and their safer sleep guidance score (out of 9) are presented in Table 3.

Table 3. The highest performing apps included in the review.

App; developer (version)	Cost; platform	IMS score[a]	Total MARS[b] score	Purpose	Safer sleep guidance criteria[c]
Pregnancy Tracker & Baby App; What to Expect (version 7.81)	Free; Google Play Store	9	4.13	Baby growth tracker that provides general advice and guidance around pregnancy and infancy	7
Baby Buddy: Pregnancy & Parent; Babyzone (version 1.2.0)	Free; Google Play Store	9	4.09	Provides personalized information and guidance through pregnancy and infancy	8
Little Ones; Little Ones (version 7.6.4)	GBP £59- GBP £99[d] (in-app); Apple App Store	7	4.09	Provides a comprehensive sleep program for babies and infants	6

Discussion

Overview

This systematic mHealth app review found that there were 12 stand-alone safer sleep apps free to download for parents and caregivers of newborns up to infancy in the United Kingdom. Almost all met the minimum acceptability criteria for quality. The apps ranged in functionality, with an average of 5.4 functions each, although only 1 had an AI feature. A total of 11 apps had written content and could be considered to contain accessible language, as demonstrated by reading ease scores of more than 60. However, none of the apps provided the option to change the language, creating a barrier for people who cannot speak or read English, and very few could change to night/dark mode, limiting usability in dark rooms. Regarding alignment to best practice guidelines, the apps mostly did not provide comprehensive content—most met at least half of the criteria, but only 2 presented all the criteria. Some apps also promoted unsafe practices.

This review showed that there is a limited number of safer sleep guidance apps available across both stores. It was challenging to find apps that contained safer sleep guidance because of the vast number of apps catering to babies, infants, and sleep, many of which were simply sleep trackers, white noise apps, alarms, or baby growth trackers. A large percentage of the apps reviewed were not limited to safer sleep guidance apps, with only 1 focusing solely on providing safer sleep guidance. The others also included general baby and infant safety advice, and many were growth and sleep trackers with guidance sections focusing on safer sleep as a small component. This finding is consistent with a previous review of the app market in Germany, finding that the content of most sleep apps was lullabies, music, or songs, and sleep information was very rare [35]. Similarly, Ejezie et al [36] concluded that digital health strategies for SIDS prevention remain limited, and mostly include online interventions (eg, web-based modules).

Although almost all of the apps we reviewed (11/12, 92%) did meet the minimum acceptability criterion for quality, only 2 of them managed to fully adhere to best practice guidelines as outlined by established UK health bodies, including NICE [28], the NHS [4], and the Lullaby Trust [5]. A few also mentioned the use of techniques that did not align with best practice, such as swaddling, and some did not include further guidance on how to do so safely. The aforementioned review conducted by Schlarb et al [35] also found that there was only a small percentage of apps available in Germany related to sleep information for parental behavior. An analysis of web search results by Chung et al [37] related to safer sleep recommendations found that only 43.5% of the 1300 websites provided accurate information. This further emphasizes the gap in accurate, safer sleep guidance and recommendations observed through this review.

Furthermore, it is important to note that although only 1 of the apps reviewed in this study used AI, this feature is increasingly being incorporated into mHealth apps [38], which raises additional considerations around data privacy and the uncertainty of AI-generated results (especially when delivering personalized medical care) [39].

Not many of the apps had been trialed or tested, and so it remains unclear whether the reviewed apps are effective in promoting safer sleep behaviors and in reducing SIDS. Previous research has shown that although families are often aware of

XSL•FO
RenderX

safer sleep guidance, this does not always translate into practice, especially when the guidance is impractical to implement [40-42]. Information-only resources (including those delivered via smartphone apps) may therefore have limited effectiveness if not provided with contextual support. There has been 1 randomized controlled trial conducted by Moon et al [43] with 1263 mothers in the United States, finding that the intervention group receiving the mHealth intervention with regular text and email messages and videos had significantly higher rates of safer sleep practice compared to the control group. However, the authors point to further research needed to assess long-term impact in order to establish whether adherence to best practice sleep guidance contributes to a reduction in SIDS and whether widespread implementation is possible [43]. The requirement for further research on whether engagement with mHealth interventions correlates with changes in safer sleep practices is also emphasized by Krishnamurti et al [44], who integrated safer sleep information into an existing app, and Aggelou et al [45], who systematically reviewed 23 studies on educational safer sleep interventions targeting caregivers.

It is also important to explore the impact of these interventions in the context of parents receiving alternative advice, as well as on their effects on parental attitudes and norms regarding safer sleep recommendations. This review recognizes that adherence to safer sleep guidance can become secondary when dealing with the responsibilities of caring for a newborn, and parents who opt to bed-share do so for a multitude of reasons, among them to provide comfort, for bonding, and for better/more sleep for both the infant and parent [46]. Additionally, previous research from Australia, New Zealand, and internationally has highlighted that cosleeping (including bed-sharing) is common [42,47,48], either intentionally or unintentionally, during feeding or periods of exhaustion [47,49]. As a result, many families develop their own safer sleep strategies, such as choosing to sleep on a chair rather than in a bed [40,49]. Our research reflects this broader issue, as three-quarters of the apps did not provide strategies for safer bed-sharing, despite the likelihood that many families will encounter these situations. Current apps available in the United Kingdom, therefore, do not adequately support parents across the full spectrum of real-world caregiving scenarios, including unintentional shared sleep and culturally normalized bed-sharing contexts.

Consequently, it is essential to provide context-specific support to families and assess alternative advice given to parents who cannot or do not follow safer sleep guidance, for example, how to safely cosleep or swaddle [43]. Ball and Keegan [50] also highlight that parents often use social media to share information around sleep and this, along with infant sleep apps, may influence cultural narratives around nighttime care. They caution that costly digital sleep technologies may undermine responsive parenting practices and capitalize on parental anxiety. Evidence also suggests that mHealth interventions can enhance adherence to safer sleep guidance by positively influencing maternal attitudes and social norms related to specific recommendations (eg, supine sleeping and room-sharing without cosleeping) [51]. Research is warranted in these areas.

Implications

As outlined above, research is needed to determine the long-term impacts of mHealth apps on preventing SIDS and to explore the context in which parents receive and follow safer sleep guidance. However, there are also several implications for app developers and established safer sleep organizations.

As already discussed, many of the apps were not limited to providing only safer sleep advice. It is therefore important to acknowledge that many people will not be interested in downloading an app that simply contains information on safer infant sleep, as this can already be found online. Rather than developing new apps, we therefore recommend that established organizations such as The Lullaby Trust [5,8] incorporate safer sleep information into the apps they have developed and manage. This is because the organization is a recognizable and trusted name in the United Kingdom that many health care workers already signpost new parents to. For example, their app “Lullaby Trust Baby Check” is already used by parents to determine whether their baby needs to see a health care professional. In a review of apps for managing acute childhood illness, this app was among the highest rated for aligning with end user requirements and was found to already support parents in the United Kingdom [52]. Another service evaluation found that most health visitors were already familiar with it and recommended it to parents of infants up to 6 months old [53]. Interestingly, and consistent with our findings, the evaluation found that health visitors wanted the app to be translated into other languages [53]. It is vital that any content for diverse communities be co-designed with them, given that there are deep-rooted cultural and traditional sleep practices that must be considered. A brief section on safer sleep (including how best to support families who are already bed-sharing) within the app could also leverage The Lullaby Trust’s reputation and help reduce digital waste by reducing the need for a new app to be developed.

Although non–app-based tools such as dedicated websites exist, it can be more convenient to have a smartphone app that already contains evidence-based information regarding safer sleep, particularly as this removes the burden of finding information and may be used offline. Developers who are considering creating apps about infancy or improving their existing apps should include engaging features that provide advice and guidance around safer sleep practices. For example, an American project leveraged simple push notifications in order to increase engagement with safer sleep and breastfeeding education modules within a pregnancy app, which was found to be particularly effective in engaging parents living in high-risk zip codes where SIDS education is most likely to have an impact [44]. When producing this content, developers should partner with health and care workers who have expertise in safer sleep practices and can translate the best practice guidance into easy-to-understand (and reliable) content. Information could be presented in a variety of ways to accommodate different visual and auditory preferences, for example, diagrams, pictures, videos, audio recordings, and writing. This, along with the ability to change languages and to switch to nighttime mode, is important to ensure maximum accessibility and engagement.

XSL•FO
RenderX

It is important to acknowledge that the criteria used to evaluate safer sleep apps in this review take a primarily risk elimination approach, strongly advising against cosleeping. A review by Kruse et al [54] on safer sleep messaging in Australia also highlighted that less than half of the organizations they reviewed provided strategies to engage in safer shared sleep and acknowledged that shared sleep may occur unintentionally or be considered a familial, cultural, or logistical preference. Families often do not disclose cosleeping to health care practitioners [49], potentially due to anticipating judgment or disapproval. A shift toward sensitive and consistent messaging that better reflects the realities of baby sleeping is needed, and this should ideally employ a risk minimization strategy, acknowledging that cosleeping does occur and that risks can be minimized [54,55]. This approach should be used in the future to evaluate safer sleep apps and the content within these apps.

Strengths and Limitations

This review followed a structured and transparent 7-step process informed by appropriate frameworks, while validated measures were used to evaluate quality, functionality, and readability. Two raters were involved in the screening and evaluations, with strong agreement. The review was further strengthened by examining adherence to evidence-based UK safer sleep guidance.

Limitations included the restriction to free-to-download apps available on the UK Apple App Store and Google Play Store at the time of the search, which may not capture apps available in other regions, other stores, or that have since become available. Additionally, conclusions regarding the impact of these apps on safer sleep practices cannot be drawn, as the review did not assess changes in parental behavior or downstream outcomes. It is therefore unclear whether the highest-scoring apps are the most effective.

Conclusion

This systematic mHealth app review identified a limited number of safer sleep guidance apps for parents and caregivers of newborns and infants across the 2 app stores in the United Kingdom. Most of these met the minimum acceptability criteria for quality and contained accessible written content. However, most of the reviewed apps did not provide comprehensive safer sleep guidance, and it was concerning to note that some encouraged practices that are against best practice guidelines. Further long-term research is needed on the effectiveness of mHealth interventions in improving adherence to safer sleep guidance and their ability to reduce SIDS. Information related to best practice guidance around safer sleep and preventing SIDS should be included in established newborn and infant apps, in partnership with trusted organizations, and should be available in several languages. This may result in the development of safer sleep guidance applications that are both trusted and accessible.

Funding

This work is funded by the National Institute for Health and Care Research (NIHR) Undergraduate Internship Programme (NIHR305965) and was supported by the National Institute for Health and Care Research Applied Research Collaboration Greater Manchester. The views expressed are those of the authors and not necessarily those of the NIHR or the Department of Health and Social Care.

Authors' Contributions

NG acquired funding and provided supervision. SY and NM conceptualized the study. SY, NM, NG, and DD developed the study protocol. SY and NM conducted the app market searches, screening, data extraction, and analysis. SY, NM, and NG drafted the manuscript. SY, NM, NG, and DD reviewed and approved the final manuscript.

Abstract

Background: Although highly effective HIV pre-exposure prophylaxis (PrEP) is available, its usage and adherence among young men who have sex with men and young transgender women remain low, reducing its overall effectiveness. The study included a 3-arm randomized clinical trial of Prepared, Protected, emPowered (P3), a comprehensive PrEP adherence digital health intervention, compared to an enhanced version, P3+, which incorporates in-app adherence coaching.

Objective: This study aims to analyze data from study participants in the P3/P3+ intervention arms to understand how different levels of user engagement with the app's features were associated with adherence to PrEP as well as the costs of each intervention and their relative cost-effectiveness.

Methods: Descriptive statistics for study variables at baseline were calculated. To examine the differences in intervention engagement and acceptability by arm, independent samples 2-tailed *t* tests for continuous variables and a chi-square analysis for categorical variables were conducted. To examine the effect of arm and engagement categories on PrEP adherence at 3 months, three logistic regression analyses were conducted: (1) the effect of arm on PrEP adherence, (2) the effect of predefined engagement categories (high vs moderate and low) on PrEP adherence, and (3) the interaction effect of arm and predefined engagement categories on PrEP adherence, along with the main effects of arm and predefined engagement categories. The study team calculated the average cost per participant and the incremental cost-effectiveness for PrEP adherence and engagement measures.

Results: A total of 163 participants were randomized to the P3 intervention (82 to the P3 arm and 81 to the P3+ arm). Participants in the P3+ arm earned higher incentives (US $90.6 vs $75.4; *P*=.04), had more app log-ins (96.6 vs 76.1; *P*=.01), used the app on more days (63.3 d vs 53.2 d; *P*=.04), and spent more time in the intervention (378.8 min vs 186.66 min; *P*<.001) compared to those in the P3 arm. There was no significant association between intervention arm and PrEP adherence at 3 months (*P*=.99). Engagement category (high vs moderate or low) was significantly associated with PrEP adherence at 3 months (*P*=.003). The overall average total monthly cost of P3 was US $1118 (SD $305.1). Average total monthly cost per P3 participant was $280 (SD $118.5), with an additional cost for P3+ of $72.

Conclusions: This study highlights the critical role of user engagement in enhancing PrEP adherence among young individuals at high risk for HIV. While the P3+ intervention led to increased engagement, this did not translate into significantly better adherence compared to the standard P3 arm. This, coupled with the increased cost and complexity of P3+ delivery, indicates that further studies are necessary to determine whether this intensified intervention is the appropriate fit.

Introduction

The introduction of pre-exposure prophylaxis (PrEP) has been a groundbreaking advancement in the drive to eliminate HIV [1]. Despite its efficacy, the overall impact of PrEP is heavily influenced by adherence levels among users [2]. High adherence to PrEP is crucial for its effectiveness in preventing HIV infection, yet PrEP adherence over time is poor, particularly among youth [3,4]. To reap the potential benefits, interventions for young men who have sex with men and young transgender women who are disproportionately impacted by HIV in the United States that can enhance and maintain PrEP adherence over time are needed [5,6].

In recent years, digital health interventions (DHIs) have emerged as promising tools in promoting health behaviors, including medication adherence [7]. These interventions offer innovative ways to engage users, provide information, and support adherence through interactive and personalized digital platforms. Engagement in DHIs has been shown to play a critical role in their efficacy in supporting behavior change across a variety of health domains [8-11]. Research has consistently demonstrated that increased user interaction with digital platforms is associated with improved outcomes, particularly in the context of HIV prevention and care [12-15].

The mechanisms through which engagement enhances efficacy are multifaceted. Active participation in DHIs can lead to increased knowledge, stronger motivation, and better self-management skills among users [16-18]. These interventions often use reminders, motivational messages, and educational content, which help sustain users' commitment to their health regimens [16,17]. Promotion of engagement through incentives and gamification has also shown promise, though studies documenting their ability to maintain engagement over time are limited [19-22].

The Adolescent Medicine Trials Network for HIV Interventions (ATN) conducted a study using the Prepared, Protected, emPowered (P3) app, a comprehensive PrEP adherence DHI, and its enhanced version, P3+, which incorporates in-app adherence coaching [23]. The P3 app included multiple features aimed at increasing user engagement, including a social wall, daily quests, and medication tracking, as well as both in-app "virtual rewards" in the form of unlocking video series produced specifically for the study and real-world rewards in the form of monetary incentives awarded based on principles of behavioral economics [24-26]. This study provided a rich dataset to explore how digital engagement correlates with PrEP adherence among a young demographic at high risk for HIV. This paper seeks to analyze data from a subset of the P3 study participants—those who were part of the intervention arms using P3 and P3+. The focus is on understanding how different levels of user engagement with the app's features were associated with adherence to PrEP as well as the costs. This analysis is crucial, as it contributes to optimizing digital health strategies to support sustained PrEP use.

Methods

Parent Study

P3 is a comprehensive PrEP adherence app which incorporates a variety of content in multiple formats including articles, videos, quizzes, and a social wall in which participants can share experiences, from success stories to challenges. P3 core components included: social prompts to foster community among participants; medication tracking and adherence support; brain builders, which included goal setting and knowledge building; and the knowledge center. P3+ is an extension of P3, in which participants receive all components in P3 and the addition of in-app adherence coaching using an adapted curriculum based on Next Step Counseling adherence counseling [27]. The study included a 3-arm randomized clinical trial conducted from March 2019 to September 2021 and followed each participant for 6 months. Participants were recruited through the ATN from 9 participant recruitment venues in Bronx, New York; Chicago, Illinois; Atlanta, Georgia; Houston, Texas; Boston, Massachusetts; Philadelphia, Pennsylvania; Tampa, Florida; Charlotte, North Carolina; and Chapel Hill, North Carolina. Recruitment methods included in-person, venue-based (including recruitment from local PrEP clinics or providers) and web-based recruitment on social media platforms. Eligible participants were (1) aged 16 to 24 years; (2) assigned male sex at birth; (3) reported sex with or intentions to have sex with men or transgender women; (4) had reliable daily access to an Android or iOS smartphone with a data plan; (5) able to speak and read English; (6) self-reported HIV-negative; and (7) were either not currently on PrEP but planned to initiate in the next 7 days and had an active PrEP prescription (prescription confirmed by study staff) or currently on PrEP and had an active PrEP prescription (prescription confirmed by study staff). Additional information about the P3 study has been previously published [23]. The original study had a baseline survey with 3- and 6-month follow-up. However, this secondary analysis only included those participants randomized to the 2 intervention arms (n=163) and data from baseline (demographic characteristics), 3-month follow-up (PrEP adherence and acceptability), and app data (engagement).

Measures

PrEP Adherence

The study team developed a composite PrEP adherence score to balance data accuracy and completeness across participants by combining biological and self-reported measures: (1) objective estimates of drug levels from dried blood spots, specifically tenofovir-diphosphate (TFV-DP) and (2) self-reported PrEP adherence in the past month. The composite score first used the participants' TFV-DP levels in the blood consistent with more than 4 pills per week considered as adherent (0="nonadherent" and 1="adherent"). For those without TFV-DP measurements (ie, missing laboratory data point), self-reported PrEP adherence from the 3-month survey was used, as prior studies have demonstrated a strong correlation between self-report and biomarker-based adherence measures [28,29]. Self-reported PrEP adherence in the past month was assessed with a single question: "In the last month, what percent

XSL•FO
RenderX

of the time did you take your PrEP as prescribed [once a day]?" with response options ranging from 0% (none of the time) to 100% (all of the time). Following previous research, participants without a TFV-DP measurement but with self-reported adherence were considered adherent if they reported taking PrEP 60% or more of the time in the past month [2]. Among participants with both TFV-DP and self-reported adherence data (n=97), the 2 measures demonstrated moderate agreement (Cohen κ=0.405), with no significant difference detected by the McNemar test (test statistic=2.25 *P*=.14), supporting the reliability of using both measures to assess adherence.

Although in-app daily pill-taking data were collected, these data were not used as the primary adherence measure due to inconsistencies in app usage and reporting, which varied widely across participants. In contrast, TFV-DP provides an objective biomarker of cumulative adherence over several weeks, and self-report offers a retrospective summary measure when biomarker data are unavailable. This dual approach allowed us to capture a more complete picture of adherence while reducing potential bias from missing or irregular app data. While the study team recognizes the value of real-time app data, the priority was to develop an adherence outcome that maximized both validity and data availability across the sample.

In summary, participants were classified as adherent to PrEP if their TFV-DP levels indicated usage of more than 4 pills per week, and as nonadherent if levels indicated fewer than 4 pills per week. For participants without TFV-DP measurements, self-reported survey data were used to minimize missingness. Those who reported taking PrEP at least 60% of the time were categorized as adherent, while those reporting less than 60% adherence were considered nonadherent.

Engagement

Engagement in P3 was defined as using at least 1 of the 3 key app features each day: medication tracker, social wall, or daily quest. Financial incentives, based on behavioral economic principles, were awarded [24,25]. Participants who interacted with any of the 3 features received US $0.50 deposited in their virtual bank account each day; those who did not interact had US $1.00 deducted. Virtual accounts were seeded with US $90 at the start of the study. Thus, participants who used the app every day for the entire 90-day study could amass US $135 at study completion; those who did not use the app at all would end the study with US $0. Three classifications of use were defined a priori based on financial incentives awarded at the end of the intervention: high use (>US $90 correlating to usage on >60 d), moderate use (US $67-$89.50 correlating to usage on 45 - 59 d), and low use (<US $67 correlating to usage on <44 d). These values were chosen to align with prior studies of app engagement and literature regarding how long it takes to form a habit [16,30]. Additional paradata were collected, including total app log-ins, total days logged in, total time spent in the app (min), and total number of days participants tracked their PrEP use (taken or not taken). For those in the P3+ arm, the total number of in-app counseling sessions was also recorded.

Acceptability

Participants were asked acceptability-related questions at the 3 months. Three questions (eg, "I trust the information in P3," "The information in P3 is easy to understand," and "The information in P3 is accurate") were adapted from Horvath et al [31] to assess end users' perceptions of the quality of the information contained in the P3 app. These questions were assessed using a 4-point Likert scale, ranging from "strongly disagree" to "strongly agree," where a higher score indicated better information quality. Then a dichotomized measure was created for each question, where responses of "agree" and "strongly agree" were interpreted as indicating high acceptability.

An adapted version (eg, questions altered slightly to align with mobile app intervention) of the Client Satisfaction Questionnaire-8 which included 8 items (eg, "How would you rate the quality of the help you have received from P3?" "Did you get the kind of help and/or support you wanted from P3?" "To what extent has P3 met your needs related to improving taking your meds?") rated on 4-point Likert scale was used to assess satisfaction with the app [32]. The scale scores were computed by summing the responses to the 8 items (range 8 - 32) with a higher score indicating a higher level of satisfaction (α=.89).

Two questions assessed participants' likelihood of future use and willingness to pay to use the app. The first item, "I would use P3 in the future if available" was rated on a 4-point Likert scale ("strongly disagree" to "strongly agree"), with higher scores indicating higher likelihood of use. Then, a dichotomized measure was created, where responses of "agree" and "strongly agree" were interpreted as an intention to use P3 in the future if it becomes available. The second item, "If P3 were available in the app store, how much would you be willing to pay for it?" Response options included "US $0.99," "US $1.99," "US $2.99," "more than $2.99," and "I would not be willing to pay for it." Responses were dichotomized into willing and unwilling to pay.

Statistical Analysis

Engagement Analysis

Descriptive statistics for study variables at baseline were calculated. To examine the differences in intervention engagement and acceptability by arm, independent samples 2-tailed *t* tests for continuous variables and a chi-square analysis for categorical variables were conducted. To examine the effect of arm and engagement categories on PrEP adherence at 3 months, three logistic regression analyses were conducted: (1) the effect of arm on PrEP adherence, (2) the effect of engagement categories (high vs moderate or low) on PrEP adherence, and (3) the interaction effect of arm and engagement categories on PrEP adherence, along with the main effects of arm and engagement categories. We also included a single demographic variable in each of the 3 models to adjust for potential confounding effects. Due to imbalanced data, dichotomized engagement categories were used instead of 3 engagement categories. Finally, adherence data, including TFV-DP levels and self-reported adherence, were collected at

XSL•FO
RenderX

a single time point during the 3-month follow-up visit, and thus the data are cross-sectional in nature. As such, analyses were conducted using cross-sectional methods, and any inferences about adherence patterns are based on a snapshot of behavior at that specific time.

Costing Analysis

The study team adopted a provider perspective and estimated the costs of P3/P3+ implementation in a community setting. This included the use of activity-based costing and, based on staff input, created an inventory of tasks associated with the management and implementation of P3 and P3+ [33]. The study team developed a survey in Qualtrics whereby each staff person at all sites reported time spent per week on the itemized task for a 2-week period. The survey was administered 4 times: October 2019, December 2019, February 2020, and November 2020 (post-COVID).

Cost per task was calculated by multiplying the median wage for the job category of the respondent staff member by the time spent on the activity. Costs per activity across staff were summed; extrapolated a monthly cost per activity based on the 2-week survey values and then averaged the monthly values by site and for all sites. Although each site provided enrollees for P3+, costs for P3+ were based on data from the North Carolina site only. Costs for P3 were based on all sites. The number of participants per month was estimated and based on the number enrolled in a given month, along with those participating in the intervention from the prior 2 months. Then, the average cost per enrollee per month was calculated. Costs for P3 app development were not included. Activities and materials specifically associated with grant requirements, such as laboratory tests, were not included in the calculations. The incremental cost-effectiveness ratio (ICER) was also calculated with respect to PrEP adherence and engagement in terms of number of app sessions, frequency, and time of app use (intensity), where the ICER is calculated as $(Cost_{P3+} - Cost_{P3})/(Outcome_{P3+} - Outcome_{P3})$ [34].

Ethical Considerations

The ATN P3 protocol, informed assent or consent documents, and related modifications were reviewed and approved by the University of North Carolina at Chapel Hill Institutional Review Board (IRB number 17 - 1951). Informed consent was obtained from all participants, and no study activities were completed prior to giving informed consent. A waiver of parental consent to participate in this research study for youth participants aged 16 to 17 years was granted by the University of North Carolina at Chapel Hill Institutional Review Board. All data and records were stored on password-protected servers. This study is registered at ClinicalTrials.gov (NCT03320512). Participants were incentivized to use the P3 app and started with a baseline amount of US $ in a virtual bank account (US $90) and gained (+US $0.50) or lost (–US $1.00) money from this initial amount each day corresponding to use and nonuse of the app, respectively. The final amount in the virtual bank account (total possible ranged from US $0.00, representing no app use, to US $135, representing perfect daily app use) was paid out as part of the study remuneration at the 3-month study follow-up. Participants were compensated with US $50 upon completion of their enrollment visit, and US $50 each at the 3- and 6-month visits (US $150 total). Participants also received US $50 for each remote specimen collection. All study data were deidentified prior to analysis.

Results

Study Participant Demographic Characteristics

A total of 163 participants were randomized to the P3 intervention (n=82, 50% to the P3 arm; n=81, 50% to the P3+ arm). Retention was 84% (n=69) and 89% (n=72) at 3 months in the P3 and P3+ arms, respectively. The mean age of participants was 21.4 (SD 2.0) years, 91.4% (n=149) identified as male, 52% (n=85) identified as non-White, and 27% (n=44) of the sample identified as Hispanic. Of the total sample, 150 (92%) participants were actively taking PrEP at the time of the study, 6 (3.7%) participants were preparing to initiate PrEP for the first time, and 7 (4.3%) participants had recently resumed PrEP after a prior discontinuation. There were no significant differences in these descriptive statistics at baseline between the P3 and P3+ arms (Table 1).

Intervention Engagement and Acceptability

Overall engagement was high in P3+ arm compared to the P3 arm (Table 2). Participants in the P3+ arm earned higher incentives ($90.6 vs $75.4; *P*=.04), had more app log-ins (96.6 vs 76.1; *P*=.01), used the app on more days (63.3 d vs 53.2 d; *P*=.04), and spent more time in the intervention (378.8 min vs 186.66 min; *P*<.001) compared to those in the P3 arm. Overall acceptability was high in both study arms, and there was no significant difference between P3 and P3+ arms.

The Effect of Intervention Arm and Engagement on PrEP Adherence

Using the composite endpoint which included both self-report and TFV-DP levels, adherence was 78.6% (n=55) in the P3 arm and 78.7% (n=59) in the P3+ arm. As shown in Table 3, there was no significant association between intervention arm and PrEP adherence at 3 months (*P*=.989). Engagement category (high vs moderate or low) was significantly associated with PrEP adherence at 3 months (*P*=.003); however, the interaction effect between intervention status and engagement categories on PrEP adherence was not significant (*P*=.577). We tested models including a single demographic variable to adjust for potential confounding, but the results remained unchanged (Table S1 in Multimedia Appendix 1).

P3+ intervention vs P3 intervention and high vs moderate/low	0.47	0.84	.58

[a]Composite outcome.

Intervention Cost

Table S2 in Multimedia Appendix 1 shows the average monthly costs per activity. Intervention implementation and management costs were, on average, US $617 (SD $270.9) per month across sites with staff meetings accounting for over half of the monthly total. Average monthly costs associated with participant interactions were US $502 (SD $78.6). Participant recruitment, at US $204 (SD $100.0), was the primary cost driver, accounting for 41% of the total, and the largest reported expense across sites. Troubleshooting was the second with Chapel Hill, the central study site, reporting relatively higher expense than other sites.

Taken together, the overall average total monthly cost of P3 was US $1118 (SD $305.1) and ranged from US $797 to $1368. Sites averaged 4.5 (SD 3.9) participants per month resulting in an average total monthly cost per participant of US $280 (SD $118.5). Table S3 in Multimedia Appendix 1 shows the additional costs associated with the P3+ intervention. Average monthly costs for ongoing management of P3+ were US $655 (SD $263.0), while those for counseling-related issues were US $565 (SD $45.0), dominated by counseling itself. An estimated 2.3 participants received counseling per month at an average cost of US $72 (2.7).

Given the difference in P3+ and P3 adherence was small and not significant, the ICER was not calculated. The ICER for the number of app sessions was US $7.06 ([US $352-US $280]/[US $86.3 - US $76.1]) per additional session used, while the ICER for time in session was US $45 per additional hour of use.

Discussion

The findings from this analysis underscore the critical role that user engagement plays in the effectiveness of DHIs aimed at enhancing adherence to PrEP among young individuals at high risk for HIV. A key finding from this study is the significant association between higher levels of engagement with the P3 intervention and increased adherence to PrEP. This aligns with prior research, which has consistently demonstrated that user engagement is a pivotal factor in the success of DHIs across various health domains, including HIV care and prevention [13,14]. Despite the high levels of engagement observed in this study, it is challenging to draw direct comparisons with other DHIs due to the lack of standardized metrics for measuring engagement. A recent scoping review focused on engagement in DHIs for sexual and gender minorities noted that only a small fraction of trials reported engagement metrics, and even fewer studies defined an “optimal” level of engagement necessary to achieve significant health outcomes [35].

The P3 app employed several strategies to boost user engagement, including financial incentives and gamification [19,23]. These methods are supported by a growing body of evidence that suggests such approaches can effectively maintain user interaction over extended periods. For example, Looyestyn et al [20] conducted a systematic review that concluded gamification often increases engagement with online health programs, although the long-term effects on health outcomes remain uncertain. However, enhancing engagement strategies through more robust and personalized approaches has the potential to further improve adherence rates [36]. Moreover, conducting longer-term studies could offer valuable insights into the lasting impact of these strategies, thereby enabling the refinement and adaptation of interventions for sustained long-term outcomes [37].

Interestingly, this study observed that while the P3+ intervention, which included in-app adherence coaching, led to increased engagement (eg, more time spent in the app and higher incentive earnings), this did not translate into significantly better adherence compared to the standard P3 arm. This, coupled with the increased cost and complexity of P3+ delivery, indicates that further studies are necessary to determine whether this intensified intervention is the appropriate fit. This finding may indicate a potential ceiling effect where additional engagement beyond a certain threshold does not necessarily result in proportional improvements in adherence. Using sequential multiple assignment randomized trials could be particularly useful in this context, as they would allow for the systematic evaluation and optimization of the intervention’s components

XSL•FO
RenderX

(and human resources) to better tailor the approach to individual needs [35]. Our results here show that increasing frequency of use was of relatively low cost, while increasing intensity of use cost US $45 an hour. As these are interim outcomes, we cannot declare whether they are cost-effective as we have no standard against which to measure the results as the literature in this area is extremely limited. Although the P3+ compared ot P3 did not increase adherence, it may have produced other health benefits that were not measured as part of the trial.

Given the challenges of sustaining engagement in standalone digital health interventions, future research may explore whether adherence support features could be effectively delivered through widely used social and dating platforms. These platforms attract substantial daily engagement from populations at high risk for HIV, suggesting potential reach. However, our study did not collect data on participants' platform preferences, usage patterns, or privacy concerns, and thus any discussion of integrating interventions into these environments remains hypothetical. Importantly, any such approach would require additional research to assess user acceptability, data security considerations, and potential risks, as well as partnerships with platform developers. If found feasible and acceptable, embedding adherence support within high-traffic commercial apps could reduce the costs of sustaining standalone interventions and may leverage existing infrastructure for personalization and scalability.

This study has several limitations that must be acknowledged. Collection of biologic outcome data was impacted by the COVID-19 pandemic, potentially affecting the accuracy of adherence measurements and the robustness of the findings. The cost analysis presented is based on data collected over a limited period, with potential disruptions also caused by the COVID-19 pandemic. Additionally, due to the small number of participants who were initiating PrEP for the first time, the study team was unable to conduct meaningful comparisons between novice and experienced PrEP users. This limited the ability to explore whether patterns of adherence or engagement differed by prior PrEP experience. Future studies with a more balanced distribution of new and experienced users are needed to examine these potential differences. Moreover, this study was unable to adjust for behavioral confounders such as sexual activity frequency, PrEP experience, and partner status, as well as demographic confounders that are known to influence the relationship between engagement and adherence. This may result in an estimated association that reflects the influence of confounders rather than the true effect of the exposure. Due to the limited sample size, we were unable to explicitly examine how these confounders affect engagement and adherence, or how they interact with one another. Future research with larger samples is warranted to enable comprehensive adjustment for these factors and to better understand their combined impact.

Furthermore, variability in site-specific factors, such as participant recruitment and staff composition, likely contributed to the wide range of cost estimates. While staff were asked to report time for non–study-related tasks, separating the two may have been challenging, particularly in relation to staff meetings. In addition, some tasks conducted in a study setting, such as recruitment, may not be a good proxy for real-world costs and are likely an overestimate. A notable limitation of this cost analysis is the exclusion of initial app development expenses, which are often among the most substantial costs for digital health interventions. This decision was made to provide a clearer estimate of the ongoing operational and maintenance costs associated with scaling the P3 and P3+ interventions in community settings, as these are the costs most likely to be absorbed by public health agencies or clinical partners. Including development costs would significantly increase the apparent total cost, potentially skewing the analysis away from the more immediate, recurring expenses that directly impact long-term sustainability. Moreover, app development costs can vary widely based on factors such as platform selection (eg, proprietary vs open-source), feature complexity, integration with existing health care systems, and ongoing user feedback. For instance, the P3 app incorporated multiple interactive elements, including social walls, daily quests, and personalized adherence coaching, each of which adds to the initial investment. Given this variability, including these costs would complicate direct cost comparisons across different digital health interventions. Nonetheless, future studies should consider a more comprehensive economic evaluation that includes both fixed and variable costs, as this will be critical for assessing the true scalability and long-term viability of such digital health solutions in real-world settings. Finally, this study provided financial incentives for app engagement which may not be sustainable outside of research contexts.

In conclusion, this study highlights the critical role of user engagement in enhancing PrEP adherence among young individuals at high risk for HIV. While increased engagement through DHIs like the P3 app correlates with higher adherence rates, the findings suggest that simply intensifying interventions, such as with the P3+ model, may not necessarily lead to proportionate improvements. The additional costs and complexities associated with more intensive approaches require careful consideration and further investigation. Future research should prioritize the development of more personalized and adaptive engagement strategies, leveraging methodologies such as sequential multiple assignment randomized trials designs to optimize intervention components in real-time. By focusing on long-term adherence and the sustainability of engagement, these efforts can better inform the design of scalable, cost-effective digital health solutions that are both effective and responsive to the evolving needs of at-risk populations.

Acknowledgments

The authors would like to collectively acknowledge and thank the Prepared, Protected, emPowered (P3) study team, P3 study participants, iTech, and the ATN for their continued support and contributions to this project.

Abstract

Background: Young African American men who have sex with men (AAMSM) experience disproportionately high HIV incidence and are less likely to achieve viral suppression compared to White men who have sex with men, an outcome that relies on antiretroviral therapy (ART) adherence. We created My Personal Health Guide, a talking relational agent–based mobile health app to improve ART adherence among young AAMSM.

Objective: The objective was to determine the efficacy of My Personal Health Guide on improving ART adherence among young AAMSM living with HIV.

Methods: We implemented a randomized controlled trial among young (aged 18-34 years) AAMSM with nonoptimal ART adherence throughout the United States between February 2020 and September 2023, predominantly through social media and by word of mouth, provider referral, and fliers in selected health care settings. Participants were randomized in a 1:1 ratio using permuted blocks of 8 to the intervention, My Personal Health Guide, or the attention control arm. ART adherence was assessed with Wilson's 3-item self-reported adherence measurement and dichotomized at ≥80%. Logistic regression models using backward selection were used to evaluate the efficacy of My Personal Health Guide on ≥80% ART adherence at 1-month follow-up.

Results: Among the 253 AAMSM at baseline, most (n=180, 71.1%) self-reported being ≥80% adherent to ART, over half (n=145, 57.3%) resided in the Southern United States, but all US regions were represented, nearly half (n=175, 42.3%) had some college education, over one-third (n=96, 37.9%) had less than optimal literacy, and approximately one-quarter (n=61, 24.1%) experienced housing insecurity in the past 6 months. The sample for analysis of the My Personal Health Guide app efficacy was 131 (intervention=76 and control=55). The odds of being ≥80% adherent to ART at 1-month follow-up were 3.97 (95% CI 1.26-12.55) times greater among participants randomized to the My Personal Health Guide app compared to the controls, after adjusting for ART adherence at baseline, treatment adherence self-efficacy, and ever being incarcerated. Additionally, for every 1-point increase in the HIV Treatment Adherence Self-Efficacy Scale, the odds of ≥80% ART adherence increased by 3% (odds ratio 1.03, 95% CI 1.00-1.06).

XSL•FO
RenderX

Conclusions: Participants randomized to receive My Personal Health Guide reported nearly 4 times greater odds of being ≥80% adherent to ART compared to the attention control group at 1-month follow-up. To our knowledge, this is the first randomized controlled trial demonstrating improved medication adherence using a relational agent–based behavioral intervention. These findings provide evidence of short-term efficacy of My Personal Health Guide to improve ART adherence among young AAMSM. We recommend further research on the inclusion of relational agents in behavioral research, especially in populations affected by stigma and nonoptimal health literacy, where this nonhuman supportive and educational approach may be complementary to health care systems.

Trial Registration: ClinicalTrials.gov NCT04217174; https://clinicaltrials.gov/study/NCT04217174

KEYWORDS

men who have sex with men; African American men who have sex with men; avatar-based mobile phone intervention; Black or African American; HIV; medical adherence; mobile apps; sexual and gender minorities; treatment adherence

Introduction

African American men who have sex with men (AAMSM) have disproportionate HIV infection rates, retention in care [1], mortality, and rates of viral nonsuppression [2-8], an outcome that relies on antiretroviral therapy (ART) adherence. Additionally, health literacy is a factor associated with ART adherence [9] that is lower among African American people than White people [10]. Therefore, interventions that bolster health literacy might improve healthy HIV-related behaviors like ART adherence, potentially resulting in personal and public health benefits.

Relational agents are computerized images that a person may react to as if they are in a relationship. A relational agent can be designed to promote healthy behavioral change. We developed My Personal Health Guide, an innovative theory-driven relational agent–based app with improvement of ART adherence as one of its objectives [11]. During iterative app development focus groups with young AAMSM living with HIV, participants reported universal acceptability for the African American realistic avatar we developed that spoke about, taught, explained, and encouraged behavior to promote healthy HIV-related outcomes [11]. Responding to meeting their adherence-related needs and interests, the app includes clear and simple language, an audiovisual format, and gamification. A pilot study performed in Chicago provided evidence that My Personal Health Guide has the potential to improve adherence [12]. Here, we present preliminary short-term follow-up results from a randomized controlled trial (RCT) of My Personal Health Guide that demonstrate evidence of improvement of ART adherence among young AAMSM living with HIV. We hypothesized that those randomized to the My Personal Health Guide app would have greater ART adherence compared to controls at 1-month follow-up post randomization. Evidence of short-term improvement in ART adherence provides scientific rationale for further research of this realistic avatar and relational agent approach as an adherence intervention and informs efforts to refine the approach to produce longer-term effects.

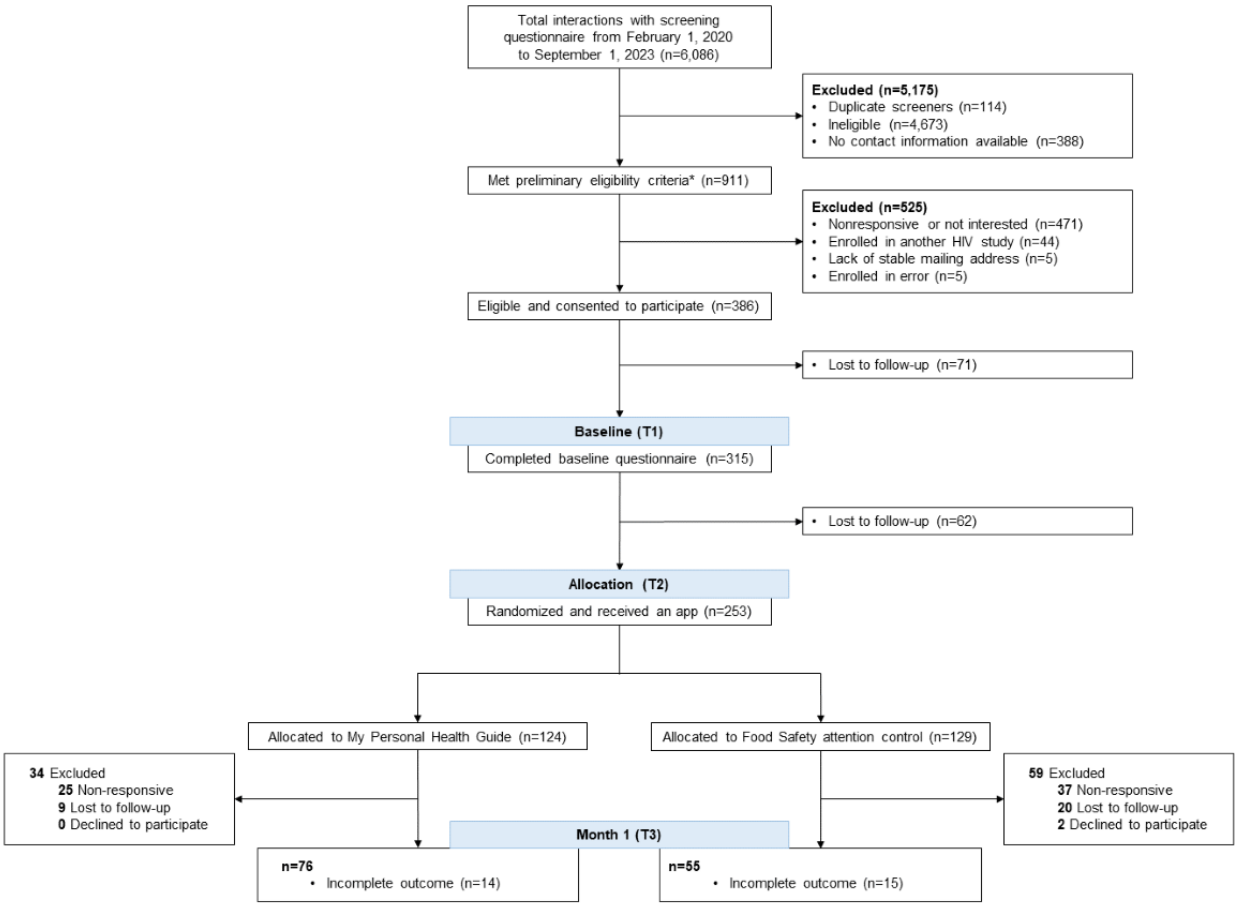
Methods

Intervention

My Personal Health Guide features a realistic talking avatar with supportive functions that were designed to inform users of HIV-related health information, encourage participants to take their medication, and facilitate adherence-related behavioral skills with reminders and push notifications to take medication and promotion of using weekly pill boxes. It also includes recordings of peers and health care providers offering personal and motivational messages. The app provides a private space, in one's own mobile phone, for hearing and seeing information relevant to healthy living with HIV. Users may replay information, which can be especially helpful to people who are uncomfortable asking questions of their health care provider, including asking for a repeat of what was said or an explanation in simple terms.

Design, Recruitment, Eligibility, and Enrollment

This RCT was performed among young AAMSM living with HIV. Participants were recruited throughout the United States between February 2020 and September 2023, predominantly through social media (eg, the dating app Jack'd and Facebook advertisements) and also by word of mouth, provider referral, and fliers in health care settings of the 3 enrollment sites: University of Illinois at Chicago, Emory University, and University of Mississippi Medical Center. Those who were eligible were assigned male sex at birth, currently identified as a man, African American or Black, aged 18-34 years, had at least one male sexual partner in their lifetime, English speaking, owned a smartphone, were initiating or prescribed oral ART, and had a history of nonoptimal ART adherence defined as having a detectable viral load within the past 4 weeks, self-reported nonoptimal ART adherence within the past 30 days, or were referred by a provider for adherence concerns. Those who were on injectable ART, participating in another HIV treatment study, or did not have a stable mailing address at the time of enrollment were ineligible for participation. This study was determined to be minimal risk, with no adverse events reported.



Data Collection, Sample Size, and Randomization

Figure 1 summarizes participant interactions with the study through the first month of follow-up. A structured,

XSL•FO
RenderX

interviewer-administered baseline questionnaire included collection of demographics, baseline knowledge of HIV (items taught in the app), self-reported adherence, incarceration history, housing stability, substance use history, self-efficacy (HIV Treatment Adherence Self-Efficacy Scale [HIV-ASES]) [13], literacy (adapted Rapid Estimate of Adult Literacy in Medicine-Short Form [REALM-SF]) [14], perceived social support (Multidimensional Scale of Perceived Social Support [MSPSS]) [15], and depression symptomatology (Patient Health Questionnaire for Depression [PHQ-9]) [16]. If a participant exhibited moderately severe or severe depressive symptomatology, they were encouraged to reach out to their provider for mental health resources. One month after the baseline interview, participants were scheduled for the app orientation and download that included explaining how to download, setting up a password, briefly pointing out features, and encouraging app use. Additionally, a check-in call was made monthly during 6 months of follow-up that asked troubleshooting questions about the app and collected self-reported ART adherence. Participants received compensation of US $40 for the baseline interview, US $75 for an appointment to download the app, and US $10 for responding to each monthly check-in call. Sample size calculations were carried out using Repeated Measures and Sample Size (RMASS2), the power calculation software for repeated measures design that allows attrition over time. The study was designed with a proposed sample size of 250 at the end of the study duration, or 295 at baseline, which would provide 80% statistical power to detect a 10% group difference in HIV care retention at the end of the study, considering a 15% attrition rate. Permuted randomization in blocks of 8 was used to allocate research participants in a 1:1 ratio to the intervention or control arm, and allocation concealment from the principal investigator, research staff, and research participants was carried out by the senior statistician. Participants randomized to the intervention arm received the My Personal Health Guide app, and those randomized to the attention control arm received a food safety app, which featured an avatar and functions related to food and nutrition, narrated illustrated stories about food safety, an educational game about sugar content in food, and information promoting oral health. The principal investigator and research participants were blinded after assignment to the intervention. Research coordinators oriented the participants to their respective app after randomization.

Figure 1. CONSORT (Consolidated Standards of Reporting Trials) diagram. Preliminary eligibility did not include verifying age and active HIV prescription.

Outcome Measurement

ART adherence was assessed with Wilson's 3-item self-reported adherence measurement, which has been validated against electronic drug monitoring for HIV medication (Cronbach α=0.83) [17]. These three questions include (1) "In the last 30 days, on how many days did you miss at least one dose of any of your HIV medication?" (with a response range from 0 to 30 days); (2) "In the last 30 days, how often did you take your HIV medication in the way you were supposed to?" (with response

XSL•FO
RenderX

options including Never, Rarely, Sometimes, Usually, Almost Always, and Always); and (3) "In the last 30 days, how good a job did you do at taking your HIV medications in the way you were supposed to?" (with response options including Very Poor, Poor, Fair, Good, Very Good, and Excellent). Answers were averaged together and converted to a percentage score on a 100-point scale. Consistent with other studies [18,19], 80% was defined as the cut point for nonoptimal ART adherence. HIV viral load was the intended primary outcome for this research. However, the trial was disturbed by the COVID-19 pandemic, and significant difficulty occurred collecting viral load from this population. Therefore, self-reported ART adherence was used.

Statistical Analysis

The primary statistical goal for this analysis was to determine the efficacy of the My Personal Health Guide app on ART adherence at 1-month follow-up. Participant demographic and study characteristics are presented as means and SDs for continuous variables and as absolute numbers (n) and proportions (%) for categorical variables stratified by randomization arm. The success of randomization was assessed using 2-tailed *t* tests for continuous baseline characteristics or chi-square tests for categorical characteristics. Baseline characteristics between individuals that completed both the baseline meeting and 1-month follow-up versus those who had missing data at 1-month follow-up were compared to ensure comparability between the samples. Bivariate comparisons were made between participant characteristics and ART adherence at baseline (≥80% vs <80%) using chi-square tests for categorical data, Cochran-Armitage tests for ordinal data, and independent *t* tests for continuous data. Logistic regression models with the backward model selection method were used to evaluate the effect of the My Personal Health Guide app, adjusted for significant factors that were associated with ART adherence at month 1, with a $P \leq .05$ considered statistically significant. Baseline adherence was adjusted for a priori. The baseline characteristics that were considered in the logistic regression models included age, ethnicity, remote participation, residence, education, employment status, sexual orientation, currently in a committed relationship, health literacy (REALM-SF), HIV-ASES, depression symptomatology (PHQ-9), perceived social support (MSPSS), ever incarcerated, housing insecurity, and substance use seriousness (serious includes cocaine, methamphetamines, crack, heroin, and opiates; less serious includes alcohol, marijuana, ecstasy, speedballs, and gamma-hydroxybutyrate; none includes no use of substances or alcohol) at baseline. Adjusted model results are presented as odds ratios (ORs) and 95% CI.

Ethical Considerations

This research was reviewed and approved by the institutional review boards of the University of Illinois Chicago, Emory University, and the University of Mississippi Medical Center (protocol #2019-1184). The research involving human data was conducted in accordance with institutional guidelines of the University of Illinois Chicago, Emory University, and the University of Mississippi Medical Center. All participants were administered written informed consent. All data were deidentified prior to analysis and dissemination. Participants were compensated up to US $125 by the 1-month follow-up by their preferred method of check, cash, or e-code.

Results

Sample Characteristics

We attempted to contact the 911 men that met preliminary eligibility criteria, responded to recruitment methods, and provided contact information. Among those, 471 were either not responsive or not interested in the study, 44 were enrolled in another HIV treatment study, and 5 did not have a stable mailing address in order to receive study materials. Five participants were erroneously enrolled in the study due to either being unable to verify having a current HIV prescription (n=3) or having been previously enrolled in the study (n=2). A total of 386 men were consented. Among these, the baseline questionnaire was completed by 315 (81.6%), and 253 (65.5%) had the study apps installed on their mobile phones 1 month later (Figure 1), including 124 (49%) randomized to My Personal Health Guide and 129 (51%) randomized to the Food Safety attention control app. After 1 month, 93 participants did not respond to contact attempts to complete the month 1 check-in call and were excluded from the current analysis. The remaining 160 participants completed the first check-in phone call, and of those, 131 had complete self-reported adherence data at month 1.

The mean age of the 253 participants at baseline was 29.4 (SD 3.7; range18-35) years; most (n=221, 87.4%) were 25-34 years of age. Few (n=18, 7%) identified as Hispanic. Most participated remotely (n=202, 79.8%). Most participants were enrolled by the University of Illinois at Chicago (n=131, 51.8%) and Emory University (n=106, 41.9%), and 16 (6%) were enrolled by the University of Mississippi Medical Center. Over half (n=145, 57.3%) of participants resided in the Southern United States, but all US regions were represented in the sample. Nearly half (n=175, 42.3%) had some college education, and over half (n=146, 57.7%) reported being employed. Three-quarters (n=180, 71.1%) identified as homosexual or gay and were not currently in a committed relationship with a male partner (n=198, 78.3%). Over one-third (n=96, 38%) had less than optimal literacy (adapted REALM-SF). Over half reported mild-severe depressive symptomatology, with 26% (n=65) reporting mild (PHQ-9=5.0-9.9), 14% (n=35) reporting moderate (PHQ-9=10.0-14.9), 9% (n=23) reporting moderately severe (PHQ-9=15.0-19.9), and 4% (n=11) reporting severe (PHQ-9>20.0) depressive symptomatology. The median HIV-ASES score was 104 (IQR 89-114). Although most (n=150, 59.3%) reported high perceived social support (MSPSS>5.0), 9% (n=23) had low (MSPSS<3.0) perceived social support, and 32% (n=80) had moderate (MSPSS=3.0-5.0) perceived social support. Approximately one-quarter experienced housing insecurity in the past 6 months (n=61, 24%), and nearly one-third were ever incarcerated (n=77, 30%). Some (n=39, 15%) reported serious substance use in the past 2 weeks. Nearly three-quarters (n=178, 70.4%) reported less serious substance use, including alcohol, marijuana, ecstasy, speedballs, or gamma-hydroxybutyrate. Most (n=180, 71.1%) self-reported

XSL•FO
RenderX

being ≥80% adherent to ART at baseline. Group comparisons for all baseline characteristics and ART adherence at baseline (Table 1) revealed that randomizations were successful.

[j]Serious includes cocaine, methamphetamines, crack, heroin, opiates; less serious includes alcohol, marijuana, ecstasy, speedballs, gamma-hydroxybutyrate.

Primary Outcome

Among the 253 participants who were randomized and downloaded an app, 131 (51.8%) completed the 1-month follow-up for ART adherence, and 122 (48.2%) did not. A significantly greater proportion of those randomized to the Food Safety app were missing 1-month follow-up data compared to the My Personal Health Guide app (74/129, 57.4% vs 48/124, 38.7%; *P*=.005; Table 2). Additionally, remote participation, employment, substance use, and ART adherence at baseline differed by complete 1-month follow-up data and were therefore considered during multivariable model construction. Bivariate analysis (Table 3) revealed the mean HIV-ASES score (mean 103, SD 15.8 vs mean 86.4, SD 28.5; *P*=.02) was significantly higher in those who had ≥80% adherence to ART at 1 month as compared to those who had <80% adherence at 1 month. The mean depression symptomatology scale (PHQ-9) was moderately significantly lower among those who were ≥80% adherent to ART at 1 month as compared to those who were <80% adherent to ART at 1 month (5.70, SD 4.96 vs 9.00, SD 7.43; *P*=.07). There was also a significantly higher prevalence of being in a committed relationship with a male partner among those who had ≥80% adherence to ART at 1 month as compared to those who had <80% adherence at 1 month (25/111, 22.5% vs 0/20, 0%; *P*=.01).

In multivariable analysis (Table 4), the odds of being ≥80% adherent to ART at 1-month follow-up were almost 4 times greater (OR 3.97, 95% CI 1.26-12.55) among participants randomized to the My Personal Health Guide app as compared to the Food Safety app after adjusting for other characteristics that were also associated with ART adherence at 1 month, including HIV-ASES and having a history of ever being incarcerated. Every 1-point increase in the HIV-ASES increased the odds of ≥80% ART adherence by 3% (OR 1.03, 95% CI 1.00-1.06). A history of ever being incarcerated reduced the odds of ≥80% ART adherence (OR 0.31, 95% CI 0.09-1.06). ART adherence at baseline was marginally associated with ≥80% ART at 1-month follow-up (OR 2.97, 95% CI 0.88-9.99).

Discussion

Principal Findings

Participants randomized to receive My Personal Health Guide demonstrated nearly 4 times greater odds of being ≥80% adherent to ART compared to participants who received the Food Safety control app at 1-month follow-up. This is a substantial magnitude, and although these are short-term follow-up results, these data provide strong evidence that a

XSL•FO
RenderX

relational agent approach to improving medication adherence is promising.

Our study is the first of its kind in the field of HIV medication adherence. We are aware of only 2 other published RCTs of a relational agent for behavior change. Rubin et al [20] performed an RCT of a relational agent to deliver a brief alcohol intervention and referral to treatment to veterans within VA primary care clinics. Their approach involved 2 meetings with the relational agent, who requested a commitment to change. They reported that their relational agent elicited concern about the consequences of drinking and bolstered motivation to change. Although they did not observe accelerated decline in drinking during 3 months with their intervention compared to their control group, they noted that their intervention group was more likely to receive referrals for follow-up and that this approach allowed for more screening and brief intervention without increasing the burden on clinic staff. Another study by Prochaska et al [21] studied a smartphone intervention called Woebot for substance use disorders that used a therapeutic relational agent delivering cognitive behavioral therapy. At 8 weeks, they reported reduced substance use occasions compared to a waitlist group. These studies demonstrate the potential for a relational agent to influence behavior and underscore the scientific rationale for their application to the field of medication adherence. Relational mobile health interventions may be particularly beneficial for younger (18-24 years) AAMSM because they are more likely to still be developing medication-taking routines and may be especially receptive to interactive mobile technologies that can bolster daily ART adherence (Hightow-Weidman et al [22]). Given that these studies and ours are RCTs, they provide evidence for consideration of relational agents in the design of behavioral interventions, especially involving conditions where stigma about diagnosis or treatment could create hesitancy with face-to-face health care provider education or counseling.

In addition to our study demonstrating a large magnitude efficacy, there are several other strengths and considerations. First, our study began shortly before the COVID-19 pandemic spread throughout the United States, disrupting in-person research with lockdowns and other restrictions. This led to a nearly entirely remote rather than facility-based administration and may have made the meeting with research staff for orientation to the app less interactive than it might have been otherwise. The remote approach could have diminished the participant's feeling of accountability to the study or facilitated participation by reducing the barrier of travel to a study activity. Second, unlike medication or immunization, our app intervention involves a passive approach. In other words, patients are encouraged to use it, but it is their choice how much of the app they experience and how often they open it. The app was designed to have new functions and experiences occur with repeated use to encourage return to the app. However, we have no control to ensure regular app exposure. Despite these issues, we observed a significant effect in achieving the adherence goal. This suggests that the effect might increase further and benefit more patients with additional app refinement and involvement of health care providers or case managers in implementation who could refer the app to their patients and check in with them at future appointments. Third, our study sample was diverse, including a large proportion who experienced housing insecurity, screened for moderate or severe depression, and reported a history of incarceration. Additionally, our sample included an overrepresentation of men living in the Southern United States, a high HIV incidence region where many experience structural barriers to HIV care [23] and where a low-cost, scalable intervention like ours could contribute to achieving higher prevalence of viral suppression and help end the HIV epidemic. Finally, our study also demonstrated an independent effect of self-efficacy on being ≥80 adherent. This finding is consistent with other studies, such as those by Dworkin et al [24], Barclay et al [25], and Waldrop-Valverde et al [26]. However, this is the first study to report this specifically in a population of young AAMSM living with HIV.

Limitations

Limitations of this study included that many participants were recruited using a social media dating app and the responsiveness of participants to the 1-month call was moderate, both of which may limit generalizability. Notably, we struggled to recruit younger (18-24 years) AAMSM; therefore, we recommend future studies use a multimodal recruitment approach. Additionally, missingness of self-reported ART adherence was high, and we observed a higher proportion of those randomized to the control with missing data at month 1. Study procedures were disrupted by the COVID-19 pandemic, necessitating the change from a facility-based trial to online. While this pivot allowed for further recruitment and retention, it compromised the collection of viral load data from participants' clinics, which was initially an outcome of interest. This change also impacted the collection of dried blood spots at the 6-month follow-up, which was initially intended to be conducted on-site and changed to be self-administered in the participant's home to accommodate COVID-19 stay-at-home orders. This resulted in a high proportion of missingness. Additionally, the laboratory methodology for the threshold of detection changed during the study period and used a higher threshold (<839 copies/mL) than the clinical definition of undetectable viral load (<200 copies/mL). Similarly, the usage of Wisepill devices to monitor ART adherence was low, so self-report was used as the primary outcome of interest. Using self-reported ART adherence also had limitations. Self-report can overestimate individual medication-taking behavior and therefore may introduce recall and social desirability bias. However, self-reported adherence is often used to assess ART adherence in both routine care and research settings and has been correlated with viral load and other objective markers of adherence [26]. Last, these findings are limited to the first month of observation. Additional follow-up analysis from this trial is planned to determine evidence of long-term effect.

Conclusion

These findings provide evidence that My Personal Health Guide has short-term efficacy in improving ART adherence among young AAMSM living with HIV and contribute to the emerging field of technology-based behavioral interventions promoting health using relational agents. We recommend further research on the inclusion of relational agents in behavioral research,

XSL•FO
RenderX

especially in populations affected by stigma and nonoptimal health literacy, where this nonhuman supportive and educational approach may be complementary to health care systems.

Acknowledgments

We thank the National Institute of Mental Health for funding this research (R01MH116721). We acknowledge Allison Huske, BS; Autumn Smith, MPH; and Elise Dressel, BS, from the University of Illinois at Chicago, School of Public Health; and Paige Jones, BS, and Blake Acebo, BS, from the University of Illinois at Chicago, School of Medicine, for their contributions to data collection.

The National Institute of Mental Health had no role in study design, data collection, data analysis, data interpretation, or writing of the report. The authors were not precluded from accessing data in the study, and they accept responsibility to submit for publication.

Data Availability

A deidentified dataset, a data dictionary defining each field in the set, the study protocol including the statistical analysis plan, and informed consent forms will be made available upon request and with publication acceptance. Per university protocol, all sensitive and high-risk data will be transmitted via an encrypted protocol, or Secure File Transfer Protocol, to individuals outside of the university with investigator support, approval from the data safety and monitoring board, and a signed data access agreement.

Authors' Contributions

MSD and SL contributed to the conceptualization. MSD, RG, and SL contributed to the funding acquisition. MSD, JJ, AJ, RG, and SL contributed to the methodology. MSD, KH, SU, JJ, and PB contributed to project administration. MSD, JJ, PB, RG, and SL contributed to the resources. MSD, JJ, and PB contributed to the supervision. KH, SU, CML, MW, and SL contributed to the data curation. KH, SU, CML, LL, and RR contributed to the formal analysis. KH, SU, and CML contributed to the investigation. KH, SU, CML, and SL contributed to the software. MSD, KH, SU, CML, JJ, LL, and RR contributed to the validation. KH, SU, and RR contributed to the visualization. MSD, KH, SU, CML, LL, and RR contributed to writing the original draft. All authors reviewed and edited the final manuscript.

Conflicts of Interest

The authors report no conflicts of interest. The authors attest that there was no use of generative artificial intelligence technology in the generation of the text, figures, or other informational content of this manuscript.

Abstract

Background: Hematological malignancies are a global health challenge, with a substantial number of deaths each year. Treatment adherence is crucial for improving patient outcomes in patients with hematological malignancies, but resource limitations and logistical challenges hinder optimal outpatient management. Digital health solutions such as the Remote Intelligence for Therapeutic Adherence (RITA) software as a medical device (SaMD) offer potential solutions by facilitating telemedicine visits and supporting patients in managing their treatment.

Objective: The aim of this study was to evaluate the performance and safety of RITA SaMD in improving patient adherence to treatment protocols for hematological malignancies.

Methods: This prospective clinical investigation enrolled patients with hematological malignancies at Azienda Socio Sanitaria Territoriale Santi Paolo e Carlo in Milan, Italy. The RITA SaMD group used the RITA platform, while the control group comprised historical patients. The primary end point was average therapeutic adherence to the prescribed drug treatment, measured as at least the 80% of the relative dose intensity, at month 3. Secondary end points were based on comparisons between the RITA SaMD group and the control group and included the average therapeutic adherence to the prescribed drug treatment at months 1 and 2, number of emergency room visits for minor and severe complications, and the average hospital stay. Multivariable logistic regression models were used to evaluate the effectiveness of RITA.

Results: Between July and December 2022, 119 patients were included in the analysis (57 in the RITA SaMD group and 62 in the control group). At multivariable analysis, the probability of being adherent to treatment at month 3 in the RITA SaMD group was significantly higher than that in the control group (odds ratio 3.0, 95% CI 1.0-8.8; P=.04). A total of 1476 self-reported adverse events (AEs) were collected through RITA SaMD usage, the majority (N=1080) being grade 1 events. During the study visits, 20 AEs were recorded by the study physician (16 in the RITA SaMD group and 4 in the control group). Of the recorded AEs during study visits, 14 were serious AEs (11 in the RITA SaMD group and 3 in the control group). None of the reported AEs was considered related to RITA SaMD usage.

Conclusions: The MargheRITA clinical investigation showed that after 3 months of using RITA SaMD, patients with hematological malignancies had 3 times higher odds ratio of being adherent to the prescribed treatment than the control group. The use of RITA SaMD facilitated the reporting of AEs, reinforcing the role of mobile health apps and software in optimizing patient outcomes. Further research is needed to fully understand its interdisciplinary potential and long-term impact on patient outcomes.

Introduction

Global incident cases of hematologic malignancies have been increasing since 1990, surpassing 1,343,000 in 2019. Still, the age-standardized death rate for all types of hematologic malignancies has been declining [1]. This implies more extended patient management for the health care system.

Treatment adherence is a critical factor in the management of patients with hematological malignancies since poor adherence can result in the emergence of resistance [2,3]. Often, patients underestimate the mild drug- or disease-related symptoms during the treatment, leading to a more severe symptomatology later on that could further impair the patient's adherence to treatment [4]. In addition, many antitumor therapies are now continuous treatments, making therapeutic adherence particularly relevant for patient outcomes. For instance, in a real-world study comparing ibrutinib and acalabrutinib, the two drugs used to treat chronic lymphocytic leukemia, patients were more likely to be adherent to treatment (defined as ≥80% adherence) if they were being treated with ibrutinib, which is administered once daily than if they were being treated with acalabrutinib, which needs to be administered twice daily [5]. Similarly, a study assessing adherence to imatinib treatment in a resource-constrained environment showed that adherence during continuous treatment was related to molecular responses in patients with chronic myeloid leukemia [6]. These data underline the importance of developing innovative approaches to improve therapeutic adherence in patients with hematological malignancies. Therefore, outpatient care models have been developed to offer patients the advantages of home-based treatments, but their implementation and optimization in clinical practice are often challenging as the health care system must deal with resource constraints, exacerbated by factors such as the aging population and improvements in survival rates [1].

In response to these challenges, innovative solutions based on digital health systems such as the use of software as a medical device (SaMD) have recently been designed to complement traditional outpatient care [7]. SaMD can potentially facilitate access to oncological treatments for a wider audience of patients, overcoming geographical and logistical barriers [7].

The onset of the COVID-19 pandemic underscored the urgency of streamlining outpatient management processes [8-10]. Among the most promising strategies to address this need is the development of specific SaMD for oncology, which facilitates telemedicine visits and provides ongoing support for patients in their daily management of the disease, its associated complications, and treatment regimens [8-11]. Compared to nonmedical device software and health care apps, SaMD is developed following the International Organization for Standardization (ISO) 13485 and the European Medical Devices Regulation (EU MDR) 2017/745 (where it is known as medical device software) ensures patient safety and is an essential tool for improving health care quality [12,13].

With this in mind, an SaMD called Remote Intelligence for Therapeutic Adherence (RITA) was developed to serve as a communication platform between doctor and patient and to support the patient in his or her therapeutic journey.

This manuscript briefly describes RITA SaMD and reports the findings of the MargheRITA clinical investigation, which evaluates the performance and safety of the RITA SaMD in improving therapeutic adherence to treatment protocols in patients with hematological malignancies.

Methods

The CONSORT-EHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and Online Telehealth) checklist version 1.6.1 [14] was used to report this study (Multimedia Appendix 1).

Study Design

This was a premarket, pivotal, confirmatory, prospective, and interventional clinical investigation in patients with hematological malignancies. Patients were screened in a single center in Italy from July to September 2022; the period from the end of enrollment on September 22, 2022, to December 16, 2022, needed to match the RITA SaMD patient to the control group patient.

Ethical Considerations

This study was conducted under the clinical investigation plan and international guidelines, including the most recent versions of the Declaration of Helsinki, the International Conference on Harmonization guidelines for Good Clinical Practice, EU MDR 2017/745 [13], ISO 14155, as well as all applicable local laws and regulations. The clinical investigation plan was approved by the local ethics committee (Milano Area 1 IEC 0019486; April 21, 2022) and the Italian Ministry of Health (protocol 2028, May 3, 2022). Signed informed consent was obtained from all patients, starting from July 4, 2022 (start of enrollment) to September 22, 2022 (end of enrollment); the period from end of enrollment to December 16, 2022, was used to match the RITA SaMD patients to the control group patients. No compensation was offered to the participants. All data were anonymized to avoid any possible identification and collected in a validated electronic case report form. The clinical investigation is registered at ClinicalTrials.gov (NCT05260203).

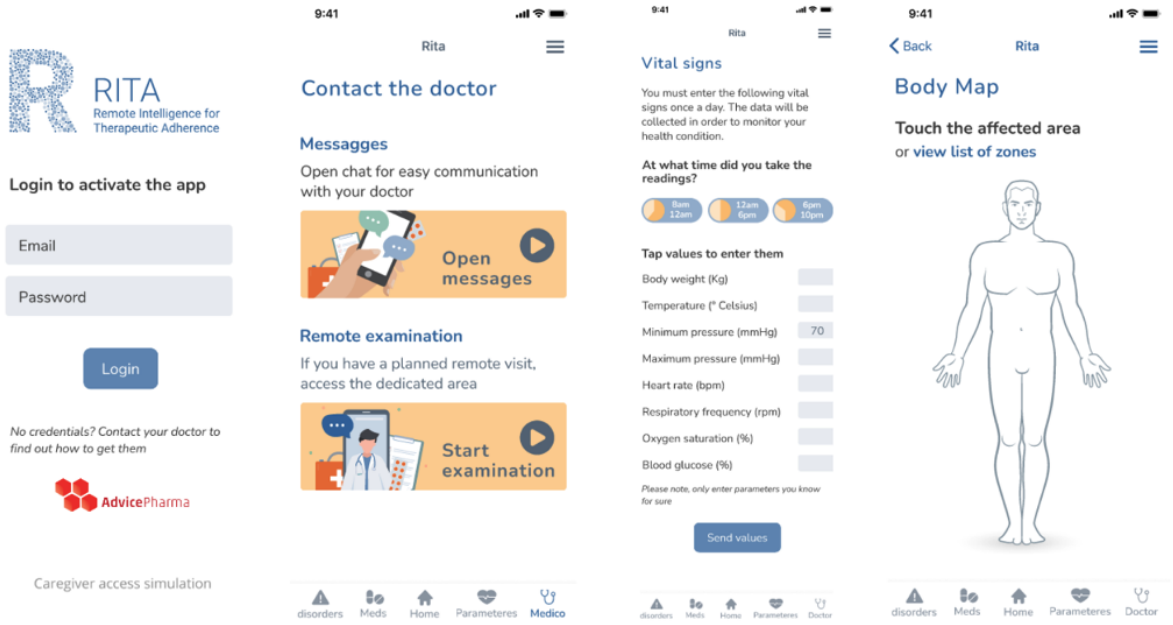
XSL•FO
RenderX

Patient Recruitment

The investigation enrolled individuals who were followed up as outpatients at Azienda Socio Sanitaria Territoriale Santi Paolo e Carlo in Milan who met the following inclusion criteria: comprehension of the investigation's objectives and procedures as well as acceptance to voluntarily sign an informed consent form before any investigation-related activities. In addition, participants needed to be at least 18 years of age and have a diagnosis of a hematological malignancy (encompassing conditions such as symptomatic multiple myeloma, solitary plasmacytoma, amyloidosis, chronic myeloid leukemia, chronic lymphocytic leukemia, lymphocytic lymphoma, Hodgkin lymphoma, B-cell non-Hodgkin lymphoma, T-cell non-Hodgkin lymphoma, acute myeloid leukemia, myelodysplasia, and chronic myeloproliferative disorder). Eligibility also required prior receipt of standard-of-care therapy, irrespective of the administration method, and was open to patients at various therapy stages (in their first or subsequent line of therapy and at the beginning of treatment or not), with a minimum life expectancy of more than 6 months. Exclusion criteria were established to ensure investigation integrity and participant well-being, excluding patients who had solely received radiotherapy, those with clinical conditions hindering treatment adherence, individuals unable to use smartphones or computers, those with major psychopathological conditions or cognitive impairments potentially affecting participation, and patients enrolled in another clinical investigation or in a clinical trial at the time of recruitment and patients with no available information on inclusion/exclusion criteria, pathology, treatments (therapeutic treatments, changes in prescribed regimens, missed doses), and outcomes, thus enabling the evaluation of study end points. Participants had the ability to opt out of the study.

RITA SaMD

RITA SaMD (Advice Pharma Group S.r.l) was designed and developed as a class I medical device in accordance with ISO 13485 and EU MDR 2017/745 and intended to increase treatment adherence in oncohematological therapeutic regimens. The RITA SaMD system includes the clinical panel, a mobile app, and the backend. The clinical panel is a web platform managed by the health care professional on which doctors access through a dedicated medical dashboard, after authentication and authorization, to record the patient’s anamnesis and diagnosis, type of drugs, and corresponding posology, both prescribed and effectively taken during follow-up (information verified and recorded at each study visit). The mobile app allows the patient to receive and communicate information about the quality of life and treatment-related adverse events (AEs), providing support in therapy management. The RITA app is designed as a monitoring and support tool for patients with hematological malignancies, allowing clinical professionals to have a clear and complete view of the patient’s state of health. The backend is part of SaMD dedicated to exchanging communications between the RITA mobile app and the clinical panel.



This software is intended to be used by oncohematologists in health care structures (clinical panel module) and by patients in a home care setting (mobile app module). It was designed on the doctor's side as a support for the management of the oncohematological patient and, on the patient's side, as a first aid tool for the management of the most common problems, as well as an efficient and noninvasive means of communication with their doctor. The system also includes the caregiver and general practitioner in the communication group.

RITA SaMD is also designed to communicate and receive information on the quality of life and side effects, thus making the medical doctor aware of the health status of his or her patient population.

Using RITA SaMD, patients could manually notify their daily physical condition as well as disorders, vital parameters (minimum blood pressure, max blood pressure, temperature, heart rate, breath frequency, oxygen saturation, blood sugar, and body weight), and therapy (drug’s name and assumption’s time). RITA SaMD collects patient complaints with a proprietary grading system, which is modeled on Common Terminology Criteria for Adverse Events (version 5.0) [15] (Figure 1). In this way, physicians could manage and resolve mild to moderate symptoms during treatment.

XSL•FO
RenderX

Figure 1. Example screenshots of Remote Intelligence for Therapeutic Adherence (RITA) software as a medical device (SaMD). Physicians were able to access RITA SaMD directly from a computer by using a web-based interface.

The RITA SaMD database has been developed on an electronic data capture technology (ICE, Advice Pharma), compliant with the regulations for clinical data management to facilitate the study data analysis.

Study Interventions

The principal investigator granted access to RITA SaMD to each patient prospectively enrolled in the study (RITA SaMD group). The follow-up visits occurred 1, 2, and 3 months after enrollment. The follow-up visits at 3 months coincided with the end of the investigation visit. Each follow-up visit was a routine standard-of-care visit; no investigation-specific assessment was performed. During this visit, the physician paid particular attention to the patient's reported AE/serious AEs (SAEs). At each follow-up visit, the physician evaluated the self-reported delivered dose intensity.

A control group was also established; this group included patients with hematological malignancies treated in the same hospital in the past 3 years. Each patient in the RITA SaMD group was paired in a 1:1 ratio with a patient in the control group of the same gender, pathology, treatment, and of the closest possible age.

End Points

The primary end point was the average therapeutic adherence to the prescribed drug treatment, measured as at least 80% of the relative dose intensity, at month 3. Mean treatment adherence was evaluated at the end of months 1, 2, and 3; the primary end point considered the 3-month mean treatment adherence, accounting for the adherence data over 3 months of follow-up. Dose intensity was defined as the ratio of self-reported delivered dose intensity to the prescribed referenced dose intensity (expressed as a percentage) during the investigation period. Data used to calculate the therapeutic adherence were recorded in the clinical panel by the referring physicians; the therapeutic adherence calculation was performed during the analysis. The effectiveness of RITA SaMD use was evaluated by comparing the results of therapeutic adherence with the control group.

At the baseline visit, only for oral medications, routine nursing interventions were provided, as nonoral medications were administered at the clinical site (hospital) by nurses or physicians. Physicians and nurses educated patients on the intake of prescribed therapy in terms of amount and modality, basic nursing care for symptoms, and related complications. Furthermore, for each oral treatment, they verbally instructed patients on how to record information about their prescribed treatments. The physicians asked to document the number of pills assumed according to the assumption scheduling, that is, daily for daily drug assumption, every 7 days for weekly assumption at each visit. No specific questionnaire or standardized tools of recording adherence of oral medications were used, allowing each patient to self-report information as preferred. This mode of recording adherence was used because it is the standard of care in use at the clinical center and because it avoided bias of data collection of this information with respect to matched control group.

During each visit of the study, clinicians reported the therapy administration information reported by patients. The answers were recorded in the electronic case report form. Doses effectively assumed, reason for the dose reductions, percentage of dose reductions, and delays in the administration (both the number of the days and the reason of the delay) were also documented. Only physicians talked with participants during the study visits to gather data. The patients daily tracked the

XSL•FO
RenderX

self-reported delivered dose intensity and then reported these data to the physician at study visits at months 1, 2, and 3.

Secondary end points were based on comparisons between the RITA SaMD group and the control group and included the average therapeutic adherence to the prescribed drug treatment at months 1 and 2, number of emergency room (ER) visits for minor and severe complications, and the average hospital stay. Safety secondary end points included physician-reported AEs during the study visits in the RITA SaMD group vs the control group. Other safety secondary end points were only evaluated in the RITA SaMD group and included self-reported AEs and adverse device effects through RITA SaMD usage.

Patient-reported outcomes (PROs) were collected at months 1, 2, and 3 in the RITA SaMD group. Among the questionnaires used were the EQ-5D-5L descriptive system [16], the EuroQol visual analog scale [17], the Instrumental Activities of Daily Living scale [18], and the Activities of Daily Living scale [19].

Statistical Analysis

The clinical investigation planned a sample size of 112 patients (56 patients in the RITA SaMD group and 56 in the control group) to provide 80% power to detect 20% improvement in treatment adherence after 3 months of RITA SaMD usage, with a 1-sided type I error rate of .05. The enrollment of 124 patients (62 patients per group) was set as the goal to account for a dropout rate of 10%.

The primary analysis included all patients observed until the end of the investigation. The patient demographics were reported using descriptive analyses by tabulating frequencies and percentages for categorical variables and mean and median values, SD, quartiles, and extreme values for continuous variables. Continuous data between RITA SaMD and control groups were compared using a 2-sided Student *t* test, after verifying that the data were normally distributed (based on the Shapiro-Wilk test) and a 2-sided Wilcoxon's rank-sum test otherwise. For categorical data, comparisons between groups were performed using the chi-square or Fisher exact test, as appropriate.

The effectiveness of RITA SaMD was compared between the RITA SaMD group and the control group by using multivariable logistic regression models, including the following factors (chosen a priori) as the main confounders: age, gender, comorbidities, and disease severity. Adjusted odds ratios (ORs) and the corresponding 95% CIs were estimated and reported. AEs occurring during the investigation follow-up were also described.

The statistical significance limit was accepted as 5%, and the results below this value ($P<.05$) were considered statistically significant. Statistical analyses were performed using SAS system software (v. 9.4; SAS Institute Inc).

Results

Patient Characteristics

The first RITA SaMD patient signed the informed consent on July 4, 2022 (start of enrollment), and the last RITA SaMD patient signed the informed consent on September 22, 2022. A total of 62 patients were enrolled in the RITA SaMD group and 62 were, therefore, matched in the control group. Among patients in the RITA SaMD group, 5 did not complete the study: 1 patient was lost to follow-up, 3 patients died from causes not related to the investigation, and 1 patient discontinued treatment after an SAE not related to the investigational device. Thus, 119 patients were analyzed for the primary end point: 57 patients in the RITA SaMD group and 62 in the control group. Baseline patient characteristics are reported in Table 1.

Performance

Primary End Point

In the primary end point analysis, 4 patients in the RITA SaMD group had missing data at the follow-up study visits. Therefore, the analyses included 115 patients at month 3. At univariable analysis, the proportion of treatment-adherent patients, that is, ≥80% adherent to treatment, in the RITA SaMD group tended to be slightly higher than that in the control group at all time points (46/57, 82.1% vs 50/62, 80.6% at month 1, 43/57, 81.1% vs 45/62, 76.3% at month 2, and 46/57, 85.2% vs 47/62, 77% at month 3) (Table 2).

Table 2. Treatment adherence to therapy.

	RITA[a] SaMD[b] group (n=57), n (%)	Control group (n=62), n (%)	*P* value
Month 1	46 (82.1)	50 (80.6)	.84
Month 2	43 (81.1)	45 (76.3)	.53
Month 3	46 (85.2)	47 (77)	.27

[a]RITA: Remote Intelligence for Therapeutic Adherence.

[b]SaMD: software as a medical device.

n terms of treatment adherence, univariable analyses revealed that differences between the two groups were not statistically significant, even when considering the mode of treatment administration (intravenous vs oral): treatment adherence was higher in the RITA SaMD Group than in the Control Group [intravenous: 22/3, 71% vs 22/30, 73.3% at Month 1 (*P*=.84), 20/29, 69% vs 16/27, 59.2% at month 2 (*P*=.45), and 23/27, 85.1% vs 18/29, 62% at month 3 (*P*=.09); oral: 24/25, 96% vs 28/32, 87.5% at month 1 (*P*=.26), 23/24, 95.8% vs 29/32, 90.6% at month 2 (*P*=.45), and 23/26, 88.5% vs 29/32, 90.6% at month 3 (*P*=.79)].

A multivariable analysis, adjusted for potential confounders (gender, age, number of concomitant pathologies, and treatment line), was performed. At month 3, the OR of the RITA SaMD group to be adherent to treatment was 3 times higher than that of the control group (adjusted OR 3.0, 95% CI 1.0-8.8; *P*=.04) (Table 3).

XSL•FO
RenderX

Table 3. Multivariable logistic regression analysis on the risk of being adherent to therapy over 3 months.

	Adjusted odds ratio (95% CI)	*P* value
Use of RITA[a] SaMD[b] app at month 3 (yes vs no)	3.0 (1.0-8.8)	.04
Sex (female vs male)	1.4 (0.5-3.8)	.53
Age (60-79 y vs 60 y)	2.5 (0.6-10.6)	.23
Age (≥80 y vs 60 y)	2.2 (0.5-10.3)	.30
Number of concomitant pathologies (1-2 vs 0)	0.9 (0.1-5.3)	.88
Number of concomitant pathologies (≥3 vs 0)	0.5 (0.1-2.3)	.35
Number of treatment lines (≥1 vs 1)	6.8 (1.4-33.3)	.02

[a]RITA: Remote Intelligence for Therapeutic Adherence.

[b]SaMD: software as a medical device.

Secondary End Points

Treatment adherence was analyzed in 118 patients at month 1 and 112 patients at month 2. The multivariable analysis with adjustment for potential confounders showed that the differences between the two groups in terms of treatment adherence were not statistically significant in the first 2 months, with an OR of 1.7 (95% CI 0.61-4.9) at month 1 and an OR of 2.0 (95% CI 0.8-5.6) at month 2.

Regarding ER visits, there were no visits in either group for minor complications. At the end of the study period, there were 9 ER visits in the RITA SaMD group requiring hospitalization and 3 in the control group, totaling 12 ER visits for severe complications. The average hospital stay was 25.3 (SD 22.7) days in the RITA SaMD group and 8.3 (SD 2.1) days in the control group. Due to the small number of events, no statistical test was performed for these end points.

Safety (Secondary End Points)

In the RITA SaMD Group, there were 16 AEs reported by the physicians during the study visits (Table 4), most of them grade 2, while in the control group, there were 4 AEs reported (Table 5). During the study, 14 SAEs occurred, 11 of which were in the RITA SaMD group. None of the recorded AEs was related to RITA SaMD usage; therefore, there were no adverse device effects.

PROs in Questionnaires

In the RITA SaMD group, 1 patient had complete questionnaires at all time points and 17 patients had complete questionnaires at month 1 and month 2. For each questionnaire, some patients were not considered in the analysis because their assessments were done out of the specified time frame, they reported incorrect values, or data were missing (Table 7).

Discussion

Principal Findings

In this clinical investigation of patients with hematological malignancies, patients using the RITA SaMD device had a 3-fold higher risk of being adherent to treatment compared with nonusers after 3 months of use, with patients who received more than 1 line of therapy having a higher likelihood to be adherent. A high number of self-reported AEs of grade 1 was collected in the RITA SaMD group.

Given that patients with hematological malignancies often must adhere to strenuous medication regimens, manage symptoms associated with treatment, and, eventually, experience late effects associated with survivorship, they would benefit greatly from digital technology aimed at decreasing these burdens [20]. Indeed, previous research in the area of mobile health has shown that the use of information and communication platforms can increase the patient's sense of autonomy and facilitate disease management, resulting in higher quality of life and treatment adherence [21].

The results of a pragmatic pilot trial comparing the use of the digital solution Safety and Adherence to Medications and Self-Care Advice in Oncology (SAMSON) with usual care in patients with hematological malignancies who started oral cancer medicines showed that the use of SAMSON was acceptable, feasible, and helpful in improving medication adherence [22].

Another experience with an online eHealth system for patients to self-report symptoms during cancer treatment, the Electronic Patient Self-Reporting of Adverse-events: Patient Information and Advice (eRAPID) demonstrated how real-time monitoring with PROs ameliorated physical well-being in terms of symptom control measured using the Functional Assessment of Cancer Therapy Scale General Physical Well-Being subscale at 6 weeks. Clinically meaningful benefits in patients' physical well-being were observed during the first 6 and 12 weeks of treatment when it is expected to see challenges controlling side effects; symptoms stabilized by week 18, when patients reach a steady state of supportive medications or chemotherapy dose adjustments [23]. Based on these observations, the predefined period of observations of 3 months that we adopted in our study was appropriate.

In our study, the number of previous treatment lines affected the odds of being adherent to treatment, with patients who underwent more than 1 line of treatment having a much higher likelihood of adhering to the prescribed drug treatment. This is somewhat in contradiction to what was found by Seal et al [24], who described how adherence declines with increasing lines of treatment but only for oral medications and not intravenous ones. Given that the number of available oral formulations of both chemotherapy and biological therapies is rising and that patients tend to prefer oral therapy, it is worth further exploring the role of mobile health and SaMD in the factors influencing adherence, such as forgetfulness or loss of motivation [25,26].

A total of 1476 AEs were self-reported in the RITA SaMD group with SaMD usage occurrence; the majority of them (73.2%) was of grade 1, showing that app usage facilitated collection of such events and may improve the recording of low-grade AEs compared with traditional methods (namely, AE recording only during medical visits). During the study visits, 20 AEs were recorded by the physician: 16 in the RITA SaMD group and 4 in the control group. Of the collected AEs

XSL•FO
RenderX

during the study visits, 14 were considered SAEs (11 in the RITA SaMD group and 3 in the control group). None of the collected AEs was considered to be related to RITA SaMD usage. In a recent study evaluating the factors impacting medication adherence in patients with hematologic malignancies who have undergone allogeneic hematopoietic stem cell transplants, although AEs associated with medication did not directly impact treatment adherence, they increased the patients' psychological distress [27]. Interestingly, the same study reported that caregiver and clinician support as well as tools to aid medication management were factors that facilitated treatment adherence [27]. RITA SaMD can, therefore, help alleviate stress by providing a way for patients to report their ailments and feel they have clinician support.

RITA SaMD allowed the collection of PROs, including quality of life data. Although the collected data were insufficient to analyze differences in therapeutic adherence relative to self-reported changes in the questionnaires' items, the fact that RITA SaMD enables the collection of PROs is an added value and may be further explored in the future. Unrecorded PROs are still sadly familiar in the literature; any SaMD that strives to help both patients and physicians work better with the health care system cannot overlook PRO recording and the real-world data it generates [17,28].

Previous research has identified necessary features in mobile health apps and software, such as symptoms and medication tracking [29]. Patients themselves also state that features that facilitate information exchange with their clinicians are important [30]. Our results in patients with hematological malignancies illustrate how RITA SaMD can help any oncology setting to promote patients' therapeutic adherence while limiting health care resources used in patient management and contribute to optimal patient care.

Strengths and Limitations

Our clinical investigation has some limitations. This study was undertaken in a single center, which might limit the generalizability of the results. Another limitation is related to the lack of randomization and the unblinded nature of the study, potentially resulting in some biases such as selection bias, recall bias, and bias due to missing data, which were addressed using appropriate methodological approaches during the study design. To overcome the selection bias, the controls originated from the same population used to enroll patients in the intervention group: they had been treated in the same hospital and followed the same treatment protocols in the 3 years before the start of enrollment of patients in the intervention arm. In addition, control patients were identified based on the availability in the hospital's database of information on inclusion/exclusion criteria, pathology, treatments, and outcomes, thus enabling the evaluation of study end points. Finally, control patients were matched to patients of the intervention group based on the same characteristics, potentially influencing the primary outcome of the study.

As a further limitation, we acknowledge that no specific questionnaire or standardized tools of recording adherence of oral medications were used, allowing each patient to self-report information as preferred. However, this mode was used because it is the standard of care in use at the clinical center and because it avoided bias of data collection of this information with respect to the matched control group. Participants were instructed to report on all the prescribed oncological therapies; however, we could not ensure that their reporting was correct and unbiased, as no methods were in place to verify participants' self-reporting. Data cleaning verified only if the number of taken doses did not exceed the number of prescribed doses. No imputation was performed; the investigators recorded the available quantities of the drugs effectively assumed in the electronic case report form.

The short follow-up time precludes any conclusion regarding long-term adherence to treatment, despite the promising results. However, the patients considered in the study had different stages of progress in cancer therapy (patients in first-line or later lines, with therapy to be started and with therapies already started); this different composition of the sample implies that the included patients might have different "levels of therapeutic fatigue" and certainly included patients with longer exposure to cancer treatments. The high level of differentiation of the patients included in the study increased the generalization of the results of this study.

Our study also has important strengths. To our knowledge, this is the first clinical investigation showing the effectiveness of an SaMD application in improving therapeutic adherence in patients with hematological malignancies. High-quality methods were implemented, including prospective registration in a publicly available clinical trial database and the use of a control group.

Conclusion

The MargheRITA clinical investigation revealed that after 3 months of using RITA SaMD, patients with hematological malignancies were 3 times more likely to be adherent to the prescribed treatment than the control group. The use of RITA SaMD facilitated the reporting of AEs and (to a minor extent) of PROs, reinforcing the role of mobile health apps and software in optimizing patient outcomes. This initial clinical investigation has confirmed the performance and safety of RITA SaMD; future studies are needed to prove its interdisciplinary application.

Acknowledgments

Francesca Paoloni (senior biostatistician) ran the statistical analysis. Laura C. Collada Ali (senior medical writing consultant), Diana Ribeiro (medical writer), and Elisa Sala (medical writer) provided editorial assistance in preparing this article. The investigators thank Laura Galli for her support, the researchers, and the patients in this clinical investigation for their involvement.

Abstract

Background: Cataract surgery is the most frequently performed surgery worldwide, crucial for restoring sight in millions. The COVID-19 pandemic and an aging population have increased barriers to timely surgery. Missed preoperative instructions and poor adherence to postoperative care contribute to surgery cancellations, delays, and potential complications. Mobile digital health interventions could enhance adherence and reduce cancellations.

Objective: This study assessed the effectiveness of the Sharp Health Companion smartphone app, built on the CareKit health platform, compared with printed instructions. The aim was to evaluate its impact on medication adherence, surgery delays and cancellations, visual outcomes, and patient experience among older adults undergoing cataract surgery.

Methods: In this randomized controlled trial, 200 patients aged 41-87 (mean 69, SD 8.2) years were enrolled at a high-volume ophthalmology practice between December 2022 and January 2024. Most participants (145/200, 73%) were 65 years or older. Patients were randomized to group 1 (printed instructions with phone reminders, n=104) or group 2 (Sharp Health Companion app supplemented with backup printed instructions, n=96). Both groups received identical perioperative instructions and medications. Data included demographics, visual acuity, medication adherence (self-reported by paper checklist or Sharp Health Companion app care-card checklist and eye medication bottle weights), surgery cancellations and delays, and satisfaction surveys administered preoperatively, on postoperative day 1, and at 30 days.

Results: Sharp Health Companion app users had fewer same-day surgery delays (1/96, 1%) than those receiving printed instructions (10/104, 10%; *P*=.01), while cancellation rates were similar (*P*=.33). Patient-reported preparedness for surgery was high and comparable between groups on postoperative day 1 (group 1: mean 9.56, SD 1.19; group 2: 9.77, SD 0.73; *P*=.16). Preparedness for recovery at postoperative month 1 was similarly high (mean 9.92, SD 0.37 vs mean 9.85, SD 0.47; *P*=.28). At 30 days postoperatively, visual acuity improvement was similar (mean 0.14, SD 0.17 vs mean 0.11, SD 0.13 logarithm of the minimum angle of resolution; *P*=.13), and complications were rare (iritis 2/98, 2% vs 1/87,1%; cystoid macular edema 1/98, 1% vs 1/87, 1%). Self-reported medication adherence favored printed instruction users (66/68, 97% vs 47/64, 73%; *P*<.001), whereas objective antibiotic-drop adherence favored app users (mean 5.36, SD 1.17 g vs mean 5.67, SD 1.00 g; *P*=.046).

Conclusions: The Sharp Health Companion app reduced same-day surgery delays and improved patient experience while supporting objective medication adherence in predominantly older adults undergoing cataract surgery. These findings suggest mobile health interventions can enhance perioperative care and efficiency, even in populations less familiar with technology.

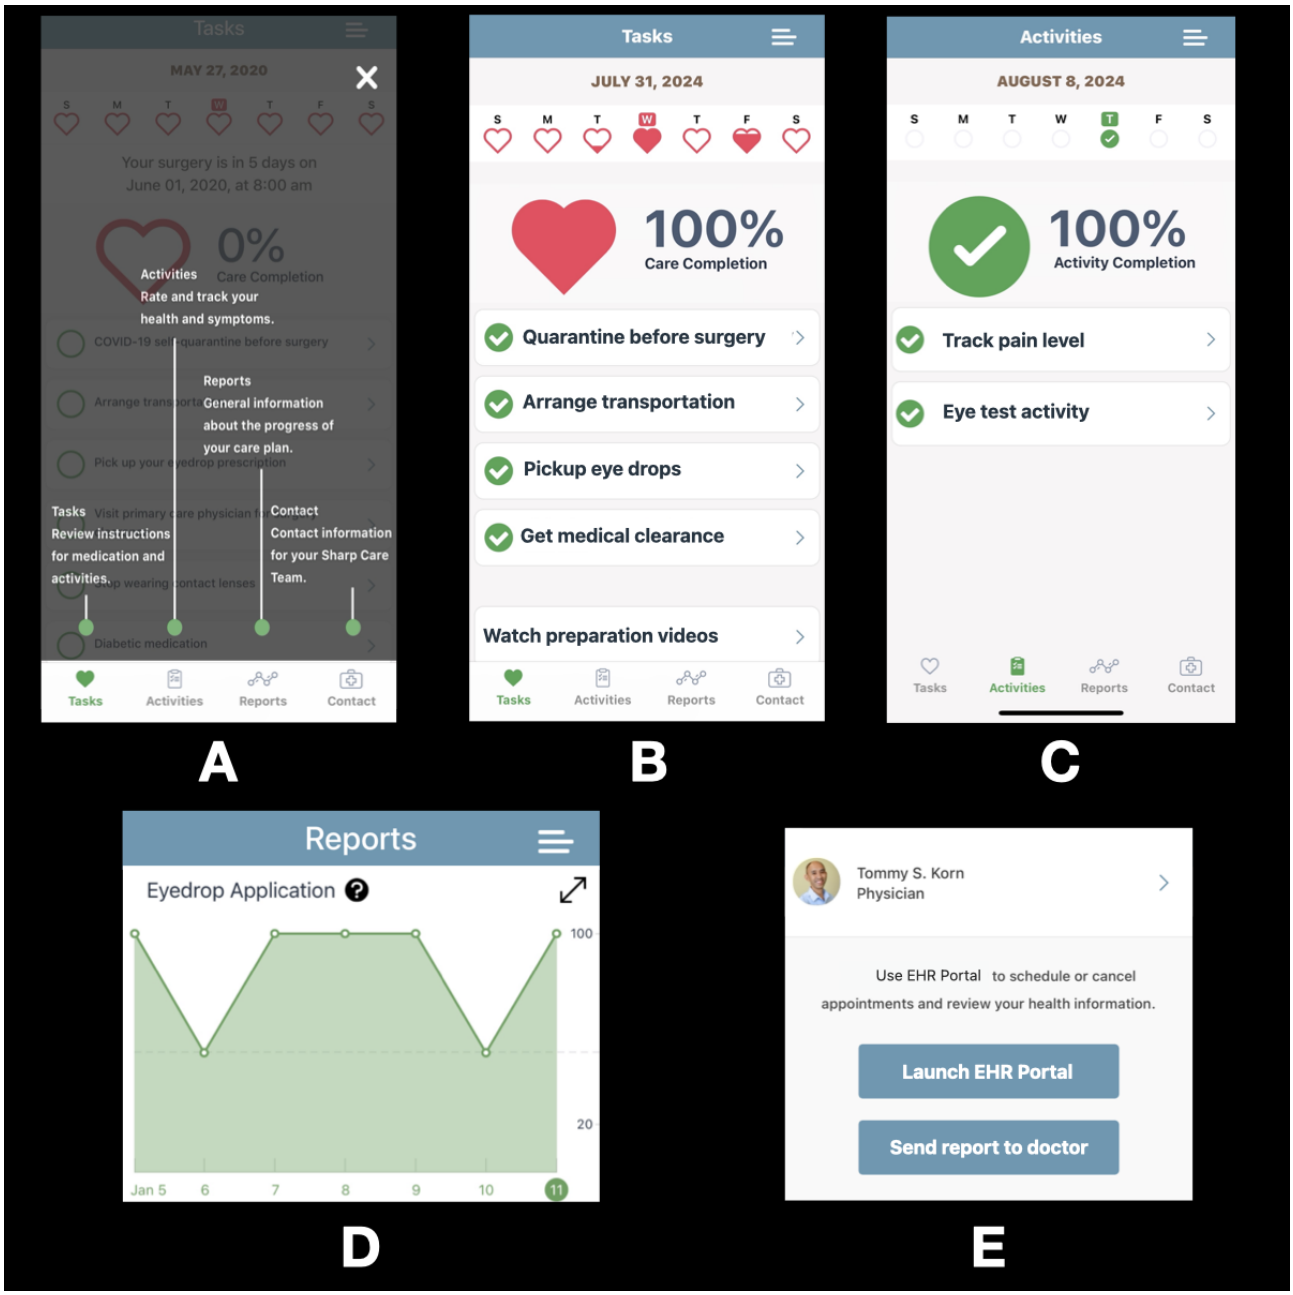
Introduction

Background

Cataracts are the leading cause of preventable blindness worldwide, affecting millions annually, significantly impacting vision, and placing a considerable strain on health care systems as the global population ages. Cataract surgery, the most commonly performed surgical procedure globally, restores eyesight and significantly improves quality of life, with over 30 million surgeries performed annually [1-3]. At Sharp HealthCare in San Diego, California, over 5000 cataract surgeries are conducted annually. However, rising global demand due to an aging population, combined with surgical backlogs exacerbated by the COVID-19 pandemic, has created substantial barriers to timely care, negatively impacting health care accessibility and patient morbidity [4-6].

Delays in surgery extend beyond administrative issues. Prolonged wait times can result in denser, more complicated cataracts that necessitate longer and technically challenging surgeries, increasing the risk of complications and resource burden [3,7]. Patient adherence to perioperative instructions, both preoperative and postoperative, is vital for optimal outcomes. Missed, forgotten, or poorly understood instructions such as dietary restrictions, medication schedules, self-quarantine requirements, and postoperative care frequently result in surgery delays and compromised surgical outcomes [8,9]. Cancellation rates increased notably during the COVID-19 pandemic, posing financial challenges to health care systems and negatively affecting patient experiences [10-12]. Adherence to postoperative medication regimens, specifically eye drops, is often problematic, potentially leading to complications and suboptimal visual recovery [13-15]. Furthermore, patients undergoing cataract surgery frequently receive intravenous sedation, which may impair memory and hinder recall of postoperative care instructions provided in the recovery room, a challenge further exacerbated by isolation during the COVID-19 pandemic [16,17].



Historically, printed instructions have guided patients through perioperative processes; however, studies indicate inconsistent adherence, with instructions frequently lost or misunderstood, leading to cancellations and adverse outcomes [18,19]. This issue intensified during the COVID-19 pandemic, highlighting significant limitations in the flexibility and responsiveness of printed materials when protocols rapidly changed [20]. Studies have also identified biases among health care providers, who may question older adults' ability to effectively use digital technology, emphasizing the importance of addressing these perceptions [21]. These barriers underscore the need to better understand the role of mobile digital health interventions to consistently support patients throughout their surgical journey.

Related Work

Recognizing the emerging trend toward increasing mobile technology adoption among seniors, Sharp HealthCare proactively explored digital health solutions prior to the COVID-19 pandemic [22]. Introduced in 2016, CareKit is an open-source platform facilitating rapid, cost-effective development of health care–focused mobile apps designed to empower patients in managing their health under clinical guidance [23]. Use of an open-source digital health platform provides critical flexibility for health care systems by creating scalable solutions that effectively address the diverse surgical needs of an ever-increasing geriatric population. Leveraging this opportunity, a multidisciplinary Sharp HealthCare team (ophthalmologists, nurses, developers, and designers) produced and piloted the Sharp Health Companion app in 2017 to support older cataract surgery patients (Figure 1 and Multimedia Appendix 1).

XSL•FO
RenderX

Figure 1. Screenshots of the Sharp Health Companion app illustrating key perioperative features: (A) interactive task overview, (B) care task completion and medication adherence checklist, (C) postoperative symptom tracking (eye pain and visual acuity), (D) patient-reported medication adherence graph, and (E) integrated care team communication portal.

Strategically, the app was initially created as a stand-alone solution that was not integrated directly with the health system's multiple electronic health record (EHR) platforms, due to an ongoing organizational transition toward a unified EHR system at the time. This approach later provided valuable flexibility, enabling straightforward future integration with the unified EHR. Initial pilot results of the Sharp Health Companion app showed improved medication adherence and reduced surgery cancellations [24].

Objective

This study examined the role of digital health tools in helping the senior population with their preparation and recovery from cataract surgery. Consistent with systematic reviews indicating that the COVID-19 pandemic accelerated seniors' adoption of digital health tools and telehealth, this study examined the capability and willingness of older patients to engage with these technologies for remote care [25]. Supported by an administrative portal, the Sharp Health Companion app allowed care teams to instantly disseminate updated surgical care instructions and rapidly evolving COVID-19 safety protocols (self-quarantine and polymerase chain reaction testing reminders) to hundreds of patients simultaneously. This real-time communication and remote monitoring capability ensured the continuity of cataract surgeries at Sharp HealthCare even as elective procedures in other specialties faced significant disruptions.

Previous research has largely focused on digital educational interventions limited to preoperative preparation, lacking comprehensive assessment throughout the full perioperative cataract surgery journey, including the day of surgery and

XSL•FO
RenderX

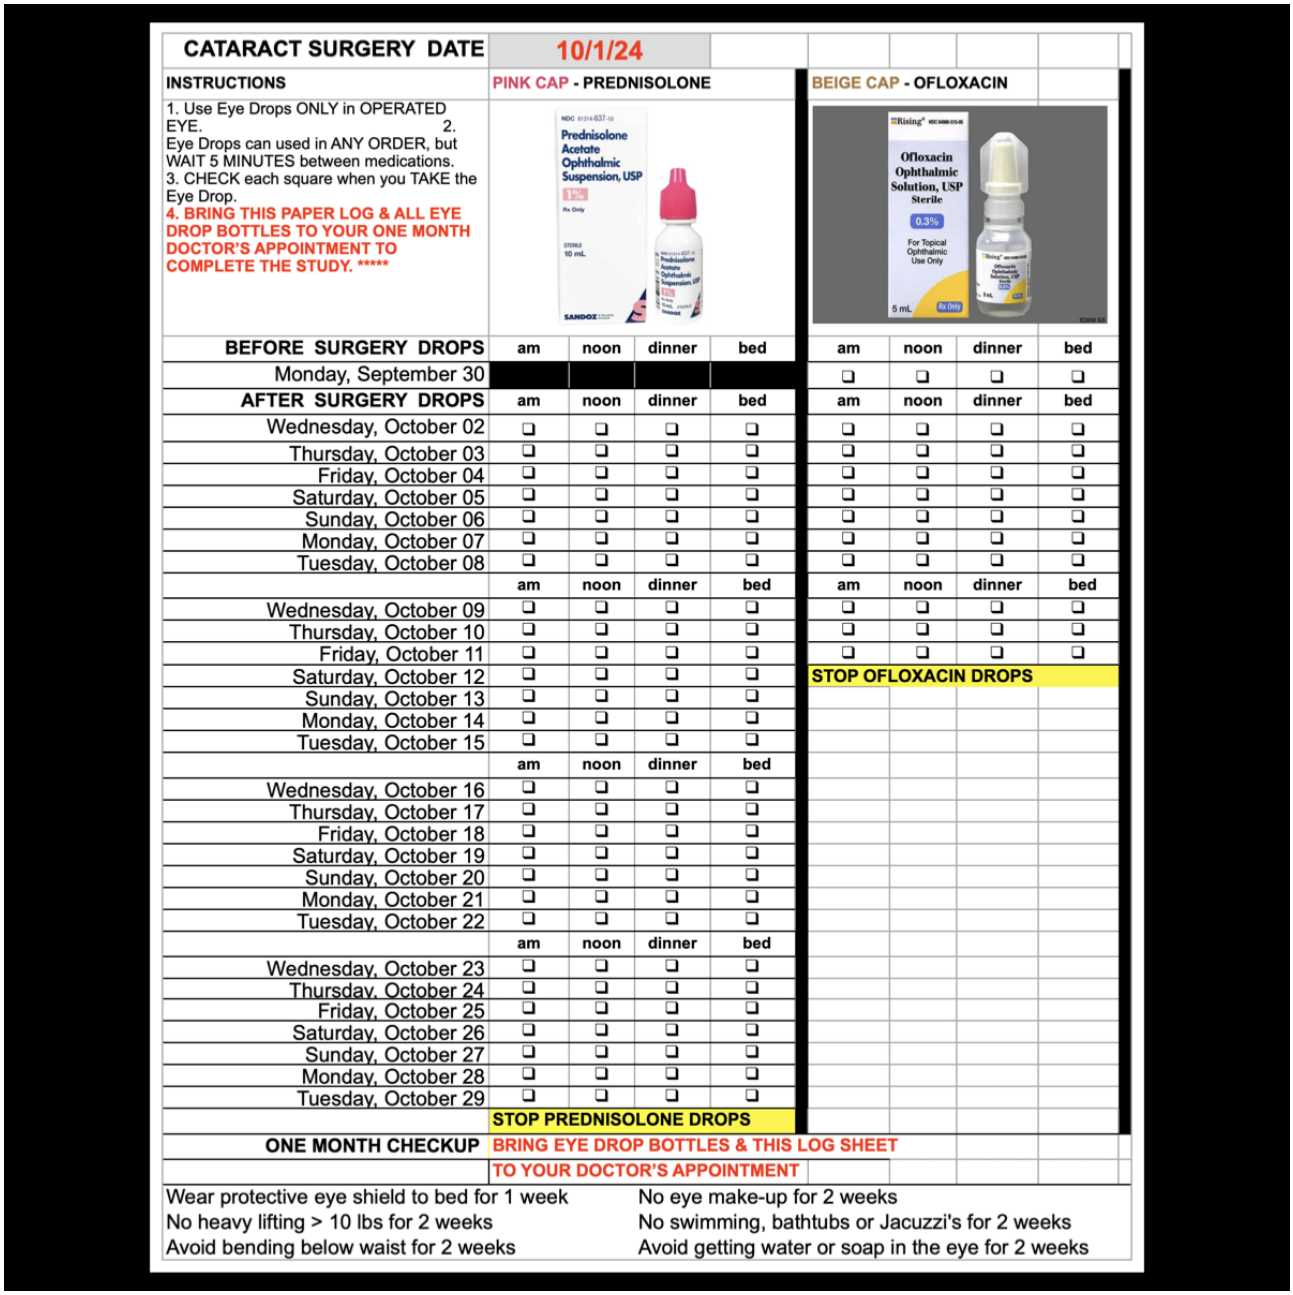
postoperative recovery phases [26,27]. The aim of this randomized controlled trial was to evaluate whether the Sharp Health Companion smartphone app could improve medication adherence and perioperative preparedness compared with traditional paper instructions among predominantly older adults undergoing cataract surgery.

Methods

Study Design and Participants

This was a prospective, randomized, masked comparative study conducted over 18 months with the objective of evaluating the effectiveness of a digital health intervention in enhancing perioperative adherence, reducing surgery cancellations, and improving patient experience and outcomes in cataract surgery. Participants were recruited from a high-volume, 2-surgeon cataract ophthalmology practice in a metropolitan setting. This study was reported in accordance with the CONSORT (Consolidated Standards of Reporting Trials) guidelines (Multimedia Appendix 2). Eligible participants were English-speaking adults aged 18 years or older, deemed appropriate surgical candidates for cataract surgery (visual symptoms such as blurred vision and/or daytime or nighttime glare not improved with refraction and prescription eyeglasses or contact lenses, best-corrected visual acuity 20/40 or worse) by their ophthalmologists. Participants were required to verbally confirm basic technical proficiency with their iPhone during the preoperative consultation prior to randomization. Clinic staff informally assessed this by asking whether participants could operate their smartphone, use secure login (eg, Face ID, Touch ID, or passcode), send SMS text messages or email, and access the institution's EHR portal app. No demonstration was required on the smartphone, ensuring patient privacy and safety. This step ensured that participants had sufficient skills to independently use the study app. Eligibility criteria included participant capacity to understand study requirements, provide informed consent, and authorize the use of their protected health information. Exclusion criteria included visual, auditory, cognitive, or motor impairments that could prevent effective use of the app. Participants with a history of prior cataract surgery were also excluded, as their previous experience would confer an advantage in navigating the perioperative process, potentially biasing the study outcome. No formal a priori power calculation was conducted. The planned target enrollment was approximately 300 participants based on feasibility estimates; however, recruitment of smartphone-capable older adults was challenging.

Randomization



Eligible participants who elected to undergo cataract surgery and consented to study participation were randomized via a digital randomization app to either group 1 or group 2. Each participant received a unique study identifier to protect personal information and ensure confidentiality. The randomization assignments were masked from the principal investigators, ophthalmologists, and research team, including ophthalmic technicians, administrative staff, and surgery schedulers, who remained masked to group allocation throughout the study.

Interventions

Both groups 1 and 2 received the standard printed instructions, and group 2 additionally used the Sharp Health Companion app; the perioperative content was identical across groups, covering preoperative, day of surgery, and postoperative care. Group 1 participants received the standard printed instructions provided at the doctor's office (Multimedia Appendix 3), which included essential presurgery protocols and a paper-based medication adherence checklist for postoperative use (Figure 2). In addition, group 1 received a 1-time automated telephone reminder the day before surgery. The brief prerecorded message confirmed the scheduled surgery date, time, and check-in location and instructions; it did not include dietary restriction instructions.

Avoid bending below waist for 2 weeks					Avoid getting water or soap in the eye for 2 weeks			

Group 2 participants used the Sharp Health Companion app, developed on the CareKit platform, which provided digital notifications for preoperative requirements such as self-quarantine and polymerase chain reaction testing (during the COVID-19 pandemic), dietary restrictions, surgery appointment details (date, time, and location), and medication reminders. The app featured interactive care checklists, educational videos, and timely eye drop medication adherence reminders delivered via iPhone and/or Apple Watch notifications (Figure 3 and Multimedia Appendix 1). Additionally, the app offered tools for visual acuity self-monitoring, easy access to care team contact information, and postoperative care instructional videos (Figure 1). As a precaution, group 2 also received the same printed instructions (Multimedia Appendix 3) as group 1, serving as a backup in the event of app malfunction or patient technical difficulties. Unlike group 1, participants in group 2 did not receive any automated telephone reminders or a printed medication adherence checklist; the app served as their primary tool for perioperative support, supplemented only by backup printed instructions.

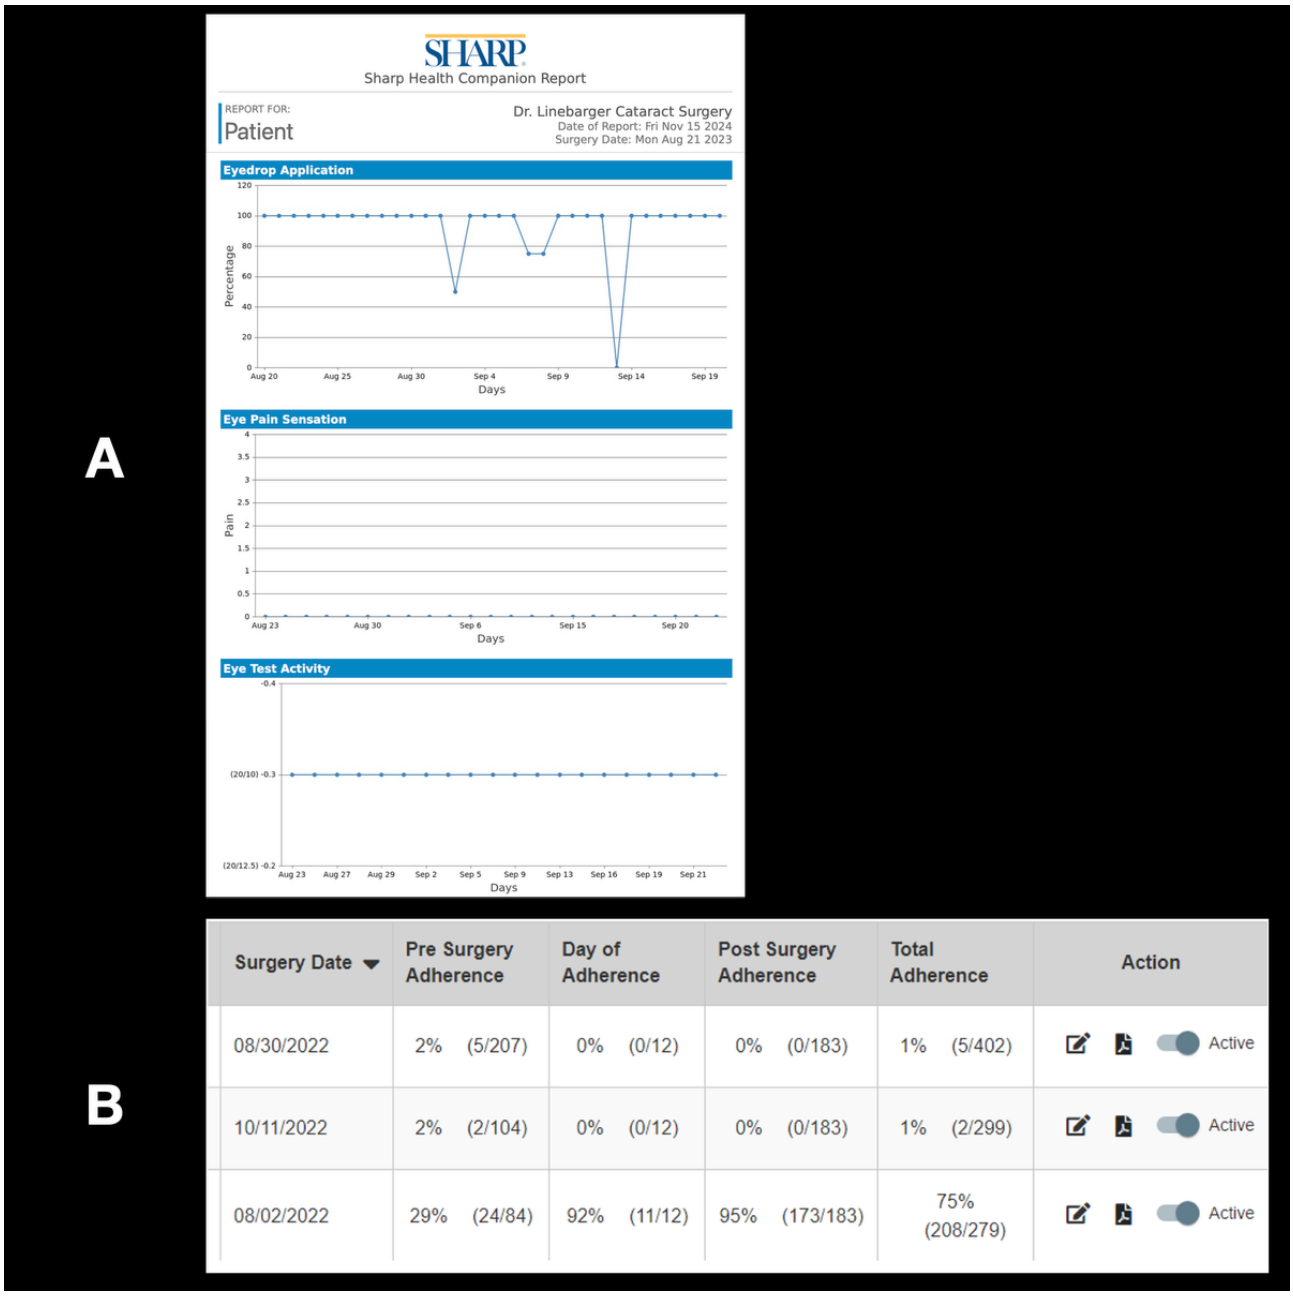
XSL•FO
RenderX

Figure 3. Sharp Health Companion app workflow: smartphone and smartwatch notifications prompt patients to administer eye drops, mark adherence tasks as complete, review instructional videos, and use an integrated 5-minute timer, tracking daily progress toward 100%.

Both groups received identical, standardized eye drop medications at no cost: 1 bottle of prednisolone acetate 1% (10 mL; Sandoz Pharmaceuticals) and 1 bottle of ofloxacin 0.3% (5 mL; Rising Pharmaceuticals), dispensed directly by the institution's pharmacy to ensure consistency.

Data Collection

Participant experience was assessed using an adapted version of the Consumer Assessment of Healthcare Providers and Systems-2.0 survey, evaluating clarity of information, preparedness, and overall surgical satisfaction (Multimedia Appendix 4). At their initial cataract consultation, eligible participants from both groups completed the survey to report demographic and technology use characteristics prior to undergoing surgery. Subjective data were collected at three time points: (1) the baseline survey (preoperative office consultation), (2) the postoperative day 1 survey, and (3) the postoperative month 1 survey (Multimedia Appendix 4). Patient confidentiality was ensured by administering surveys on a HIPAA (Health Insurance Portability and Accountability Act)-compliant, enterprise-grade SurveyMonkey platform accessed via secure health system iPads configured in kiosk mode. Participants entered only their assigned study identifier number for the surveys; no personally identifiable information was collected.



Objective medication adherence was determined by weighing antibiotic and steroid eye drop bottles returned at the 30-day postoperative visit. Returned bottles were weighed using an analytical balance (Apollo GX-603A; A&D Weighing), accurate to ±0.001 g, with all exterior packaging removed. To establish a baseline, the average weight of 5 unopened bottles of each medication was recorded: prednisolone acetate 1% (10 mL) weighed 17.223 g, and ofloxacin 0.3% (5 mL) weighed 8.466

XSL•FO
RenderX

g. Each participant was prescribed exactly 1 bottle of each medication for the postoperative course, and all medications were obtained from the same manufacturer to ensure consistency. Bottle weights at 30 days were compared to these baselines to determine the amount of medication consumed. All participants from both groups were instructed to return their bottles to precisely quantify medication usage.

In addition, group 1 participants were asked to return their printed medication adherence checklists at the final visit (Figure 2). Group 2 adherence was monitored through a HIPAA-secure, encrypted back-end portal that restricted retrospective reporting beyond 24 hours, ensuring an accurate reflection of daily medication adherence (Figure 4).

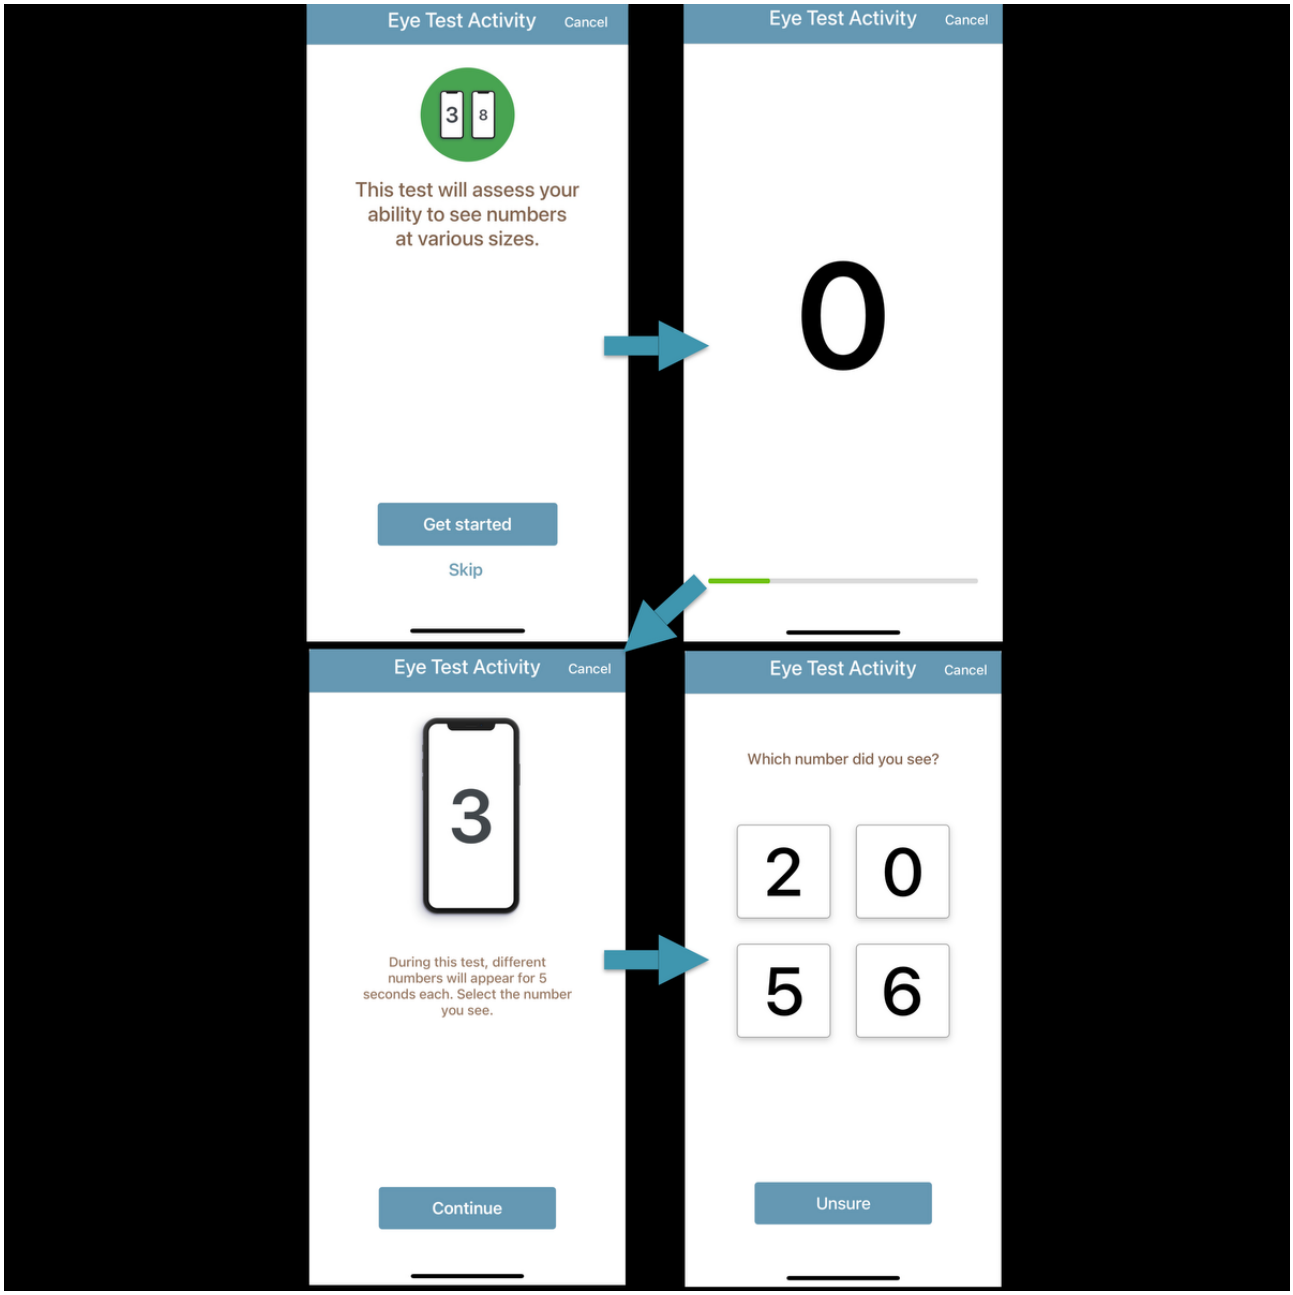


Figure 4. (A) Patient-generated report from the Sharp Health Companion app, showing self-reported medication adherence (eye drops), pain levels, and visual acuity assessments. Patients could review this summary and securely share it with their care team before and after cataract surgery. (B) Care team view from the HIPAA (Health Insurance Portability and Accountability Act)–secure back-end portal, displaying objective eye drop adherence data linked to each participant's study identifier, enabling clinicians to monitor adherence trends and provide timely support.

Visual acuity was assessed by ophthalmic technicians using an Early Treatment Diabetic Retinopathy Study chart on the logarithm of the minimum angle of resolution (logMAR) scale. Measurements were recorded preoperatively and at 1 day and 30 days postoperatively, allowing comparison of surgical effectiveness between groups. Additionally, group 2 participants had optional access to a visual acuity self-assessment activity within the Sharp Health Companion app, enabling independent self-monitoring of vision recovery following cataract surgery (Figure 5). The care team could remotely access and review data from this vision activity throughout the postoperative period if participants chose to use this optional feature.

XSL•FO
RenderX

Figure 5. Sharp Health Companion app's integrated vision self-assessment workflow, guiding patients through instructions and sequential vision testing. The ability to correctly identify smaller numbers indicates better visual acuity (eye performance).

Outcomes and Measurements

The primary outcomes included patient satisfaction with the care experience, surgery delays and cancellations, and subjective and objective medication adherence. A surgery delay was prespecified as a postponement of >2 hours with the procedure still completed on the scheduled day; a surgery cancellation was defined as a same-day procedure not performed. Reasons were abstracted from the surgery schedule and chart notes by masked staff at the conclusion of the study.

Subjective medication adherence was defined as the number of prescribed eye drop doses marked as completed divided by the total number of prescribed doses. For both groups, antibiotic drops were initiated 1 day before surgery and administered 4 times daily (4 doses preoperatively), then continued at the same frequency for 10 days postoperatively (40 doses in total). Steroid drops were initiated on the day of surgery and taken 4 times daily for 30 days (120 total doses). Group 1 participants manually checked off each completed dose on printed checklists (Figure 2), while group 2 participants recorded each administered dose digitally within the Sharp Health Companion app (Figures 3 and 4B). The app required daily reporting and did not allow retrospective entries beyond 24 hours, capturing real-time adherence data.

Study completion was a composite outcome that included cataract surgery performed, attendance at all scheduled postoperative visits, completion of all 3 surveys, and return of both antibiotic and steroid bottles at 30 days. In addition, group 1 participants were required to return the printed medication adherence checklist, while group 2 participants' medication adherence was verified through the Sharp Health Companion app portal monitored by the research team (Figure 4). Secondary

XSL•FO
RenderX

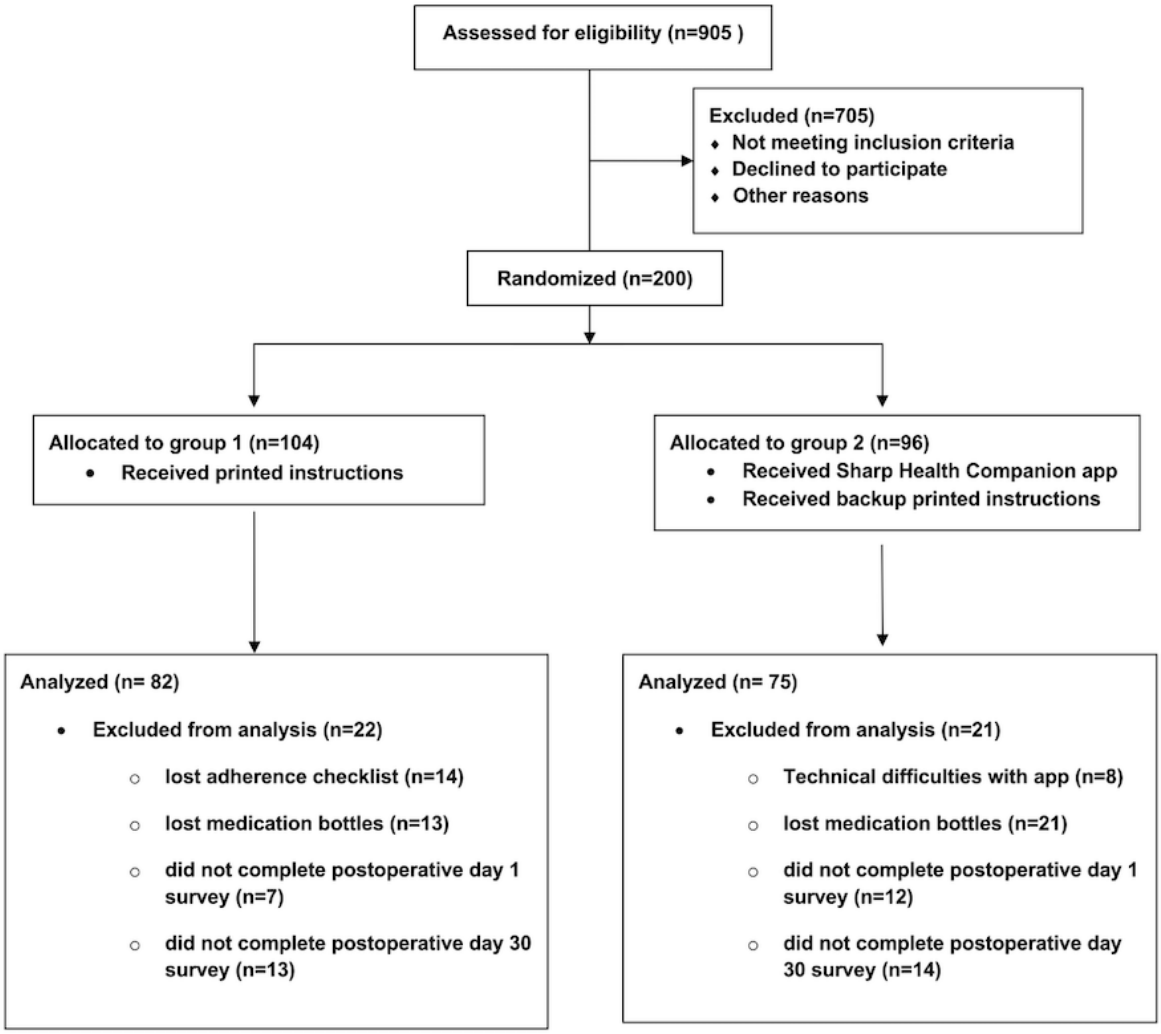
outcomes encompassed postoperative visual acuity and postsurgical complications, such as cystoid macular edema and uveitis at the final 30-day appointment after cataract surgery. Postoperative iritis was determined by slit-lamp examination, documenting anterior chamber cells/flare requiring treatment by the ophthalmologist. Cystoid macular edema was diagnosed clinically and confirmed with optical coherence tomography when indicated. The likelihood of recommending the health care organization item was measured on a 1-10 scale (1=not at all likely to 10=extremely likely).

Statistical Analysis

Statistical analyses were conducted using SPSS Statistics for Mac (version 31.0; IBM Corp). Continuous outcomes were compared with independent *t* tests, and categorical outcomes with chi-square tests. All analyses adhered to the intention-to-treat principle, with participants analyzed in the groups to which they were randomized, regardless of adherence or protocol deviations. Statistical significance was set at $P<.05$.

Ethical Considerations

This study was approved by the Sharp HealthCare Institutional Review Board (approval number 2209803) and adhered to institutional guidelines and the principles of the Declaration of Helsinki. All participants provided informed consent via DocuSign and received a digital and/or printed copy of the California Experimental Subject's Bill of Rights. Participants were informed of their ability to withdraw at any time during the study without affecting their clinical care. To protect privacy, participants were assigned unique identifiers, surveys were administered via HIPAA-compliant software (SurveyMonkey Enterprise, kiosk mode), and app data were encrypted on secure servers. Participants did not receive financial compensation. Prescribed eye medications (prednisolone acetate 1% and ofloxacin 0.3%) were provided at no cost as part of study participation.



Results

Participant Demographics

Between December 2022 and January 2024, a total of 905 patients were referred for cataract surgery, and 200 were enrolled and randomized into 2 groups: group 1 (printed instruction participants; n=104) and group 2 (Sharp Health Companion app participants; n=96; Figure 6). Participants ranged in age from 41 to 87 years, with an overall mean age of 69 (SD 8.2) years. The app group was slightly younger than the printed instruction group (mean 67.1, SD 8.7 years vs mean 69.9, SD 7.8 years; $P=.02$). Most participants were aged ≥65 years (145/200, 73%), with no difference between groups ($P=.25$). The majority were female (140/200, 70%), and gender distribution did not differ between groups ($P=.50$). Racial and ethnic distributions were also comparable ($P=.39$). Nearly all participants reported Wi-Fi access (185/200, 93%), slightly higher in the printed instruction group (100/104, 96% vs 85/96, 89%; $P=.04$). Comfort with smartphone apps (1=least comfortable to 5=most comfortable) was higher among app participants (mean 3.67, SD 0.68 vs mean 3.36, SD 0.82; $P<.001$). Smartwatch ownership was more common among app users (55/96, 57% vs 38/104, 37%; $P=.003$). Prior experience with smartphone EHR portal apps was similar between groups ($P=.15$; Table 1).

Preparedness and Clarity of Instructions: Postoperative Day 1 Survey

Participants completed an in-office survey 1 day after cataract surgery to assess preparedness, clarity, and usability of preoperative instructions (Table 2 and Multimedia Appendix 4). Most participants reviewed their instructions within 2-7 days before surgery (100/181, 55%), with no significant difference in timing between groups (*P*=.21). Among app participants, 56% (47/84) used both the Sharp Health Companion app and backup printed instructions before surgery.

[d]Pearson chi-square test.

[e]Statistically significant (P<.05).

[f]Independent t test.

Regarding clarity of instructions, response distributions ("yes, definitely," "yes, somewhat," or "no") did not differ significantly between groups (P=.63). Most participants rated their instructions as "definitely easy to understand," with slightly higher ratings among app users compared with printed instruction users (83/84, 99% vs 86/96, 90%; P=.02). Preparedness ratings on a 1-10 scale (1=least prepared to 10=most prepared) were high and similar in both groups (mean 9.56, SD 1.19 vs mean 9.77, SD 0.73). Surgery experience ratings were likewise high (P=.32).

Among app users, 63% (53/84) reported using backup printed instructions to some extent, while the minority 37% (31/84) did not need them. When comparing the Sharp Health Companion app to other medical apps, 54% (44/84) rated it as easier and more valuable, and 46% (37/84) as about as easy and valuable; none rated it as less valuable. Most app participants (68/84, 87%) indicated they would "definitely" use the Sharp Health Companion app for future medical or surgical procedures, and the remainder (10/84, 13%) responded, "yes, somewhat." Finally, a small number of participants contacted the surgeon's office for clarification about surgery logistics, with no significant difference between groups (9/97, 9% vs 6/84, 7%; P=.62).

Cataract Surgery Delays and Cancellations

Surgery delays were significantly more frequent among participants receiving printed instructions than those using the Sharp Health Companion app (10/104, 10% vs 1/96, 1%; P=.01). Delays were defined as procedures postponed by >2 hours but completed on the scheduled day, most commonly due to participants arriving at the incorrect surgery location or time. Surgery cancellations occurred in 15 participants overall, with similar proportions in the printed instruction and app groups (6/104, 6% vs 9/96, 9%; P=.33). The primary reasons included acute illness, participant-initiated withdrawal, and financial or insurance issues (Table 3).

Table 3. Cataract surgery delays and cancellations (n=200).

Outcome measure	Group 1 (printed instructions; n=104), n (%)	Group 2 (Sharp Health Companion app; n=96), n (%)	P value
Delayed surgery	10 (10)	1 (1)	.01[a,b]
Missed dietary restrictions	2 (2)	0 (0)	
Wrong location/time	6 (6)	1 (1)	
Other reasons	2 (2)	0 (0)	
Canceled surgery	6 (6)	9 (9)	.33[c]
Illness	3 (3)	2 (2)	
Missed dietary restrictions	1 (1)	0 (0)	
Wrong location/time	1 (1)	0 (0)	
Self-canceled	1 (1)	5 (5)	
Insurance/financial reasons	0 (0)	1 (1)	
Not a candidate	0 (0)	1 (1)

Study Completion and Adherence to Protocol

Study completion rates were high and comparable between groups (82/104, 79% vs 75/96, 78%). Among app users, engagement with specific features varied. Most participants used both the Sharp Health Companion app and backup printed instructions (42/75, 56%), while smaller subsets used the app alone (24/75, 32%) or printed instructions only (9/75, 12%). About half completed the vision self-assessment (38/75, 51%) and eye pain self-assessment (37/75, 49%) activities within the app. Loss of medication bottles was slightly higher in the app group (21/75, 28%) compared to the printed instruction group (13/82, 16%) but the difference was not statistically significant (P=.07). Some participants (8/75, 11%) in the app group reported technical issues, such as forgotten login credentials or intermittent software errors that interfered with adherence tracking. Overall, adherence and study completion were comparable between groups, indicating that the addition of the Sharp Health Companion app did not adversely affect protocol compliance (Table 4).

Lost medication bottles	13 (16)	21(28)	.07[a]
Technical difficulties with the app	N/A	8 (11)	.90[a]

[a]Chi-square test.

[b]N/A indicates response options that were not applicable to a group (eg, group 1 did not have access to the Sharp Health Companion app).

Preparedness and Clarity of Instructions: Postoperative Month 1 Survey

At the month 1 follow-up visit, nearly all participants in both groups reported receiving complete and clear preoperative information (Table 5 and Multimedia Appendix 4). Almost all participants indicated that someone in the surgeon's office provided all the information they needed about their eye surgery, and nearly all rated the preoperative instructions as easy to understand. Mean preparedness ratings before and after surgery were uniformly high and comparable between groups, and no statistically significant differences were noted. All participants in both groups reported clear recovery instructions, and overall surgery experience ratings remained similar. Among app users, the majority (49/82, 60%) relied solely on the Sharp Health Companion app, while the remainder also used backup printed instructions. Most app users rated the app as easier or more valuable than other medical apps (49/82, 60%) and nearly all indicated they would use a similar app again for other surgeries or medical procedures (78/82, 95%). Participants from both groups rated their likelihood of recommending Sharp HealthCare to a friend or colleague based on their experience highly (mean 9.83, SD 0.59 vs mean 9.74, SD 0.91), with no significant difference between groups (*P*=.43).

Clinical Outcomes Following Cataract Surgery: Month 1 Visit

Clinical outcome data were available for 185 participants, including 98 in the printed instruction group and 87 in the app group. This accounted for 15 participants whose surgeries were canceled (6 in the printed instruction group and 9 in the app group). At the month 1 postoperative visit, mean visual acuity (logMAR) was comparable between the printed instruction and app groups (mean 0.14, SD 0.17 vs mean 0.11, SD 0.13; *P*=.13; Table 6). Postoperative inflammation and macular edema were uncommon, with no significant differences noted. Iritis occurred in 2/98 (2%) in the printed instruction group and 1/87 (1%) in the app group, and cystoid macular edema occurred in 1/98 (1%) and 1/87 (1%), respectively. No other postoperative complications were identified.

Table 6. Clinical outcomes following cataract surgery: month 1 visit (n=185).

Outcome Measure	Group 1 (printed instructions; n=98)	Group 2 (Sharp Health Companion app; n=87)	*P* value
Visual acuity (ETDRS[a]; logMAR[b]), mean (SD)	0.14 (0.17)	0.11 (0.13)	.13[c]
Postoperative iritis incidence, n (%)	2 (2)	1 (1)	>.99[d]
Postoperative cystoid macular edema incidence, n (%)	1 (1)	1 (1)	>.99[d]

[b]logMAR: logarithm of the minimum angle of resolution.

[c]Independent *t* test.

[d]Fisher exact test.

Eye Medication Adherence: Patient-Reported vs Objective Measures

Medication adherence data were available for 132 participants, including 68 in the printed instruction group and 64 in the app group. This total reflects participants who returned their medication bottles and completed adherence documentation; others were excluded because printed checklists were misplaced or bottles were lost or not returned at the end of the study.

Self-reported medication adherence was significantly higher among participants using printed checklists than those using the app (66/68, 97% vs 47/64, 73%; *P*<.001; Table 7). Objective medication adherence, assessed by returned eye medication bottle weights, showed broadly similar findings between groups. Residual antibiotic bottle weights were higher in the printed instruction group (mean 5.67, SD 1.00 g vs mean 5.36, SD 1.17 g; *P*=.046), while steroid bottle weights were comparable (mean 11.80, SD 2.00 g vs mean 11.39, SD 1.95 g; *P*=.14).

Table 7. Eye medication adherence: self-reported vs objective measures (n=132).

Measure	Group 1 (printed instructions; n=68)	Group 2 (Sharp Health Companion app; n=64)	*P* value
Self-reported eye drop medication adherence, mean (%)[a]	97	73	<.001[b,c]
Final antibiotic bottle weight (g), mean (SD)	5.67 (1.00)	5.36 (1.17)	.05[a,b]
Final steroid bottle weight (g), mean (SD)	11.80 (2.00)	11.39 (1.95)	.14[a]

[a]Adherence represents the mean percentage of prescribed doses completed per participant (161 total doses per patient in both groups).

[b]Independent *t* test.

[c]Statistically significant (*P*<.05).

Discussion

Principal Findings

This randomized controlled trial found that use of the Sharp Health Companion smartphone app improved medication adherence, increased patient confidence, and reduced cataract surgery delays compared with printed instructions.

This study uniquely evaluated how a perioperative app during the COVID-19 pandemic could help predominantly older patients receive seamless care, highlighting digital health's potential to sustain patient engagement during evolving health care conditions. A key finding was the significantly lower rate of surgery delays in the app group 2 compared with the printed group 1, suggesting improved patient readiness and adherence to preoperative instructions. Patient noncompliance with preoperative guidelines, such as dietary restrictions, commonly

XSL•FO
RenderX

leads to surgery cancellations and delays, incurring significant hospital and societal costs [12]. The app's automated reminders and checklists likely mitigated these oversights, aligning with previous findings from a spine surgery mobile app study where app interventions reduced delays and cancellations [28].

Similar postoperative visual acuity improvements were observed in both groups, underscoring that both digital and printed instruction–based methods can support successful cataract surgery outcomes. The comparable, low rates of complications (postoperative iritis and cystoid macular edema) in both groups suggest that the app did not increase the risk of adverse outcomes. These data support using an app alongside printed instructions in routine cataract surgery care.

Comparison With Prior Work

This study is among the first randomized, controlled trials evaluating a smartphone app vs standard printed instructions specifically in ophthalmology and cataract surgery. A recent European study also explored an app-based perioperative approach with cataract surgery but focused on the app's user-friendliness and patient acceptance of digital education [27]. In contrast, this study comprehensively evaluated the full perioperative experience of predominantly older adults undergoing cataract surgery, incorporating subjective patient experiences, objective adherence measures, clinical outcomes, and relevant health system metrics.

Prior studies across various surgical domains, including neurosurgery, general surgery, and orthopedic surgery, have consistently demonstrated improvements in adherence, patient satisfaction, and reductions in cancellations and unplanned visits with digital interventions [29,30]. This study's focused approach on older patients undergoing cataract surgery addresses a critical gap in digital health research, complementing broader telehealth adoption trends during the COVID-19 pandemic [31].

Adherence and Patient Behavior

We observed notable differences in medication adherence: participants using printed checklists reported higher adherence compared with app users, yet objective measures (eye drop bottle weights) indicated superior adherence among app users. This discrepancy likely reflects a combination of factors. Patients often overreport adherence on printed checklists due to social desirability and recall biases [32], whereas the app required real-time tracking and prevented retrospective entries, potentially capturing a more accurate representation of daily use. Bottle weights also reflect unavoidable variability, such as wastage from repeated instillation attempts, differences in patient technique, or clinical variation in dosing intensity (eg, additional drops prescribed for postoperative inflammation). Multiple studies in ophthalmology and other surgical disciplines have similarly demonstrated that self-reported adherence overestimates true use compared with objective electronic monitoring [33-35]. Importantly, improved objective adherence did not negatively affect clinical outcomes, as visual acuity improvements and postoperative complication rates were comparable between groups, confirming the effectiveness and safety of digital perioperative guidance.

Patient Experience and Acceptability

Patient experience is a critical aspect of perioperative care, and the Sharp Health Companion app received overwhelmingly positive feedback from participants. Despite advanced age, many app users reported ease of use, comfort after initial onboarding, and appreciation for automatic reminders on eye drops and fasting. Many participants noted feeling calmer and more prepared, highlighting the app's psychological benefits. Our findings align with broader evidence from similar studies where predominantly older adults demonstrated high acceptance and usability of perioperative apps [36]. Importantly, tailored digital tools have shown value for patients with limited health literacy, providing standardized, clear instructions that may surpass traditional printed instruction methods in effectiveness [37-39].

Limitations

This study had several limitations. The sample was limited to English-speaking iPhone users. Although an Android version of the Sharp Health Companion app was initially developed, extensive software and hardware fragmentation among Android devices resulted in persistent technical issues and inconsistent user experiences. To ensure a uniform and reliable user experience and accurately address the study objectives, we chose to exclusively enroll iPhone users in this prospective study. Limiting the study to English speakers may also restrict generalizability, and future research should test multilingual app versions to improve accessibility in more diverse populations. Consequently, this potentially limited the generalizability of our findings across diverse patient populations and other smartphone platforms. Additionally, this study was conducted at a single, high-volume urban ophthalmology practice, and our findings may not reflect experiences in rural or lower-income settings that can affect mobile health adoption [40].

There was an unexpected statistically significant difference in participants' age, comfort with smartphone apps between groups, and usage of smartwatches, raising the possibility of inadvertent selection bias or unequal participant enthusiasm for digital technology despite randomization. Future studies could address this limitation through stratified randomization based on participants' baseline technology comfort.

Additionally, significantly more participants in group 2 regularly used smartwatches, potentially providing an inherent advantage through increased familiarity with digital notifications and convenient adherence prompts that may have influenced study outcomes. Additionally, group 2 (app users) received backup printed instructions for safety reasons, potentially conferring an advantage by providing supplementary resources unavailable to group 1 participants.

The predominance of female participants, although consistent with broader trends in digital health research among predominantly older adults reflecting higher health care engagement among women, may limit the generalizability of results to a broader population [41].

The study excluded patients with prior cataract surgeries, focusing only on first-time cataract surgery patients. This control

XSL•FO
RenderX

helped standardize patient experience and outcomes, but may limit the generalizability of findings to patients with previous surgical experience. All participants were provided with free eye medications, potentially influencing adherence rates positively compared with typical real-world experiences where medication costs could impact adherence.

A notable proportion of participants in both groups did not complete all study procedures, resulting in missing adherence data due to lost medication bottles or incomplete postoperative surveys from missed follow-up appointments. This finding is consistent with inherent challenges noted in previous clinical studies involving predominantly older adults, who may experience difficulties with medication management, memory, or adherence documentation [39].

Furthermore, subjective survey responses regarding patient experience and satisfaction are vulnerable to social desirability and recall bias, potentially leading to inflated satisfaction or adherence reporting. Although we used deidentified objective adherence measures (medication bottle weights), the complete elimination of subjective bias in self-report metrics was not feasible.

Finally, the follow-up duration of this study was limited to immediate postoperative outcomes (up to 30 days), and we did not evaluate long-term medication adherence or sustained engagement with the app beyond the initial postoperative period. Future research should include longer-term assessments to fully capture sustained benefits and adherence behaviors.

Conclusions and Future Directions

Cataract surgery is the most commonly performed surgical procedure globally. With an aging population, demand for this essential vision-restoring surgery continues to rise. This study demonstrates that the Sharp Health Companion app is a feasible, acceptable, and effective mobile digital tool to support patients, predominantly older adults, throughout their cataract surgery journey. As one of the first randomized controlled trials in ophthalmology directly comparing a digital health intervention against traditional printed instructions, it contributes robust evidence that digital platforms can safely and effectively enhance geriatric surgical care. Specifically, our study suggests the role of digital apps in geriatric surgical care may help reduce delays, increase medication adherence, and enhance patient experience.

Leveraging the CareKit open-source platform enabled rapid, cost-effective development of the Sharp Health Companion app, progressing from concept to minimum-viable product in just 8 months, substantially quicker than typical app development cycles. This accelerated timeline proved especially beneficial when the COVID-19 pandemic unexpectedly emerged, allowing our institution to swiftly adapt perioperative care protocols and continue elective cataract surgeries even as other elective procedures faced significant disruption. Our study also demonstrates older patients' capability and willingness to adopt digital health tools, emphasizing the importance of agile digital health tools in rapidly evolving and challenging health care scenarios.

Our findings suggest that perioperative app companions for older adults could soon become standard tools across various surgical disciplines. Future research should expand these digital care apps to broader populations supporting multiple languages and explore integration with advanced technologies, including artificial intelligence, spatial computing, and cost-effective electronic medication monitoring. Patient-centered digital solutions hold promise for optimizing outcomes, enhancing care experiences, supporting clinician efficiency, and improving overall health system performance.

Acknowledgments

The authors thank the Sharp HealthCare Foundation for supporting this study. We are also grateful to colleagues across Sharp HealthCare and Sharp Rees-Stealy Medical Group, as well as developers from Thread Research, Mobile Programming, and Apple for their technical input. We also thank Kelly J Ko for his counsel. Finally, we thank the patients from the San Diego community whose participation made this study possible.

Generative artificial intelligence tools (Microsoft 365 Copilot) were used for minor language editing, specifically word count, minor grammar corrections, and formatting consistency. All substantive study content, analysis, interpretation, final edits, and approval were performed by the authors.

Data Availability

The datasets generated and analyzed during this study are not publicly available due to patient privacy and Health Insurance Portability and Accountability Act regulations. Deidentified summary data supporting the findings of this study are available from the corresponding author upon reasonable request with approval by the Sharp HealthCare Institutional Review Board.

Abstract

Background: Sustained engagement is a central challenge for digital therapeutics. In routine operations, inactivity-triggered supports (eg, SMS reminders and telephone follow-up) are used to nudge patients back after lapses, but evidence in digital erectile dysfunction (ED) therapy is limited.

Objective: This study aims to evaluate whether low-threshold support in the form of SMS reminders and structured telephone outreach, both triggered after 7 or more days of inactivity, improves engagement and patient-centered outcomes in a certified German digital health application (Digitale Gesundheitsanwendung [DiGA]) for ED.

Methods: In a pragmatic, calendar-time (rotating-week) quasi-experimental allocation, 470 men with physician-diagnosed ED entered 1 of 3 groups: control (no additional support), SMS (automated reminders), or call (structured telephone contact). Analyses were conducted as assigned. The primary end point was active weeks (number of weeks with ≥1 completed session) during the 12-week study period, derived from app logs with built-in completion rules. A prespecified mechanistic end point captured any reactivation after an inactive week (yes or no). Secondary end points included Clinical Global Impression-Improvement (CGI-I), week-12 5-item International Index of Erectile Function (IIEF-5), intention to continue therapy, and documented continuation ("conversion") within 3 months. Covariate-adjusted models included age, BMI, smoking, and baseline pharmacotherapy; calendar-week sensitivity was planned.

Results: Participants completed a mean of 6.34 (SD 4.44) active weeks. Unadjusted means favored both support groups (control: 5.79; call: 6.57; SMS: 6.80); the prespecified SMS-vs-control contrast was nominally significant (P=.049, small effect). In covariate-adjusted models, planned pairwise contrasts were not significant. In a calendar-adjusted sensitivity model, the omnibus group term reached significance, but adjusted pairwise contrasts remained nonsignificant; stricter adherence definitions led to the same overall inference. By contrast, any reactivation after inactivity was more common in the intervention groups than in the control group (omnibus chi-square test P=.008), consistent with the intended mechanism of breaking inactivity spells. The call group showed a higher intention to continue therapy (49% vs 38% in the control arm; P=.04); conversion did not differ. CGI-I and IIEF-5 showed no arm-wise differences over 12 weeks; follow-up availability was limited in routine care.

Conclusions: Inactivity-triggered supports in a real-world ED DiGA reactivated use after lapses, and telephone outreach increased motivation to continue, while effects on weekly dose were small and not significant after adjustment, and clinical outcomes did not differ over 12 weeks. Programs may consider a stepped approach (SMS first-line nudge and call as escalation) and target system bottlenecks that decouple motivation from realized continuation. Further work should test longer-term outcomes, targeting, and generalizability.

KEYWORDS

adherence; behavioral therapy; DiGA; digital health; digital therapy; Digitale Gesundheitsanwendung; erectile dysfunction; mHealth; mobile health; nudging; SMS; telephone intervention

Introduction

The increasing digitization of the health care system, particularly through the Digital Healthcare Act (Digitale-Versorgung-Gesetz [DVG]), has allowed physicians in Germany to prescribe digital health applications (Digitale Gesundheitsanwendung [DiGA]) since December 2019. These applications offer innovative approaches to improving patient care and are specifically designed to close outpatient care gaps and increase treatment quality.

A crucial factor for the success of digital therapy approaches is therapy adherence, defined as the extent to which patients consistently and sustainably follow medical and therapeutic recommendations [1]. In the case of erectile dysfunction (ED), a condition involving both physical and psychological components, continuous engagement with the therapeutic content is essential for successful treatment outcomes [2,3]. In practice, however, many patients discontinue digital therapies prematurely, often due to a lack of motivation, insufficient personal support, or technical barriers [4].

To address this challenge, nudging strategies, such as automated SMS reminders or personal telephone calls, are gaining increasing attention. Studies have shown their effectiveness in enhancing adherence in chronic conditions [5-8]. Nevertheless, there is still a lack of studies specifically investigating the benefits of such interventions in the context of digital ED therapy.

The DiGA Kranus Edera, which has been permanently listed in the DiGA directory since 2023 [9] based on its randomized controlled trial results, follows a holistic treatment approach that combines physical exercises with psychological modules in a mobile app [10,11]. Building on this foundation, the present retrospective evaluation investigates whether digital support measures, such as SMS reminders or telephone calls, can improve adherence and motivation during the course of this digital therapy.

This study aims to analyze the effect of such strategies on therapy adherence (primary end point: active training weeks) as well as on other patient-related outcomes (eg, Clinical Global Impression-Improvement [CGI-I], continuation intent, and actual therapy continuation). Furthermore, the study investigates whether certain sociodemographic or clinical factors, such as age, BMI, or preexisting conditions, affect adherence. The findings aim to contribute to the optimization of digital therapy concepts and more personalized patient engagement in the digital health care setting [12].

Methods

Ethical Considerations

This retrospective real-world analysis of the Kranus Edera digital therapy program was reviewed by the Charité - Universitätsmedizin Berlin Ethics Committee (Ethikausschuss am Campus Benjamin Franklin) and approved under protocol EA4/104/24 (committee vote: December 9, 2024; confirmation letter: December 16, 2024). The study analyzed secondary, deidentified usage data exported from routine operations; no research procedures were conducted by the academic team. At program enrollment, users agreed to the provider's terms and privacy policy permitting the use of deidentified data for quality improvement and research. The ethics committee confirmed that the original consent covers this secondary analysis; therefore, no additional consent was required. Participants could opt out of SMS or telephone contact during routine operations; such preferences were honored by the provider. Before transfer to the academic team, all records were deidentified (ie, no names, telephone numbers, or other direct identifiers). Operational messaging and call logs containing identifiers were not shared. Analyses were conducted under a data use arrangement compliant with the General Data Protection Regulation (GDPR) and institutional policies; only deidentified aggregate data are reported. No compensation was provided for this retrospective secondary analysis; participants received standard program communications (SMS messages and calls) as part of routine care.

Study Design

This evaluation is a quasi-experimental retrospective cohort analysis based on anonymized usage data from the Kranus Edera DiGA, exported from the provider's internal database. Data from patients who began therapy between May 28, 2023, and October 20, 2023, were included; the observation window covered 12 weeks from therapy initiation. The support strategies (telephone calls and SMS reminders) were implemented by the provider as part of routine operations; the academic team did not design or assign these interventions and analyzed their real-world use post hoc. The aim was to compare adherence and clinical outcomes among the call, SMS, and control (no additional support) groups. The study protocol was approved by the Ethics Committee of Charité - Universitätsmedizin Berlin (EA4/104/24; Multimedia Appendix 1). All data were fully anonymized prior to analysis and processed in accordance with the Declaration of Helsinki and the GDPR.

Hypotheses

Based on existing literature on digital health interventions and adherence behavior, the following hypotheses were prespecified for this study:

- Patients receiving support interventions (telephone calls or SMS reminders) will demonstrate significantly higher therapy adherence, operationalized as the number of active weeks during the 12-week program, compared with patients in the control group without support.
- Patients in the support groups will report higher subjective treatment satisfaction, measured using the CGI-I scale, and greater improvement in erectile function, measured by the

XSL•FO
RenderX

change in 5-item International Index of Erectile Function (IIEF-5) scores, compared with patients in the control group.
- Patients receiving support interventions will show a higher intention to continue the therapy after the initial 12-week program compared with patients without support.
- Higher therapy adherence (number of active weeks) will be positively associated with subjective treatment improvement (CGI-I) and real-world therapy continuation behavior (conversion rate).

Group Assignment

Participants were allocated at enrollment by the provider's prespecified weekly rotation used in routine operations. The unit of allocation was the calendar week (no individual randomization by the research team):

- Week W: telephone support
- Week W+1: SMS support
- Week W+2: usual care or control (no proactive outreach)
- Week W+3: telephone support, and the sequence repeats

Assignment depended only on each participant's enrollment date (therapy initiation) and was independent of individual characteristics. This pragmatic scheme minimized operational burden and contamination between groups while creating quasi-experimental variation. Because assignment was tied to calendar time, primary analyses adjusted for prespecified baseline covariates and were complemented by calendar-adjusted sensitivity models that included a standardized enrollment-time covariate. We also examined robustness to calendar time using alternative time codings and exploratory interaction tests. All analyses were conducted as assigned (intention-to-treat).

Clinical Eligibility

To align the cohort with the product's intended population in routine care, we included:

- Male adults (aged ≥18 years) with physician-confirmed ED
- Baseline IIEF-5 at therapy initiation with an IIEF-5 score of ≤21 (at least mild ED)
- First-time Kranus Edera use within the study window (May 28, 2023-October 20, 2023)

Definition and rationale: the IIEF-5 is a validated questionnaire assessing erectile function (total score: 5-25, higher scores indicate better erectile function; 4-week recall period). A cutoff score of ≤21 corresponds to at least mild ED (no ED, 22-25; mild, 17-21; mild-to-moderate, 12-16; moderate, 8-11; severe, 5-7) and is commonly used to identify clinically relevant ED.

Analytic Exclusions

From the eligible pool, we excluded:

- Repeat users within the study window
- Records lacking the minimum variables required for analysis (eg, all weekly usage data missing)

Comorbidities (eg, hypertension and diabetes) were not exclusion criteria; they were described and, where appropriate, used as covariates.

Prescribing Context and Contraindications

Kranus Edera is prescribed in Germany through the DiGA pathway. Prescribers are responsible for indication and contraindication screening according to the product's instructions for use. Because this was a retrospective, deidentified data export, individual prescription records were not available; eligibility was operationalized using the variables above. A full list of contraindications and precautions (eg, unstable angina, recent myocardial infarction, New York Heart Association class III-IV heart failure, high-risk arrhythmias, etc, with *ICD-10* [*International Statistical Classification of Diseases, Tenth* Revision] codes where applicable) is provided in Multimedia Appendix 2.

App Structure and Modules

Overview

Kranus Edera delivers a 12-week, guided digital therapy for ED, combining (1) basic pelvic floor muscle training (PFMT), (2) pelvic floor physiotherapy, (3) cardiovascular endurance sessions, (4) brief mindfulness and mental exercises (eg, breathing and stress regulation), and (5) educational and sexual therapy content (knowledge modules on ED etiology, lifestyle, medication, and partner communication). The program is progressive: difficulty and training load increase across weeks, and the app adapts suggested tasks based on completion and self-reported ease.

- Pelvic floor (PFMT): short, technique-focused basic drills (approximately 3-7 minutes) emphasizing anterior pelvic floor activation, relaxation, and coordination.
- Cardiovascular training: time-based walking or aerobic sessions with targets expressed in seconds or minutes (approximately 10-30 minutes), aligned with guideline-consistent aerobic activity to support endothelial function.
- Physiotherapy: longer guided physiotherapy videos (approximately 5-10 minutes) to facilitate PFMT and physical activity.
- Mental exercises: brief (approximately 5 minutes) audio-guided breathing and mindfulness exercises to reduce performance anxiety and support adherence.
- Knowledge and education: lessons of approximately 3-7 minutes on ED mechanisms, risk factors, medication classes, lifestyle, and communication strategies.

Session Cadence and Examples

Typical weekly plans include multiple short sessions (eg, 3-5 PFMT or physiotherapy tasks, 1-3 cardiovascular sessions totaling approximately 20-90 minutes across the week, 1-2 mental exercises, and 1-7 knowledge modules). Example exercises include supine pelvic contractions with breath cueing, bridges, hip openers, interval running cardio, 4-7-8 breathing, and myth-busting lessons on ED. A week-by-week module map with example tasks and nominal durations is provided in Multimedia Appendix 3.

Standards and Prior Evidence

The app's multidomain design (PFMT, aerobic activity, education, and psychological support) mirrors guideline

XSL•FO
RenderX

recommendations for multimodal ED management and demonstrated clinically meaningful improvements in IIEF-5 in a randomized, single-blind controlled trial of this app (EDDIG) [10].

Description of the Support Interventions

We evaluated 2 inactivity-triggered, weekly reactivation strategies implemented in routine operations.

Telephone support (call arm): when a participant had ≥7 consecutive inactive days (no logged activity in any domain), an automated flag prompted outreach. Calls were delivered by technical support staff from the provider's digital therapeutics support team (nonclinical), trained in basic troubleshooting and motivational interviewing and working according to a standardized standard operating procedure. Trained staff attempted up to 3 calls per episode (same day, next day, and the following day), between 9 AM and 7 PM local time. Calls followed a standardized opener and brief problem-solving script (technical troubleshooting or motivational and organizational support), aiming to set 1 concrete activity within 48 hours; red-flag symptoms prompted escalation. Participants could opt out of telephone contact. In routine operations, outreach cycles were repeated if inactivity persisted and were typically capped after 3 consecutive weeks of nonengagement.

SMS support (SMS arm): a weekly automated check sent 1 prescripted, week-specific SMS message when ≥7 inactive days were present. Messages were delivered in the morning (7 AM-11 AM), normalized short lapses, and prompted 1 short, week-appropriate module. The channel was one-way by design; replies were handled ad hoc during routine operations. Participants could opt out of SMS messages. As in the call arm, rechecks occurred weekly, and SMS outreach was typically capped after 3 consecutive weeks of persistent inactivity.

Operational rationale for the 7-day trigger: the ≥7-day threshold was defined by the provider for standard operating procedure simplicity and operational feasibility (weekly check and weekly nudge) and to target early reactivation after a full week of nonuse. This retrospective study did not set that threshold; we analyzed its real-world use. Notably, the same 7-day lapse key performance indicator has been used in prior digital adherence work (eg, medication refill gaps and SMS nudging frameworks) and in broader digital health reengagement strategies [6-8].

Design intent and end point alignment: both support strategies were designed to reactivate participants once per week rather than escalate intensity daily. Accordingly, the primary adherence end point was active weeks (≥1 activity per week), and the mechanism-aligned end point was reactivation after prior inactivity (active in week t given inactivity in week t–1). Stricter intensity and dose metrics are reported as sensitivity or exploratory outcomes.

Measurement of the Primary End Point

Overview

The prespecified primary end point was the number of active weeks (range 0-12 weeks) during the 12-week program. A week was considered active if the user completed ≥1 training session; multiple sessions in the same week still counted as 1 active week. Session completion required passing app-enforced criteria (completion of the full exercise flow and confirmation screens); merely opening the app or brief taps did not qualify. Participants remained in their assigned group according to the intention-to-treat principle; weeks with no telemetry were counted as inactive.

Link to the Intervention's Reactivation Mechanism

Outreach (telephone or SMS) was triggered only after ≥7 consecutive inactive days, with the goal of weekly reactivation. Completion of any session paused further outreach until the next inactivity episode. Thus, active weeks directly capture the intended proximal effect (breaking inactivity within the program's weekly cadence).

This operationalization is consistent with established practice in digital health evaluations that derive adherence from objective usage traces rather than self-report [13] and aligns with payer reporting in Germany, where weekly engagement is a core indicator in DiGA evaluations (eg, Techniker Krankenkasse annual reports [14]).

Robustness Checks

We additionally report (1) the reactivation rate, defined as the proportion of weeks t that were active given that week t–1 was inactive (denominator = all person-weeks following an inactive week); (2) active-weeks version 2 (≥2 sessions or ≥30 minutes of cardiovascular exercise); (3) multidomain engagement (≥2 of 5 weekly goals met); and continuous dose measures (total sessions and median sessions per active week). These thresholds reflect the program's recommended cadence (3-5 physiotherapy or PFMT sessions, 1-3 cardiovascular sessions, and mental exercises and education). Adherence derivation steps (pseudocode) are provided in Multimedia Appendix 3.

Measurement of Secondary End Points

CGI-I

To evaluate patients' subjective impression of change, a modified version of the CGI-I scale was used. At the end of the 12-week program, participants were asked via an email-based questionnaire, "How would you rate your current erectile function compared to before the therapy?"

Responses were given on a 7-point scale from 1=very much worse to 7=very much improved. For consistency with the original CGI-I interpretation, scores were recoded so that lower values indicated greater improvement. The scale was used in a self-rated, ED-specific format, in line with prior validation studies [15,16].

IIEF-5 (Erectile Function) and ΔIIEF-5

Erectile function was measured with the IIEF-5, a validated patient-reported outcome assessing erectile function over the past 4 weeks (items: erection confidence, firmness, penetration ability, maintenance, and intercourse satisfaction) [17]. Each item is scored from 1 to 5; the total score ranges from 5 to 25, with higher scores indicating better erectile function. Common severity bands were as follows: no ED, 22-25; mild, 17-21; mild-to-moderate, 12-16; moderate, 8-11; and severe, 5-7. Baseline IIEF-5 was collected at therapy initiation; a follow-up

XSL•FO
RenderX

IIEF-5 was offered voluntarily in the app during week 12. Change in erectile function (ΔIIEF-5) was computed as the week-12 score minus the baseline score, so positive values reflected improvement. Baseline IIEF-5 was also used as a covariate in adjusted outcome models.

Intention to Continue Therapy

Patients' intention to continue the digital intervention was assessed at the end of the 12-week program via a standardized email-based survey. Participants were asked the following dichotomous question: "Would you like to continue the therapy?" (response options: "yes" or "no").

Although this single-item question is not part of a validated instrument, it serves as a pragmatic proxy for patient satisfaction and perceived utility of the intervention. In line with previous adherence research, stated intention has been interpreted as an early indicator of behavioral engagement and treatment acceptance, particularly in digital health contexts where user motivation is critical to sustained use [12]. The variable was coded as binary (1=yes and 0=no).

Therapy Continuation Rate

Actual therapy continuation, also referred to as conversion, was operationalized based on patients' real-world therapy behavior. Using the manufacturer's internal database, it was determined whether a participant continued the same therapy within 3 months after completion of the initial 12-week therapy cycle.

This binary outcome (1=therapy continued and 0=no continuation) reflects objective, externally validated treatment behavior beyond self-report. As a behavioral end point, it offers insight into long-term therapeutic adherence and real-world uptake of the intervention under routine care conditions.

Statistical Analysis

Overview

All analyses followed an intention-to-treat principle based on calendar-week operational allocation (control, call, and SMS). Because assignment followed calendar-time operational changes, we adjusted for baseline covariates (age, BMI, smoking status, and baseline IIEF-5 where applicable) and acknowledge the possibility of residual time-trend confounding. We prespecified a calendar-time sensitivity analysis in which the primary adherence model additionally included a standardized enrollment-time covariate; we report the omnibus group test and Bonferroni-adjusted pairwise contrasts from that model. Exploratory analyses assessed alternative time codings and group-by-time interactions.

Descriptive Statistics

We summarized the total sample and the groups (control, call, and SMS) with means and SDs. Distributional diagnostics (skewness and kurtosis, histograms, and probability-probability plots) informed model choice. With n>30 per group, 2-tailed *t* tests and general linear models (GLM) were considered robust to moderate nonnormality; BMI showed slight positive skewness but remained within acceptable bounds.

Primary Adherence End Point (Mechanism-Aligned)

The prespecified primary end point was active weeks (number of weeks with ≥1 completed session, 0-12). Group differences were tested with independent-samples *t* tests (call vs control; SMS vs control) and one-way GLM or analysis of covariance (ANCOVA) with group as the factor and age, BMI, and smoking status as covariates. We report adjusted means (estimated marginal means), 95% CIs, and Bonferroni-adjusted pairwise comparisons.

Clinical Outcomes (IIEF-5 and CGI-I)

The primary model for IIEF-5 was an ANCOVA of week-12 IIEF-5 with baseline IIEF-5 (and age, BMI, and smoking status) as covariates. This approach is preferred to testing change scores because it typically offers greater precision when baseline and follow-up are correlated and helps mitigate baseline imbalance and regression to the mean in nonrandomized cohorts.

- Sensitivity: we additionally report ΔIIEF-5 = week 12 − baseline (*t* tests or GLM) for comparability with prior work; interpretation prioritizes the ANCOVA results.
- CGI-I: analyzed directly using a GLM or ANCOVA with the same covariates (CGI-I is itself an improvement scale).

For the ANCOVA models, we checked homogeneity of regression slopes, residual normality, and influential observations; conclusions were unchanged.

Intent to Continue and Conversion

Group differences in intent to continue (implementation outcome) were tested using chi-square tests and logistic regression with group as the main factor and age, BMI, and smoking status as covariates (reporting adjusted odds ratios [ORs] and 95% CIs). Conversion (documented continuation) was analyzed analogously. Because responses were voluntary, these were treated as complete-case outcomes, and response rates are reported; we do not infer clinical efficacy from intention.

Additional Adherence Measures

Threshold-based adherence was assessed as the proportion of participants achieving ≥6, ≥8, and ≥9 active weeks using chi-square tests, with adjusted risk differences and ORs reported with 95% CIs. Adherence intensity was evaluated as the median number of sessions per active week using nonparametric tests alongside GLMs when the data were skewed. Domain-specific goal attainment was assessed as the number of weeks participants met weekly goals in pelvic floor training, pelvic floor physiotherapy, cardiovascular exercise, mental exercises, and knowledge modules, as well as the percentage of all weekly goals achieved across the 12-week intervention, using GLMs or chi-square tests as appropriate. Additional adherence metrics included the number of "stricter" active weeks (version 2), defined as ≥2 sessions per week or ≥30 minutes of cardiovascular exercise per week, and the number of multidomain weeks, defined as weeks in which participants met goals in at least 2 of the 5 intervention domains.

XSL•FO
RenderX

Mechanism-Specific Reactivation and Persistence

Reactivation was defined as being active in week t given inactivity in week t−1. Among participants with ≥1 opportunity, we compared any reactivation (yes or no) using chi-square tests and modeled the reactivation rate (reactivations and opportunities) with ANCOVA using the same covariates.

Persistence, defined as time to the first inactive week, was analyzed using Kaplan-Meier analysis with log-rank tests; participants who remained active throughout the 12 weeks were censored at week 12. We also computed the longest active streak.

Missingness, Nonresponder, and Bias Checks

Primary models used complete cases for the end point of interest; descriptive analyses used pairwise deletion. We compared baseline characteristics and adherence between responders and nonresponders (follow-up completion) using *t* tests and chi-square tests and fitted a logistic regression predicting follow-up completion (covariates plus group) to assess differential missingness by group.

Sensitivity Analyses

We repeated key analyses excluding participants reporting baseline pharmacotherapy (any phosphodiesterase type 5 [PDE-5] inhibitors, Schwellkörper-Autoinjektionstherapie [SKAT], or medicated urethral system for erection [MUSE]). When assumptions were questionable, we added nonparametric companion analyses (Mann-Whitney or Kruskal-Wallis).

All tests were 2-sided with α=.05. We report effect sizes (mean differences, adjusted mean differences, ORs, and hazard ratios where applicable) with 95% CIs. Analyses were conducted using SPSS (version 30; IBM Corp) with the GLM, univariate ANOVA, Kaplan-Meier survival, and logistic regression procedures.

Results

Description of the Study Population

The study population consisted of 470 men with physician-diagnosed ED. The mean baseline IIEF score was 13.1 (SD 4.65), indicating moderate to severe ED. Thus, this cohort represents a clinically relevant population with typical ED characteristics.

The average BMI was 27.3 (SD 4.33) kg/m^2, which falls within the preobesity range according to the World Health Organization (WHO) classification [18]. This value is comparable to the average BMI of German men aged 45-64 years (approximately 27.5-27.7 kg/m^2) [19].

Participants were, on average, aged 48 (SD 14.2) years, with a broad age distribution centered in middle adulthood, an age group in which ED is increasingly common and often overlaps with metabolic risk factors [20].

Functional capacity was high, with 83% (390/470) of participants able to perform 40 minutes of cardiovascular exercise and 96% (451/470) able to move independently.

This high level of functional independence suggests that, despite comorbidities, the cohort was predominantly physically active.

These prevalences align with known risk factors for ED and are partially elevated compared with the general German male population, consistent with the clinical nature of this sample [21]. Nearly half of the men used PDE-5 inhibitors; other invasive or pharmacological therapies, such as SKAT or MUSE, were rare.

Baseline Group Comparability

Baseline demographic and clinical characteristics were broadly similar across groups (usual care [control], telephone support, and SMS). Continuous variables are summarized as mean (SD) and compared descriptively; where hypothesis tests are reported, one-way ANOVA was used for continuous variables and chi-square tests (or Fisher exact tests where expected cell counts were sparse) for categorical variables. To quantify balance independent of sample size, we report absolute standardized mean differences alongside *P* values.

The mean age was 48 (SD 14.2) years, and the mean BMI was 27.3 (SD 4.3) kg/m^2, with no between-group differences (ANOVA *P*=.74 and *P*=.89, respectively). Functional capacity and independence were high across groups (able to perform 40 minutes of cardiovascular exercise: 390/470, 83%; independent mobility: 451/470, 96%). The prevalence of common comorbidities was comparable, including hypertension (129/470, 27.4%), dyslipidemia (93/470, 19.8%), and diabetes mellitus (51/470, 10.9%). Baseline pharmacotherapy also did not differ significantly between groups (PDE-5 inhibitor use: 230/470, 48.9% overall; SKAT or MUSE: 6/470, 1.3%; any pharmacotherapy approximately 50%; all chi-square tests: not significant). Key factors relevant to outcomes and missingness (current smoking: 111/470, 23.6%; history of prostatectomy: 34/470, 7.2%) were similarly distributed.

Between-group differences at baseline were small by ANOVA or chi-square testing. For the prespecified covariates (age, BMI, current smoking, baseline pharmacotherapy, and baseline IIEF-5), no statistically significant differences were detected (Table 1). Primary models adjusted for age, BMI, smoking status, and baseline pharmacotherapy.

XSL•FO
RenderX

Table 1. Baseline characteristics by group. Values are mean (SD) or n (%). *P* values are from one-way ANOVA (continuous variables) or chi-square tests (categorical variables). Denominators vary because of item-level missingness; percentages are based on the nonmissing denominator for each variable.

Characteristic	Total (N=470)	Control (n=180)	Call (n=150)	SMS (n=140)	*P* value

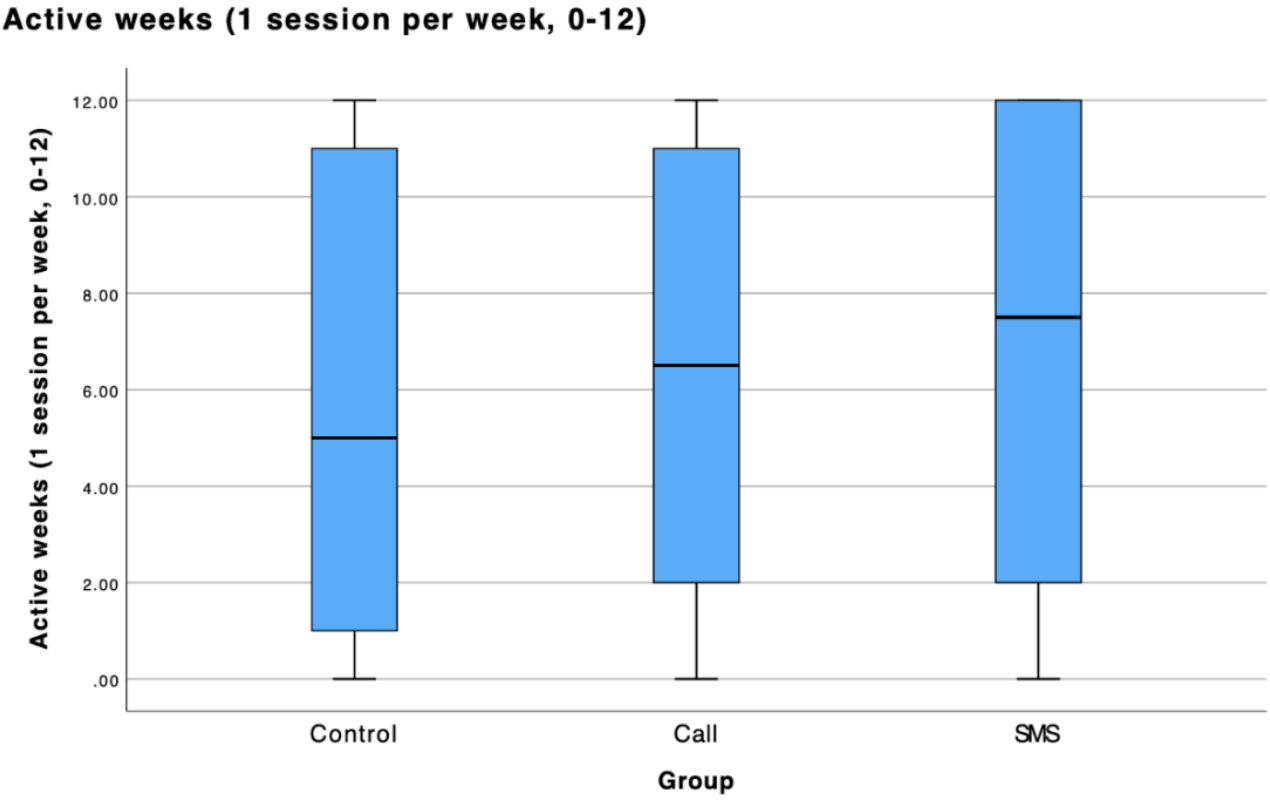
[a]PDE-5: phosphodiesterase type 5.

[b]SKAT: Schwellkörper-Autoinjektionstherapie.

[c]MUSE: medicated urethral system for erection.

Primary Outcome: Therapy Adherence

Definition and Hypothesis



Therapy adherence was prespecified as the number of active weeks (range 0-12 weeks) during the 12-week program; a week was “active” if the user completed ≥1 training session in the app (completion enforced by app logic). The confirmatory hypothesis specified 2 planned contrasts, call vs control and SMS vs control, with α=.05 (2-sided) for each contrast.

Descriptives

Across the cohort (N=470), participants completed a mean of 6.34 (SD 4.44) active weeks. Group distributions were approximately symmetric, with small skewness in each group. The median number of active weeks was 5.0 weeks in the control group, 6.5 weeks in the call group, and 7.5 weeks in the SMS group. Figure 1 shows the unadjusted distribution of active weeks by group.

XSL•FO
RenderX

Figure 1. Boxplot of active training weeks by group. The plot displays the distribution of weekly exercise adherence across the control, call, and SMS groups. Median adherence was highest in the SMS group, with slightly lower variability than in the control group.

Unadjusted Planned Contrasts

Group means were 5.79 (SD 4.54) for the control group, 6.57 (SD 4.22) for the call group, and 6.80 (SD 4.48) for the SMS group. The omnibus one-way ANOVA suggested a trend ($F_{2,467}$=2.333; *P*=.09). Prespecified pairwise tests vs the control group were as follows: call vs control, Δ=0.78 weeks (95% CI −0.17 to 1.73; *P*=.11, not significant); SMS vs control, Δ=1.01 weeks (95% CI 0.01-2.00; *P*=.049); Cohen *d* for SMS vs control was 0.22 (small). Bonferroni-adjusted GLM pairwise comparisons were nonsignificant.

Adjusted analyses

GLM models adjusted for age, BMI, smoking status, and baseline pharmacotherapy showed no significant planned pairwise contrasts in active weeks; the unadjusted SMS advantage was attenuated after adjustment. In a calendar-adjusted sensitivity that additionally included a standardized enrollment-time covariate, the omnibus group effect was small but statistically significant, whereas Bonferroni-adjusted pairwise contrasts remained nonsignificant. Corresponding adjusted estimates are reported in Multimedia Appendix 4.

Sensitivity Analyses

Using stricter adherence definitions (≥2 sessions per week or ≥30 minutes of cardiovascular exercise per week), a multidomain engagement definition (≥2 of 5 weekly goals), and intensity measures (total sessions and median sessions per active week) yielded the same conclusion, with no significant adjusted group differences.

Mechanism-Aligned Proximal Signal

Unadjusted, the call and SMS groups showed higher mean reactivation rates than the control group (control group 0.167; call group 0.223; SMS group 0.235). In a GLM adjusted for age, BMI, smoking status, and baseline pharmacotherapy, between-group differences in the reactivation rate were small and not significant ($F_{2,467}$=1.438; *P*=.24; partial η^2=0.008). By contrast, the probability of any reactivation differed across groups on an unadjusted 3 × 2 test (χ^2_2=9.7; *P*=.008), with higher proportions in call and SMS groups than in the control group.

Persistence and Clinical Outcomes

Time to first inactivity did not differ between groups (log-rank *P*=.36). In ANCOVA of week-12 IIEF-5 adjusted for baseline IIEF-5, age, BMI, smoking status, and baseline pharmacotherapy, the group effect was not significant; adjusted pairwise comparisons were also nonsignificant. Table 2 summarizes the unadjusted group means for the primary and secondary outcomes for transparency; inferential conclusions rely on the adjusted models described above.

XSL•FO
RenderX

[c]ΔIIEF-5: change in the 5-item International Index of Erectile Function.

[d]Chi-square tests were used for categorical outcomes.

[e]Not applicable.

Secondary Outcomes

CGI-I

Posttherapy CGI-I data were available for 48.3% (227/470) of participants. Group means were similar (control 4.93, SD 1.60; call 4.95, SD 1.36; SMS 5.08, SD 1.22), corresponding on average to a rating of "minimally improved," and no between-group differences were detected in unadjusted contrasts (control vs call $P>.99$; control vs SMS $P>.99$; omnibus $F_{2,224}=0.220$; $P=.80$). In models adjusted for age, BMI, smoking status, baseline pharmacotherapy, and enrollment-week fixed effects, the group term remained nonsignificant. Further details are available under "Clinical: CGI-I (Adjusted with Covariates)" in Multimedia Appendix 4.

ΔIIEF

ΔIIEF data were available for 27% (127/470) of participants, limiting statistical power. The mean change was 3.20 (SD 3.35; range −7 to +13). Group means did not differ (omnibus ANOVA $F_{2,124}=0.503$; $P=.61$; Bonferroni-adjusted pairwise comparisons, all $P\geq.99$). Consistent with this finding, an ANCOVA of week-12 IIEF-5 adjusted for baseline IIEF-5, age, BMI, smoking status, and baseline pharmacotherapy showed no group effect. Further details are available under "Clinical: IIEF-5 Week 12 (ANCOVA)" in Multimedia Appendix 4.

Intention to Continue Therapy (Binary)

Overall, 40.9% (192/470) of participants indicated an intention to continue. By group, 37.8% (68/180) were in the control group, 49.3% (74/150) were in the call group, and 35.7% (50/140) were in the SMS group. An unadjusted omnibus chi-square test showed a group difference in intention to continue ($\chi^2_2=6.7$; $P=.04$). In the adjusted logistic regression model, the call group vs the control group showed higher odds of intention to continue (OR 1.61, 95% CI 1.03-2.50; $P=.04$), whereas SMS vs control was not significant. Overall model fit was modest (model $\chi^2_6=11.7$; $P=.07$; low pseudo-R^2), so this result should be interpreted as a small adjusted difference. Exploratory adjusted logistic regression models are reported in the section "Intention to Continue Therapy - Logistic Regression (Adjusted)" in Multimedia Appendix 4.

Actual Continuation of Therapy (Conversion)

Overall, 27.2% (128/470) of participants continued therapy. By group, 26.1% (47/180) were in the control group, 32% (48/150) were in the call group, and 23.6% (33/140) were in the SMS group. An unadjusted omnibus chi-square test showed no group difference ($\chi^2_2=2.8$; $P=.25$).

Exploratory Correlations

Exploratory bivariate correlations are reported in the section "Correlations: Active Weeks With Baseline and Clinical Variables" in Multimedia Appendix 4. Adherence correlated negatively with BMI ($r=-0.123$; $P=.007$) and current smoking ($r=-0.112$; $P=.02$). Correlations with age, baseline pharmacotherapy, and baseline IIEF-5 were small, and the correlation with ΔIIEF was not significant ($r=0.020$; $P=.82$).

Discussion

Principal Findings

For the primary adherence end point (active weeks, defined as ≥1 completed session per week), unadjusted means favored both support groups (control 5.79; call 6.57; SMS 6.80). The prespecified SMS vs control contrast reached $P=.049$ with a small effect (Cohen $d=0.22$), whereas the call vs control contrast was not significant. In models adjusted for age, BMI, smoking status, and baseline pharmacotherapy, between-group differences were not statistically significant, and the SMS advantage was attenuated. In a calendar-adjusted sensitivity model, the omnibus group term reached significance, yet Bonferroni-adjusted pairwise contrasts vs the control group did not; effect sizes were small. Together with the null findings for the clinical end points, this supports our interpretation that the support strategies primarily aid reactivation after lapses rather than materially increasing the weekly dose. Sensitivity analyses using stricter

XSL•FO
RenderX

adherence definitions (≥2 sessions per week or ≥30 minutes of cardiovascular exercise; multidomain weekly goals; thresholds of ≥6, ≥8, and ≥9 active weeks) led to the same conclusion: small or null adjusted differences across groups.

For the mechanistic outcomes, any reactivation after an inactive week occurred more often in the intervention groups than in the control group (omnibus chi-square P=.008), indicating that outreach was associated with a higher likelihood of at least 1 return to use after inactivity. Persistence (time to first inactivity) did not differ by group (log-rank P=.36).

Clinical secondary outcomes were null overall: adjusted analyses of CGI-I and week-12 IIEF-5 showed no group effects, and the SMS group did not differ from the control group on these end points. Concurrent pharmacotherapy neither explained the engagement signals (active weeks and any reactivation) nor modified the intervention effects; interaction tests by baseline pharmacotherapy status were nonsignificant. Given the self-reported nature of the pharmacotherapy data and the lack of dose and timing information, these analyses are exploratory.

Taken together, these end point results suggest that the mechanics of the support strategy worked as intended at the event level: nudges helped break inactivity spells (ie, reactivation) while producing only small changes in week-to-week adherence totals. In addition, the telephone intervention increased stated intention to continue therapy vs the control group (n/N, 49% vs n/N, 38%; P=.04; small effect). Prior evidence indicates that personal contact can strengthen perceived support and reduce uncertainty, which may explain the greater stated willingness to continue [22]. In the real-world pathway studied, continuation typically requires renewed physician involvement after 3 months; thus, stated intention to continue therapy functions as a pragmatic implementation outcome and a proximal indicator of readiness to pursue maintenance treatment. The absence of between-group differences in documented therapy continuation within 3 months likely reflects system-level constraints (eg, access and scheduling) that can decouple motivation from realized continuation [23]. Finally, covariate associations aligned with prior work: higher BMI and current smoking were independently associated with fewer active weeks, underscoring the relevance of lifestyle factors for digital engagement [24].

Overall, the interventions modestly influenced weekly adherence, successfully reactivated some users after inactivity, and, especially for telephone contact, increased motivation to continue therapy [22-27].

Hypotheses Revisited

We prespecified that inactivity-triggered supports would increase weekly engagement (H1), that telephone support might increase stated intention to continue therapy (H2), and that clinical outcomes could differ between groups (H3, exploratory). The results supported H1 in a mechanism-aligned way: the support groups, particularly the SMS group, showed higher odds of any reactivation after ≥7 days of inactivity, with small gains in active weeks; however, within-week dose did not materially increase. H2 was supported: the telephone group reported a higher intention to continue therapy at week 12. H3 was not supported: IIEF-5 and CGI-I did not differ between groups. Because IIEF-5 was collected only at the end of the intervention among users who remained engaged, we consider the clinical outcomes exploratory and include a nonresponder analysis (baseline responder vs nonresponder contrasts and a logistic regression model of follow-up completion with covariates and study group; the group term was not associated with completion). Given the short 12-week follow-up and the quasi-experimental design, we interpret the observed effects as engagement-focused (preventing dropout through weekly reactivation) rather than evidence of therapeutic efficacy and therefore avoid causal claims.

Comparison With Prior Work

Prior research has shown that digital reminders, especially SMS messages, can support adherence across chronic conditions, including type 2 diabetes and cardiovascular disease [6-8]. Meta-analytic and trial evidence similarly point to mobile prompts as practical “nudges” for health behavior change [24,26-29]. This study extends these principles to a sexual medicine setting, where adherence involves completing exercise-based therapeutic sessions rather than taking medication. In our data, the SMS group showed a nominal improvement in active weeks in the unadjusted analysis, but adjusted analyses indicated small, nonsignificant differences vs the control group. This pattern is consistent with the broader literature, in which effect sizes for digital nudges are often modest and context-dependent [6-8,28,29].

At the same time, not all large, pragmatic evaluations have found benefits. A recent randomized trial by Ho et al [30] testing reminder and nudge strategies and personalized data feedback for chronic cardiovascular medications did not improve adherence (proportion of days covered) relative to usual care, underscoring how clinical context, target behavior, and implementation details shape effectiveness.

Finally, our observation that telephone support increased stated intention to continue therapy complements prior work on the motivational value of personal contact, while the absence of a corresponding increase in documented therapy continuation highlights a well-described intention-behavior gap in health care [31]. Together, these findings suggest that scalable digital nudges may help restart engagement after lapses, whereas relational outreach can shift motivation. Both are relevant but may be insufficient on their own without system-level supports that translate motivation into sustained behavior.

Strengths and Limitations

This evaluation was conducted within routine operations, using a rotating calendar-week schedule to deliver SMS and telephone outreach in the same workflow patients encounter. That pragmatic embedding enhances external validity and supports scalability. We also aligned the outcomes with the intervention’s mechanism of action, prioritizing the proximal ability of outreach to restart use after a ≥7-day lapse and summarizing week-to-week participation as “active weeks” (≥1 completed session). Because adherence was derived from app telemetry with enforced completion rules, recorded sessions reflect purposeful therapeutic activity rather than passive app use.

XSL•FO
RenderX

Finally, the cohort of 470 men with physician-diagnosed ED was clinically relevant and well characterized; baseline profiles were broadly comparable across groups, and prespecified covariates (age, BMI, smoking status, and baseline pharmacotherapy) were accounted for in the adjusted analyses.

This study used a quasi-experimental allocation by calendar week rather than individual randomization. Although this approach facilitated implementation in a real-world setting and minimized contamination between participants, it introduces potential biases, including unmeasured confounding and time-related effects. Although we adjusted for covariates and examined calendar-time sensitivity, residual and time-varying confounding cannot be excluded, and the design was unblinded. Industry collaboration was limited to the design of reminders and, despite safeguards (independent statistical cross-checks, governance procedures, conflict-of-interest disclosures, and planned code and data sharing), had no influence on data analysis, interpretation, or reporting. Clinical end points were limited by voluntary follow-up in routine care (IIEF-5 and CGI-I), which reduced statistical power and raised the possibility of missing-not-at-random mechanisms; nonresponder analyses did not indicate between-group differences in follow-up, but the clinical findings are interpreted as exploratory. Log-based adherence measures, while objective, do not capture training quality or within-week dose beyond completion thresholds, and passive engagement is not observed; active weeks therefore summarize participation but may underestimate intensity. The observation window was 12 weeks, so durability is unknown. Notably, the higher stated intention to continue therapy after telephone outreach did not translate into higher documented therapy continuation within 3 months, plausibly reflecting system-level constraints (eg, access, scheduling, and represcription). The single-item intention measure is susceptible to response and social desirability bias and should be viewed as an implementation indicator rather than a clinical outcome. Baseline pharmacotherapy was self-reported without dose or timing verification; interaction tests did not suggest effect modification by medication status, but these analyses remain exploratory. Finally, generalizability may be limited because the findings arise from a single DiGA within Germany's reimbursement and 12-week prescription context and may not extend to other health care systems, payment models, or digital therapeutics with different content or support workflows; replication with longer follow-up is warranted.

Implications for Clinical Practice and Future Research

Taken together, our findings suggest that inactivity-triggered outreach can reliably restart engagement after lapses, whereas the sustained week-to-week dose increased only modestly and did not remain significant after covariate adjustment. The interventions were associated with a higher probability of reactivation following an inactive week, and telephone outreach was additionally associated with a greater stated intention to continue therapy at 12 weeks; by contrast, adjusted differences in total active weeks were small, and clinical end points (IIEF-5 and CGI-I) did not differ between groups. In practice, automated SMS reminders are best used as a scalable first-line nudge to break ≥7-day inactivity spells, aligning support with the mechanism most clearly affected (ie, reactivation). Telephone outreach should be reserved for escalation, targeting patients who remain inactive after SMS or who are at higher risk of disengagement, where it may enhance motivation to continue therapy. A pragmatic approach is to combine and sequence support strategies (SMS followed by telephone outreach if the patient remains inactive), integrate them with appointment scheduling or represcription workflows, and continuously monitor barriers to therapy continuation (eg, access and logistics) that can decouple motivation from realized continuation. Expectations for clinical impact should be calibrated accordingly: within the 12-week observation period, we observed no between-group differences in clinical outcomes; therefore, these support strategies should be positioned primarily as engagement tools. Any downstream clinical benefits will likely require longer follow-up and/or stronger changes in dose intensity. In short, support strategies modestly influenced weekly adherence totals but were most effective at reactivating use after lapses, with telephone contact additionally increasing motivation; programs should therefore emphasize preventing dropout at the event level and apply stepped, risk-targeted escalation while avoiding overinterpretation of short-term adherence changes as clinical efficacy.

Conclusions

In this pragmatic, calendar-time–allocated evaluation of a digital ED therapy, inactivity-triggered support showed mechanism-aligned effects on engagement. Across groups, outreach was associated with a higher probability of any reactivation after an inactive week (ie, breaking inactivity spells). In addition, the telephone intervention yielded a higher stated intention to continue therapy at 12 weeks vs the control group, a pragmatic implementation outcome in settings where continuation typically requires renewed prescription. By contrast, differences in weekly adherence totals (active weeks) were small and not statistically significant after covariate adjustment, and clinical end points (IIEF-5 and CGI-I) did not differ between groups over 12 weeks.

Taken together, these findings support a practical division of labor:

- Automated SMS reminders as a scalable first-line nudge to prevent dropout by reactivating users after lapses; and
- Telephone outreach as a more resource-intensive escalation that may shift motivation (higher intention to continue).

These are engagement tools, not stand-alone efficacy treatments. Any downstream clinical benefit will likely depend on sustained exposure and system factors (eg, access to follow-up care) that translate motivation into realized continuation. The promise of simple, low-cost digital communication in routine care remains noteworthy [32], but effect sizes were modest, and causal inference is limited by the quasi-experimental design.

Future work should test stepped, adaptive support (eg, SMS reminders followed by telephone outreach for persistent inactivity), optimize timing and targeting, address conversion bottlenecks (scheduling and represcription), and evaluate longer-term clinical outcomes and cost-effectiveness. Replication in other health systems and with alternative digital therapeutics will clarify generalizability and help define where,

for whom, and at what intensity digital nudges deliver the most value.

Acknowledgments

The authors thank the technical support team for implementing the company's call/SMS support procedures during routine care and the participants who used Kranus Edera as part of their treatment. The authors also thank the Charité - Universitätsmedizin Berlin ethics office for guidance.

Generative AI tools (ChatGPT [GPT 5] and Claude [Sonnet 4.5]) were used for language editing and for assistance with SPSS syntax refactoring and debugging. All statistical analyses, model specifications, and interpretation were designed, executed, and verified by the authors. No AI systems were used to generate, analyze, or interpret the data, and no identifiable data were entered into public AI systems. The authors critically reviewed all AI-assisted text and code suggestions and take full responsibility for the content.

Funding

This research received no specific grant from any funding agency in the public, commercial, or not-for-profit sectors. The provider of Kranus Edera (Kranus Health) supplied a deidentified analysis dataset under a data-use arrangement.

The provider implemented the operational outreach workflow and supplied the deidentified dataset. The academic investigators designed the retrospective evaluation, performed the analyses independently, and interpreted the findings.

Data Availability

The participant-level dataset analyzed during the current study is owned by Kranus Health GmbH and is available from Zenodo under restricted access [33]. Access requires a data-use agreement with the rights holder and is limited to research and teaching; no reidentification or redistribution is permitted. The full analysis code (SPSS version 30) and variable codebook are openly available at Zenodo [34].

Abstract

Background: Meditation apps are increasingly popular but face significant engagement challenges. Most research does not meaningfully capture real-world engagement or associated user characteristics. Engagement patterns and reasons for engaging or disengaging remain relatively unexplored.

Objective: This study aimed to examine Medito app user engagement over the first 30 days after download and how intended use, demographics, user traits, and mental health factors predict engagement.

Methods: A prospective online survey was conducted among 668 Medito app users from 30 countries. Factors assessed included demographic factors (eg, age, sex, education, employment, and country of residence); user factors (eg, number of apps tried, hours of experience, meditation-related adverse events, expectations, readiness to change, and personality); and mental health factors (eg, quality of life, perceived stress, psychological distress, well-being, and satisfaction with life). Detailed engagement data included days of use, meditations completed, app opens, and minutes of use obtained via a data-sharing agreement with Medito. Minutes of use in the first 30 days after download served as the main outcome variable.

Results: App use was relatively low, with 50% (328/655) of users engaging for a total of 16 minutes or less in the first month after download (median 16.11, IQR 0 - 74.51 min). Fewer than 20% (124/655, 18.86%) of users continued using the app after 14 days. Intended use (mean 418.56, SD 472.5) significantly exceeded actual use (mean 70.02, SD 176.81; d=0.710; P<.001). In terms of user factors, expectation match (ie, extent to which outcomes from the app matched initial expectations; ρ=0.214; P=.002), expectations for anxiety (ρ=0.102; P=.01), expectations for attention or focus (ρ=0.091; P=.02), and conscientiousness (ρ=0.124; P=.003) were associated with higher engagement. Neuroticism was negatively associated with engagement (ρ=−0.103; P=.010). For mental health factors, satisfaction with life (ρ=0.123; P=.002) and well-being (ρ=0.135, P<.001) were associated with higher engagement, while perceived stress (ρ=−0.107; P=.007), psychological distress (ρ=−0.138, P<.001), and quality of life (ρ=−0.100; P=.011) were associated with lower engagement. Only readiness to change showed unique associations with higher engagement (semipartial r=0.156; P<.001). Regression analysis showed that only perceived stress predicted higher engagement (β=.020; P=.04). However, when mental health was included as a single component, expectations for anxiety (β=.015; P=.049) and readiness to change (β=.011; P=.048) predicted greater engagement, and mental ill health predicted lower engagement (β=−0.008; P=.049).

Conclusions: Overall, app engagement is generally quite low. Acute stress motivated meditation app use, while chronic stress disrupted it. Engagement is optimal when experiences match expectations and users are prepared to make a change. More transparency is necessary in the promotion of meditation apps so that users have a realistic understanding of the time and effort required to achieve benefits.

Introduction

Background

Mental health is a global issue, with 1 billion people living with a mental health disorder—a 50% increase since 1990 [1]. Mental health interventions require 10 to 15 times more resources (eg, medicines, personnel, and equipment) than other health interventions to impact disability-adjusted life years (a measure of the burden of disease through years lost to death and disability), thereby straining limited resources [2]. Smartphone-based meditation apps offer a scalable solution to provide general mental health support [3]. However, with fewer than 10% of individuals who download an app regularly using it beyond 1 week [4] and dose-response examinations suggesting high minimum practice requirements [5,6], most users are unlikely to achieve clinically significant improvements as a result of using a meditation app. A better understanding of what predicts engagement with meditation apps would help support overall use and the targeting of users most likely to benefit. While engagement rates in meditation apps and associated factors have been explored [4,7], to date, limited research has examined how baseline characteristics predict meditation app use over time, which could inform our understanding of which individuals may benefit most from these apps.

Mindfulness-Based Programs, Apps, and Efficacy

Meditation apps make up the majority of mental health apps [8], with the 2 leading apps, Headspace (Headspace Inc) and Calm (Calm Inc), collectively accounting for 70% of the market share in the mental health app sector [9]. Several evidence-based not-for-profit apps have emerged in recent years, such as the Medito app (Medito Foundation) [10]. Unlike traditional mindfulness-based programs (MBPs), which involve group and individual sessions that average 6 hours per week [11,12], most meditation apps involve no human support and have a lower suggested time commitment [5]. While MBPs show moderate improvements in a variety of mental health outcomes [8,13], apps produce significant but smaller effects compared with passive controls [14,15]. App efficacy is undermined by higher attrition rates in randomized controlled trials of apps than those of face-to-face MBPs (see section "*Attrition, Adherence, and Engagement*"), with most users abandoning apps within a week of download [4].

Attrition, Adherence, and Engagement

A challenge in digital meditation research is that engagement is not reported in one-quarter of studies [16] and, where noted, is largely attrition rather than meaningful app use. Engagement measures the amount, frequency, and duration of use, while attrition refers to abandonment or noncompletion rates in an intervention or study. Traditional in-person MBPs have low attrition from study measures (13% - 20%) [17], while attrition from study measures in meditation app randomized controlled trials is approximately 42%, with 90% attrition from application use after a week in naturalistic populations [4,14]. Adherence refers to compliance with an intervention that has a clinically effective "dose" [18]. Adherence captures engagement beyond attrition but is less relevant in nonclinical meditation apps that have no empirically ascertained minimal dose [6]. In our previous analyses of retrospective use patterns, meditation apps were only used, on average, 2.5 times per month.

A further challenge is that digital meditation studies often rely on self-reported adherence or attrition, offering limited insight into use patterns, reasons for disengaging, or real-world use with lower motivation and minimal guidance. Intended and self-reported engagement are typically higher than actual engagement levels and reflect distinct constructs, with some findings suggesting no relationship between reported and actual smartphone use [4,19-21]. Previous work has explored real-world use patterns [4,19,20], predictors of use [7,14], and associations with engagement as well as the relationship between well-being and app use [22,23]. Despite this work exploring factors and use, little is known about which user characteristics predict sustained engagement during the critical first month of use. Understanding prospective indicators of early use patterns may reveal user trajectories, distinguishing the features of those who engage from those who disengage.

Our previous study examined factors associated with meditation app use in general [7], but the retrospective nature of the study limited our ability to identify causality and may have been affected by inaccurate recall [24-26]. Given the importance of consistent engagement in achieving meaningful outcomes [27] and gaps in engagement reporting, examining predictors of engagement with accurate, objective data during crucial habit-building stages [28] could provide valuable insights into what drives meaningful engagement in meditation apps. Prior work has captured retention rates for the first 30 days of use based on publicly available data. A 30-day period provides insight across typical large early drop-offs in app use. This time frame supports an understanding of both individuals who engage and those who disengage.

Reasons for Engaging or Disengaging

Factors predicting app use often focus extensively on app characteristics alone [29] but have recently been extended to include sociodemographics, behavior change, and mental health factors. User factors that affect engagement are explorative but broadly reflect theories of habit formation and planned behavior [30,31].

User Factors: Sociodemographics

Sociodemographic factors may influence engagement in meditation apps. Older age and higher levels of education have been associated with greater engagement in meditation or mobile health apps [23,32], which may be due to poorer health outcomes or health literacy, although use to address health-related issues appears to be common [33,34]. Lower engagement has been found among minority groups in the United States [35,36]. Comparisons of engagement across countries are limited, although one cross-sectional survey found that residing in the United Kingdom was positively associated with engagement [7]. Most meditation app users have relatively high levels of income, although lower-income users may be more engaged in US samples [37,38]. Being female was found to be associated with lower engagement [7]. Barriers include difficulty finding a suitable space for practice and challenging thoughts [39,40]. Spiritual motivations for meditation also

XSL•FO
RenderX

correlate with engagement [5]. Personality factors also predict engagement or cause meditation-related challenges [41], and the latter may result in discontinuation of practice [41]. Agreeableness, conscientiousness, openness, and neuroticism have all been found to predict engagement in meditation [37,42-45], although neuroticism has been linked to more perceived barriers to meditation [46,47].

User Factors: Expectations and Experiences of Progress in Behavior Change

Behavior change factors may also be relevant to meditation app engagement, such as the alignment of expectations and experience. In a prior cross-sectional study, expectations of efficacy (eg, for sleep, stress, and other outcomes) correlated with engagement [7]. Ongoing engagement is promoted by experiences of progress [39,48]. Failure of an intervention to meet expectations predicts (dis-)engagement more than matched expectations [49,50]. Unmet or low expectations reduce perceived usefulness, while matched or exceeded expectations positively influence opinion and behavior [51]. App design can influence expectations, as features such as goal setting and feedback increase perceived efficacy [52]. Fewer perceived barriers and a more positive perception of meditation predict engagement in both meditation in general and meditation apps [32,37,53]. Other factors linked to engagement include higher perceived effectiveness and a higher growth mindset [37].

Mental Health Factors

The relationship between baseline mental health and meditation app engagement remains unclear. Our preceding cross-sectional study found no clear association of engagement with mental health factors [7]. Prior studies suggest that higher anxiety and motivations for mental health are associated with lifetime use, although the relationship with engagement remains unclear [37]. Experiences of mental ill health can lead to more barriers or difficulty engaging in behavior change [54]. As people often use meditation apps for mental health reasons, research should further investigate how baseline mental health factors may contribute to engagement.

Prospective Study Designs

Prospective study designs allow researchers to assess causality in engagement directly and measure baseline factors in real time. Prospective work is also beneficial for determining factors that fluctuate over time. Apps may improve mental health outcomes [8], which could positively or negatively reinforce app use. Additionally, as continual app users are likely to provide higher app ratings over time, understanding baseline expectations will provide insight into whether expectations for efficacy are significant in predicting use.

This Study

This prospective study sought to examine the pattern of engagement seen in new users of the free not-for-profit meditation app, Medito, over the first 30 days of download. The study addressed the following questions, with the following hypotheses stated in the preregistration. Note that question 3 and hypothesis 3 are question 4 and hypothesis 4, respectively, in the preregistration. Preregistration question 3 and hypothesis 3 were not addressed in this manuscript.

- Question 1. What is the *pattern* of engagement in the Medito meditation app in the first 30 days after download?
- Hypothesis 1. Engagement rates will decrease over time.
- Question 2. What is the relationship between *intended use and actual use* of the Medito meditation app?
- Hypothesis 2. Intended use of the Medito app will be associated with actual use (ie, engagement level per primary outcome).
- Question 3. Are there baseline *user factors* that will predict engagement levels over a 30-day period?
- Hypothesis 3. Prospective ratings of readiness to change, expectations for sleep efficacy, expectations for anxiety, expectations for efficacy, and expectations for thriving will predict engagement levels over the 30-day period.

Deviations and Clarifications

Note that the order of preregistration questions has been adjusted to improve logical flow. In addition, question 1 originally referred to the "Medito mindfulness app," which has been changed to "Medito meditation app" for clarity and consistency. Question 4 in the preregistration is question 2 in the manuscript, and question 2 is now question 3. "Use" in hypothesis 4 is conceptualized as engagement level as shown by the primary outcome variable. While we initially obtained follow-up data, the number of people who returned follow-up data was relatively small. Therefore, question 3 in the preregistration is not addressed in this manuscript.

Methods

Ethical Considerations

Ethical Approval and Participant Consent

This study was conducted according to ethical guidelines and was approved by the Office of Research Ethics and Integrity, University of Melbourne (2024-29651-52025-2).

Participants consented to participate in the study via the online Qualtrics survey. Consent information was provided in the online survey, and a plain language statement was available for download. The plain language statement can be found in Multimedia Appendix 1. The consent information included explicitly clarifying the participant's understanding of their right to withdraw at any time without explanation. Participants consented to secondary analyses. The survey flow prevented anyone who did not provide consent from completing the survey, and all responses included were double-checked for consent provision.

Participant Compensation

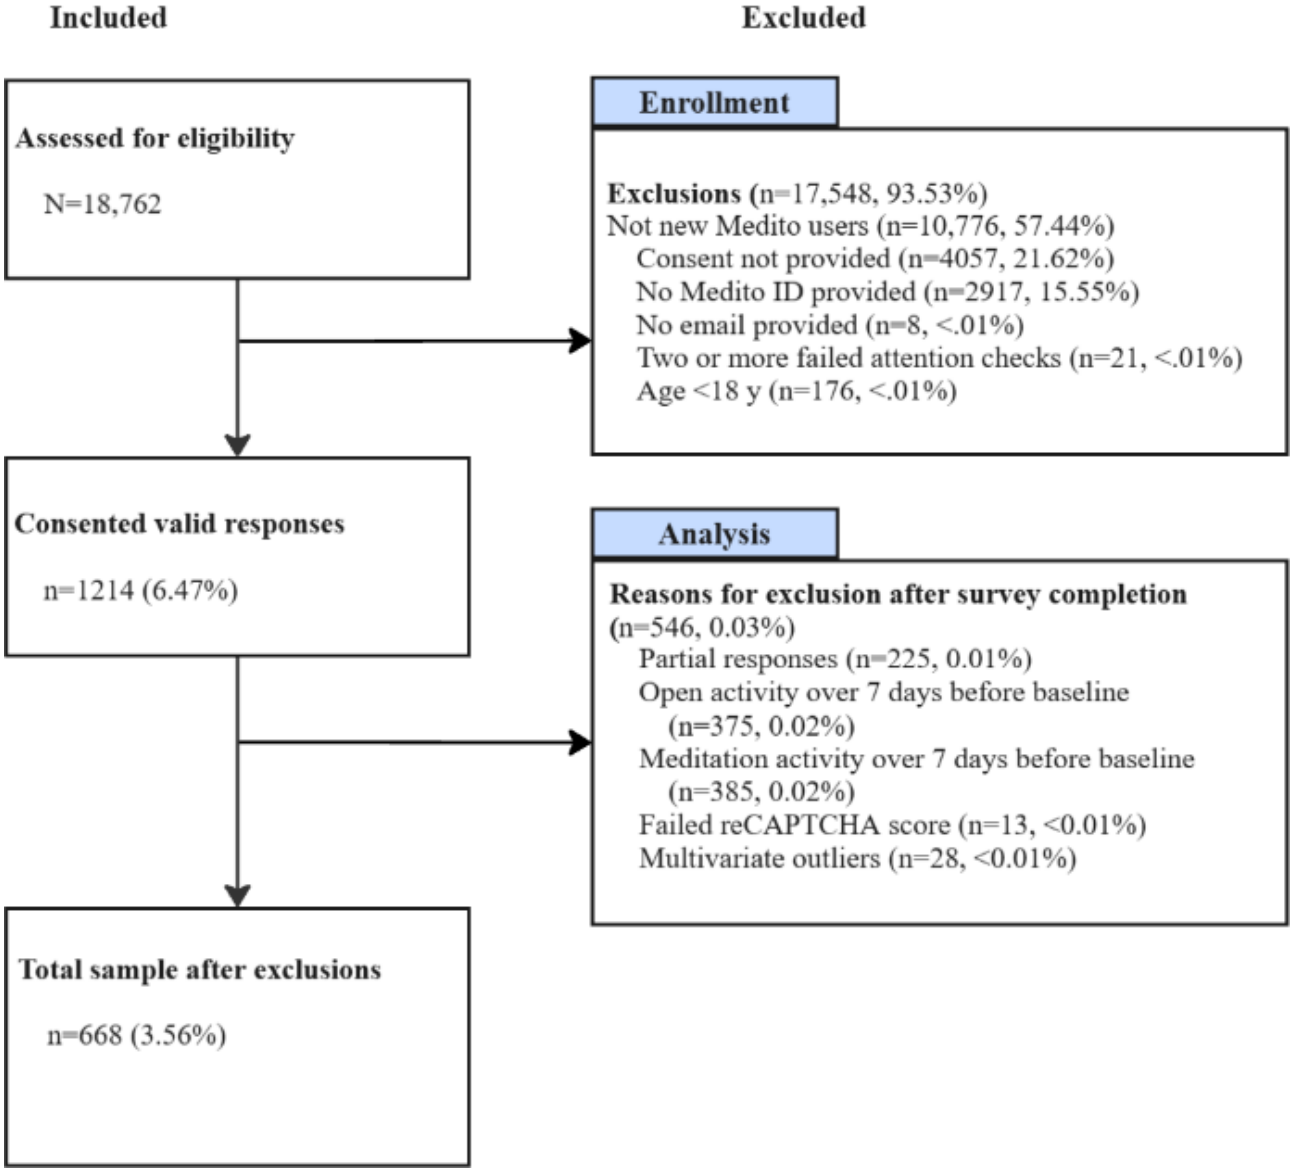
Our consenting sample before exclusions consisted of 1214 participants. Participants were compensated with one entry into a gift card draw for each survey completed, for 2 possible entries across both surveys. One AUD $250 (US $176.05) gift card was drawn per 250 sequential survey completions, resulting in 4 gift cards for the baseline survey and 1 for the follow-up. This equated to a total prize pool of AUD $1250 (US $825.25).

XSL•FO
RenderX

Privacy and Confidentiality

Participant data with identifying information (such as first name, first initial of last name, and email address) were retained for compensation purposes but stored securely according to relevant privacy guidelines and encrypted with Transport Layer Security encryption (also known as HTTPS).

Study Design and Setting



Medito App

Medito is a free meditation app offering guided audio meditations, available on the iOS and Android app stores. Meditators can choose individual sessions or follow structured programs, such as a 30-day introductory challenge.

Data Collection

The 2 methods of data collection were via a data sharing agreement with the Medito app developers and through a Qualtrics survey. Users provided their Medito ID number when consenting to the research team analyzing their app use. The baseline survey included a screening question, "Did you download Medito for the first time within the past day?" to target new users. The baseline survey was completed at the point of sign-up, and the follow-up survey was distributed for completion 30 days after baseline completion. Participant flow is discussed in the following section and displayed in Figure 1.

Figure 1. Participant flow diagram. The exclusion groups within the enrollment and analysis stages are not mutually exclusive.

Eligibility and Recruitment

Inclusion and Exclusion

Participants had to have downloaded Medito within the previous 24 hours to be eligible. Survey access was restricted to major countries that are predominantly English speaking, along with members of the European Union: Australia, Austria, Belgium, Bulgaria, Canada, Croatia, Cyprus, Czech Republic, Denmark, Estonia, Finland, France, Germany, Greece, Hungary, Ireland, Italy, Latvia, Lithuania, Luxembourg, Malta, the Netherlands, New Zealand, Poland, Portugal, Romania, Spain, Sweden, the United States, and the United Kingdom. These countries were selected due to the predominance of English speakers and

XSL•FO
RenderX

approximate financial parity to ensure ethical compensation and consistency in privacy laws.

Participant Flow

See Figure 1 and Supplementary 1 in Multimedia Appendix 1 for a detailed description of participant flow.

Procedure

Participants were sourced directly from Medito to complete a survey hosted by Qualtrics and advertised on the Medito app platform. The survey was live on the Medito platform from July 20 to August 30, 2024. Follow-up surveys were automatically sent 30 days after baseline completion. Surveys could be completed online using a laptop or mobile device.

Outcome Variables

Engagement Data

Medito provided detailed app usage data, including app opens count, meditation tracks completed, track length, track title, time of activity, meditation tracks started, and streaks (days of consecutive use). Information provided by Medito and used in analysis included Medito IDs for linking data to survey responses, activity time stamps for opens and track listens, and duration of meditation tracks. The total minutes of engagement in the first 30 days were calculated by summing the duration of each track completed in the 30 days following the user's first app open.

Study Outcomes

Total minutes of use in the first 30 days were the primary outcome variable to address research questions 1, 2, and 4. Minutes of use were calculated as a total over the 30-day period following the first time the app was opened by adding the durations of tracks completed. Days of use, meditations completed, and app opens were also collected to provide a holistic view of engagement in addressing question 1. App opens allowed for a comparison between daily app activity in our sample compared with Baumel et al [4]. Intended use patterns were collected to compare with actual use and to address question 4. The follow-up survey addressed the relationship between app factors and engagement outlined in question 3, which will be published elsewhere.

Data Sources and Measurement

Overview

Participants reported their age, gender (eg, male, female, nonbinary, genderfluid, or other), income, and education level. Participants reported the number of apps they had tried, including Medito, ranging from 1 (Medito only) to ≥5. Participants also reported hours of meditation experience in the following ranges: beginner (0 - 100 h), intermediate (101 - 1000 h), and expert (≥1001 h). Mental health factors included satisfaction with life, meditation-related adverse event impairment level and length, well-being, perceived stress, distress, and quality of life. Expectations were assessed for various domains (eg, sleep, stress, anxiety, attention, happiness, thriving, and performance enhancement), as well as whether the app matched expectations, how confident the user was in improvement, what degree of improvement was expected, and how ready they were to change. Personality factors were based on the Big Five Inventory [55].

Meditation-Related Adverse Events Abbreviated 3-item

Part 1 of the Meditation-Related Adverse Events [56], a 2-part scale that assesses meditation-related events, was completed. The first part of the scale consists of 3 items assessing the frequency of perceived adverse effects, the extent of related functional impairment, and the length of functional impairment. Each item has a Likert-style response format, ranging from never to frequently for frequency, not at all to severely for impairment, and 1 day or less to 1 year or longer for length of impairment.

The EuroQoL Health and Wellbeing Assessment–Short Form

The EuroQoL [57] assessment is a newly formulated quality of life measure. The scale consists of 9 items on a 5-point scale, where 1 represents "no difficulty," "none of the time," or "no physical pain" and 5 represents "unable," "most or all of the time," or "very severe physical pain," depending on the context. In this study, the scale had good internal consistency (α=.86; ω=0.72).

Perceived Stress Scale

The Perceived Stress Scale [58] is a brief measure of subjective stress. It ranges from 0 (never) to 4 (almost always). In this study, the scale had reasonable internal consistency (α=.71; ω=0.69).

The Kessler Psychological Distress Scale

The Kessler Psychological Distress Scale (K10) [59] was used to assess psychological distress in the last 30 days. The scale consists of 10 items assessing anxiety and depressive symptoms on a 5-point scale, ranging from 1 (none of the time) to 5 (all of the time). In this study, the scale had excellent consistency (α=.91; ω=0.78).

The Short Warwick-Edinburgh Mental Wellbeing Scale

The Short Warwick-Edinburgh Mental Wellbeing Scale [60] was used to assess positive elements of mental health and well-being. This scale consists of 7 items on a scale of 1 to 5, ranging from 1 (none of the time) to 5 (all of the time). In this study, the scale showed good consistency (α=.85; ω=0.75).

The Satisfaction With Life Survey (1-item)

The Satisfaction With Life Survey [61] Single Item is a 1-item version of the more established Satisfaction with Life Survey. The scale has reasonable criterion validity with the full Satisfaction With Life Survey (zero-order r=0.62 - 0.64; disattenuated r=0.78 - 0.80 [61]). The single-item measure asks participants to rate life satisfaction from 1 (extremely dissatisfied) to 7 (extremely satisfied).

Expectancy for Various Domains

Medito was rated in general for how effective the user thought it was for the following: anxiety, attention or focus, happiness, thriving, and performance enhancement. The rating scale ranged from 1 (not at all effective) to 7 (extremely effective).

XSL•FO
RenderX

Readiness to Change 1-item

The Readiness to Change 1-item [62] assessment is a 10-point scale that assesses an individual's preparedness to enact a behavioral change. The scale ranges from 0 (not prepared to change) to 10 (already changing). It is based on the transtheoretical model of behavior change stages [63,64]. The readiness ruler captures a construct related to actual readiness [63,65].

The Big Five Inventory Short Form 2

The Big Five Inventory Short Form 2 is a 30-item [55] questionnaire that assesses 5 domains of personality as subscales: extraversion, agreeableness, conscientiousness, negative emotionality, and open-mindedness. Each subscale contains 6 items. The subscales representing various personality domains were assessed for internal consistency using Cronbach α and McDonald ω. Cronbach α and ω consistency ranged from poor to excellent (extraversion: ω=0.57; α=.74; agreeableness: ω=0.56, α=.67; conscientiousness: ω=0.59, α=.73; neuroticism: ω=0.69, α=.85; and openness: ω=0.44, α=.63).

Statistical Analysis

The target sample size was 1000 participants at baseline, providing 90% power to detect a small effect size of r=0.102 at α=.05 [14]. The effect size of r=0.102 was hypothesized based on prior meta-analyses effect size estimates. The target sample size was determined using G*Power (Heinrich Heine University Düsseldorf) software [66]. Due to unexpected exclusions based on preexisting app use (~30% - 32% of the eligible sample), the final baseline sample size was 668 participants. With this reduced sample, the study retained 90% power to detect an effect of r=0.177.

Intended use was individually reported by users across sessions per day, minutes per session, and days per week. The indicated levels of intended use per person were used to calculate the intended total minutes of use over the first 30 days.

A paired-samples 2-tailed t test was conducted to compare intended use and actual use (in minutes). Zero-order correlations were calculated to investigate the overall relationship between the factor and the dependent variable. Semipartial correlations were calculated to investigate the unique relationship between a given factor and engagement, controlling for other factors. A regression model was used to investigate which factors showed significant associations with engagement, accounting for multiple predictors. The main outcome variable was total minutes of use over the first 30 days of app use. All factors that approached a significant zero-order association with engagement (P<.10) were included in the regression model.

A principal component analysis (PCA) was used to address multicollinearity among predictors and reduce dimensionality in our data. The PCA identified single components within the mental health and expectation outcomes. These were used in additional regression models to further investigate contributions among correlated predictors.

Results

Participant Characteristics: Descriptives

Participants ranged from age 18 to 74 (mean 32.2, SD 11.99) years and were close to evenly split between male (n=322, 48.20%) and female (n=318, 47.60%) participants. A small proportion reported nonbinary, gender fluid, or other gender (n=28, 4.20%). Most participants lived in the European Union (n=240, 35.96%) or the United States (n=239, 35.78%). Approximately two-thirds of our sample had completed education above high school (n=458, 68.59%). Most participants were employed full time (n=310, 46.41%) or part time (n=114, 17.08%). Approximately one-fifth were unemployed (n=123, 18.41%). Income was adjusted within countries into 5 brackets, with each bracket covering approximately 20% of the income range for that country. People were evenly distributed across the 4 lower income brackets adjusted for income levels across countries, with fewer (n=77, 11.53%) people in the top income bracket for their country. Notably, participants reported relatively high levels of perceived stress [67] and moderate-to-high psychological distress levels [68] compared to normative English and Australian samples (Table 1).

Perceived stress (PSS-4[a])	7.20 (3.11)
Psychological distress (K10[b])	23.87 (8.29)

[a]PSS-4: Perceived Stress Scale-4.

[b]K10: 10-item Kessler Psychological Distress Scale.

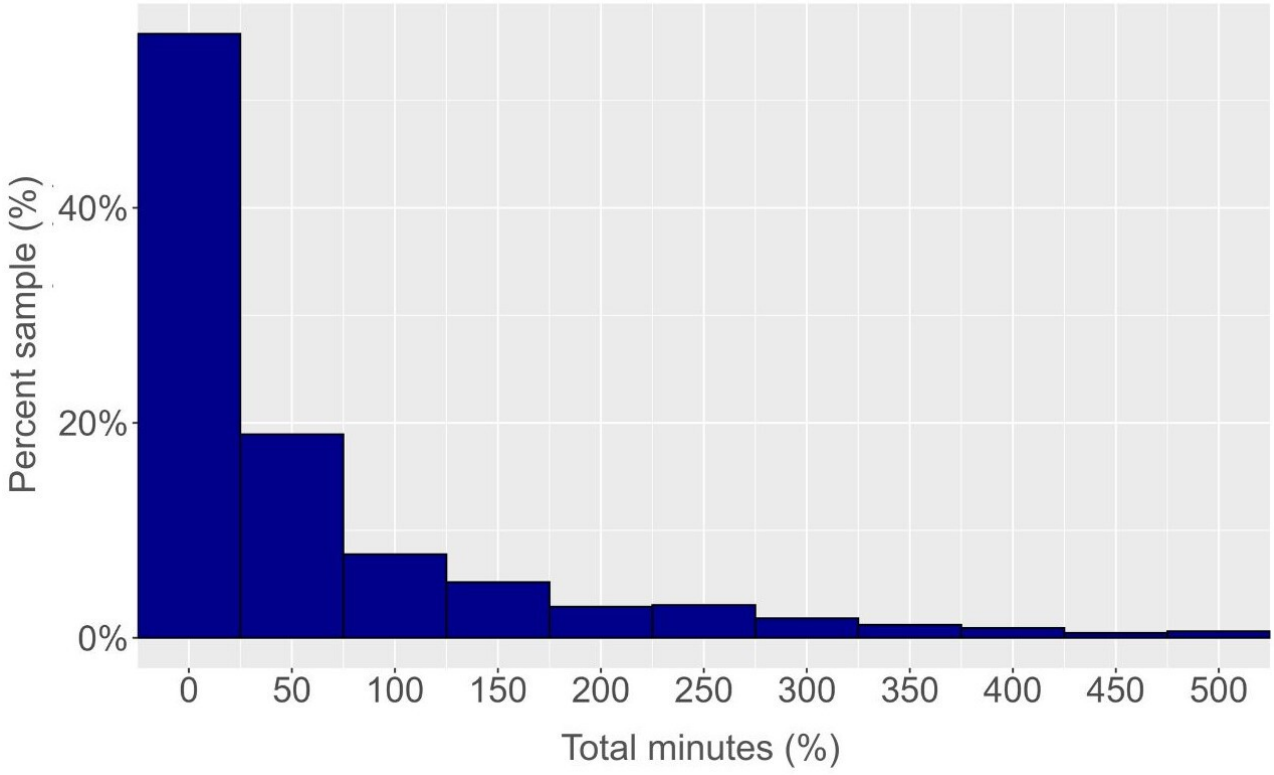
Statistical Recording Issues

From July 20 to August 13, Medito indicated a technical anomaly in the recording of statistics for tracks completed and streaks. However, analyses indicated the glitch was unlikely to have seriously affected the data (Supplementary 2 and Supplementary 3 in Multimedia Appendix 1).

Overall Engagement

To research app engagement, we assessed user engagement levels via total minutes. We further clarified patterns of use by assessing weekly minutes and days of use (Table 2). Engagement was highly positively skewed (mean 70, SD 176.81; median 16.11, IQR 0-74.51 during the first 30 days), suggesting that most participants had low engagement. Most sessions lasted 10 to 11 minutes; approximately half of the users in our sample did not engage beyond approximately one guided meditation. The majority (520/655, 79.4%) of participants engaged for less than 100 minutes in the first 30 days of use (Figure 2 and Table 3), despite the majority of participants intending to engage for 10 minutes per day over the 30-day period (Figures 3 and 4). Engagement dropped quickly over time; on day 7, only 27.68% (n=181) of participants used the app. Approximately one-fifth (n=124, 18.86%) were still engaged on day 14, while 16.26% (n=107) were still engaged at day 30. Overall, a higher proportion of users were engaged each day than in the sample of Baumel et al [4], with a median daily use of 17.47%, compared with 4.10% (see Figure 5 for comparison). No differences in engagement were found by age, sex, education, religion, income, or country (Figures 3 and 6 and Supplementary 4 and Supplementary 5 in Multimedia Appendix 1).

Table . App use descriptives.



Engagement variable	Values, n (%)	Values, mean (SD)	Percentile				
			5%	25%	50%, median (IQR)	75%	95%
Total minutes	655 (98.05)	70.02 (176.81)	0.00	0.00	16.11 (0-74.51)	74.51	292.49
Total sessions completed	668 (100)	10.29 (11.12)	1.00	2.00	6.00 (2-14)	14	34
Tracks started	518 (77.54)	12.48 (14.96)	1.00	3.00	8.00 (3-19)	19	45.15
Duration (d)[a]	455 (68.11)	13.80 (11.80)	0.01	1.43	11.96 (1.43-27)	27	29.75
Minutes per session[b]	468 (70.06)	11.34 (11.57)	2.68	5.01	10.00 (5.01-11.75)	11.75	29.95

[a]Duration in days equals the number of days between first opening the app and the most recent use within the 30-day period.

[b]Minutes per session were calculated by taking the statistic for minutes and dividing it by sessions completed for the mean and percentile ranges.

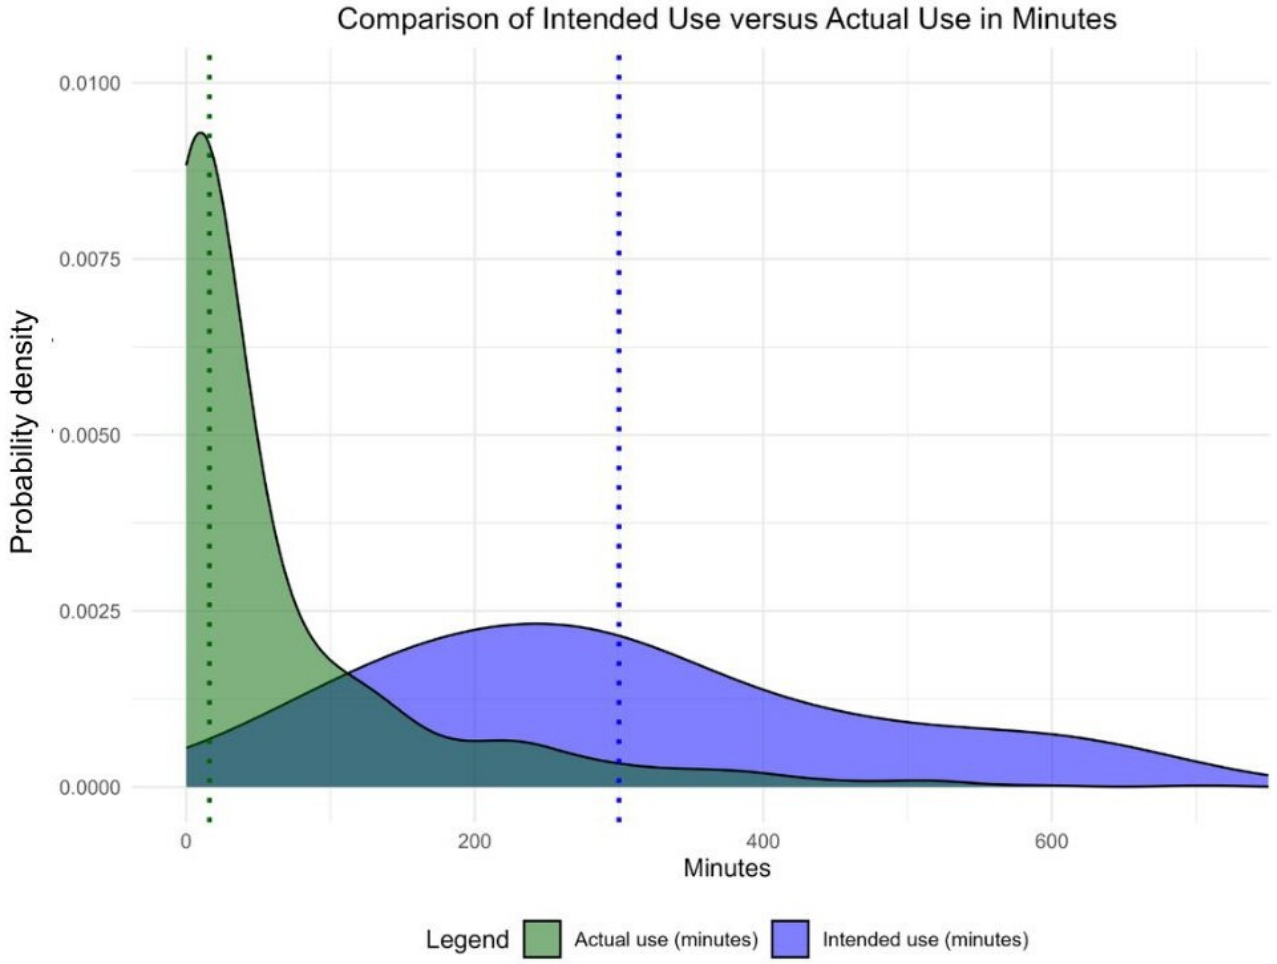
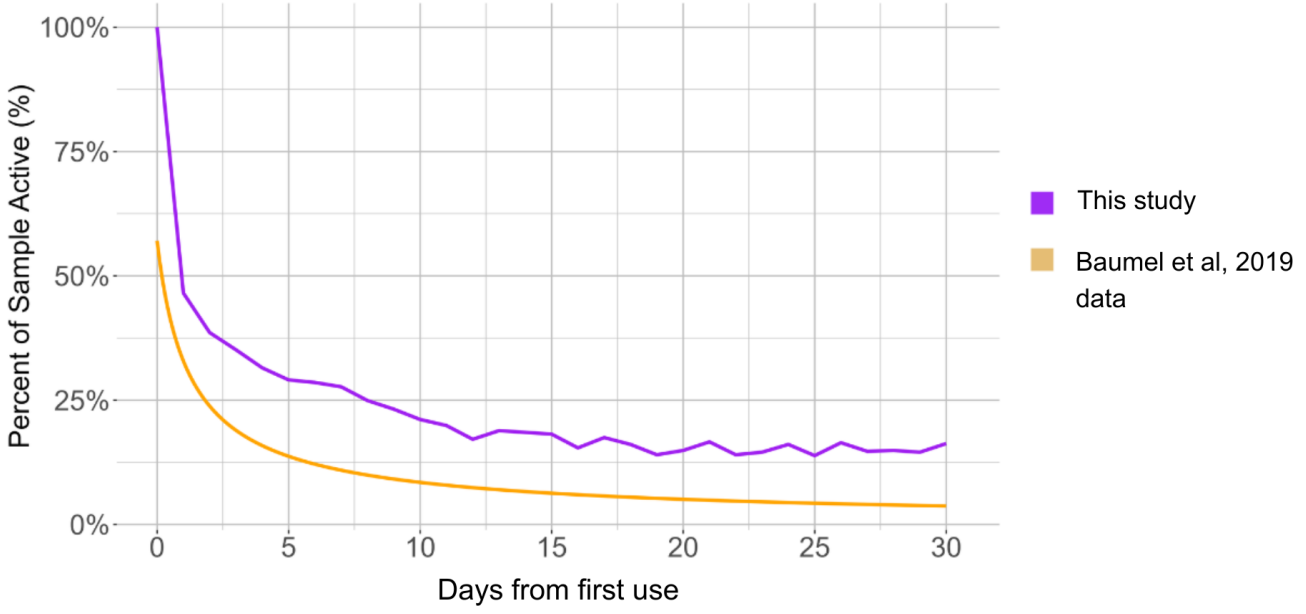
Figure 3. Smoothed density plots showing intended use. Panel A shows intended minutes per session, panel B shows sessions per day, and panel C shows days per week. Panels A to C show intended use by Medito users at the time of download, reported in sessions per day, minutes per session, and days per week. Participants reported intended sessions per day on a scale of 1 to 5 and intended minutes per session from 0 to 60 in approximately 5-min increments (excluding between 30 and 45 min). Intended days per week ranged from 1 to 7 d. Most users (>50%) reported intending to use the app for one 10-min session daily.

XSL•FO
RenderX

Figure 4. Density curves showing intended and actual minutes of use within the first 30 days, with minutes on the x-axis and probability density on the y-axis. The blue dotted line represents the median intended minutes, and the green dotted line represents the median actual minutes.





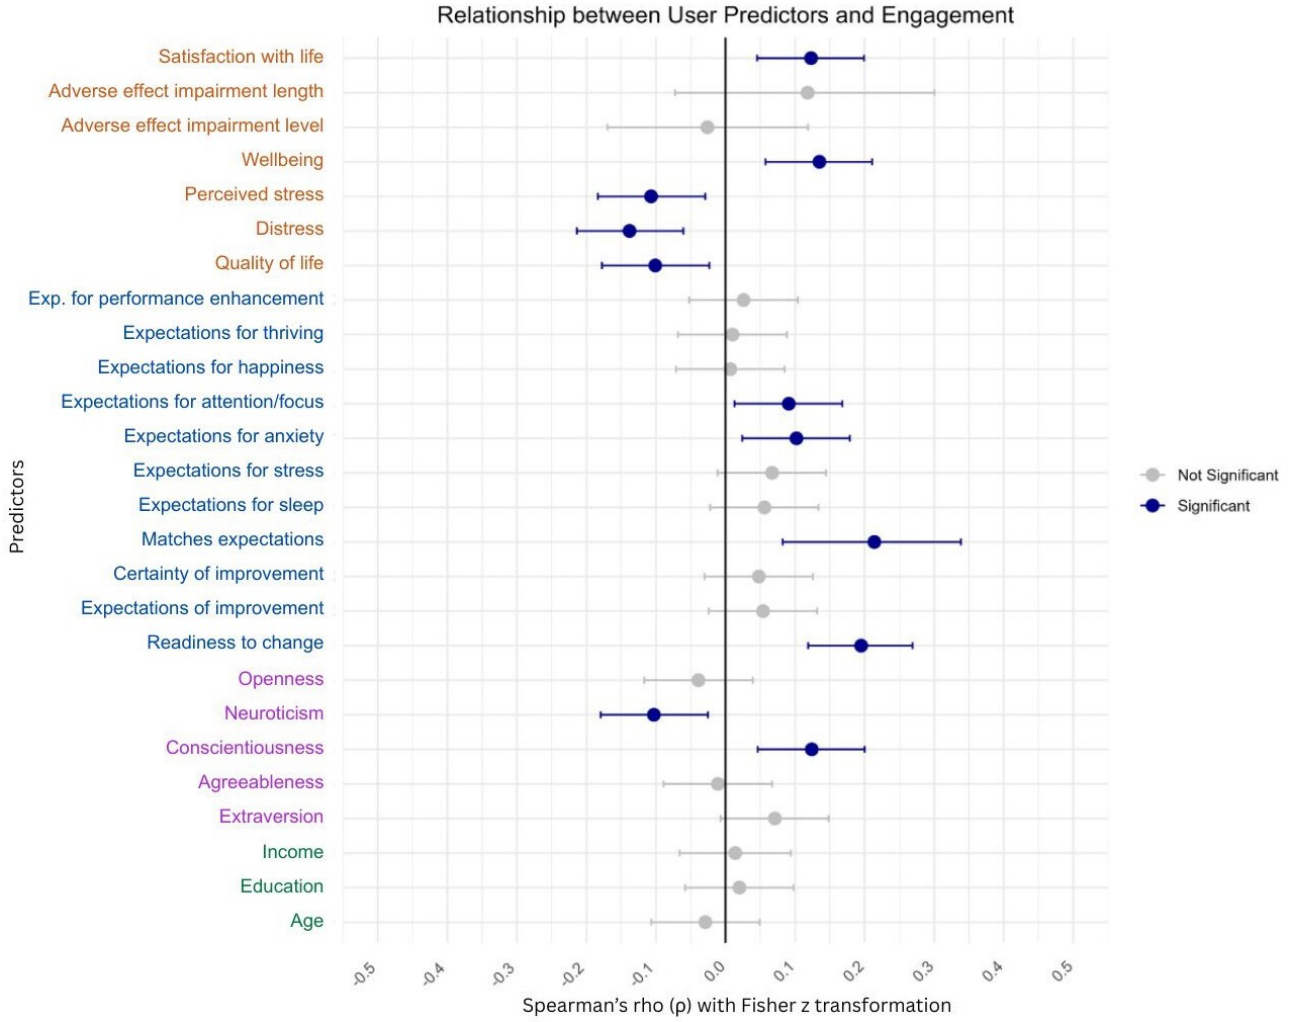


Figure 5. Curve showing the percentage of the sample actively using the app each day after download. App use on a given day represents the percentage of the sample who used the app on that day. The percentage of the sample active per day was used to provide a direct comparison with the findings of Baumel et al [4]. The yellow line represents an estimated curve from Baumel et al [4] and does not reflect the variation in app opens on each given day. The purple line represents the trend line of active use each day in the first 30 days of use in this study.

XSL•FO
RenderX

Figure 6. Spearman ρ coefficients of association between predictor factors and total minutes of use over the first 30 days. Whiskers represent 95% CI generated using Fisher z transformation. Dark blue represents significant association at $P<.05$; gray represents nonsignificant associations. Orange represents mental health factors, dark blue represents expectations factors, purple represents personality factors, and green represents sociodemographic factors. Quality of life is reverse coded; therefore, a negative association indicates that higher quality of life relates to higher engagement.

Patterns of Engagement

Figure 5 shows the percentage of participants actively using the app each day following download.

Intended Versus Actual Use

Figure 3 illustrates participants' intended app use at the time of download across 3 dimensions: minutes per session, sessions per day, and days per week.

Intended Use in Comparison With Actual Use

To address question 2, we investigated the relationship between intended and actual use. There was a weak associative relationship (r=0.094; P=.02). Figure 4 shows the density curve and median intended use stated as baseline (purple) compared with actual use over the first 30 days (green). Users intended a median of 300 (IQR 192.86-482.14) minutes over the first 30 days but only engaged for a median of 16 (IQR 0-74.51) minutes. In other words, median intended use was nearly 19 times greater than actual use. This suggests that users who intended to meditate more were more likely to do so (ρ=0.106; P=.007).

However, as expected, there was a large difference whereby intended use was significantly higher than actual use (mean difference 350.61, SD 493.53, 95% CI 312.72-388.51 min; Cohen d=0.710; t_{653}=18.168; $P<.001$; Figure 4).

Predictors of Engagement: User Factors (Question 2, Hypothesis 2)

Zero-order correlations for user factors are displayed in the forest plot below (Figure 6). Zero-order correlations, semipartial correlations, and regression beta weights are reported in Table 4.

[h]BFI2: Big Five Inventory Short Form 2 (30-item).

Mental Health Factors

All mental health factors were negatively associated with engagement in the zero-order correlations, indicating that poorer mental health, regardless of scale direction, was linked to lower engagement (Table 4). Only psychological distress showed a negative semipartial relationship with engagement that approached significance (sr=−0.070; *P*=.09). Perceived stress was the only significant mental health factor in the multiple regression, showing a positive association to engagement (β=.02; *P*=.04), contrasting with its zero-order correlation.

User Factors

Readiness to change showed the largest zero-order and semipartial correlation (ρ=0.194, *P*<.001; and sr=0.156; *P*<.001). Of the personality factors, conscientiousness and neuroticism (positive relationship) and neuroticism (negative relationship) correlated with engagement (ρ=0.125, *P*=.002; and ρ=−0.102, *P*=.009). Expectations for anxiety (ρ=0.102; *P*=.01) and attention (ρ=0.091; *P*=.02) were weakly positively associated with engagement. No user factors were significant in the regression model.

Regression Models With PCA Components

Multicollinearity was observed within the regression (Figure S2 in Multimedia Appendix 1). As a result, we undertook PCAs for mental health and expectations factors. Both mental health and expectations each showed one central factor with high loadings from contributing factors that accounted for a majority of the variance (Tables S9-S12 in Multimedia Appendix 1). Regression models were conducted using the mental health and expectations components found in the PCA (Tables S6-S8 in Multimedia Appendix 1).

With both components included, no factor or component achieved significance, and the amount of variance was reduced substantially (R^2=0.02; Table S7 in Multimedia Appendix 1). In a regression containing the expectations component, only perceived stress was significant (β=.022; *P*=.03), and the expectations component was nonsignificant, in line with prior results (Table S8 in Multimedia Appendix 1). In a regression containing the mental health component, the mental health component (β=−0.008; *P*=.049), readiness to change (β=.011; *P*=.048), and expectations for anxiety (β=.015; *P*=.049) were significant (Table 5). Deviating from the main model, readiness to change and expectations for anxiety were significant positive predictors when controlling for overlap among measures of

XSL•FO
RenderX

mental health. Furthermore, the mental health component, representing mental ill health, also negatively predicted engagement. The negative relationship between mental ill health and engagement suggests that worse mental health results in lower engagement.

Discussion

Principal Findings

This study investigates low rates of meditation app engagement in prior literature by examining prospective predictors of use. Minutes of use in the first 30 days after download were compared with user characteristics among 668 participants. While our findings align with prior works [4], our data showed a more gradual decline in use than has previously been observed. Actual use departed from intended use, with participants meditating about 350 minutes less (on average) than planned. Most participants aimed to meditate for 10 minutes daily but only engaged in approximately one 10-minute session. Nevertheless, there was a correlation between intended and actual use, suggesting that those who intended to meditate more practiced slightly more. The gap between intended and actual meditation time reinforces prior findings regarding the intention-behavior gap and engagement challenges with digital interventions [4,19-21,69].

Contrary to hypotheses, perceived stress was the only significant predictor of engagement in the regression model. Expectations for anxiety (positive) and readiness to change (positive) reached significance when modeling mental health as a single component. Higher stress may motivate behavioral change, reinforced by beliefs in meditation's efficacy for anxiety to manage acute stress. Our findings suggest that baseline characteristics, including stress, expectations, and readiness to change, predict initial meditation app use, implicating these factors in habit-building as well as drop-off.

Mental Health

As expected, measures of mental ill health, such as distress and perceived stress, were associated with lower engagement, while measures of positive mental health, such as satisfaction with life and well-being, were associated with greater engagement. Depression is related to low adherence to, and attrition from, meditation and health interventions [54]. This may reflect a broader message about the ability for people experiencing mental ill health to engage in meditation apps. People with significant psychological distress and psychoticism may disengage prematurely due to the increased likelihood of meditation-related adverse events [70]. Mental ill health also often reduces executive functioning, cognitive functioning, and affective functioning, which can interfere with one's ability to set goals or follow through on health-related goals or behaviors [71]. A reduction from normal functioning is itself a key criterion for many psychological disorders. This is not a new issue for engagement in mental health interventions but underscores that mental health difficulties hinder the meaningful engagement required to experience change. Having good mental well-being, on the other hand, may relate to greater energy, motivation, and self-efficacy when making behavior change, all of which are either further promoted and reinforced by consistent meditation app use. People scoring higher on well-being and satisfaction may also face less difficulty with the act of meditation, as they may have less difficulty dealing with negative thoughts or experience fewer negative thoughts overall [53].

While not mental health per se, consistent with this pattern, lower quality of life is associated with lower engagement. This means health issues in general may mean more difficulty in engaging, although barriers to health care motivate initial engagement [33]. Low quality of life may result in a lower capacity to self-regulate, plan, or cope with challenges [72].

The relationship between perceived stress shifted direction from negative (on its own) to positive (controlling for other variables),

XSL•FO
RenderX

suggesting that there may be a unique contribution of acute stress unrelated to mental health. The perceived stress scale potentially reflects different latent variables when presented on its own (acute stress) versus as part of a mental health component variable (chronic stress) [73]; therefore, controlling for mental health may remove shared variance related to chronic stress, leaving the remaining variance to reflect more acute experiences. While mental health and chronic stress may present a barrier to engagement [54,74], our most robust finding shows that higher perceived stress drives higher engagement. Meditation apps have shown preliminary efficacy for perceived stress [75], and population-level work shows that people may seek out meditation to address unmet needs in mental health [33].

Our nonclinical population reported high levels of perceived stress and psychological distress relative to normative samples. Individuals may have downloaded the meditation app as a step toward alleviating their distress but may have found it harder to engage with significant mental ill health or chronic stress, reflected in the negative relationship between the mental health component and engagement. Given the moderate effects of meditation apps on perceived stress [14], some level of perceived relief may be felt early, promoting further engagement. Preliminary evidence suggests one session of meditation may be enough to produce at least a temporary reduction in perceived stress [76].

Readiness and Expectations

Readiness to change accounted for the most unique variance and approached significance in the regression model, showing the strongest zero-order correlation with engagement. However, robust regression downweights outliers, which contribute to discrepancies between semipartial correlations and regression beta weights, may have reduced the contributions of readiness to change in the regression model (Table 5). Readiness was no longer significantly associated when controlling for other factors but significant with a single mental health component. When mental ill health and/or poor well-being were modeled as one component, variance potentially capturing desire to address life dissatisfaction and/or acute stress might then best be captured by readiness to change. The meaningful positive association of readiness to change is consistent with prior work showing that readiness to change is a central facet of behavior change [7,65] and that intrinsic motivation predicts subsequent behavior [32], and that intrinsic motivation predicts subsequent behavior [32].

Out of the expectations domains, only expectations for anxiety accounted for substantial unique variance and remained significant when modeling one mental health component. This may indicate that alleviating anxiety motivates app-based meditation and aligns with mental health as a common motivator for commencing meditation [6]. While it could not be included in the main regression model due to limited responses (n=221), expectation match showed the strongest correlation with engagement. This indicates that while expectations are important, users may discontinue practice if benefits are not observed or anxiety is potentially exacerbated [77], as app-based meditation shows smaller effect sizes for anxiety than depression or perceived stress [14,77]. In other words, expectations interact with experience to influence behavior.

Personality

Conscientiousness and neuroticism were both significantly associated with engagement but were not significant in the regression model. This is in contrast to prior work that suggests agreeableness, neuroticism, and openness are related to meditation engagement [43]. It is logical that conscientiousness would predict higher engagement, given that conscientious traits are focused on self-discipline [55]. Previously, longitudinal studies found that higher baseline conscientiousness predicts higher adherence to meditation, which in turn predicts higher stress reduction [78]. However, one might also logically expect openness to be important in trying a new habit. It may be that since buy-in for meditation apps is much lower than, for example, signing up for an extended in-person course, openness matters less than simply the diligence of continuing (ie, conscientiousness).

Neuroticism negatively predicting engagement is consistent with our finding that mental health factors are negatively associated with engagement and the mental health component negatively predicts engagement in the regression. Higher neuroticism, or the tendency to experience negative emotion, relates to a higher perception of barriers to meditation, likely due to the impact of rumination on self-efficacy, readiness, and the subjective experience of meditation [42,46,79]. Difficult or negative thoughts are common challenges in beginning meditation [48], and people high in neuroticism may face more negative thoughts or perceive these thoughts as more of an obstacle. Sitting with one's thoughts may be more difficult for those with a more negative predisposition. Neuroticism is distinct from low mood or mental ill health, as it reflects an overall underlying tendency to negativity; however, neuroticism is a strong predictor of mental ill health, as neuroticism exacerbates stress and interferes with coping [80]. However, interventions for mental health can modestly reduce neuroticism [81,82], suggesting that persistence has positive outcomes, although it is important to differentiate between challenges that are part of the learning process and harmful adverse events [56].

While the prior study by Khwaja et al [43] investigated meditation app use via self-report usage logs, and our previous survey used objective app data but retrospective factors, this study uses objective app engagement data with a larger sample, which may be more reliable. Personality may play a smaller role in engagement than perceived stress and readiness to change during relatively short periods of monitoring use.

Overall, people are commencing meditation app use when they believe the app is effective and are cognizant of their stress. The significance of the mental health component, readiness, expectations, and perceived stress suggests a connection between engagement and awareness of mental ill health and/or acute stress, making a conscious decision to address it and believing that the intervention will work.

Limitations

This study was limited by a reduced sample size with power to detect effects equivalent to r=0.177. While it is possible that

XSL•FO
RenderX

we were underpowered, it is notable that other meditation and mental health app engagement studies have observed larger effect sizes, suggesting that the true effects are smaller than what has been previously suggested [14,17,37,53]. Generalizability is limited, as the study focused on a single meditation app, although this is a common approach [19,20]. This ensured design and quality consistency but restricts applicability to other apps. Future work could compare engagement levels across apps.

A technical error in the recording of tracks completed occurred during the study period. No significant difference was found in the relationship between completed and started tracks. Nonetheless, the glitch may have introduced additional noise, affecting our ability to detect relationships. The inclusion of started tracks in the engagement variable could have partially accounted for unrecorded tracks, but without knowing the percentage of each track completed, engagement duration would remain unclear.

Our model only accounted for a small amount of variance (R^2=0.041, 4%), compared to 13% to 24% found in other behavior change studies [45,83]. This suggests key factors are missing. However, prior work largely relied on cross-sectional reports or recall, relating more to baseline or intended behavior rather than objective engagement level. Other studies examining out-of-class meditation practice predicted 21% variance [45]. Unconsidered factors may include app preferences, unconsidered demographic differences, psychological traits, or contextual variables. Predicting meditation may also be harder than other health-related behaviors due to less short-term tangible reinforcement, higher perceived effort, and the intentional nature of the behavior as opposed to the habitual or automatic nature of other behavior change. Future research could build on the current and preceding studies to further refine predictors and improve model power.

Future Directions

Future work could compare 30-day follow-up data with initial findings and detect whether changes over time predict engagement. This could explore differences between expectations and perceptions after initial versus ongoing use. A greater gap between baseline and follow-up ratings might suggest that exceeded expectations may promote engagement, whereas expectations not met or matched may have a lesser influence. Notably, however, steep discontinuation rates may necessitate large sample sizes to make such work possible. If only 10% to 20% of users are still actively engaged after 30 days, samples would need to be substantial to include a large enough proportion of continuing users.

Additionally, follow-up data may allow for mobile app ratings such as the user Mobile Application Rating Scale, which would provide clearer insights into users' app perceptions after 3 days of use. Digital therapeutic alliance or the relationship between the user and the digital intervention [84] and user Mobile Application Rating Scale [85] engagement (ie, appeal) merits further investigation as they have some of the strongest zero-order correlations with engagement [7].

Conclusions

This study reveals that half of new meditation app users disengage within the first 2 weeks of use, and the majority disengage by the end of 30 days. While most users plan daily engagement, they tend to complete only a single 10-minute session. Perceived stress is the strongest predictor of engagement, while mental health, readiness to change, and expectations for anxiety management show predictive use. While most users disengage, those who are under stress, do not have pronounced mental ill health, are motivated to make changes, and/or have reasonably high expectations that a meditation app can reduce anxiety are more likely to continue using the app. Given the growing role of meditation apps in public mental health [3,4], understanding the motivations and expectations of meditation app users at baseline provides valuable insight into how and why meditation apps are being used in nonclinical populations.

Abstract

Background: Mobile health (mHealth) technologies, including smartphone health apps and wearable trackers, are increasingly used to promote health behaviors. However, their impact on physical and mental well-being remains complex, with both benefits and potential unintended negative consequences.

Objective: This study aimed to examine the relationship between mHealth use (ie, health app and wearable tracker) and 2 health outcomes (BMI and emotional distress), as well as the mediating roles of healthy eating, sleep, and physical activity based on a representative sample.

Methods: We analyzed data from a nationally representative sample of US adults aged 33 to 43 years (N=1931). Chi-square tests and 1-way ANOVA were used to compare demographic differences between mHealth users and nonusers. A path model examined the relationship between mHealth use (ie, smartphone health apps and wearable trackers) and health outcomes (ie, BMI and emotional distress), with lifestyle factors (ie, healthy eating, physical activity, and sleep) as mediators. Mediation analyses tested indirect effects through these lifestyle factors.

Results: mHealth users were more likely to be female, married, have higher levels of education and income, and have health insurance. The primary use of mHealth was the management of physical activity. Smartphone health app use positively correlated with wearable tracker use (β=.394; *P*<.001). Smartphone health app use predicted greater BMI (β=.068; *P*=.006), whereas wearable tracker use did not significantly predict BMI. Smartphone health app use was unrelated to emotional distress, while wearable tracker use was associated with lower emotional distress (β=–.074; *P*=.003). Mediation analyses showed that physical activity negatively mediated the relationships between both types of mHealth use and health outcomes, indicating that mHealth users were more physically active, which was linked to lower BMI and emotional distress. Sleep hours mediated only the association between wearable tracker use and health outcomes, such that greater tracker use was related to fewer sleep hours, predicting higher BMI and emotional distress. Finally, healthy eating mediated only the associations between mHealth use and emotional distress, suggesting that healthier dietary behaviors among mHealth users contributed to lower emotional distress.

Conclusions: mHealth technologies can potentially promote healthier behaviors, but their effectiveness depends on users taking the initiative to sustain lifestyle changes. While wearable trackers may aid in mental well-being, their association with reduced sleep warrants further investigation.

KEYWORDS

mobile health; wearable trackers; eating; dietary; physical activity; sleep; emotional distress; body mass index

Introduction

Background

Mobile health (mHealth) technologies, including smartphone apps and wearable trackers, have become increasingly popular tools for managing personal health and wellness. Approximately half of the US population has at least 1 mHealth app on their mobile devices [1], and 21% of US adults regularly use a wearable tracker or smartwatch, a number that has increased due to the COVID-19 pandemic and the subsequently growing fitness culture [2]. While previous studies have highlighted socioeconomic disparities in mHealth adoption [3], these technologies continue to expand in popularity due to their convenience, personalized nature, and growing integration with health care systems [4,5]. Research increasingly supports mHealth's potential for managing health outcomes, such as weight management [6] and emotional regulation [7].

Despite the growing body of evidence, a significant gap remains: studies that aim to assess the effectiveness of mHealth technology either focus on behavioral lifestyle as the end

XSL•FO
RenderX

outcome or examine physical or mental health outcomes without exploring the underlying mechanism. It is critical to empirically investigate whether short-term behavioral changes induced by mHealth technology are linked to long-term health outcomes. Therefore, a more comprehensive analysis is needed to clarify the direct and indirect associations between mHealth use and health outcomes. By examining lifestyle factors such as diet, sleep, and physical activity as mediators, this study aims to provide deeper insights into the potential mechanisms driving these relationships. On the basis of a nationally representative sample of middle-aged US adults, this study explores the relationships between mHealth use (ie, health apps and wearables) and both physical and mental health outcomes (ie, BMI and emotional distress), while also examining the mediating roles of lifestyle factors (ie, diet, sleep, and physical activity).

mHealth Technology Use

Smartphone health apps and wearable trackers have seen increased adoption, with distinct demographic patterns among their users. Research shows that age and socioeconomic status play a critical role in mHealth adoption rates. For instance, these technologies are predominantly used by younger individuals with higher levels of education and income who come from more affluent households [8]. A gender difference also stands out in mHealth use, as research has found that women are 2.3 times more likely to use wearable health trackers, a trend further substantiated by data from the Pew Research Center [2,9].

Over a decade of research has reported that health apps and wearable trackers are used for various health purposes such as weight management, stress coping, substance use disorder recovery support, chronic condition monitoring, telemedicine support, and electronic medical records [10-13]. The types of health aspects managed through these technologies are expanding to lifestyle domains, including documenting dietary habits, monitoring physical activity, and tracking sleep patterns [14,15]. By providing real-time feedback, mHealth tools encourage users to reflect on their behaviors and make informed decisions, leading to better management of various health aspects.

mHealth and Weight Management

Weight management is a critical focus of mHealth technologies due to its profound implications for physical well-being. A systematic review found that mHealth technologies had a small but statistically significant effect on BMI reduction in children and adolescents [16]. While research supports the association between mHealth technology use and weight management, this relationship is likely mediated by lifestyle factors such as eating habits [17], sleep patterns [18], and physical activities [19,20]. For instance, app use is associated with healthy eating motives, decisions, and behaviors [21,22]. Wearable technologies further enhance self-monitoring by automatically detecting eating behaviors and tracking dietary intake [23,24]. Additionally, mHealth tools help reduce sedentary behavior and encourage physical activity [9]. A meta-analysis found that the use of activity trackers was associated with an average daily increase of 1800 steps, 40 minutes of walking, and 1 kg weight loss [25]. Sleep tracking is also designed as a key feature of mobile devices, aiming to improve sleep quality. Sleep-tracking features in mHealth tools enable users to identify patterns, address sleep issues, and access actionable insights that improve sleep and related health outcomes [26,27]. Evidence, although limited, shows wearable tracker use improves sleep quality among the health population [28].

mHealth and Emotional Distress

Previous research has shown that mHealth technologies can monitor mental health and alleviate emotional distress [29,30], with users reporting a greater sense of responsibility for their well-being and confidence in the accuracy of app-generated assessments [31]. Additional studies have suggested that engagement with mood-tracking apps can potentially improve users' ability to cope with unpleasant emotions and thoughts [32].

Additional studies suggest that lifestyle factors, especially physical activity and dietary habits, mediate these effects [33-36]. For example, a US national survey found that wearable users reported lower psychological distress, attributing this to longer workouts [37]. A randomized trial found that mindfulness app users, compared to nonusers, reported reduced emotional eating and stress levels, suggesting mHealth contributes to stress reduction by reducing emotional eating [38]. Additionally, mobile devices can track meal timing, location, and social context to encourage communal eating and reduce skipping meals, which correlates with elevated stress, anxiety, and depression [39]. Research on the mediating role of sleep in the relationship between mHealth use and emotional well-being remains limited. While one study suggests that sleep app use is positively associated with perceived well-being [40], it remains unclear whether actual sleep serves as a mediating factor in this process.

Taken together, the literature provides consistent evidence for meaningful relationships between mHealth and health (ie, BMI and emotional distress), as well as how lifestyle behaviors might play roles in such relationships. Detangling the lifestyle mechanisms will inform strategies for optimizing mHealth tools to improve overall health and guide future interventions. In tackling the gaps, we posed four hypotheses (H): (1) H1: the use of (a) smartphone health apps and (b) wearable trackers is associated with lower BMI; (2) H2: the use of (a) smartphone health apps and (b) wearable trackers is associated with lower emotional distress; (3) H3: healthy eating, sleep hours, and physical activities mediate the relationships between (a) the use of smartphone health apps and BMI and (b) the use of wearable trackers and BMI; and (4) H4: healthy eating, sleep hours, and physical activities mediate the relationships between (a) the use of smartphone health apps and emotional distress and (b) the use of wearable trackers and emotional distress.

Methods

Participants

Data were retrieved from the National Longitudinal Study of Adolescent to Adult Health (Add Health), a 5-wave nationally representative sample of adolescents' health and health-related behaviors in the United States. Add Health uses a complex,

XSL•FO
RenderX

stratified, and cluster sampling design [41]. More than 20,000 adolescents in grades 7 to 12 (aged 12 - 19 years) from more than 80 high schools and 52 feeder middle schools were interviewed at school and home in wave I (1994-1995). The participants' backgrounds were diverse in terms of locations, school types, regions, and ethnicities. Participants were followed up in 1996 (wave II; aged 13 - 20 years), 2001 to 2002 (wave III; aged 18 - 26 years), 2008 (wave IV; aged 24 - 32 years), and 2016 to 2018 (wave V; aged 33 - 43 years).

Ethical Considerations

Permission to conduct a secondary analysis was approved by Kean University's Institutional Review Board. The original consent and institutional review board authorization included provisions for secondary data analyses; thus, additional consent was not required. In this study, we conducted analyses using the deidentified public-use data from wave V of the full Add Health sample (2016 - 2018). The final analytic sample consisted of 1931 participants who provided valid responses to health technology questions.

Measures

Smartphone Health App Use

Participants indicated whether they used smartphone apps to track or manage their health. Responses were coded as 1 for "yes" and 0 for "no."

Wearable Tracker Use

Participants reported whether they had ever used a fitness or activity tracker. Responses were coded as 1 for "yes" and 0 for "no."

Healthy Eating

Participants reported the frequency of (1) consuming food from fast-food restaurants and (2) drinking nondiet sweetened beverages over the past 7 days. The frequencies were summed and reverse-coded so that higher scores indicated healthier eating behaviors.

Sleep Hours

Participants reported their average number of sleep hours per day/night.

Physical Activity

Participants reported how often they engaged in various physical activities (eg, biking, weightlifting, swimming, and golfing) over the past 7 days. These frequencies were summed to create a composite physical activity score such that higher scores indicate a higher level of physical activity.

BMI

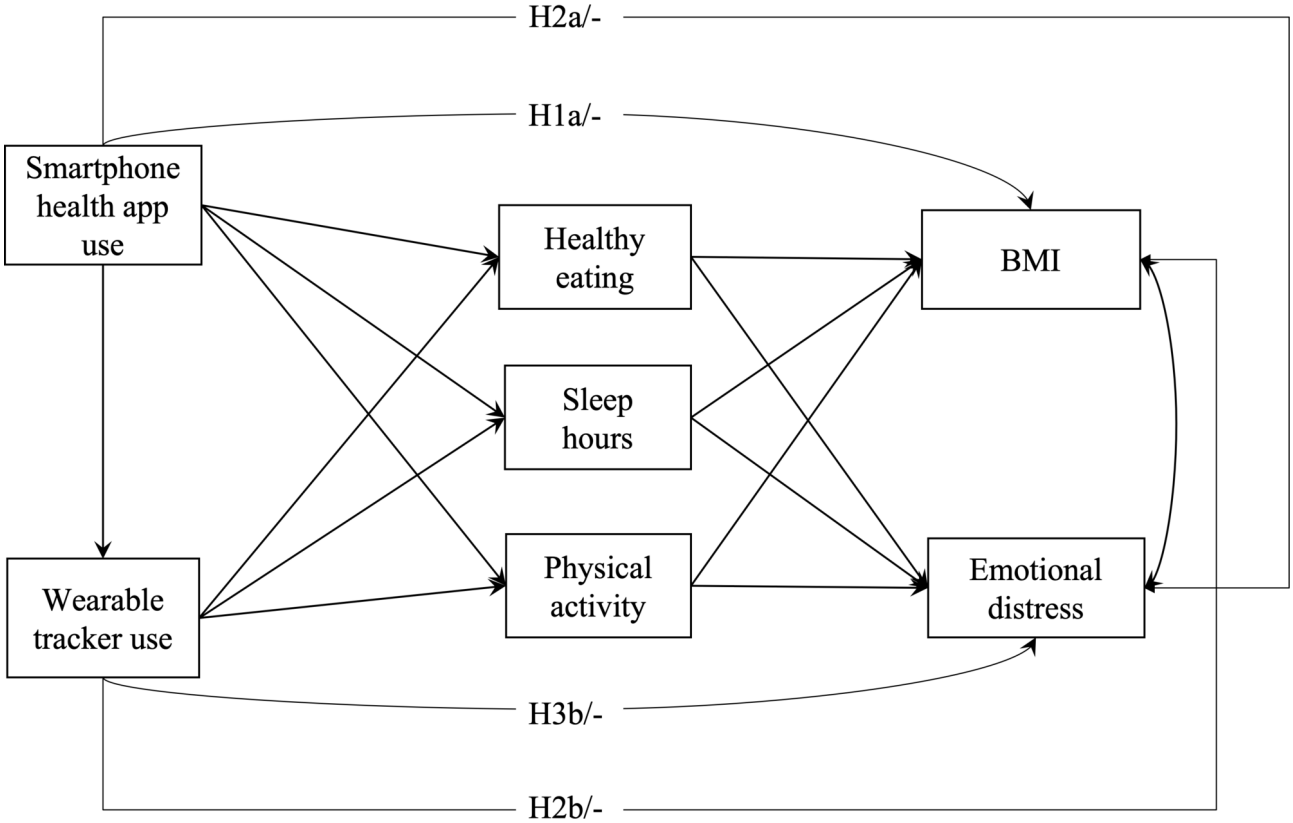
BMI was calculated based on participants' self-reported height and weight, following the formula BMI=weight (in kilograms)/height (in meters)^2 [42].

Emotional Distress

Emotional distress was measured using a set of items assessing participants' feelings over the past 7 days. Participants indicated how often each of the following statements was true for them on a 4-point Likert scale: (1) "I felt that I could not shake off the blues, even with help from my family and friends," (2) "I felt depressed," (3) "I was happy" (reverse-coded), (4) "I felt sad," and (5) "I felt that life was not worth living." Responses were scored on a scale ranging from 1="Never or rarely" to 4="Most of the time or all of the time." A composite score was calculated, with higher scores indicating greater emotional distress (α=.82).

Covariates

Participants' age at survey completion, biological sex, education, household income, race, and ethnicity were included as covariates in all analyses.



Analytic Approach

We used R (R Foundation for Statistical Computing) to perform all analyses. The "tableone" package was used to provide descriptive statistics and perform statistical comparisons between users and nonusers of mHealth [43]. More specifically, chi-square tests were performed on categorical variables, and 1-way ANOVA was used for continuous variables to compare differences.

To test the hypotheses, path analysis was performed using "lavaan" package [44]. The hypothesized paths are depicted in Figure 1. In the model, mobile technology use variables (ie, smartphone health app use and wearable tracker use) were specified as predictors of health outcomes (ie, BMI and emotional distress), with 3 lifestyle variables (ie, healthy eating, sleep hours, and physical activity) included as mediators. Mediation analyses were conducted to assess the indirect effects of mobile technology use on health outcomes through lifestyle mediators. All path coefficients were estimated using maximum likelihood with robust SEs to address nonnormality, and full information maximum likelihood estimation was used to handle missing data. Indirect effects were assessed using bias-corrected bootstrapped 95% CIs based on 5000 resamples. Age, sex, education, household income, race, and ethnicity were controlled for as covariates.

Figure 1. Hypothesized paths testing the relationship among mobile technology use, lifestyle mediators, and health outcomes. Note: H1: the use of (a) smartphone health apps and (b) wearable trackers is associated with lower BMI; H2: the use of (a) smartphone health apps and (b) wearable trackers is associated with lower emotional distress; H3: healthy eating, sleep hours, and physical activities mediate the relationships between (a) the use of smartphone health apps and BMI and (b) the use of wearable trackers and BMI; H4: healthy eating, sleep hours, and physical activities mediate the relationships between (a) the use of smartphone health apps and emotional distress and (b) the use of wearable trackers and emotional distress. H3 and H4 hypothesize that healthy eating, sleep hours, and physical activity mediate the relationship between mobile health use (smartphone health app use and wearable tracker use) and health outcomes (BMI and emotional distress).

As the public-use version of Add Health Wave V does not include design variables (weights, primary sampling units, or strata), all analyses were conducted without applying survey design variables. Given that the primary objective was to examine internal associations rather than to produce nationally representative estimates, unweighted path analyses were deemed appropriate, and the findings should be interpreted accordingly [45].

Results

Descriptives

Our analysis, based on a nationally representative sample, revealed distinct demographic trends among smartphone health app users and wearable tracker users. Specifically, smartphone health app users and wearable tracker users share the following characteristics in common: they are more likely to be female, married, have higher levels of education and income, and possess health insurance, compared with their nonuser counterparts. In addition, smartphone health app users are more likely to be younger, identify as liberal, and have 1 or no children compared to nonusers. Wearable tracker users are more likely to own the place where they live compared to their nonuser counterparts. Detailed participants' characteristics can be found in Table 1.

Participants use smartphones to manage a range of personal health aspects, with physical activity (714/842, 84.8%) being the most common, followed by diet management (399/838, 47.6%) and other aspects (Table 2). Female users (534/851, 62.7%) also reported using smartphones for menstrual cycle tracking (182/534, 34.1%) and pregnancy tracking (57/534, 11%). See Table 2 for the full list of health management aspects. Descriptive statistics and a correlation matrix for endogenous variables in the path model were reported in Table 3.

[b]*P*<.001.

Path Model (H1 and H2)

The final path model demonstrated a good fit with the data (χ^2_1=0.9, *P*=.02; root mean square error of approximation=0.048, 90% CI 0.02-0.09; comparative fit index=0.998; standardized root mean square residual=0.005). Results showed that the use of smartphone health apps positively predicted the use of wearable trackers (β=.394; *P*<.001). The use of smartphone health apps predicted higher BMI (β=.068; *P*=.006); thus, H1a was not supported. However, the use of wearable trackers did not significantly predict BMI (β=.047; *P*=.05); thus, H1b was also not supported. Results showed that the use of smartphone health apps did not predict emotional distress (β=−.016; *P*=.49), while the use of wearable trackers significantly predicted lower emotional distress (β=−.074; *P*=.003); thus, H2a was not supported, while H2b was supported. See Figure 2 for the full path model.

XSL•FO
RenderX

Figure 2. Path model: the relationships among mobile health (smartphone health app use, wearable tracker use), lifestyle mediators (healthy eating, sleep hours, and physical activity), BMI, and emotional distress. Note: solid lines indicate that the path coefficients were significantly different from 0, whereas path coefficients that were not significantly different from 0 were removed for presentation simplicity. Covariates controlled include age, sex, education, household income, race, and ethnicity. Unweighted n=1786. *P<.05, **P<.01, ***P<.001.

Mediation Analyses (H3 and H4)

Table 4 presents the indirect path coefficients from the mediation analyses to examine H3 and H4. To summarize the pattern, physical activity negatively mediated the associations between both types of mHealth use (health app and wearable tracker) and health outcomes (BMI and emotional distress). Nevertheless, sleep hours positively mediated only the relationship between wearable tracker use and health outcomes. Finally, healthy eating negatively mediated only the associations between both types of mHealth use and emotional distress.

Discussion

Principal Results

This study, based on a nationally representative sample of adults in their late 30s to early 40s, found that mHealth users are more likely to be female, married, and of higher socioeconomic status. These users primarily engage with mobile technologies for tracking physical activity, followed by a range of other personal health aspects. Overall, our findings reveal a nuanced relationship between mHealth use and health outcomes: contrary to expectations, the use of smartphone health apps was associated with higher BMI, and the use of wearable trackers did not significantly predict BMI. However, the use of wearable trackers, not smartphone health apps, was linked to lower emotional distress. Mediation analyses further highlighted the complex mechanisms underlying these associations. Physical activity negatively mediated the relationships between both types of mHealth use and adverse health outcomes. This indicates that mHealth users were more likely to engage in physical activities, which predicted lower BMI and less emotional distress. Sleep hours mediated only the association between wearable tracker use and both health outcomes. This suggests that wearable tracker use was associated with fewer sleep hours, which predicted higher BMI and greater emotional distress. Finally, healthy eating mediated only the relationship between mHealth use and emotional distress. This suggests that mHealth users were more likely to adopt healthy dietary change, which was related to lower emotional distress.

Comparison With Prior Work

Our findings regarding mHealth use and BMI highlight the mediating role played by lifestyle factors in shaping physical health. Aligned with previous studies, on a positive note, individuals who used smartphones or wearables for health management reported engaging in increased physical activity [9,25], which was associated with lower BMI [17,19,20]. This finding supports the idea that mHealth technologies can potentially serve as effective tools for promoting lifestyle changes that lead to successful weight control. However, while these apps provide valuable information and motivation, their potential effectiveness depends on users taking actionable steps toward improving their health. It is possible that some individuals rely on health apps for tracking or goal setting but struggle with adherence to recommended behaviors, resulting in limited or even counterproductive health outcomes [46]. It is worth noting that the positive direct association between smartphone health app use and BMI can be interpreted in the other way around; people who are of higher BMI tend to use

XSL•FO
RenderX

health apps more because they see the need [47]. Future research should explore the psychological and behavioral mechanisms underlying this association.

The relationship between mHealth use and emotional distress also reveals important implications. Using wearable trackers is directly and indirectly associated with lower emotional distress, supporting their potential for mental health intervention [29,31,37]. While smartphone health app use did not show a direct connection to emotional distress, healthy eating and physical activity emerged as key mediators [37-39]. This finding underscores the importance of promoting both a healthy diet and physical activity for emotional well-being rather than relying solely on physical activity [21,33,39]. Future mHealth interventions could enhance their impact by incorporating personalized dietary and workout recommendations to better support emotional well-being.

Finally, an unexpected yet important finding is that wearable tracker use is negatively associated with sleep, which, in turn, is linked to both higher BMI and emotional distress. While our data support the well-established link between sleep and BMI [18], as well as sleep and emotional distress [34,35], they did not provide evidence that mHealth tools designed to improve sleep actually increase the absolute number of sleep hours. This may explain the limited evidence we found regarding the effectiveness of mHealth tools in improving sleep. Even in 1 study that reported wearable tracker use as positively associated with improved sleep, the focus was on perceived sleep quality rather than sleep duration [28]. Additionally, another study cited found that individuals using the wearable tracker had higher levels of well-being before than after its use [40].

There were several speculations on why sleep plays such an alarming mediating role in the relationship between wearable tracker use and health. While wearable devices provide valuable insights into sleep patterns, some users may develop a reliance on these tools, leading to obsessive tendencies where self-worth becomes tied to achieving predefined health metrics, potentially exacerbating emotional distress [37]. Misinterpretation of health data or false alarms may also contribute to heightened anxiety [37], and frequent notifications from these devices can also create a sense of urgency or fear as users may associate them with potential health concerns [48]. Notably, only the use of wearable trackers red-flagged this pattern, while smartphone health app use does not correlate with sleep. This raises the question of whether wearing a physical device itself might cause some sleep disturbances [26]. However, our results do not establish causality; it is also possible that individuals who already experience sleep deprivation and struggle with physical and mental health issues turn to wearable trackers for assistance. Future research is needed to explore these dynamics in greater depth and consider using a tracker to objectively measure sleep or consider sleep quality rather than mere quantity.

Practical Implications

The findings from this study offer several key implications for the design, development, and implementation of mHealth technologies. First, mHealth designers should prioritize integrating behavioral support features that guide users from self-monitoring to sustained lifestyle changes, given that simply using a smartphone health app without following corresponding lifestyle guidance may be associated with counterproductive outcomes. Health care providers and public health professionals should also avoid an overemphasis on outcome-oriented obsessive-tracking behaviors. Second, mHealth holds promise for mental health intervention, and mHealth solutions could incorporate evidence-based dietary and physical activity programs to further enhance emotional resilience and mental health benefits. Finally, developers should prioritize user-centered design approaches that minimize sleep disruption, such as optimizing comfort, reducing unnecessary notifications, and providing clearer guidance on interpreting sleep data. By addressing these challenges, mHealth technologies can be better optimized to support long-term health benefits while mitigating potential downsides, ultimately improving both physical and emotional well-being among users.

Limitations

There are several limitations of this study. First, measurement limitations should be acknowledged. For example, the healthy eating measure captures only a subset of dietary behaviors and does not reflect broader aspects of diet quality, the physical activity measure combines frequencies of heterogeneous activities without accounting for intensity, and the sleep variable measures only duration and does not capture quality, disturbances, or restorative aspects of sleep. And the reliance on self-reports may be subject to recall, response, and social desirability biases. Future research could use more comprehensive instruments, include validated indices of behavioral constructs, and incorporate objective health metrics (eg, biometrics from wearables) to enhance data reliability. Second, while this study identifies associations between mHealth use and health outcomes, causal relationships cannot be inferred. Longitudinal studies or experimental designs would provide stronger evidence of causality. Finally, given the growing diversity of mHealth apps, future research should explore how specific app features (eg, gamification and artificial intelligence–driven recommendations) influence user engagement and health behaviors.

Conclusions

This study underscores the potential of mHealth technologies to improve health outcomes through their influence on lifestyle behaviors. However, their impact is not uniform, and unintended negative consequences such as reduced sleep from wearable tracker use warrant further investigation. By addressing these challenges, mHealth technologies can better fulfill their promise of supporting individuals in achieving healthier lifestyles and advancing population health.

Abstract

Background: Mindfulness-based stress reduction (MBSR) is recommended as a noninvasive, evidence-based treatment for chronic low back pain (CLBP); however, access and uptake are often constrained among medically underserved populations. Telehealth-delivered MBSR may scale access, yet little is known about the characteristics of underserved patients who have experience using telehealth and are willing to enroll in pragmatic trials evaluating MBSR.

Objective: This study examined individual- and county-level social vulnerability characteristics associated with telehealth use experience among people living with CLBP who enrolled in OPTIMUM (Optimizing Pain Treatment in Medical Settings Using Mindfulness), a pragmatic randomized clinical trial of telehealth-delivered MBSR.

Methods: We conducted a cross-sectional analysis of baseline measures from the OPTIMUM trial, focusing on participants from a safety-net health institution and a federally qualified health center. The primary outcome was telehealth use experience (having had a prior telehealth visit at or before enrollment). Guided by Andersen's Behavioral Model of Health Services Use, we evaluated predisposing, enabling, and need factors. Prespecified measures included the following: demographics; employment and education; internet access and comfort using Zoom; neighborhood indices (Area Deprivation Index [ADI], Social Vulnerability Index [SVI]); rurality; back-pain duration; and validated patient-reported outcomes. Multivariable logistic regression was used to estimate adjusted odds ratios (AORs) and 95% CIs.

Results: Of 244 enrolled participants (mean age 50.6, SD 13.5 y; n=162, 66.7% female; n=124, 50.8% non-Hispanic Black), 174 (71.3%) reported previous telehealth use. Predisposing factors associated with lower telehealth use included race or ethnicity (non-Hispanic Black: AOR 0.38, 95% CI 0.2 - 0.8; Hispanic: AOR 0.21, 95% CI 0.06 - 0.7) and part-time employment (AOR 0.33, 95% CI 0.1 - 0.9) vs full-time employment, whereas educational attainment above or below a high school degree was associated with higher odds of telehealth use (AORs 2.7 - 3.2). Enabling factors showed that lower comfort with Zoom was associated with lower telehealth use (AOR 0.5, 95% CI 0.2 - 0.9), whereas home internet access was common and not independently significant in adjusted models. Neighborhood socioeconomic disadvantages, social vulnerability, and rurality did not demonstrate significant associations. Needs factors indicated that longer CLBP duration was positively associated with telehealth experience (>5 y: AOR 3.5, 95% CI 1.4 - 8.8). Other patient-reported outcomes, comorbidity burden, and surgical history were not significantly associated.

Conclusions: In a safety-net and federally qualified health center context, prior telehealth experience was common among patients with CLBP willing to enroll in a telehealth-delivered MBSR trial. Although certain predisposing factors (race or ethnicity, employment status) were associated with lower odds of telehealth experience, these factors did not prevent trial enrollment. Targeted outreach to improve digital comfort and inclusive engagement strategies may further reduce disparities and support broader implementation of telehealth for CLBP.

KEYWORDS

telehealth; mindfulness-based stress reduction; low back pain; safety net; pragmatic trial; digital literacy; social determinants of health

Introduction

Chronic low back pain (CLBP) is a costly problem that results in US $100 to 200 billion per year in expenditures [1,2]. Many medical approaches used to treat CLBP are associated with adverse events and negative side effects [3,4]. Current treatment guidelines therefore recommend evidence-based, noninvasive approaches as first-line treatments for CLBP [5,6]. Mindfulness-based stress reduction (MBSR) is a recommended evidence-based treatment that focuses on increasing participants' awareness and acceptance of moment-to-moment experiences, including physical discomfort and difficult emotions [7]. Prior research has found that medically underserved populations have an increased prevalence of chronic pain, less access to pain care, and poorer outcomes [8-11]. Telehealth-delivered MBSR offers a low-risk, effective, and viable alternative to conventional in-person delivery for patients with CLBP [12].

Telehealth refers to the use of electronic information and telecommunications (eg, videoconferencing) to provide clinical services [13]. Although prior to the COVID-19 pandemic, telehealth equipment was available, there was low usage due to a myriad of factors related to billing practices, patient and physician comfort, and familiarity with using the technology [14,15]. Use of telehealth leading up to the COVID-19 pandemic was more likely to be used by affluent, privately insured populations [16]. The COVID-19 pandemic created a unique and sudden need for virtual health visits for both urgent and nonurgent health visits, leading to an unprecedented expansion of telehealth access among underserved populations [17-19]. Expanded telehealth accessibility enhanced the potential to scale MBSR treatment to underserved populations.

In 2021, we launched OPTIMUM (Optimizing Pain Treatment In Medical Settings Using Mindfulness), a pragmatic randomized clinical trial comparing MBSR with usual care within primary care clinics for patients with CLBP at a safety-net hospital, federally qualified health centers, and a large academic health system. The COVID-19 pandemic created an urgent need for non–face-to-face care, prompting the conversion of MBSR from in-person to telehealth-delivered MBSR. While telehealth may improve access to MBSR, little data existed regarding how attractive this treatment would be to patients at safety net hospitals and federally qualified health centers. Safety-net hospitals and federally qualified health centers provide essential inpatient and outpatient services to low-income, uninsured people residing in rural areas and people with limited access to health care, that is, medically underserved populations [20].

Given the disparities and emerging telehealth opportunities, this study aimed to explore the impact of prior telehealth use on enrollment in the OPTIMUM trial. Therefore, the purpose of the study was to examine the individual- and county-level social vulnerability characteristics of people living with CLBP who were willing to enroll in OPTIMUM, a telehealth-delivered MBSR randomized pragmatic trial.

Methods

Theoretical Framework

Andersen's Behavioral Model of Health Services Use has been widely used to analyze factors associated with health service use. The results suggest that health service usage is primarily motivated by individual illness, but the quality and quantity of health service usage vary significantly based on socioeconomic factors, such as income or health-insurance status [21-23]. The model posits 3 dimensions: predisposing factors (eg, age, education), enabling factors (eg, income, hospital density), and need factors (eg, health status) that influence health care usage [24-26]. Examining these dimensions may also be a suitable model when exploratory research is needed due to lack of previous studies on telehealth use among underserved patients with CLBP, as in this study.

Study Design and Setting

This cross-sectional analysis was conducted on the baseline study measures data from the OPTIMUM trial, a multisite pragmatic randomized trial of telehealth-delivered MBSR for patients with CLBP. Data collection occurred between April 2021 and August 2023, with 12-month outcome data collection completed in November 2024. All variables were collected upon enrollment. OPTIMUM was embedded into primary care clinics at 3 health systems (Boston Medical Center, Massachusetts; University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania; and Piedmont Health Services, in partnership with the University of North Carolina [UNC] Chapel Hill). The 3 health systems serve predominantly underserved patients: Boston Medical Center is a safety-net institution serving an urban, low-income, racially and ethnically diverse population. UNC Chapel Hill has 2 sites: an academic center–based family medicine clinic and a federally qualified health center network serving many rural patients and those underrepresented in research. The University of Pittsburgh serves an urban or suburban population. Because we were interested in the factors involved in telehealth use experience for underserved populations, we restricted our analysis to the baseline measurements of participants from the safety-net health setting (Boston Medical Center) and the federally qualified health centers (UNC at Chapel Hill, Piedmont Health Services).

XSL•FO
RenderX

Recruitment

Research staff at each participating clinic approached potentially eligible patients during clinic visits, through telephone outreach, or via clinician referrals. Staff verified eligibility, provided study information, and obtained informed consent. Participants were screened to ensure they met inclusion criteria: age ≥18 years, diagnosis of CLBP, willing and able to provide telephone informed consent, able to speak and read English, absence of markers suggesting a serious condition, and a Pain, Enjoyment of Life and General Activity (PEG) scale score ≥3. Participants were excluded if they had an unexplained fever or weight loss, pregnancy, metastatic cancer, or cohabitation with another study participant.

Participants of the OPTIMUM Study

Patients who met eligibility criteria were randomly assigned to medical group visits plus 90-minute, instructor-led MBSR treatment for 8 consecutive weeks via telehealth or to usual care alone. At the beginning of the MBSR session, for approximately 30 minutes, the primary care provider met briefly and privately with each participant through a telehealth visit (in a breakout room in the HIPAA [Health Insurance Portability and Accountability Act] compliant Zoom platform) to review medical aspects of treatment, focused specifically on the patient's back pain. Participants were administered several measures at baseline, 8-week, 6-month, and the 12-month follow-up [27]. Further information about OPTIMUM is published elsewhere [27].

Because this analysis focused on understanding telehealth use experience among underserved populations, we restricted the analytic sample to participants enrolled from Boston Medical Center (safety-net setting) and UNC or Piedmont Health Services (federally qualified health centers).

Outcome

Our outcome of interest in this paper was telehealth use experience as measured at enrollment, that is, telehealth use experience. Telehealth use experience includes the use of telehealth prior to or during the COVID-19 pandemic.

Predictor Variables

The online baseline data included measures of demographics, back-related pain, treatments, the impact of pain on quality of life, pain beliefs, medical history, health habits, and traumatic experiences. Dimensions of Andersen's Behavioral Model of Health Services Use and variables are as follows:

1. Predisposing factors: Age in 2021, sex, race or ethnicity, educational level, marital status, employment status, and health beliefs or psychological predispositions (Pain Catastrophizing Questionnaire [28], CAMS-R [Cognitive and Affective Mindfulness Scale-Revised] [29])
2. Enabling factors: Annual income, access to internet at home, comfort levels with Zoom or virtual meetings (confidence in their ability to use the platform), Area Deprivation Index (ADI), Social Vulnerability Index (SVI; both SVI and ADI are well-established indices that have been used to assess socioeconomic disadvantage and vulnerability [30,31]), and rural-urban commuting area
3. Needs factors: Number of years with low back pain; receiving disability or workers' compensation due to low back pain or unemployed for 1 month or more due to low back pain [32]; Charlson Comorbidity Index [33]; number of low back surgeries; PROMIS-29 (Patient-Reported Outcomes Measurement Information System-29) domains, including sleep disturbance, fatigue, physical function, pain interference, ability to participate in social roles or activities, cognitive function, anxiety, and depression [34]; pain impact score; PEG [35]; TAPS (tobacco, alcohol, prescription medication, and other substance use) [36]

Statistical Analyses

This study is reported in accordance with the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) guidelines (Checklist 1) [37] for cross-sectional studies. For descriptive analysis, we assessed the characteristics based on telehealth use experience (had previous telehealth visit or never had telehealth visit). Chi-square or Fisher exact tests were used for categorical variables, and Wilcoxon rank-sum tests were used for continuous variables.

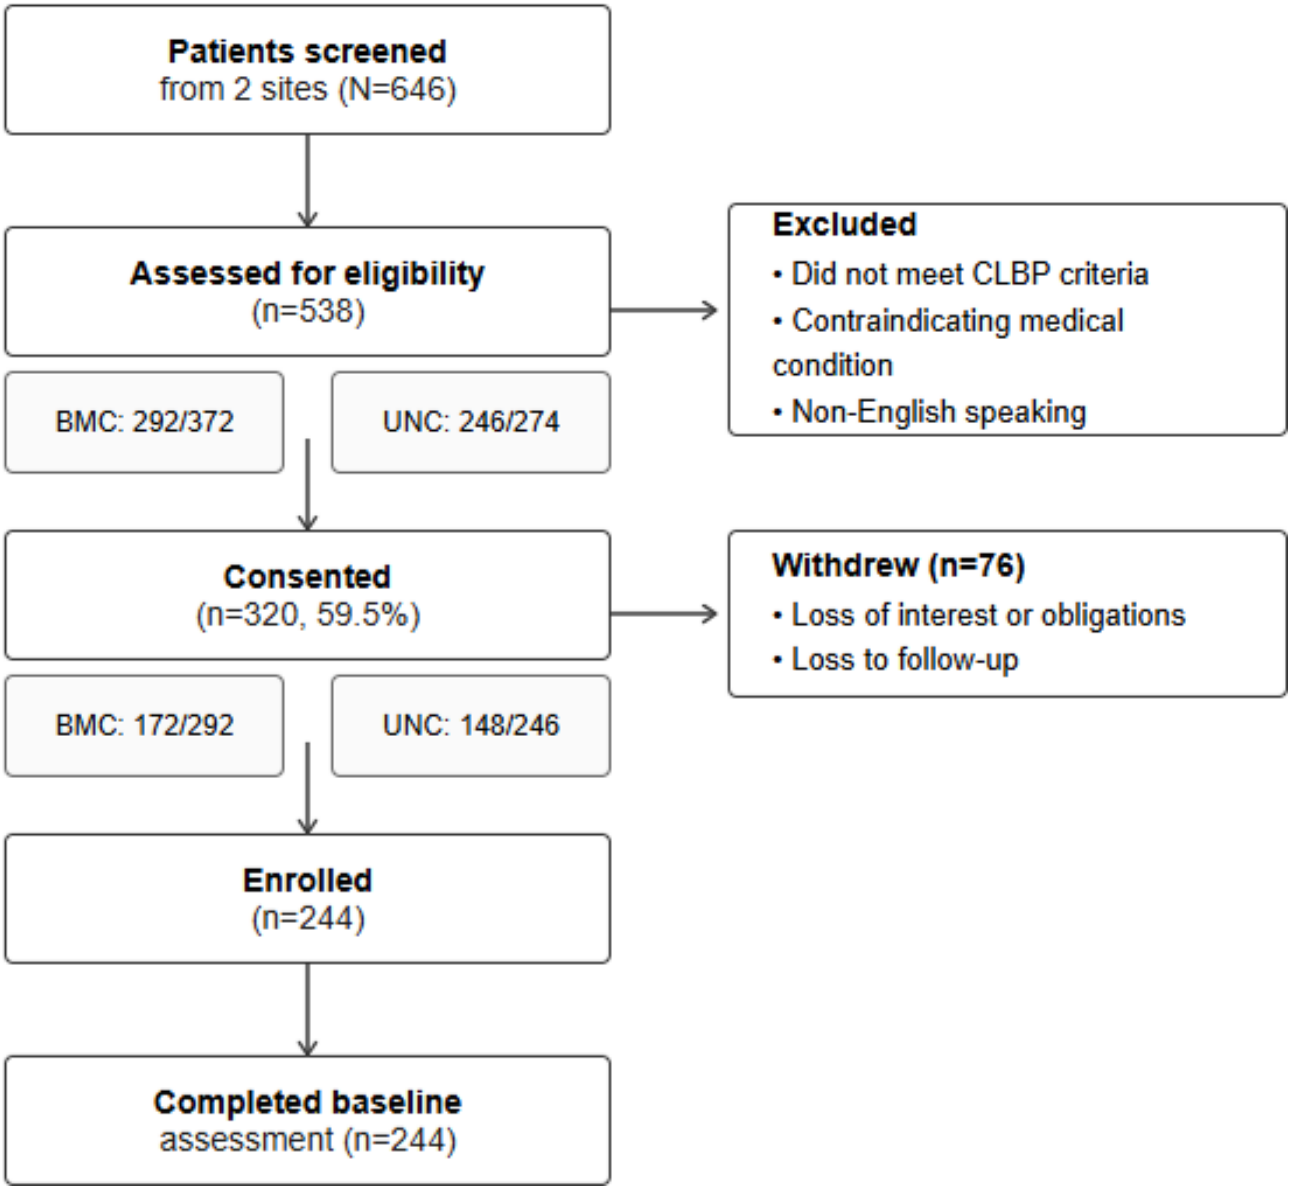
Missing data were minimal (<5% for most variables). The low level of missingness did not warrant multiple imputation, which would have been unlikely to materially change the results. For continuous variables, histograms and Q-Q plots were used to assess normality. Nonnormally distributed variables were analyzed using nonparametric tests (Wilcoxon rank-sum). Categorical variables were analyzed using chi-square or Fisher exact tests depending on cell counts.

Bivariate analyses served as a screening step for multivariable modeling. A liberal threshold (α=.10) was used to avoid excluding potential predictors. Multivariable logistic regression retained variables with P<.05 in unadjusted models. Formal multiple-comparison correction was not applied because the primary goal was to build an adjusted model to identify factors associated with telehealth use experience, rather than to conduct multiple independent hypothesis tests.

The analytic sample was determined by available baseline data from the safety-net and federally qualified health center sites. These sites were selected based on the study objective of understanding telehealth use among underserved populations; thus, sample size was dictated by enrolled participants meeting eligibility criteria within these settings. We report both unadjusted odds ratios (ORs) and adjusted odds ratios (AORs) and 95% CIs as applicable. All analyses were conducted in SAS (version 9.4) with P<.05 considered statistically significant unless otherwise specified.

Ethical Considerations

All study procedures were approved by the single Institutional Review Board at the University of Pittsburgh (STUDY20110378). All participants provided informed consent before the study and agreed to the use of their data for research purposes, including secondary analyses. Participation in the OPTIMUM study was voluntary, and participants could decline without consequences. To protect participants' privacy and confidentiality, only anonymized data were used for this analysis, and results are reported in aggregate so that no



XSL•FO
RenderX

individual participant can be identified. Participants were compensated US $30 for completing study measures administered at baseline and follow-up.

Results

Out of 646 patients with CLBP from the safety-net health setting (Boston Medical Center) and the federally qualified health centers (UNC at Chapel Hill, Piedmont Health Services), 538 were assessed for eligibility, of whom 320 (59.5%) were eligible and consented. Of the 320 patients who consented, 244 completed baseline measures. Among those who initially enrolled but later withdrew, reasons included loss of interest, work or family obligations, or loss to follow-up. Patients who declined or were excluded were typically ineligible due to not meeting CLBP criteria, having contraindicated medical conditions, or being unable to complete consent in English (Figure 1). Analytic sample sizes were as follows: race or ethnicity (n=238), employment status (n=243), internet access (n=240), comfort with Zoom (n=241), and sex at birth (n=243). We performed a complete case analysis for multivariable modeling, yielding a final sample of 233.

Figure 1. Participant flow diagram. CLBP: chronic low back pain; BMC: Boston Medical Center; UNC: University of North Carolina.

Several factors were associated with having telehealth use experience. *Predisposing factors* such as race or ethnicity and employment status showed significant differences. Non-Hispanic White participants had the highest telehealth uptake at 84.1% (58/69), while Hispanic participants had the lowest at 56.5% (13/23; Table 1). In both the unadjusted and adjusted models (Tables 2 and 3), non-Hispanic Black participants had lower odds of telehealth use (OR 0.38, 95% CI 0.2 - 0.8). Hispanic participants also had lower odds in both models, with an unadjusted OR of 0.25 (95% CI 0.09 - 0.7) and an AOR of 0.21 (95% CI 0.06 - 0.7). Employment status was significantly associated with telehealth use experience (P=.03). Those who were employed part-time were less likely to have used telehealth (AOR 0.33, 95% CI 0.1 - 0.9) in the adjusted model compared to those who worked full-time. Education demonstrated a positive trend, ranging from 62.3% (71/114) among those with a high school degree to 85.7% (12/14) among those with doctoral education, but the overall P=.07 was not significant.

XSL•FO
RenderX

The pain catastrophizing questionnaire and CAMS-R were not significant (P=.40 and P=.87, respectively). Age, sex, and marital status were not significant predictors in the adjusted model (Table 3).

Comfort levels with Zoom or virtual meeting (reference: high comfort level)		
Low comfort level	0.5 (0.2 - 0.9)	.04[b]

[a]OR: odds ratio.

[b]Statistically significant at *P*<.05.

Among *enabling factors*, access and comfort with technology were strongly associated with telehealth use. Participants who had internet at home and had the ability to use Zoom had a telehealth usage rate of 72.8% compared to 41.7% among those without access (*P*=.04). Comfort with Zoom ranged from "not at all" 39.1% (9/23), to "quite a bit" 83.6% (56/67), to "very much" comfortable 72.2% (78/108); lower comfort levels were associated with lower odds of telehealth use experience (AOR 0.5, 95% CI 0.2 - 0.9). Most of the sample, 169 of 236 (71.6%) participants, were in the low ADI (≤50) national percentile block group, indicating neighborhoods with lower levels of socioeconomic disadvantage. The mean SVI score was 0.7 (SD 0.3), indicating a moderate-to-high level of vulnerability. See Multimedia Appendix 1 for ADI and SVI quartiles, quintiles, mean scores, and specific cutoff points (ie, >50th percentile vs <50th percentile). Overall, annual income, ADI, SVI, and rurality (metro vs nonmetro or rural) were not significant factors associated with telehealth use experience in both the unadjusted and the adjusted models.

Among *needs factors*, years with back pain strongly predicted telehealth use experience: 51.5% (35/68) among those with less than 5 years, 76.5% (88/115) among those with 5 to 15 years, and 83.6% among those with more than 15 years of pain (*P*<.001). In the adjusted model, more than 5 years of pain was associated with higher odds of telehealth use experience (AOR 3.5, 95% CI 1.4 - 8.8). Having received or applying for disability or workers' compensation benefits due to low back pain was not a significant factor in telehealth use. Other need indicators such as PEG, pain impact score, PROMIS-29 domains (sleep disturbance, fatigue, physical function, pain interference, ability to participate in social roles or activities, cognitive function, anxiety, and depression), comorbidity index, and lower back operations were not significantly associated with telehealth use experience.

Discussion

Principal Findings

This cross-sectional analysis examined the individual- and county-level social vulnerability characteristics of those who had and those who never had a telehealth visit at enrollment among participants from a safety-net hospital and a network of federally qualified health centers in the OPTIMUM trial. We found that 174 of 244 (71.3%) participants had prior experience with telehealth. While a large portion of our sample had previously used telehealth, there were many who had not, thus indicating that while telehealth may be well received by many patients, it remains more accessible to certain groups of patients than others [17,38].

Similar to previous research, we found that females reported a higher experience with telehealth usage compared to males [19]. Our analysis indicated that compared to non-Hispanic White participants, non-Hispanic Black and Hispanic participants had

XSL•FO
RenderX

lower odds of telehealth use experience. Given the range of health disparities across the United States, it is reasonable to assume that not all people benefit from using telehealth. In the pre–COVID-19 period, telehealth visits were significantly lower among Hispanic patients than among non-Hispanic White patients and non-Hispanic Black patients [39]. Although telehealth use increased among these groups during the COVID-19 period, disparities persist with reliable internet connectivity, digital literacy, and user comfort with technology among these populations [40,41].

In the adjusted models, we did not find a statistically significant association in our data between internet access and telehealth use experience, which may be explained by factors unique to our sample, such as high number of participants with internet access (228/244, 93.4%) and a large portion of our sample (213/244, 87.3%) having a high school degree or higher, which may have impacted significance. Previous research has found that while internet access is a foundational requirement for telehealth, it is not the only or even the most significant factor determining telehealth use when compared to, or in combination with, education, employment status, and digital literacy [42,43].

Unsurprisingly, lower comfort with Zoom and other virtual meeting platforms was associated with markedly lower odds of telehealth use experience. Prior research has found that the strongest predictor for telehealth use among participants was their comfort with technology rather than access alone [44]. Additionally, we found that in comparison to a high school degree, having less than a high school degree or more than a high school degree was associated with greater odds of previous telehealth use after adjustment. Our findings add to the mixed results of previous studies, which have found either no differences associated with telehealth use or that lower education and income were associated with lower telehealth use [45,46].

Our findings indicated that participants who had 5 or more years of CLBP had higher telehealth use experience, which may have influenced their desire to participate in the telehealth trial. Previous research has shown that patients with chronic pain are more likely to use telehealth because it offers easy access to specialists and reduces the amount of time taken off work to travel to an appointment [47-49].

We found no statistically significant association between ADI, SVI ranking, and the odds of previous telehealth use. Characteristics of our sample may explain possible reasons why ADI and SVI ranking was not significantly associated with previous telehealth. Among 244 participants, a large portion of our sample (n=213, 87.3%) had a high school degree or higher, lived in the metro area (n=222, 90.9%), and had access to the internet at home (n=228, 93.4%). Other research on the association between ADI, SVI, and telehealth usage shows mixed results. While some studies link higher disadvantage (higher ADI or SVI) to lower telehealth usage, others report no significant association between these indices and telehealth, suggesting factors such as age or technology access may play a larger role [50-52].

Strengths and Limitations

Our study has several strengths and limitations. The strengths of our study include a large sample size of an understudied population with CLBP. Additional strengths include the use of reliable and valid measurements. A limitation of this study is that all participants voluntarily enrolled in a telehealth trial and were required to have internet access in some form, which may indicate a higher comfort level with technology and limit the generalizability of the findings. Additionally, participants in our sample were more likely to receive a telehealth visit because they lived in communities with higher telehealth use (eg, urban communities served by large health systems).

Another limitation was the comfort with Zoom or virtual meeting platforms measure, which captured participants' confidence in using these platforms. The measure did not discern whether participants had adequate digital literacy skills, just if they felt confident using those platforms. Other limitations include the following: (1) the cross-sectional nature of the study design, which precludes any ability to draw causal inferences; (2) self-reported variables, introducing the likelihood of recall bias; and (3) the recruitment of most participants from metro areas. Prior research has found that while both metro and rural underserved populations own and use digital health technology, rural residents are less likely to communicate with their health providers using that technology [53].

Implications and Recommendations

The results of our study have important implications. First, given the high economic burden of CLBP and the growing emphasis on evidence-based treatments such as MBSR, telehealth offers a promising alternative for medically underserved populations. Factors that served as enablers included home internet access and greater comfort with Zoom. Targeted outreach and culturally tailored engagement strategies are needed to address disparities related to race or ethnicity and employment status. Policymakers and health care stakeholders must take proactive measures to mitigate these disparities, enhance access, and ensure that telehealth fulfills its potential to improve outcomes for all patients with CLBP.

Conclusions

In a safety-net and federally qualified health center context, prior telehealth experience was common among patients with CLBP willing to enroll in a telehealth-delivered MBSR trial. Although certain predisposing factors (race or ethnicity, employment status) were associated with lower odds of telehealth experience, these factors did not prevent trial enrollment. Thus, targeted outreach to improve digital comfort and inclusive engagement strategies may further reduce disparities and support broader implementation of telehealth for CLBP.

Abstract

Background: The growth of mobile health has underscored the critical importance of equitable internet access in promoting healthy aging. Among older adults, particularly those in digitally underserved populations, access to mobile data is often limited due to affordability and technological barriers, leading to a phenomenon known as “data deprivation.” This form of digital inequality limits the older adults’ ability to participate in social, recreational, and community-based activities, which are protective against isolation and decline in later life. In South Korea, where unlimited smartphone data plans have become increasingly accessible, a unique opportunity exists to examine the real-world association of improved data accessibility on older adults’ social lives and digital engagement.

Objective: This study aimed to examine whether switching to unlimited smartphone data plans enhances social participation among older adults in South Korea. It also explored whether this relationship differs by demographic and socioeconomic characteristics, such as age, gender, region, household composition, and income level. The study focused on offline domains of social participation, including hobby gatherings, religious services, volunteering, and routine activities such as shopping.

Methods: Data were drawn from the Korea Media Panel Survey (2016 - 2022), a nationally representative longitudinal dataset. The final sample included 5021 individuals. Social participation was measured using a self-reported 8-item scale (8 - 64 points) covering outdoor activities, volunteering, and more. A difference-in-differences approach was used to assess the association of switching from limited to unlimited smartphone data plans on social activity scores. Subgroup analyses examined heterogeneity by gender, household composition, income, and region.

Results: Overall, among individuals aged 60 years and older, switching to an unlimited data plan was not associated with a statistically significant change in social activity scores. However, within this group, those aged 70 years and older showed a more notable—though not statistically significant—improvement (differential of 1.54, 95% CI −0.41 to 3.50). In contrast, older men living alone experienced a significant differential improvement of 6.44 (95% CI 3.39 to 9.50) points, compared with those who remained on limited plans.

Conclusions: Although the overall association of unlimited data plans was limited, certain vulnerable subgroups—particularly older men living alone—experienced meaningful gains. These findings suggest that improving mobile data accessibility may enhance social engagement among digitally underserved older adults. Compared with more complex or resource-intensive interventions, expanding access to unlimited smartphone data plans may offer a relatively simple and scalable strategy to support healthy aging and reduce social isolation.

KEYWORDS

data accessibility; data deprivation; social participation; older adults; unlimited data plans; wellness

Introduction

Across the Organization for Economic Cooperation and Development (OECD) countries, the population aged 65 years and older has significantly increased from under 9% in 1960 to 18% by 2021 [1]. The average of old age–related social expenditure (including pensions, health care, and long-term care) as a percentage of gross domestic product for OECD countries increased almost 1.5 times from 2000 to 2022, highlighting the growing economic burdens of an aging

XSL•FO
RenderX

population [2]. In South Korea, the proportion of individuals aged 65 years and older is anticipated to reach approximately 40% by 2050, making it the fastest-aging nation among OECD countries [3]. Furthermore, South Korea has the highest older adult poverty rate among the 37 OECD member countries [4]. This significant aging issue necessitates effective policies to improve the lives of older adults. South Korea's approach to this trend could provide valuable insights for other countries grappling with aging-related challenges.

The public health objective for older adults is to promote and maintain functional well-being, known as healthy aging. Successful aging requires preventing diseases, maintaining physical and mental function, and actively engaging in social participation, a principle endorsed by the World Health Organization (WHO) for national public health policies amidst population aging challenges [5]. Social scientists have long emphasized the importance of the relationship between social networks (active social participation) and health, arguing that social networks influence human health through 5 pathways: provision of social support, social influence, social participation and attachment, access to material goods and resources, and negative social interactions [6]. Social participation fostering healthy relationships is gaining attention as a concept of wellness and geriatric health [7]. The classification of social participation varies depending on the criteria, but generally aligns with the framework proposed by Berkman et al [8]. They noted that examples of social activity, known as social participation or engagement, may involve meeting friends, attending events, volunteering, fulfilling occupational duties, or participating in group recreational activities [8].

Previous studies have demonstrated a relationship between the quality of life, health outcomes of older adults, and social participation [9-11]. Specifically, reports indicate that older adult social participation is influenced by gender [12], region of residence [13], and household members [14]. However, traditional methods to enhance older adult social participation must evolve as society transitions into a digital era. Digital health is being highlighted as a mediator for this [15]. Studies have shown that higher smartphone use among older adults correlates with greater overall life satisfaction [16,17].

Older adults face a digital divide due to the lack of an environment that allows them to freely access the internet compared with other generations [18]. While prior research has largely focused on digital literacy, less attention has been paid to foundational access barriers—particularly mobile data affordability and availability [19,20]. Smartphone usage involves multiple dimensions, including device ownership, connectivity, and digital skills. However, access to stable and affordable data remains a prerequisite for all subsequent digital engagement. In this context, we introduce the concept of "data deprivation," defined as the lack of consistent and affordable access to mobile data services. Unlike digital exclusion, which refers to general access to digital technologies, or "digital literacy," which relates to skills and competencies, data deprivation emphasizes material constraints—such as limited data plans or high costs—that restrict older adults' ability to participate online. We argue that this form of deprivation is a foundational driver of digital inequality, particularly among socioeconomically vulnerable older adults, and must be addressed before other digital inclusion efforts can be effective. Furthermore, data accessibility is not only essential for general social engagement but also for promoting digital health participation among older adults. In the context of mobile health (mHealth), which emphasizes the use of mobile devices to support public health and clinical care, access to mobile data accessibility serves as a bridge linking digital health technologies with real-world social engagement. Recent studies have shown that mHealth tools increasingly integrate features for mental wellness, social connection, and lifestyle tracking [21,22].

Without affordable and stable mobile internet accessibility, older adults may be unable to use health-related mobile apps, participate in online health communities, or benefit from remote monitoring technologies that support chronic disease management [23]. While previous discussions around older adult health have focused on economic or geographic access, this study brings attention to mobile data accessibility as a foundational but often overlooked determinant [24]. In this regard, our study aims to extend the discourse in digital equity by highlighting how mobile data accessibility, a prerequisite for mHealth use, may influence health-related behaviors such as social participation.

The relationship between internet use and social activity has long been debated through 2 opposing theoretical perspectives. The social reward hypothesis suggests that internet use enhances psychological well-being and social connectedness, especially among those with limited offline interactions [25]. In contrast, the displacement hypothesis argues that increased time online can replace face-to-face interactions, ultimately reducing social engagement and well-being [26]. While these theories have primarily been applied to younger populations, limited research has examined their relevance to older adults, who may have distinct digital usage patterns and social needs. While the social reward hypothesis has been the dominant perspective for adolescents prone to internet addiction [27,28], it may not be directly applicable to older adults. Most existing research has focused on reducing smartphone or internet use [29,30], with limited attention given to how these technologies might benefit older adults. As a result, it remains unclear which theoretical perspective—reward or displacement—better explains digital engagement among older adults, highlighting the need for empirical investigation in this population.

A unique aspect of the South Korean context is the widespread availability of unlimited smartphone data plans. Unlike expensive limited plans or Wi-Fi, which may pose cost or spatial restrictions, unlimited plans allow users to access the internet freely, regardless of time or place [31]. This feature offers a rare opportunity to examine whether removing mobile data constraints can enhance digital engagement and social participation among older adults. The observed effects in vulnerable subgroups suggest that improving mobile data accessibility could complement existing policies aimed at supporting social participation among older adults. Compared with complex and resource-intensive interventions, enhancing access to unlimited data plans could offer a relatively simple and scalable strategy. South Korea's unique context—characterized by rapid population aging, high older

XSL•FO
RenderX

adult poverty, and the widespread availability of unlimited data plans—provides an appropriate setting to examine the association between mobile data accessibility and social participation. Additionally, we examined how gender, residence, and household composition moderated the relationship between data accessibility and social participation in this context.

Methods

Data

In this study, we used data from the Korea Media Panel Survey (2016-2022). The Korea Media Panel Survey, constructed by the Korea Information Society Development Institute and funded by the Korean government, targets the same sample over an extended period to accumulate data [32]. This dataset aims to track changes in media environments and usage behaviors of households and individuals, providing fundamental data for in-depth research and policy development. We conducted face-to-face interviews with over 5000 households and individuals annually across 17 regions nationwide. The survey is divided into two main parts: one investigating media device ownership, subscription to broadcasting and communication services, and expenditure status; and the other examining life satisfaction, self-esteem, and similar factors.

Study Population

In this study, data from 9788 participants in the 2016 Korea Media Panel Survey were used as baseline data. Participants who were already using a smartphone unlimited data plan in 2016 (n=1854) and those not present in both 2016 and 2022 (n=2396) were excluded. Participants with missing values in key variables such as smartphone plan type, social activity score, or baseline covariates (n=517) were also excluded. The final analytic sample consisted of 5021 participants.

Variables

Social Participation

The dependent outcome in this study was social participation, for which the Korea Media Panel Survey used an 8-item self-report questionnaire [32]. Participants rated the frequency of their engagement in 8 types of activities on an 8-point Likert scale, ranging from “almost never” to “almost every day.” The activities included outdoor sports, social gatherings, volunteer and political activities, religious participation, hobbies, attending performances or exhibitions, watching sports, and outdoor shopping. These categories reflect the domains of social activity proposed by Berkman et al [8]. Total scores ranged from 8 to 64, with higher scores indicating more frequent social participation. This variable was only measured in 2016 and 2022.

Assessment of Unlimited Smartphone Data Plan

A smartphone unlimited data plan allows users to consume mobile data without any restrictions. Therefore, users can freely engage in activities such as web browsing, streaming, gaming, and social media. In this study, we use “data accessibility” to refer to the extent to which users can use mobile data without limitations such as data caps or additional charges. This is conceptually distinct from “data access,” which indicates the basic physical or technical availability of an internet connection or device. Based on changes in the unlimited smartphone data plan, which was the primary independent variable, the participants were divided into 2 groups: those who switched to an unlimited data plan in 2022 from a nonunlimited plan in 2016 (coded as “1”), and those who did not switch (coded as “0”).

Other Covariates

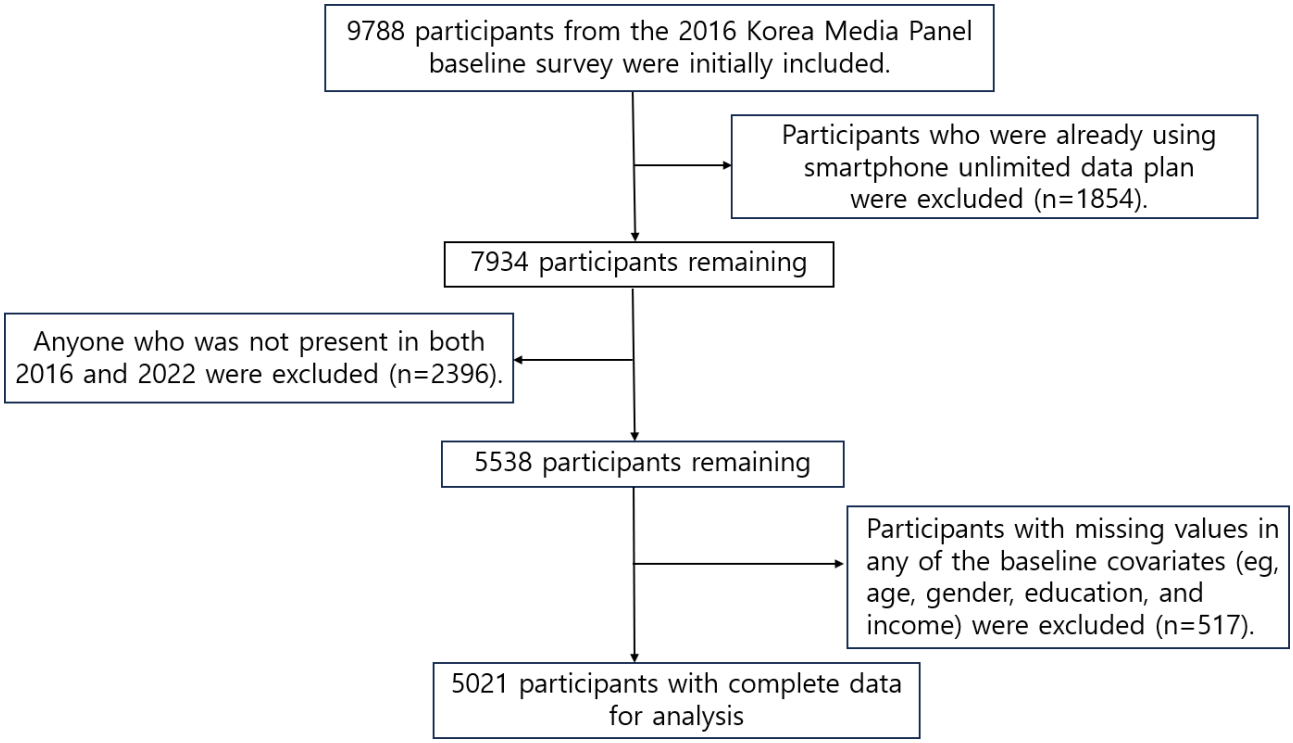
To address the potential confounders that might influence both the independent and dependent variables, covariates were selected based on Berkman et al’s [8] social integration framework, which emphasizes how demographic and socioeconomic factors shape health through pathways such as social participation, access to resources, and social support. Additionally, variable selection was informed by prior empirical studies on social participation in later life, including Finlay and Kobayashi [33]. Specifically, we controlled for demographic characteristics (age, gender, educational attainment, marital status, employment status, household composition, and region) and socioeconomic status (household income quartile). Variables were categorized as follows: age groups (under 20, 20 - 29, 30 - 39, 40 - 49, 50 - 59, 60 - 69, and ≥70 years); educational attainment (below middle school, high school, and college or higher); marital status (married, divorced or separated, and unmarried); employment status (unemployed, salaried employee, and self-employed or unpaid family worker); region (capital area, metropolitan, and city or province); household income quartiles; and household composition (living alone, living with a spouse only, and living with other household members excluding a spouse).

Statistical Analysis

The data analysis was performed in 3 parts. First, to evaluate the covariate balance between the unlimited data plan and limited data plan groups, baseline characteristics were compared using standardized differences, with a difference of less than 0.1 (10%) typically considered insignificant. All variables were measured in 2016. For the subsequent analysis, only participants who did not use unlimited smartphone data in 2016 were selected and analyzed. Second, we applied a difference-in-differences (DID) regression model to estimate the effect of adopting unlimited smartphone data plans on social activity scores. The model included an interaction term between a treatment indicator (1=adopted unlimited plan by 2022; 0=remained on limited plan) and a time indicator (1=2022; 0=2016), while adjusting for baseline covariates such as age, gender, education, marital status, employment, income, household composition, region, and Wi-Fi access. SEs were clustered at the individual level. Third, a subgroup analysis was conducted for individuals aged 60 years and older, stratifying the sample by household composition, household income quartiles, and region, to explore whether the effects of adopting unlimited smartphone data plans differed across these demographic and household characteristics. Sampling weights were constructed following the procedures described in the Korea Media Panel Survey user guide, including initial design weights, nonresponse adjustment, and population benchmarking through raking ratio, as outlined in the panel survey’s

XSL•FO
RenderX

methodological documentation. These weights were applied in all descriptive and regression analyses [34]. For baseline characteristics, we reported descriptive statistics and assessed between-group balance using standardized mean differences. CIs for regression estimates were obtained using robust standard errors clustered at the individual level. All statistical analyses were performed using SAS (Statistical Analysis System; version 9.4 M6; SAS Institute Inc).



Ethical Considerations

This study used data from the Korea Media Panel Survey, a resource openly available for academic research. As the data do not contain identifiable private information, ethical approval was exempted by the institutional review board of Severance Hospital, South Korea (4-2024-0212). Informed consent was obtained from participants at the time of the original data collection, and the dataset was fully anonymized prior to analysis. No additional consent was required for this secondary data analysis. Participants' privacy and confidentiality were protected through the use of deidentified data. No compensation was provided, as this study involved secondary analysis of an existing dataset.

Results

The final analytic sample consisted of 5021 participants with complete data (Figure 1). Table 1 presents the general characteristics of the study populations at baseline according to the smartphone unlimited data plan. Men outnumbered women among those who used unlimited data plans, who were mostly in their 40s and under 20s.

Variables	Unlimited data plan[b]			
	Total (n=5021), n (%)	No→Yes (n=1404), n (%)	No→No (n=3617), n (%)	Standardized difference
Household composition				0.559
Single-person household	347 (6.91)	46 (3.28)	301 (8.32)	
Couple-only household	1226 (24.42)	166 (11.82)	1060 (29.31)	
Multigenerational household	3448 (68.67)	1192 (84.90)	2256 (62.37)	

[a]Values with unweighted frequency (weighted %) are presented. Standardized differences were used to compare baseline characteristics between groups. A value <0.1 was considered indicative of negligible imbalance.

[b]Unlimited smartphone data refers to a mobile plan offering unrestricted access to data usage without caps or limitations.

[c]The capital region of South Korea, encompassing Seoul and its surrounding metropolitan areas, serves as the political, economic, and cultural hub of the country, while metropolitan cities represent major urban areas and their environments, functioning as significant administrative and economic centers. City or province divisions in South Korea act as regional governmental bodies responsible for local governance and administration.

[d]Indicates whether Wi-Fi (wireless internet) is installed within the household.

Table 2 presents DID estimates of changes in social activity score before and after switching to an unlimited smartphone data plan by age group. Among people aged 60 years and older, the social activity score increased by 0.43 (95% CI −0.65 to 1.50; *P*=.44) points for those who switched from limited plans to unlimited plans between 2016 and 2022, though this change was not significant. When further stratified by age, individuals aged 70 years and older showed a numerically larger differential improvement of 1.54 (95% CI −0.41 to 3.50; *P*=.12) points. While suggestive, this finding was not statistically significant and should be interpreted with caution.

Table . Difference-in-differences estimates of changes in social activity score before and after using smartphone unlimited data plan.

Outcome	Unadjusted means (social activity score[a])						Absolute difference in differences		
	Limited[b,c]→Limited			Limited[c]→Unlimited[d]			Adjusted[e] (95% CI)	SE	*P* value
	Before[f]	After[f]	Difference	Before	After	Difference			
Age (y)									
<20	21.55	21.58	0.03	21.55	22.78	1.23	1.24 (–0.58 to 3.07)	0.93	.18
20-39	22.32	24.32	2.00	22.32	23.97	1.65	0.12 (–1.00 to 1.23)	0.57	.84
40-59	20.53	21.73	1.20	20.53	21.70	1.17	–0.44 (–1.19 to 0.32)	0.38	.25
≥60	17.16	17.83	0.67	17.16	20.06	2.90	0.43 (–0.65 to 1.50)	0.55	.44
60-69	17.99	19.65	1.66	17.99	20.16	2.17	–0.29 (–1.60 to 1.03)	0.67	.67
≥70	16.43	16.91	0.48	16.43	19.78	3.35	1.54 (–0.41 to 3.50)	1.00	.12

[a]Social activity score refers to the total combined score of 8 social participation and the maximum score is 64 points.

[b]Limited: smartphone limited data plan.

[c]The baseline excludes smartphone users with unlimited data plans.

[d]Unlimited: smartphone unlimited data plan.

[e]Adjusted for age, gender, education, marriage status, employment status, household income, region, Wi-Fi installation status, and family members.

[f]"Before" and "After" indicate the mean social activity score in the pre- and post-periods, respectively.

Gender-stratified subgroup analyses (Tables 3 and 4) indicated an increase in the estimated social activity score among the older adult group that switched to unlimited smartphone plans, stratified by independent variables (household composition, household income, and region). Particularly for older adult men living alone, the differential improvement was 6.44 (95% CI 3.39 to 9.50; *P*<.001) points higher for those who switched to unlimited data plans than those who remained on limited plans

XSL•FO
RenderX

from 2016 to 2022. The estimate for socially isolated older men was higher in magnitude; however, as subgroup analyses are exploratory, these results should be interpreted with caution. Similarly, older adult men living in metropolitan areas were 3.47 (95% CI 0.15 to 6.78; *P*=.04) points higher than those who remained on limited plans, suggesting that differences in digital access across regions may affect the potential effectiveness of mobile interventions. For household income, differential improvement was observed in the low-income (DID change 1.54 points, 95% CI −0.05 to 3.60; *P*=.14) and high-income (DID change 7.67 points, 95% CI −3.03 to 18.38; *P*=.16) groups (suggesting that the change to unlimited plans had an association with social participation), but it was not significant. As shown in Table 4, the effects of several covariates were not as evident for older adult women as they were for older adult men. Among older adult women, the effects of unlimited data access were generally smaller and less consistent across subgroups. However, women living alone still showed a notable improvement of 3.38 (95% CI −0.55 to 7.30; *P*=.09) points, highlighting that living arrangement may be a more influential factor than gender alone.

Table . Gender-stratified subgroup analysis results by independent variables in male adults aged 60 years and older (n=1594)

Variables	Adults, n	Unadjusted means (social activity score[a])						Absolute difference-in-differences

Discussion

Principal Findings

This study used a DID design to examine the potential association between unlimited smartphone data plans and changes in social participation of older adults. Notably, the findings were numerically larger among men and older adults living alone. These results suggest that unlimited data plans could be explored as a potential digital inclusion strategy for specific vulnerable subgroups.

Prior studies have primarily examined the relationship between improved digital literacy and increased social engagement among this population [16,17]. In contrast, our findings suggest that providing unrestricted smartphone access—regardless of digital literacy level—may be explored as a potentially meaningful intervention. This highlights the unique challenges faced by older adults who cannot freely use smartphones in the digital age. For instance, we found that living alone was significantly associated with lower social activity scores, indicating limited opportunities for social interaction compared with those living with others [35,36]. As a result, these individuals may depend more on digital tools for connection. The provision of unlimited data plans—by removing spatiotemporal restrictions on internet access—may reduce barriers to social participation for these individuals. While the small sample size limits the significance of the results, a notable differential change was observed in the incomes of those living

XSL•FO
RenderX

in metropolitan areas. A previous study identified community-based activities as central to older adults' social participation [30]. In rural or smaller communities, older adults often benefit from closer-knit social networks and community activities. In contrast, those living in metropolitan areas may face greater social isolation and thus rely more heavily on digital means for connection. This could explain why the provision of unlimited smartphone data showed a suggestive, numerically larger association with their social participation [37].

While no statistically significant overall effect was observed among individuals aged 60 years and older, subgroup analyses revealed a significant improvement in social activity scores for specific populations—most notably, older men living alone. These findings suggest that older adults' ability to participate in social participation increasingly depends on access to digital devices and mobile data. For those with limited financial resources, the cost of data plans or smartphones may pose significant barriers, reflecting the broader economic inequality in digital participation. Gender-stratified analysis revealed that older men living alone experienced a numerically larger improvement in social activity following the adoption of unlimited smartphone data plans. This finding is particularly meaningful given that older men are generally less socially active than women [38], suggesting that enhanced digital access may help narrow gender disparities in social engagement. The effect was even more evident among male residents of metropolitan areas, indicating that digital connectivity plays a critical role in enabling social participation for this subgroup. The unlimited smartphone data plan differs from Wi-Fi. It reduces spatiotemporal constraints on internet use and encourages older adults to engage in social participation. Compared with traditional interventions such as community-based programs or digital literacy education [16,17], providing unlimited smartphone data plans offers a lower-cost and scalable alternative to enhance social participation among older adults. By reducing structural barriers to digital access, this approach could help address digital inclusion more directly and efficiently.

Implications

These subgroup findings suggest that policymakers could consider subsidizing mobile data plans for vulnerable older populations, such as those living alone or in metropolitan areas. Conducted in South Korea—where smartphone penetration is high and unlimited data plans are relatively affordable—this study highlights how improved digital access can enhance social participation among older adults. The findings of this study may be relevant to other settings with high smartphone penetration, although their applicability will depend on local infrastructure, affordability, and broader socioeconomic context.

Limitations

This study has some limitations. First, due to data source limitations, we analyzed data only from 2016 and 2022. Second, our analysis included only the covariates calibrated in this study, potentially omitting other unmeasured covariates that could influence the relationship between unlimited data use and social activity scores. Third, we lack precise information on the timing of participants' transition to unlimited data plans. Therefore, we cannot pinpoint the exact time of participants' switch to unlimited data and its subsequent association with their social activity scores over the 6-year period. To address this, we assumed an average switch point sometime in the middle years. In addition, we conducted multiple subgroup analyses to explore heterogeneous effects across demographic and household characteristics. While these analyses provide valuable insight, they also introduce the possibility of spurious findings due to multiple comparisons. Thus, subgroup results should be interpreted with caution and seen as exploratory.

In addition, we did not formally assess whether the assumptions of linear regression—such as normality of residuals, homoscedasticity, and absence of multicollinearity—were met. This may limit the robustness of our estimates and should be addressed in future studies. Finally, the data only included 2 time points (2016 and 2022), which limited our ability to verify the parallel trends assumption—an essential prerequisite for the validity of DID analyses. Although we aimed to minimize baseline imbalance and carefully selected covariates, the inability to test parallel trends remains a critical methodological limitation. Future research using panel data with multiple time points would allow for formal testing of this assumption and a more robust causal inference.

Conclusions

This is the first study to use unlimited smartphone data plans to examine changes in social activity among older adults. By using longitudinal data with repeated measures of the same participants, we effectively captured changes in social activity over time. Therefore, our findings can inform policy discussions and contribute to the important public health goal of promoting social engagement among older adults.

This study unveils a significant association between older adults' adoption of unlimited smartphone plans and their social engagement, suggesting that switching to an unlimited plan may be associated with increased social participation. Ensuring older adults have unrestricted internet access to electronic devices is crucial before initiating digital literacy initiatives. These findings highlight the potential of improving data accessibility as a supportive lever for promoting social participation in older adults, offering a comparatively simple and scalable approach alongside existing policy measures.

Abstract

Background: Suboptimal adoption and engagement rates of digital health applications present challenges to their effectiveness, particularly in chronic disease management such as fibromyalgia. Up to half of patients do not download the prescribed digital health applications or actively engage with them, making effective onboarding a critical opportunity for improvement.

Objective: We aimed to investigate the impact of 3 different patient onboarding strategies on adoption, adherence, and engagement with a digital health application for the symptom management of chronic pain syndromes.

Methods: We conducted a 4-week nonrandomized prospective study comprising patients (aged ≥18 years) with chronic musculoskeletal pain who fulfilled the fibromyalgia criteria and were using a new self-monitoring and management application after onboarding. The pain organizer and companion system consists of symptom reporting, symptom monitoring, and an advice and exercise section. Participants in group 1 (standard) received an email-based onboarding with detailed instructions on application download, registration, use, usability data capture, data security, and study procedures without any in-person assistance. Group 2 (video) received the same email plus a video tutorial explaining the application's use also without any in-person assistance. Group 3 (assisted) underwent an enhanced in-person onboarding, which included hands-on support for application setup and guided instructions from a health care professional. Primary outcomes included adoption, engagement, and adherence, measured respectively by successful application download with at least 1 log-in, cumulative activations, and connection at least once per week over 4 weeks.

Results: A total of 48 patients were recruited (mean age 45.7, SD 12.2; range 19-79 years). In the assisted group, all 15 participants in the assisted onboarding group downloaded the application compared to 63% (10/16) in the standard group and 77% (13/17) in the video group. A significant difference in adoption between the in-person onboarding group (group 3) and the remote groups (groups 1 and 2) with P=.009 was observed. Overall engagement, measured by cumulative app activation, ranged between 0 and 28 log-ins, with no significant difference (P=.18) in mean log-ins across the 3 groups. Overall adherence was low with 27% (13/48) of participants meeting adherence criteria and a retention rate of 46% (22/48) at week 4. Responses to the System Usability Scale survey were limited to 8 responses but achieved a score of 70.31, indicating good usability of the application.

Conclusions: Unassisted downloading and account creation might be barriers to adopting a digital health app among patients with chronic musculoskeletal pain.

Introduction

Digital health solutions, including mobile applications and digital therapeutics, have emerged as promising tools in modern health care delivery. A growing body of evidence suggests that digital health solutions, when effectively adopted and integrated into patient care, can result in positive health outcomes. These technologies offer the potential to enhance patient engagement, improve treatment adherence, and empower individuals to actively manage their health, particularly in the context of chronic conditions [1-3]. However, the active use of digital interventions influences their effectiveness. It was found that increased user engagement with digital interventions is linked to greater improvements in outcomes [4]. However, despite the increasing availability and potential benefits of digital health solutions, achieving high levels of adoption and engagement remains a significant challenge [5-7]. Studies consistently report that only about half of prescribed digital health solutions are downloaded by patients, leading to low use rates and missed opportunities for improved health management [8,9]. This discrepancy between the potential benefits of digital health solutions and their limited adoption and engagement rates raises critical questions about the factors influencing adoption and the potential strategies for enhancing adoption [10]. Implementation science examines whether an intervention is delivered as intended and investigates strategies to enhance its integration into real-world settings, using outcomes such as adoption, engagement, and retention to assess implementation success [11].

Increased adoption rates not only facilitate the effective use of these technologies but also hold the potential to positively impact patient outcomes, reduce health care costs, and improve overall health care delivery [3,12]. Among the various factors affecting adoption and engagement, the onboarding process plays a pivotal role [6]. Onboarding refers to the initial introduction of a patient to a digital health solution including, for example, downloading, registering, and device pairing [13,14]. A major reason for the low adoption of mobile health (mHealth) applications is concerns about data security and privacy [15,16]. Another barrier to adoption is the lack of support from physicians [17]. However, according to Dahlhausen et al [18], health care professionals (HCPs) hold significant potential to enhance adherence to digital therapeutics. Moreover, Hernandez-Ramos et al [14] found low self-reported digital health literacy among study participants reporting difficulties with new tools such as mHealth apps. They addressed this issue by providing onboarding support (eg, downloading and installing the application) to digital health platforms.

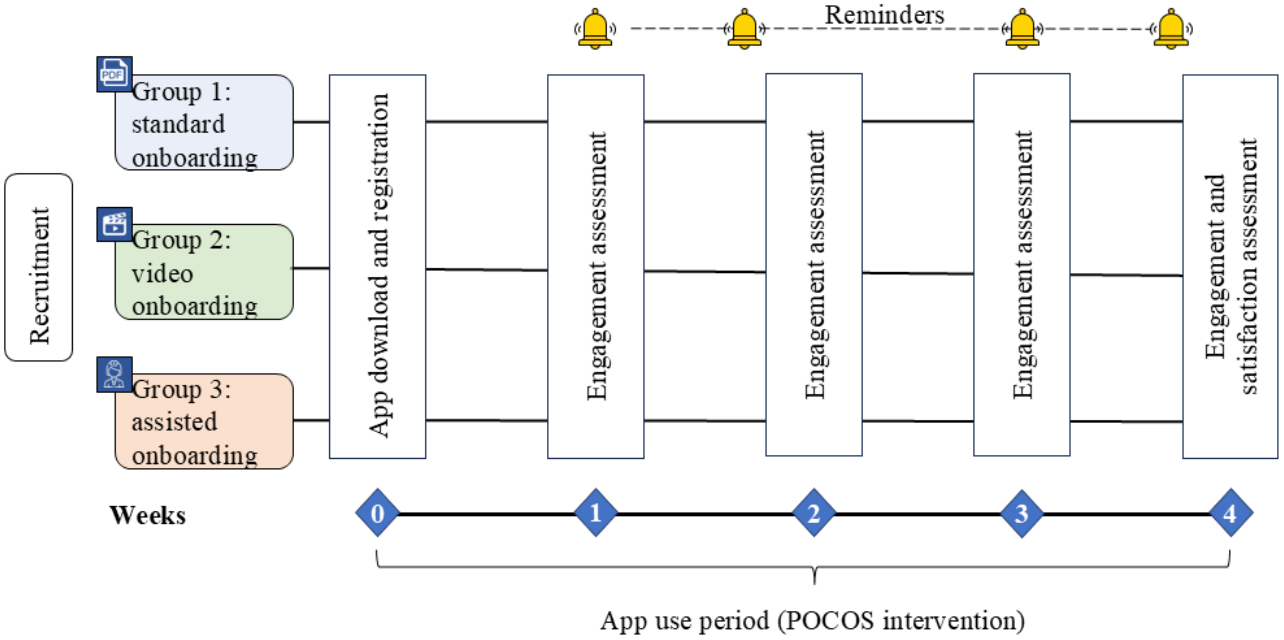
Therefore, onboarding serves as a critical opportunity to engage and motivate patients, establish trust, and familiarize them with the functionalities and benefits of the technology. A well-designed onboarding process can potentially address patient concerns, mitigate barriers to adoption, and optimize the user experience, ultimately increasing the likelihood of sustained engagement and use of the digital health solution. Given the importance of adoption and the critical role of onboarding strategies, it is essential to explore how different onboarding approaches influence adoption rates, user engagement, and retention of digital health solutions. Despite the importance of onboarding, many studies focus only on engagement strategies or barriers to adoption after the initiation of the digital intervention [10,15,16,19-24]. In this study, we aim to address this gap by investigating the effect of patient onboarding strategies, used as an implementation strategy, on the adoption, engagement, and retention of a digital health solution for chronic conditions, specifically for the management of chronic musculoskeletal pain. By evaluating the impact of tailored onboarding approaches compared with a standard onboarding process, we seek to identify effective strategies that can increase adoption, enhance retention, and optimize the overall benefits of digital health interventions.

Methods

Study Participants

The study included individuals who had been diagnosed with chronic musculoskeletal pain resistant to conventional treatment. Participants had to be aged ≥18 years and have the capability to use a mobile app–based intervention. Additionally, participants needed to possess an email account and a smartphone capable of downloading and using the study-specific self-monitoring and self-management application. Individuals with insufficient proficiency in French to provide informed consent or complete study procedures were excluded. Participants were recruited from the University Hospital Lausanne after they underwent a 2-week in-house multimodal pain program due to being refractory to outpatient treatment. These patients typically present with severe pain as well as high levels of anxiety, depression, catastrophizing, and cognitive impairments, including deficits in attention and memory.

Ethical Considerations



Ethics approval was obtained from the Commission Cantonale d'éthique de la Recherche sur l'être Humain (CER-VD 2021-01680). Informed written consent was given by all participants prior to their inclusion in the study. The study was conducted ethically in accordance with the World Medical Association Declaration of Helsinki. Data were deidentified to protect participant privacy and maintain confidentiality. Participants did not receive any compensation for taking part in this study.

Study Design

This comparative, nonrandomized 4-week study examined the effect of different onboarding strategies on the adoption of an mHealth application and retention of use in patients with chronic musculoskeletal pain (Figure 1). Eligible participants were enrolled sequentially into the following three groups (each representing a different onboarding strategy):

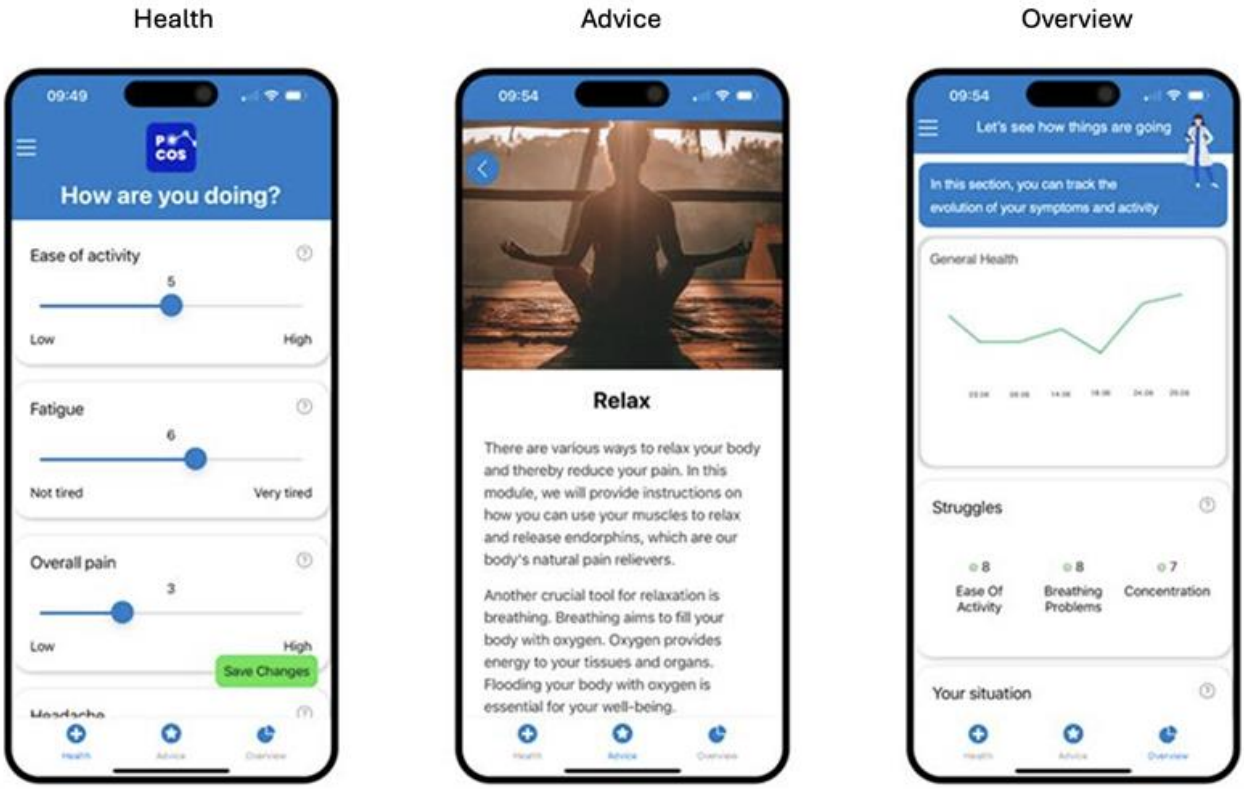
XSL•FO
RenderX

Figure 1. Study design. Patient-reported outcomes were collected through the pain organizer and companion system (POCOS) app. Engagement was assessed through usability data, and satisfaction was assessed using the System Usability Scale. Reminders to use the POCOS app were delivered via SMS text messages.

1. Group 1 (standard onboarding group): participants in this group received a standard onboarding process that was delivered entirely remotely via email. This onboarding included step-by-step instructions for downloading and registering an account, information on application use and usability data collection, details regarding data security, an overview of study procedures related to the self-monitoring and self-management application, and a concise summary of the application's core features and functionalities. The manual can be accessed in Multimedia Appendix 1 (in French).
2. Group 2 (video onboarding group): participants in this group underwent the same onboarding process as group 1 but were also provided with an onboarding video. This video, of 3 minutes duration, walked the participants through a comprehensive demonstration of how to use various features and functionalities of the application. The video can be accessed [25].
3. Group 3 (assisted onboarding group): participants in this group received onboarding assistance from a dedicated study HCP via a 30-minute in-person session at the University Hospital Lausanne. The HCP guided each participant individually through the onboarding process and assisted in downloading, registering, logging in, and entering initial data into the application. Furthermore, the HCP provided personalized support and explanations, addressing any questions or concerns raised by the participants during the onboarding session. To minimize bias, the HCP followed a script.

Participants in all 3 groups had access to the same user manual to guide them through application use. The onboarding procedures in groups 1 and 2 were fully remote, while group 3 was in person. Blinding of HCPs and participants was not feasible due to the nature of the intervention.

All participants had the possibility to reach out for support via email or phone for assistance with any step during the study time.



Adoption and engagement are well-documented challenges in mHealth applications, with several studies identifying key barriers and influencing factors. The literature emphasizes the importance of reminders, user-friendly and robust technical design, data privacy and security, tailored content, and personal support [19,20,26]. To address these factors and enhance adherence and engagement, we incorporated them into the study design alongside the specific onboarding strategies. All participants received weekly SMS text message reminders to engage with the pain organizer and companion system (POCOS) application and to provide usability data. To mitigate concerns around data privacy and security, information on secure data handling was explicitly addressed during onboarding. The POCOS application was co-designed with patients and HCPs and features a user-friendly interface with reliable technical performance [27].

POCOS User Interface

POCOS is a self-monitoring and management application, which was tested in a previous study [27,28]. This application consists of 3 components: symptom reporting, symptom monitoring, and an advice and exercise section (Figure 2). Moreover, the content can be tailored by patients, as they can freely navigate through the application. Following the onboarding phase, participants in all 3 groups were asked to use POCOS 2 to 3 times a week for 1 month. During this period, patient-reported outcomes related to chronic pain (fatigue, concentration, sleep quality, memory, pain, ease of activity, and anxiety) were asked to be reported by patients via the application at baseline, after 2 weeks, and after 4 weeks of using the application. At the end of the study, participants received a link via text message to fill out a System Usability Scale (SUS) survey.

XSL•FO

Outcomes Measures

Primary Outcomes

The primary outcomes of this study were adoption, adherence, and engagement with the application. Adoption was defined as the uptake or intention to try or use a new intervention [29]. The primary measure was the adoption rate of the self-monitoring and self-management application among participants. Adoption rates were assessed by calculating the percentage of participants who successfully downloaded the application and logged in at least once.

Adherence was measured as the percentage of participants who continued using the application after the initial download and remained engaged with at least 1 connection per week throughout the 1-month period.

Engagement was assessed over the 4-week period using the number of log-ins and time spent with the application, two commonly used application engagement metrics [30].

Secondary Outcome

The secondary outcome of this study was patient satisfaction, assessed at the end of the study using the SUS survey. In the survey, participants were asked how they liked the application and how satisfied they were with the onboarding support that they had received.

Data Collection and Management

Data collection for this study was fully decentralized and involved a combination of participant-reported data and application-collected use data. Participants were provided with secure log-in credentials to access the self-monitoring and self-management application. All data were coded (deidentified) and stored in a secure, password-protected database. The application use and engagement metrics, such as account registration and frequency of application use, were recorded. These engagement measures were obtained passively via the database or actively through screenshots of application use that had to be sent biweekly by participants to the research team. At the end of the study, participants received a link for a follow-up SUS survey, and all responses were fully anonymized.

Statistical Analysis

Descriptive statistics were calculated for all variables, including means and SDs for continuous variables and frequencies and percentages for categorical variables. Differences in continuous outcomes between the 3 onboarding groups were assessed using the Kruskal-Wallis *H* test, as the data did not meet the assumption of normality. Group differences and associations between categorical variables (adoption and adherence) were assessed using the chi-square test or Fisher exact test (if <5 observations per category). Generalized linear modeling (linear or logistic, as appropriate) was used to examine the associations between user characteristics and engagement. To analyze survival rate and time among the different groups, we used Kaplan-Meier survival functions with a log-rank (Mantel-Cox) test. Two-sided *P* values <.05 were considered statistically significant, and 95% CIs were used. All analyses were performed with SPSS software (version 29.0.2.0; IBM Corp). We analyzed with an intention-to-treat approach.

Results

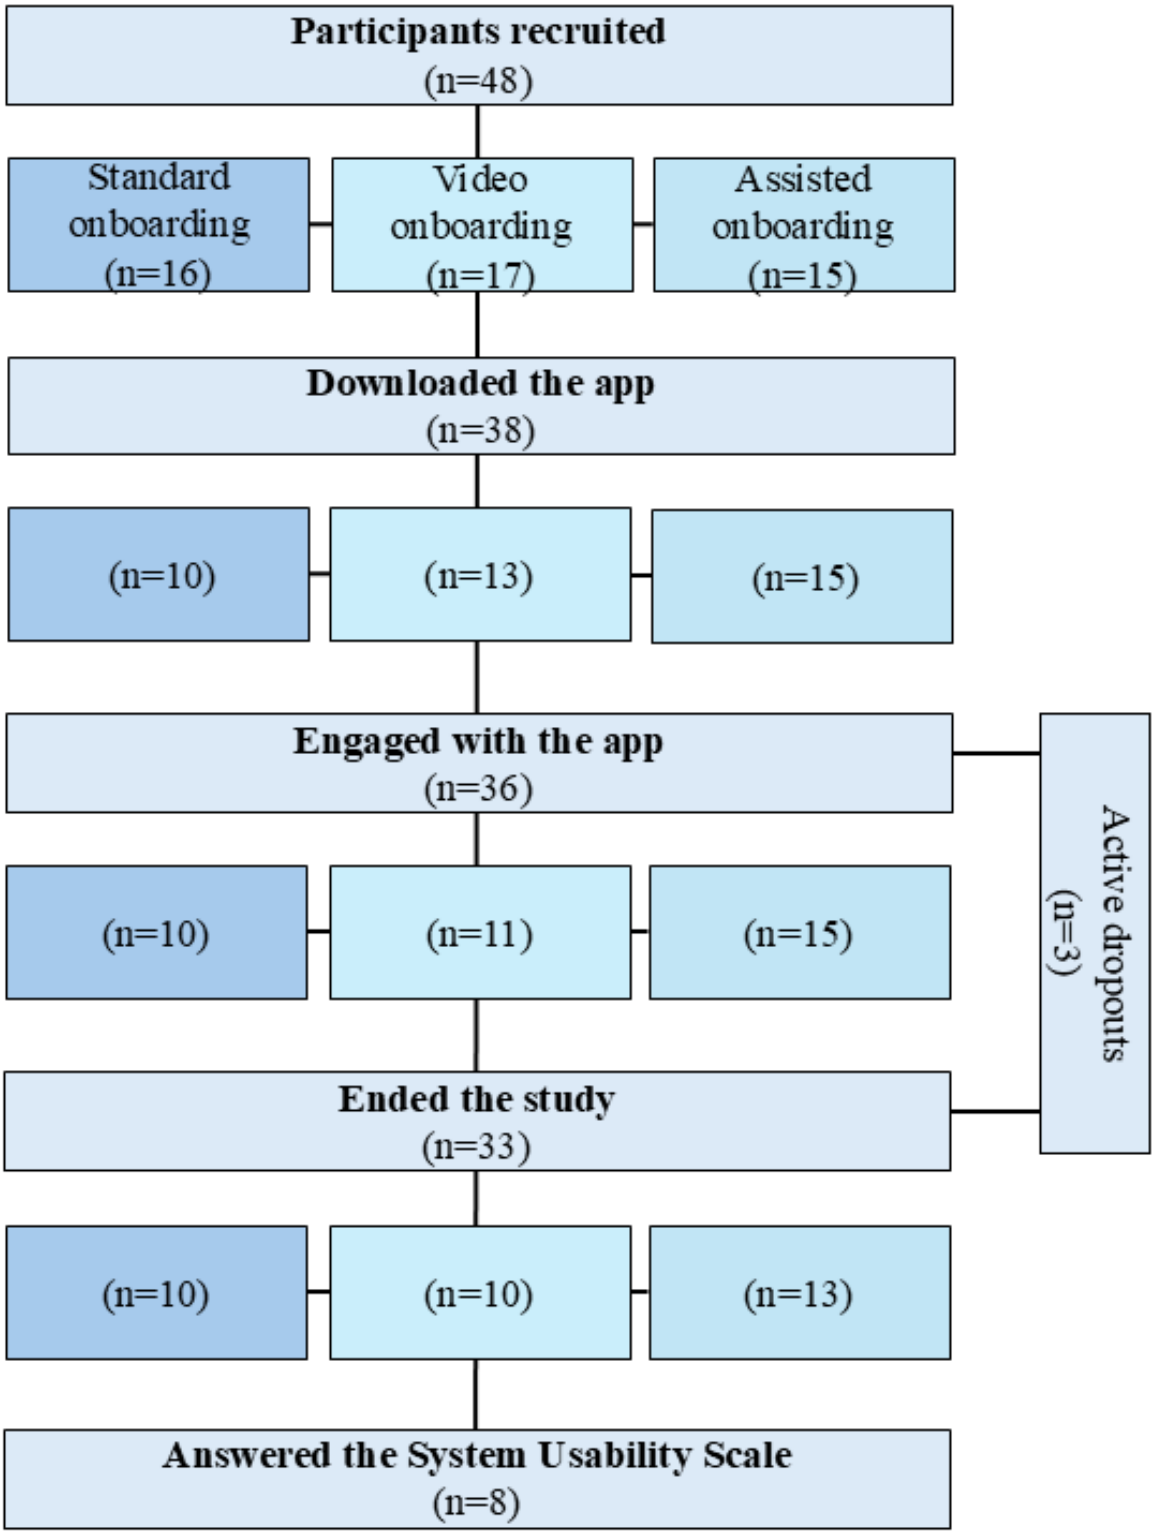
Overview

A total of 48 patients with chronic musculoskeletal pain were recruited from 2023 to 2025 and sequentially distributed into 3 groups: 16 (33%; standard), 17 (35%; video), and 15 (31%; assisted) participants per group. Mean age was 45.7 (SD 12.2) years, and 40 (83%) participants were female. Overall, 39 (81%) participants had depression, 12 (25%) had anxiety, and 18 (38%) were opioid users. All participants fulfilled the fibromyalgia criteria. No clinically meaningful differences in baseline characteristics were observed. Detailed clinical information per group is shown in Table 1.

Table 1. Clinical and demographic characteristics of the study participants (N=48).

Characteristics	Standard onboarding[a]	Video onboarding	Assisted onboarding
Comorbidities, n (%)			
Fibromyalgia criteria fulfilled	16 (100)	17 (100)	15 (100)
Depression			
Yes	13 (81)	14 (82)	12 (80)
No	2 (13)	3 (18)	3 (20)
Anxiety			
Yes	2 (12)	6 (35)	4 (27)
No	13 (81)	11 (65)	11 (73)
Opioid use			
Yes	5 (31)	6 (35)	7 (47)
No	11 (69)	11 (65)	8 (53)
Sex, n (%)			
Female	16 (100)	13 (76)	11 (73)
Male	0 (0)	4 (24)	4 (27)
Age (y), mean (SD)	46.3 (14)	45.9 (12)	44.9 (10)

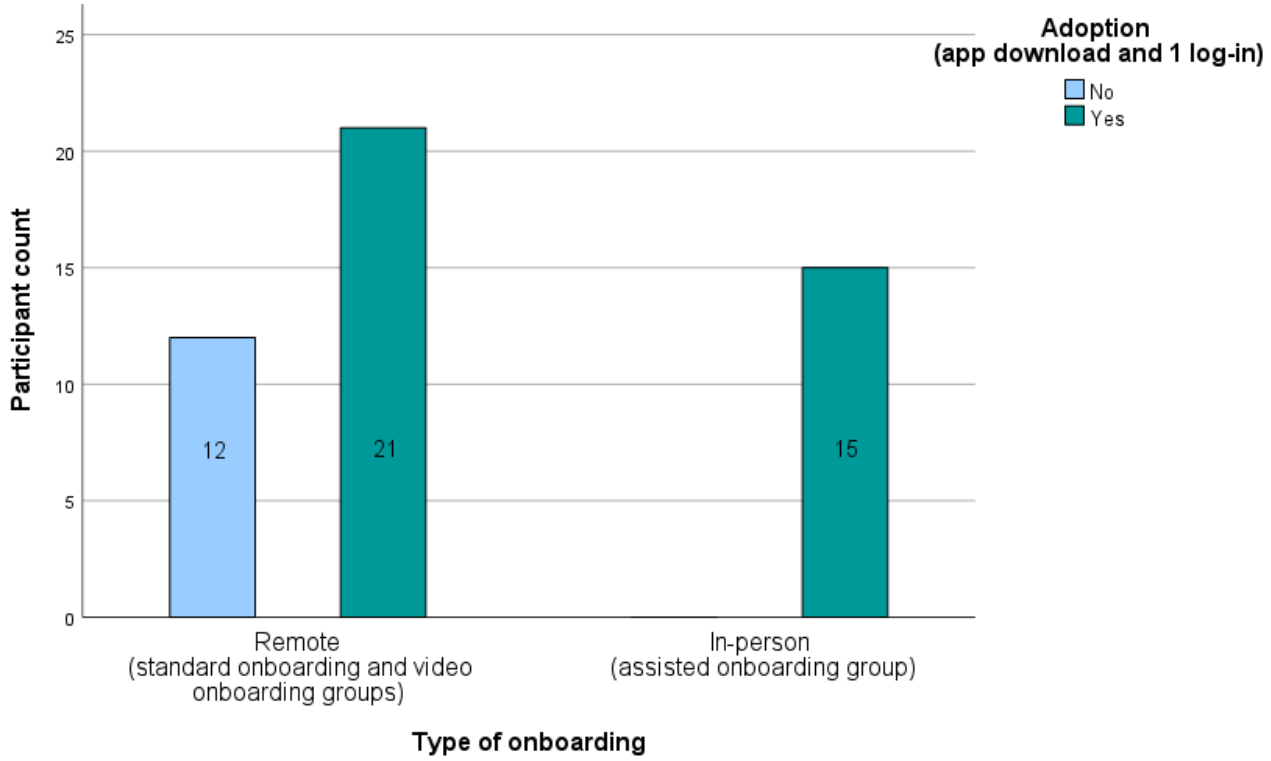
[a]n=1 is missing for depression and anxiety in the standard onboarding group.



Adoption: Downloads and First Engagement

Overall, 81% (39/48) of participants downloaded the application after they received the instructions. All 15 participants in the assisted onboarding group downloaded and registered the application, while 63% (10/16) of participants registered an account in the standard onboarding without assistance. In the video group, 76% (13/17) of participants downloaded and registered an account. In total, 24% (4/17) of participants in the video group contacted the research team for assistance as they struggled with completing the onboarding independently. Support was given via phone or email by the research team. Of these 15 assisted participants, 1 (7%) had additional help from a relative to complete the downloading. Of them, 3 (20%) participants successfully managed to create their accounts, while 1 (7%) was lost in follow-up. Overall, 75% (36/48) of participants adopted the application, meaning that they successfully downloaded and tested the application at least once. About 69% (33/48) completed the study, meaning that they did not actively drop out of the study. Figure 3 shows the flow of participants in the different groups.

In a combined analysis of remote onboarding (standard and video onboarding) vs assisted in-person onboarding, adoption was significantly higher in the in-person onboarding group (*df*=1, Cramer *V*=0.389; *P*=.009; Figure 4).



XSL•FO
RenderX

Figure 3. Participant flow per onboarding type.

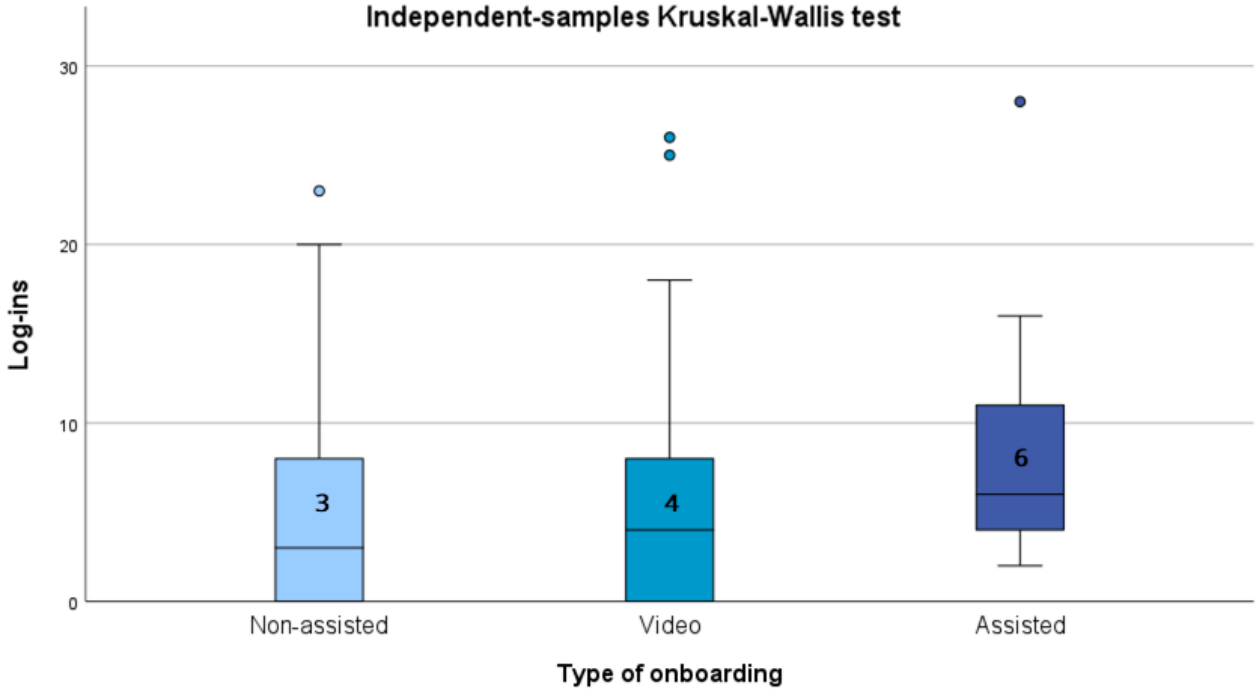
XSL•FO
RenderX

Figure 4. Adoption of the application in the remote onboarding vs the in-person onboarding group.

Dropouts

Two participants in the assisted onboarding actively terminated the study prematurely after 14 days and 16 days. Reasons for dropout were a broken phone and poor health status. Another dropout occurred in the video group after 2 weeks. The participant mentioned feeling that they are not useful in contributing to the study. Baseline characteristics were comparable between participants who actively dropped out and those retained.

Time-to-Account Creation



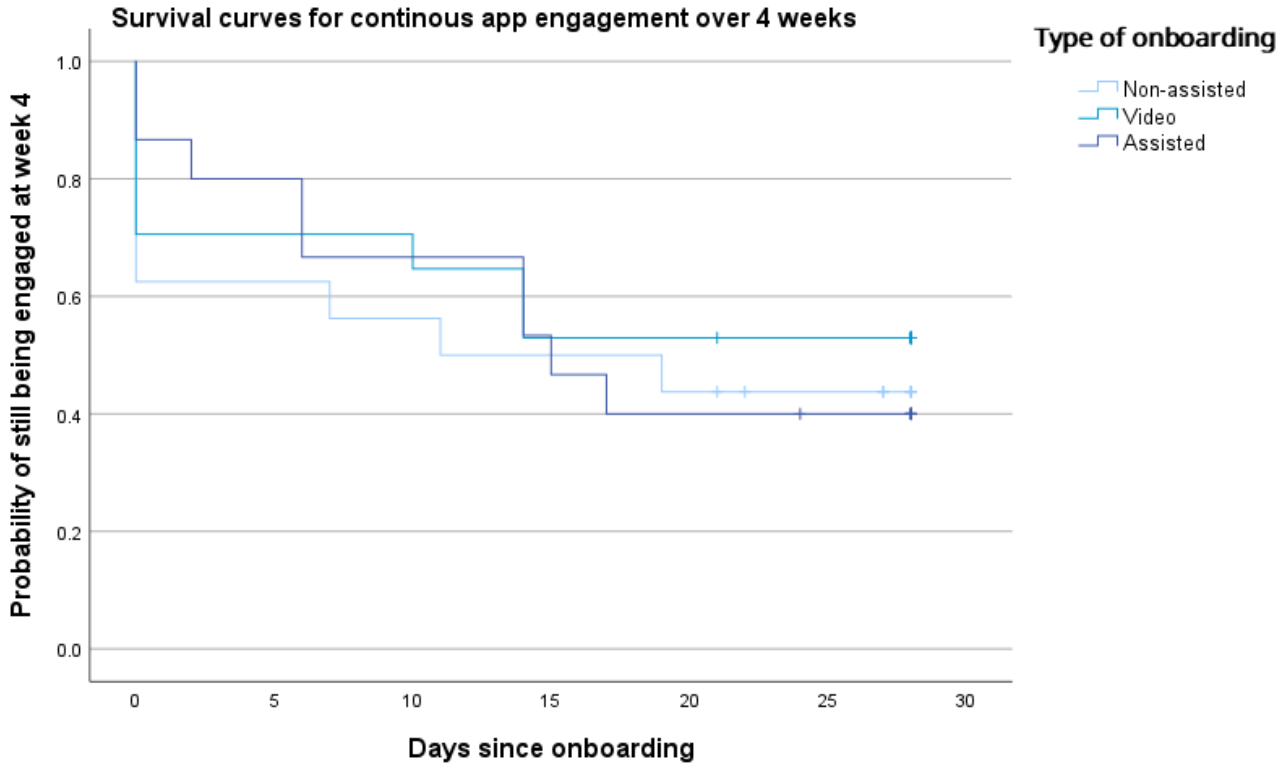
The time between account creation and the onboarding date was calculated for all participants who downloaded the application in the standard and video onboarding groups. The mean time to download was 5.61 (SD 6) days, with a range of 0 to 23 days. In total, 36% (12/33) of participants downloaded the application before the first reminder (at the end of the first week) and 64% (21/33) after the first reminder. There was no significant difference observed between the standard and the video group (P=.63).

Engagement: Minutes, Log-Ins, and Survival

In total, 96 screenshots of usability data were expected to be provided by participants. About 25% (12/48) of participants submitted usability data; however, these data were mostly incomplete (eg, only providing the minutes spent on the application for a single day). Out of the usability data obtained in minutes, participants used the application for 14 to 68 minutes during a week. Cumulative log-ins were passively collected. The number of log-ins for the duration of the study ranged from 0 to 28, with an overall mean of 7 (SD 7.68). A Kruskal-Wallis test showed no significant differences between the 3 groups (Kruskal-Wallis test df=2, median 3, IQR 8 vs median 4, IQR 11vs median 6, IQR 8; P=.18), as displayed in Figure 5. As no group differences were observed for onboarding type, we additionally ran a linear regression including the available covariates (sex, age, depression, anxiety, and opioid use) to examine their influence on engagement (number of log-ins during the 1-month period). Anxiety was a significant predictor of log-ins (β=−5.148, 95% CI −10.2 to −0.09; P=.046).

XSL•FO
RenderX

Figure 5. Median number of log-ins per onboarding group.



For the Kaplan-Meier survival analysis, we examined how many participants were still using the application during the final week of the 4-week study period. Time-to-event was defined as the number of days between onboarding and the participant's last log-in. An event was considered to have occurred if a participant did not use the application during the final study week, meaning that their last log-in occurred before week 4. A log-rank (Mantel-Cox) test revealed no significant difference in survival distributions between the onboarding groups (χ^2_2=0.4; *P*=.82; Table 2). The overall survival rate was 46% (22/48), with a mean survival time of 15.9 days. Among the groups, the video-onboarded participants showed the highest probability of continued application use, with a survival rate of 53% (9/17) and a mean survival time of 17.1 (SE 3.0) days (Figure 6).

Table 2. Survival data stratified by onboarding type.

Type of onboarding	Participants, n (%)	Events, n (%)	Survival rate (%)	Survival duration (days), mean (SE)
Standard	16 (33)	9 (56)	44	14.6 (3.2)
Video	17 (35)	8 (47)	53	17.1 (3.0)
Assisted	15 (31)	9 (60)	40	16.1 (2.8)

XSL•FO
RenderX

Figure 6. Survival curves for the probability of still engaging with the application in the last week of the study per onboarding type.

Adherence

Out of the 48 participants, only 13 (27%) were adherent with at least 1 connection per week for 4 weeks. Adherence was not influenced by onboarding group membership.

Participant Satisfaction: SUS

About 17% (8/48) of participants answered the SUS survey, leading to an overall score of 70.31. This score suggests a "good" usability level, as SUS scores typically range as follows: >78.8 (excellent usability), 70-85= (good usability), 50-69= (acceptable usability), and <51.6 =(poor usability) [31]. Only 50% (3/6) of participants provided feedback on their satisfaction with the onboarding type they received (standard and assisted groups); they were all satisfied and mentioned that the instructions that they received were clear and sufficient. Suggestions to improve the application by participants included fixing technical bugs, adding other language options, expanding content, integrating goal-setting features, enabling chat options with peers and HCPs, improving the design, providing links to scientific evidence and statistics about the disease, adding subtitles to videos, including a place to take notes, incorporating exercises or advice from ergotherapists, and implementing nudging strategies.

Discussion

Principal Findings

In this study, we found that in-person assisted onboarding significantly increased the adoption of a newly developed self-management application among patients with chronic musculoskeletal pain. While 81% (39/48) of participants downloaded the application and 75% (36/48) used it at least once (ie, adopted it), sustained use declined notably after approximately 2 weeks, with only 46% (22/48) still using the application by the fourth week. Mean and median log-in frequencies were highest in the assisted onboarding group and progressively lower with decreasing levels of support. However, onboarding type did not significantly influence overall engagement, as measured by median log-ins throughout the study period, nor adherence to regular use. The only significant predictive factor for app engagement we found was anxiety. Usability and satisfaction with onboarding were also assessed; however, due to the limited number of participants who provided detailed usability metrics in minutes, no statistical comparisons between onboarding groups could be performed for these outcomes.

Assisted in-person onboarding was effective for the adoption of the POCOS application and facilitated the timely initiation of application use, in contrast to the other two groups where account creation generally occurred a week later, aligning with the first reminder they received. Studies using health applications should consider implementing assisted onboarding to guarantee a seamless start to the study. On average, participants logged into the application 7 times during the study, and the time spent using the app ranged from 14 to 68 minutes per week. Our results regarding adoption and engagement are comparable to those reported in other mHealth studies in populations with chronic pain [32,33]. For example, in one study evaluating a chronic pain management app, 45% of participants remained engaged after 1 month [33], while in another study, 39% of participants completed the 3-month self-management program of a chronic pain app [32]. In addition, mHealth studies primarily focusing on depression and anxiety [7-9,34] may also be considered, as these conditions

XSL•FO
RenderX

are highly prevalent among patients with chronic pain. Compared to our study, fewer participants downloaded the app in these studies, which may be explained by the fact that one group in our study received tailored support. In one of these studies, higher baseline depression and anxiety scores were associated with lower app use; similarly, anxiety was negatively associated with engagement in our study. This relationship warrants further investigation.

However, overall adherence in these studies was higher than in our study. This difference may be partly explained by the fact that patients with chronic pain often experience, in addition to depression and anxiety, other comorbidities and persistent pain, which may further complicate engagement and adherence. In particular, our sample included patients with complex chronic pain conditions, all of whom were refractory to treatment. Besides measuring engagement, it is important to define what meaningful engagement is [35]. For example, more log-ins do not automatically mean that a patient engaged more with the application. To analyze this, the minutes spent on the application would need to be structurally captured. Moreover, meaningful engagement not only is time related but also can include engagement with certain parts of the application, regularity of use, or sustained use for a certain period. Another aspect is that patients' symptoms might improve over time, and therefore, the application becomes less needed, which could be shown in less use [35]. Therefore, it is important to investigate which part or combination of the application is effective or how much time patients have to spend on the application to achieve an improvement of their symptoms when designing studies with therapeutic applications. A systematic review of mHealth interventions for chronic pain self-management reported study durations ranging from 4 to 24 weeks [36]. In comparison, the survival time observed in our study with the POCOS application was relatively short. If the effectiveness of the application is to be assessed in future studies, extending survival time by implementing strategies to foster user engagement will likely be necessary. The successful phone support that has been provided for participants who reached out for help with downloading and account registration suggests that remote but assisted onboarding could be another option to improve adoption. Future research should investigate whether this approach could be an option on a larger scale, as this would offer more flexibility for patients and HCPs than in-person assisted onboarding. It remains unclear why none of the participants in the standard onboarding group reached out to the research team for additional support to download and create an account, while in the video group, 4 participants reached out. We assume that after watching the video showing and explaining the application, participants from video group got more motivated and incentivized to use the application than the participants from the standard group.

Application engagement was consistent across onboarding groups, likely because the application was user-friendly and the user manual was clear and sufficient. The SUS score of 70.31 supports the hypothesis that the application has good usability. However, the score must be interpreted with care due to the limited response rate. Feedback from participants showed that there is room for improvement in the technical functionality and content of the application. This could be addressed with another round of cocreation and design workshops with patients, as well as input from other HCPs.

Although engagement strategies were considered during the application's development, other factors may also play a role and warrant further investigation. For example, previous studies have identified several patient-level factors that negatively influence engagement with mHealth applications, including higher pain levels, depression, longer disease duration, male sex, and lower sociodemographic status or education level [20,37]. Participants in our cohort were characterized by high levels of pain and depression and had a long-standing, treatment-refractory condition, which may have negatively affected adherence and sustained engagement with the application. Patients with chronic pain are considered particularly challenging with regard to adherence compared to other patient groups. This is partly due to their long-term experience with limited symptom relief. The complexity and multimodal nature of their treatments result in a high treatment burden. Additionally, emotional factors such as depression, anxiety, and frustration are more prevalent in this population and can negatively affect motivation and confidence in managing treatment, further reducing adherence [38-40]. Studies investigating adherence to medication among patients with chronic pain have shown, for example, that patients often report taking their medication as prescribed, while in reality they self-adjust their intake. Medication nonadherence in this population is a known issue, although it varies across countries, ranging from 8% to 60%. A systematic review found that age, pain intensity, and the patient-caregiver relationship were negatively associated with adherence to analgesic medication in patients with chronic pain [38,41-43]. While there is extensive literature on medication adherence, less is known about adherence to mHealth interventions, particularly in populations with chronic pain. It is possible that behaviors or factors that negatively influence medication adherence may also translate into reduced adherence when using digital health applications. For example, a study investigating predictors of patient engagement with an app for chronic pain patients reported that those experiencing higher levels of pain showed better engagement with the app than patients whose pain was less severe [44]. Identifying more characteristics in patients with chronic musculoskeletal pain associated with higher application use could enable the development of patient profiles, recognizing that mHealth solutions may not be equally suitable for all individuals.

Beyond the limited return of SUS survey responses, participants provided minimal insight into their application use behavior (eg, minutes spent on the application). The active provision of usability data seems to be too demanding for participants and should be switched fully to passive collection, as has been done with the log-ins. To improve adherence, measures such as increased follow-up, support and monitoring by study personnel, or reimbursement for study tasks could be an option [45].

Limitations

Although our study provided insights into the barriers of managing the onboarding process without assistance, there are

XSL•FO
RenderX

some limitations. We did not track whether participants of group 2 watched the video or how often; however, we were able to track the views and downloads as a total. Therefore, we cannot say with certainty that every participant watched the video. However, on the basis of 17 views and 33 downloads, it is most likely that each of the 17 participants in group 2 had watched the video at least once. The application used in this study is still under development, which led to the occurrence of a technical bug during the 2-week period. The section with advice had disappeared for 3 patients, which might have demotivated some patients from using the application regularly. Although the usability of the application was assessed in this study, no conclusion can be drawn from the SUS score due to the small amount of feedback that has been obtained. A formal sample size calculation was not undertaken, as this study was designed as a feasibility study. Therefore, the sample size was based on practical considerations rather than on estimating or detecting an effect size. Therefore, this study had a small sample size and should be replicated with a larger cohort to assess the robustness and replicability of the findings. Future studies should also include more detailed patient characteristics and demographics to provide a more comprehensive understanding of the factors influencing adoption and engagement. In particular, variables such as depression and anxiety should be measured on a continuous scale rather than only as binary indicators, to capture the full range of symptom severity and their potential impact on engagement. Moreover, as patients were together undergoing a 2-week in-house multimodal chronic pain program before the study and commonly maintained contact beyond its completion, randomization was not feasible owing to a substantial risk of cross-group contamination.

Conclusions

Onboarding without in-person assistance appears to potentially hinder the adoption of digital health applications, even among relatively younger users (mean age 45.7, SD 12.2 years). While these apps are designed to support remote access and use, HCPs should still consider offering guidance during the initial setup, particularly for downloading and registration.

Acknowledgments

The authors thank all participants who took part in the study. ChatGPT (version 5.3; OpenAI) was used to check grammar and sentence structure but not to write the manuscript.

Abstract

Background: Skin cancer incidence is rising globally, increasing pressure on dermatology services and making efficient triage increasingly important. AI-driven skin cancer mobile health apps may help address this need, but their usefulness depends on whether users trust the advice and intend to follow it. Teledermatologist supervision has been proposed to combine AI efficiency with human clinical oversight, but dermatologist shortages make it critical to understand whether such supervision improves patient trust and adherence at the population level, or whether AI-only advice suffices for most users.

Objective: This study tests whether teledermatologist supervision in an AI-driven skin cancer app affects patient trust and adherence intentions, compared with AI-only advice, and whether these effects differ by motivational context and risk assessment level.

Methods: The randomized controlled, online vignette experiment with repeated measures was conducted from May to June 2025 as a single-center study among Dutch adults via an academic hospital-based patient panel. Eligible participants were adult members of the Erasmus MC Digital Patient Panel invited by email; those not completing all 4 vignette trials were excluded from the analysis. Participants completed 4 simulated mobile app scenarios varying in advice source (AI-only vs hybrid teledermatologist and AI) and risk assessment level (high vs low). The primary outcomes were trust in the advice (0 - 100 scale) and adherence intention (recoded 3-level ordinal scale). Mixed-effects models were used to analyze the data.

Results: Of the 2707 patient panel members, 879 participated (response rate: 32.5%). Participants were aged 18 to 93 (mean 62.5, SD 12.64) years; 50.4% (n=443) were female, and 21.4% (n=188) had a history of skin cancer. Participants were randomly allocated to motivation conditions (concern: n=438 vs curiosity: n=441). Trust was higher for hybrid advice than AI-only advice (mean 76.9, SE 0.73 vs mean 65.7, SE 0.73; estimated difference 11.98; partial η^2=0.22; *P*<.001). The odds of adherence were 1.7 times greater with hybrid vs AI-only (odds ratio 1/0.59=1.7, 95% CI 1.28-2.22; *P*<.001). High-risk assessments increased adherence (odds ratio 2.9, 95% CI 2.2-3.8; *P*<.001), with a moderated effect by motivation (*P*=.03), showing stronger adherence with concern vs curiosity. The effect of advice source on adherence was fully mediated by trust.

Conclusions: Teledermatologist supervision of AI-based advice robustly increased patient trust and adherence intentions, particularly for high-risk assessments and concerned users. Our experiment is innovative in testing teledermatologist supervision in a population-level AI skin cancer app and in examining how motivational context shapes responses to advice. Unlike studies focused on postreferral teledermatology or chatbot-based advice, this study isolates the effect of hybrid AI-human advice in a store-and-forward screening context. These findings suggest that developers and health care implementers may consider integrating teledermatologist supervision to maximize patient trust of and adherence to advice, potentially improving triaging efficiency and safety.

Introduction

Background

Globally, the incidence of both melanoma [1-3] and other skin cancer [4,5] is increasing, with related deaths projected to increase by 68% from 2020 to 2040 [6]. The increased incidence compounds the already significant strain on dermatology services, causing delays in diagnosis and treatment in some regions [7]. Teledermatology [8], whereby a dermatologist makes their assessment remotely using digital technologies, has helped address this challenge by postreferral triaging [9,10], achieving improved accessibility and cost savings of 6.3% to 45.3% per patient [11,12] by potentially avoiding unnecessary appointments with the general practitioner [13]. However, widescale teledermatology is likely unrealistic, given global dermatologist shortages [14-16].

Using AI in place of teledermatology has been proposed [17-19], as experiments found AI to diagnose lesion images more accurately than both nonspecialists [20] and dermatologists [21]. Certain use cases for AI in dermatology are promising (Du‐Harpur et al [22]), for example, as an aid for diagnosing [23-25] or in triaging [26]. In fact, both AI alone and AI with a dermatologist check were found to be more cost-effective in postreferral triage than face-to-face assessments or teledermatology [26]. Combining teledermatology and AI postreferral enhances care quality, streamlines processes, and reduces costs [27], and consequently, hybrid models are recommended to help expand access [28,29] and are often preferred by patients [23,24]. However, less research has been conducted on AI-teledermatology apps at the population level, which can face practical challenges, such as users not being sufficiently reassured by low-risk assessments and seeking doctor appointments anyway, as found in a Dutch study [30]. The app in the study [30] increased premalignant or malignant lesion detection by 32%, while also tripling to quadrupling benign lesion claims, indicating population-level overdiagnosis. Furthermore, patients receiving a low-risk assessment from the app had twice as many claims for benign skin lesions, suggesting that they were neither reassured by the app nor their general practitioner [30]. Therefore, adherence to low-risk advice for population-level apps needs to be high to mitigate the risk of increased health care demand. Using AI-based apps to prevent unnecessary appointments appears achievable, as a feasibility study reported that 54% of patients who visited the general practitioner with benign lesions and had low-risk app ratings would have felt reassured enough to cancel their general practitioner visit [13].

People's adherence may differ based on their reason for using the app. For highly concerned users, the perceived threat [31] of skin cancer cannot be alleviated by an algorithm [32], so they will still seek follow-up appointments regardless of the app's risk assessment. In contrast, users motivated by curiosity, which is often a reason to seek health information [33], may be less inclined to follow-up with their general practitioner even if advised by their app. How users' adherence is influenced by motivational context (ie, concern or curiosity) and risk assessment (ie, low or high risk) is unexplored, yet it is critical to understand if AI-based apps in dermatology are able to alleviate health care demand at the population level. Trust is key [34] as patients who trust their clinicians show greater confidence in clinicians' decisions [35] and better adherence [36,37], and presumably the same would apply to health apps. An online experiment [38] found that trust in advice is highest when given by a doctor, followed by human-AI collaboration, and least when offered by AI alone. However, the experiment [38] involved real-time involvement of a doctor, but in teledermatology, a store-and-forward format [39] is common, where patients upload photos [28] for later assessment. Furthermore, the experiment's [38] AI-only option was a chatbot, not an AI photo analysis.

Although population-level AI skin cancer apps have shown feasibility [13], it remains unclear whether teledermatologist supervision improves users' trust and intended adherence when advice is delivered in a patient-facing, store-and-forward format. This study aims to address this gap by assessing user responses to store-and-forward–style, AI-based dermatology apps using a vignette-based experimental design. Vignette experiments have been established as a valid, reliable, and practical method in health care research, offering strong criterion validity while bypassing the ethical and practical constraints of real-world experiments [40].

Research Question and Hypotheses

The current study poses the question: How do advice source (AI alone or hybrid) and user motivation (curiosity vs concern) shape patient trust and adherence intentions to the provided advice within the context of AI-supported teledermatology? Three preregistered hypotheses are posed:

1. H1: Trust (H1a) and adherence intentions (H1b) will be higher for hybrid advice vs AI-only (main effect of advice source on trust and adherence intentions).
2. H2: High-risk assessments will increase adherence intentions (H2a), particularly in the concern condition (H2b) (a main effect of risk assessment and an interaction of motivation and risk assessment on adherence intentions).
3. H3: Trust will mediate the effect of advice source on adherence intentions.

Methods

Trial Design

Our randomized controlled, online vignette experiment with repeated measures uses a 2×2×2 design, with motivational context (concern vs curiosity) as a between-participants factor and advice source (AI-only vs hybrid) and risk assessment (high vs low) as within-participants factors. The dependent variables include trust and adherence to medical advice. Figure 1 presents a study design flowchart. The public was not involved in the design, conduct, or reporting of the trial.

Figure 1. Experimental design flowchart for a 2×2×2 randomized vignette experiment among Dutch adults recruited from the Erasmus MC Patient Panel, Rotterdam, the Netherlands, May to June 2025. Participants were randomized to curiosity or concern, and then completed 4 simulated app trials varying in advice source (AI-only vs hybrid teledermatologist + AI) and risk assessment (low vs high). Participants were assigned to motivation conditions between participants, then received both advice source types and risk assessment levels in randomized order (within participants). Each completed 4 trials of risk assessments, with trust and adherence intentions measured after each trial.

XSL•FO
RenderX

Sample Size

An a priori power analysis was conducted in G*Power 3.1.9.6 [41] for the planned within-between interaction in a repeated measures ANOVA (test family: *F* tests; statistical test: ANOVA: repeated measures, within-between interaction). Because no directly comparable prior studies were available, we conservatively assumed a small-to-medium effect size of f(V)=0.25 [42], α=.05, power=0.80, 2 groups (motivation factor), 4 measurements (2×2 within-participants factors), and nonsphericity correction (=1). This yielded a minimum total sample size of 168 [41].

Materials

The experiment was created using Qualtrics and conducted in Dutch. No personnel were required to conduct the study as it was automated and online. The experiment included an introduction to AI, experiment instructions (Multimedia Appendix 1), 2 motivation texts, and image stimuli for the motivation conditions (Multimedia Appendix 2). Additionally, 4 simulated mobile health app trials, varying in combinations between advice source and risk assessment, were included (see Figure 2 and Multimedia Appendix 3).

Ethical Considerations

This study was approved by the Medical Ethics Committee of Erasmus MC (MEC-2025 - 0371) and conducted in accordance with the procedures of the Erasmus MC Digital Patient Panel [43]. Informed consent was obtained through panel membership registration, by which members agree to be approached for research participation and may opt out of any individual study at any time; no separate consent procedure was required within the study itself. All data were collected anonymously through the panel infrastructure; no personally identifiable information was linked to experimental responses, ensuring participant confidentiality. Participants received no financial or material compensation for participation. No harms were posed on participants as it was an online study, and no concomitant care was provided. All efforts have been made to ensure that individual participants cannot be identified in any images of the manuscript or supplementary material.

Procedure

As this study involved a hypothetical vignette-based experiment assessing patient-reported trust and adherence intentions rather than a health-related intervention delivered to patients or a health-related outcome, prospective trial registration was not required under International Committee of Medical Journal Editors guidelines [44]. The study was nonetheless preregistered on the Open Science Framework [45] to enhance transparency of our research on May 26, 2025, after recruitment had begun but before any data inspection, cleaning, or analysis. The experiment was emailed to 2707 panel members between May 22 and June 10, 2025, with the first response being on May 22. The data collection period was defined by the panel administrators. After demographics and an AI attitudes scale, participants were randomly assigned by Qualtrics to motivation conditions (concern or curiosity; see Multimedia Appendix 2). They completed 4 trials in 2 randomized blocks, varying advice source (AI-only vs hybrid) and risk assessment (high vs. low). Each trial presented 1 advice output, followed by trust and adherence intention measures.

Consequently, each participant saw 4 assessment outputs, 1 high-risk and 1 low-risk per advice source. After each assessment, participants answered 1 item measuring trust and another measuring their intention to adhere to the advice. Finally, participants were debriefed about the aim of the study.

Outcomes

In a preexperiment questionnaire, participants answered questions on demographic data (age, gender, and skin cancer history) and their attitudes toward AI in health care, measured using a Dutch version of the validated 4-item AI Attitude Scale (AIAS-4) [46], with participants indicating their level of agreement on scales from 1 (“Not at all”) to 10 (“Completely agree”). After each trial, trust was rated on a continuous slider (0=no trust, 100=full trust) with the question “How much trust do you have in this result?” This single-item format was chosen to minimize respondent burden across 4 repeated trials. While single-item measures cannot capture all dimensions of trust, they can provide reliable and valid indicators of overall trust judgments [47].

Adherence was assessed by asking “What would you do next regarding your mole?” Participants selected 1 of 5 response options (Table 1), which were recoded, with input from a clinician, into a 3-level ordinal adherence variable for both risk assessment levels. The recoding scheme was designed to reflect medically meaningful levels of adherence. Because the clinical implications of the same response differ depending on whether the AI advice indicated high or low risk, the classification of the responses varied by risk condition.

Table . Recoding of postvignette adherence intention responses into a 3-level ordinal outcome in a randomized vignette experiment on an AI-supported skin cancer app among Dutch adults recruited from the Erasmus MC Patient Panel, Rotterdam, the Netherlands, May to June 2025[a].

Response option	High-risk advice	Low-risk advice	Justification
"I would make an appointment with my GP the same day."	High adherence	Neglect	It is high adherence for high risk because there is same-day intention to make an appointment. Conversely, it is neglect for low risk because an appointment is made.
"I would make an appointment within a week."	Moderate adherence	Neglect	For high risk, this option is moderate adherence because an appointment is still made but with suboptimal urgency. Conversely, it is neglect for low risk because an appointment is made.
"I would make an appointment when I have time; I am not immediately worried."	Neglect	Moderate adherence	For high risk, this option is clearly neglect because there is a lack of clear intention to make a doctor's appointment. For low risk, it is moderate adherence because they might make an appointment but there is not a clear intention.
"I would monitor the mole and only make an appointment if it changes."	Neglect	High adherence	For high risk, this option is considered neglect because the user intends to wait for further signs before making an appointment. In contrast, for low risk, it is desirable that an appointment is not made, unless the mole changes.
"I would not seek any further medical assessment."	Neglect	High adherence	For high risk, this decision is clear neglect because no intention to make an appointment is present. In contrast, for low risk, it is high adherence because there is no sign that the user intends to make an appointment.

[a]Participants were asked "What would you do next regarding your mole?"

Statistical Methods

Analyses were conducted using both SPSS (version: 28.0.1.0(142); IBM Statistics) and RStudio (2025.05.1 Build 513). For H1, a linear mixed-effects model (LMM) was used with trust as the continuous outcome, advice source and risk assessment as within-participants factors, motivation as a between-participants covariate, and participant as a random intercept. Although the Shapiro-Wilk test was significant, the residuals appeared normally distributed and no other assumptions were violated, and we proceeded with the LMM. Effect size was calculated using the following equation: $\eta p2 = F \times dfeffect F \times dfeffect + dferror$.

For H1b and H2, a cumulative link mixed model (CLMM) [48,49] was used given the ordinal nature of adherence intentions. Category counts were sufficient. Logit plots supported proportional odds assumption for advice source and motivation, but risk assessment violated it. To address this, 2 binary generalized linear mixed model sensitivity analyses were conducted: 1 contrasting high adherence vs moderate adherence/neglect combined and 1 contrasting neglect vs high/moderate adherence combined. The latter reflects the theoretically motivated distinction between engagement (high and moderate adherence) and complete disengagement (neglect). The results of both sensitivity analyses are reported alongside the primary CLMM findings. A CLMM was conducted with adherence intentions, predicted by the independent variables: advice source, risk assessment, motivation, and their interactions, with a random intercept for participant ID.

For H3, the main effects of trust, advice source, and their interaction on adherence intentions were tested using a CLMM, with no proportional odds assumption violations for any predictor. A mediation analysis was conducted to test the indirect effect of advice source on adherence intentions via trust as the product of 2 paths: source → trust and trust → adherence intentions, assessed through a Monte Carlo simulation with 10,000 draws. To obtain unbiased estimates, both the CLMM for trust's effect on adherence intentions (path b) and the LMM for source's effect on trust (path a) were rerun without any interaction terms.

Reporting Guidelines

We reported this randomized vignette experiment in accordance with [50] the CONSORT (Consolidated Standards of Reporting Trials) abstract extension [51], CONSORT-EHEALTH (Consolidated Standards of Reporting Trials of Electronic and

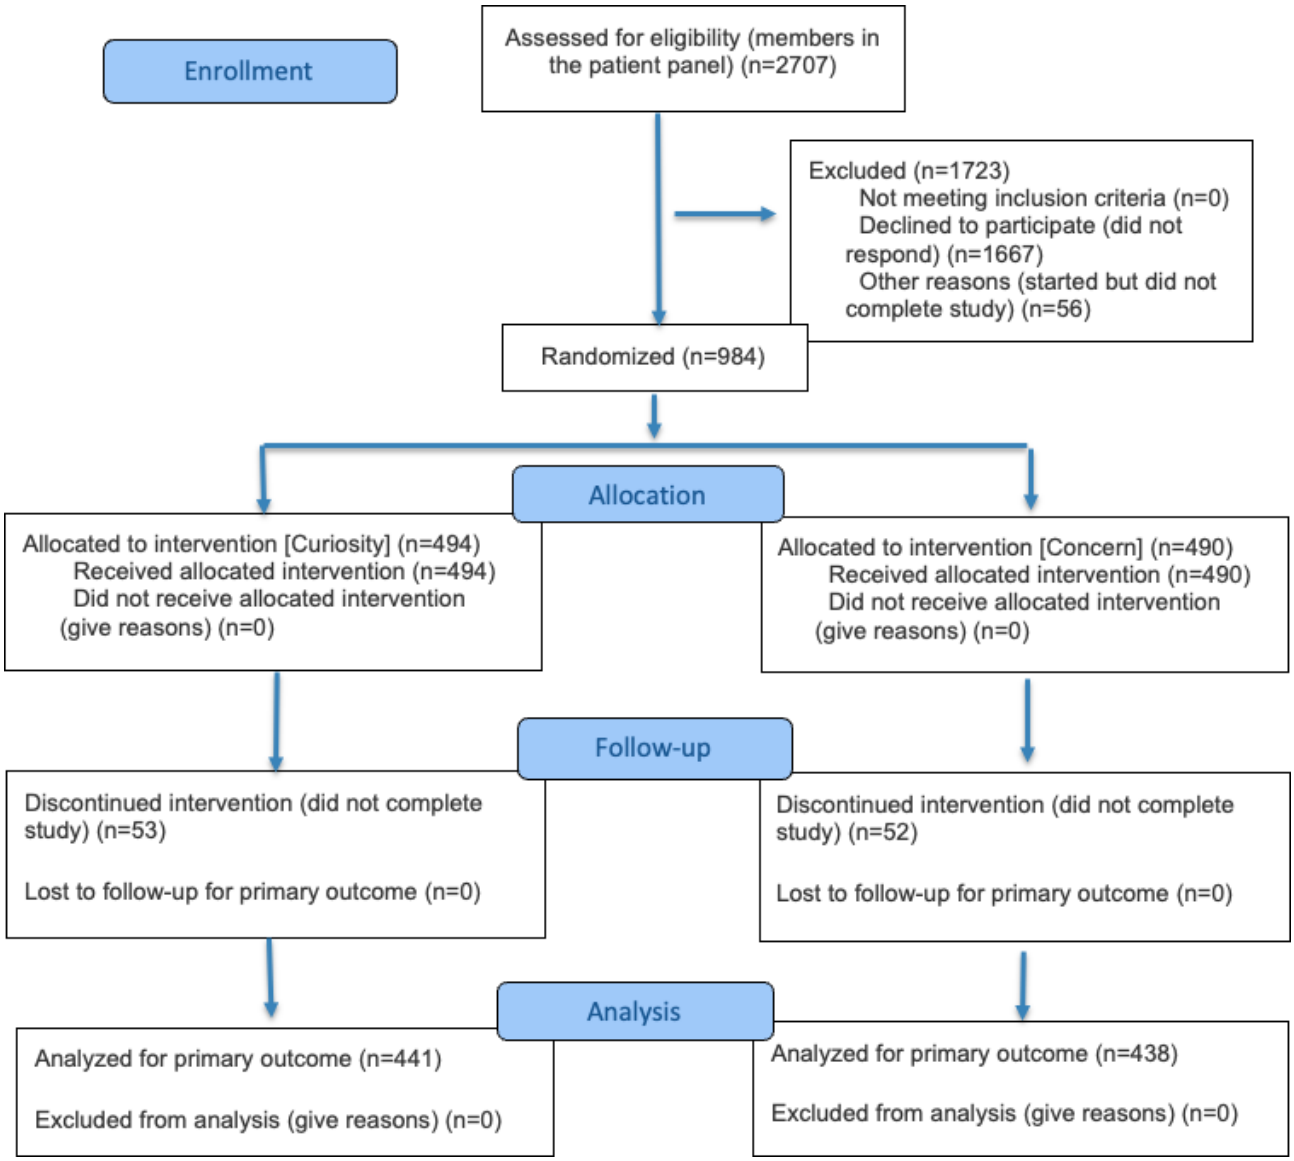
XSL•FO
RenderX

Mobile Health Applications and Online Telehealth) guidelines (Checklist 1) [52], and TIDieR (Template for Intervention Description and Replication) guidelines [53].

Changes to Trial Protocol

We made the following four changes compared to the preregistration [45]:

1. A wording clarification for H2
2. Substitution of mixed-factor ANOVA with LMM for trust
3. Substitution of mixed-factor ANOVA with CLMM for adherence
4. Replacement of the regression-based mediation with Monte Carlo mediation using mixed-model path estimates



Points 2 and 3 allow for random intercepts for each participant, enhancing the modeling of individual variability [54]. A full account of deviations from the preregistration, including justification for each change, is documented in a Transparent Changes file on the OSF project page [45] and in Multimedia Appendix 4.

Results

Participant Flow

The study received 1040 responses in total. Of the 2707 patient panel members, there were 879 full completions, resulting in a response rate of 32.5% (Figure 3).

Figure 3. CONSORT (Consolidated Standards of Reporting Trials) flow diagram of participant screening, randomization, exclusions, and analysis in the randomized vignette experiment among Dutch adults recruited from the Erasmus MC Patient Panel, Rotterdam, the Netherlands, May to June 2025.

Excluded participants were slightly older than included participants (mean 64.9, SD 12.31 y vs mean 62.5, SD 12.62 y; t_{1030}=2.19, d=0.19; P=.03). There were no statistically significant differences in baseline AI attitudes (mean 5.95, SD 2.33 vs mean 6.17, SD 2.08; P=.30), gender distribution (P=.22), personal skin cancer history (P=.82), or motivation assignment (P=.95).

Baseline Data

The median completion time was 4 minutes 56 seconds (IQR 2:55-3:45; range 1:28-175:26). Participants had a mean age of

XSL•FO
RenderX

62.5 (SD 12.64, range 18 - 93) years with balanced gender distribution (female: n=443, 50.4%; male: n=433, 49.3%). A total of 188 (21%) reported a prior skin cancer diagnosis. The average AIAS-4 score was 6.17 (SD 2.08; n=879), indicating a slightly positive attitude toward AI.

Effects on Primary Outcomes of Trust and Adherence Intentions

H1a Influence of Advice Source on Trust

The LMM revealed a significant main effect of advice source on trust ($F_{1,2643}$=758.50; *P*<.001); trust was higher for hybrid (estimated marginal mean 76.88, SE 0.73) than AI-only (estimated marginal mean 65.68, SE 0.73), with an estimated difference of 11.98 (95% CI 10.39-13.58). This relatively narrow interval indicates a precise estimate of the source effect on trust. Advice source's effect size was large (partial η^2=0.22), supporting hypothesis H1a that participants trust hybrid-based assessments more than AI-only assessments. Table S1 in Multimedia Appendix 5 shows the tests of fixed effects, while Table S2 in Multimedia Appendix 5 shows the estimates of fixed effects.

H1b and H2: Influence of Advice Source, Risk Assessment, and Motivational Context on Adherence Intentions

In all CLMMs, odds ratios (ORs) reflect the cumulative odds of being in a higher adherence intention category, with values greater than 1 indicating increased odds of stronger adherence intentions. The CLMM found a significant main effect of advice source (*b*=–0.52, SE 0.14; *z*=–3.84; *P*<.001) on adherence intentions (see the full table in Multimedia Appendix 6). The OR for hybrid compared to AI was approximately 0.59 (OR 1/0.59=1.7, 95% CI 1.28-2.22; *P*<.001), indicating that participants were about 1.7 times more likely to be in a higher adherence intention category under the hybrid advice source condition compared to the AI-only advice, supporting hypothesis H1b. The CI suggests a reasonably precise estimate of this effect.

The CLMM also found a significant main effect of risk assessment on adherence intentions (*b*=–1.07, SE =0.14; *z*=–7.86; *P*<.001). Because lower scores indicate stronger adherence intentions, this means that participants who received a high-risk assessment were about 3 times more likely (OR 2.9, 95% CI 2.2-3.8) to report higher adherence intentions compared to those with low-risk diagnoses. The relatively narrow CI indicates a precise estimate of the risk effect.

Importantly, a significant interaction between risk and motivation was found (*riskHigh* × *motivationCuriosity; b*=0.40, SE =0.19; *z*=2.13; *P*=.03). This indicates that the boost in adherence intentions associated with high risk was weaker among curiosity-motivated participants compared to those motivated by concern, which can also be seen in Table 2.

Table . Distribution of adherence intention responses by motivation condition, advice source, and risk assessment in a randomized vignette experiment among Dutch adults recruited from the Erasmus MC Patient Panel, Rotterdam, the Netherlands, May to June 2025[a].

Motivation	Source	Risk	Total, n	High adherence intention, n (%)	Moderate adherence intention, n (%)	Neglect, n (%)
Concern	AI	High	438	264 (60.3)	142 (32.4)	32 (7.3)
Concern	AI	Low	438	192 (43.8)	89 (20.3)	157 (35.8)
Concern	Hybrid	High	438	297 (67.8)	120 (27.4)	21 (4.8)
Concern	Hybrid	Low	438	246 (56.2)	65 (14.8)	127 (29)
Curiosity	AI	High	441	247 (56)	141 (32)	53 (12)
Curiosity	AI	Low	441	206 (46.7)	94 (21.3)	141 (32)
Curiosity	Hybrid	High	441	281 (63.7)	130 (29.5)	30 (6.8)
Curiosity	Hybrid	Low	441	255 (57.8)	64 (14.5)	122 (27.7)

[a]Percentages were calculated within each motivation × source × risk condition.

In practical terms, individuals driven by concern showed a larger increase in adherence intentions when receiving a high-risk assessment than those driven by curiosity.

Sensitivity Analysis

Overview

To address the proportional odds assumption violation for risk assessment, 2 binary generalized linear mixed model sensitivity analyses were conducted with the same predictors and participant random intercepts. The first contrasted high adherence intentions vs moderate/neglect; the second contrasted neglect vs high/moderate adherence, reflecting the theoretically motivated distinction between engagement (high and moderate) and disengagement (neglect).

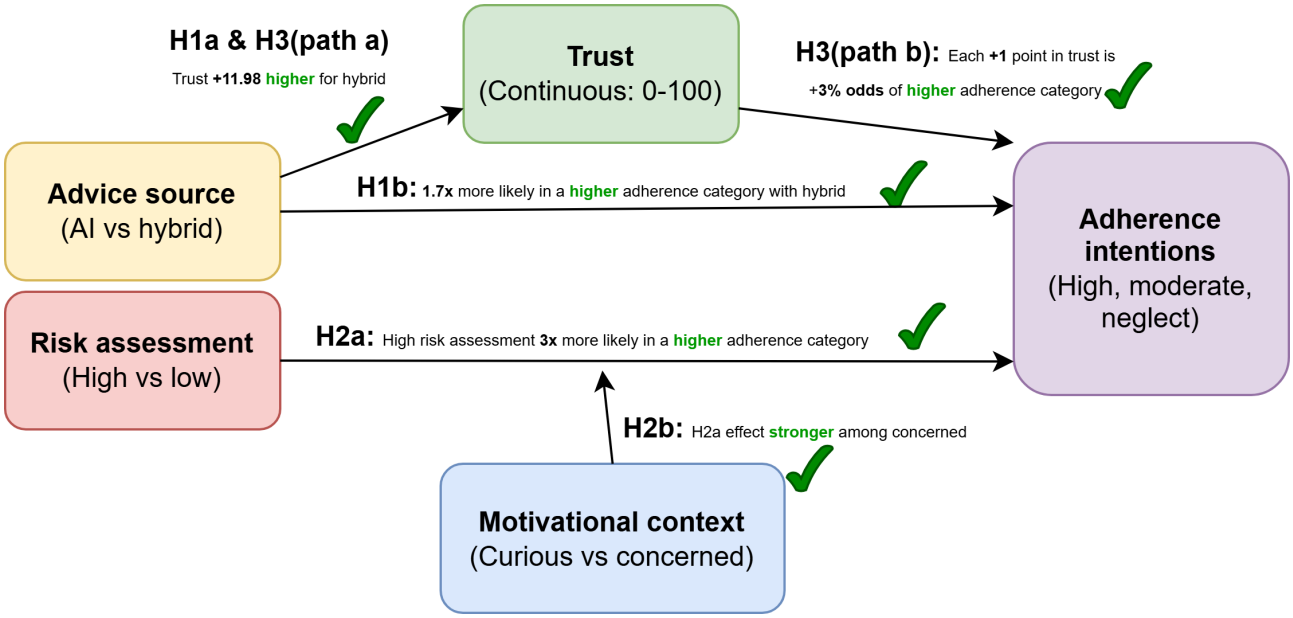
Main effects replicated across both models: hybrid source increased odds of high adherence intentions (OR 1.45, 95% CI 1.08-1.94; *P*=.01), and high-risk assessment strongly reduced odds of neglect (OR 9.40, 95% CI 6.04-14.63; *P*<.001). Critically, the risk × motivation interaction replicated in the neglect model (OR 0.44, 95% CI 0.25-0.78; *P*=.005), confirming that concern-motivated participants were significantly less likely to neglect a high-risk assessment compared to curiosity-motivated participants—consistent with the CLMM finding that the boost in adherence intentions from high risk

XSL•FO
RenderX

was larger for concern than curiosity. The interaction did not reach significance in the high adherence intentions model (P=.11), indicating that the effect is specifically concentrated at the disengagement threshold rather than the high engagement threshold. These analyses confirm that the CLMM findings are robust to the proportional odds violation. The relatively narrow CIs indicate that these effects were estimated with good precision.

H3: Trust Will Mediate the Effect of Advice Source on Adherence Intentions

CLMM on Adherence Intentions by Trust and Advice Source



The CLMM—with participant as a random intercept—showed that greater trust significantly increased odds of stronger adherence intentions. Advice source had no main (P=.29) or interaction effect (P=.17), indicating trust's influence on adherence intentions was consistent across sources (see Multimedia Appendix 7). These results suggest that trust mediates advice source's effect on adherence intentions, supporting hypothesis H3, contrasting with H1b where advice source affected adherence when trust was not accounted for.

Mediation Analyses via Monte Carlo Simulation

The indirect effect of advice source on adherence intentions via trust was estimated as the product of 2 paths: source → trust and trust → adherence intentions, assessed through a Monte Carlo simulation with 10,000 draws. To obtain unbiased estimates, both CLMM for trust's effect on adherence (path b) and LMM for source's effect on trust (path a) were rerun without any interaction terms. The CLMM showed a statistically significant negative effect of trust on adherence intentions (estimate=–0.030, SE =0.002; P<.001), indicating that higher trust predicted better adherence. The LMM revealed a highly significant and negative effect of AI source compared to the reference hybrid source (estimate=–11.20, SE =0.41; P<.001), indicating lower trust under AI-only advice. Combining these path coefficients, the indirect effect was estimated as 0.34 with a 95% CI (0.29-0.39), excluding zero and indicating good precision as well as full mediation (H3). The relatively narrow CI indicates that this mediated effect was estimated with good precision. This positive indirect effect suggests that hybrid advice sources increase adherence intentions by enhancing trust.

Figure 4 provides an overview of the results of the main hypothesis tests.

Figure 4. Summary of preregistered hypotheses and main results from the randomized vignette experiment among Dutch adults recruited from the Erasmus MC Patient Panel, Rotterdam, the Netherlands, May to June 2025. Ticks (✔) indicate hypotheses supported by the evidence.

Discussion

Principal Findings

This randomized controlled, vignette experiment aimed to answer the question "How do advice source (AI alone or Hybrid) and user motivation (curiosity vs concern) shape patient trust and adherence intentions to the provided advice within the context of AI-supported teledermatology?" The 879 participating adults reported trusting risk assessments from a hybrid source (AI plus a teledermatologist) more than AI-only assessments and reported higher intentions to follow the advice. Mediation analysis showed that trust fully explained this effect, meaning that hybrid advice increased adherence intentions by increasing the participants' trust. A high risk of a malignancy (rather than a low risk) further strengthened the intention to follow the advice, particularly among participants who use the app out of concern rather than out of curiosity. Notably, the sensitivity analysis revealed that the interaction between motivational context and risk assessment level was specific to the disengagement threshold: concern-motivated participants were significantly less likely to neglect a high-risk assessment compared to curiosity-motivated participants, while the 2 groups did not differ substantially in rates of high adherence intentions. This suggests that users motivated by curiosity are more likely to neglect when receiving high-risk assessments, compared to users who are already concerned. From a health behavior perspective, this is consistent with protection motivation theory

XSL•FO
RenderX

[55], which posits that threat appraisal motivates protective behavior most strongly when perceived vulnerability is high and personally relevant. Curiosity-driven users—who may perceive themselves as less personally at risk—may be more prone to dismissing unexpected high-risk findings as a false alarm.

The results also identified trust as the central mechanism through which hybrid advice improves adherence intentions, highlighting the value of integrating teledermatologist supervision into AI-driven skin cancer apps to maximize triaging efficiency. An overview of the main results can be found in Figure 4. Our findings differ slightly from those of Soellner and Koenigstorfer [56], who found that the mediators between increased patient compliance and human physician supplementing AI were perceived social presence and innovativeness, suggesting multiple mediating factors are induced by human clinician presence. Similarly, Reis et al [57] found patients preferred human-only chat responses for reliability, empathy, and willingness to follow advice, compared with an AI chatbot or a hybrid chat. Soellner and Koenigstorfer [56] presented AI in a positive manner and communicated a clear purpose, mentioning AI's capability in diagnosing skin lesion photos. In contrast, Reis et al [57] used chatbot transcripts without clarifying AI's role, possibly explaining the preference for human-only advice rather than hybrid. These findings suggest hybrid advice works best when users understand the AI's purpose, not as a full substitute for human care [58]. Therefore, it is recommended to ensure patients understand the purpose of AI's involvement, alleviating patients' concerns about losing human involvement in health care [59], and for making human-AI collaboration more effective.

Practical Implications

Although including a human teledermatologist was found to increase the likelihood of higher adherence intentions by a factor of 1.7, and users' trust in the assessment from 66% to 77%, always including human teledermatologist supervision may be increasing workload too much [26]. Both AI-alone and hybrid models are more cost-effective postreferral than face-to-face assessments without AI [26], but only offering teledermatology to cases where the AI assessment is high risk, or shifting the usage of AI to postreferral by a primary health care provider, may be an effective compromise, depending on the intervention requirements and goals. This is particularly relevant given that Smak Gregoor et al [30] found that low-risk app assessments failed to prevent unnecessary appointments, tripling benign lesion claims. Offering teledermatology review to concerned users with low-risk assessments may be a strategy to prevent in-person appointments, depending on the health care system. To avoid users neglecting high-risk assessments, strategies are required to ensure that those who use the app out of curiosity take the assessment seriously. High-risk assessments may require tailored messaging for users who do not present with preexisting concern, to prevent disengagement in precisely the cases where action is most warranted.

Strengths and Limitations

Our study provides insights on intended adherence to low-risk/benign assessments—reflecting most real-world cases—rather than comparing stage 0 skin cancer with stage 2 as did Soellner and Koenigstorfer [56], which represents the minority of cases. Thus, our results provide insights into drivers of patients' adherence intentions prior to triaging, which is crucial for avoiding overdiagnosis [9,30]. It is worthy of noting that the vignettes in our study altered the motivation (curiosity vs concern), which is intertwined with perceived lesion risk. This was done intentionally to create credible vignettes. However, it is plausible that a user of an app has low perceived lesion risk and is not curious but is using the app for other reasons. Further research could investigate whether using the app because it was encouraged by a family doctor, or family member, or for any other reason influences adherence to the app's advice.

Our study did not consider costs of teledermatology integration, so AI-only solutions may be more cost-effective despite lower adherence intentions and trust although hybrid solutions appear to be most effective postreferral [26]. The study sample was drawn from the Erasmus MC Patient Panel, representing highly engaged health care users with typically higher digital literacy and education levels than in the general population, which may limit generalizability.

The vignette-based experiment involved participants experiencing hypothetical scenarios, and stated trust and adherence intentions may not fully reflect behavior during actual app use. The use of predetermined simulated app outputs rather than participant-uploaded images prioritizes internal validity by isolating the effects of advice source and risk level, though it may reduce perceived personal relevance compared to a real app scenario. However, vignette responses have been shown to correspond closely with real clinical behavior [60], and relative comparisons between conditions are generally robust to hypothetical bias [61,62]. The mixed design—with motivational context as a between-participants factor and advice source and risk level as within-participants factors—allowed for controlled manipulation of key variables while accounting for individual differences. The crossover design used randomized trial order, meaning each condition appeared first equally often across participants, so any contrast effects would be unsystematic and unlikely to bias results in a particular direction. Nonetheless, the possibility that participants compared conditions rather than evaluating each independently remains a limitation inherent to within-participants designs, and trust and adherence may further differ when participants submit an actual image and perceive the assessment as personally relevant to their own lesion. Trust was measured using a single-item slider, which, while practical for repeated trial-level measurement, cannot capture the multidimensional nature of trust. Although single-item trust measures have been shown to produce reliable and valid results comparable to multi-item scales [47], a validated instrument such as the 11-item Trust in Physician Scale by Thom et al [63] may have revealed differential effects of advice source on specific facets of trust—such as perceived competence or benevolence—rather than on overall trust judgments alone [34]. Administering such a scale after each of 4 trials would, however, have imposed considerable respondent burden. Future research could use multi-item trust scales in a between-participants design to examine this more comprehensively.

Conclusions

The findings of this preregistered online experiment support the hypothesis that adding hybrid (teledermatologist and AI) advice increases trust, which, in turn, improves intended adherence, particularly for high-risk assessments and concerned users. This study is innovative in testing teledermatologist supervision in a population-level AI skin cancer app and in examining how motivational context shapes responses to advice. It differs from existing studies focused on postreferral teledermatology [26] or chatbot-based advice [38] by isolating the effect of hybrid AI-human advice in a store-and-forward screening context. These findings can inform the design of AI-based health care apps such that maximal triaging efficiency is achieved. Practically, these results support consideration of teledermatologist supervision in AI-based triage systems where maximizing trust, adherence, and safe follow-through are priorities.

Acknowledgments

The authors would like to thank Mr Christos Diamantidis, MD, for his advice on the coding of the adherence intention answer options, as described in Table 1. The data were obtained through the Erasmus MC Patient Panel [43] (quality instrument), organized by the Directorate of Quality & Patient Care of Erasmus Medical Centre.

Generative AI Use

According to the GAIDeT taxonomy (2025), the following tasks were delegated to GenAI tools under full human supervision: code generation, code optimization, data cleaning, data curation and organization, data analysis, visualization, proofreading and editing, formulation of conclusions, and translation. The GenAI tool used was Perplexity, which uses a variety of models, and ChatGPT 5.6 Terra. Responsibility for the final manuscript lies entirely with the authors. GenAI tools are not listed as authors and do not bear responsibility for the final outcomes. Declaration submitted by RS, MM

Funding

This work was supported by the Netherlands Organisation for Health Research and Development (ZonMw) through a Vidi grant (grant number 09150172210015) awarded to LZ.

Data Availability

Data used in this study are available upon request—please contact secretariaat.mgz@erasmusmc.nl. The available data include (1) the Qualtrics printout PDF, (2) R and SPSS analysis codes, and (3) the anonymized dataset.
